HYPERCUBIC SORTING NETWORKS*

TOM LEIGHTON† AND C. GREG PLAXTON‡

Abstract. This paper provides an analysis of a natural d-round tournament over $n = 2^d$ players and demonstrates that the tournament possesses a surprisingly strong ranking property. The ranking property of this tournament is used to design efficient sorting algorithms for several models of parallel computation:

(i) a comparator network of depth $c \cdot \lg n$, $c \approx 7.44$, that sorts the vast majority of the $n!$ possible input permutations;
(ii) an $O(\lg n)$-depth hypercubic comparator network that sorts the vast majority of permutations;
(iii) a hypercubic sorting network with nearly logarithmic depth;
(iv) an $O(\lg n)$-time randomized sorting algorithm for any hypercubic machine (other such algorithms have been previously discovered, but this algorithm has a significantly smaller failure probability than any previously known algorithm); and
(v) a randomized algorithm for sorting n $O(m)$-bit records on an $(n \lg n)$-node omega machine in $O(m + \lg n)$ bit steps.

Key words. parallel sorting, sorting networks, hypercubic machines

1. Introduction.

A *comparator network* is an n-input, n-output acyclic circuit made up of wires and 2-input, 2-output comparator gates. The input wires of the network are numbered from 0 to $n-1$, as are the output wires. The input to the network is an integer vector of length n where the ith component of the vector is received on input wire i, $0 \le i < n$. The two outputs of each comparator gate are labeled "min" and "max," respectively, while the two inputs are not labeled. On input x and y, a comparator gate routes $\min\{x, y\}$ to its "min" output and routes $\max\{x, y\}$ to its "max" output. It is straightforward to prove (by induction on the depth of the network) that any comparator network induces some permutation of the input vector on the n output wires. We say that a given comparator network *sorts* a particular vector if and only if the value routed to output i is less than or equal to the value routed to output $i+1$, $0 \le i < n-1$.

An n-input comparator network is a *sorting network* if and only if it sorts every possible input vector. It is straightforward to prove that any n-input comparator network that sorts the $n!$ permutations of $\{0, \ldots, n-1\}$ is a sorting network. In fact, any n-input comparator network that sorts the 2^n possible 0-1 vectors of length

n is a sorting network. The latter result is known as the 0-1 principle for sorting networks [11, section 5.3.4].

It is natural to consider the problem of constructing sorting networks of optimal depth. Note that at most $\lfloor n/2 \rfloor$ comparisons can be performed at any given level of a comparator network. Hence the well-known $\Omega(n \lg n)$ sequential lower bound for comparison-based sorting implies an $\Omega(\lg n)$ lower bound on the depth of any n-input sorting network. An elegant $O(\lg^2 n)$-depth upper bound is given by Batcher's bitonic sorting network [4]. For small values of n, the depth of bitonic sort either matches or is very close to matching that of the best constructions known (a very limited number of which are known to be optimal) [11, section 5.3.4]. Thus, one might suspect the depth of Batcher's bitonic sorting network to be optimal to within a constant factor or perhaps even to within a lower-order additive term. Consider Knuth's Exercise 5.3.4.51 (posed as an open problem; see [11]): Prove that the asymptotic value of $\hat{S}(n)$ is not $O(n \cdot \lg n)$, where $\hat{S}(n)$ denotes the minimal size (number of comparator gates) of an n-input sorting network of *any* depth. The source of the difficulty of this particular exercise was subsequently revealed by Ajtai, Komlós, and Szemerédi [2], who provided an optimal $O(\lg n)$-depth construction known as the *AKS sorting network*.

While the AKS sorting network represents a major theoretical breakthrough, it suffers from two significant shortcomings. First, the multiplicative constant hidden within the O-notation is sufficiently large that the result remains impractical. Second, the structure of the network is sufficiently "irregular" that it does not seem to map efficiently to common interconnection schemes. In fact, Cypher proved that any emulation of the AKS network on the cube-connected cycles requires $\Omega(\lg^2 n)$ time [7]. The latter issue is of significant interest, since a primary motivation for considering the problem of constructing small-depth sorting networks is to obtain a fast parallel sorting algorithm for a general-purpose parallel computer. In other words, it would be highly desirable to identify a small-depth sorting network that could be implemented efficiently on a topology that is also useful for performing operations other than sorting.

In this paper we pursue a new approach to the problem of designing small-depth sorting networks with "regular" structure. Our notion of regularity is enforced by restricting the set of permutations that can be used to connect successive levels of gates in a comparator network. In particular, we say that a comparator network is *hypercubic* if and only if successive levels are connected either by a shuffle or an unshuffle (inverse shuffle) permutation. (These terms are defined more precisely in section 3.) Knuth's Exercise 5.3.4.47 [11], posed as an open problem, may be viewed as asking for the depth complexity of *shuffle-only sorting networks*, in which every pair of adjacent levels is connected by a shuffle permutation. Batcher's bitonic sort provides an $O(\lg^2 n)$ upper bound for this problem, and recently, Plaxton and Suel [17] established an $\Omega(\lg^2 n / \lg \lg n)$ lower bound. (The same lower bound holds for the class of unshuffle-only sorting networks.)

From a practical point of view, Knuth's shuffle-only requirement would seem to be overly restrictive. It is motivated by a certain correspondence between hypercubic comparator networks and the class of *hypercubic machines* (e.g., the hypercube, butterfly, cube-connected cycles, omega, and shuffle-exchange). This correspondence allows any shuffle-only comparator network to be efficiently emulated (i.e., with constant slowdown) on any hypercubic machine. (We remark that "hypercubic machines" are more commonly referred to as "hypercubic networks" [12, Chapter 3]. We prefer the term "hypercubic machines" in the present context only because we use the

term "networks" to refer to comparator networks.) However, the class of hypercubic machines is most often characterized in terms of efficient emulation of so-called "normal" hypercube algorithms [12, Chapter 3], which effectively allow the data to be either shuffled or unshuffled at each step. (More formally, a hypercube algorithm is "normal" if it satisfies the following two conditions: (i) in any given step of the computation, communication occurs across a single dimension; and (ii) in any pair of successive steps, communication occurs across an adjacent pair of dimensions.) Thus, hypercubic comparator networks, as defined above, would seem to represent the most natural class of comparator networks corresponding to hypercubic machines.

Our approach to the design of efficient hypercubic sorting networks is based on the following *d-round no-elimination tournament* defined over $n = 2^d$ players, $d \geq 0$. For $d = 0$, the tournament has 0 rounds; no matches are played. For $d > 0$, $n/2$ matches are played in the first round according to an arbitrary pairing of the n players. The next $d - 1$ rounds are defined by recursively running a no-elimination tournament among the $n/2$ winners and (in parallel) a disjoint no-elimination tournament among the $n/2$ losers. (We chose to call this a "no-elimination" tournament to contrast it with the more usual "single-elimination" or "double-elimination" formats in which a player drops out of the tournament after suffering one or two losses.)

In a no-elimination tournament, each player achieves a unique sequence of match outcomes (wins and losses, 1's and 0's) of length d. Let player i be the player that achieves a win-loss sequence corresponding to the d-bit number i; for example, in a 5-round tournament the sequence `WLLWL` would correspond to $i = 10010_2 = 18$. Assume that the outcomes of all matches are determined by an underlying total order. Further assume that there are n distinct amounts of prize money available to be assigned to the n possible outcome sequences. How should these amounts be assigned? Clearly the largest amount of money should be assigned to player $n-1 = \mathtt{W}^d$, who is guaranteed to be the best player. Similarly, the smallest prize should be awarded to player $0 = \mathtt{L}^d$. On the other hand, it is not clear how to rank the remaining $n-2$ win-loss sequences. For instance, in an 8-round tournament, should the sequence `WLWLLWLL` be rated above or below the sequence `LLLWWWWW`? Intuition and standard practice say that the player with the 5–3 record should be ranked above the player with the 3–5 record. As we will show in section 5, however, this is not true for the sequences `WLWLLWLL` and `LLLWWWWW`. In fact, we will see that the standard practice of matching and ranking players based on numbers of wins and losses is not very good. Rather we will see that it is better to match and rank players based on their precise sequences of previous wins and losses.

The analysis of section 5 not only implies that `WLWLLWLL` is a better record than `LLLWWWWW` but also provides an efficient algorithm for computing a fixed permutation π of $\{0, \ldots, n-1\}$ such that with probability at least $1 - 2^{-n^\varepsilon}$, for some constant $\varepsilon > 0$, the actual rank of all but a small, fixed subset of the players is well approximated by $\pi(i)$, $0 \leq i < n$. (See Theorem 5.1 for a more precise formulation of this result.)

Why does the no-elimination tournament admit such a strong ranking property? Intuitively, a comparison will yield the most information if it is made between players expected to be of approximately equal strength; the outcome of a match between a player whose previous record is very good and one whose previous record is very bad is essentially known in advance, and hence will normally provide very little information. The no-elimination tournament has the property that when two players meet in the ith round, they have achieved the same sequence of outcomes in two independent no-elimination tournaments T_0 and T_1 of order $i - 1$. By symmetry, exactly half of the $n!$ possible input permutations will lead to a win by the player representing T_0

and half will lead to a win by the player representing T_1.

The remainder of the paper is organized as follows. In section 2 we discuss our applications of the no-elimination tournament. In section 3 we provide a number of definitions. In section 4 we present several basic lemmas. In section 5 we analyze the sorting properties of the no-elimination tournament. Note that section 5.3 contains a number of important technical definitions related to the no-elimination tournament. In sections 6–11 we present the applications of the no-elimination tournament discussed in section 2. In section 12 we offer some concluding remarks.

2. Overview of applications. In sections 6–11 we use the strong ranking property of the no-elimination tournament to design efficient sorting algorithms for a variety of different models of parallel computation. Most of our results are probabilistic in nature; for such results, the success probability is expressed in the form

$$1 - 2^{-2^{f(d)}}$$

for some function $f(d)$. (The parameter d is equal to $\lg n$, where n is the input size.) For the purposes of this introduction, it will be convenient to define a number of substantially different levels of "high probability" in terms of the function $f(d)$. Let us say that an event occurs *with very high probability* if $f(d) = \lg d + O(1)$, *with very*^{2} *high probability* if $f(d) = \Theta(\sqrt{d})$, with *very*^{3} *high probability* if

$$f(d) = \frac{d}{2^{\Theta(\sqrt{\lg d})}}$$

with very^4 *high probability* if $f(d) = \Theta(\frac{d}{(\lg d)\cdot \lg^* d})$, and with *very*^{5} *high probability* if $f(d)$ can be set to any function that is $o(d)$. Note that an event occurs with very high probability if and only if the corresponding failure probability is polynomially small in terms of n. As it happens, all of the main probabilistic claims made in this paper hold with very^2 high probability or better. We have defined the very high probability threshold only for the purpose of contrasting the results of section 10 with those of previous authors.

We now survey the applications of sections 6–11. In section 6 we define a comparator network of depth $c \cdot \lg n$, $c \approx 7.44$ that sorts a randomly chosen input permutation with very^5 high probability (see Theorem 6.1). (We remark that this comparator network is not hypercubic. A hypercubic version of the construction is discussed in the next paragraph.) At the expense of allowing the network to fail on a small fraction of the $n!$ possible input permutations, this construction improves upon the asymptotic depth of the best previously known sorting networks by several orders of magnitude [2, 15]. We make use of the AKS construction as part of our network. However, the use of the AKS construction can be avoided at the expense of decreasing the success probability from very^5 to very^3 high. (The depth bound remains unchanged.) The topology of our very^3 high probability network is quite simple and does not make use of expanders.

In section 7 we present a hypercubic version of the construction of section 6. In particular, we define an $O(\lg n)$-depth hypercubic comparator network that sorts a randomly chosen input permutation with very^3 high probability (see Theorem 7.1). We have not calculated the constant factor within the $O(\lg n)$-depth bound, which is moderately larger than the constant of approximately 7.44 associated with our nonhypercubic construction.

In sections 8 and 9 we provide a general method for constructing a sorting network from a comparator network that sorts most permutations. More specifically, section 8 describes how to construct a (hypercubic) high-order merging network from a (hypercubic) comparator network that sorts most input permutations. In section 9, we make use of a hypercubic high-order merging network to develop a recurrence for the depth complexity of hypercubic sorting networks. The analysis of this recurrence, presented in Appendix A, yields the main nonprobabilistic claim of our paper, namely, that there exist hypercubic sorting networks of depth

$$2^{O\left(\sqrt{\lg \lg n}\right)} \cdot \lg n.$$

Note that this bound is $o(\lg^{1+\varepsilon} n)$ for any constant $\varepsilon > 0$. (See Theorem 9.1 for a more precise form of the upper bound.) Given the aforementioned $\Omega(\lg^2 n / \lg \lg n)$ lower bound of Plaxton and Suel [17], our upper bound establishes a surprisingly strong separation between the power of shuffle-only comparator networks and that of hypercubic comparator networks.

Unfortunately, each of the network constructions given in sections 6, 7, and 9 is nonuniform in the following sense: No deterministic polynomial-time algorithm is known for generating the family of networks for which existence has been established. On the positive side, existence of a randomized polynomial-time generation algorithm for each of these network families is a straightforward consequence of our results.

In section 10, an optimal $O(\lg n)$-time randomized sorting algorithm is given for any hypercubic machine. The algorithm runs in $O(\lg n)$ time on every input permutation with very[4] high probability and uses only $O(1)$ storage at each processor. Furthermore, a very[2] high probability version of the algorithm has no more than 2 records at the same processor (where the "2" is only necessary for implementing compare-interchange operations) and requires essentially no auxiliary variables. (A global OR operation involving a single bit at each processor is used to check whether or not the sort has been completed.) A number of optimal-time randomized sorting algorithms were previously known for certain hypercubic machines. For example, the Flashsort algorithm of Reif and Valiant [19] is in this category. However, none of these algorithms has a success probability better than "very high." Probability of failure aside, Flashsort requires more storage than our algorithm, since it makes use of a $\Theta(\lg n)$-sized priority queue at each processor. On the other hand, a very high probability sorting algorithm with constant size queues has been given previously by Leighton et al. [13]. Like Batcher's $O(\lg^2 n)$ bitonic sorting algorithm, the very[2] high probability version of our sorting algorithm is *nonadaptive* in the sense that it can be described solely in terms of oblivious routing and compare-interchange operations; there is no queueing. (The very[4] high probability version is adaptive because it makes use of the Sharesort algorithm of Cypher and Plaxton as a subroutine [9].)

Note that the permutation routing problem, in which each processor has a packet of information to send to another processor, and no two packets are destined to the same processor, is trivially reducible to the sorting problem. (The idea is to sort the packets based on their destination addresses.) Hence, our sorting bounds also apply to that fundamental routing problem. In fact, standard reductions [12, section 3.4.3] allow us to apply our sorting algorithm to efficiently solve a variety of other routing problems as well (e.g., many-to-one routing with combining). Interestingly, all previously known optimal-time algorithms for permutation routing on hypercubic machines [13, 18, 20] are randomized, and do not achieve a success probability better than "very high." Thus, the results of section 10 provide a permutation routing

algorithm for hypercubic machines with a much smaller probability of failure than any previously known $O(\lg n)$-time algorithm.

Our final application is described in section 11, where we give a randomized algorithm for sorting n $O(m)$-bit records on an $(n \cdot \lg n)$-node omega machine in $O(m + \lg n)$ bit steps with very[2] high probability. This is a remarkable result in the sense that the time required for sorting is shown to be no more than a constant factor larger than the time required to examine a record (assuming, as is typical, that $m = \Omega(\lg n)$). The only previous result of this kind that does not rely on the AKS sorting network is the recent work of Aiello et al. [1], which provides a randomized bit-serial *routing* algorithm that runs in optimal time with very high probability on the hypercube. That paper does not address either the combining or sorting problems, however, and does not apply to any of the bounded-degree hypercubic machines (e.g., the butterfly, cube-connected cycles, omega, and shuffle-exchange). All previously known algorithms for routing and sorting on bounded-degree hypercubic machines, and for sorting on the hypercube, require $\Omega(\lg^2 n)$ bit steps.

A defect of the randomized sorting algorithms described in sections 10 and 11 is that each requires a table of permutation information to be precomputed and stored in the nodes of the machine before the algorithm is executed. Fortunately, this defect may be viewed as a relatively minor one since: (i) the table needs to be computed only once for a given machine size n (i.e., the same table can be used to sort all $n!$ possible input permutations in the time bounds stated above); (ii) the table occupies only a constant number of words per machine node; and (iii) there is a deterministic polynomial-time (in n) algorithm for computing the table. For the purposes of this paper, it is convenient to define such a "table-based" randomized sorting algorithm as *polynomial-time uniform* if and only if it satisfies properties (i), (ii), and (iii). All of the randomized sorting algorithms presented in this paper are polynomial-time uniform. (In fact, the tables used by our algorithms can be easily computed in NC.)

3. Definitions. In the sections that follow, we present basic definitions related to notational conventions, vectors, permutations, 0-1 vectors, (hypercubic) comparator networks, randomness, network composition, and network families. A number of definitions related to our analysis of the 0-1 no-elimination tournament are postponed until section 5.

3.1. Notational conventions. Our type conventions and defined constants are summarized in Tables 1 and 2, respectively. (We remark that primed and subscripted

TABLE 2
Constants.

Symbol	Constant
e	2.7182818...
γ_c	see equation (7)
μ_c	see equation (8)
υ_c	see equation (9)

variables have the same type as their unprimed and unsubscripted counterparts.)

The functions $\lg x$ and $\text{pow}(x)$ denote $\log_2 x$ and 2^x, respectively.

For all nonnegative integers a and i, let a_i denote bit i in the binary representation of a. (Bit 0 is the least significant bit.)

3.2. Vectors. A *d-vector*, $d \geq 0$, is an integer vector of length $\text{pow}(d)$. For any d-vector x, we index the components of x from 0 through $\text{pow}(d) - 1$ and denote the ith component $x(i)$.

A d-vector x is *sorted* if and only if $x(i) \leq x(i+1)$, $0 \leq i < \text{pow}(d) - 1$.

For any d-vector x, the ith *a-cube* of d-vector x, $0 \leq a \leq d$, $0 \leq i < \text{pow}(d-a)$, is the a-vector y such that $y(j) = x(i \cdot \text{pow}(a) + j)$, $0 \leq j < \text{pow}(a)$.

3.3. Permutations. A *permutation* π of length k, $k \geq 0$, is a vector of length k satisfying the following condition: For each i, $0 \leq i < k$, there is a j, $0 \leq j < k$, such that $\pi(j) = i$. If length-k permutation π is applied to length-k vector x, the resulting length-k vector x' is such that $x'(\pi(i)) = x(i)$, $0 \leq i < k$.

For all length-k permutations π and π', the length-k permutation obtained by applying π to π' is denoted $\pi \circ \pi'$.

A *d-permutation*, $d \geq 0$, is a permutation of length $\text{pow}(d)$.

Let $\Pi(d)$ denote the set of all $\text{pow}(d)!$ d-permutations.

For $0 \leq a \leq d$, let $\Pi(d, a)$ denote the $\text{pow}(a)!$ d-permutations π in $\Pi(d)$ such that: (i) π permutes within a-cubes; and (ii) π applies the same a-permutation within each a-cube.

The *shuffle d-permutation*, denoted $\hookleftarrow_d$, has ith component $i_{d-2} \cdots i_0 i_{d-1}$, $0 \leq i < \text{pow}(d)$. The *k-shuffle d-permutation*, denoted $\hookleftarrow_d^k$, is the d-permutation obtained by composing k shuffle d-permutations.

The *unshuffle d-permutation*, denoted $\hookrightarrow_d$, has ith component $i_0 i_{d-1} \cdots i_1$, $0 \leq i < \text{pow}(d)$ and is equal to the inverse of the shuffle d-permutation. Thus, $\hookrightarrow_d = \hookleftarrow_d^{-1}$. The *$k$-unshuffle d-permutation*, denoted $\hookrightarrow_d^k$, is the d-permutation obtained by composing k unshuffle d-permutations. Note that $\hookleftarrow_d^k = \hookrightarrow_d^{-k}$ for all k.

3.4. 0-1 Vectors. A *0-1 d-vector* is a d-vector over $\{0, 1\}$. Let $\Phi(d)$ denote the set of all $\text{pow}(\text{pow}(d))$ 0-1 d-vectors.

For $0 \leq k \leq \text{pow}(d)$, let $\Phi(d, k)$ denote the set of all

$$\binom{\text{pow}(d)}{k}$$

0-1 d-vectors with k 0's and $(\text{pow}(d) - k)$ 1's.

A 0-1 d-vector is *trivial* if and only if it belongs to $\Phi(d, 0) \cup \Phi(d, \text{pow}(d))$. (Otherwise, it is *nontrivial*.)

For any d-permutation π, and all k such that $0 \leq k \leq \text{pow}(d)$, we define the *kth 0-1 d-vector corresponding to d-permutation* π, denoted ϕ_π^k, as follows:

$$\phi_\pi^k(i) = \begin{cases} 0 & \text{if } 0 \leq \pi(i) < k, \\ 1 & \text{if } k \leq \pi(i) < \text{pow}(d). \end{cases}$$

Note that ϕ_π^k belongs to $\Phi(d, k)$.

For any d-permutation π, let $\Phi_\pi = \cup_{0 \leq k \leq \text{pow}(d)} \phi_\pi^k$.

Let ϕ be a 0-1 d-vector, i be the maximum index for which $\phi(i) = 0$ (or -1 if ϕ belongs to $\Phi(d, 0)$), and j be the minimum index for which $\phi(j) = 1$ (or pow(d) if ϕ belongs to $\Phi(d, \text{pow}(d))$). We say that ϕ has a *dirty region of size* $i-j+1$ corresponding to the sequence of components $\langle \phi(j), \ldots, \phi(i) \rangle$. Observe that ϕ is sorted if and only if $i = j - 1$. (Thus, the dirty region of a sorted 0-1 vector is defined to be empty and has size 0.)

A 0-1 d-vector is *a-sorted*, $0 \leq a \leq d$, if and only if it has a dirty region of size at most pow(a).

For nonnegative integers a and b, let $\Phi_M(a, b)$ denote the set of all 0-1 $(a + b)$-vectors ϕ such that every a-cube of ϕ is sorted.

We remark that if 0-1 d-vector ϕ is a-sorted, then the 0-1 d-vector ϕ' obtained by applying $\hookrightarrow_d^a$ to ϕ belongs to $\Phi_M(d - a, a)$. Furthermore, each $(d - a)$-cube of ϕ' has the same number of 0's to within 1.

3.5. (Hypercubic) comparator networks. This paper studies the depth complexity of certain classes of comparator networks. For the sake of brevity, we will use the term "network" to mean "comparator network" throughout the remainder of the paper.

For nonnegative integers a and d, a *depth-a d-network* consists of a disjoint *levels*, numbered from 0 to $a-1$, each of which has pow(d) associated *input* and *output wires*. (Note that every depth-0 d-network is the empty network.) The input and output wires of each level are numbered from 0 to pow$(d) - 1$. Output wire j on level i and input wire j on level $i + 1$ represent the same wire, $0 \leq i < a - 1$, $0 \leq j < \text{pow}(d)$. The level 0 input wires (resp., level $a - 1$ output wires) of a given network $\mathcal{N}$ are also referred to as the input wires (resp., output wires) of $\mathcal{N}$.

In order to complete our definition of a network, it remains only to define the structure and behavior of a single level. If $d = 0$, each level consists of a single wire, and the lone input is passed directly to the output. For $d > 0$, each level consists of two phases: a permutation phase followed by an operation phase.

In the permutation phase, some d-permutation π is applied to the pow(d) input wires of the level. We refer to the resulting ordered set of pow(d) wires as the *intermediate wires* of the level. In an execution of the permutation phase, the values received by the input wires are passed to the intermediate wires according to d-permutation π: Intermediate wire $\pi(j)$ receives its value from input wire j, $0 \leq j < \text{pow}(d)$.

In the operation phase, the values carried by the pow(d) intermediate wires are passed through a set of pow$(d - 1)$ 2-input, 2-output *gates*, numbered from 0 to pow$(d - 1) - 1$. Intermediate wires (resp., output wires) $2 \cdot j$ and $2 \cdot j + 1$ are input to (resp., output from) the jth gate of the level. There are five kinds of gates in our d-networks: "0," "1," "+," "−," and "?." The action of each of these gates is described below.

"0": On input (x, y), a "0" gate produces output (x, y).

"1": On input (x, y), a "1" gate produces output (y, x).

"+": On input (x, y), a "+" gate produces output $(\min\{x, y\}, \max\{x, y\})$.

"−": On input (x, y), a "−" gate produces output $(\max\{x, y\}, \min\{x, y\})$.
"?": On input (x, y), a "?" gate produces output (x, y) with probability 1/2, and output (y, x) with probability 1/2. This gate is only used in sections 10 and 11.

A d-network is *hypercubic* if and only if the d-permutation applied in each level of the d-network is either $\hookleftarrow_d$ or $\hookrightarrow_d$.

3.6. Randomness. A d-network $\mathcal{N}$ is *deterministic* if and only if $\mathcal{N}$ satisfies the following conditions: (i) the d-permutation applied in the permutation phase of each level is fixed; (ii) the type of each gate is fixed; and (iii) no gate is of type "?."

In general, we allow our d-networks to be random. A depth-a d-network $\mathcal{N}$ is *random* if and only if $\mathcal{N}$ is given by some fixed probability distribution over the set of all deterministic depth-a d-networks. (Each time an input vector is passed to a random network $\mathcal{N}$, the network behaves as a randomly chosen deterministic network drawn from the distribution defining $\mathcal{N}$.)

We have introduced the notion of a random network primarily as a technical convenience, since the random aspects of any construction can be eliminated using Lemma 4.8. Unfortunately, reliance on Lemma 4.8 leads to network constructions that are not polynomial-time uniform.

In sections 10 and 11, we make use of the "?" gate. A d-network $\mathcal{N}$ is *coin-tossing* if and only if $\mathcal{N}$ satisfies the following conditions: (i) the d-permutation applied in the permutation phase of each level is fixed; and (ii) the type of each gate is fixed. Note that: (i) "?" gates are allowed in a coin-tossing d-network; and (ii) every deterministic d-network is a coin-tossing d-network. (We do not consider random coin-tossing networks in any of our applications. Rather we view the "?" gate as an alternative to the form of randomness introduced above.)

A d-vector is *a-random*, $0 \le a \le d$, if and only if it is chosen from a probability distribution that assigns the same probability to any pair of d-vectors related by some d-permutation in $\Pi(d, a)$.

Let $\Pi_R(d)$ and $\Pi_R(d, a)$ denote the uniform distributions over $\Pi(d)$ and $\Pi(d, a)$, respectively.

Let $\Phi_R(d, k)$ denote the uniform distribution over $\Phi(d, k)$.

For all p in $[0, 1]$, let $\Phi_B(d, p)$ denote the distribution that assigns probability

$$p^k \cdot (1 - p)^{\mathrm{pow}(d)-k}$$

to each 0-1 d-vector in $\Phi(d, k)$. Note that a random 0-1 d-vector drawn from this distribution corresponds to the sequence of outcomes of d independent, p-biased Bernoulli trials.

If $\mathcal{D}$ (resp., $\mathcal{D}'$) is the probability distribution over $\Phi(d)$ that assigns probability p_i (resp., p'_i) to the d-bit binary string $i_{d-1} \cdots i_0$, $0 \le i < \mathrm{pow}(d) = n$, then define $\mathcal{D} \le \mathcal{D}'$ if and only if there exist real numbers x_{ij} in $[0, 1]$, $0 \le i < n$, $0 \le j < n$, such that:

(i) $\sum_{0 \le i < n} x_{ij} = 1$, $0 \le j < n$;
(ii) $p'_i = \sum_{0 \le j < n} x_{ij} \cdot p_j$, $0 \le i < n$; and
(iii) $x_{ij} > 0$ only if $i_k \ge j_k$, $0 \le k < d$.

Note that conditions (i) and (ii) ensure that $\sum_{0 \le i < n} p_i = \sum_{0 \le i < n} p'_i = 1$. Informally, $\mathcal{D} \le \mathcal{D}'$ if and only if it is possible to sample from $\mathcal{D}$ by first sampling from $\mathcal{D}'$ and then changing (according to a probability distribution that may depend on the particular sample chosen from $\mathcal{D}'$) a randomly chosen subset of the 1's to 0's.

3.7. Network composition. The main goal of this paper is to provide efficient (i.e., small-depth) constructions of d-networks having certain sorting-related properties. In simple cases, we present our constructions by explicitly specifying the permutation phase and operation phase of each level of the d-network. However, this approach would be too cumbersome for some of our more complicated constructions.

In general, we present a given d-network as the "composition" of a sequence of explicitly specified d-networks, explicitly specified d-permutations, and recursively specified d-networks. The following mechanical procedure can be used to convert such a sequence into a d-network.

1. "Unwind" the recurrence to obtain a sequence of explicitly specified d-networks and d-permutations.
2. Repeatedly apply the composition rules specified below to adjacent pairs in the sequence until the sequence has been reduced to either (i) a single d-network $\mathcal{N}$ or (ii) a d-network $\mathcal{N}$ followed by a d-permutation π. (The composition rules are easily seen to be associative; hence, the order of application is immaterial.) In case (i), $\mathcal{N}$ is the desired d-network. In case (ii), the desired d-network $\mathcal{N}'$ is obtained by appending a single level to $\mathcal{N}$, where: (i) the permutation π is applied in the permutation phase and (ii) the operation phase consists of $\text{pow}(d-1)$ "0" gates.

We now specify the three composition rules (network-network, permutation-network, and permutation-permutation) that can be applied in step 2 above.

1. Let $\mathcal{N}$ and $\mathcal{N}'$ denote d-networks of depth a and b, respectively. Then the composition of the pair $(\mathcal{N}, \mathcal{N}')$ is the depth-$(a+b)$ d-network $\mathcal{N}''$ such that: (i) the first a levels of $\mathcal{N}''$ are given by $\mathcal{N}$ and (ii) the last b levels of $\mathcal{N}''$ are given by $\mathcal{N}'$.
2. For any depth-a d-network $\mathcal{N}$ and d-permutation π, the composition of the pair $(\pi, \mathcal{N})$ is the depth-a d-network $\mathcal{N}'$ obtained from $\mathcal{N}$ by replacing the permutation π' applied in the permutation phase of level 0 with the permutation $\pi \circ \pi'$.
3. For all d-permutations π and π', the composition of the pair (π, π') is $\pi \circ \pi'$.

Our recursive d-network constructions employ recursion over a-cubes for some a such that $0 \leq a \leq d$. To achieve efficient performance, it is desirable for the the depth of a recursive construction over a-cubes to be a function of a, and not d. The following definitions are extremely helpful for establishing results of this kind.

A d-network $\mathcal{N}$ is *a-partitionable*, $0 \leq a \leq d$, if and only if $\mathcal{N}$ can be partitioned into $\text{pow}(d-a)$ disjoint a-networks $\mathcal{N}_i$, $0 \leq i < \text{pow}(d-a)$, where the input (resp., output) wires of $\mathcal{N}_i$ correspond to the ith input (resp., output) a-cube of $\mathcal{N}$.

Let $\mathcal{N}$ denote an a-partitionable d-network and define $\mathcal{N}_i$ as in the preceding paragraph, $0 \leq i < \text{pow}(d-a)$. Then $\mathcal{N}$ is a *(d,a)-network*, $0 \leq a \leq d$, if and only if the $\mathcal{N}_i$'s are all identical.

We remark that: (i) every d-network is a (d,d)-network; (ii) the set of (d,a)-networks is closed under composition; (iii) for all (d,a)-networks $\mathcal{N}$ and d-permutations π in $\Pi(d,a)$, the composition of the pair $(\pi, \mathcal{N})$ is a (d,a)-network; and (iv) Lemma 4.10 provides a useful alternative characterization of the class of a-partitionable hypercubic d-networks.

3.8. Network families. It is straightforward to prove by induction on the leveled structure of any d-network that the output d-vector is related to the input d-vector by some d-permutation. We say that a d-network is a *sorting network* if and only if, in addition, every possible input d-vector leads to a sorted output d-vector. (In the

case of a random d-network, a given input d-vector may not always produce the same output d-vector. We say that a given input vector is sorted by a random network $\mathcal{N}$ if and only if it is guaranteed to be sorted by $\mathcal{N}$.) As indicated in section 1, a d-network $\mathcal{N}$ is a sorting network if and only if: (i) $\mathcal{N}$ sorts all d-permutations in $\Pi(d)$ or (ii) $\mathcal{N}$ sorts all 0-1 d-vectors in $\Phi(d)$. Because of these facts, we will often find it useful to restrict our attention to inputs drawn from $\Pi(d)$ or $\Phi(d)$.

For any d-network $\mathcal{N}$, let $Sort(\mathcal{N})$ denote the set of all integer d-vectors sorted by $\mathcal{N}$.

For any (d, a)-network $\mathcal{N}$, let $Sort(\mathcal{N}, a)$ denote the set of all integer input d-vectors to $\mathcal{N}$ for which every output a-cube is sorted.

The *depth-a shuffle-"+" d-network* is the depth-a hypercubic d-network in which every level consists of the d-permutation $\hookleftarrow_d$ followed by a set of $\mathrm{pow}(d-1)$ "+" gates. We define other networks similarly; for example, each level of a depth-a unshuffle-"0" d-network consists of the d-permutation $\hookrightarrow_d$ followed by a set of $\mathrm{pow}(d-1)$ "0" gates.

A d-network $\mathcal{N}$ is in $Sort_N(d, \varepsilon)$ if and only if the output of $\mathcal{N}$ is sorted with probability at least $1-\varepsilon$ on any d-random 0-1 input d-vector.

A (d, a)-network $\mathcal{N}$ is in $Sort_N(d, a, \varepsilon)$ if and only if each output a-cube of $\mathcal{N}$ is sorted with probability at least $1-\varepsilon$ on any a-random 0-1 input d-vector.

A (d, a)-network $\mathcal{N}$ is in $Sort_N(d, a, b, \varepsilon)$, $0 \le b \le a$, if and only if each output a-cube of $\mathcal{N}$ is b-sorted with probability at least $1-\varepsilon$ on any a-random 0-1 input d-vector.

A 0-1 d-vector ϕ is *a-mostly-sorted* with respect to permutation π, $0 \le a \le d$, if and only if after applying d-permutation π, the length-$(\mathrm{pow}(d) - \mathrm{pow}(a))$ prefix of the resulting 0-1 d-vector is a-sorted.

A (d, a)-network $\mathcal{N}$ is in $Most_N(d, a, b, \varepsilon)$, $0 \le b \le a$, if and only if there exists a d-permutation π in $\Pi(d, a)$ such that each output a-cube of $\mathcal{N}$ is b-mostly-sorted with respect to π with probability at least $1-\varepsilon$ on any a-random 0-1 input d-vector.

For nonnegative integers a and b, an *(a, b)-merge* operation takes as input $\mathrm{pow}(b)$ sorted lists of length $\mathrm{pow}(a)$ and produces a single sorted list of length $\mathrm{pow}(a+b)$.

A $(d, a+b)$-network $\mathcal{N}$ is in $Merge_N(d, a, b)$ if and only if $\mathcal{N}$ performs an (a, b)-merge operation on each $(a+b)$-cube. We assume the following input convention within each $(a+b)$-cube A: The ith sorted input list is provided in ascending order in a-cube i of A, $0 \le i < \mathrm{pow}(b)$.

A *d-insertion* operation, $d \ge 0$, takes as input a sorted list of length $\mathrm{pow}(d) - 1$ and one additional input, and produces a sorted list of length $\mathrm{pow}(d)$.

A (d, a)-network $\mathcal{N}$ is in $Insert_N(d, a)$, $0 \le a \le d$, if and only if $\mathcal{N}$ performs an a-insertion operation on each a-cube. We assume the following input convention within each a-cube: The sorted list is provided in ascending order on input wires 0 through $\mathrm{pow}(a) - 2$ of the a-cube, and the additional input is provided on input wire $\mathrm{pow}(a) - 1$ of the a-cube.

In the preceding paragraphs we defined a number of network families. In each case, the name of the family is subscripted by the letter "N" (for "network"). For any particular family $\mathcal{F}_N$, we define $\mathcal{F}_D$ as the minimum depth of any network in $\mathcal{F}_N$. (For example, $Sort_D(d, a, b, \varepsilon)$ denotes the minimum depth of any network in $Sort_N(d, a, b, \varepsilon)$.) Furthermore, we let $\mathcal{F}_N^h$ denote the set of all hypercubic networks in $\mathcal{F}_N$, and $\mathcal{F}_D^h$ denote the minimum depth of any network in $\mathcal{F}_N^h$.

4. Basic lemmas. In this section, we present a number of basic lemmas.

LEMMA 4.1. *A d-network $\mathcal{N}$ is a sorting network if and only if*

$$\Phi(d) \subseteq Sort(\mathcal{N}).$$

Proof. This lemma is known as the 0-1 principle for sorting networks and is proven in [11, section 5.3.4]. (The proof is given in the context of deterministic networks. The extension to random networks is immediate, however, since a random network $\mathcal{N}$ is a sorting network if and only if every deterministic network that is assigned a nonzero probability by the distribution associated with $\mathcal{N}$ is a sorting network.) □

LEMMA 4.2. *For any d-network $\mathcal{N}$ and d-permutation π, we have*

$$\pi \in \mathit{Sort}(\mathcal{N}) \Longleftrightarrow \Phi_\pi \subseteq \mathit{Sort}(\mathcal{N}).$$

Proof. This result follows from a slight modification to the proof of the 0-1 principle cited above. □

LEMMA 4.3. *For all a and d such that $0 < a \leq d$, we have*

$$\mathit{Merge}_D(d, a-1, 1) \leq a,$$
$$\mathit{Merge}^h_D(d, a-1, 1) = O(a).$$

Proof. These bounds are established by Batcher's bitonic merge network [4]. For a hypercubic construction, additional depth is required in order to conform with the input and output conventions adopted in section 3. (Our input and output conventions have been chosen to simplify the presentation and not to minimize the constant factors associated with our hypercubic constructions.) This is accomplished by preceding Batcher's bitonic merge network with an appropriate fixed permutation π. (Note that such a fixed permutation does not contribute to the depth of a nonhypercubic construction.)

The role of the fixed permutation π is twofold: (i) to reverse one of the two sorted input lists within each a-cube, as required by Batcher's bitonic merge, and (ii) to "compensate" for the series of a shuffle permutations accompanying the merge (as described below). It is straightforward to implement an appropriate permutation π with an $O(a)$-depth hypercubic d-network. (We could use Lemma 4.7 for this purpose, although the permutation π is simple enough to implement directly.) A depth-a shuffle-"+" d-network can then be used to implement Batcher's bitonic merge network within each a-cube. □

LEMMA 4.4. *For all a and d such that $0 \leq a \leq d$, we have*

$$\mathit{Insert}_D(d, a) \leq a,$$
$$\mathit{Insert}^h_D(d, a) = O(a).$$

Proof. This bound is also established by Batcher's bitonic merge network [4]. In contrast with the construction of Lemma 4.3, no list reversal is required since the input is already in bitonic form. (We remark that in the classic sorting network model, where a given level may contain fewer than $\mathrm{pow}(d-1)$ gates, it is possible to match this depth bound while achieving size $\mathrm{pow}(d)-1$ instead of $d \cdot \mathrm{pow}(d)$ [14] (also see [12, section 3.5.4]). The basic idea is to use a tree-like network.) □

LEMMA 4.5. *For all a and d such that $0 \leq a \leq d$, we have*

$$\mathit{Sort}^h_D(d, a, 0) = O(a^2).$$

Proof. This bound is due to Batcher [4] and follows from repeated application of Lemma 4.3. □

LEMMA 4.6. *For all a and d such that $0 \leq a \leq d$, we have*

$$Sort_D(d, a, 0) = O(a).$$

Proof. This bound is due to Ajtai, Komlós, and Szemerédi [2]. Unfortunately, the constant factor associated with the AKS sorting network is impractically large. □

LEMMA 4.7. *For each d-permutation π in $\Pi(d, a)$ there is a hypercubic (d, a)-network $\mathcal{N}$ with the following properties:* (i) *$\mathcal{N}$ implements the permutation π;* (ii) *$\mathcal{N}$ has depth exactly $2 \cdot a$;* (iii) *the d-permutation $\hookrightarrow_d$ is applied in the permutation phase of each of the first a levels of $\mathcal{N}$;* (iv) *the d-permutation $\leftrightarrow_d$ is applied in the permutation phase of each of the last a levels of $\mathcal{N}$; and* (v) *every gate of $\mathcal{N}$ is either* "0" *or* "1." *Furthermore, the gate assignments of $\mathcal{N}$ can be computed in time polynomial in* $\mathrm{pow}(a)$.

Proof. This is a straightforward consequence of the work of Beneš [5]. In particular, for $a = d$, the Beneš permutation network corresponds to a hypercubic d-network satisfying properties (i), (iii), and (v). Furthermore, properties (ii) and (iv) are very nearly satisfied by the same construction; the d-network has depth $2 \cdot d - 1$ and applies the d-permutation $\leftrightarrow_d$ in the last $d - 1$ levels. It follows trivially that the claim of the lemma holds for $a = d$. (We can simply append a dummy shuffle level to the depth-$(2 \cdot d - 1)$ Beneš permutation network corresponding to an unshuffled version of π.)

For implementing a permutation in $\Pi(d, a)$, we apply our modified Beneš construction to each a-cube via the corresponding (d, a)-network of depth $2 \cdot a$. (The original Beneš construction could not be used in this manner; for $0 < a < d$, it would not map input a-cubes to output a-cubes.) □

LEMMA 4.8. *Let $\mathcal{D}$ denote an arbitrary probability distribution over the set of all d-vectors and $\mathcal{N}$ denote a random coin-tossing depth-a d-network. If $\mathcal{N}$ sorts a random d-vector drawn from $\mathcal{D}$ with probability at least p, then there exists some deterministic depth-a d-network $\mathcal{N}'$ with the same property.*

Proof. A simple averaging argument. (Note that $\mathcal{N}$ is drawn from some fixed probability distribution over the set of all deterministic depth-a d-networks.) □

LEMMA 4.9. *Let random* 0-1 *d-vector ϕ be drawn from an arbitrary probability distribution over $\Phi(d)$ and π be a random d-permutation drawn from $\Pi_R(d, a)$. Then the* 0-1 *d-vector ϕ' obtained by applying π to ϕ is a-random.*

Proof. The proof is straightforward. □

LEMMA 4.10. *Let $\mathcal{N}$ denote a depth-b hypercubic d-network, and for each i, $0 \leq i \leq b$, let $f^+(i)$ (resp., $f^-(i)$) denote the number of levels j of $\mathcal{N}$, $0 \leq j < i$, such that $\hookrightarrow_d$ (resp., $\leftrightarrow_d$) is applied in the permutation phase. Let $f(i) = f^+(i) - f^-(i)$, $0 \leq i \leq b$. For all a such that $0 \leq a < d$, $\mathcal{N}$ is a-partitionable if and only if* (i) *$0 \leq f(i) \leq a$, $0 \leq i < b$, and* (ii) *$f(b) = 0$.*

Proof. Let $g^+(i) = \max_{0 \leq j \leq i} f(j)$ and $g^-(i) = \min_{0 \leq j \leq i} f(j)$, $0 \leq i \leq b$. Note that $g^+(i) \geq 0$ and $g^-(i) \leq 0$, $0 \leq i \leq b$.

Let $A_{i,j}$ denote the set of level i output wires y of $\mathcal{N}$ such that there is a path to y from some input wire x in the jth input a-cube, $0 \leq i < b$, $0 \leq j < \mathrm{pow}(d - a)$.

It is straightforward to prove by induction on i that

$$A_{i,j} = \{y : j_{k-a} = y_{k-f(i)},\ \max\{a, g^+(i)\} \leq k < d - g^-(i)\}. \tag{1}$$

Thus,

$$|A_{i,j}| = \mathrm{pow}(\min\{d, \max\{a, g^+(i)\} - g^-(i)\}). \tag{2}$$

Note that if $|A_{i,j}| > \text{pow}(a)$ for some i and j, $0 \leq i < b$, $0 \leq j < \text{pow}(d-a)$, then $\mathcal{N}$ is not a-partitionable. It follows from equation (2) that $\mathcal{N}$ is not a-partitionable if $g^+(b) > a$ or $g^-(b) < 0$.

It remains to prove that if $g^-(b) = 0$ and $g^+(b) \leq a$, then $\mathcal{N}$ is a-partitionable if and only if $f(b) = 0$. Accordingly, assume that $g^-(b) = 0$ and $g^+(b) \leq a$. By equation (1), $A_{b,j}$ corresponds to the jth output subcube if and only of $f(b) = 0$, $0 \leq j < \text{pow}(d-a)$, completing the proof. □

LEMMA 4.11. *Let $\mathcal{N}$ be a random coin-tossing depth-a d-network, and p (resp., p') denote the probability that a particular output wire x receives a 0 when the input to $\mathcal{N}$ is a d-vector drawn from the probability distribution $\mathcal{D}$ (resp., $\mathcal{D}'$). If $\mathcal{D} \leq \mathcal{D}'$ then $p \geq p'$.*

Proof. If $\mathcal{N}$ is deterministic, the claim follows easily from consideration of the following "monotone" property of deterministic networks: When the value passed to a single input wire is changed from 0 to 1 (resp., from 1 to 0) no output changes from 1 to 0 (resp., 0 to 1).

If $\mathcal{N}$ is not deterministic, then it is given by some fixed probability distribution $\mathcal{D}''$ over the set of all deterministic depth-a d-networks. Since the claim holds for every deterministic network, we can prove that the claim holds for $\mathcal{N}$ by averaging over $\mathcal{D}''$. □

5. Analysis of the no-elimination tournament. Let us define a 0-1 *no-elimination (d,p)-tournament*, $d \geq 0$, as an execution of the depth-d shuffle-"+" d-network on a random 0-1 input d-vector drawn from the distribution $\Phi_B(d,p)$. In this section, we analyze the behavior of the 0-1 no-elimination tournament. Our analysis culminates with Lemma 5.16, which establishes that the 0-1 no-elimination tournament has a surprisingly strong ranking property. This ranking property is used to carry out the applications of subsequent sections. (It is noteworthy that the depth-d shuffle-"+" d-network is equivalent to Batcher's bitonic merge network. We have chosen not to adopt Batcher's terminology because we plan to expose a property of the network that is largely unrelated to merging.)

The central idea underlying the proof of Lemma 5.16 is that for almost all output wires x of a 0-1 no-elimination (d,p)-tournament, the probability that x receives a 0 (which is a function of p) exhibits sharp threshold behavior; there is a probability q (which depends on x) such that x is extremely unlikely (resp., likely) to receive a 0 whenever p is at least a bit smaller (resp., larger) than q. Thus, if we permute the output wires of the 0-1 no-elimination (d,p)-tournament according to the sorted order of their associated threshold probabilities, we will tend to produce an approximately sorted 0-1 output vector.

The proof of Lemma 5.16 is rather lengthy and is organized into a number of sections. In section 5.1 we define and analyze certain output probability polynomials. In section 5.2 we study the inverse functions associated with these output probability polynomials. In section 5.3 we provide a number of auxiliary definitions. In section 5.4 we present several technical lemmas. In section 5.5 we complete the proof of Lemma 5.16.

5.1. The output polynomials. In this section we analyze the probability that each wire in a 0-1 no-elimination (d,p)-tournament carries a 0. We define the output probability polynomials $\sigma_\alpha(p)$ and prove two basic lemmas concerning these polynomials.

LEMMA 5.1. *Let x_0 and x_1 denote the two intermediate wires associated with some gate in a 0-1 no-elimination (d,p)-tournament. Then the events E_0 = "x_0*

receives a 0" and E_1 = "x_1 receives a 0" are independent.

Proof. Assume without loss of generality that: (i) x_0 is intermediate wire $2 \cdot j$ on level i; and (ii) x_1 is intermediate wire $2 \cdot j+1$ on level i, $0 \leq i < d$, $0 \leq j < \text{pow}(d-1)$. Note that the index of every level 0 input wire with a path to x_0 has a 0 in bit position $d-i-1$. Similarly, the index of every level 0 input wire with a path to x_1 has a 1 in bit position $d-i-1$. Thus, wires x_0 and x_1 depend on disjoint subsets of the level 0 input wires, and the claim of the lemma follows. □

With each binary string α, we associate the function $\sigma_\alpha(p)$, defined inductively as follows:

(i) $\sigma_\epsilon(p) = p$;
(ii) $\sigma_{\alpha 0}(p) = 2 \cdot \sigma_\alpha(p) - \sigma_\alpha(p)^2$; and
(iii) $\sigma_{\alpha 1}(p) = \sigma_\alpha(p)^2$.

One may easily verify that for each binary string α, the following conditions hold: (i) $\sigma_\alpha(0) = 0$; (ii) $\sigma_\alpha(1) = 1$; (iii) $\sigma_\alpha(p)$ is monotonically increasing for p in $[0,1]$; (iv) $\sigma_\alpha(p)$ is a degree-pow($|\alpha|$) polynomial in p. Conditions (i), (ii), and (iii) imply that $\sigma_\alpha(p)$ is in $[0,1]$ for all p in $[0,1]$.

LEMMA 5.2. *Output wire j of a 0-1 no-elimination (d,p)-tournament receives a 0 with probability $\sigma_\alpha(p)$, where $\alpha = j_{d-1} \cdots j_0$.*

Proof. We prove instead the following stronger claim for all i and j such that $0 \leq i < d$, $0 \leq j < \text{pow}(d)$:

(i) Input wire j at level i receives a 0 with probability $\sigma_\alpha(p)$, where $\alpha = j_{i-1} \cdots j_0$.
(ii) Intermediate wire j at level i receives a 0 with probability $\sigma_\alpha(p)$, where $\alpha = j_i \cdots j_1$.
(iii) Output wire j at level i receives a 0 with probability $\sigma_\alpha(p)$, where $\alpha = j_i \cdots j_0$.

For $i = 0$, part (i) of the claim is immediate since $\sigma_\epsilon(p) = p$. Now let us assume that part (i) of the claim holds for some i, $0 \leq i < d$. Then part (ii) of the claim holds for i since the value received by input wire j is passed to intermediate wire $j_{d-2} \cdots j_0 j_{d-1}$. Similarly, it is easy to show that if part (iii) of the claim holds for some i, $0 \leq i < d-1$, then part (i) holds for $i+1$, since output wire j at level i is the same as input wire j at level $i+1$.

It remains only to prove that if part (ii) of the claim holds for some i, $0 \leq i < d$, then part (iii) holds for i. Accordingly, let x_0 and x_1 denote the pair of intermediate wires associated with some gate y at level i, assume that part (ii) of the claim holds for these wires, and that the associated d-bit indices of x_0 and x_1 are $\beta\alpha 0$ and $\beta\alpha 1$, respectively, where $|\alpha| = i$. Then

$$\Pr\{x_0 \text{ receives a } 0\} = \Pr\{x_1 \text{ receives a } 0\} = \sigma_\alpha(p),$$

and these probabilities are independent by Lemma 5.1. Hence, the "min" output of gate y (i.e., the output wire with index $\beta\alpha 0$ at level i) receives a 0 with probability

$$2 \cdot \sigma_\alpha(p) - \sigma_\alpha(p)^2 = \sigma_{\alpha 0}(p),$$

and the "max" output of gate y (i.e., the output wire with index $\beta\alpha 1$ at level i) receives a 0 with probability

$$\sigma_\alpha(p)^2 = \sigma_{\alpha 1}(p),$$

as required. □

Let α and β denote the binary sequences corresponding to the win-loss sequences `WLWLLWLL` and `LLLWWWWW` mentioned in section 1. We can easily calculate that $\sigma_\alpha(1/2) \approx$

0.796 and $\sigma_\beta(1/2) \approx 0.882$, suggesting that the player with record α should be rated above the player with record β.

LEMMA 5.3. *For all binary strings α and β, and all p in $[0,1]$,*

$$\sigma_{\beta\alpha}(p) = \sigma_\alpha(\sigma_\beta(p)).$$

Proof. For $\alpha = \epsilon$, the result is immediate since $\sigma_\epsilon(p) = p$. For $|\alpha| > 0$, we prove the result by induction on $|\alpha|$. For the base case, assume that $\alpha = x$ where x is either 0 or 1. Since $\sigma_0(p) = 2 \cdot p - p^2$ and $\sigma_1(p) = p^2$, we find that $\sigma_{\beta x}(p) = \sigma_x(\sigma_\beta(p))$, as required. Our induction hypothesis is that the claim holds for all α and β with $|\alpha| \leq i$, for some $i \geq 1$. For the induction step, we will prove that the claim holds for all α, β with $\alpha = \alpha' x$, x equal to 0 or 1, and $|\alpha'| = i$. The proof follows from three applications of the induction hypothesis, since

$$\sigma_{\beta\alpha}(p) = \sigma_{\beta\alpha' x}(p) = \sigma_x(\sigma_{\beta\alpha'}(p)) = \sigma_x(\sigma_{\alpha'}(\sigma_\beta(p))) = \sigma_{\alpha' x}(\sigma_\beta(p)) = \sigma_\alpha(\sigma_\beta(p)). \qquad \square$$

5.2. The inverses of the output polynomials. In order to better understand the behavior of the output polynomial σ_α, it will be useful to study its inverse function. In particular, for any binary string α, we define $\Gamma_\alpha(z)$ to be the function such that

$$\Gamma_\alpha(\sigma_\alpha(p)) = p$$

for all p in $[0,1]$. Unlike σ_α, Γ_α is not a polynomial for $|\alpha| \geq 1$. However, like σ_α, there is a simple inductive scheme for computing Γ_α. This is demonstrated by the following lemma.

LEMMA 5.4. *For all binary strings α, and all z in $[0,1]$,*

$$\begin{aligned} \Gamma_\epsilon(z) &= z, \\ \Gamma_{0\alpha}(z) &= 1 - \sqrt{1 - \Gamma_\alpha(z)}, \\ \Gamma_{1\alpha}(z) &= \sqrt{\Gamma_\alpha(z)}. \end{aligned}$$

Proof. Since $\sigma_\epsilon(p) = p$ for all p in $[0,1]$, σ_ϵ is the identity function, and thus Γ_ϵ is also the identity function. Hence $\Gamma_\epsilon(z) = z$ for all z in $[0,1]$.

By Lemma 5.3, we have

$$\begin{aligned} \sigma_{0\alpha}(p) &= \sigma_\alpha(\sigma_0(p)) \\ &= \sigma_\alpha(2 \cdot p - p^2) \end{aligned}$$

for all p in $[0,1]$. Setting $p = \Gamma_{0\alpha}(z)$, we find that

$$\begin{aligned} \sigma_\alpha(2 \cdot \Gamma_{0\alpha}(z) - \Gamma_{0\alpha}(z)^2) &= \sigma_{0\alpha}(\Gamma_{0\alpha}(z)) \\ &= z \\ &= \sigma_\alpha(\Gamma_\alpha(z)). \end{aligned}$$

Since σ_α is a monotonically increasing function, we have

$$2 \cdot \Gamma_{0\alpha}(z) - \Gamma_{0\alpha}(z)^2 = \Gamma_\alpha(z).$$

Solving for $\Gamma_{0\alpha}(z)$, we obtain

$$\Gamma_{0\alpha}(z) = 1 - \sqrt{1 - \Gamma_\alpha(z)},$$

as desired.

The proof that $\Gamma_{1\alpha}(z) = \sqrt{\Gamma_\alpha(z)}$ proceeds in a similar fashion. By Lemma 5.3, we have

$$\begin{aligned}\sigma_{1\alpha}(p) &= \sigma_\alpha(\sigma_1(p)) \\ &= \sigma_\alpha(p^2)\end{aligned}$$

for all p in $[0,1]$. Setting $p = \Gamma_{1\alpha}(z)$, we find that

$$\begin{aligned}\sigma_\alpha(\Gamma_{1\alpha}(z)^2) &= \sigma_{1\alpha}(\Gamma_{1\alpha}(z)) \\ &= z \\ &= \sigma_\alpha(\Gamma_\alpha(z)).\end{aligned}$$

Since σ_α is a monotonically increasing function, we have

$$\Gamma_{1\alpha}(z)^2 = \Gamma_\alpha(z)$$

and thus

$$\Gamma_{1\alpha}(z) = \sqrt{\Gamma_\alpha(z)},$$

as desired. □

Let α and β denote the binary sequences corresponding to the win-loss sequences `WLWLLWLL` and `LLLWWWWW` mentioned in section 1. We can easily calculate that $\Gamma_\alpha(1/2) \approx 0.437$ and $\Gamma_\beta(1/2) \approx 0.381$, suggesting that the player with record α should be rated above the player with record β.

Note that $\Gamma_\alpha(0) = 0$ and $\Gamma_\alpha(1) = 1$ for all binary strings α. The following lemma is analogous to Lemma 5.3.

LEMMA 5.5. *For all binary strings α and β, and all z in $[0,1]$,*

$$\Gamma_{\beta\alpha}(z) = \Gamma_\beta(\Gamma_\alpha(z)).$$

Proof. The proof is similar to that of Lemma 5.3. □

5.3. Auxiliary definitions. In this section, we state a number of definitions related to the analysis of the no-elimination tournament. These definitions are used primarily in sections 5.4 and 5.5, but also appear in subsequent sections.

For all $x < y$ in $[0,1]$, $\lambda \geq 1$, and $d \geq 0$, let

$$\Delta(x,y) = \lg \frac{y \cdot (1-x)}{(1-y) \cdot x}, \tag{3}$$

$$h_\alpha(x,y) = \frac{\Delta(\Gamma_\alpha(x), \Gamma_\alpha(y))}{\Delta(x,y)}, \tag{4}$$

$$H_\lambda(x,y,d) = \sum_{\alpha:|\alpha|=d} h_\alpha(x,y)^\lambda, \tag{5}$$

$$\eta(\lambda) = \sup_{0<x<y<1} \left\{ h_0(x,y)^\lambda + h_1(x,y)^\lambda \right\}, \tag{6}$$

$$\gamma_c = \inf_{\lambda \geq 1} \frac{\lg \eta(\lambda) + \lambda}{\lambda + 1} \approx 0.822, \tag{7}$$

$$\mu_c = \sup_{\lambda \geq 1} \frac{1 - \lg \eta(\lambda)}{\lambda} = \lg(4 - 2 \cdot \sqrt{2}) \approx 0.228, \tag{8}$$

$$\upsilon_c = -2 \cdot \lg \mu_c = -2 \cdot \lg \lg(4 - 2 \cdot \sqrt{2}) \approx 4.260. \tag{9}$$

Informally, we think of $\Delta(x, y)$ as a measure of the "distance" between x and y for $x < y$ in $[0, 1]$. The function $h_\alpha(x, y)$ may then be viewed as the fractional decrease in the distance between x and y that results from applying Γ_α to both x and y. In section 5.4, we use an inductive potential argument, with potential function $H(x, y, d)$, to show that $h_\alpha(x, y)$ is very small for most α. The function $\eta(\lambda)$ arises in the process of bounding the size of the potential function. The constants γ_c and μ_c are related to the notion of an admissible triple, which we define below. (Note that the constant γ_c and μ_c appear in the statements of Lemmas 5.6 and 5.7, respectively.) The constant υ_c appears in the exponent of the depth bound of section 9.

Setting $\lambda = 3$, we can use Lemma 5.11 and elementary calculus to show that

$$\eta(3) = \frac{10 + 7 \cdot \sqrt{2}}{16},$$

which is attainable for $z = 1/2$. This implies $\gamma_c \leq [\lg(10 + 7 \cdot \sqrt{2}) - 1]/4 \approx 0.829$ and $\mu_c \geq [5 - \lg(10 + 7 \cdot \sqrt{2})]/3 = \lg(4 - 2 \cdot \sqrt{2}) \approx 0.228$. Using numerical calculations, it can be shown that $\gamma_c \approx 0.822$, which is attained for $\lambda \approx 3.609$ and $\eta(\lambda) \approx 1.133$. On the other hand, the supremum of $(1 - \lg \eta(\lambda))/\lambda$, $\lambda \geq 1$, is actually achieved for $\lambda = 3$, so $\mu_c = \lg(4 - 2 \cdot \sqrt{2})$.

DEFINITION 5.1. *A triple (γ, ε, d), where $0 < \gamma < 1$, $0 \leq \varepsilon < 1/2$, and $d \geq 0$, is defined to be* admissible *if and only if*

$$\gamma \cdot d \cdot (\lambda + 1) \geq d \cdot \lg \eta(\lambda) + \lambda \cdot [d + \lg \lg(1/\varepsilon) + 2 - \lg(1 - 2 \cdot \varepsilon)]$$

for some $\lambda \geq 1$.

Definition 5.1 is somewhat messy to apply directly. The following pair of technical lemmas characterize two classes of admissible triples that arise in our applications.

LEMMA 5.6. *For each function $\varepsilon(d) = \text{pow}(-\text{pow}(O(d)))$, there is a function*

$$f(d) = O(\lg \lg(1/\varepsilon(d)))/d$$

such that $(\gamma, \varepsilon(d), d)$ is an admissible triple for all $d \geq 0$ and $\gamma_c + f(d) \leq \gamma < 1$.

Proof. This follows from routine calculations involving Definition 5.1 and equation (7). □

LEMMA 5.7. *For each function $\varepsilon(d) = \text{pow}(-\text{pow}(\mu \cdot d))$, where $\mu(d) = \mu_c - \frac{1}{f(d)}$ with $f(d) = \omega(1)$ and $f(d) = o(d)$, there is a function $g(d) = o(1)$ such that*

$$\left(1 - \frac{3 - g(d)}{4 \cdot f(d)}, \varepsilon(d), d\right)$$

is an admissible triple for all $d \geq 0$.

Proof. This follows from routine calculations involving Definition 5.1 and equation (8). □

5.4. Several technical lemmas. In this section, we prove a number of technical lemmas that are used only in section 5.5 of the paper. Lemma 5.8 shows that the notion of "distance" associated with the function $\Delta(x, y)$ is always at least twice the difference $y - x$. Lemma 5.9 provides a useful method for recursively rewriting expressions of the form $h_{\beta\alpha}(x, y)$. Lemma 5.10 gives a maximization result that is used within Lemma 5.11 to obtain a simplified definition of $\eta(\lambda)$. Lemma 5.12 proves that the potential function $H(x, y, d)$ is bounded from above by $\eta(\lambda)^d$. Lemma 5.13

shows that for certain small values of ε, the difference $\Gamma_\alpha(1-\varepsilon) - \Gamma_\alpha(\varepsilon)$ is small for most binary strings α.

LEMMA 5.8. *For all $x < y$ in $[0,1]$,*

$$y - x \le \Delta(x,y)/2.$$

Proof. Define

$$\rho(z) = \frac{1}{4} \cdot \ln \frac{z}{1-z} - z$$

for z in $[0,1]$. Since

$$\frac{d\rho(z)}{dz} = \frac{1}{4} \cdot \left(\frac{1}{z} + \frac{1}{1-z} \right) - 1 \ge 0$$

for z in $[0,1]$, we know that $\rho(z)$ is a nondecreasing function of z. Hence,

$$\begin{aligned} \frac{\Delta(x,y)}{4 \cdot \lg e} - (y-x) &= \frac{\lg \frac{y \cdot (1-x)}{(1-y) \cdot x}}{4 \cdot \lg e} - y + x \\ &= \rho(y) - \rho(x) \\ &\ge 0, \end{aligned}$$

and thus

$$y - x \le \frac{\Delta(x,y)}{4 \lg e} \le \Delta(x,y)/2. \qquad \square$$

LEMMA 5.9. *For all $x < y$ in $[0,1]$, we have* (i) $h_\epsilon(x,y) = 1$, *and* (ii) *for all binary strings α and β,*

$$h_{\beta\alpha}(x,y) = h_\beta(\Gamma_\alpha(x), \Gamma_\alpha(y)) \cdot h_\alpha(x,y).$$

Proof. Since Γ_ϵ is the identity function, $h_\epsilon(x,y) = 1$ for all $x < y$ in $[0,1]$. We prove the second part of the lemma by observing that

$$\begin{aligned} h_{\beta\alpha}(x,y) &= \frac{\Delta(\Gamma_{\beta\alpha}(x), \Gamma_{\beta\alpha}(y))}{\Delta(x,y)} \\ &= \frac{\Delta(\Gamma_{\beta\alpha}(x), \Gamma_{\beta\alpha}(y))}{\Delta(\Gamma_\alpha(x), \Gamma_\alpha(y))} \cdot \frac{\Delta(\Gamma_\alpha(x), \Gamma_\alpha(y))}{\Delta(x,y)} \\ &= \frac{\Delta(\Gamma_\beta(\Gamma_\alpha(x)), \Gamma_\beta(\Gamma_\alpha(y)))}{\Delta(\Gamma_\alpha(x)\Gamma_\alpha(y))} \cdot h_\alpha(x,y) \\ &= h_\beta(\Gamma_\alpha(x), \Gamma_\alpha(y)) \cdot h_\alpha(x,y), \end{aligned}$$

where the second last equation follows from Lemma 5.5. $\square$

LEMMA 5.10. *Let f_0, f_1, and f denote strictly increasing and continuously differentiable functions on $(0,1)$, and set*

$$g(x,y,\lambda) = \left(\frac{f_0(y) - f_0(x)}{f(y) - f(x)} \right)^\lambda + \left(\frac{f_1(y) - f_1(x)}{f(y) - f(x)} \right)^\lambda$$

for $0 < x \le y < 1$ and $\lambda \ge 1$. Then for all $x \le y$ in $(0,1)$,

$$g(x,y,\lambda) \le \sup_{z\in(0,1)} g(z,z,\lambda).$$

Proof. Note that because f_0, f_1, and f are strictly increasing and differentiable, l'Hôpital's rule implies that $g(x,y,\lambda)$ is well defined even if $x = y$.

Given any $x < y$ in $(0,1)$, we prove below that there exists a p such that $x < p < y$ and

$$\max\{g(x,p,\lambda), g(p,y,\lambda)\} \ge g(x,y,\lambda).$$

This is sufficient to prove that the maximum of $g(x,y,\lambda)$ occurs for $x \sim y$.

Choose p so that

$$f(p) = \frac{f(x)+f(y)}{2}.$$

We can always find such a p between x and y since f is a continuous function. Then set

$$\begin{aligned} u_0 &= f_0(p) - f_0(x), \\ u_1 &= f_0(y) - f_0(p), \\ v_0 &= f_1(p) - f_1(x), \\ v_1 &= f_1(y) - f_1(p), \\ w &= f(p) - f(x) \\ &= f(y) - f(p). \end{aligned}$$

Note that u_0, u_1, v_0, v_1, and w are all strictly positive since f_0, f_1, and f are strictly increasing.

By definition,

$$\begin{aligned} g(x,p,\lambda) &= \left(\frac{u_0}{w}\right)^\lambda + \left(\frac{v_0}{w}\right)^\lambda, \\ g(p,y,\lambda) &= \left(\frac{u_1}{w}\right)^\lambda + \left(\frac{v_1}{w}\right)^\lambda, \\ g(x,y,\lambda) &= \left(\frac{u_0+u_1}{2\cdot w}\right)^\lambda + \left(\frac{v_0+v_1}{2\cdot w}\right)^\lambda. \end{aligned}$$

For $\lambda \ge 1$, the function z^λ is convex, and thus

$$\frac{z_0^\lambda + z_1^\lambda}{2} \ge \left(\frac{z_0+z_1}{2}\right)^\lambda$$

for all z_0 and z_1. Hence,

$$\begin{aligned} \left(\frac{u_0}{w}\right)^\lambda + \left(\frac{u_1}{w}\right)^\lambda &\ge 2\cdot\left(\frac{u_0+u_1}{2\cdot w}\right)^\lambda, \\ \left(\frac{v_0}{w}\right)^\lambda + \left(\frac{v_1}{w}\right)^\lambda &\ge 2\cdot\left(\frac{v_0+v_1}{2\cdot w}\right)^\lambda. \end{aligned}$$

Summing the preceding pair of inequalities, we find that

$$g(x,p,\lambda) + g(p,y,\lambda) \geq 2 \cdot g(x,y,\lambda),$$

and hence $\max\{g(x,p,\lambda), g(p,y,\lambda)\} \geq g(x,y,\lambda)$, as desired. □

LEMMA 5.11. *For all* $\lambda \geq 1$,

$$\eta(\lambda) = \sup_{0 \leq z \leq 1} \left[\left(\frac{1+\sqrt{z}}{2} \right)^{\lambda} + \left(\frac{1+\sqrt{1-z}}{2} \right)^{\lambda} \right].$$

Proof. We have

$$\begin{aligned}
&h_0(x,y)^{\lambda} + h_1(x,y)^{\lambda} \\
&= \left(\frac{\Delta(\Gamma_0(x), \Gamma_0(y))}{\Delta(x,y)} \right)^{\lambda} + \left(\frac{\Delta(\Gamma_1(x), \Gamma_1(y))}{\Delta(x,y)} \right)^{\lambda} \\
&= \left(\frac{\lg \frac{\Gamma_0(y) \cdot (1-\Gamma_0(x))}{(1-\Gamma_0(y)) \cdot \Gamma_0(x)}}{\lg \frac{y \cdot (1-x)}{(1-y) \cdot x}} \right)^{\lambda} + \left(\frac{\lg \frac{\Gamma_1(y) \cdot (1-\Gamma_1(x))}{(1-\Gamma_1(y)) \cdot \Gamma_1(x)}}{\lg \frac{y \cdot (1-x)}{(1-y) \cdot x}} \right)^{\lambda} \\
&= \left(\frac{\lg \frac{\Gamma_0(y)}{1-\Gamma_0(y)} - \lg \frac{\Gamma_0(x)}{1-\Gamma_0(x)}}{\lg \frac{y}{1-y} - \lg \frac{x}{1-x}} \right)^{\lambda} + \left(\frac{\lg \frac{\Gamma_1(y)}{1-\Gamma_1(y)} - \lg \frac{\Gamma_1(x)}{1-\Gamma_1(x)}}{\lg \frac{y}{1-y} - \lg \frac{x}{1-x}} \right)^{\lambda} \\
&= \left(\frac{f_0(y) - f_0(x)}{f(y) - f(x)} \right)^{\lambda} + \left(\frac{f_1(y) - f_1(x)}{f(y) - f(x)} \right)^{\lambda},
\end{aligned}$$

where

$$\begin{aligned}
f_0(z) &= \lg \frac{\Gamma_0(z)}{1 - \Gamma_0(z)} \\
&= \lg \frac{1 - \sqrt{1-z}}{\sqrt{1-z}}, \\
f_1(z) &= \lg \frac{\Gamma_1(z)}{1 - \Gamma_1(z)} \\
&= \lg \frac{\sqrt{z}}{1 - \sqrt{z}}, \\
f(z) &= \lg \frac{z}{1-z}.
\end{aligned}$$

It is easily verified that $f_0(z)$, $f_1(z)$, and $f(z)$ are strictly increasing and continuously differentiable in $(0,1)$. By Lemma 5.10, this means that the supremum of $h_0(x,y)^{\lambda} + h_1(x,y)^{\lambda}$ occurs for $x \sim y$. Using l'Hôpital's rule and elementary calculus, we can show that

$$\begin{aligned}
\lim_{\varepsilon \to 0} h_0((1-\varepsilon) \cdot y, y) &= \frac{df_0(y)/dy}{df(y)/dy} \\
&= \frac{1 + \sqrt{1-y}}{2}.
\end{aligned}$$

Reasoning in a similar fashion, we can also show that

$$\lim_{\varepsilon \to 0} h_1((1-\varepsilon) \cdot y, y) = \frac{df_1(y)/dy}{df(y)/dy}$$

$$= \frac{1+\sqrt{y}}{2}.$$

The proof of the lemma now follows from the definition of $\eta(\lambda)$. □

LEMMA 5.12. *For all $x < y$ in $[0,1]$, $\lambda \geq 1$, and $d \geq 0$, we have*

$$H_\lambda(x,y,d) \leq \eta(\lambda)^d.$$

Proof. For $d = 0$, the result is immediate since $H_\lambda(x,y,0) = 1$. For $d > 0$, Lemma 5.9 implies that

$$\begin{aligned} H_\lambda(x,y,d) &= \sum_{\alpha:|\alpha|=d-1} \left(h_{0\alpha}(x,y)^\lambda + h_{1\alpha}(x,y)^\lambda\right) \\ &= \sum_{\alpha:|\alpha|=d-1} \left(h_0(\Gamma_\alpha(x),\Gamma_\alpha(y))^\lambda + h_1(\Gamma_\alpha(x),\Gamma_\alpha(y))^\lambda\right) \cdot h_\alpha(x,y)^\lambda \\ &\leq \sum_{\alpha:|\alpha|=d-1} \eta(\lambda) \cdot h_\alpha(x,y)^\lambda \\ &= \eta(\lambda) \cdot H_\lambda(x,y,d-1). \end{aligned}$$

Hence, $H_\lambda(x,y,d) \leq \eta(\lambda)^d$, as required. □

LEMMA 5.13. *For any admissible triple (γ,ε,d), there are at most $\mathrm{pow}(\gamma \cdot d)$ length-d binary strings α such that*

$$\Gamma_\alpha(1-\varepsilon) - \Gamma_\alpha(\varepsilon) > (1 - 2\cdot\varepsilon) \cdot \mathrm{pow}((\gamma-1)\cdot d)/4.$$

Proof. By Lemma 5.8, the definition of h_α, and the definition of Δ, we have

$$\begin{aligned} \Gamma_\alpha(1-\varepsilon) - \Gamma_\alpha(\varepsilon) &\leq \Delta(\Gamma_\alpha(\varepsilon),\Gamma_\alpha(1-\varepsilon))/2 \\ &= h_\alpha(\varepsilon,1-\varepsilon)\cdot\Delta(\varepsilon,1-\varepsilon)/2 \\ &\leq h_\alpha(\varepsilon,1-\varepsilon)\cdot\lg(1/\varepsilon). \end{aligned}$$

Hence, it is sufficient to prove that at most $\mathrm{pow}(\gamma\cdot d)$ length-d binary strings α satisfy

$$h_\alpha(\varepsilon,1-\varepsilon) > \frac{(1-2\cdot\varepsilon)\cdot\mathrm{pow}((\gamma-1)\cdot d)}{4\cdot\lg(1/\varepsilon)}.$$

Suppose the latter claim were false. Then

$$\begin{aligned} H_\lambda(\varepsilon,1-\varepsilon,d) &> \mathrm{pow}(\gamma\cdot d)\cdot\left[\frac{(1-2\cdot\varepsilon)\cdot\mathrm{pow}((\gamma-1)\cdot d)}{4\cdot\lg(1/\varepsilon)}\right]^\lambda \\ &= \mathrm{pow}(\gamma\cdot d\cdot(\lambda+1) - \lambda\cdot[d + \lg\lg(1/\varepsilon) + 2 - \lg(1-2\cdot\varepsilon)]) \\ &\geq \eta(\lambda)^d, \end{aligned}$$

which contradicts Lemma 5.12. □

5.5. The no-elimination tournament theorem. In this section, we complete the proof of Lemma 5.16.

LEMMA 5.14. *For any admissible triple (γ,ε,d), there exists a set A of at least $\mathrm{pow}(d) - \mathrm{pow}(\gamma\cdot d)$ output wires of the depth-d shuffle-"+" d-network, and a fixed permutation π of A, such that for each p the set A can be partitioned into three sets B, A^-, and A^+ where:*

(i) *the set of output wires B is mapped to a contiguous interval by the permutation π,*
(ii) $|B| < \mathrm{pow}(\gamma \cdot d)$,
(iii) A^- *(resp., A^+) is the set of all output wires in $A \setminus B$ mapped to positions lower (resp., higher) than B by π, and*
(iv) *after execution of a* 0-1 *no-elimination (d,p)-tournament, each output wire in A^- (resp., A^+) receives a* 1 *(resp.,* 0*) with probability less than ε.*

Proof. Let (γ, ε, d) denote a given admissible triple, and choose A to be the set (guaranteed to exist by Lemma 5.13) of at least $\mathrm{pow}(d) - \mathrm{pow}(\gamma \cdot d)$ output wires indexed by length-d binary strings α such that

$$\Gamma_\alpha(1-\varepsilon) - \Gamma_\alpha(\varepsilon) \le \delta,$$

where $\delta = (1 - 2 \cdot \varepsilon) \cdot \mathrm{pow}((\gamma - 1) \cdot d)/4$. (Note that $0 < \delta < 1/4$ since (γ, ε, d) is an admissible triple.) We remark that, using Lemma 5.4, $\Gamma_\alpha(z)$ can be computed in $O(|\alpha|)$ arithmetic operations (counting square root as a single operation) for any z in $[0,1]$. Hence, the set A can be computed in $O(d \cdot \mathrm{pow}(d))$ operations. (This may be viewed as a relatively efficient time bound since, for example, it is linear in the size of the depth-d shuffle-"+" d-network.)

In fact, we can compute an appropriate permutation π within the same asymptotic time bound: We set π to the permutation of set A that sorts the $\Gamma_\alpha(\varepsilon)$ values in ascending order. Ties may be broken arbitrarily. It remains to prove that our choice of A and π satisfies the requirements of the lemma.

Let $p^- = \max\{0, p - \delta\}$ and $p^+ = \min\{1, p + \delta\}$. (Recall that p is the 0-1 no-elimination tournament input parameter.) Let B denote the set of binary strings α in A for which $\Gamma_\alpha(\varepsilon)$ is contained in $[p^-, p]$. Because the σ_α's are monotonically increasing, and using linearity of expectation, we have

$$\begin{aligned}
\sum_{\alpha:|\alpha|=d} |\sigma_\alpha(p^+) - \sigma_\alpha(p^-)| &= \sum_{\alpha:|\alpha|=d} \big(\sigma_\alpha(p^+) - \sigma_\alpha(p^-)\big) \\
&= \left(\sum_{\alpha:|\alpha|=d} \sigma_\alpha(p^+)\right) - \left(\sum_{\alpha:|\alpha|=d} \sigma_\alpha(p^-)\right) \\
&= (p^+ - p^-) \cdot \mathrm{pow}(d) \\
&\le 2 \cdot \delta \cdot \mathrm{pow}(d).
\end{aligned}$$

For each α in B we have $\sigma_\alpha(p^-) \le \varepsilon$. (If $p^- = 0$ then $\sigma_\alpha(p^-) = \sigma_\alpha(0) = 0$, and if $p^- = p - \delta$ then $\sigma_\alpha(p^-) \le \sigma_\alpha(\Gamma_\alpha(\varepsilon)) = \varepsilon$.) Furthermore, for each α in B we have $\sigma_\alpha(p^+) \ge 1 - \varepsilon$. (If $p^+ = 1$ then $\sigma_\alpha(p^+) = \sigma_\alpha(1) = 1$, and if $p^+ = p + \delta$ then $\sigma_\alpha(p^+) \ge \sigma_\alpha(\Gamma_\alpha(1-\varepsilon)) = 1 - \varepsilon$.) Hence,

$$|\sigma_\alpha(p^+) - \sigma_\alpha(p^-)| \ge 1 - 2 \cdot \varepsilon.$$

The preceding inequalities imply that

$$\begin{aligned}
|B| &\le 2 \cdot \delta \cdot \mathrm{pow}(d)/(1 - 2 \cdot \varepsilon) \\
&< \mathrm{pow}(\gamma \cdot d).
\end{aligned}$$

Note that the set of binary strings B satisfies conditions (i) and (ii) of the lemma. For the given choice of B, define sets A^- and A^+ to satisfy condition (iii). It remains only to address condition (iv).

Let α denote the binary string associated with an arbitrary output in A^-. Thus, $\Gamma_\alpha(\varepsilon) < p^-$, which implies $\Gamma_\alpha(1-\varepsilon) < p$. Hence, $\sigma_\alpha(p) > 1-\varepsilon$. (The probability that output α receives a 1 is less than ε.)

Similarly, let α denote the binary string associated with some output in A^+. Thus, $\Gamma_\alpha(\varepsilon) > p$ and hence $\sigma_\alpha(p) < \varepsilon$. (The probability that output α receives a 0 is less than ε.) □

LEMMA 5.15. *Let d, k, n, and p be such that $d \geq 0$, $n = \mathrm{pow}(d)$, $0 \leq k < n$, and $p = k/n$. Let $\mathcal{N}$ denote an arbitrary d-network, and assume that output wire x of $\mathcal{N}$ receives a 0 (resp., 1) with probability $q \leq \varepsilon$ when the input to $\mathcal{N}$ is drawn from $\Phi_B(d,p)$. Further assume that output wire x receives a 0 (resp., 1) with probability q_i when the input is drawn from $\Phi_R(d,i)$, $0 \leq i < n$. Then $q_k \leq 2 \cdot \varepsilon$.*

Proof. Informally, the lemma states that network $\mathcal{N}$ behaves similarly on inputs drawn from $\Phi_B(d,p)$ and $\Phi_R(d,k)$. Note that

$$\begin{aligned} q &= \sum_{0 \leq i < n} \binom{n}{i} p^i (1-p)^{n-i} q_i \\ &\geq \sum_{k \leq i < n} \binom{n}{i} p^i (1-p)^{n-i} q_i \\ &\geq q_k \sum_{k \leq i < n} \binom{n}{i} p^i (1-p)^{n-i} \\ &\geq q_k/2, \end{aligned}$$

where the last two inequalities follow from Lemma 4.11 and Theorem B.1, respectively. □

LEMMA 5.16. *For any admissible triple (γ, ε, d), we have*

$$\mathit{Most}^h_D(d, d, \lfloor \gamma \cdot d \rfloor, O(\mathrm{pow}(d) \cdot \varepsilon)) \leq d.$$

Proof. Let $\mathcal{N}$ denote the depth-d shuffle-"+" d-network. It follows from Lemmas 5.14 and 5.15 that $\mathcal{N}$ belongs to $\mathit{Most}^h_N(d, d, \lfloor \gamma \cdot d \rfloor, O(\mathrm{pow}(d) \cdot \varepsilon))$, justifying the claimed inequality.

(We have opted to omit the detailed proof of the above claim, which is straightforward but tedious. An outline of the proof is as follows. First, we rewrite the proof obligation by successively expanding the definitions of $\mathit{Most}^h_N(d, d, \lfloor \gamma \cdot d \rfloor, O(\mathrm{pow}(d) \cdot \varepsilon))$, $\lfloor \gamma \cdot d \rfloor$-mostly-sorted, and $\lfloor \gamma \cdot d \rfloor$-sorted. Having done this, we arrive at a new proof obligation in which the input to network $\mathcal{N}$ is assumed to be drawn from $\Phi_R(d,k)$, $0 \leq k < \mathrm{pow}(d)$. Furthermore, the new proof obligation is such that it would follow immediately from Lemma 5.14 if only the input were assumed to be drawn from $\Phi_B(d,p)$ instead of $\Phi_R(d,k)$. Lemma 5.15 is then used to complete the proof by relating the behavior of network $\mathcal{N}$ on inputs drawn from $\Phi_B(d,p)$ to its behavior on inputs drawn from $\Phi_R(d,k)$.) □

LEMMA 5.17. *For any admissible triple (γ, ε, a) and all d, $0 \leq a \leq d$, we have*

$$\begin{aligned} &\mathit{Most}_D(d, a, \lfloor \gamma \cdot a \rfloor, O(\mathrm{pow}(a) \cdot \varepsilon)) \leq a, \\ &\mathit{Most}^h_D(d, a, \lfloor \gamma \cdot a \rfloor, O(\mathrm{pow}(a) \cdot \varepsilon)) = O(a). \end{aligned}$$

Proof. It follows easily from Lemma 5.16 that the (d,a)-network consisting of the d-permutation $\hookrightarrow^a_d$ followed by the depth-a shuffle-"+" d-network has the desired properties. The additional depth required to implement the d-permutation $\hookrightarrow^a_d$ is

$\min\{a, d-a\} \leq a$ for a hypercubic construction and 0 for a nonhypercubic construction. □

Lemma 5.16 formalizes a central claim of the paper, namely, that the 0-1 no-elimination tournament has a surprisingly strong ranking property. Though stated in the 0-1 domain, Lemma 5.16 can easily be interpreted in the permutation domain. Such an interpretation is provided by the following theorem, which is stated without proof. (We remark that the extra factor of $\text{pow}(d)$ in the error bound arises because $|\Phi_\pi| = \text{pow}(d)+1$ for any d-permutation π. Also, Lemma 5.17, and not Theorem 5.1, is used to derive the results of subsequent sections.)

THEOREM 5.1. *Let (γ, ε, d) be an admissible triple, and define set A and permutation π as in the proof of Lemma* 5.14. *Let a random d-permutation drawn from $\Pi_R(d)$ be input to a depth-d shuffle-"+" d-network, and let π' denote the permutation induced on the output wires of A. Then the permutation obtained by applying π to π' is sorted to within* $\text{pow}(\gamma \cdot d)$ *positions with probability at least* $1 - O(\text{pow}(2 \cdot d) \cdot \varepsilon)$. □

Finally, we remark that the factors of $\text{pow}(d)$, $\text{pow}(a)$, and $\text{pow}(2 \cdot d)$ appearing in the error bounds associated with Lemmas 5.16 and 5.17 and Theorem 5.1 are not best possible. Lowering these factors would require a much more careful analysis, however, and from a theoretical point of view, would yield essentially no improvement in the results of subsequent sections. (Our applications make use of Lemma 5.17 with ε set far smaller than $\text{pow}(-c \cdot d)$ for any constant $c > 0$.) Of course, from a practical standpoint, it would be interesting to pin down the error bounds more accurately. For sufficiently small values of d, we remark that a computer program can be used to obtain very accurate error estimates.

6. A small-constant-factor network that sorts most inputs. Given Lemma 5.16, it is now a relatively simple task to design a logarithmic-depth network that sorts a random 0-1 input vector with high probability. The transformation consists of two basic components informally outlined below:

1. A procedure for augmenting the network of Lemma 5.16, which guarantees that all but a small fixed subset of the outputs are approximately sorted on a random 0-1 input vector with high probability, to obtain a network which guarantees that the entire output vector is approximately sorted on a random 0-1 input vector with high probability.
2. Recursive application of the network obtained from the previous step, with occasional merge operations in order to correct for items that fall into the wrong recursive subproblem due to boundary effects.

If the network of Lemma 5.16 worked on all 0-1 input vectors, and if we didn't care about constant factors, then it would be straightforward to devise a logarithmic-depth sorting network using the approach described above. Since we do care about constant factors and have to worry about probabilities, however, our solution will be somewhat more involved, and the proof will be somewhat more tedious. Nevertheless, we will still follow the basic approach outlined above in order to establish Lemma 6.1, the main technical result of this section.

LEMMA 6.1. *For all a and d such that $0 \leq a \leq d$, and each function $\varepsilon(d) = \text{pow}(-\text{pow}(o(d)))$, there is a function $f(d) = o(1)$ such that*

$$Sort_D(d, a, \varepsilon(a)) \leq \frac{2 - \gamma_c^2 + f(a)}{1 - \gamma_c} \cdot a.$$

Furthermore, there is a deterministic d-network that achieves this bound.

Note that $(2-\gamma_c^2)/(1-\gamma_c) \approx 7.44$. The following theorem provides an interpretation of Lemma 6.1 in the permutation domain.

THEOREM 6.1. *For each function $\varepsilon(d) = \mathrm{pow}(-\mathrm{pow}(o(d)))$, there is a function $f(d) = o(1)$ and a deterministic d-network of depth*

$$\frac{2-\gamma_c^2+f(d)}{1-\gamma_c} \cdot d$$

that sorts a random d-permutation drawn from $\Pi_R(d)$ with probability at least $1-\varepsilon(d)$.

Proof. Let $n = \mathrm{pow}(d)$. If π is a random d-permutation drawn from $\Pi_R(d)$, then ϕ_π^k is drawn at random from $\Phi_R(d,k)$, $0 \le k \le n$. By Lemma 6.1 (with $a = d$), there is a deterministic d-network $\mathcal{N}$ of the desired depth that sorts a random 0-1 d-vector drawn from $\Phi_R(d,k)$, $0 \le k \le n$, with probability at least $1-\varepsilon(d)$ for each function $\varepsilon(d) = \mathrm{pow}(-\mathrm{pow}(g(d)))/(n+1)$ with $g(d) = o(d)$. By Lemma 4.2, d-network $\mathcal{N}$ sorts d-permutation π if and only if it sorts the $n+1$ 0-1 d-vectors in Φ_π. This occurs with probability at least $1-(n+1)\cdot\varepsilon(d) = 1-\mathrm{pow}(-\mathrm{pow}(g(d)))$, as required. □

LEMMA 6.2. *For all a, b, and d such that $0 \le b \le a \le d$, and all ε and ε' in $[0,1]$, we have*

$$\mathit{Sort}_D(d, a, \varepsilon + 2\cdot\varepsilon') \le \mathit{Sort}_D(d,a,b,\varepsilon) + \mathit{Sort}_D(d,b,\varepsilon') + 2\cdot\mathit{Merge}_D(d,b,1).$$

Proof. We may assume that $a > b$, since the claim is trivial otherwise. We argue that a (d,a)-network in $\mathit{Sort}_N(d, a, \varepsilon + 2\cdot\varepsilon')$ can be constructed by composing the following: (a) any (d,a)-network in $\mathit{Sort}_N(d,a,b,\varepsilon)$; (b) a random d-permutation drawn from $\Pi_R(d,b)$; (c) any (d,a)-network in $\mathit{Sort}_N(d,b,\varepsilon')$; (d) any $(d,b+1)$-network in $\mathit{Merge}_N(d,b,1)$; (e) the d-permutation π in $\Pi(d,a)$ that maps wire i to wire $(i+\mathrm{pow}(b)) \bmod \mathrm{pow}(a)$, $0 \le i < \mathrm{pow}(a)$, within each a-cube; (f) any $(d,b+1)$-network in $\mathit{Merge}_N(d,b,1)$; (g) the d-permutation π^{-1}; and (h) the d-permutation in $\Pi(d,a)$ that exchanges the lowest and highest b-cubes within each a-cube. (Note that this construction does indeed give a (d,a)-network.)

We may assume that the input is an a-random 0-1 d-vector. Consider an arbitrary a-cube A. After stage (a) of the construction, A is b-sorted with probability at least $1-\varepsilon$. The output of stage (b) is b-random by Lemma 4.9. Hence, each b-cube of A is sorted with probability at least $1-\varepsilon'$ after stage (c). Furthermore, with probability at least $1-\varepsilon$, no two nonconsecutive b-cubes of A receive nontrivial input.

In what follows, we complete the proof by showing that A is sorted after stage (h) whenever (i) A is b-sorted after stage (a), and (ii) every b-cube of A is sorted after stage (c). (Note that these conditions are satisfied with probability at least $1-\varepsilon-2\cdot\varepsilon'$.)

Accordingly, assume that conditions (i) and (ii) hold. Then A is sorted after stage (c) with the exception of at most two nontrivial b-cubes of A. If A contains 0 or 1 nontrivial b-cubes after stage (c), then A is easily seen to be sorted after stages (c), (d), and (h). If there are 2 nontrivial b-cubes in A after stage (c) then they are adjacent. If b-cubes $2\cdot j$ and $2\cdot j+1$ are nontrivial for some integer j, $0 \le j < \mathrm{pow}(a-b-1)$, then A is sorted after stages (d) and (h). If b-cubes $2\cdot j+1$ and $2\cdot j+2$ are nontrivial for some integer j, $0 \le j < \mathrm{pow}(a-b-1)-1$, then stage (d) has no effect and the output of stage (h) is sorted. □

Lemmas 4.3, 4.6, and 6.2 together imply that

$$\mathit{Sort}_D(d,a,\varepsilon) \le \mathit{Sort}_D(d,a,b,\varepsilon) + O(b) \tag{10}$$

for all a, b, and d such that $0 \le b \le a \le d$, and all ε in $[0,1]$.

LEMMA 6.3. *For all a, b, and d such that $0 \le b \le a \le d$, and all ε in $[0,1]$, we have*

$$\mathit{Sort}_D(d, a, b+1, \varepsilon) \le \mathit{Most}_D(d, a, b, \varepsilon) + \mathit{Insert}_D(d, a-b).$$

Proof. We argue that a (d,a)-network in $\mathit{Sort}_N(d, a, b+1, \varepsilon)$ can be constructed by composing the following: (a) any (d,a)-network in $\mathit{Most}_N(d, a, b, \varepsilon)$; (b) an appropriate d-permutation π in $\Pi(d, a)$; (c) the d-permutation $\hookrightarrow_d^b$; (d) any $(d, a-b)$-network in $\mathit{Insert}_N(d, a-b)$; and (e) the d-permutation $\hookleftarrow_d^b$. (Note that this construction does indeed give a (d,a)-network.)

We may assume that the input is an a-random 0-1 d-vector. By the definition of $\mathit{Most}_N(d, a, b, \varepsilon)$, there is some d-permutation π in $\Pi(d, a)$ such that each a-cube is b-mostly-sorted with respect to π with probability at least $1-\varepsilon$ after stage (a). This is the desired stage (b) d-permutation π. Consider an arbitrary a-cube A. In what follows, we complete the proof by showing that if A is b-mostly-sorted with respect to π after stage (a), then A is $(b+1)$-sorted after stage (e).

Accordingly, let us assume that A is b-mostly-sorted with respect to π after stage (a). Then each $(a-b)$-cube of A contains an insertion instance after stage (c). Thus, each $(a-b)$-cube of A is sorted after stage (d). Furthermore, note that each $(a-b)$-cube of A contains the same number of 0's to within 2. Hence A has a dirty region of size at most $2 \cdot \mathrm{pow}(b) = \mathrm{pow}(b+1)$ after stage (e), as desired. □

LEMMA 6.4. *For all a, b, and d such that $0 \le b \le a \le d$, and all γ, ε, and ε' in $[0,1]$, we have*

$$\begin{aligned}\mathit{Sort}_D(d, a, b'+3, \varepsilon + 2\cdot\varepsilon') \le \mathit{Sort}_D(d, a, b, \varepsilon) + \mathit{Sort}_D(d, b+2, b'+1, \varepsilon') \\ + \mathit{Merge}_D(d, b-b', 1),\end{aligned}$$

where $b' = \lfloor \gamma \cdot (b+2) \rfloor$.

Proof. We may assume that $b > b'+3$ and $a > b+2$, since the claim is trivial otherwise. Let $m = \mathrm{pow}(a-b-2)$. We argue that a (d,a)-network in $\mathit{Sort}_N(d, a, b'+3, \varepsilon + 2\cdot\varepsilon')$ can be constructed by composing the following: (a) any (d,a)-network in $\mathit{Sort}_N(d, a, b, \varepsilon)$; (b) a random d-permutation drawn from $\Pi_R(d, b+2)$; (c) any $(d, b+2)$-network in $\mathit{Sort}_N(d, b+2, b'+1, \varepsilon')$; (d) an appropriate d-permutation π in $\Pi(d, a)$; (e) any $(d, b-b'+1)$-network in $\mathit{Merge}_N(d, b-b', 1)$; and (f) an appropriate d-permutation π' in $\Pi(d, a)$. (Note that this construction does indeed give a (d,a)-network.)

We may assume that the input is an a-random 0-1 d-vector. By the definition of $\mathit{Sort}_N(d, a, b, \varepsilon)$, each a-cube is b-sorted with probability at least $1-\varepsilon$ after stage (a). The output of stage (b) is $(b+2)$-random by Lemma 4.9. Hence, each $(b+2)$-cube is $(b'+1)$-sorted with probability at least $1-\varepsilon'$ after stage (c). Consider an arbitrary a-cube A, and let B_i denote the ith $(b+2)$-cube of A, $0 \le i < m$.

After stage (c), note that the following claims hold with probability at least $1-\varepsilon-2\cdot\varepsilon'$: (i) the dirty region of A has size at most $\mathrm{pow}(b)+2\cdot\mathrm{pow}(b'+1) \le \mathrm{pow}(b+1)$, and (ii) every B_i is $(b'+1)$-sorted. Let B_i^- (resp., B_i^+) denote $(b+1)$-cube 0 (resp., 1) of B_i. (In other words, B_i^- and B_i^+ are the "low half" and "high half" of B_i, respectively.) If condition (i) holds, then the dirty region of A is either confined to some B_i, or to some (B_{i-1}^+, B_i^-) pair, $0 < i < m$. Let us say that case 1 holds if, after stage (c), the dirty region of A is confined to some B_i and conditions (i) and (ii) hold. Similarly, case 2 holds if, after stage (c), the dirty region of A is confined to some (B_{i-1}^+, B_i^-) pair and conditions (i) and (ii) hold. Otherwise, case 3 holds. Note that case 3 holds with probability at most $\varepsilon + 2\varepsilon'$.

We now define the d-permutation π to be applied in stage (d). Break each $(b+1)$-cube B_i^+ (resp., B_i^-) into $\mathrm{pow}(b'+1)$ equal-sized sets $B_{i,j}^+$ (resp., $B_{i,j}^-$) by applying the $(b+1)$-permutation $\hookrightarrow_{b+1}^{b'+1}$ and then partitioning into $(b-b')$-cubes. (In other words, the set $B_{i,j}^+$ consists of those wires in B_i^+ with indices congruent to j modulo $\mathrm{pow}(b'+1)$, $0 \le j < \mathrm{pow}(b'+1)$.) In the arguments that follow, let C_i denote $B_{i-1}^+ \cup B_i^-$ and C_i^j denote the jth $(b-b'+1)$-cube of C_i, $0 < i < m$, $0 \le j < \mathrm{pow}(b'+1)$. The d-permutation π is defined in such a way that: (i) the wires in B_0^- and B_{m-1}^+ are left alone, and (ii) for each (B_{i-1}^+, B_i^-) pair, $0 < i < m$, the wires of $B_{i-1,j}^+$ and $B_{i,j}^-$ are brought into opposite halves of $(b-b'+1)$-cube C_i^j in preparation for the merge step of stage (e), $0 \le j < \mathrm{pow}(b'+1)$.

If either case 1 or case 2 holds after stage (c), note that the following claims hold after stage (d), $0 < i < m$; (i) all of the $B_{i-1,j}^+$'s and $B_{i,j}^-$'s are sorted, and (ii) all of the $B_{i-1,j}^+$'s (resp., $B_{i,j}^-$'s) have the same number of 0's to within 2.

If either case 1 or case 2 holds after stage (c), note that the following claims hold after stage (e), $0 < i < m$: (i) every C_i^j is sorted, and (ii) all of the C_i^j's have the same number of 0's to within 4.

We now define the d-permutation π' of stage (f) so that: (i) the wires in B_0^- and B_{m-1}^+ are left alone, and (ii) for each i, $0 \le i < m-1$, the C_i^j's are interleaved (in place) by applying the $(b+1)$-permutation $\hookleftarrow_{b+1}^{b'+1}$.

Let $C_0 = B_0^-$, $C_m = B_{m-1}^+$, and assume that either case 1 or case 2 held after stage (c). Then the following conditions hold after stage (f): (i) C_i has a dirty region of size at most $4 \cdot \mathrm{pow}(b'+1) = \mathrm{pow}(b'+3)$, $0 \le i \le m$, and (ii) no two nonconsecutive C_i's are nontrivial. If 0 or 1 of the C_i's are nontrivial then A is $(b'+3)$-sorted, and we are done. Otherwise, we can assume that C_i and C_{i+1} are nontrivial for some particular i, $0 \le i < m$. It follows easily that case 2 held after stage (c), and that the output of A after stage (f) is the same as after stage (c); hence, the dirty region of A has size at most $\mathrm{pow}(b'+1)$ after stage (f). □

Lemmas 4.4, 5.17, and 6.3 together imply that

$$Sort_D(d, a, \lfloor \gamma \cdot a \rfloor + 1, O(\mathrm{pow}(a) \cdot \varepsilon)) \le 2 \cdot a - \lfloor \gamma \cdot a \rfloor$$

for any admissible triple (γ, ε, a) and all d such that $0 \le a \le d$. Lemma 5.6 implies that for any function $\varepsilon(a) = \mathrm{pow}(-\mathrm{pow}(o(a)))$, there is a function $f(a) = o(1)$ such that $(\gamma_c + f(a), \varepsilon, a)$ is an admissible triple for all $a \ge 0$. Hence,

$$Sort_D(d, a, \lfloor \gamma(a) \cdot a \rfloor + 1, \mathrm{pow}(-\mathrm{pow}(o(a)))) \le 2 \cdot a - \lfloor \gamma(a) \cdot a \rfloor, \tag{11}$$

with $\gamma(a) = \gamma_c + o(1)$. Substituting the bounds of equation (11) (with $a = b+2$) and Lemma 4.3 (with $(a, d) = (b - \lfloor \gamma \cdot (b+2) \rfloor + 1, d)$) into the inequality of Lemma 6.4, we find that

$$\begin{aligned} &Sort_D(d, a, \lfloor (\gamma_c + o(1)) \cdot (b+2) \rfloor + 3, \mathrm{pow}(-\mathrm{pow}(o(b))) + \varepsilon') \\ &\le Sort_D(d, a, b, \varepsilon') + (3 - 2 \cdot \gamma_c + o(1)) \cdot b, \end{aligned}$$

for all ε' in $[0, 1]$. Starting with equation (11), and then iteratively applying the preceding inequality (with $b \approx \gamma \cdot a, \gamma^2 \cdot a, \gamma^3 \cdot a, \ldots$), until equation (10) can be "inexpensively" applied (e.g., with $b = o(a)$) we find that

$$Sort_D(d, a, \mathrm{pow}(-\mathrm{pow}(o(a)))) \le \frac{2 - \gamma_c^2 + o(1)}{1 - \gamma_c} \cdot a$$

for all a and d such that $0 \leq a \leq d$. Using Lemma 4.8 to eliminate the random aspects of the preceding construction, the proof of Lemma 6.1 is now complete. (We remark that randomization has not been used in the operation phase of any level in our construction. Furthermore, the only nontrivial probability distributions used in the permutation phase of any level are the $\Pi_R(d, a)$ distributions, $0 < a \leq d$.)

Note that we have used the AKS sorting network as part of our construction. It should be emphasized, however, that the AKS sorting network is only used to allow the function $\varepsilon(d)$ of Lemma 6.1 to be set as small as possible. For example, one could prove Lemma 6.1 with $\varepsilon(d) = \mathrm{pow}(-\mathrm{pow}(o(\sqrt{d})))$ by cutting off the preceding recurrence at $b = o(\sqrt{d})$ and applying bitonic sort, instead of cutting it off at $b = o(d)$ and applying the AKS sorting network.

7. An optimal-depth hypercubic network that sorts most inputs. In this section, we establish the existence of a depth-$O(d)$, hypercubic d-network that sorts most inputs. Once again we make use of the high-level strategy described at the beginning of section 6, except that we make use of Lemma 5.17 instead of Lemma 5.16. In contrast with section 6, however, we do not concern ourselves with constant factor issues. This leads to a much simpler construction. In particular, we do not require a hypercubic analogue of Lemma 6.4.

LEMMA 7.1. *Let $\psi(a)$ be any function such that $Sort^h_D(d, \psi(a), 0) = O(d)$, $0 \leq a \leq d$. For each function $\varepsilon(d) = \mathrm{pow}(-\mathrm{pow}(\psi(d)))$, we have*

$$Sort^h_D(d, a, \varepsilon(a)) = O(a).$$

Furthermore, there is a deterministic d-network that achieves this bound. □

By Lemma 4.5, the function ψ appearing in the statement of Lemma 7.1 is $\Omega(\sqrt{d})$. In fact, by Theorem 9.1, we have

$$\psi(d) = \Omega\left(\frac{d}{\mathrm{pow}(\sqrt{\upsilon_c \cdot \lg d}) \cdot \lg d}\right). \tag{12}$$

The following theorem provides an interpretation of Lemma 7.1 in the permutation domain.

THEOREM 7.1. *Let the function ψ be as defined in Lemma 7.1. For each function $\varepsilon(d) = \mathrm{pow}(-\mathrm{pow}(\psi(d)))$, there is a deterministic hypercubic d-network of depth $O(d)$ that sorts a random d-permutation drawn from $\Pi_R(d)$ with probability at least $1 - \varepsilon(d)$.*

Proof. The proof is similar to that of Theorem 6.1. □

LEMMA 7.2. *For all a, b, and d such that $0 \leq b \leq a \leq d$, and all ε and ε' in $[0, 1]$, we have*

$$Sort^h_D(d, a, \varepsilon + 2 \cdot \varepsilon') \leq Sort^h_D(d, a, b, \varepsilon) + Sort^h_D(d, b, \varepsilon') + 2 \cdot Merge^h_D(d, b, 1) + O(a).$$

Proof. The proof is similar to that of Lemma 6.2. The only difference is that we use an $O(a)$-depth hypercubic (d, a)-network (guaranteed to exist by Lemma 4.7) to implement each of the d-permutations of stages (b), (e), (g), and (h). This accounts for the additive $O(a)$ term on the right-hand side of the inequality. □

LEMMA 7.3. *For all a, b, and d such that $0 \leq b \leq a \leq d$, and all ε in $[0, 1]$, we have*

$$Sort^h_D(d, a, b + 1, \varepsilon) \leq Most^h_D(d, a, b, \varepsilon) + Insert^h_D(d, a - b) + O(a).$$

Proof. The proof is similar to that of Lemma 6.3. The only difference is that we use an $O(a)$-depth hypercubic (d, a)-network (guaranteed to exist by Lemma 4.7) to implement each of the d-permutations of stages (b), (c), and (e). This accounts for the additive $O(a)$ term on the right-hand side of the inequality. □

Lemmas 4.4, 5.17, and 7.3 together imply that

$$Sort_D^h(d, a, \lfloor \gamma \cdot a \rfloor + 1, O(\mathrm{pow}(a) \cdot \varepsilon)) = O(a) \tag{13}$$

for all d and any admissible triple (γ, ε, a) such that $0 \leq a \leq d$. Let δ be any constant, $0 < \delta < 1 - \gamma_c$. By Lemma 5.6, there is a function $g(d) = \Theta(d)$ such that $(\gamma_c + \delta, \mathrm{pow}(-\mathrm{pow}(g(a))), a)$ is an admissible triple for all $a \geq 0$. Hence,

$$Sort_D^h(d, a, \lfloor \gamma \cdot a \rfloor + 1, \mathrm{pow}(-\mathrm{pow}(\Theta(a)))) = O(a),$$

with $\gamma = \gamma_c + \delta$, and $0 \leq a \leq d$. Lemmas 4.3 and 7.2 (with $b = \lfloor \gamma \cdot a \rfloor + 1$) now give

$$Sort_D^h(d, a, \mathrm{pow}(-\mathrm{pow}(\Theta(a))) + 2 \cdot \varepsilon') \leq Sort_D^h(d, \lfloor \gamma \cdot a \rfloor + 1, \varepsilon') + O(a).$$

for all ε' in $[0, 1]$. Iteratively applying the preceding inequality, we find that

$$Sort_D^h(d, a, \mathrm{pow}(-\mathrm{pow}(\Theta(b)))) \leq Sort_D^h(d, b, 0) + O(a)$$

for all a, b, and d such that $0 \leq b \leq a \leq d$. Substituting $\psi(a)$ for b, where the function ψ is as defined in the statement of Lemma 7.1, we obtain

$$Sort_D^h(d, a, \mathrm{pow}(-\mathrm{pow}(\psi(a)))) = O(a)$$

for all a and d such that $0 \leq a \leq d$. Using Lemma 4.8 to eliminate the random aspects of the preceding construction, the proof of Lemma 7.1 is now complete. (We remark that randomization has not been used in the operation phase of any level in our construction. Furthermore, the only use of randomization in the permutation phase arises from applying Lemma 4.7 to implement random d-permutations drawn from $\Pi_R(d, a)$, $0 < a \leq d$.)

8. Deterministic merging. Many sorting algorithms, both sequential as well as parallel, are based on merging. For instance, sequential merge sort and Batcher's bitonic sorting network are both based on 2-way merging. Since merging two sorted lists of length $\mathrm{pow}(d)$ requires $\Omega(d)$ depth, one cannot hope to obtain a $o(d^2)$-depth sorting network (hypercubic or otherwise) by repeated 2-way merging. This section describes how to use a network $\mathcal{N}$ that sorts most inputs to construct a high-order merging network $\mathcal{N}'$, that is, an m-way merging network for some $m \gg 2$. A similar technique has recently been used by Ajtai, Komlós, and Szemerédi as part of an improved version of their original sorting network construction [3]. The multiplicative constant associated with the new construction is significantly lower than the constant established by Paterson [15], though it remains impractical.

The main idea underlying the results of this section may be informally outlined as follows. An n-input network is an m-way merging network if and only if it correctly merges all possible input vectors consisting of m sorted vectors of length n/m. But as in the case of sorting networks, we can easily prove the following 0-1 principle for merging networks: Any n-input network that correctly merges every input vector consisting of m sorted 0-1 vectors of length n/m is an m-way merging network. A key observation is that the total number of 0-1 vectors which can be obtained by

concatenating m sorted 0-1 vectors of length n/m is $(n/m+1)^m$, which is fairly small (compared to 2^n, the total number of 0-1 vectors, for example) when m is not too large. As a result, we can use an averaging argument to prove that, given any network $\mathcal{N}$ which for all k sorts a sufficiently high fraction (dependent on m) of the $\binom{n}{k}$ 0-1 vectors with k 0's and $n-k$ 1's, there exists a permutation π such that the network $\mathcal{N}'$ obtained by composing π with $\mathcal{N}$ sorts *all* of the $(n/m+1)^m$ 0-1 vectors consisting of m sorted 0-1 vectors of length n/m; in other words, $\mathcal{N}'$ is an m-way merging network with the same size and depth as network $\mathcal{N}$.

LEMMA 8.1. *Let $\mathcal{N}$ denote a (hypercubic) (d,a)-network that sorts each a-cube with probability at least $1-\varepsilon$ on any a-random* 0-1 *input d-vector, $m=\mathrm{pow}(d-a)$, Φ denote a subset of $\Phi(d)$, $\Phi^{(i)}\subseteq\Phi(a)$ denote the projection of the ith a-cube of Φ onto $\Phi(a)$, $0\le i<m$, and $\Phi'=\cup_{0\le i<m}\Phi^{(i)}$. If $|\Phi'|<1/\varepsilon$, then there exists a d-permutation π in $\Pi(d,a)$ such that the (hypercubic) (d,a)-network $\mathcal{N}'$ obtained by composing π with $\mathcal{N}$ satisfies*

$$\Phi\subseteq \mathit{Sort}(\mathcal{N}',a).$$

Proof. By definition, (hypercubic) (d,a)-network $\mathcal{N}$ can be partitioned along input a-cubes into m disjoint, identical a-networks $\mathcal{N}_a$. Thus, it is sufficient to construct an a-permutation π' such that the (hypercubic) a-network $\mathcal{N}'_a$ obtained by composing π' with $\mathcal{N}_a$ satisfies

$$\Phi'\subseteq \mathit{Sort}(\mathcal{N}'_a).$$

To determine a suitable a-permutation π', we construct the undirected bipartite graph with vertex sets $U=\Phi'$ and $V=\Pi(a)$, and an edge from vertex ϕ in U to vertex π in V if and only if the 0-1 a-vector ϕ is sorted by the a-network obtained by composing a-permutation π with $\mathcal{N}_a$. The degree of every vertex in U is at least $(1-\varepsilon)\cdot(\mathrm{pow}(a))!$, and so the sum of the degrees of the vertices in U is at least $(1-\varepsilon)\cdot|U|\cdot(\mathrm{pow}(a))!$. This sum is identical to that attained over V, so some vertex π' in V has degree at least $(1-\varepsilon)\cdot|U|>|U|-1$. Since the degree of π' is an integer, vertex π' is connected to every vertex in U. Thus, the a-network obtained by composing a-permutation π' with network $\mathcal{N}_a$ sorts every element of Φ'. □

LEMMA 8.2. *For nonnegative integers a' and b', let $\mathcal{N}$ be defined as in Lemma* 8.1 *with $a=a'+b'$ and*

$$(\mathrm{pow}(a')+1)^{\mathrm{pow}(b')}<1/\varepsilon.$$

Let Φ denote the set of all 0-1 *d-vectors ϕ such that each a-cube of ϕ belongs to $\Phi_M(a',b')$. Then there exists a d-permutation π in $\Pi(d,a)$ such that the (hypercubic) (d,a)-network $\mathcal{N}'$ obtained by composing π with $\mathcal{N}$ satisfies*

$$\Phi\subseteq \mathit{Sort}(\mathcal{N}',a).$$

Proof. We can apply Lemma 8.1 (with $\Phi'=\Phi_M(a',b')$) since

$$\begin{aligned}|\Phi_M(a',b')| &= (\mathrm{pow}(a')+1)^{\mathrm{pow}(b')}\\ &< 1/\varepsilon.\end{aligned}$$ □

Note that in Lemmas 8.1 and 8.2, the depth of $\mathcal{N}'$ exceeds that of $\mathcal{N}$ only by the depth required to implement a d-permutation in $\Pi(d,a)$. By Lemma 4.7, this additional depth is at most $2\cdot a$ for a hypercubic construction. (For a nonhypercubic construction, no additional depth is required to implement a fixed permutation.)

9. A near-optimal hypercubic sorting network. In this section, we construct a hypercubic sorting network with nearly logarithmic depth. At a high level, the construction is simply based on recursive high-order merging: the input is partitioned into some number of equal-sized lists, each of these lists is sorted recursively, and the resulting set of sorted lists are merged together. The recursion is cut off by applying bitonic sort on subproblems that are sufficiently small. The primary question that remains to be addressed is how to perform the merge step efficiently. Lemmas 9.1 and 9.2 make use of the results of section 8 (specifically, Lemma 8.2) to reduce the merge step to a smaller sorting problem.

LEMMA 9.1. *Let $\nu(d)$ be any function such that $\nu(d) = \omega(1)$ and $\nu(d) = o(d)$, and let $\varepsilon(d) = \mathrm{pow}(-\mathrm{pow}(\mu(d) \cdot d))$ where $\mu(d) = \mu_c - \frac{1}{\nu(d)}$. For all a, b, and d such that $0 \le b \le a \le d$, we have*

$$Sort_D^h(d, a, O(\mathrm{pow}(b) \cdot \varepsilon(b))) \le Sort_D^h(d, b, 0) + O(a \cdot \nu(a)).$$

Proof. By Lemma 5.7, there exists a function $\gamma(d) = 1 - \frac{3-o(1)}{4 \cdot \nu(d)}$ such that $(\gamma(a), \varepsilon(a), a)$ is an admissible triple for all $a \ge 0$. For such an admissible triple, equation (13) then implies

$$Sort_D^h(d, a, \lfloor \gamma(a) \cdot a \rfloor + 1, O(\mathrm{pow}(a) \cdot \varepsilon(a))) = O(a).$$

Lemmas 4.3 and 7.2 now give

$$Sort_D^h(d, a, O(\mathrm{pow}(a) \cdot \varepsilon(a)) + 2 \cdot \varepsilon') \le Sort_D^h(d, \lfloor \gamma(a) \cdot a \rfloor + 1, \varepsilon') + O(a),$$

for all ε' in $[0, 1]$. Iteratively applying the preceding inequality, we find that

$$Sort_D^h(d, a, O(\mathrm{pow}(b) \cdot \varepsilon(b))) \le Sort_D^h(d, b, 0) + O(a \cdot \nu(a))$$

for all a, b, and d such that $0 \le b \le a \le d$. □

LEMMA 9.2. *Let the function ν be as defined in Lemma 9.1, and let $\mu(d) = \mu_c - \frac{2}{\nu(d)}$. Then*

$$Merge_D^h(d, a - \lfloor \mu(b) \cdot b \rfloor, \lfloor \mu(b) \cdot b \rfloor) \le Sort_D^h(d, b, 0) + O(a \cdot \nu(a))$$

for all a, b, and d such that $(2 + \lg a) \cdot \nu(b) \le b \le a \le d$.

Proof. Let $\varepsilon(d) = \mathrm{pow}(-\mathrm{pow}(\mu'(d) \cdot d))$ where $\mu'(d) = \mu_c - \frac{1}{\nu(d)}$. By Lemma 9.1,

$$Sort_D^h(d, a, O(\mathrm{pow}(b) \cdot \varepsilon(b))) \le Sort_D^h(d, b, 0) + O(a \cdot \nu(a))$$

for all a, b, and d such that $0 \le b \le a \le d$. Hence, for b sufficiently large, there exists a hypercubic (d, a)-network $\mathcal{N}$ of depth $Sort_D^h(d, b, 0) + O(a \cdot \nu(a))$ that sorts each a-cube with probability at least $1 - \varepsilon'$ on any a-random 0-1 input d-vector, where

$$\begin{aligned} \varepsilon' &= \mathrm{pow}(2 \cdot b) \cdot \varepsilon(b) \\ &= \mathrm{pow}(\mathrm{pow}(1 + \lg b) - \mathrm{pow}(\mu'(b) \cdot b)) \\ &< \mathrm{pow}(-\mathrm{pow}(\mu'(b) \cdot b - 1)). \end{aligned}$$

The result now follows from Lemma 8.2 since

$$\begin{aligned} (\mathrm{pow}(a - \lfloor \mu(b) \cdot b \rfloor) + 1)^{\mathrm{pow}(\lfloor \mu(b) \cdot b \rfloor)} &< \mathrm{pow}(2 \cdot a \cdot \mathrm{pow}(\mu(b) \cdot b)) \\ &= \mathrm{pow}(\mathrm{pow}(\mu(b) \cdot b + 1 + \lg a)) \\ &= \mathrm{pow}(\mathrm{pow}(\mu'(b) \cdot b + 1 + \lg a - b/\nu(b))) \\ &\le \mathrm{pow}(\mathrm{pow}(\mu'(b) \cdot b - 1)) \\ &< 1/\varepsilon'. \end{aligned}$$

□

A recurrence for $Sort^h_D(d, a, 0)$ can be developed using the preceding lemma. Note that

$$Sort^h_D(d, a, 0) \leq \min_{0 \leq b \leq a} Sort^h_D(d, a-b, 0) + Merge^h_D(d, a-b, b)$$

for all a, b, and d such that $0 \leq b \leq a \leq d$. (This inequality is immediate, since we can always sort a-cubes by: (i) sorting $(a-b)$-cubes, and (ii) merging the sorted $(a-b)$-cubes within each a-cube.) Let the functions ν and μ be as defined in Lemma 9.2. Applying Lemma 9.2 to the preceding inequality, we obtain

$$Sort^h_D(d, a, 0) \leq \min_{(2+\lg a)\cdot\nu(b) \leq b \leq a} Sort^h_D(d, a - \lfloor \mu(b) \cdot b \rfloor, 0) + Sort^h_D(d, b, 0) + O(a \cdot \nu(a))$$

for all a, b, and d such that $0 \leq b \leq a \leq d$. Fixing d and letting $S(a) = Sort^h_D(d, a, 0)$, we can write this recurrence more simply as

$$S(a) \leq \min_{(2+\lg a)\cdot\nu(b) \leq b \leq a} S(a - \lfloor \mu(b) \cdot b \rfloor) + S(b) + O(a \cdot \nu(a)).$$

In Appendix A it is proven that

$$S(a) = O(a \cdot \mathrm{pow}(\sqrt{\upsilon_c \cdot \lg a}) \cdot \lg a).$$

(The constant υ_c is defined in equation (9).) The preceding bound is proven with $\nu(d) = \Theta(\sqrt{\lg d})$, and seems to be the best upper bound obtainable using this recurrence. Setting $a = d$, we obtain a proof of the following theorem.

THEOREM 9.1. *For all $d \geq 0$, we have*

$$Sort^h_D(d, 0) = O(d \cdot \mathrm{pow}(\sqrt{\upsilon_c \cdot \lg d}) \cdot \lg d). \qquad \square$$

10. An optimal randomized hypercubic sorting algorithm. In section 7, we constructed a depth-$O(d)$ hypercubic sorting network that sorts most d-permutations. In the present section, we modify that result to obtain a polynomial-time uniform $O(d)$-depth, coin-tossing hypercubic network that sorts *every* d-permutation (and hence, every d-vector) with high probability. We then use this coin-tossing network to develop a polynomial-time uniform hypercubic algorithm that sorts every d-vector in $O(d)$ time with high probability.

We define a *hypercubic algorithm* as any normal hypercube algorithm. (See [12, section 3.1.3], for example, for a definition of the class of normal hypercube algorithms.) Every depth-a hypercubic sorting d-network corresponds to a (possibly nonuniform) hypercubic sorting algorithm that runs in $O(a)$ time on any $\mathrm{pow}(d)$-processor hypercubic machine. Of course, the converse is not true in general; most of the basic operations allowed within a normal hypercube algorithm (e.g., the usual set of arithmetic operations) cannot be performed by a hypercubic sorting network.

A sorting network is hard-wired and has a fixed depth, or "running time," that is independent of the input. On the other hand, a sorting algorithm can have an arbitrarily large gap between its worst-case and average-case running times. For example, consider a sorting algorithm with the following structure:

1. Apply a random d-permutation drawn from $\Pi_R(d)$ to the input d-vector.
2. Attempt to sort the resulting d-vector using a time-$T(d)$ method that correctly sorts most d-permutations.

3. Check whether step 2 was successful. If so, halt. If not, return to step 1.

The worst-case running time of such an algorithm is infinite, while the average-case running time could be as low as $O(T(d))$. One might attempt to develop a hypercubic sorting algorithm with this structure by using the d-network of Theorem 7.1 to implement step 2 with $T(d) = O(d)$. Step 3 is trivial to implement in $O(d)$ time. However, two difficulties remain to be addressed.

The first difficulty is that step 1 is not easily implemented by a hypercubic algorithm. We will overcome this difficulty by making use of a depth-d shuffle-"?" d-network to randomly permute the input data. Although the d-permutation π applied by such a d-network is not d-random, we prove in Lemma 10.2 below that π is sufficiently random for our purposes.

The second difficulty is that the hypercubic algorithm corresponding to Theorem 7.1 is not polynomial-time uniform. This undesirable characteristic stems from our use of Lemma 4.8 to remove the random aspects of our hypercubic network construction. As discussed at the end of section 7, there is only one source of randomness in our construction: Whenever we apply the shuffle-"+" (d, a)-network of Lemma 5.17, we first apply an a-random d-permutation. We overcome the second difficulty by replacing such a-random d-permutations with a depth-a unshuffle-"0" d-network followed by a depth-a shuffle-"?" d-network.

Lemmas 10.2 and 10.3 below prove that we can approximately sort *every* d-permutation with high probability by applying a depth-d shuffle-"?" d-network followed by a depth-$\lceil d/2 \rceil$ shuffle-"+" d-network. Lemma 10.1 widens the range of input distributions for which the analysis of section 5 can be applied. (Recall that the σ_α functions were defined in section 5.1.)

LEMMA 10.1. *Let $\mathcal{N}$ denote a coin-tossing d-network, and assume that for each length-d binary string α, input wire α is set to* 0 *with probability p_α, and to* 1 *otherwise. Further assume that the set of events $E_\alpha \stackrel{\text{def}}{=}$ "input wire α receives a* 0" *are mutually independent. Then the output wire with index α receives a* 0 *with probability at least $\sigma_\alpha(p^-)$ and at most $\sigma_\alpha(p^+)$, where $p^- = \min_\alpha p_\alpha$ and $p^+ = \max_\alpha p_\alpha$.*

Proof. The proof is immediate from Lemma 4.11. □

LEMMA 10.2. *Let a, b, and d denote nonnegative integers such that $d = a + b$, (γ, ε, a) be an admissible triple,*

$$\delta = (1 - 2 \cdot \varepsilon) \cdot \mathrm{pow}((\gamma - 1) \cdot a)/4,$$
$$\varepsilon' = 2 \cdot e^{-2 \cdot \delta^2 \cdot \mathrm{pow}(b)},$$

and $\mathcal{N}$ denote the depth-$(a + d)$ d-network obtained by composing the following: (i) *a depth-d shuffle-"?" d-network, and* (ii) *a depth-a shuffle-"+" d-network. Then there exists a set A of at least* $\mathrm{pow}(d) - \mathrm{pow}(\gamma \cdot a + b)$ *output wires of $\mathcal{N}$, and a fixed permutation π of A, such that the following condition holds with probability at least* $1 - \mathrm{pow}(d) \cdot \varepsilon - \mathrm{pow}(a) \cdot \varepsilon'$ *after execution of $\mathcal{N}$ on any* 0-1 *input d-vector ϕ: If permutation π is applied to A, then the resulting length-$|A|$* 0-1 *output vector is $(\gamma \cdot a + b)$-sorted.*

Proof. Let the 0-1 vector ϕ in $\Phi(d, k)$ be input to d-network $\mathcal{N}$, and set $p = k/\mathrm{pow}(d)$. Throughout this proof, the symbols α and β will be used to denote binary strings of length a and b, respectively. A *random execution* will refer to an execution of d-network $\mathcal{N}$ on input ϕ.

For each β, define $C_0(\beta)$ (resp., $C_2(\beta)$, $C_3(\beta)$) as the set of $\mathrm{pow}(a)$ level-0 input wires (resp., level-d input wires, level-$(a + d - 1)$ output wires) with indices of the

form $\alpha\beta$ (resp., $\alpha\beta$, $\beta\alpha$) for some α. For each α, define $C_1(\alpha)$ as the set of $\text{pow}(b)$ level-$(a-1)$ output wires with indices of the form $\beta\alpha$ for some β.

For each β, define p_β to be the fraction of 0's induced by input ϕ on $C_0(\beta)$ (i.e., the number of 0's assigned to $C_0(\beta)$ divided by $\text{pow}(a)$). Note that $p = (\sum_\beta p_\beta)/\text{pow}(b)$. For each α, let X_α denote the random variable corresponding to the number of 0's received by the wires of $C_1(\alpha)$ in a random execution, and let $q_\alpha = X_\alpha/\text{pow}(b)$. Note that, unlike the p_β's, each q_α is a random variable. Furthermore, the random variable X_α is easily seen to be the sum of $\text{pow}(b)$ independent Bernoulli trials, where trial β has success probability p_β. Thus, a standard Chernoff-type argument [6] implies

$$\Pr\{|X_\alpha - p \cdot \text{pow}(b)| \geq \vartheta \cdot \text{pow}(b)\} \leq 2 \cdot e^{-2 \cdot \vartheta^2 \cdot \text{pow}(b)} \tag{14}$$

for all $\vartheta \geq 0$. Define a random execution to be *δ-balanced* if

$$p - \delta \leq q_\alpha \leq p + \delta$$

for all α. By equation (14), a random execution is δ-balanced with probability at least $1 - \text{pow}(a) \cdot \varepsilon'$ (set $\vartheta = \delta$.)

Note that the last a levels of d-network $\mathcal{N}$ form a (d, a)-network. Hence, these levels can be partitioned into $\text{pow}(b)$ disjoint depth-a shuffle-"+" a-networks $\mathcal{N}_\beta$, where the input and output wires of $\mathcal{N}_\beta$ correspond to $C_2(\beta)$ and $C_3(\beta)$, respectively. Let $E_{\alpha\beta}$ denote the event that input α of $\mathcal{N}_\beta$ (i.e., level-d input wire $\alpha\beta$ of $\mathcal{N}$) receives a 0 in a random execution. Let $f_{\alpha\beta}(p)$ denote the probability that $E_{\alpha\beta}$ occurs in a random δ-balanced execution. Let $g_{\beta\alpha}(p)$ denote the probability that output α of $\mathcal{N}_\beta$ (i.e., output $\beta\alpha$ of $\mathcal{N}$) receives a 0 in a random δ-balanced execution. Note that $f_{\alpha\beta}(p) = q_\alpha$, since wire α of $C_2(\beta)$ receives the value of a wire chosen uniformly at random from $C_1(\alpha)$. Furthermore, since the sets $C_1(\alpha)$ are mutually disjoint, we find that for each β and for each fixed setting of the q_α values, the $\text{pow}(a)$ events $E_{\alpha\beta}$ are mutually independent. Lemma 10.1 can therefore be applied to each a-network $\mathcal{N}_\beta$ and yields

$$\sigma_\alpha(p - \delta) \leq g_{\beta\alpha}(p) \leq \sigma_\alpha(p + \delta)$$

for all α and β.

Define A to be the set (guaranteed to exist by Lemma 5.13) of at least $\text{pow}(d) - \text{pow}(\gamma \cdot a + b)$ output wires of $\mathcal{N}$ indexed by length-d binary strings $\beta\alpha$ such that

$$\Gamma_\alpha(1 - \varepsilon) - \Gamma_\alpha(\varepsilon) \leq \delta.$$

We set π to the permutation of set A that sorts the $\Gamma_\alpha(\varepsilon)$ values in ascending order. Ties may be broken arbitrarily. (As discussed in the proof of Lemma 5.14, the set A and permutation π can be computed efficiently.) It remains to prove that our choice of A and π satisfies the requirements of the lemma.

Let $p^- = \max\{0, p - 2 \cdot \delta\}$, $p^+ = \min\{1, p + 2 \cdot \delta\}$, and B denote the set of binary strings α in A for which $\Gamma_\alpha(\varepsilon)$ is contained in $[p^-, p + \delta]$. Because the σ_α's are monotonically increasing, and using linearity of expectation, we have

$$\begin{aligned}
\sum_\alpha |\sigma_\alpha(p^+) - \sigma_\alpha(p^-)| &= \sum_\alpha \big(\sigma_\alpha(p^+) - \sigma_\alpha(p^-)\big) \\
&= \left(\sum_\alpha \sigma_\alpha(p^+)\right) - \left(\sum_\alpha \sigma_\alpha(p^-)\right) \\
&= (p^+ - p^-) \cdot \text{pow}(a) \\
&\leq 4 \cdot \delta \cdot \text{pow}(a).
\end{aligned}$$

For each α in B we have $\sigma_\alpha(p^-) \leq \varepsilon$, $\sigma_\alpha(p^+) \geq 1-\varepsilon$, and hence

$$|\sigma_\alpha(p^+) - \sigma_\alpha(p^-)| \geq 1 - 2 \cdot \varepsilon.$$

The preceding inequalities imply that

$$\begin{aligned} |B| &\leq 4 \cdot \delta \cdot \mathrm{pow}(a+b)/(1-2\cdot\varepsilon) \\ &= \mathrm{pow}(\gamma \cdot a + b). \end{aligned}$$

Note that the set of binary strings B is mapped to a contiguous interval by permutation π. Let A^- (resp., A^+) denote the set of all binary strings in $A \setminus B$ mapped to positions lower (resp., higher) than B by π.

Let $\beta\alpha$ denote the binary string associated with an arbitrary output in A^-. Thus $\Gamma_\alpha(\varepsilon) < p^-$ (so $p^- > 0$ and $p - \delta > 0$), which implies $\Gamma_\alpha(1-\varepsilon) < p - \delta$ and hence $\sigma_\alpha(p-\delta) > 1-\varepsilon$. Combining this inequality with the lower bound of equation (10), we find that $g_{\beta\alpha}(p) > 1-\varepsilon$. (The probability that output $\beta\alpha$ receives a 1 is less than ε.)

Similarly, let α denote the binary string associated with some output in A^+. Thus $\Gamma_\alpha(\varepsilon) > p + \delta$ (so $p + \delta < 1$), which implies $\sigma_\alpha(p+\delta) < \varepsilon$. Combining this inequality with the upper bound of equation (10), we find that $g_{\beta\alpha}(p) < \varepsilon$. (The probability that output $\beta\alpha$ receives a 0 is less than ε.)

We conclude that if permutation π is applied to A, the resulting length-$|A|$ 0-1 vector has a dirty region of size at most $|B| = \mathrm{pow}(\gamma \cdot a + b)$ with probability at least $1 - \mathrm{pow}(d) \cdot \varepsilon - \mathrm{pow}(a) \cdot \varepsilon'$. □

LEMMA 10.3. *Let $\mathcal{N}$, A, and π be defined as in Lemma* 10.2*, with $a = \lceil d/2 \rceil$ and $b = \lfloor d/2 \rfloor$. Then there exist constants γ and ε in $(0,1)$ such that the following condition holds with probability at least $1 - O(\mathrm{pow}(-\mathrm{pow}(\varepsilon \cdot d)))$ after execution of $\mathcal{N}$ on any* 0-1 *input vector ϕ: If permutation π is applied to A, then the resulting length-$|A|$* 0-1 *output vector is $(\gamma \cdot d)$-sorted.*

Proof. This is a straightforward consequence of Lemmas 5.6 and 10.2. □

Given Lemma 10.3, we can easily prove an analogue of Lemma 7.3 that uses "?" gates instead of random permutations. (It is important to note that the (d,a)-network associated with the construction of Lemma 10.3 is composed of the following four stages: (a) a depth-a unshuffle-"0" d-network; (b) a depth-a shuffle-"?" d-network; (c) a depth-$\lceil a/2 \rceil$ unshuffle-"0" d-network; and (d) a depth-$\lceil a/2 \rceil$ shuffle-"+" d-network.) We can then use the scheme of section 7 to prove Theorem 10.1 below with

$$\varepsilon(d) = \mathrm{pow}(-\mathrm{pow}(\Theta(\sqrt{d}))).$$

Unfortunately, we cannot take advantage of the improvement associated with equation (12) because the construction of section 9 is not polynomial-time uniform.

THEOREM 10.1. *For each function $\varepsilon(d) = \mathrm{pow}(-\mathrm{pow}(O(\sqrt{d})))$, there is a polynomial-time uniform $O(d)$-depth coin-tossing hypercubic d-network that sorts any input d-vector probability at least $1 - \varepsilon(d)$.*

The scheme of section 7 can also be used to prove Theorem 10.1 below with the function ε as defined in Theorem 10.2. In this case, we can dramatically decrease the failure probability by making use of the Sharesort algorithm of Cypher and Plaxton [9]. Sharesort is a polynomial-time uniform hypercubic sorting algorithm with worst-case running time $O(d \cdot \lg^2 d)$ [9]. Note that Sharesort runs in $O(d)$ time on $O(d/\lg^2 d)$-cubes. Hence, we can modify the scheme of section 7 by cutting off the sorting recurrence at $\Theta(d/\lg^2 d)$-cubes instead of $\Theta(\sqrt{d})$-cubes (as allowed by bitonic sort).

Unfortunately, Sharesort does not correspond to a hypercubic sorting network since, for example: (i) Sharesort makes copies of keys, and (ii) Sharesort performs a variety of arithmetic operations on auxiliary integer variables. For these reasons, we have not been able to make use of Sharesort in previous sections of the paper.

A small improvement to the Sharesort bound is known when polynomial-time "preprocessing" (to compute certain look-up tables) is allowed. In particular, the running time of Sharesort can be improved to $O(d \cdot (\lg d) \cdot \lg^* d)$ in that case [8]. This improvement has been incorporated into the $\varepsilon(d)$ bound of Theorem 10.2. If exponential preprocessing is allowed, the running time of Sharesort can be improved further to $O(d \cdot \lg d)$ [8]. However, it is not clear whether the latter result could be used to improve the $\varepsilon(d)$ bound of Theorem 10.2. (The lack of uniformity can be eliminated through randomization. However, the failure probability of the resulting algorithm seems to be strictly higher than that given by Theorem 10.2.)

THEOREM 10.2. *Let* $f(d) = \Theta(\frac{d}{(\lg d) \cdot \lg^* d})$. *For each function*

$$\varepsilon(d) = \text{pow}(-\text{pow}(f(d))),$$

there is a polynomial-time uniform randomized hypercubic sorting algorithm that runs in $O(d)$ *time* (*on any input* d*-vector*) *with probability at least* $1 - \varepsilon$.

11. An optimal bit-serial randomized hypercubic sorting algorithm. An *order-d omega machine* is a $((d+1) \cdot \text{pow}(d))$-processor machine, $d \geq 0$. Each processor has an associated ID of the form (i, j), $0 \leq i \leq d$, $0 \leq j < \text{pow}(d)$. We define the *ith level* of a given order-d omega machine as the set of $\text{pow}(d)$ processors with IDs of the form (i, j), $0 \leq j < \text{pow}(d)$. The processors of an order-d omega machine are interconnected according to the following rules:

1. There is no wire between any pair of processors in nonconsecutive levels.
2. For all i such that $0 \leq i < d$, there is a wire connecting processor (i, j) to processor $(i+1, j')$ if and only if $j_k = j'_{k+1}$, $0 \leq k < d-1$.

Omega machines belong to the class of butterfly-like machines discussed in [12, section 3.8.1].

Observe that there is a close correspondence between an order-d omega machine $\mathcal{M}$ and a depth-d shuffle d-network $\mathcal{N}$. In particular, consider the 1-1 function $f(i, j)$ that maps processor (i, j) of $\mathcal{M}$ to the following: (i) level-i input wire j of $\mathcal{N}$, $0 \leq i < d$, and (ii) level-$(i-1)$ output wire j of $\mathcal{N}$, $0 < i \leq d$. (Recall that level-i input wire j and level-$(i-1)$ output wire j represent the same wire, $0 < i < d$. Hence, f is indeed a function.) Then there is a wire between processors (i, j) and $(i+1, j')$ in $\mathcal{M}$ if and only if wires $f(i, j)$ and $f(i+1, j')$ in $\mathcal{N}$ are connected to a common gate x, with $f(i, j)$ as an input wire and $f(i+1, j')$ as an output wire.

In the bit model, it is assumed that a processor can only perform one bit operation per time step. Thus, b bit steps are required to send a b-bit message to an adjacent processor. Similarly, b bit steps are required to compare two b-bit operands located at the same processor. In this section, we provide a bit-serial polynomial-time uniform randomized algorithm for sorting $\text{pow}(d)$ $O(b)$-bit records on an order-d omega machine in $O(b + d)$ bit steps. This time bound is easily seen to be optimal. For $b = \Omega(d)$, the processor bound is also optimal. Our algorithm can be adapted to achieve the same asymptotic performance on any butterfly-like machine.

DEFINITION 11.1. *A* bit-serial omega emulation scheme *for a depth-a word-size-b d-network* $\mathcal{N}$ *is a bit-serial algorithm that* (i) *runs on an order-d omega machine,* (ii) *emulates the execution of* $\mathcal{N}$ *on any d-vector of b-bit integers, and* (iii) *receives (resp.,*

produces) the jth component of the input (resp., output) d-vector at processor (d, j), $0 \leq j < \mathrm{pow}(d)$.

We remark that the somewhat unnatural input-output convention used in the preceding definition (level d is used instead of level 0) is not essential. We could easily modify the results of this section to hold if the input and output are provided at level 0.

DEFINITION 11.2. *A depth-$(2 \cdot b)$ hypercubic d-network $\mathcal{N}$ is* a-pass, $0 \leq b \leq a \leq d$, *if and only if the d-permutation $\hookrightarrow_d$ (resp., $\hookleftarrow_d$) is applied in the permutation phase of the first (resp., last) b levels of $\mathcal{N}$.*

LEMMA 11.1. *There is an $O(a + b)$-bit-step bit-serial omega emulation scheme for any coin-tossing a-pass word-size-b d-network.*

Proof. The proof is straightforward. (Note that each of our five gate types can be implemented in a bit-serial fashion. For the "+" and "−" gates, such a bit-serial implementation requires that the inputs be provided most-significant-bit first.) □

DEFINITION 11.3. *A depth-$O(a)$ hypercubic d-network $\mathcal{N}$ is* a-multipass, $0 \leq a \leq d$, *if and only if $\mathcal{N}$ can be decomposed into an $O(1)$-length sequence of a-pass networks.*

LEMMA 11.2. *There is an $O(a + b)$-bit-step bit-serial omega emulation scheme for any coin-tossing a-multipass word-size-b d-network.*

Proof. This follows from a constant number of applications of Lemma 11.1. Note that only levels d through $d-a$ of the order-d omega machine are used by the emulation scheme. □

DEFINITION 11.4. *A hypercubic d-network $\mathcal{N}$ is* (γ, a, k)-geometric, $\gamma \geq 0$, $0 \leq a \leq d$, $k \geq 0$, *if and only if $\mathcal{N}$ can be decomposed into a length-k sequence of d-networks $\langle \mathcal{N}_i \rangle$ such that:* (i) $0 \leq \gamma \leq 1$ *and $\mathcal{N}_i$ is $\lfloor \gamma^{i+1} \cdot a \rfloor$-multipass, $0 \leq i < k$, or* (ii) $\gamma > 1$ *and $\mathcal{N}_i$ is $\lfloor \gamma^{i-k} \cdot a \rfloor$-multipass, $0 \leq i < k$.*

DEFINITION 11.5. *A (γ, a, k)-geometric d-network is* compact *if and only if*

$$\sum_{0 \leq i < k} \left(\lfloor \gamma^{i+1} \cdot a \rfloor + 1 \right) \leq d.$$

LEMMA 11.3. *There is an $O(b + d)$-bit-step bit-serial omega emulation scheme for any coin-tossing compact (γ, a, k)-geometric word-size-b d-network $\mathcal{N}$.*

Proof. We give the proof for the case $0 \leq \gamma \leq 1$. The case $\gamma > 1$ is similar. (Note that if we "reverse" a (γ, a, k)-geometric d-network, we obtain a $(1/\gamma, a, k)$-geometric d-network.)

Decompose the given d-network $\mathcal{N}$ into a sequence of networks $\langle \mathcal{N}_i \rangle$ as in Definition 11.4. Thus, network $\mathcal{N}_i$ is $(f(a, i) - 1)$-multipass where

$$f(a, i) = \lfloor \gamma^{i+1} \cdot a \rfloor + 1,$$

$0 \leq i < k$. Let $\mathcal{M}$ denote an order-d omega machine, and

$$g(i) = d - \sum_{0 \leq j < i} f(a, j),$$

$0 \leq i < k$. To obtain an efficient bit-serial omega emulation scheme for network $\mathcal{N}$, we use Lemma 11.2 to emulate $\mathcal{N}_i$ on the contiguous set of levels $A_i = \{g(i), g(i) - 1, \ldots, g(i+1)+1\}$ of $\mathcal{M}$, $0 \leq i < k$. (The input to $\mathcal{N}_i$ is provided at level $g(i)$. Hence, Lemma 11.2 implies that the output to network $\mathcal{N}_i$ is produced at level $g(i)$.) Note that (i) the A_i's are well defined (i.e., each is a set of level numbers in the range 0 to

d) since $\mathcal{N}$ is compact, and (ii) the A_i's are pairwise disjoint. Property (ii) ensures that the emulation schemes associated with distinct $\mathcal{N}_i$'s do not interfere with one another.

It remains to prove that we can efficiently communicate the output of network $\mathcal{N}_i$, which is produced at level $g(i)$, to level $g(i+1)$, $0 \leq i < k-1$. (Once the output of $\mathcal{N}_i$ reaches level $g(i+1)$, the emulation of $\mathcal{N}_{i+1}$ over the set of levels A_{i+1} can begin.) For example, it would suffice to efficiently map the value on wire j of level $g(i)$ to wire j of level $g(i+1)$, $0 \leq j < \text{pow}(d)$. Unfortunately, it is very expensive to implement such an identity d-permutation on the machine $\mathcal{M}$.

The key observation, however, is that we do not need to implement the identity d-permutation between levels $g(i)$ and $g(i+1)$. Because the $f(a,i)$'s form a non-increasing sequence, $0 \leq i < k$, there is no interaction between distinct $f(a,i+1)$-cubes in any d-network $\mathcal{N}_j$ such that $i+1 \leq j < k$. Hence, it is sufficient to implement a d-permutation π such that: (i) level-$g(i)$ $f(a,i+1)$-cubes are mapped to level-$g(i+1)$ $f(a,i+1)$-cubes, and (ii) the identity $f(a,i+1)$-permutation is applied within each $f(a,i+1)$-cube.

We now prove that a d-permutation π of the desired form can be implemented in $O(f(a,i)+f(a,i+1))$ bit steps while using only levels $A_i \cup A_{i+1}$ of $\mathcal{M}$. (The reader may wonder why the preceding O-bound does not depend on b. This bound refers only to the "additional" number of bit steps required to implement the d-permutation π. Because our entire emulation scheme is pipelined bit-serially, we can account for the word size by adding $O(b)$ at the end of our analysis.) In particular, the d-permutation π that we apply from level $g(i)$ to level $g(i+1)$ satisfies

$$\pi(j) = j_{f(a,i)+f(a,i+1)-1} \cdots j_{f(a,i+1)} j_{d-1} \cdots j_{f(a,i)+f(a,i+1)} j_{f(a,i+1)-1} \cdots j_0,$$

$0 \leq j < \text{pow}(d)$. The d-permutation π can easily be implemented in $O(f(a,i) + f(a,i+1))$ additional bit steps as follows. First, within level $g(i)$, we apply the d-permutation π' defined by

$$\pi'(j) = j_{d-1} \cdots j_{f(a,i)+f(a,i+1)} j_{f(a,i+1)-1} \cdots j_0 j_{f(a,i)+f(a,i+1)-1} \cdots j_{f(a,i+1)},$$

$0 \leq j < \text{pow}(d)$. Note that π' belongs to $\Pi(d, f(a,i)+f(a,i+1))$. By Lemma 4.7, π' can be implemented in $O(f(a,i)+f(a,i+1))$ bit steps using only levels $A_i \cup A_{i+1}$ of $\mathcal{M}$. We now complete the implementation of d-permutation π by repeatedly unshuffling the data from level $g(i)$ to level $g(i+1)$. (This takes $f(a,i)$ bit steps and uses only the set of levels A_i.)

The total running time of our emulation scheme is easily seen to be

$$O\left(b + \sum_{0 \leq i < k} f(a,i)\right) = O(b + d - g(k-1))$$

bit steps. However, one final detail remains to be addressed, since our emulation scheme leaves the output at level $g(k-1)$ instead of level d. We can move the output to level d by applying an appropriate fixed permutation π' from level $g(k-1)$ to level d. The entire machine $\mathcal{M}$ can be used for this purpose. Thus, the Beneš routing technique of Lemma 4.7 yields an immediate $O(b+d)$ bound. In fact, an $O(b+d-g(k-1))$ bound can easily be achieved by (i) shuffling the data from level $g(k-1)$ to level d, and (ii) applying an appropriate permutation π'' in $\Pi(d, d-g(k-1))$.

Thus, the total running time of our revised emulation scheme is $O(b+d-g(k-1))$, which is $O(b+d)$ since $\mathcal{N}$ is compact. □

THEOREM 11.1. *There is a polynomial-time uniform $O(b+d)$-bit-step bit-serial omega emulation of the family $\{\mathcal{N}_d\}$ of coin-tossing d-networks of Theorem* 10.1.

Proof. Examining the construction of Theorem 10.1, we find that $\mathcal{N}_d$ can be decomposed into the following: (a) a $(1, d, 1)$-geometric coin-tossing d-network; (b) a $(1/3, d, O(\lg d))$-geometric coin-tossing d-network; (c) a $(1, O(\sqrt{\lg d}), O(\sqrt{\lg d}))$-geometric deterministic d-network; (d) a $(3, d, O(\lg d))$-geometric coin-tossing d-network; and (e) a $(1, d, 1)$-geometric coin-tossing d-network. (Note that the constants $1/3$ and 3 appearing above are somewhat arbitrarily chosen. The "slack" in our definitions creates a range of acceptable values.)

The coin-tossing d-networks of stages (a), (b), (d), and (e) are easily seen to be compact. Stage (c) corresponds to the use of bitonic sort to cut off the sorting recurrence at $O(\sqrt{\lg d})$-cubes. Note that we are free to choose the constant within the $O(\sqrt{\lg d})$ bound arbitrarily small. Hence, we can ensure that the deterministic d-network of stage (c) is also compact. The theorem then follows by Lemma 11.3. (The emulation is polynomial-time uniform since (i) the family of coin-tossing networks of Theorem 10.1 is polynomial-time uniform, and (ii) the emulation scheme underlying Lemma 11.3 is polynomial-time uniform.) □

THEOREM 11.2. *For each function $\varepsilon(d) = \mathrm{pow}(-\mathrm{pow}(O(\sqrt{d})))$, there is a polynomial-time uniform $O(b+d)$-bit-step randomized bit-serial algorithm for an order-d omega machine that sorts any input d-vector of b-bit integers with probability at least $1 - \varepsilon(d)$.*

Proof. The claim is an immediate consequence of Theorems 10.1 and 11.1. □

12. Concluding remarks. We have defined the class of "hypercubic" sorting networks and established a nearly logarithmic upper bound on the depth complexity of such networks. Of course, it would be very interesting to close the remaining gap. Given the techniques developed in this paper, the problem of constructing an optimal $O(\lg n)$-depth hypercubic sorting network has been reduced to the problem of constructing an $O(\lg n)$-depth comparator network that sorts a randomly chosen input permutation with probability at least $1 - 2^{-n^{\varepsilon}}$ for some constant $\varepsilon > 0$.

One unfortunate characteristic of our hypercubic sorting network construction is its lack of uniformity. In particular, no deterministic polynomial-time algorithm is known for generating the family of networks for which existence has been established. On the positive side, existence of a randomized polynomial-time generation algorithm is a straightforward consequence of our results.

While the multiplicative constant of approximately 7.44 established for the sorting network construction of section 6 appears to be quite reasonable, the construction remains impractical. This is due to the fact that there is a trade-off between the value of the multiplicative constant and the success probability (the probability that a random input permutation is sorted by the network); for practical values of n, a significant increase in the constant is required in order to prove any reasonable success probability.

Appendix A. Analysis of the sorting recurrence. Let c_1 be a positive constant, let a_0 and c_2 denote sufficiently large positive constants (to be determined), and consider the function $T(a)$, $a \geq 0$, defined by the following recurrence. Let $T(a) = O(1)$ for $a \leq a_0$, and

$$T(a) = \min_{(2+\lg a)\cdot\nu(b) \leq b \leq a} T(a - \lfloor \mu(b) \cdot b \rfloor) + T(b) + c_1 \cdot a \cdot \nu(a) \tag{A.15}$$

for $a > a_0$, where

$$\nu(d) = c_2 \cdot \sqrt{\lg d},$$
$$\mu(d) = \mu_c - \frac{2}{\nu(d)}.$$

Note that our choice of the function $\nu(d)$ satisfies the requirements of Lemma 9.2, since $\nu(d) = \omega(1)$ and $\nu(d) = o(d)$. Furthermore, the function $\mu(d)$ is defined as in Lemma 9.2. Hence, any upper bound for $T(a)$ is also an upper bound for the function $S(a)$ defined towards the end of section 9. In this section, we prove that

$$T(a) = O(a \cdot \mathrm{pow}(\sqrt{\upsilon_c \cdot \lg a}) \cdot \lg a).$$

(The constant υ_c is defined in equation (9).) We prove two technical lemmas before analyzing the recurrence of equation (A.15).

LEMMA A.1. *For every pair of real numbers x and y such that $0 \le x \le y$, we have*

$$\sqrt{x \cdot y} - \sqrt{x \cdot y - x \cdot \sqrt{x \cdot y}} \ge x/2.$$

Proof. Examining the Taylor series expansion of $\sqrt{1-\varepsilon}$, we find that

$$\sqrt{1-\varepsilon} \le 1 - \varepsilon/2$$

for all ε in $[0, 1]$. Hence,

$$\begin{aligned}\sqrt{x \cdot y} - \sqrt{x \cdot y - x \cdot \sqrt{x \cdot y}} &= \sqrt{x \cdot y} - \sqrt{x \cdot y} \cdot \sqrt{1 - \sqrt{x/y}} \\ &\le \sqrt{x \cdot y} - \sqrt{x \cdot y} \cdot \left(1 - \frac{\sqrt{x}}{2 \cdot \sqrt{y}}\right) \\ &= x/2. \qquad \square\end{aligned}$$

LEMMA A.2. *For any $a > a_0$, let*

$$a' = a - \lfloor \mu(b') \cdot b' \rfloor,$$

where

$$b' = \left\lfloor \frac{a}{\mathrm{pow}(\sqrt{\upsilon_c \cdot \lg a})} \right\rfloor.$$

For a sufficiently large choice of the constant a_0, the following bounds hold:

(i) $1 < a' \le a - \frac{\mu(b') \cdot a}{\mathrm{pow}(\sqrt{\upsilon_c \cdot \lg a})} + 2 < a$,
(ii) $\mu(b') \ge \mu_c - \frac{4}{c_2 \cdot \sqrt{\lg a}}$,
(iii) $2 \cdot \mathrm{pow}(\sqrt{\upsilon_c \cdot \lg a}) = o(a/\sqrt{\lg a})$,
(iv) $1 < (2 + \lg a) \cdot \nu(b') \le b' < a$, *and*
(v) $\sqrt{\upsilon_c \cdot \lg a} - \sqrt{\upsilon_c \cdot \lg a - \upsilon_c \cdot \sqrt{\upsilon_c \cdot \lg a}} > \upsilon_c/2$.

Proof. Part (v) follows from Lemma A.1. The remaining inequalities follow from straightforward asymptotic estimates. $\square$

THEOREM A.1. *There is a positive constant c_0 such that*

$$T(a) \leq c_0 \cdot a \cdot \mathrm{pow}(\sqrt{\upsilon_c \cdot \lg a}) \cdot \lg a$$

for all $a > 1$.

Proof. We prove the claim of the lemma by induction on a. The claim is trivial for $1 < a \leq a_0$, since we are free to choose the constant c_0 arbitrarily large. Now fix $a > a_0$ and assume the claim holds for all smaller values of a. Define a' and b' as in Lemma A.2.

By part (i) of Lemma A.2, we can apply the induction hypothesis to bound $T(a')$ since $1 < a' < a$. Using parts (i), (ii), and (iii) of Lemma A.2, we find that

$$\begin{aligned} T(a') &\leq c_0 \cdot a' \cdot \mathrm{pow}(\sqrt{\upsilon_c \cdot \lg a'}) \cdot \lg a' \\ &\leq c_0 \cdot \left(a - \frac{\mu(b') \cdot a}{\mathrm{pow}(\sqrt{\upsilon_c \cdot \lg a})} + 2\right) \cdot \mathrm{pow}(\sqrt{\upsilon_c \cdot \lg a}) \cdot \lg a \\ &\leq c_0 \cdot a \cdot \mathrm{pow}(\sqrt{\upsilon_c \cdot \lg a}) \cdot \lg a - c_0 \cdot \mu_c \cdot a \cdot \lg a + c_0 \cdot \left(\frac{4}{c_2} + o(1)\right) \cdot a \cdot \sqrt{\lg a}. \end{aligned}$$

By part (iv) of Lemma A.2, we can apply the induction hypothesis to bound $T(b')$ since $1 < b' < a$. Using part (v) of Lemma A.2 and equation (9), we find that

$$\begin{aligned} T(b') &\leq c_0 \cdot b' \cdot \mathrm{pow}(\sqrt{\upsilon_c \lg b'}) \cdot \lg b' \\ &\leq c_0 \cdot a \cdot \mathrm{pow}\left(\sqrt{\upsilon_c \cdot \lg a - \upsilon_c \cdot \sqrt{\upsilon_c \cdot \lg a}} - \sqrt{\upsilon_c \cdot \lg a}\right) \cdot \left(\lg a - \sqrt{\upsilon_c \cdot \lg a}\right) \\ &\leq c_0 \cdot \mu_c \cdot a \cdot \lg a - c_0 \cdot \mu_c \cdot a \cdot \sqrt{\upsilon_c \cdot \lg a}. \end{aligned}$$

By part (iv) of Lemma A.2, we can set $b = b'$ in the recurrence of equation (A.15) since $(2 + \lg a) \cdot \nu(b') \leq b' < a$. Thus,

$$\begin{aligned} T(a) &\leq T(a') + T(b') + c_1 \cdot a \cdot \nu(a) \\ &\leq c_0 \cdot a \cdot \mathrm{pow}(\sqrt{\upsilon_c \cdot \lg a}) \cdot \lg a \\ &\quad + \left[c_0 \cdot \left(\frac{4}{c_2} + o(1) - \mu_c \cdot \sqrt{\upsilon_c}\right) + c_1 \cdot c_2\right] \cdot a \cdot \sqrt{\lg a}. \end{aligned}$$

For a_0 sufficiently large, we can choose the constants c_0 and c_2 so that the coefficient of $a\sqrt{\lg a}$ is negative, yielding

$$T(a) \leq c_0 \cdot a \cdot \mathrm{pow}(\sqrt{\upsilon_c \cdot \lg a}) \cdot \lg a,$$

as required. ∎

Appendix B. Locating the "median" of the binomial distribution. The purpose of this appendix is to establish Theorem B.1, which is used in the proof of Lemma 5.15.

LEMMA B.1. *Let k and n be integers such that $0 \leq k \leq n$, p be a real number in $[0,1]$ such that $np = k$, and X be a random variable drawn from $B(n,p)$ (i.e., the binomial distribution with parameters n and p). Let Y be a random variable corresponding to the number of successes in n independent Bernoulli trials with associated success probabilities p_i, $0 \leq i < n$, such that $\sum_{0 \leq i < n} p_i = k$. Then*

$$\begin{aligned} \Pr(X < k) &\geq \Pr(Y < k), \\ \Pr(X > k) &\geq \Pr(Y > k). \end{aligned}$$

Proof. These inequalities are established (in a more general form) by Hoeffding in [10, Theorem 4]. □

LEMMA B.2. *Let k, n, p, and X be as defined in Lemma* B.1. *If $0 \le p \le 1/2$, then let Y' and Y'' be random variables drawn from $B(2k, 1/2)$ and $B(n-2k, 0)$, respectively. Otherwise, let Y' and Y'' be random variables drawn from $B(2(n-k), 1/2)$ and $B(2k-n, 1)$, respectively. Let $Y = Y' + Y''$. If*

$$\Pr(X = k) \ge \Pr(Y = k)/2,$$

then

$$\min\{\Pr(X \le k), \Pr(X \ge k)\} \ge 1/2.$$

Proof. By symmetry, $\Pr(Y \le k) = \Pr(Y \ge k) = [1 + \Pr(Y = k)]/2$. The claimed inequality then follows easily using Lemma B.1. □

LEMMA B.3. *For each pair of integers k and n such that $0 \le k \le n$, let*

$$u_{k,n} = \binom{n}{k} \left(\frac{k}{n}\right)^k \left(1 - \frac{k}{n}\right)^{n-k}.$$

(If $n = k$, then $u_{k,n} = 1$.) Then $u_{k,n} \ge \frac{k^k}{e^k k!}$.

Proof. Fix $k \ge 0$, and let $v_n = u_{k,n}$ for $n \ge k$. It is sufficient to prove that the sequence $\langle v_n \rangle$ is nonincreasing for $n \ge k$ and that

$$\lim_{n \to \infty} v_n = \frac{k^k}{e^k k!}. \tag{B.16}$$

To see that the sequence $\langle v_n \rangle$ is nonincreasing for $n \ge k$, note that

$$\begin{aligned} \frac{v_{k+1}}{v_k} &= \left(\frac{k}{k+1}\right)^k \\ &\le 1, \end{aligned}$$

and for $n > k$ we have

$$\begin{aligned} \frac{v_{n+1}}{v_n} &= \left(1 + \frac{1}{n-k}\right)^{n-k} \Big/ \left(1 + \frac{1}{n}\right)^n \\ &\le 1. \end{aligned}$$

(The preceding inequality follows from the fact that the function $f : \mathbf{R} \to \mathbf{R}$ defined by $f(x) = (1 + \frac{1}{x})^x$ is strictly increasing for all $x \ge 1$.)

To verify equation (B.16), note that

$$\begin{aligned} v_n &= \frac{n!}{k!(n-k)!} \cdot \frac{k^k}{n^k} \cdot \frac{(n-k)^{n-k}}{n^{n-k}} \\ &= \frac{k^k}{k!} \cdot \frac{n!}{(n-k)!} \cdot \frac{(n-k)^{n-k}}{n^n} \\ &\sim \frac{k^k}{k!} \left(1 - \frac{k}{n}\right)^n \\ &\sim \frac{k^k}{e^k k!}. \end{aligned}$$

□

LEMMA B.4. *For each nonnegative integer k, let*

$$w_k = \frac{k^{k+1}2^{2k}k!}{(k+1)e^k(2k)!}.$$

Then the sequence $\langle w_k \rangle$ is nondecreasing for $k \geq 1$.

Proof. Note that

$$\frac{w_{k+1}}{w_k} = \frac{2(1+\frac{1}{k})^k(k+1)^3}{ek(k+2)(2k+1)}$$

and

$$\lim_{k\to\infty} \frac{w_{k+1}}{w_k} = 1.$$

Thus, it is sufficient to prove that the function $f : \mathbf{R} \to \mathbf{R}$ defined by

$$f(x) = \frac{(1+\frac{1}{x})^x(x+1)^3}{x(x+2)(2x+1)}$$

is nonincreasing for $x \geq 1$. One may easily verify that

$$\frac{df(x)}{dx} = \frac{(x+1)^2(1+\frac{1}{x})^x}{x^2(x+2)^2(2x+1)^2} \cdot g(x),$$

where

$$g(x) = -x^2 - 6x - 2 + x(x+1)(x+2)(2x+1)\left[\ln\left(1+\frac{1}{x}\right) - \frac{1}{x+1}\right].$$

Hence, for $x > 0$, $\frac{df(x)}{dx} \leq 0$ if and only if $g(x) \leq 0$. For $x \geq 1$, we have $\ln(1+\frac{1}{x}) \leq \frac{1}{x} - \frac{1}{2x^2} + \frac{1}{3x^3}$, and hence

$$\begin{aligned} g(x) &\leq -x^2 - 6x - 2 + x(x+1)(x+2)(2x+1)\left(\frac{1}{x(x+1)} - \frac{1}{2x^2} + \frac{1}{3x^3}\right) \\ &= -\frac{23x}{6} - \frac{7}{6} + \frac{4}{3x} + \frac{2}{3x^2} \\ &< 0. \qquad \square \end{aligned}$$

LEMMA B.5. *For all nonnegative integers k, we have*

$$\frac{k^k}{e^k k!} > \binom{2k}{k} 2^{-2k-1}.$$

Proof. It is easy to verify that the claim holds for $0 \leq k \leq 2$. For $k \geq 3$, consider the sequence $\langle w_k \rangle$ defined in Lemma B.4. By Lemma B.4, $w_k \geq w_3 \approx 0.538 > 1/2$ for $k \geq 3$. Hence

$$\begin{aligned} \frac{k^k}{e^k k!} &> \frac{k+1}{k}\binom{2k}{k}2^{-2k-1} \\ &> \binom{2k}{k}2^{-2k-1}. \qquad \square \end{aligned}$$

LEMMA B.6. *Let k, n, p, X, and Y be as defined in Lemma* B.2. *Then*

$$\Pr(X = k) > \Pr(Y = k)/2.$$

Proof. If $0 \le p \le 1/2$, then

$$\begin{aligned}\Pr(X = k) &= \binom{n}{k}\left(\frac{k}{n}\right)^k\left(1 - \frac{k}{n}\right)^{n-k}\\ &\ge \frac{k^k}{e^k k!}\\ &> \binom{2k}{k}2^{-2k-1}\\ &= \Pr(Y = k)/2,\end{aligned}$$

where the two inequalities follow from Lemmas B.3 and B.5, respectively.

Similarly, if $1/2 < p \le 1$, we have

$$\begin{aligned}\Pr(X = k) &= \binom{n}{k}\left(\frac{k}{n}\right)^k\left(1 - \frac{k}{n}\right)^{n-k}\\ &= \binom{n}{n-k}\left(\frac{n-k}{n}\right)^{n-k}\left(1 - \frac{n-k}{n}\right)^{n-(n-k)}\\ &\ge \frac{(n-k)^{n-k}}{e^{n-k}(n-k)!}\\ &> \binom{2(n-k)}{n-k}2^{-2(n-k)-1}\\ &= \Pr(Y = k)/2. \qquad \square\end{aligned}$$

LEMMA B.7. *Let k, n, p, and X be as defined in Lemma* B.1. *Then*

$$\min\{\Pr(X \le k), \Pr(X \ge k)\} \ge 1/2.$$

Proof. The proof is immediate from Lemmas B.2 and B.6. $\square$

THEOREM B.1. *Let n be a nonnegative integer, p be a real number in $[0, 1]$, and X be a random variable drawn from $B(n, p)$. Then*

$$\min\{\Pr(X \ge \lfloor np \rfloor), \Pr(X \le \lceil np \rceil)\} \ge 1/2.$$

Proof. Define real numbers p^- and p^+ so that $np^- = \lfloor np \rfloor$ and $np^+ = \lceil np \rceil$. Let X^- (resp., X^+) denote a random variable drawn from $B(n, p^-)$ (resp., $B(n, p^+)$). Note that for all real numbers x, we have

$$\begin{aligned}\Pr(X \ge x) &\ge \Pr(X^- \ge x),\\ \Pr(X \le x) &\ge \Pr(X^+ \le x).\end{aligned}$$

Combining these inequalities with the bound of Lemma B.7, we obtain

$$\begin{aligned}\Pr(X \ge \lfloor np \rfloor) &\ge \Pr(X^- \ge \lfloor np \rfloor) \ge 1/2,\\ \Pr(X \le \lceil np \rceil) &\ge \Pr(X^+ \le \lceil np \rceil) \ge 1/2. \qquad \square\end{aligned}$$

Acknowledgments. Thanks to Rostislav Caha, Don Coppersmith, Ming Kao, Sheralyn Listgarten, Yuan Ma, Bruce Maggs, and Torsten Suel for valuable discussions. We would also like to thank the anonymous referees who provided numerous valuable comments for improving the presentation of the paper.

THE SHRINKAGE EXPONENT OF DE MORGAN FORMULAS IS 2*

JOHAN HÅSTAD†

Abstract. We prove that if we hit a de Morgan formula of size L with a random restriction from R_p, then the expected remaining size is at most $O(p^2(\log \frac{1}{p})^{3/2}L + p\sqrt{L})$. As a corollary we obtain an $\Omega(n^{3-o(1)})$-formula-size lower bound for an explicit function in P. This is the strongest known lower bound for any explicit function in NP.

Key words. lower bounds, formula size, random restrictions, computational complexity

AMS subject classification. 68Q25

PII. S0097539794261556

1. Introduction.

Proving lower bounds for various computational models is of fundamental value to our understanding of computation. Still, we are very far from proving strong lower bounds for realistic models of computation, but at least there is more or less constant progress. In this paper we study formula size for formulas over the basis $\wedge$, $\vee$, and $\neg$. Our technique is based on random restrictions which were first defined and explicitly used in [2], although some earlier results can be formalized in terms of this type of random restrictions.

To create a random restriction in the space R_p we, independently for each variable, keep it as a variable with probability p and otherwise assign it the value 0 or 1 with equal probabilities $\frac{1-p}{2}$. Now suppose we have a function given by a de Morgan formula of size L. What will be the expected formula size of the induced function when we apply a random restriction from R_p? The obvious answer is that this size will be at most pL.

Subbotovskaya [11] was the first to observe that actually formulas shrink more. Namely, she established an upper bound

$$O(p^{1.5}L + 1) \tag{1}$$

on the expected formula size of the induced function. This result allowed her to derive an $\Omega(n^{1.5})$ lower bound on the de Morgan formula size of the parity function.

This latter bound was superseded by Khrapchenko [12, 13], who, using a different method, proved a tight $\Omega(n^2)$ lower bound for the parity function. His result implied that the parity function shrinks by a factor $\theta(p^2)$, and provided an upper bound $\Gamma \leq 2$ on the *shrinkage exponent* Γ, defined as the least upper bound of all γ that can replace 1.5 in (1).

New impetus for research on the expected size of the reduced formula was given by Andreev [9] who, based upon Subbotovskaya's result, derived an $n^{2.5-o(1)}$ lower bound on the de Morgan formula size for a function in P. An inspection of the proof reveals that his method actually gives the bound $n^{\Gamma+1-o(1)}$ for the same function.

New improvements of the lower bound on Γ followed. Nisan and Impagliazzo [5] proved that $\Gamma \geq \frac{21-\sqrt{73}}{8} \approx 1.55$. Paterson and Zwick [6], complementing the technique from [5] with very clever and natural arguments, pushed this bound further to $\Gamma \geq \frac{5-\sqrt{3}}{2} \approx 1.63$.

One can also define the corresponding notion for read-once formulae. For such formulas it was established in [3] that $\Gamma_{ro} = 1/\log_2(\sqrt{5}-1) \approx 3.27$. This result was made tight in [1], in that a polylogarithmic factor in the bounds was removed.

In this paper we continue (and possibly end) this string of results by proving that $\Gamma = 2$. To be more precise we prove that the remaining size is $O(p^2(\log \frac{1}{p})^{3/2}L + p\sqrt{L})$. As discussed above, this gives an $\Omega(n^{3-o(1)})$ lower bound for the formula size of the function defined by Andreev.

Our proof is shown by a sequence of steps. We first analyze the probability of reducing the formula to a single literal. When viewing the situation suitably, this first lemma gives a nice and not very difficult generalization of Khrapchenko's [12, 13] lower bounds for formula size. As an illustration of the power of this lemma we next show, without too much difficulty, how to establish the desired shrinkage when the formula is balanced. The general case is more complicated due to the fact that we need to rely on more dramatic simplifications. Namely, suppose that $\phi = \phi_1 \wedge \phi_2$ and ϕ_1 is much smaller than ϕ_2. Then, from an intuitive point of view, it seems like we are in a good position to prove that we have substantial shrinkage since it seems quite likely that ϕ_1 is reduced to the constant 0 and we can erase all of ϕ_2. The key new point in the main proof is that we have to establish that this actually happens. In the balanced case, we did not need this mechanism. The main theorem is established in two steps. First we prove that the probability that a formula of size at least 2 remains after we have applied a restriction from R_p is small, and then we prove that the expected remaining size is indeed small.

It is curious to note that all except our last and main result are proved under arbitrary but "favorable" conditioning, while we are not able to carry this through for the main theorem.

2. Notation. A *de Morgan formula* is a binary tree in which each leaf is labeled by a literal from the set $\{x_1, \ldots, x_n, \bar{x}_1, \ldots, \bar{x}_n\}$ and each internal node v is labeled by an operation which is either $\wedge$ or $\vee$. The *size* of a formula ϕ is defined as the number of leaves and is denoted by $L(\phi)$. The *depth* $D(\phi)$ is the depth of the underlying tree. The *size* and the *depth* of a Boolean function f are, respectively, the minimal size and depth of any de Morgan formula computing f in the natural sense. For convenience we define the size and depth of a constant function as 0.

A *restriction* is an element of $\{0, 1, *\}^n$. For $p \in [0, 1]$ a random restriction ρ from R_p is chosen by randomly and independently setting each variable to $*$ with probability p and to $0, 1$ with equal probabilities $\frac{1-p}{2}$. The interpretation of giving the value $*$ to a variable is that it remains a variable, while in the other cases the given constant is substituted as the value of the variable.

All logarithms in this paper are to the base 2. We use the notation x_i^ϵ to denote x_i when $\epsilon = 0$ and $\bar{x}_i$ when $\epsilon = 1$. We also need the concept of a filter.

DEFINITION 2.1. *A set of restrictions Δ is a* filter *if, when $\rho \in \Delta$ and $\rho(x_i) = *$, then for $\epsilon \in \{0, 1\}$ the restriction ρ' obtained by setting $\rho'(x_j) = \rho(x_j)$, for every $j \neq i$ and $\rho'(x_i) = \epsilon$ also belongs to Δ.*

For any event E we will use $Pr[E|\Delta]$ as shorthand for $Pr[E|\rho \in \Delta]$. Note that the intersection of two filters is a filter.

3. Preliminaries. We analyze the expected size of a formula after it has been hit with a restriction from R_p. The variables that are given values are substituted into the formula after which we use the following rules of simplification:

- If one input to a $\vee$-gate is given the value 0, we erase this input and let the other input of this gate take the place of the output of the gate.
- If one input to a $\vee$-gate is given the value 1 we replace the gate by the constant 1.
- If one input to a $\wedge$-gate is given the value 1, we erase this input and let the other input of this gate take the place of the output of the gate.
- If one input to a $\wedge$-gate is given the value 0, we replace the gate by the constant 0.
- If one input of a $\vee$-gate is reduced to the single literal x_i ($\bar{x}_i$), then $x_i = 0$ (1) is substituted in the formula, giving the other input to this gate. If possible we do further simplifications in this subformula.
- If one input of a $\wedge$-gate is reduced to the single literal x_i ($\bar{x}_i$), then $x_i = 1$ (0) is substituted in the formula, giving the other input to this gate. If possible we do further simplifications in this subformula.

We call the last two rules the *one-variable simplification rules*. All rules preserve the function that the formula is computing. Observe that the one-variable simplification rules are needed to obtain a nontrivial decrease of the size of the formula, as can be seen from the pathological case in which the original formula consists of an $\vee$ (or $\wedge$) of L copies of a single variable x_i. If these rules did not exist, then with probability p the entire formula would remain and we could get an expected remaining size which is pL. Using the above rules we prove that instead we always get an expected remaining size which is at most slightly larger than p^2L.

In order to be able to speak about the reduced formula in an unambiguous way, let us be more precise about the order in which we do the simplification. Suppose that ϕ is a formula and that $\phi = \phi_1 \wedge \phi_2$. We first make the simplification in ϕ_1 and ϕ_2 and then only later make the simplifications which are connected with the top gate. This implies that the simplified ϕ will not always consist of a copy of simplified ϕ_1 and a copy of simplified ϕ_2, since the combination might give more simplifications. In particular, this will happen if ϕ_1 is simplified to one variable x_i since $x_i = 1$ will be substituted in the simplified ϕ_2. Whenever a one-variable simplification rule actually results in a change in the other subformula, we say that a one-variable simplification is *active* at the corresponding gate.

We let $\phi\lceil_\rho$ denote a formula that results when the above simplifications are done to ϕ. As usual, $L(\phi\lceil_\rho)$ denotes the size of this formula.

It is important to note that simplifications have a certain commutativity property. We say that two restrictions ρ_1 and ρ_2 are *compatible* if they never give two different constant values to the same x_i. In other words, for any x_i the pair $(\rho_1(x_i), \rho_2(x_i))$ is one of the pairs $(*,*), (*,0), (*,1), (0,*), (0,0), (1,*)$, or $(1,1)$. For compatible restrictions we can define the combined restriction $\rho_1 \circ \rho_2$ which, in the mentioned seven cases, takes the values $*, 0, 1, 0, 0, 1, 1$, respectively. This combined restriction is the result (on the variable level) of first doing ρ_1 and then doing ρ_2 on the variables given $*$ by ρ_1. Note that the fact that ρ_1 and ρ_2 are compatible makes the combining operator commutative. We need to make sure that combination also acts in the proper way on formulas.

LEMMA 3.1. *Let ρ_1 and ρ_2 be two compatible restrictions. Then for any ϕ,*

$$(\phi\lceil_{\rho_1})\lceil_{\rho_2} = (\phi\lceil_{\rho_2})\lceil_{\rho_1} = \phi\lceil_{\rho_1\circ\rho_2}.$$

Proof. Let ρ denote $\rho_1 \circ \rho_2$. Clearly, we need only establish $(\phi\lceil_{\rho_1})\lceil_{\rho_2} = \phi\lceil_\rho$ since the other equality follows by symmetry. We proceed by induction over the size of

ϕ. When the size is 1 the claim is obvious. For the general case we assume that $\phi = \phi_1 \wedge \phi_2$ (the case $\phi = \phi_1 \vee \phi_2$ being similar) and we have two cases:

1. Some one-variable simplification rule is active at the top gate when defining ϕ_{ρ_1}.
2. This is not the case.

In the second case, there is no problem since there is no interaction between ϕ_1 and ϕ_2 until after both ρ_1 and ρ_2 have been applied. Namely, by induction $\phi_j\lceil_\rho = (\phi_j\lceil_{\rho_1})\lceil_{\rho_2}$ for $j = 1, 2$, and since we do all simplification to the subformulas before we do any simplification associated with the top gate, the result will be the same in both cases.

In the first case, assume that $\phi_1\lceil_{\rho_1} = x_j^\epsilon$. This means that $x_j = \bar{\epsilon}$ is substituted in $\phi_2\lceil_{\rho_1}$. Viewing this as a restriction $\rho^{(j)}$ giving a non-$*$ value to only one variable, ϕ_2 is simplified to $(\phi_2\lceil_{\rho_1})\lceil_{\rho^{(j)}}$. Now we have three possibilities depending on the value of ρ_2 on x_j.

When $\rho_2(x_j) = \epsilon$, then $(\phi_1\lceil_{\rho_1})\lceil_{\rho_2} \equiv 0$ and by induction $\phi_1\lceil_\rho \equiv 0$ and hence $(\phi\lceil_{\rho_1})\lceil_{\rho_2} = \phi\lceil_\rho \equiv 0$.

When $\rho_2(x_j) = \bar{\epsilon}$, then by induction $(\phi_1\lceil_{\rho_1})\lceil_{\rho_2} = \phi_1\lceil_\rho \equiv 1$, and since $\rho^{(j)}$ is compatible with (even a subassignment of) ρ_2 we have

$$(\phi\lceil_{\rho_1})\lceil_{\rho_2} = ((\phi_2\lceil_{\rho_1})\lceil_{\rho^{(j)}})\lceil_{\rho_2} = (\phi_2\lceil_{\rho_1})\lceil_{\rho_2} = \phi_2\lceil_\rho = \phi\lceil_\rho,$$

where we again used the induction hypothesis.

When $\rho_2(x_j) = *$ and since (by induction) $\phi_1\lceil_\rho = (\phi_1\lceil_{\rho_1})\lceil_{\rho_2} = x_j^\epsilon$ when simplifying by ρ, ϕ_2 will also be simplified by the restriction $\rho^{(j)}$ and will be $(\phi_2\lceil_\rho)\lceil_{\rho(j)}$, which, by induction, is equal to $\phi_2\lceil_{\rho\circ\rho^{(j)}}$. On the other hand, when simplifying by ρ_1 and then by ρ_2, ϕ_2 reduces to $((\phi_2\lceil_{\rho_1})\lceil_{\rho^{(j)}})\lceil_{\rho_2}$ which, by applying the induction hypothesis twice, is equal to $\phi_2\lceil_{\rho_1\circ\rho^{(j)}\circ\rho_2}$. Since $\rho_1 \circ \rho^{(j)} \circ \rho_2 = \rho \circ \rho^{(j)}$, the lemma follows. □

We will need the above lemma in the case of analyzing what happens when we use the one-variable simplification rules. In that case the restriction ρ_2 will just give a non-$*$ value to one variable. Since the lemma is quite simple and natural, we will not always mention it explicitly when we use it.

Two examples to keep in mind during the proof are the following:

1. Suppose that ϕ computes the parity of m variables and is of size m^2. Then if p is small, the probability that ϕ will depend on exactly one variable is about $pm = p\sqrt{L(\phi)}$, and if p is large, we expect that the remaining formula will compute the parity of around pm variables and thus be of size at least $(pm)^2 = p^2 L(\phi)$.
2. Suppose that ϕ is the $\wedge$ of $L/2$ copies of $x_1 \vee x_2$. By our rules of simplification, this will not be simplified if both x_1 and x_2 are given the value $*$ by the restriction. Hence, with probability p^2 the entire formula remains and we get expected remaining size of at least $p^2 L$.

4. Reducing to size 1. We start by estimating the probability that a given formula reduces to size one. For notational convenience we set $q = \frac{2p}{1-p}$. This will be useful since we will change the values of restrictions at individual points and, if we change a non-$*$ value to $*$, we multiply the probability by q. Since we are interested in the case when p is small, q is essentially $2p$.

LEMMA 4.1. *Let ϕ be a formula of size L and ρ be a random restriction in R_p. Let E_δ be the event that ϕ is reduced to the constant δ by ρ for $\delta = 0, 1$. Furthermore let Δ be any filter. Then $Pr[L(\phi\lceil_\rho) = 1|\Delta]$ is bounded by*

$$q\left(LPr[E_0|\Delta]Pr[E_1|\Delta]\right)^{1/2}.$$

Remark. Most of the time the implied bound $q\sqrt{L/4}$ (which follows from $x(1-x) \leq 1/4$) will be sufficient.

Proof. Let ρ be a restriction that satisfies $L(\phi\lceil_\rho) = 1$ and belongs to Δ and suppose that ρ makes ϕ into the literal x_i^ϵ. By definition, $\rho(x_i) = *$ and we have two fellow restrictions ρ^δ, $\delta = 0, 1$, where ρ^δ is obtained by changing $\rho(x_i)$ to $xor(\epsilon, \delta)$. ρ^δ contributes to the event E_δ and by the definition of a filter belongs to Δ. Hence, we can identify the set of restrictions we are interested in with edges between restrictions that reduce the formula to the constants 0 and 1, respectively, and we are on familiar ground.

Let A be the set of restrictions that satisfy E_0 and belong to Δ, and let B be the set of restrictions that satisfy E_1 and belong to Δ. We partition $A \times B$ into rectangles $A_j \times B_j$, where for each j there is some variable x_{i_j} which takes a different value in A_j and B_j. This was first done in [10] (also see [7]), but here we will need a slight generalization and thus we choose to use the more intuitive framework introduced by Karchmer and Wigderson [4].

In the normal KW-game P_1 gets an input, x, from $f^{-1}(1)$ while P_0 gets an input, y, from $f^{-1}(0)$ and their task is to find a coordinate i such that $x_i \neq y_i$. This is solved by tracing the formula from the output to an input maintaining the property that the two inputs give different values to the gates on the path. This is achieved in the following way. At an $\wedge$-gate, P_0 points to the input of this gate that evaluates to 0 on y. Similarly, at an $\vee$-gate P_1 points to the input that evaluates to 1 on x.

We extend this game by giving P_δ a restriction ρ_δ that simplifies the formula to the constant δ. The task is to find an x_i on which the two restrictions take different values (we allow answers where one restriction takes the value $*$ and the other takes the value 0 or 1).

To solve this game, both players start by setting $\rho_\delta(x_j) = 1$ for each j such that $\rho_\delta(x_j) = *$. After this they play the standard KW-game. If the path ends at literal x_i^ϵ, then in the extended restrictions $\rho_\delta(x_i) = xor(\delta, \epsilon)$. Note that if $\rho_\delta(x_i) = 0$, then this was the initial value (since we only change values to 1), while if $\rho_\delta(x_i) = 1$ then the initial value was 1 or $*$. In either case we solve the problem.

The extended KW-game creates a partition of $A \times B$ and let $A_j \times B_j$ be the inputs that reach leaf j. Note that the fact that the set of inputs that reach a certain leaf is a product set follows from the fact that each move of the game is determined by one of the players based only on his own input. Let C_j be the set of restrictions ρ that satisfy $L(\phi\lceil_\rho) = 1$ and belong to Δ and such that the pair (ρ^0, ρ^1) reaches leaf j. By necessity the literal that appears at leaf j is the literal to which ρ reduced the formula. Now, note that the probability of C_j is bounded by q times the probability of A_j. This follows since the mapping $\rho \mapsto \rho^0$ gives a one-to-one correspondence of C_j with a subset of A_j and that $Pr(\rho) = qPr(\rho^0)$ for each ρ. We have the same relation between C_j and B_j; hence

$$Pr[L(\phi\lceil_\rho) = 1|\Delta] = \sum_j Pr[C_j|\Delta] \leq \sum_j q\left(Pr[A_j|\Delta]Pr[B_j|\Delta]\right)^{1/2}$$

$$\leq q\left(\sum_j 1\right)^{1/2}\left(\sum_j Pr[A_j|\Delta]Pr[B_j|\Delta]\right)^{1/2} = q\left(LPr[A|\Delta]Pr[B|\Delta]\right)^{1/2}$$

where we used the Cauchy–Schwarz inequality. □

Remark. Please note that the theorem of Khrapchenko is indeed a special case of this lemma. Khrapchenko starts with $A \subseteq f^{-1}(0)$, $B \subseteq f^{-1}(1)$, and C which is a set of edges of the form (a, b) where $a \in A$, $b \in B$, and the hamming distance between a and b is one. As noted above, each such edge naturally corresponds to a restriction ρ by setting $\rho(x_i) = a_i$ when $a_i = b_i$ and $\rho(x_{i_0}) = *$ for the unique coordinate i_0 such that $a_{i_0} \neq b_{i_0}$. Abusing notation, we can identify the restriction and the edge. Now setting $\Delta = A \cup B \cup C$ we get a filter, and since

$$\frac{Pr[C]}{q|C|} = \frac{Pr[A]}{|A|} = \frac{Pr[B]}{|B|},$$

the lemma reduces to Khrapchenko's theorem, i.e.,

$$L \geq \frac{|C|^2}{|A| \cdot |B|}.$$

5. The balanced case. In the general case we cannot hope to have an estimate which depends on the probability of reducing to either constant. The reason is because formulas that describe tautologies do not always reduce to the constant 1.

It remains to take care of the probability that the remaining formula is of size greater than 1.

DEFINITION 5.1. *Let $L^2(\phi)$ be the expected size of the remaining formula where we ignore the result if it is of size* 1*, i.e., $L^2(\phi) = \sum_{i=2}^{\infty} iPr[L(\phi\lceil_\rho) = i]$. Furthermore, let $L^2(\phi|\Delta)$ be the same quantity conditioned on $\rho \in \Delta$. Here we think of ρ as taken randomly from R_p and thus $L^2(\phi)$ depends on the parameter p. We will, however, suppress this dependence.*

To familiarize the reader with the ideas involved in the proof, we first prove the desired result when the formula is balanced. Here we will take the strictest possible definition of "balanced," namely that the formula is a complete binary tree, and just establish the size of the reduced formula as a function of its original depth.

THEOREM 5.2. *Let ϕ be a formula of depth d and ρ a random restriction in R_p. Let Δ be any filter and assume that $q \leq (d2^{1+d/2})^{-1}$; then*

$$L^2(\phi|\Delta) \leq q^2 d 2^{d-1}.$$

Proof. The proof is by induction over the depth. The base case ($d = 1$) is obvious. Now suppose $\phi = \phi_1 \wedge \phi_2$ (the $\vee$-case is similar), where the depth of each ϕ_i is $d - 1$ and hence the size is bounded by 2^{d-1}. We need to consider the following events:

1. $L(\phi_i\lceil_\rho) \geq 2$ for $i = 1$ or $i = 2$.
2. $L(\phi_1\lceil_\rho) = 1$, and the size of ϕ_2 after the simplification by ρ and the application of the one-variable simplification rule is at least 1.
3. $L(\phi_2\lceil_\rho) = 1$, and the size of ϕ_1 after the simplification by ρ and the application of the one-variable simplification rule is at least 1.

The estimate for $L^2(\phi|\Delta)$ is now

$$2 \cdot q^2(d-1)2^{d-2} + Pr[case\ 2] + Pr[case\ 3].$$

The first term comes from any subformula of size at least 2 appearing in either of the three cases, while the other two terms cover the new contribution in the respective cases.

Let us analyze the probability of case 2. Let p_i^ϵ be the probability that ϕ_1 reduces to x_i^ϵ. We know from Lemma 4.1 that

$$\sum p_i^\epsilon \leq q2^{(d-3)/2}.$$

Now consider the conditional probability that, given that ϕ_1 reduces to x_i^ϵ, ϕ_2 does not reduce to a constant. The condition that ϕ_1 reduces to x_i^ϵ can be written as "$\rho \in \Delta' \wedge \rho(x_i) = *$" for some filter Δ'. The reason for this is that if ρ reduces ϕ_1 to x_i^ϵ, then changing any $\rho(x_j)$, $j \neq i$ from $*$ to a constant the resulting restriction still reduces ϕ_1 to x_i^ϵ. This follows by Lemma 3.1. Thus we should work with the conditioning $\rho \in \Delta \bigcap \Delta' \wedge \rho(x_i) = *$. Now we substitute $x_i = \bar{\epsilon}$ in ϕ_2 and we can forget the variable x_i and just keep the restrictions in $\Delta \bigcap \Delta'$ that satisfy $\rho(x_i) = *$ (as restrictions on the other $n-1$ variables). This yields a filter Δ''. Thus we want to estimate the conditional probability that $\phi_2\lceil_{x_i=\epsilon}$ does not reduce to a constant given that $\rho \in \Delta''$. Now we are in position to apply induction, and hence this probability can be estimated by

$$q2^{(d-3)/2} + \frac{1}{2}q^2(d-1)2^{d-2},$$

where the first term is given by Lemma 4.1 and the second term is a bound on $\frac{1}{2}L^2(\phi_2|\Delta'')$. Using $q \leq (d2^{1+d/2})^{-1}$ we get the total bound $q2^{d/2-1}$. This implies that the total probability of case 2 is bounded by

$$\sum p_i^\epsilon q2^{d/2-1} \leq q^2 2^{d-5/2}.$$

The probability of case 3 can be bounded the same way and finally

$$2 \cdot q^2(d-1)2^{d-2} + q^2 2^{d-3/2} \leq q^2 d2^{d-1},$$

and the proof is complete. □

It is not difficult to extend Theorem 5.2 to larger d, but we leave the details to the reader.

6. The probability of size at least 2 remaining. The reason why things are so easy in the balanced case is that we need not rely on very complicated simplifications. In particular, we did not need the fact that a subformula can kill its brother. This will be needed in general, and we start with the following lemma.

LEMMA 6.1. *Let ϕ be a formula of size L and ρ be a random restriction in R_p. Let Δ be any filter, and assume that $q \leq (2\sqrt{L \log L})^{-1}$. Then the probability that $L(\phi\lceil_\rho) \geq 2$ conditioned on $\rho \in \Delta$ is at most $q^2 L(\log L)^{1/2}$.*

Proof. We prove the lemma by induction over the size of the formula. It is not hard to see that the lemma is correct when $L \leq 2$. Suppose that $\phi = \phi_1 \wedge \phi_2$ (the $\vee$-case is similar) where $L(\phi_i) = L_i$, $L_1 + L_2 = L$, and $L_1 \leq L_2$. We divide the event in question into the following pieces:

1. $L(\phi_1\lceil_\rho) \geq 2$.
2. $L(\phi_1\lceil_\rho) = 1$, and even after the one-variable simplification rule is used the size of the simplified ϕ_2 is at least 1.
3. ϕ_1 is reduced to the constant 1 by ρ and $L(\phi_2\lceil_\rho) \geq 2$.

The probability of the first event is by induction bounded by $q^2 L_1 (\log L_1)^{1/2}$. Suppose the probability, conditioned on $\rho \in \Delta$, that ϕ_1 is reduced to the constant 1 is Q. Call the corresponding set of restrictions Δ'. Note that Δ' is a filter. Then using the induction hypothesis with the conditioning $\Delta \bigcap \Delta'$ we get the probability of the third event to be bounded by

$$Q q^2 L_2 (\log L_2)^{1/2}.$$

Let us now estimate the probability of the second case. The probability that $L(\phi_1 \lceil_\rho) = 1$ is, by Lemma 4.1, bounded by $q \left(L_1 Q(1-Q)\right)^{1/2}$. To estimate the conditional probability that, given $L(\phi_1 \lceil_\rho) = 1$, ϕ_2 remains to be of size at least 1, we reason exactly as in the proof of Theorem 5.2. Hence, this probability can be estimated by

$$q\sqrt{L_2/4} + q^2 L_2 (\log L_2)^{1/2},$$

where the first term comes from an application of Lemma 4.1 and the second term from the inductive assumption. Thus, for the second case we get the total bound

$$q \left(L_1 Q(1-Q)\right)^{1/2} \times \left(q\sqrt{L_2/4} + q^2 L_2 (\log L_2)^{1/2} \right)$$

$$\leq q^2 \left(L_1 L_2 Q(1-Q)\right)^{1/2} \leq q^2 \left(L_1 L_2 (1-Q)\right)^{1/2},$$

where we used $q \leq (2\sqrt{L \log L})^{-1} \leq (2\sqrt{L_2 \log L_2})^{-1}$. We want to bound the sum of the estimates for probabilities of cases 2 and 3. Differentiating

$$Q L_2 (\log L_2)^{1/2} + \left(L_1 L_2 (1-Q)\right)^{1/2}$$

with respect to Q yields

$$L_2 (\log L_2)^{1/2} - \frac{1}{2} \left(\frac{L_1 L_2}{1-Q} \right)^{1/2}.$$

Thus the derivative is 0 when

$$(1-Q) = \frac{L_1}{4 L_2 \log L_2},$$

and this corresponds to a maximum since the second derivative is negative. Using this optimal value for Q we get a total estimate which is

$$q^2 L_1 (\log L_1)^{1/2} + q^2 L_2 (\log L_2)^{1/2} - \frac{q^2}{4} L_1 (\log L_2)^{-1/2} + \frac{q^2}{2} L_1 (\log L_2)^{-1/2}$$

$$= q^2 L_1 (\log L_1)^{1/2} + q^2 L_2 (\log L_2)^{1/2} + \frac{q^2}{4} L_1 (\log L_2)^{-1/2},$$

and we need to prove that this is less than $q^2 L (\log L)^{1/2}$ when $L_1 \leq L_2$ and $L = L_1 + L_2$. This is only calculus, but let us give the proof.

First note that $\log L_2 \geq \log \lceil L/2 \rceil \geq \frac{1}{2} \log L$ when $L \geq 3$; hence it is sufficient to bound

$$q^2 L_1 (\log L_1)^{1/2} + q^2 L_2 (\log L_2)^{1/2} + \frac{q^2}{2} L_1 (\log L)^{-1/2}.$$

Now if we set $H(x) = x(\log x)^{1/2}$ it is not difficult to see that $H''(x)$ is positive for $x \geq 2$ and hence the above expression is convex for $L_1 \geq 2$. This means that it is maximized either for $L_1 = 1, 2$ or $L_1 = L_2$. The first two cases correspond to the inequalities

$$(L-1)(\log(L-1))^{1/2} + \frac{1}{2}(\log L)^{-1/2} \leq L(\log L)^{1/2}$$

and

$$2 + (L-2)(\log(L-2))^{1/2} + (\log L)^{-1/2} \leq L(\log L)^{1/2}$$

which are easily seen to hold for $L \geq 3$ and $L \geq 4$, respectively. To check the required inequality when $L_1 = L_2$ we need to prove that

$$L(\log L/2)^{1/2} + \frac{L}{4}(\log L)^{-1/2} \leq L(\log L)^{1/2}.$$

This follows from $\sqrt{x} - \sqrt{x-1} \geq \frac{1}{2\sqrt{x}}$, which is valid for all $x \geq 1$. □

7. Main shrinkage theorem. We are now ready for our main theorem.

THEOREM 7.1. *Let ϕ be a formula of size L and ρ be a random restriction in R_p. Then the expected size of $\phi\lceil_\rho$ is bounded by*

$$O\left(p^2\left(1 + \left(\log\left(\min\left(\frac{1}{p}, L\right)\right)\right)^{3/2}\right)L + p\sqrt{L}\right).$$

Crucial to this theorem is the following lemma.

LEMMA 7.2. *Let ϕ be a formula of size L and ρ be a random restriction in R_p. If $q \leq (2\sqrt{L\log L})^{-1}$, then*

$$L^2(\phi) \leq 30q^2L(\log L)^{3/2},$$

while if $\frac{1}{2} \geq q \geq (4\sqrt{L\log L})^{-1}$, then

$$L^2(\phi) \leq 200q^2L(\log q^{-1})^{3/2}.$$

First note that Theorem 7.1 follows from Lemma 7.2 together with Lemma 4.1; thus it is sufficient to prove Lemma 7.2. Also note that Lemma 7.2 and Theorem 7.1 do not consider conditional probabilities. There are two reasons for this. It is not needed and the proof does not seem to allow it.

Proof of Lemma 7.2. The hard part of the lemma is the case when q is small. We will start by establishing this case. As before we proceed by induction. The base case ($L = 1$) is obvious. Suppose that $\phi = \phi_1 \wedge \phi_2$ (the $\vee$-case is similar), where $L(\phi_i) = L_i$, $L_1 + L_2 = L$, and $L_1 \leq L_2$.

Our basic estimate for $L^2(\phi)$ is $L^2(\phi_1) + L^2(\phi_2)$, which by induction can be bounded by

$$S(L_1, L_2) = 30q^2L_1(\log L_1)^{3/2} + 30q^2L_2(\log L_2)^{3/2}.$$

We need to revise this estimate, and in particular, we need to consider the events which contribute either to the event described by the basic estimate ($L(\phi_i\lceil_\rho) \geq 2$ for $i = 1$, or $i = 2$) or to the event we are trying to estimate ($L(\phi\lceil_\rho) \geq 2$):

1. We have $L(\phi_i\lceil_\rho) \geq 2$ for $i = 1$ and $i = 2$.
2. $L(\phi_i\lceil_\rho) = 1$ for $i = 1$ or $i = 2$, and the one-variable simplification rule was active at the top gate.
3. $L(\phi_1\lceil_\rho) = L(\phi_2\lceil_\rho) = 1$, and the one-variable simplification rule was not active at the top gate.
4. $L(\phi_1\lceil_\rho) = 1$, $L(\phi_2\lceil_\rho) \geq 2$, and the one-variable simplification rule was not active at the top gate.
5. $L(\phi_2\lceil_\rho) = 1$, $L(\phi_1\lceil_\rho) \geq 2$, and the one-variable simplification rule was not active at the top gate.
6. The function ϕ_1 is reduced to the constant 0 while $L(\phi_2\lceil_\rho) \geq 2$.
7. The function ϕ_1 is reduced to the constant 1 while $L(\phi_2\lceil_\rho) \geq 2$.
8. The function ϕ_2 is reduced to the constant 0 while $L(\phi_1\lceil_\rho) \geq 2$.
9. The function ϕ_2 is reduced to the constant 1 while $L(\phi_1\lceil_\rho) \geq 2$.

Let us first investigate what corrections we need to make to our basic estimate in the various cases.

Case 1. The basic estimate is correct.

Case 2. Suppose that ϕ_1 reduces to x_i^ϵ. If the resulting formula is of size at least 2, then ϕ_2 was of size at least 2 before we did the simplification of substituting $\bar{\epsilon}$ for x_i. This reduced the size of ϕ_2 by at least one. This means that the formula size of ϕ is at most the formula size of ϕ_2 before we did this simplification. However, in our basic estimate we have not taken this simplification into account, and thus we need not add anything to our basic estimate in this case.

Case 3. In this case we need to add 2 to our basic estimate. We will need to do some work to estimate the probability of this case.

Case 4. In this case we need to add 1 to our basic estimate. Also, the probability of this event needs a little bit of work.

Case 5. In this case we need to add 1 to our basic estimate. From our previous work we can estimate the probability of this event simply by the probability that the remaining size of ϕ_1 is at least 2 and that by Lemma 6.1 this probability is bounded by

$$q^2 L_1 (\log L_1)^{1/2}.$$

Cases 6 *and* 8. In these cases we can subtract at least 2 from our original estimate. This follows since in these cases we erase a formula of size at least 2 which contributed needlessly to the basic estimate. We will use only Case 6.

Cases 7 *and* 9. The basic estimate is correct.

The above reasoning gives the total bound

$$S(L_1, L_2) + 2Pr[case\ 3] + Pr[case\ 4] + Pr[case\ 5] - 2Pr[case\ 6].$$

We have already bounded $Pr[case\ 5]$, and for the other probabilities we will establish the following lemmas.

LEMMA 7.3. *If* $q \leq (2\sqrt{L_1 \log L_1})^{-1}$, *then*

$$Pr[case\ 3] \leq 20q^2 L_1 + \frac{1}{2} q^2 L_1 (\log L_1)^{1/2} + \frac{1}{2} Pr[case\ 6].$$

LEMMA 7.4. *If* $q \leq (2\sqrt{L_1 \log L_1})^{-1}$, *then*

$$Pr[case\ 4] \leq q^2 L_1 + Pr[case\ 6].$$

Let us check that this is sufficient to prove Lemma 7.2 in the case where q is small.

$$S(L_1, L_2) + 2Pr[case\ 3] + Pr[case\ 4] + Pr[case\ 5] - 2Pr[case\ 6]$$

$$\leq S(L_1, L_2) + 41q^2L_1 + q^2L_1(\log L_1)^{1/2}.$$

We need to prove that this is bounded by $30q^2L(\log L)^{3/2}$ for all possible L_1. Substituting $L_2 = L - L_1$ and differentiating twice we see that this is a convex function of L_1 when $2 \leq L_1 \leq L/2$. This means that it is maximized either for $L_1 = 1, 2$ or $L_1 = L_2$.

For $L_1 = 1$ we need to establish

$$30(L-1)(\log(L-1))^{3/2} + 41 \leq 30L(\log L)^{3/2},$$

which is easily checked to be true for $L = 2$ and $L = 3$. For $L \geq 4$ the inequality follows from

$$L(\log L)^{3/2} \geq (L-1)(\log L)^{3/2} + 2.$$

For $L_1 = 2$ we need to check

$$30(L-2)(\log(L-2))^{3/2} + 60 + 82 + 1 \leq 30L(\log L)^{3/2},$$

which for $L \geq 4$ follows from

$$L(\log L)^{3/2} \geq (L-2)(\log L)^{3/2} + 2 \cdot 2^{3/2}$$

and $60 \cdot 2^{3/2} > 143$.

Finally, for $L_1 = L/2$ we need to estimate

$$30L(\log L/2)^{3/2} + L/2(41 + (\log L/2)^{1/2}),$$

and using the inequality $x^{3/2} - (x-1)^{3/2} \geq x^{1/2}$, which is valid for any $x \geq 1$, this can be bounded by

$$30L(\log L)^{3/2} - 30L(\log L)^{1/2} + \frac{43}{2}L(\log L)^{1/2} \leq 30L(\log L)^{3/2}.$$

Thus we are done.

Hence we need only establish Lemmas 7.3 and 7.4. The basic principle is to start with a set of restrictions that contributes to the bad case (cases 3 and 4, respectively) and create a set of restrictions that contribute to the good case, namely case 6. In this process there will be some "spills" and hence we need the additive terms. Lemma 7.4 is by far easier, and since the basic outline is the same, we start with this lemma.

Proof of Lemma 7.4. Let C be the set of restrictions such that ϕ_1 reduces to exactly one variable or its negation and such that the reduced ϕ_2 does not contain this variable. Let A be the set of restrictions that is formed by setting the variable that remains in ϕ_1 in such a way to make ϕ_1 reduce to the constant 0, and let B be the corresponding set that makes ϕ_1 reduce to 1. Each element in C corresponds to an edge between A and B and we can (as in the proof of Lemma 4.1) let this define a path in ϕ_1. Thus each leaf in ϕ_1 corresponds to a set $A_j \times B_j$ which reaches this leaf and a subset C_j of C such that for any $\rho \in C_j$, its neighbors belong to A_j and B_j,

respectively. The sets $A_j \times B_j$ form a partition of $A \times B$. Further suppose that the literal at leaf j of ϕ_1 is $x_{d_j}^{\epsilon_j}$. Note that this implies that if $\rho \in C_j$, then ρ simplifies ϕ_1 to $x_{d_j}^{\epsilon_j}$.

Let q_j be the conditional probability that, when ρ is chosen uniformly from C_j, $L(\phi_2\lceil_\rho) \geq 2$. The probability of case 4 is then given by

$$\sum_j Pr[C_j]q_j.$$

If we take any restriction ρ contributing to this event and change the value of ρ at x_{d_j} to ϵ_j then we get a restriction ρ' contributing to Case 6. This follows since x_{d_j} does not appear in the reduced ϕ_2. The set of restrictions created at leaf j will be of total probability $q^{-1}Pr[C_j]q_j$ and we seem to be in good shape. However, the same restriction ρ' might be created at many leaves and hence we would be overcounting if we would just sum these probabilities for various j. In addition, note that ρ' belongs to A, and if it is created at leaf j, then it belongs to A_j. Now, since $A_j \times B_j$ forms a partition of $A \times B$, we have for any $\rho \in A$

$$\sum_{j|\rho \in A_j} Pr[B_j] = Pr[B] \leq 1.$$

This means that if we multiply the total probability of restrictions created at leaf j by $Pr[B_j]$, we avoid overcounting. Thus the sure contribution to the probability of Case 6 is

$$\sum_j q^{-1}Pr[C_j]Pr[B_j]q_j.$$

We need to compare this to $\sum_j Pr[C_j]q_j$. For the j for which $Pr[B_j] \geq q$, the term in the sum for Case 6 is bigger than the corresponding term for Case 4, while for other j, we use that $Pr[C_j] \leq qPr[B_j] \leq q^2$; thus summing over those j gives a contribution of at most q^2L_1. We have proved Lemma 7.4. □

Next we turn to Lemma 7.3. This will be more complicated, mainly because the restrictions contributing to Case 6 are more difficult to construct.

Proof of Lemma 7.3. Let A_j, B_j, and C_j be as in the previous proof. For fixed j let r_j be the conditional probability that $L(\phi_2\lceil_\rho) = 1$ given that $\rho \in C_j$. We divide the leaves into two cases depending on whether $r_j \leq 20qPr[B_j]^{-1}$. If we restrict the summation to those j that satisfy this inequality, then

$$\sum_j Pr[C_j]r_j \leq \sum_j qPr[B_j]20qPr[B_j]^{-1} \leq 20q^2L_1$$

and this gives the first term on the right-hand side of Lemma 7.3. We thus concentrate on the case when $r_j \geq 20qPr[B_j]^{-1}$.

Let $A^{2,j}$ and $B^{2,j}$ be the subsets of C_j which reduce ϕ_2 to 0 and 1, respectively. Let ρ be a restriction that belongs to C_j and contributes to Case 3. Assume that ρ reduces ϕ_2 to x_d^ϵ. We can obtain a restriction ρ' in $A^{2,j}$ (if $\epsilon = 1$) or $B^{2,j}$ (if $\epsilon = 0$) by setting $\rho'(x_k) = \rho(x_k)$ for $k \neq d$ and $\rho'(x_d) = 1$. To see that $\rho' \in C_j$, note that before we play the KW-game we give all variables given the value $*$ by ρ the value 1. Thus the executions on ρ and ρ' are identical and $\rho' \in C_j$. Also, clearly ρ' forces ϕ_2 to $\bar{\epsilon}$. Now suppose that

$$\sum_{\rho|\rho' \in A^{2,j}} Pr[\rho] \geq \sum_{\rho|\rho' \in B^{2,j}} Pr[\rho] \tag{2}$$

(the other case being symmetric). Suppose that $A^{2,j}$ consists of the restrictions $\rho_1 \dots \rho_k$. For ρ_i we define a set of *critical variables*, and x_k is in this set if

- $\rho_i(x_k) = 1$.
- creating the restriction ρ_i' by setting $\rho_i'(x_l) = \rho_i(x_l)$ for every $l \neq k$ while $\rho_i'(x_k) = *$ creates a restriction in C and $\phi_2 \lceil_{\rho_i'}$ reduces to $\bar{x}_k$.

Note that, as observed above, $\rho' \in C$ in fact implies that $\rho' \in C_j$ since $\rho \in C_j$, and we go from ρ' to ρ by changing the value on a variable from $*$ to 1.

Suppose that there are s_i critical variables for ρ_i. By definition, each restriction contributing to the conditional probability r_j gives one critical variable for one $\rho_i \in A^{2,j}$ exactly when ϕ_2 is reduced to a negated variable; otherwise it gives no contribution. By (2) the first case happens in at least half the cases and hence we have

$$r_j = \alpha Pr[C_j]^{-1} \sum_i q s_i Pr[\rho_i]$$

for some α satisfying $1 \leq \alpha \leq 2$. We now create a set of restrictions in the following way. We obtain $\binom{s_i}{2}$ new restrictions from ρ_i by choosing two critical variables for ρ_i, and for each such choice (s,t) create a restriction $\rho_i^{(s,t)}$ by setting $\rho_i^{(s,t)}(x_k) = \rho_i(x_k)$ for every $k \notin \{s,t\}$ while $\rho_i^{(s,t)}(x_s) = \rho_i^{(s,t)}(x_t) = *$. This way, we get a set of restrictions of total probability $q^2\binom{s_i}{2}Pr[\rho_i]$.

Let us relate the total probability of these constructed restrictions to r_j. Note that

$$\begin{aligned} r_j^2 &= \left(\alpha Pr[C_j]^{-1} \sum_i (q s_i Pr[\rho_i])\right)^2 \\ &\leq \alpha^2 \left(Pr[C_j]^{-1} \sum_i (q^2 s_i^2 Pr[\rho_i])\right) \cdot \left(Pr[C_j]^{-1} \sum_i Pr[\rho_i]\right) \\ &= \alpha^2 Pr[C_j]^{-1} Pr[A^{2,j}|C_j] \sum_i q^2 s_i^2 Pr[\rho_i], \end{aligned}$$

where the inequality comes from the Cauchy–Schwarz inequality. Now

$$\begin{aligned} \sum_i q^2 \binom{s_i}{2} Pr[\rho_i] &= \sum_i \frac{1}{2} q^2 s_i^2 Pr[\rho_i] - \sum_i \frac{1}{2} q^2 s_i Pr[\rho_i] \\ &\geq \frac{r_j^2 Pr[C_j]}{2\alpha^2 Pr[A^{2,j}|C_j]} - \frac{q}{2\alpha} r_j Pr[C_j] \\ &\geq \left(\frac{1}{2\alpha^2} - \frac{1}{40\alpha}\right) r_j^2 Pr[C_j] \geq \frac{1}{10} r_j^2 Pr[C_j], \end{aligned}$$

since $\alpha \leq 2$ and $r_j \geq 20q$.

Remark. Note that the constructed restrictions need not be in C_j. The reason is that there is no control when a variable is changed from being fixed to being $*$. In particular, if we were trying to estimate a conditional expectation, we would be in deep trouble, since it need not be the case that these recently constructed restrictions satisfy the condition.

Let us look more closely at these obtained restrictions. They give the value $*$ to the variable x_{d_j} since the restriction that we started with belonged to C_j. They also give the value $*$ to the two special variables x_s and x_t.

We now change the value at x_{d_j} to ϵ_j in an attempt to force ϕ_1 to 0. Note that this attempt might not always be successful since, once x_s and x_t become unassigned, ϕ_1 might also depend on those variables (as well as on others). We leave this problem for the time being. Let us analyze the set of restrictions created in this way.

At leaf j we created a set of restrictions of total probability at least $q^{-1}\frac{1}{10}Pr[C_j]r_j^2$. However, the same restriction might appear many times and we need to adjust for this fact. Take any restriction ρ created from $\rho_i \in A^{2,j}$. First note that ρ determines the identity of the two special variables x_s and x_t. These are, namely, the only variables x_k given the value $*$ by ρ with the property that setting $\rho(x_k) = 1$ makes ϕ_2 depend on only one variable. This follows since we recreate a restriction from C_j with the additional property that x_{d_j} is set, but since we are considering cases when ϕ_2 was independent of x_{d_j}, setting a value to x_{d_j} does not matter. To complete the characterization of x_s and x_t, note that after setting any other variable x_k to any value it is still true that ϕ_2 depends on both x_s and x_t.

Let x_s be the variable with lower index of the variables x_s and x_t which we just have identified. Consider the restriction ρ' obtained by setting $\rho'(x_s) = 1$ while $\rho'(x_k) = \rho(x_k)$ for every $x_k \neq x_s$. We claim that ρ' belongs to A_j. Remember that $A_j \times B_j$ was the set of inputs reaching leaf j when playing the KW-game on the formula ϕ_1. To see this claim let ρ'' be obtained by setting $\rho''(x_k) = \rho'(x_k)$ for $x_k \neq x_{d_j}$ while $\rho''(x_{d_j}) = *$. By the conditions for x_t being a critical variable for ρ_i, $\rho'' \in C_j$ and hence $\rho' \in A_j$.

Thus, starting with ρ we have created a unique restriction ρ' such that whenever ρ is created at leaf j then $\rho' \in A_j$. Thus, reasoning as in the proof of Lemma 7.4, if we multiply the probability of the restrictions produced at leaf j by $Pr[B_j]$, then we avoid making an overestimate. This means that we have created a set of restrictions of total probability at least

$$\sum_j \frac{1}{10} q^{-1} Pr[C_j] r_j^2 Pr[B_j].$$

The created restrictions are of two types: either they do reduce the formula ϕ_1 to 0 or they do not. In the former case they contribute to Case 6 (since ϕ_2 depends on x_s and x_t), and we have to estimate the probability of the latter case. We claim that in this case the reduced ϕ_1 contains both the variables x_s and x_t. This follows, since setting $\rho(x_s) = 1$ or $\rho(x_t) = 1$ simplifies ϕ_1 to 0 which in its turn is basically the fact $\rho' \in A_j$ established above. By Lemma 6.1 it follows that the probability of this case is bounded by $q^2 L_1 (\log L_1)^{1/2}$. Summing up we have

$$\begin{aligned} Pr[case\ 3] = \sum_{j=1}^{L_1} Pr[C_j] r_j &= \sum_{j|r_j\ small} Pr[C_j] r_j + \sum_{j|r_j\ large} Pr[C_j] r_j \\ &\leq 20 q^2 L_1 + \frac{1}{20} \sum_j q^{-1} Pr[C_j] r_j^2 Pr[B_j] \\ &\leq 20 q^2 L_1 + \frac{1}{2} \left(Pr[case\ 6] + q^2 L_1 (\log L_1)^{1/2} \right), \end{aligned}$$

where the first inequality uses the bound for r_j and the last inequality is based on the above reasoning. The proof of Lemma 7.3 is complete. □

All that remains is to complete the proof of Lemma 7.2 when $q \geq (4\sqrt{L \log L})^{-1}$. To simplify the calculations we will, in this case, prove the slightly stronger bound

$$L^2(\phi) \leq 200 q^2 L (\log q^{-1})^{3/2} - 2.$$

First note that when $(4\sqrt{L\log L})^{-1} \le q \le (2\sqrt{L\log L})^{-1}$, the second bound follows from the first bound since

$$\begin{aligned}200q^2L(\log q^{-1})^{3/2} &\ge 200q^2L(1/2\log L)^{3/2} \ge 62q^2L(\log L)^{3/2}\\ &\ge 30q^2L(\log L)^{3/2} + 32(4\sqrt{L\log L})^{-2}L(\log L)^{3/2}\\ &\ge 30q^2L(\log L)^{3/2} + 2.\end{aligned}$$

It remains to establish the second bound when $q \ge (2\sqrt{L\log L})^{-1}$, and we do this by induction over L. Assume that $\phi = \phi_1 \wedge \phi_2$, (the $\vee$-case being similar) where $L(\phi_i) = L_i$, $L_1 + L_2 = L$, and $L_1 \le L_2$. This implies that we can always use the second bound when bounding $L^2(\phi_2)$. We have two cases, depending on whether or not $q \le (4\sqrt{L_1\log L_1})^{-1}$. If $q \ge (4\sqrt{L_1\log L_1})^{-1}$ then, using the induction hypothesis and $L^2(\phi) \le L^2(\phi_1) + L^2(\phi_2) + 2$, the result follows immediately.

To take care of the other case, notice that our estimates for the corrections to the basic estimates depended only on L_1. This means that in this case we get the total bound

$$L^2(\phi_1) + L^2(\phi_2) + 41q^2L_1 + q^2L_1(\log L_1)^{1/2},$$

and using the induction hypothesis (the first case for ϕ_1 and the second for ϕ_2) we can bound this by

$$\begin{aligned}&30q^2L_1(\log L_1)^{3/2} + (200q^2L_2(\log q^{-1})^{3/2} - 2) + q^2L_1(41 + (\log L_1)^{1/2})\\ &\quad\le 90q^2L_1(\log q^{-1})^{3/2} + (200q^2L_2(\log q^{-1})^{3/2} - 2) + 43q^2L_1(\log q^{-1})^{1/2}\\ &\quad\le 200q^2L(\log q^{-1})^{3/2} - 2,\end{aligned}$$

and the proof is complete. □

8. Application to formula-size lower bounds. As mentioned in the introduction, it is well known that shrinkage results can be used to derive lower bounds on formula size. Let us briefly recall the function which seems to be the most appropriate for this purpose. The input bits are of two types. For notational simplicity assume that we have $2n$ input bits and that $\log n$ is an integer that divides n. The first n bits define a Boolean function H on $\log n$ bits. The other n bits are divided into $\log n$ groups of $n/\log n$ bits each. If the parity of the variables in group i is y_i then the output is $H(y)$. We call this function A as it was first defined by Andreev [9].

THEOREM 8.1. *The function A requires formulas of size*

$$\Omega\left(\frac{n^3}{(\log n)^{7/2}(\log\log n)^3}\right).$$

Proof. Assume that we have a formula of size S which describes A. We know ([8, Chapter 4, Theorem 3.1]) that there is a function of $\log n$ variables which requires a formula size which is

$$\Omega\left(\frac{n}{\log\log n}\right).$$

We fix the first set of values to describe such a function. This might decrease the size of the formula, but it is not clear by how much, and hence we just note that the resulting formula is of size at most S. Apply an R_p-restriction with $p = \frac{2\log n\log\log n}{n}$ on the

remaining formula. By our main theorem the resulting formula will be of expected size at most $O(Sn^{-2}(\log n)^{7/2}(\log\log n)^2+1)$. The probability that all variables in a particular group are fixed is bounded by

$$(1-p)^{\frac{n}{\log n}} \le e^{-\frac{pn}{\log n}} \le (\log n)^{-2}.$$

Since there are only $\log n$ groups, with probability $1-o(1)$ there remains at least one live variable in each group. Now since a positive random variable is at most twice its expected size with probability at least $1/2$, it follows that there is a positive probability that we have at most twice the expected remaining size and some live variable in each group. It follows that

$$O\left(Sn^{-2}(\log n)^{7/2}(\log\log n)^2\right) \ge \Omega\left(\frac{n}{\log\log n}\right),$$

and the proof is complete. □

We note that there are indeed formulas for the function A of size $O(n^3(\log n)^{-1})$, and hence our bounds are close to optimal.

9. Conclusions. There remain two interesting questions on shrinking:

- *What is the shrinkage exponent for monotone formulas*? In some sense we have established that it is 2; namely, one of the two examples given in the introduction is monotone and shrinks only by a factor p^2. This is the example of $L/2$ copies of $x_1 \wedge x_2$. This is not a natural example, and if it is the only one, we are asking the wrong question. We can get around this example by using 2-variable and 3-variable simplification rules. We could also ask a slightly different question, namely, what is the minimal α such that for arbitrary small p there is a monotone formula of size $O(p^{-\alpha})$ that is trivialized by a restriction from R_p with probability at most $1/2$?

  Apart from its inherent interest, a successful answer to this question would in most cases (depending on the exact form of the answer) lead to an $\omega(n^2)$ lower bound for monotone formulas for the majority function.
- *Are these annoying log factors really needed*? This is really of minor importance. If they were indeed needed it would be surprising.

Acknowledgments. I am most grateful to Sasha Razborov and V.N. Lebedev for catching gaps in the proofs in previous versions of this paper. Together with Andy Yao, Sasha Razborov was also very helpful in giving ideas in the initial stages of this research. Finally, I am most grateful to two anonymous referees for their careful reading of the manuscript.

SHARED MEMORY CONSISTENCY CONDITIONS FOR NONSEQUENTIAL EXECUTION: DEFINITIONS AND PROGRAMMING STRATEGIES*

HAGIT ATTIYA†, SOMA CHAUDHURI‡, ROY FRIEDMAN§, AND JENNIFER L. WELCH¶

Abstract. To enhance performance on shared memory multiprocessors, various techniques have been proposed to reduce the latency of memory accesses, including pipelining of accesses, out-of-order execution of accesses, and branch prediction with speculative execution. These optimizations can, however, complicate the user's model of memory. This paper attacks the problem of simplifying programming on two fronts.

First, a general framework is presented for defining shared memory consistency conditions that allows nonsequential execution of memory accesses. The interface at which conditions are defined is between the program and the system and is architecture-independent. The framework is used to generalize three consistency conditions—sequential consistency, hybrid consistency, and weak consistency—for nonsequential execution. Thus, familiar consistency conditions can be precisely specified even in optimized architectures.

Second, three techniques are described for structuring programs so that a shared memory that provides the weaker (and more efficient) condition of hybrid consistency appears to guarantee the stronger (and more costly) condition of sequential consistency. The benefit of these techniques is that sequentially consistent executions are easier to reason about. The first technique statically classifies accesses based on their type. This approach is extremely simple to use and leads to a general technique for writing efficient synchronization code. The third technique is to avoid data races in the program, which was previously studied in a somewhat different setting.

Precise, yet short and comprehensible, proofs are provided for the correctness of the programming techniques. Such proofs shed light on the reasons these techniques work; we believe that the insight gained can lead to the development of other techniques.

offers the potential of greatly increased performance, and shared memory is an attractive communication paradigm. Unfortunately, access to shared memory locations is a major bottleneck for the performance of multiprocessors. The high latency of memory operations is due to the amount of time needed to execute memory operations locally and to the interprocessor communication delay, which increases with the number of processors.

Many uniprocessor architecture techniques have been developed and implemented to hide the latency of memory operations by allowing operations to overlap. These techniques include performing memory accesses in parallel, pipelining memory accesses, initiating accesses out of order, and speculative execution (in which the system predicts the outcome of future conditional branches and begins memory accesses for the predicted branch). Specific instances include [1, 20, 24, 34, 35, 37, 39, 40]. Since these techniques deviate from the sequential order of memory accesses specified by the program, we call them "nonsequential."

In multiprocessors, memory is often replicated and distributed to compensate for the interprocessor communication delay. A consistency condition for shared memory specifies what guarantees are provided about the values returned in the presence of concurrent accesses to different copies of the memory. A variety of consistency conditions have previously been proposed for shared memory architectures, e.g., [3, 4, 8, 9, 12, 18, 19, 21, 23, 25, 28, 29]. Clearly, the consistency condition limits the optimizations that can be implemented.

A natural question is how to define consistency conditions that allow nonsequential execution of memory accesses, in a manner that admits optimized systems. A further question is how to program these optimized systems with these generalized consistency conditions in a safe and effective manner.

In this paper, we focus on the interface between programs and the shared memory under consistency conditions that allow nonsequential execution. We present a framework for defining such conditions as properties of executions, rather than as properties of hardware implementations. We hope that this aspect of our framework will elucidate these somewhat complex conditions for algorithm designers, programmers, and perhaps compiler designers. We demonstrate our framework by extending three consistency conditions to allow for nonsequential execution of memory accesses. For one particular condition that allows efficient implementations, we present and prove the correctness of three programming techniques that provide the illusion of a stronger and more natural condition. The first approach is based on a static labeling of the memory accesses in the program according to their type. The second approach is to access shared data only inside appropriately protected critical sections. The third approach is to avoid data races, an approach pioneered in [3, 4, 22, 23] for hardware implementations.

1.2. Detailed description. Our first contribution is a framework for defining consistency conditions that is general enough to allow nonsequential execution of memory operations. This framework combines the following two features: (1) The interface at which conditions are specified in our model is between the program and the system instead of being specified as the internal behavior of the system. This is the interface used in [12, 25, 28] and, in our opinion, is the natural one to use for specification to be independent of implementation. (2) The framework allows for arbitrary optimizations by the system, including especially speculative execution of memory accesses. Recent experiments have shown that if the program has complex control flow then only moderate speedup can be achieved by parallelism without speculative execution (e.g., [26, 41]).

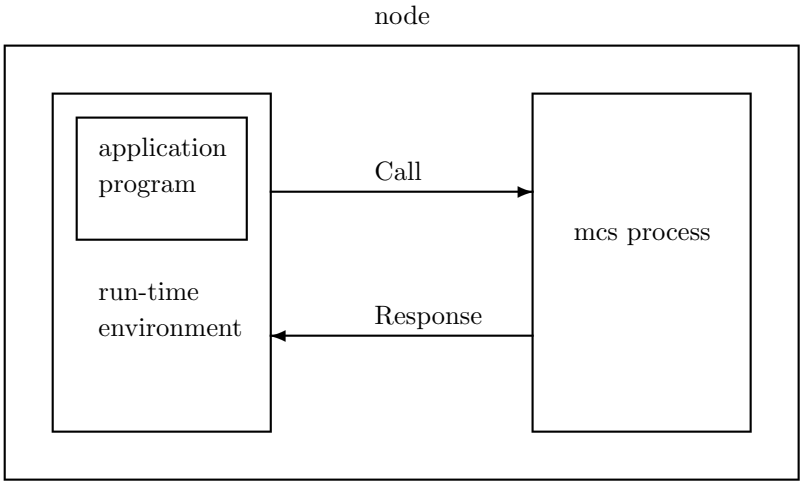

FIG. 1. *A node.*

The framework is then used to extend three known consistency conditions for nonsequential execution. Our extensions have two pleasing properties: (1) The conditions are defined for all programs, not just programs that satisfy certain conditions. (2) We give a formal, yet intuitive, treatment of explicit control instructions, which are crucial for expressing the flow of control in a program and in analyzing its correctness on nonsequential implementations.

Our framework assumes a system consisting of a collection of nodes. At each node there is an *application program*, a *memory consistency system* (mcs) process, and a *run-time environment*. An illustration of a node is given in Figure 1. An application program contains instructions to access shared memory and conditional branch instructions. The mcs processes at all the nodes collectively implement the shared objects that are manipulated by the application programs. The run-time environment at a node executes the shared memory instructions by interacting with the local mcs process; its decision as to which instructions to execute relies on the application program at that node. (We use the term *run-time environment* to refer to the combination of the functionality of a compiler, which sees the whole program, and a conventional run-time system, which makes decisions dynamically based on partial knowledge.) In our framework, consistency conditions are specified as a guarantee on the run-time environments at all nodes with respect to the program at each node. It is the responsibility of both the mcs process and the run-time environment to provide this guarantee.

A straightforward run-time environment would simply submit operations to the mcs one at a time in the order specified by the program. To achieve various optimizations, however, the run-time environment might submit operations out of order, might have multiple operations pending at a time, and might anticipate branches (sometimes incorrectly). We do not address the specific algorithm used by the run-time environment. (That is another very interesting problem, beyond the scope of this paper.) Instead, our goal is to model the run-time environment sufficiently abstractly so that any of a large number of specific run-time environments can fit into this framework. Obviously the run-time environment cannot do just anything—the optimizations that it performs should be transparent to the application program. The

strongest condition we require of a correct run-time environment is that there exist a way (after the fact) to take a subset of the operations performed by the run-time environments at all the nodes and order them to be consistent with some "sequential execution" of the programs at all the nodes. (Some of the operations performed by the run-time environment might end up not being used; for instance, if they resulted from an incorrect prediction about a branch. These operations can be ignored when determining whether there is a corresponding sequential execution.) We emphasize that the order in which operations *appear* to execute is what is important, not the order in which they *actually* execute.

Our framework incorporates rollback and compensating operations in an implicit manner. In particular, we allow the run-time environment to communicate with the mcs in order to perform other operations on the data that are not part of the application programs but that are necessary for achieving the desired consistency condition (for example, operations to restore the state of the shared variables due to incorrect predictions). These operations are ignored when the subset of operations consistent with a sequential execution is taken.

Given this framework, we generalize three known consistency conditions: sequential consistency, weak consistency, and hybrid consistency.

Our second contribution addresses the issue of writing programs for hybrid consistency and formally proving their correctness. *Hybrid consistency* is an efficient and expressive consistency condition [12]; it captures some of the essential features of several other consistency conditions appearing in the literature [3, 15, 18, 19]. Memory access operations are classified as either *strong* or *weak*. This classification is crucial to the following definition of the consistency condition, as observed by the programmer: A global ordering is imposed on strong operations at different processes, but little is guaranteed about the ordering of weak operations at different processes beyond what is implied by their interleaving with the strong operations. The classification also provides hints to the run-time environment concerning which optimizations can be applied to which accesses. Clever use of the classification can improve the performance of programs.

Unfortunately, it is more difficult to program memories that support hybrid consistency than to program memories that support sequential consistency, since the guarantees provided by the former are weaker than those provided by the latter. For instance, how should the programmer decide which accesses should be strong and which should be weak in order to improve performance yet still ensure correctness? A way to cope with this problem is to develop rules and transformations for executing programs that were written for sequentially consistent memories on hybrid consistent memories. The benefit is that sequentially consistent executions are easier to reason about while hybrid consistency can be implemented more efficiently. We consider several techniques for turning programs written for sequential consistency into programs that work for hybrid consistency. Precise, yet short and comprehensible, proofs are provided for the correctness of the programming techniques. Such proofs shed light on the reasons these techniques work; we believe that the insight gained can lead to the development of other techniques.

The first approach we present is based on statically labeling specific accesses as strong according to their type. We prove that programs in which all writes are strong run on hybrid consistent shared memory implementations as if they were sequentially consistent. There is a symmetric result that every hybrid consistent execution of a program in which all reads are strong is sequentially consistent [11]. This theorem requires further assumptions on the execution; although these assumptions are shown

to be necessary, they make the strong read technique impractical.

The second approach is based on the mutual exclusion paradigm and uses the first approach as a tool. One proposed way to program with hybrid-like consistency conditions [18, 21] is to protect accesses to shared data with critical sections and then to use strong operations in the mutual exclusion code and weak operations inside the critical section. When the critical sections are significant in size, the extra cost to execute the strong operations in the mutual exclusion algorithm is more than compensated for by the efficiency of the weak operations in the critical sections. We take a careful look at this paradigm for hybrid consistency and show that it is applicable, although care must be taken. Specifically, we show that many mutual exclusion algorithms designed to work on a sequentially consistent memory can be modified to work correctly on a hybrid consistent memory. The modification is to label all writes in the entry and exit sections as strong and all other operations as weak and to insert a dummy write in an appropriate place. However, this transformation only works for *noncooperative* algorithms in which processes do not participate in the mutual exclusion protocol unless they are actively vying for entry into the critical section.

The third approach for programming with hybrid consistency is to run data-race-free programs. This approach was pioneered by [3, 4, 21, 22, 23] in the context of hardware implementations. (See section 2 for a more detailed discussion.) A *data race* occurs when two accesses to the same location occur, at least one is a write, and there is no synchronization between them. Data races in a program are considered bad practice; they add to the uncertainty of concurrent programs, beyond what is already implied by the fact that different processes may run at different rates and memory accesses may have variable duration. (Some debuggers even regard data races as bugs in the program.) Methods have been developed to detect and report data races, also called *access anomalies*; e.g., [6, 16, 18, 17, 30, 32, 33]. It is reasonable to assume that data-race-free programs account for a substantial portion of all concurrent programs. We formally prove that data-race-free programs run on hybrid consistent shared memory implementations as if they were sequentially consistent; this result is shown in our programmer-oriented framework.

Although many parallel programs are expected to be data-race-free, we cannot ignore the drawbacks of these programs. Proving that a program is data-race-free, even for restricted cases, is co-NP-hard [31]. Also, it is sometimes difficult to find the exact location of the data race in the program [32]. Our static methods provide an alternative and show that it is not necessary to make a program data-race-free in order to guarantee correct behavior. These methods are especially well suited to applications in which reads greatly outnumber writes (or vice versa).

The rest of the paper is organized as follows. Section 2 discusses related work. Section 3 describes our system model. The modified definitions of sequential consistency, weak consistency, and hybrid consistency are given in section 4. The static methods for programming with hybrid consistency are discussed in section 5. Data-race-free programs are discussed in section 6. We conclude with a discussion of the results in section 7.

2. Related work. Many existing formal treatments of memory consistency conditions [12, 23, 25, 28, 38] assume that memory operations are executed sequentially—one at a time and in program order. Several recent papers proposed formalisms to allow some nonsequential optimizations [3, 4, 21, 22, 23]. In this section, we compare our work with these formalisms.

Gibbons, Merritt, and Gharachorloo developed a framework for defining consis-

tency condition which is based on a series of I/O automata, and used this framework to define *release consistency*, a formalization of the Stanford DASH shared memory model [22, 23]. This definition, as well as the definition of weak ordering [18, 19], is given at the interface between the mcs and the network. Hence, the resulting consistency conditions are not convenient for programmers and theoreticians. In particular, the definitions in [22, 23] are very detailed and complex. In contrast, in our framework as well as in [12, 25, 28], consistency conditions are defined at the interface between the application program and the system; consistency conditions are defined by describing the way operations are viewed (or ordered) and not the way operations are executed. Hence, our approach is more programmer oriented.

Adve and Hill developed another programmer oriented formalism, called *SCNF* [2, 5], using the assumption that programmers always want to work assuming sequentially consistent memories. In this approach, a consistency condition is a contract between software and hardware. That is, hardware must behave as if it was sequentially consistent for all programs that obey certain properties; various consistency conditions differ in the properties they require from programs. Examples of such conditions include, e.g., DRF0 [3], DRF1 [4], PL_{pc1}, and PL_{pc2} [2]. For each of these programming models, Adve and Hill introduce sufficient conditions for hardware; hardware that follows these conditions executes programs that obey the corresponding programming model as if it was sequentially consistent. The problem with this approach is that the resulting consistency conditions are not defined for programs that do not obey the required properties. This limits the programming style, even in cases where other programming styles could yield better performance. The sufficient conditions introduced by Adve and Hill for DRF0, DRF1, PL_{pc1}, and PL_{pc2} [2] extend the definition of these conditions for all programs. The approach taken by Adve and Hill is to develop a programming model and then suggest how to tailor the hardware to support it. We take the complementary approach, first developing a consistency condition, and then developing programming methods for it.

Our framework includes an explicit model of the program, including control instructions. Our notion of the control flow of the program is derived syntactically from the code. Adve and Hill's sufficient conditions for DRF0, DRF1, PL_{pc1}, and PL_{pc2} [2], which permits nonsequential execution of memory operations, is based on the notion of a read operation controlling a write operation by the same processor. It is not obvious that this notion captures all the possible ways one operation can control another. Other previous work on specifying consistency conditions has either totally ignored control instructions [7, 12, 14, 25, 28] or has only made the informal requirement that uniprocessor control dependencies are preserved [3, 21, 23].

Gibbons and Merritt [22] present a framework that deals formally with pipelining of memory operations. Their framework, recast in our terms, is based on the run-time environment submitting the memory accesses to the mcs, together with a partial order restricting the allowable reorderings of the accesses. Because the interaction between the run-time environment and the mcs is based on partial orders, their framework does not encompass arbitrary out-of-order or speculative execution of operations and it seems difficult to extend it to do so. We have taken a complementary approach and focused on modeling the program and its behavior, leaving unspecified the details of the interaction between the run-time environment and the mcs. Consequently, our framework allows arbitrary out-of-order and speculative execution of operations.

The idea that data-race-free programs can be executed on more relaxed implementations of shared memory as if they were sequentially consistent was pioneered in [2, 3, 4]. Similar results for other consistency conditions were also proved in [10, 22, 23].

We have applied this approach for hybrid consistency, using our framework. Admittedly, hybrid consistency may disallow some optimizations considered in several of the above papers. However, we believe the accessibility of our technical development provides insight concerning the interplay between conditions on the program and memory consistency conditions.

Another approach was taken by Shasha and Snir [37]. They consider multiprocessor programs, written assuming sequential consistency, and investigate where to insert memory barrier operations (fences) so that if operations are executed in pipeline, but the fences are obeyed, then the result is as if the programs were executed sequentially. Their results are based on a partial order that has to hold between instruction instances, representing program order and causality. The execution is sequentially consistent only if this order is acyclic. Therefore, they insert the minimal amount of fences that will make the induced partial order acyclic.

Singh proved sufficient conditions for executions generated by optimized hardware, e.g., pipelined RAM, causal memory, and hybrid consistency, to be sequentially consistent [38]. Unlike the approach taken in this paper and by other researchers in this area, e.g., [2, 3, 4, 10, 22, 23], the approach taken by Singh examines the executions generated by the optimized hardware and not the programs that should be run on it.

The framework developed in this paper was extended in [13] to formally define *alpha consistency*, capturing the semantics provided by DEC-Alpha based multiprocessors (see section 4.1). Two programming methodologies similar to the ones developed in this paper are presented in [13]: (a) every data-race-free program runs on an alpha consistent memory as if it was sequentially consistent, and (b) any noncooperative mutual exclusion algorithm based on sequential consistency can be transformed into a correct solution based on alpha consistency. However, since the Alpha does not support strong operations in the same sense as hybrid consistency (or release consistency),[1] the definition of data-race-free programs and the method for handling mutual exclusion algorithms in [13] are different from those in this paper.

3. Framework. In this section, we present our formal definitions.

3.1. System components. An *application program* consists of a sequence of instructions, each with a unique label. There are two (disjoint) types of instructions: (shared) memory instructions and control instructions. A *memory instruction* specifies an access to a shared object. The specific kind of access depends on the data type of the object.[2] A *control instruction* consists of a *condition* (a boolean function of the process' local state) and a *branch* (jump to the instruction with the given label).

The *memory consistency system* (mcs) implements the shared objects that are manipulated by the application programs. It consists of a process at each node as well as possibly other hardware. Every object is assumed to have a *serial specification* (cf. [25]) defining a set of *(memory) operations*, which are ordered pairs of calls and responses, and a set of *(memory) operation sequences*, which are the allowable sequences of operations on that object. For example, in the case of a read/write object, the ordered pair [$\text{Read}_i(x)$, $\text{Return}_i(x, v)$] forms an operation (p_i reads v from x) for any p_i, x, and v, as does [$\text{Write}_i(x, v)$, $\text{Ack}_i(x)$] (p_i writes v to x). The set of operation sequences consists of all sequences in which every read operation returns

[1] The *memory-barrier* operation of the Alpha does not impose any interprocess ordering of operations.

[2] Our framework does not restrict the data types; however, our programming techniques deal only with read/write operations.

the value of the latest preceding write operation (the usual read/write semantics). The interface to the mcs consists of *calls* (also called invocations) and *responses* on particular objects.

The *run-time environment* at a node takes as input the application program and executes instructions on the mcs. An *operation* is a specific instance of an execution of an instruction. A memory operation consists of two parts: a call (to the mcs process) and a matching response (from the mcs process). A control operation consists of an evaluation of its condition. A control operation is represented by the result (true or false) of the evaluation. Thus the run-time environment must keep track of the local state of the application process in order to perform the evaluation. The run-time environment and mcs process may also communicate concerning issues, such as rollback and compensating operations, necessary to implement certain optimizations. This communication can be modeled with calls to and responses from the mcs process.

An *event* is a call, response, or control operation (condition evaluation). An *execution* (of the system) is a sequence of events such that there is a correspondence between calls and responses (matching object and process), and each response follows its corresponding call.

3.2. Sequential executions. Although an execution is a sequence of events, it can also be viewed as containing operations. Each control operation is itself an event. The memory operations in an execution are obtained by matching up corresponding call and response events; we assume that the run-time environment matches the call and response events defining the memory operations. We also assume that the run-time environment identifies, possibly after the fact, a subset of all the operations executed. This subset consists of the operations that we want to consider as "really happening," and there must be an ordering of this subset that satisfies certain properties. Two important properties, which we present next, are satisfying the serial specifications of the objects (called "legal") and being consistent with a sequential execution of the program (called "admissible").

First, we give a piece of notation. If τ is a sequence of operations and op_i precedes op_j in τ, we write:

$$op_i \xrightarrow{\tau} op_j.$$

A sequence τ of operations is *legal* if for each object x, $\tau|x$, the subsequence of τ consisting of exactly the operations involving x, is in the serial specification of x.

The notion of a sequential execution of the program is formalized with the notion of a flow control sequence for a process p_i. We build up inductively an execution of p_i's program in which every instruction finishes executing before the next one begins. Given process p_i's program, a *flow control sequence*, fcs_i, is a sequence of operations defined as follows. The first element of fcs_i is an instance of the first instruction in p_i's program. Suppose the kth element of fcs_i, denoted by op, is an instance of instruction I in the program. If op is a control operation and its condition evaluates to true, then the $(k+1)$st element of fcs_i is an instance of the instruction whose label is the branch of instruction I. Otherwise the $(k+1)$st element of fcs_i is an instance of the instruction immediately after I in the program. A flow control sequence can be either finite or infinite (for nonterminating programs). Note that the flow control sequence implies a total order on the operations appearing in it; we denote this order by $\stackrel{fcs_i}{\Longrightarrow}$.

Let fcs_i be a flow control sequence for p_i. A sequence τ of memory operations is *fully fcs_i-admissible* if $\tau|i$, the subsequence of τ consisting exactly of operations

involving p_i, is equal to the subsequence of fcs_i consisting exactly of the memory operations. Intuitively, this implies that the ordering of operations by p_i in τ agrees with some flow control sequence fcs_i for p_i and does not end unless the program terminates. A sequence τ of memory operations is *partially fcs_i-admissible* if $\tau|i$ is a prefix of the subsequence of memory operations in fcs_i. Intuitively, this implies that, so far, the ordering implied by the flow control sequence is obeyed by τ, but it is not necessarily completed yet.

A sequence τ of memory operations is *fully* (resp., *partially*) *admissible* with respect to a set of flow control sequences $\{fcs_i\}_{i=1}^{n}$, one for each p_i, if it is fully (resp., partially) fcs_i-admissible for all i.

A sequence of memory operations is a *sequential execution* if it is legal and fully admissible (with respect to some set of flow control sequences).

CLAIM 3.1. *Any legal, partially admissible sequence of memory operations is a prefix of a sequential execution and vice versa.*

3.3. Weak and strong operations. In some consistency conditions it is possible to mark certain instructions in a program as *strong*; all other instructions are *weak*. An instance of a strong instruction is a *strong operation* and an instance of a weak instruction is a *weak operation*. (Strong and weak operations provide different levels of consistency and are part of the definition of hybrid consistency.) In the case of read/write objects this means that it is possible to use strong reads, strong writes, weak reads, and weak writes. In the rest of the paper, we use op_i to denote an operation invoked by p_i (weak or strong), and by sop_i we denote a strong operation invoked by process p_i. We use superscripts, e.g., $op_i^1, op_i^2, \ldots$, to distinguish between operations invoked by the same process (note that the superscript does *not* imply any ordering of the operations). We sometimes use a shorthand notation for read and write operations and denote by $r_i(x, v)$ a read operation (weak or strong) invoked by process p_i returning v from x; we denote by $w_i(x, v)$ a write operation (weak or strong) invoked by process p_i writing v to x. Similarly, $sr_i(x, v)$ is a strong read operation invoked by process p_i returning v from x; $sw_i(x, v)$ is a strong write operation invoked by process p_i writing v to x.

3.4. Control operations and the influence relation. When defining and analyzing consistency conditions, it is important to take into account the effects of control operations. A specific example of the pitfalls associated with failing to do so appears in section 4, where we present our new consistency conditions. To capture the effect of control operations, we define a partial order on operations in a flow control sequence; this partial order is featured in the consistency conditions presented below. Based on the relation fcs_i we define a partial order $\stackrel{co_i}{\Longrightarrow}$ called the *control order*. Formally, for any two memory operations op_i^1 and op_i^2, $op_i^1 \stackrel{co_i}{\Longrightarrow} op_i^2$ if there exists a control operation op_i^3 such that $op_i^1 \stackrel{fcs_i}{\Longrightarrow} op_i^3 \stackrel{fcs_i}{\Longrightarrow} op_i^2$.

We now formalize the notion of one operation influencing another, which relies on the control order. Let τ be a sequence of memory operations and let co_i be a partial order on the operations that is consistent with τ, for each p_i. An operation op_j^1 *directly influences* an operation op_k^2 *in* τ (with respect to the co_i's) if one of the following holds:

1. $op_j^1 \stackrel{co_j}{\Longrightarrow} op_k^2$ and op_j^1 is a read. (Note that $j = k$ in this case.) That is, op_j^1 is a read operation which could affect the execution of op_k^2 through a control operation.
2. $op_k^2 = r_k(y, v), op_j^1 = w_j(y, v)$, $op_j^1 \stackrel{\tau}{\longrightarrow} op_k^2$ and there does not exist $w_h(y, u)$

such that $u \neq v$ and $w_j(y,v) \xrightarrow{\tau} w_h(y,u) \xrightarrow{\tau} r_k(y,v)$. That is, op_k^2 is a read of the value written by op_j^1 and there is no intervening write of a different value.

The *influence* relation is the transitive closure of direct influence. Thus the influence relation is also defined with respect to a set of partial orders. Although we will not usually explicitly mention these partial orders, the influence relation will be used with admissible operation sequences and the relevant partial orders will be the control orders for the corresponding flow control sequences.

Note that an operation directly influences another operation only if it is ordered before it in τ. Since the influence relation is the transitive closure of direct influence, we have the following claim.

CLAIM 3.2. *If op_j^1 influences op_k^2 in τ, then $op_j^1 \xrightarrow{\tau} op_k^2$.*

The following lemma captures the intuition that if a read operation $op_j^1 = r_j(x,v)$ does not influence operation op_k^2, then op_k^2 would have been generated even if op_j^1 had read a value other than v.

LEMMA 3.3. *Let τ be a sequence of memory operations that is partially admissible with respect to a set of flow control sequences $\{fcs_i\}_{i=1}^n$. Let operation op_j^1 in τ be a read $r_j(x,v)$ that does not influence any operation in τ. Let τ' be the result of taking τ and changing op_j^1 to be $r_j(x,w)$ for some $w \neq v$. Then τ' is partially admissible for some set of flow control sequences $\{fcs'_i\}_{i=1}^n$.*

4. Defining nonsequential consistency conditions. In this section, we define three consistency conditions that generalize previously known ones for the nonsequential case. The reason they are generalizations is that in nonoptimized systems, where operations at each process are invoked in program order and only one operation may be pending at a time, fcs_i is simply the sequence of operations in the order they were invoked. We then discuss (by an example) the importance of considering control operations (e.g., if-statements) when specifying consistency conditions.

Sequential consistency [28] is a strong consistency condition stating that there exists a sequential execution that is consistent with the way the actual execution appears to every process. Sequential consistency allows one to reason about a concurrent system using familiar uniprocessor techniques. Since uniprocessor systems are easier to reason about than concurrent systems, this is helpful. Thus many systems (try to) provide sequential consistency. However, providing sequential consistency can incur some costs. For instance, providing sequential consistency in message-based systems requires the response time of some operations to depend on the end-to-end message delay [14, 29]. Later in this paper, we show several programming techniques for achieving sequential consistency when the system only provides a weaker, and preferably cheaper, condition.

DEFINITION 4.1 (sequential consistency). *An execution R is* sequentially consistent *if there exists a subset S of the memory operations in R, a set $\{fcs_i\}_{i=1}^n$ of flow control sequences, and a legal permutation τ of S such that τ is fully admissible with respect to $\{fcs_i\}_{i=1}^n$.*

Note that since τ is a permutation of S, and since τ is fully admissible with respect to $\{fcs_i\}_{i=1}^n$, S must include all operations that appear in all flow control sequences. Hence, S cannot just be chosen arbitrarily. In particular, unless the program is empty, S cannot be empty.

Weak consistency [12, 29] is a very relaxed condition; it does not impose any global ordering on any kind of operations. Its importance lies in the fact that it may be implemented very efficiently, and despite its weakness, there is a large class of

programs for which it suffices. It requires that there exist a subset of the memory operations in the execution and a set of flow control sequences such that for each process, there is a legal permutation of those operations that is consistent with the process' own flow control sequence. Note that each processor may have a different permutation, or "view," of the operations.

DEFINITION 4.2 (weak consistency). *An execution R is* weakly consistent *if there exist a subset S of the memory operations in R and a set of flow control sequences $\{fcs_i\}_{i=1}^{n}$, one for each p_i, such that for each p_i, there exists a legal permutation τ_i of S that is fully fcs_i-admissible.*

Hybrid consistency [12] is intermediate between sequential and weak consistency; it combines the expressiveness of the former and the efficiency of the latter. Hybrid consistency distinguishes between two types of operations—strong and weak. It states that there must be a subset of the memory operations in the execution, a total order on the strong operations among them, and a set of flow control sequences satisfying the following. For each process, there is a legal permutation of the operations in the subset that is consistent with four orders: the process' own flow control sequence, every other process' control order, the total order on the strong operations, and the relative order of every pair of strong and weak operations by another process in that process' flow control sequence. Furthermore, all accesses of the same process to the same location will be viewed by all the processes in the same order. It is possible to implement hybrid consistency in such a way that weak operations are extremely fast [12].

DEFINITION 4.3 (hybrid consistency). *An execution R is* hybrid consistent *if there exist a subset S of the memory operations in R, a set of flow control sequences $\{fcs_i\}_{i=1}^{n}$, and a permutation ρ of the strong operations in S such that for each process p_i, there exists a legal permutation τ_i of S with the following properties:*

1. *τ_i is fully fcs_i-admissible, i.e., it is consistent with the process' own flow control sequence.*
2. *If $op_j^1 \overset{co_j}{\Longrightarrow} op_j^2$, then $op_j^1 \overset{\tau_i}{\longrightarrow} op_j^2$, for any j, i.e., it is consistent with every other process' control order.*[3]
3. *If $op_j^1 \overset{fcs_j}{\Longrightarrow} op_j^2$ and at least one is strong, then $op_j^1 \overset{\tau_i}{\longrightarrow} op_j^2$, for any j, i.e., it is consistent with the relative order of every pair of strong and weak operations by another process in that process' flow control sequence.*
4. *If $op_j^1 \overset{\rho}{\longrightarrow} op_k^2$ (implying both are strong), then $op_j^1 \overset{\tau_i}{\longrightarrow} op_k^2$, for any j and k, i.e., it is consistent with the total order on the strong operations.*
5. *If $op_j^1 \overset{fcs_j}{\Longrightarrow} op_j^2$ and op_j^1 and op_j^2 access the same location, then $op_j^1 \overset{\tau_i}{\longrightarrow} op_j^2$, for any j, i.e., all accesses of the same process to the same location will be viewed by all the processes in the same order.*

We now discuss the last property in more detail. It states that all operations on the same object by the same process p_j are viewed by every other process in the same order as they are viewed by p_j. This property does not appear in the original definition of hybrid consistency [12]; however, it is necessary in order for some of our results to hold, as is shown in section 6.3. Evidence suggests it is a reasonable assumption, since some previous authors make the even stronger assumption that all processes view all operations on the same object, no matter which process invoked them, in the same order.[4]

[3] This condition is not part of the original definition of hybrid consistency [12], which did not include control operations.

[4] In [3, 22, 23], a total order on all the writes to the same location is assumed. In addition, it is

To illustrate the problem that occurs if hybrid consistency were defined without considering control operations, consider the following example, assuming x and y are initially 0 and all instructions are weak:

p_1's program	p_2's program
$\text{tmp}_1 := \text{read}(x)$;	$\text{tmp}_2 := \text{read}(y)$;
if $\text{tmp}_1 = 5$ then	if $\text{tmp}_2 = 5$ then
$\text{write}(y, 5)$;	$\text{write}(x, 5)$;

In this program, the values returned by the reads affect the decision of whether to invoke the writes, and the invocations of the writes affect the possible values returned by the reads. For example, assume this program is being executed on a hybrid consistent memory and all operations are weak. If we ignore the existence of control instructions, the definition would allow the following execution R:

$$R|p_1 = r_1^1(x,5), w_1^2(y,5),$$
$$R|p_2 = r_2^1(y,5), w_2^2(x,5).$$

To show R is hybrid consistent we take

$$\tau_1 = w_2^2(x,5), r_1^1(x,5), w_1^2(y,5), r_2^1(y,5),$$
$$\tau_2 = w_1^2(y,5), r_2^1(y,5), w_2^2(x,5), r_1^1(x,5).$$

Note that condition 2 is not satisfied, since the sequences do not preserve the order of operations separated by control operations.

The program for p_1 allows the read(x) to return 5, whereas x could have taken the value 5 only if p_1 writes 5 to y, which will happen only if p_1 reads 5 in x. It is important to eliminate such executions with circular inference relations, where the prediction about the result of a control operation could affect its actual result.[5] If such behavior is allowed, then writing programs and arguing about them becomes almost impossible.

One might want to allow the programmer to choose whether or not a control operation should enforce an ordering. This can be done in a manner similar to the distinction we make between strong and weak memory operations. Introducing "weak" control operations in this manner further complicates the programming model; therefore, we have decided not to include them in our model.

4.1. Discussion of the definitions.

Viewing order vs. execution order. We would like to emphasize that the order in which operations may be viewed by different processes need not reflect the order in which they are executed. For example, consider the program in Figure 2. Due to the control order, every process must view the write to z after the read from x. On the other hand, a sophisticated run-time environment (or compiler) could detect that the write to z would be invoked regardless of the outcome of the read from x. Therefore,

---

assumed that a value read from a specific location can be uniquely identified with a write operation. Thus, all the processes view all the writes to the same location in the same order. Since a value read from a specific location can be uniquely identified with a write operation, each read is viewed by all the processes to be between the same writes to that location. These two assumptions imply that all the processes view all the operations on the same object in the same order.

[5] See [37] for more discussion of circular relations in the execution of programs.

```
p1's program
tmp := read(x);
if tmp = v then
     write(y, u);
write(z, w);
```

FIG. 2. *Viewing order vs. execution order.*

*tmp$_1$:= read(&x);	*tmp$_2$:= read(&y);

FIG. 3. *Limitations of the framework.*

the run-time environment can invoke the write to z before the read from x. This is allowed by the definition of hybrid consistency since it is possible to order the write to z after the read from x (even if they were executed in reverse order).

Limitations of the framework. Our framework for defining consistency conditions does not support dependencies through registers and indirect addressing. For example, the program in Figure 3 is not handled by our framework. (We use & and * for indirect addressing in the style of C/C++.) Followup work [13] extends the framework to include RISC-type addressing, i.e., registers can be used to provide the data or the address for an operation (instead of just constants, as in this paper). It shows that all the results of this paper hold in the extended framework as well, although the definitions are slightly more complicated.

Programmability vs. hardware optimizations. The definition of hybrid consistency includes several choices which reflect our opinions about the guarantees required by programmers from a consistency condition. These choices may disallow some hardware optimizations. We would like to stress, however, that these choices are not an inherent part of the framework. Specifically, if a particular choice we make does not allow an invaluable hardware optimization, then the definition of the consistency condition can be easily changed to support this optimization.

As an example, consider the program in Figure 4. In this program, the two writes by p_1 are labeled as strong, while the two reads of p_2 are labeled as weak; assume that the initial values of x and y are 0. The definition of hybrid consistency requires that every process views its own weak reads in the same order as they appear in its flow control sequence. Hence, if the first read by p_2 returns 1 from y, then the second read by p_2 cannot return 0 from x.

We believe that this is the semantics expected by programmers. However, this implies that an implementation of hybrid consistency cannot afford to execute weak reads out of order unless it provides rollback. This happens due to the fact that when the run-time system decides on the execution order for two weak reads by the same process, it may not know whether there are concurrent strong writes to the same objects (as in Figure 4). Yet, if it important to allow hardware optimizations that require a process to view its own weak reads out of order; then the definition of hybrid consistency can be easily changed by removing the first condition in Definition 4.3. We remark that in this case, the result about running data-race-free programs (Theorem 6.6) remains correct, but the programming techniques developed in section 5 are

p_1's program	p_2's program
swrite$(x, 1)$;	read(y);
swrite$(y, 1)$;	read(x);

FIG. 4. *The ordering of weak reads.*

no longer valid.

5. Static approach. In this section, we present techniques for writing programs for hybrid consistent shared memories that are based on statically classifying accesses according to their type (read or write) and the object they access. In section 5.1, we show that every hybrid consistent execution of a program in which all writes are strong is sequentially consistent. This result is used to develop an efficient synchronization code in section 5.2. In [11], we present the symmetric result that every hybrid consistent execution of a program in which all reads are strong is sequentially consistent. In order to prove this theorem, further assumptions on the execution must be made. Although these assumptions are shown to be necessary, they make the result impractical.

5.1. Strong writes. We prove the following theorem.

THEOREM 5.1. *Every hybrid consistent execution of a program in which all writes are strong and all reads are weak is sequentially consistent.*

Proof. Let R be such an execution. Let S be a subset of memory operations in R, fcs_i for each p_i be a flow control sequence, ρ be a permutation of the strong operations (namely, the writes) in S, and τ_i for each p_i be a legal permutation of S as guaranteed by the definition of hybrid consistency. We will insert the (weak) read operations into ρ to construct τ, a legal permutation of S that is fully admissible with respect to the fcs_i's.

A read by process p_i is inserted after any write that precedes it in τ_i and before any write that follows it in τ_i. This can be done since τ_i agrees with ρ on the order of strong operations. Furthermore, it will be inserted after any read by p_i that precedes it in τ_i and before any read by p_i that follows it in τ_i. The ordering of read operations by different processes is unimportant.

Clearly, τ is a permutation of S. Since τ_i preserves the ordering of operations by p_i, it follows that τ is fcs_i-admissible for all i.

The fact that τ is legal follows from the fact that τ_i is legal, that τ_i agrees with ρ on the order of strong operations, and from the construction of τ. □

5.2. Using strong writes to program with critical sections. Theorem 5.1 is useful for designing and proving correctness of programs which rely on hybrid consistency. A simple way to use it is to take a program which is designed for sequential consistency, label each write as a strong write and each read as a weak read, and run it on a hybrid consistent memory. However, there is even a more efficient way to employ the above theorem. If the program has explicit synchronization code dedicated to coordinating memory access operations, while the rest of the code ignores synchronization issues, then it is possible to apply Theorem 5.1 only to the synchronization code and label all other memory accesses—both reads and writes—as weak. We demonstrate this method for mutual exclusion. Given a mutual exclusion algorithm designed for sequentially consistent memories, we produce a modified algorithm by adding one strong write (to a location which is never read from) to the entry section and by labeling all the writes in the synchronization part of the code as strong, while

all other memory accesses are labeled as weak. We prove that the modified algorithm guarantees mutual exclusion (in a strong sense) on hybrid consistent memories.

Several papers on relaxed consistency conditions refer to the common method of programming with critical sections as a justification for the separation of strong and weak operations. In [21, p. 19], it is argued that

> for example, a large class of programs are written such that accesses to shared data are protected within critical sections. Such programs are called *synchronized programs*, whereby writes to shared locations are done in a mutually exclusive manner (no other reads or writes can occur simultaneously). In a synchronized program, all accesses (except accesses that are part of the synchronization constructs) can be labeled as *ordinary*$_L$.

Our result shows that there is a more efficient way to utilize synchronized programs. If the mutual exclusion algorithm is noncooperative, then it is not necessary to label reads that are part of the synchronization constructs (i.e., entry and exit sections) as strong (provided that an extra write is added).

We remind the reader that an algorithm for mutual exclusion consists of four disjoint sections for each process—entry, critical, exit, and remainder (cf. [36]). In the *entry* section, a process tries to gain access to the *critical* section; the *exit* section is executed by each process upon leaving the critical section; the *remainder* section is the rest of the code. Processes cycle through the four sections of their code. Informally, an algorithm guarantees mutual exclusion provided that the following hold:

Mutual exclusion: no two processes are inside the critical section at the same time, and

Deadlock freedom: if there exists a process that is continually in its entry section from some point on, then there exists another process that enters (and leaves) its critical section infinitely often.

A mutual exclusion algorithm provides code for the entry and exit sections. It should treat the code in the critical and remainder sections as black boxes (with some restrictions, as discussed below).

The above definition of mutual exclusion assumes that the order in which operations are executed reflects the order in which they are viewed by the processes. However, our formalism for defining consistency conditions puts restrictions only on the order in which operations are viewed, which may not correspond directly to the order in which they are executed. To be able to cope with these conditions, we define *logical mutual exclusion* as follows. Given a mutual exclusion algorithm (program), consider a flow control sequence for process p_i, and let CS_i^k be the set of operations invoked by process p_i during the kth time that p_i executes the critical section in this sequence.

Algorithm $\mathcal{A}$ guarantees *logical mutual exclusion based on a consistency condition* C provided that the following hold. Let σ be an execution of $\mathcal{A}$ that is allowed by C and let $\{\tau_r\}_{r=1}^n$ be a set of sequences as required in the definition of C (the views of the different processes). Consider the CS_i^k's induced by $\overset{fcs_i}{\Longrightarrow}$.

Logical mutual exclusion: For any four operations $op_i^1, op_i^2 \in CS_i^k$ and $op_j^1, op_j^2 \in CS_j^l$, $op_i^1 \overset{\tau_q}{\longrightarrow} op_j^1$ if and only if $op_i^2 \overset{\tau_s}{\longrightarrow} op_j^2$, for all processes p_q and p_s. As before, this implies that there is a total order on all critical section executions; furthermore, this ordering is the same in all τ_r's.

Deadlock freedom: For every process p_q, if τ_q is infinite and there exists a process p_i that is in its entry section from some point on in τ_q, then there is another

process p_j that enters (and leaves) its critical section infinitely often in τ_q.

In the rest of this section we mean logical mutual exclusion whenever we refer to mutual exclusion.

Our result assumes that the mutual exclusion algorithm does not communicate with the algorithm that is executed inside the critical section or remainder section. Specifically, we assume that variables that are accessed in the entry or exit section are not accessed in the critical or remainder sections. To capture this property, let the *exclusion set* of a mutual exclusion algorithm $\mathcal{A}$ be the set of shared variables read in the entry or exit sections of $\mathcal{A}$; this set is denoted $exc(\mathcal{A})$.

DEFINITION 5.2. *A mutual exclusion algorithm $\mathcal{A}$ is* noncooperative *if every process which executes the critical section or the remainder section of $\mathcal{A}$ does not write any variable in $exc(\mathcal{A})$; otherwise, the algorithm is* cooperative.[6]

We assume that the mutual exclusion algorithm is designed to run with any code in the critical section (subject to the above restriction) and that it can be run in asynchronous systems (i.e., the algorithm does not depend on any timing behavior).

CLAIM 5.3. *There is at least one write to a variable in $exc(\mathcal{A})$ in the exit section of every* noncooperative *mutual exclusion algorithm based on sequential consistency.*

Proof. Assume, by way of contradiction, that there exists a noncooperative mutual exclusion algorithm $\mathcal{A}$ such that there is no write to any of the variables of $exc(\mathcal{A})$ in the exit section of $\mathcal{A}$. Assume that we run the algorithm with the following critical section (for every process p_i), under the assumption that x is initially 0:

$tmp_i = r(x)$,
$tmp_i := tmp_i + 1$,
$w(x, tmp_i)$.

Recall that tmp_i and x are not accessed in the entry and exit sections of $\mathcal{A}$. Consider now a sequentially consistent execution R of $\mathcal{A}$ with this critical section in which p_0 starts at time 0 and runs until it enters the critical section, completes it, and exits; then p_1 starts and runs until it enters the critical section, completes it, and exits. Denote by t the time at which p_0 completes the read operation from x.

We claim that there is a sequentially consistent execution R' of $\mathcal{A}$ with this critical section in which p_0 starts at time 0 and runs until time t, when it completes the read operation; then p_1 starts and runs until it enters the critical section, completes it, and exits; then p_0 completes its critical section and exits. R' exists because we assumed that the algorithm is asynchronous. Note that there is no write in the exit section of $\mathcal{A}$ and there is no write to variables in $exc(\mathcal{A})$ in the critical section of p_0. Thus, all the values read by p_1 in its entry section in R' are equal to the values it reads in its entry section in R; since, in R, p_1 must eventually enter the critical section (to avoid deadlock), it must eventually enter the critical section in R'.

Clearly, R' violates the definition of mutual exclusion, since p_0 and p_1 are inside the critical section at the same time. Furthermore, note that in R' both p_0 and p_1 read the value 0 from x and thus the final value of x at the end of R' is 1. This final value could not be obtained in any execution that preserves logical mutual exclusion. □

Given a noncooperative algorithm $\mathcal{A}$ for the mutual exclusion problem based on sequential consistency, label every write in the entry and exit sections as strong and

[6] The definition of noncooperative algorithms given in [12] allows processes that are executing the critical section to access variables in $exc(\mathcal{A})$. The additional requirement made here seems quite reasonable, since we usually want to treat the mutual exclusion algorithm as a general solution, independent of the rest of the code, and to use it as a subroutine. This is also the approach taken in many of the known solutions to the mutual exclusion problem [36]. A more detailed discussion and motivation for noncooperative mutual exclusion algorithms appears in [12].

every read in the entry and exit sections as weak; operations inside the critical section or remainder section are labeled as weak. Next, add a strong write to some object $nac(\mathcal{A})$ that is not accessed elsewhere in the program such that this write will be the last instruction executed (in a flow control sequence) before each critical section. Call this modified algorithm $\mathcal{A}'$.

In order to prove that $\mathcal{A}'$ guarantees mutual exclusion based on hybrid consistency, we have to show that it is free of deadlocks and that it guarantees logical mutual exclusion.

LEMMA 5.4. *$\mathcal{A}'$ guarantees deadlock freedom based on hybrid consistency.*

Proof. Assume, by way of contradiction, that there exists a hybrid consistent execution σ of $\mathcal{A}'$ that has a deadlock. Denote by $\{\tau_j\}_{j=1}^n$ the set of sequences of operations as guaranteed by the definition of hybrid consistency. Let σ' be the execution that results by eliminating from σ all operations that are not invoked inside (w.r.t. the flow control sequences) the entry or exit section of $\mathcal{A}'$. Since the algorithm is noncooperative, there are no writes to variables in $exc(\mathcal{A}')$ outside (w.r.t. the flow control sequences) the entry and exit sections of $\mathcal{A}'$. Thus, σ' includes all the writes (in σ) to variables in $exc(\mathcal{A}')$, and thus, σ' is hybrid consistent. Specifically, define for each j a flow control sequence fcs'_j by eliminating from fcs_j all the operations of p_j that do not appear in σ'. Thus, the set of sequences $\{\tau'_j\}_{j=1}^n$ that results from eliminating all the operations that do not appear in σ' from $\{\tau_j\}_{j=1}^n$ obeys all the requirements in the definition of hybrid consistency (w.r.t. the $\{fcs'_j\}_{j=1}^n$). Note that all the writes in σ' are strong, and thus, by Theorem 5.1, σ' is sequentially consistent. Furthermore, in σ' there is a deadlock. Since there are no reads from $nac(\mathcal{A})$, the execution σ'' that results from eliminating all the writes to $nac(\mathcal{A})$ is also sequentially consistent and there is a deadlock in σ''. Note that σ'' is an execution of $\mathcal{A}$ in the case of an empty critical section. Thus, there is a sequentially consistent execution of $\mathcal{A}$ that has a deadlock. This is a contradiction. □

LEMMA 5.5. *$\mathcal{A}'$ guarantees logical mutual exclusion based on hybrid consistency.*

Proof. Recall that a sequential execution is a sequence of operations. Hence, each sequential execution of a program can be viewed by itself as a sequence τ of operations that obeys the requirements in the definition of sequential consistency. Therefore, since $\mathcal{A}$ guarantees mutual exclusion based on sequential consistency, every sequential execution of $\mathcal{A}$ must guarantee logical mutual exclusion as defined above. We will show that if $\mathcal{A}'$ does not guarantee mutual exclusion based on hybrid consistency, we may build a sequential execution of $\mathcal{A}$ in which mutual exclusion is violated.

Let σ be a hybrid consistent execution of an instance of $\mathcal{A}'$ in which every execution of the critical section consists of two writes, and let $\{\tau_j\}_{j=1}^n$ be the set of sequences of operations as guaranteed in the definition of hybrid consistency.

Call the last operation executed by a process before entering the critical section the *entry point*. Note that the entry point is a write operation on $nac(\mathcal{A})$. By Claim 5.3, there is at least one write in the exit section. Call the first write in the exit section the *exit point*. Each pair of matching entry and exit points is called a *critical pair*. We now show that in each τ_i all the critical pairs are ordered in a nonoverlapping way, which gives the result for critical section executions.

Assume, by way of contradiction, that there exists a sequence τ_j in which two critical pairs overlap. Assume that $[op_k^1, op_k^2]$ and $[op_l^1, op_l^2]$ are critical pairs that overlap, and assume, without loss of generality, that $op_k^2 \xrightarrow{\tau_j} op_l^2$. Let σ' be the execution that results by eliminating from σ all operations that are not invoked inside entry and exit sections of $\mathcal{A}'$. Since the algorithm is noncooperative, σ' includes all the writes (in σ) to variables in $exc(\mathcal{A}')$, and thus, σ' is hybrid consistent. By Theorem

5.1, σ' is sequentially consistent. Thus, we may build a legal sequence of operations τ in the same way as in the proof of Theorem 5.1. That is, the strong writes are ordered in τ in the order they appear in any sequence τ_i. A read by process p_i is inserted after any write that precedes it in τ_i and before any write that follows it in τ_i. Furthermore, it will be inserted after any read by p_i that precedes it in τ_i and before any read by p_i that follows it in τ_i. The ordering of read operations by different processes in unimportant. Note that τ is a sequential execution of $\mathcal{A}'$ in the case of an empty critical section.

By the construction of τ, and since we assumed that $[op_k^1, op_k^2]$ and $[op_l^1, op_l^2]$ are overlapping in τ_j, the latest of op_k^1 and op_l^1 precedes both op_k^2 and op_l^2 in τ. Consider the prefix τ' of τ that ends with the latest of op_k^1 and op_l^1. Note that any operation in τ' that is invoked during the exit sections that correspond to $[op_k^1, op_k^2]$ and $[op_l^1, op_l^2]$ is a read. Remember that there are no reads from $nac(\mathcal{A})$. Thus, τ'', the result of eliminating from τ' all reads that are invoked during the exit sections that corresponds to $[op_k^1, op_k^2]$ and $[op_l^1, op_l^2]$ and all writes to $nac(\mathcal{A})$, is a prefix of a sequential execution of $\mathcal{A}$. Denote the writes in the critical section that corresponds to $[op_k^1, op_k^2]$ by w_k^1 and w_k^2 and the writes in the critical section that corresponds to $[op_l^1, op_l^2]$ by w_l^1 and w_l^2. Add w_k^1, w_l^1, w_k^2, and w_l^2 in this order to τ'' to form τ'''. Since all operations that were added to τ'' are writes, τ''' is legal and is therefore a prefix of a sequential execution. Moreover, $w_k^1 \xrightarrow{\tau'''} w_l^1$ but $w_l^1 \xrightarrow{\tau'''} w_k^2$, which is a violation of logical mutual exclusion. Thus, τ''' can be extended to a sequential execution of $\mathcal{A}$ that violates mutual exclusion. This is a contradiction to the assumption that every sequential execution of $\mathcal{A}$ guarantees logical mutual exclusion.

Thus, we have shown that all critical pairs appear in every sequence τ_j in a nonoverlapping manner. Since the exit points are strong writes, all the processes agree (in the τ_j's) on the same nonoverlapping order for the critical pairs. Hence, we need only to show that the order in which critical pairs are ordered in every sequence τ_j is unique.

Let cp, cp', and cp'' be three critical pairs such that cp is ordered before cp' and after cp'' in any τ_i. Since the exit point of cp is a strong operation, and since it is ordered before the entry point of cp', all the operations of cp are ordered before the entry point of cp'. Since the entry point of cp is a strong operation, and since it is ordered after the exit point of cp'', all the operations of cp are ordered after cp''. Thus, (logical) mutual exclusion is also guaranteed by the algorithm. □

Note that, in cooperative algorithms, a process that participates in the mutual exclusion protocol, but does not wish to enter the critical section, can access variables in the exclusion set while executing the remainder section. If these accesses are labeled as weak, the solution might not be correct anymore. A simple example (of a token passing mutual exclusion algorithm) is detailed in [11].

6. Running data-race-free programs. In this section we prove that data-race-free programs behave on hybrid consistent memory implementations as if they were sequentially consistent. Hybrid consistency is a weaker condition than sequential consistency, and can be implemented more efficiently [12, 14, 29]. Clearly, having data-race-free programs behave on hybrid consistent memory implementations as if they were sequentially consistent is a desirable property, since many concurrent programs attempt to be data-race-free. In our opinion, the proofs in this section are more transparent than proofs of similar results using other formalisms [22, 23]. This also demonstrates the usefulness of our framework for investigating and proving properties of consistency conditions in general (cf. [13]).

6.1. Definition of data-race-free programs. Let op_i^1 and op_j^2 be two operations appearing in some sequence of memory operations α. Then

- $op_i^1 \overset{po}{\Longrightarrow} op_j^2$ if $i = j$ and $op_i^1 \overset{\alpha}{\longrightarrow} op_j^2$.
- $op_i^1 \overset{so}{\Longrightarrow} op_j^2$ if both op_i^1 and op_j^2 are strong operations and $op_i^1 \overset{\alpha}{\longrightarrow} op_j^2$.

The relation *happens before*, denoted by $\overset{hb}{\Longrightarrow}$, is the transitive closure of the union of $\overset{po}{\Longrightarrow}$ and $\overset{so}{\Longrightarrow}$. This definition is similar to the definition of *happens before* in [3] and is closely related to the definition of *happened before* defined by Lamport [27] for message passing systems.

Two memory accesses *conflict* if they both access the same memory location and at least one of them is a write. A *data race* occurs in a sequence of memory operations when two conflicting memory accesses are not ordered by the happens before relation.

DEFINITION 6.1. *A program is* data-race-free *if none of its sequential executions contains a data race.*

These definitions are modeled after those in [3].

6.2. Running data-race-free programs on hybrid consistent memory. We prove that every hybrid consistent execution of a data-race-free program is sequentially consistent.

To prove this result, we consider a legal sequence of memory operations τ_i, as guaranteed for some process p_i in the definition of hybrid consistency, that is *minimal* with respect to the number of *switched* operations (operations by the same process p_j whose order in τ_i is not consistent with p_j's flow control sequence). We show that if τ_i is not fully admissible (i.e., a sequential execution), then there exists a prefix of a sequential execution of the program that contains a data race. If τ_i is not fully admissible, it must contain at least one pair of switched operations. We locate the "first" pair of switched operations in τ_i, such that no other pair of switched operations is ordered between them. Because τ_i is minimal we know this pair was switched to preserve legality. This fact is used to show that there is a data race between some pair of operations that precedes this switched pair. Our main problem is to place these two operations (and the data race between them) in a legal and partially admissible sequence. This is done by taking the two operations and the operations that influence them and ordering them as in τ_i, and adding any operations necessary to preserve the flow control sequences of all processes. The key point to prove about the resulting sequence is its legality. In doing so, we either change the value that a read returns (and invoke Lemma 3.3), or, if this does not help, we show that there is a data race earlier in the sequence. Thus we have constructed a prefix of a sequential execution with a data race, which is a contradiction. The details follow.

Fix a data-race-free program `Prog`, a hybrid consistent execution R of `Prog`, and as guaranteed by the definition of hybrid consistency, a subset S of the memory operations and a flow control sequence fcs_i for each process p_i.

Fix an arbitrary process p_i. Let T be the set of all operation sequences τ_i that satisfy Definition 4.3 (hybrid consistency). For τ_i in T, an ordered pair of operations of p_j, $\langle op_j^2, op_j^1 \rangle$, is *switched* in τ_i if $op_j^2 \overset{\tau_i}{\longrightarrow} op_j^1$, but $op_j^1 \overset{fcs_j}{\Longrightarrow} op_j^2$.

Let τ_i be some element of T with a minimal set of switches. That is, there does not exist $\tau_i' \in T$, such that the set of pairs of switched operations of all processes in τ_i' is strictly contained in the set of pairs of switched operations of all processes in τ_i.

We prove the main theorem of this section by way of contradiction, using the following lemma.

LEMMA 6.2. *If τ_i is not fully admissible, then there exists a prefix of a sequential*

execution of `Prog` *which contains a data race.*

Proof. Assume that τ_i is not fully admissible. We first prove the following claim, which locates the pair of operations that is a candidate for a data race.

CLAIM 6.3. *There exist two operations* $op_j^2(x,v)$ *and* $op_k^1(x,w)$ *in* τ_i *such that*

1. $op_j^2(x,v) \xrightarrow{\tau_i} op_k^1(x,w)$,
2. *there is a data race between* $op_j^2(x,v)$ *and* $op_k^1(x,w)$ *in* τ_i, *and*
3. *there is no pair of switched operations in* τ_i *up to* $op_k^1(x,w)$.

Proof. Since τ_i is not fully admissible, there exists at least one pair of switched operations in τ_i. Let $\langle op_j^2(x,v), op_j^1(y,u)\rangle$ be the first ordered pair of switched operations, i.e., there is no other pair of switched operations which is completely ordered before $op_j^1(y,u)$ in τ_i. If there is more than one ordered pair that share the same second operation (namely, op_j^1), then choose the pair whose first operation is latest.

Since τ_i is minimal, $op_j^2(x,v)$ and $op_j^1(y,u)$ are switched in order to preserve legality.

Since the operations are by the same process p_j, and since the order of operations by the same process to the same object is preserved (last property in Definition 4.3), it follows that $x \neq y$. Thus, there exists an operation $op_k^1(x,w)$ which conflicts with $op_j^2(x,v)$ and $op_j^2(x,v) \xrightarrow{\tau_i} op_k^1(x,w) \xrightarrow{\tau_i} op_j^1(y,u)$.

If there is a strong operation by p_j between op_j^2 and op_j^1 (including one of them), then the third property in Definition 4.3 implies that they cannot be switched. Therefore, there are no strong operations by p_j between op_j^2 and op_j^1 in τ_i, including op_j^2 and op_j^1.

It is also the case that $j \neq k$. Suppose otherwise. Either op_j^2 and op_k^1 are switched or else op_k^1 and op_j^1 are switched. In the first case, $\langle op_j^2, op_k^1\rangle$ would have been the pair chosen and in the second case, $\langle op_k^1, op_j^1\rangle$ would have been the pair chosen.

Since $j \neq k$, op_j^2 and op_k^1 conflict, and there is no strong operation by p_j between them, there is a data race between op_j^2 and op_k^1 in τ_i. Thus the claim is shown. □

Let I be the set of operations in τ_i that influence either op_j^2 or op_k^1 (including op_j^2 and op_k^1 themselves). Let τ_i' be the shortest prefix of τ_i that includes every operation in I. Let π be the subsequence of τ_i' which contains exactly the set of all operations in I. The following claim shows that π is consistent with $\overset{fcs_l}{\Longrightarrow}$ for all l.

CLAIM 6.4. *For every pair of operations* op_l^1 *and* op_l^2, *if* $op_l^1 \xrightarrow{\pi} op_l^2$, *then* $op_l^1 \overset{fcs_l}{\Longrightarrow} op_l^2$.

Proof. By Claim 3.2, the influence relation is consistent with $\xrightarrow{\tau_i}$. Therefore, no operation in I follows op_k^1 in τ_i, implying that op_k^1 is the last operation in τ_i'. By condition 3 in Claim 6.3, τ_i' does not include any pair of switched operations, and neither does π. □

Now, we construct a new partially admissible (with respect to the fcs_i's) sequence π' by adding to π every operation op_l^1 not in π, such that $op_l^1 \overset{fcs_l}{\Longrightarrow} op_l^2$ and op_l^2 is in π, for each process l, as follows. For every such operation that was originally in τ_i', add it in the same place as in τ_i'. For all other operations, add them arbitrarily, maintaining consistency with $\overset{fcs_l}{\Longrightarrow}$, for all l. By the definition of hybrid consistency, every added operation op_l^1 that is not in τ_i' must be weak. This is because op_l^1 precedes op_l^2 in $\overset{fcs_l}{\Longrightarrow}$, but follows op_l^2 in τ_i, a possibility precluded of any strong operation by hybrid consistency (condition 3 in Definition 4.3).

We would now like to determine if π' is a legal sequence. By the definition of the

influence relation and τ_i, π is a legal sequence. In particular, all reads in π are legal. Thus, if there are illegal reads in π', then each illegal read is either a read that was added to π, or a read that became illegal because of some write that was added to π.

Consider every illegal read r_l in π' that was added to π. We claim that r_l does not influence any operation in π', with respect to the co_i's. Suppose it does. Since r_l is a read, it must influence an operation through a control relation, i.e., $r_l \stackrel{co_l}{\Longrightarrow} op_l$, for some l. Since r_l is not in I, op_l is not in I. Thus op_l was included in π' because there exists op'_l in I such that $op_l \stackrel{fcs_l}{\Longrightarrow} op'_l$. This implies that $r_l \stackrel{co_l}{\Longrightarrow} op'_l$ and that r is in I. We therefore have a contradiction.

Now, for each of the illegal reads in π' that were added to π, change its value to match the value of the most recent write to the same object. (Note that this can be done since an illegal read in π' does not influence any other operation in π'.) Call this sequence π''. Apply Lemma 3.3 successively for each fixed-up read, starting with π', to deduce that π'' is partially admissible with respect to some set of flow control sequences $\{fcs'_l\}_{l=1}^{n}$. So, if there are no illegal reads in π'', then π'' is legal and it follows that it is a prefix of a sequential execution of `Prog`.

To complete the proof of the lemma where π'' is legal, we now show that π'' contains a data race between $op_j^2(x, v)$ and $op_k^1(x, w)$. By Claim 6.3, there is no strong operation by p_j between op_j^2 and op_k^1 inclusive in τ'_i; also, note that no strong operation was added to π. Also, $j \neq k$; thus op_j^2 and op_k^1 are not ordered by the happens-before relation.

We are left with the case in which there is an illegal read in π''. It became illegal due to the insertion of some write. Let $r_q^1(z, v_1)$ be the first illegal read in π'', and let $w_p^1(z, v_2)$, $v_1 \neq v_2$ be the corresponding inserted write. Denote by σ the shortest prefix of π'' which includes $r_q^1(z, v_1)$. Let σ' be the same sequence where $r_q^1(z, v_1)$ is replaced by $r_q^2(z, v_2)$. We complete the proof by showing the following claim.

CLAIM 6.5. *σ' is a prefix of a sequential execution of* `Prog` *which contains a data race between r_q^2 and w_p^1.*

Proof. We first show that $r_q^1 \stackrel{\tau_i}{\longrightarrow} w_p^1$. Assume otherwise that $w_p^1 \stackrel{\tau_i}{\longrightarrow} r_q^1$. Since w_p^1 is not in I, it must not influence r_q^1 in τ_i. Therefore, there is another write $w_r^2(z, v_1)$ ordered between w_p^1 and r_q^1 which influences r_q^1 in τ_i. But then w_p^1, w_r^2, and r_q^1 would be ordered similarly in π'. This gives a contradiction to the assumption that r_q^1 becomes illegal due to the insertion of w_p^1.

So we can assume that $r_q^1 \stackrel{\tau_i}{\longrightarrow} w_p^1$; it follows that w_p^1 is not in τ'_i, implying that w_p^1 is weak. We claim that $p \neq q$. Otherwise, if $p = q$, then $w_p^1(z, v_2) \stackrel{fcs_p}{\Longrightarrow} r_q^1(z, v_1)$. By the last property of hybrid consistency, it follows that $w_p^1(z, v_2) \stackrel{\tau_i}{\longrightarrow} r_q^1(z, v_1)$, which is a contradiction. Therefore $p \neq q$.

We now show that $r_q^1(z, v_1)$ and $w_p^1(z, v_2)$ are not ordered by the happens before relation in π'', and hence, they are not ordered by the happens before relation in σ. Suppose they were. Then, there is a strong operation sop_p in between w_p^1 and r_q^1 in π''. Therefore, $w_p^1 \stackrel{fcs_p}{\Longrightarrow} sop_p$ and thus $w_p^1 \stackrel{\tau_i}{\longrightarrow} sop_p$. Therefore, sop_p is not in τ'_i since w_p^1 is not in τ'_i, and hence is weak, which is a contradiction. Therefore, $r_q^1(z, v_1)$ and $w_p^1(z, v_2)$ are not ordered by the happens before relation in π'', and hence, in σ. Thus, there exists a data race between $r_q^1(z, v_1)$ and $w_p^1(z, v_2)$ in σ. It follows that σ' contains a data race.

Now, σ' is a legal sequence of operations due to the change in the value returned by the read, implied by replacing r_q^1 with r_q^2. Since $r_q^2(z, v_2)$ is the last operation in σ', it clearly does not influence any operation in σ'. By Lemma 3.3, σ' is partially

admissible for some set of flow control sequences $\{fcs''_l\}_{l=1}^{n}$. Therefore, σ' is a prefix of sequential execution of `Prog` which contains a data race between $r_q^2(z, v_2)$ and $w_p^1(z, v_2)$, as needed. □

Hence, we have shown that if τ_i is not fully admissible, then there exists a prefix of a sequential execution of `Prog` which contains a data race. □

The proof of the following theorem is now immediate.

THEOREM 6.6. *Every hybrid consistent execution of a data-race-free program is sequentially consistent.*

Proof. Let R be a hybrid consistent execution of a data-race-free program `Prog`. Fix a subset S of the memory operations in R and a set of flow control sequences fcs_i from the definition of hybrid consistency. Choose a process p_i. Let τ_i be a minimal legal permutation of S as guaranteed by the definition of hybrid consistency. Since `Prog` is data-race-free, no sequential execution has a data race. Then by Lemma 6.2, τ_i is fully admissible. Thus, R is a sequentially consistent execution of `Prog`. □

6.3. Reordering process' operations. The original definition of hybrid consistency in [12] did not include the last property, i.e., that all writes by the same process to the same object appear in the views of all other processes in the order implied by the flow control sequence of their invoking process. (The original definition also did not consider control operations.) Thus two weak operations by the same process p_i accessing the same location could be viewed by other processes in a different order from the order in which they appear in fcs_i. We show that under this behavior it is not true that every hybrid consistent execution of a data-race-free program is sequentially consistent.

Consider the following data-race-free program, assuming x and y are initially 0 and all instructions are weak:

p_1's program	p_2's program
$\text{tmp}_1 := \text{read}(x)$;	$\text{tmp}_2 := \text{read}(y)$;
$\text{write}(x, 5)$;	$\text{write}(y, 5)$;
if $\text{tmp}_1 = 5$ then	if $\text{tmp}_2 = 5$ then
$\text{write}(y, 5)$;	$\text{write}(x, 5)$.

Consider the following execution R:

$$R|p_1 = r_1^1(x, 5), w_1^2(x, 5), w_1^3(y, 5),$$
$$R|p_2 = r_2^1(y, 5), w_2^2(y, 5), w_2^3(x, 5).$$

Although R is not sequentially consistent (we leave it to the reader to verify this), it is hybrid consistent:

$$\tau_1 = w_2^2(y, 5), r_2^1(y, 5), w_2^3(x, 5), r_1^1(x, 5), w_1^2(x, 5), w_1^3(y, 5),$$
$$\tau_2 = w_1^2(x, 5), r_1^1(x, 5), w_1^3(y, 5), r_2^1(y, 5), w_2^2(y, 5), w_2^3(x, 5).$$

7. Discussion. As the demand for powerful computers grows faster than the technology to develop new processors, the need for highly parallel multiprocessors increases. However, in order to fully utilize such machines, convenient paradigms for writing concurrent programs must be developed. These paradigms should allow the user to enjoy the same simple model of the world as in uniprocessors, without sacrificing the performance of the whole system. These two goals are somewhat contradictory. Recent results indicate that there is a tradeoff between the similarity of a distributed shared memory to real shared memory, and the efficiency of the hardware.

In this paper we have tried to bridge these two contradictory goals. We presented a general framework which encompasses the functionality of the compiler and the runtime system and models their interaction with the memory consistency system. Our framework allows the definition of known consistency conditions to be combined with implementations that exploit optimizations for reducing the latency of memory accesses. To the best of our knowledge, our definitions are unique in explicitly modeling the whole program, rather than just looking at the memory operations in isolation.

We also characterized requirements on programs that guarantee that they will behave on hybrid consistent memories as if they are sequentially consistent. This allows programmers to reason about certain classes of programs assuming sequential consistency, yet run them on more efficient hardware. The approaches we studied were (1) labeling all writes as strong and all reads as weak, (2) using the previous scheme to implement efficient mutual exclusion, and (3) running data-race-free programs. Note that the first two approaches do not necessarily yield data-race-free programs.

In this paper, we have assumed that the application program at each node is a serial code or, in other words, consists of a single thread of execution. We believe our framework and results can be naturally extended to support multithreading as well. We briefly outline one approach. Instead of a flow control sequence, define a *flow control (partial) order* based on two new control operations, *fork* and *join*. A fork operation splits the code into several parallel threads of execution and a join operation joins several parallel threads of execution into one thread of execution. Operations that belong to the same thread of execution are ordered as in a flow control sequence and after the previous fork operation (if there exists one). Operations that belong to different parallel threads are not ordered by the flow control order. All operations that belong to threads that were joined by a join operation are ordered before the join operation that joined their threads. The definitions of the consistency conditions remain the same, with the one exception that we use the flow control orders instead of the flow control sequences.

This work is part of an ongoing attempt to understand consistency conditions and their implications on programming, compiler design, and architecture. Much research is still needed before this goal can be met. While more efficient, fault-tolerant algorithms for implementing various consistency conditions still need to be developed, our paper takes a complementary approach; it provides a clean and formal framework for investigating systematic methods, rules, and compiler techniques to transform programs written for strong consistency conditions into correct programs for weaker consistency conditions.

Acknowledgments. We would like to thank Kourosh Gharachorloo, Phil Gibbons, Martha Kosa, and Michael Merritt for helpful comments. The anonymous referees made helpful comments which improved the presentation.

TWO-DIMENSIONAL PERIODICITY IN RECTANGULAR ARRAYS*

AMIHOOD AMIR† AND GARY BENSON‡

Abstract. String matching is rich with a variety of algorithmic tools. In contrast, multidimensional matching has had a rather sparse set of techniques. This paper presents a new algorithmic technique for two-dimensional matching: *periodicity analysis*. Its strength appears to lie in the fact that it is inherently two-dimensional.

Periodicity in strings has been used to solve string matching problems. Multidimensional periodicity, however, is not as simple as it is in strings and was not formally studied or used in pattern matching. In this paper, we define and analyze two-dimensional periodicity in rectangular arrays. One definition of string periodicity is that a periodic string can self-overlap in a particular way. An analogous concept is true in two dimensions. The *self-overlap vectors* of a rectangle generate a regular pattern of locations where the rectangle may originate. Based on this regularity, we define four categories of periodic arrays—*nonperiodic, lattice periodic, line periodic, and radiant periodic*—and prove theorems about the properties of the classes.

We give serial and parallel algorithms that find all locations where an overlap originates. In addition, our algorithms find a *witness* proving that the array does not self-overlap in any other location. The serial algorithm runs in time $O(m^2)$ (linear time) when the alphabet size is finite, and in $O(m^2 \log m)$ otherwise. The parallel algorithm runs in time $O(\log m)$ using $O(m^2)$ CRCW processors.

1. Introduction.

String matching is a field rich with a variety of algorithmic ideas. The early string matching algorithms were mostly based on constructing a pattern automaton and subsequently using it to find all pattern appearances in a given text ([KMP-77, AC-75, BM-77]). Recently developed algorithms [G-85, V-85, V-91] use periodicity in strings to solve this classic string matching problem. Lately, there has been interest in various two-dimensional approximate matching problems, largely motivated by low-level image processing ([KS-87, AL-91, AF-91, ALV-90]). Unlike string matching, the methods for solving multidimensional matching problems are scant. This paper adds a *new algorithmic tool* to the rather empty tool chest of multidimensional matching techniques: two-dimensional periodicity analysis.

String periodicity is an intuitively clear concept and the properties of a string period are simple and well understood. Two-dimensional periodicity, however, presents some difficulties. Periodicity in the *plane* is easy to define. However, we seek the period of a *finite rectangle*. We have chosen to concentrate on a periodicity definition that implies the ability for *self-overlap*. In strings, such an overlap allows definition of

a smallest period whose concatenation produces the entire string. The main contribution of this paper is showing that for rectangles also, the overlap produces a "smallest unit" and a regular pattern in which it appears in the array. The main differences are that this "smallest unit" is a vector rather than a subblock of the array, and that the pattern is not a simple concatenation. Rather, based on the patterns of vectors that can occur, there are four categories of array periodicity: *nonperiodic, line periodic, radiant periodic*, and *lattice periodic*. As in string matching, this regularity can be exploited.

The strength of periodicity analysis appears to lie in the fact that it is inherently a two-dimensional technique, whereas most previous work on two-dimensional matching has reduced the matrix problem to a problem on strings and then applied one-dimensional string matching methods. The two-dimensional periodicity analysis has already proven useful in solving several multidimensional matching problems [ABF-94, ABF-93, ABF-97, KR-94]. We illustrate with two examples.

The original motivation for this work was our research in image preserving compression. We wanted to solve the following problem: given a two-dimensional pattern P and a two-dimensional text T which has been compressed, find all occurrences of P in T without decompressing the text. The goal is a sublinear algorithm with respect to the size of the original *uncompressed* text. Some initial success in this problem was achieved in [ALV-90], but those authors' algorithm, being automaton based, seems to require a large amount of decompression. In [AB-92b, ABF-97], we used periodicity to find the first *optimal* pattern matching algorithm for compressed two-dimensional texts.

Another application is the two-dimensional exact matching problem. Here the text is not compressed. Baker [B-78] and, independently, Bird [Bi-77] used the Aho and Corasick [AC-75] dictionary matching algorithm to obtain a $O(n^2 \log |\Sigma|)$ algorithm for this problem. This algorithm is automaton based, and therefore the running time of the text scanning phase is dependent on the size of the alphabet. In [ABF-94] we used periodicity analysis to produce the first two-dimensional exact matching algorithm with a linear time *alphabet independent* text scanning phase.

Since the work presented here first appeared [AB-92a], the analysis of radiant-periodic patterns has been strengthened [GP-92, RR-93], and periodicity analysis has additionally proven useful in providing optimal parallel two-dimensional matching algorithms [ABF-93, CCG+93], as well as in solving a three-dimensional matching problem [KR-94].

This paper is organized as follows. In section 2, we review periodicity in strings and extend this notion to two dimensions. In section 3, we give formal definitions, describe the classification scheme for the four types of two-dimensional periodicity, and prove some theorems about the properties of the classes. In section 4 we present serial and parallel algorithms for detecting the type of periodicity in an array. The complexity of the serial algorithm is $O(m^2)$ (linear time) when the alphabet size is finite, and $O(m^2 \log m)$ otherwise. The parallel algorithm runs in time $O(\log m)$ with $O(m^2)$ CRCW processors. In addition to knowing where an array can self-overlap, knowing where it cannot and why is also useful. If an overlap is not possible, then the overlap produces some mismatch. Our algorithms find a single mismatch location or *witness* for each self-overlap that fails.

2. Periodicity in strings and arrays. In a periodic string, a smallest period can be found whose concatenation generates the entire string. In two dimensions, if an array were to extend infinitely so as to cover the plane, the one-dimensional notion

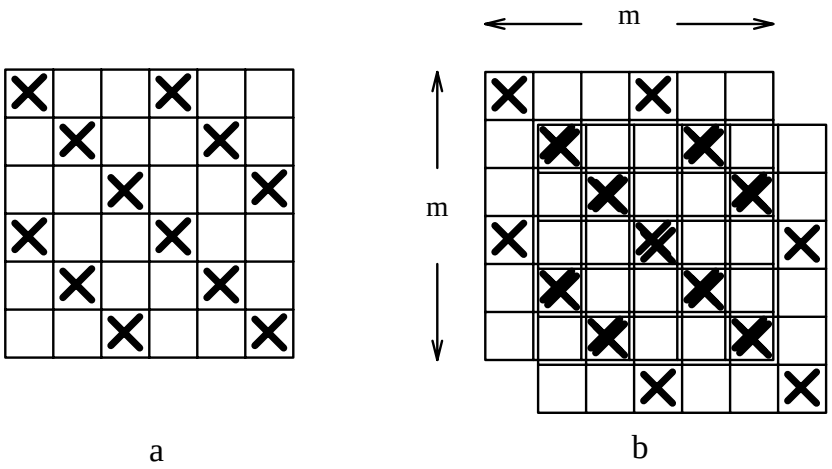

FIG. 1. (a) *A periodic pattern.* (b) *A suffix matches a prefix.*

of a period could be generalized to a unit cell of a lattice. But a rectangular array is not infinite and may cut a unit cell in many different ways at its edges.

Instead of defining two-dimensional periodicity on the basis of some subunit of the array, we instead use the idea of *self-overlap*. This idea applies also to strings. A string w is *periodic* if the longest prefix p of w that is also a suffix of w is at least half the length of w. For example, if $w = abcabcabcabcab$, then $p = abcabcabcab$, and since p is over half as long as w, w is periodic. This definition implies that w may overlap itself starting in the fourth position.

The preceding idea easily generalized to two dimensions as illustrated in Figure 1.

DEFINITION 2.1. *Let A be a two-dimensional array. Call a* prefix *of A a rectangular subarray that contains one corner of A. (In the figure, the upper left corner.) Call a* suffix *of A a rectangular subarray that contains the diagonally opposite corner of A (in the figure, the lower right corner). We say A is* periodic *if the largest prefix that is also a suffix has dimensions at least as large as some fixed percentage d of the dimensions of A.*

In the figure, if $d \leq \frac{5}{6}$, then A is periodic. As with strings, if A is periodic, then A may overlap itself if the prefix of one copy of A is aligned with the suffix of a second copy of A. Notice that both the upper left and lower left corners of A can define prefixes, giving A two directions in which it can be periodic. As we will describe in the next section, the classification of periodicity type for A is based on whether it is periodic in either or both of these directions.

3. Classifying arrays. Our goal here is classifying an array A into one of four periodicity classes. For clarity of presentation we concentrate on square arrays. We later show how to generalize all results to rectangles. We begin with some definitions of two-dimensional periodicity and related concepts (Figure 2).

DEFINITION 3.1. *Let $A[0 \ldots m-1, 0 \ldots m-1]$ be an $m \times m$ square array. Each element of A contains a symbol from an alphabet Σ. A subarray of A is called a block. Blocks are designated by their first and last row and column. Thus, the block $A[0 \ldots m-1, 0 \ldots m-1]$ is the entire array. Each corner of A defines a quadrant. Quadrants are labeled counterclockwise from upper left, quadrants* I, II, III, *and* IV.

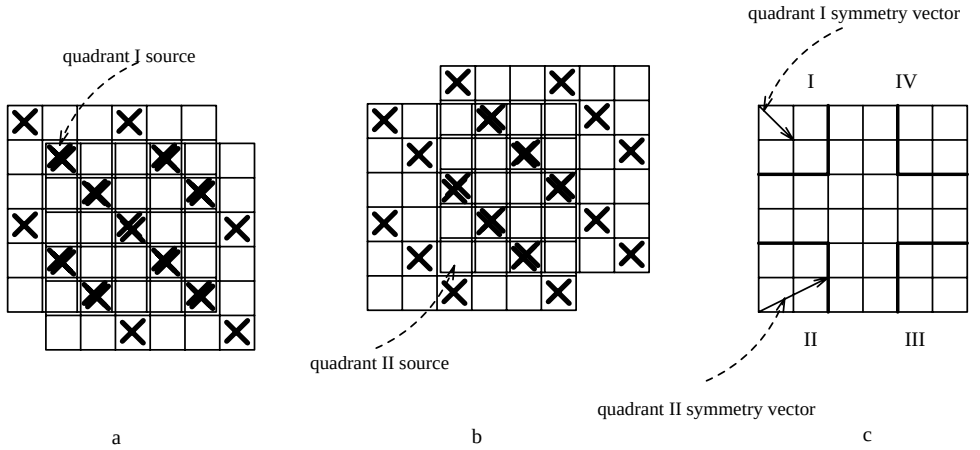

FIG. 2. *Two overlapping copies of the same array.* (a) *A quadrant* I *source.* (b) *A quadrant* II *source.* (c) *The symmetry vectors.*

Each quadrant has size q*, where* $1 \le q \le \lceil \frac{m}{2} \rceil$*. (Quadrants may share part of a row or column.) Quadrant* I *is the block* $A[0 \dots q-1, 0 \dots q-1]$*. The choice of* q *may depend on the application. For this paper,* $q = \lceil \frac{m}{3} \rceil$*.*

DEFINITION 3.2. *Suppose we have two copies of* A*, one directly on top of the other. The copies are said to be* in register *because some of the elements overlap (in this case, all the elements) and overlapping elements contain the same symbol. If the two copies can be repositioned so that* $A[0,0]$ *overlaps* $A[r,c]$ $(r \ge 0, c > 0)$ *and the copies are again in register, then we say that the array is* quadrant I symmetric*, that* $A[r,c]$ *is a* quadrant I source*, and that vector* $\vec{v} = r\vec{y} + c\vec{x}$ *is a* quadrant I symmetry vector*. Here,* $\vec{y}$ *is the vertical unit vector in the direction of increasing row index and* $\vec{x}$ *is the horizontal unit vector in the direction of increasing column index. If the two copies can be repositioned so that* $A[m-1,0]$ *overlaps* $A[r,c]$ $(r < m-1, c \ge 0)$ *and the copies are again in register, then we say that the array is* quadrant II symmetric*, that* $A[r,c]$ *is a* quadrant II source*, and that* $\vec{v} = (r-m+1)\vec{y} + c\vec{x}$ *is a* quadrant II symmetry vector*.*

Analogous definitions exist for quadrants III and IV, but by symmetry, if $\vec{v}$ is a quadrant III(IV) symmetry vector, then $-\vec{v}$ is a quadrant I(II) symmetry vector. We will usually indicate a vector $\vec{v} = r\vec{y} + c\vec{x}$ by the ordered pair (r,c). Note that symmetry vector (r,c) defines a mapping between identical elements, that is, (r,c) is a symmetry vector iff $A[i,j] = A[i+r, j+c]$ wherever both elements are defined. In particular, if (r,c) is a symmetry vector, then it maps the block $A[i \dots j, k \dots l]$ to the identical block $A[i+r \dots j+r, k+c \dots l+c]$.

In the remainder of this paper, we use the terms *source* and *symmetry vector* interchangeably.

DEFINITION 3.3. *The* length *of a symmetry vector is the maximum of the absolute values of its coefficients. A* lexicographic ordering *of quadrant* I *vectors (quadrant* II *vectors) is accomplished by sorting the vectors first by length, and then, for vectors of the same length, by reverse sorting them by column coefficient and then sorting them by row coefficient (by reverse sorting them by absolute value of row coefficient and then sorting them by column coefficient). A* shortest *vector is the smallest in its lexicographic ordering. The* basis vectors *for array* A *consist of the shortest quadrant*

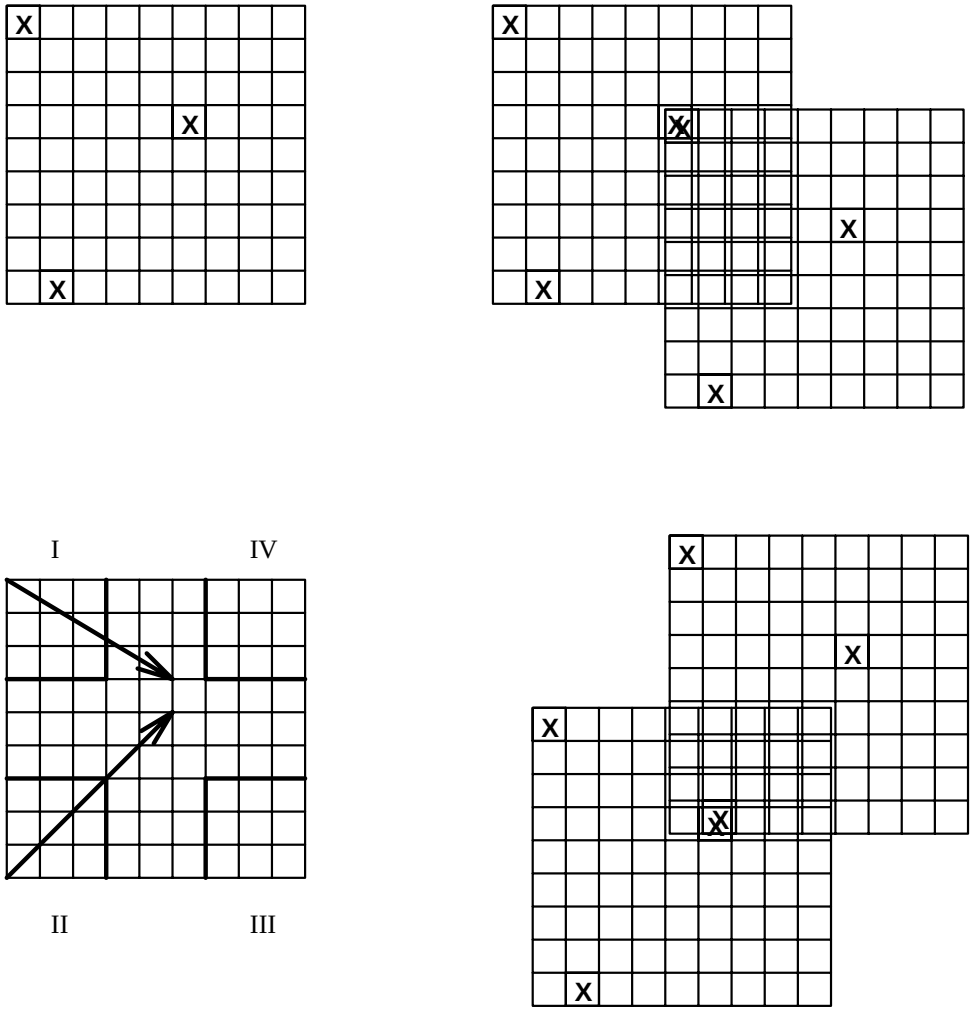

FIG. 3. *Nonperiodic array.*

I *vector* (r_1, c_1) *(if any) and the shortest quadrant* II *vector* (r_2, c_2) *(if any). If the length of a symmetry vector is* $< p$ *where* $p = \lceil \frac{m}{3} \rceil$ *then the vector is* periodic.

We are now ready to classify a square array A into one of four periodicity classes based on the presence or absence of periodic vectors in quadrants I and II. Following the classification, we prove some theorems about the properties of the classes. In section 4 we present algorithms for finding *all* the sources in an array.

The four classes of two-dimensional periodicity are (Figures 3–6)

- *nonperiodic* — the array has no periodic vectors.
- *lattice periodic* — the array has periodic vectors in both quadrants. All quadrant I sources which occur in quadrant I fall on the nodes of a lattice which is defined by the basis vectors. The same is true for quadrant II sources in quadrant II. Specifically, let $\vec{v}_1 = (r_1, c_1)$ and $\vec{v}_2 = (r_2, c_2)$ be the periodic basis vectors in quadrants I and II, respectively. Then, an element in quadrant I is a quadrant I source iff it occurs at index $A[ir_1 + jr_2, ic_1 + jc_2]$ for integers i, j. An element in quadrant II is a quadrant II source iff it occurs at index

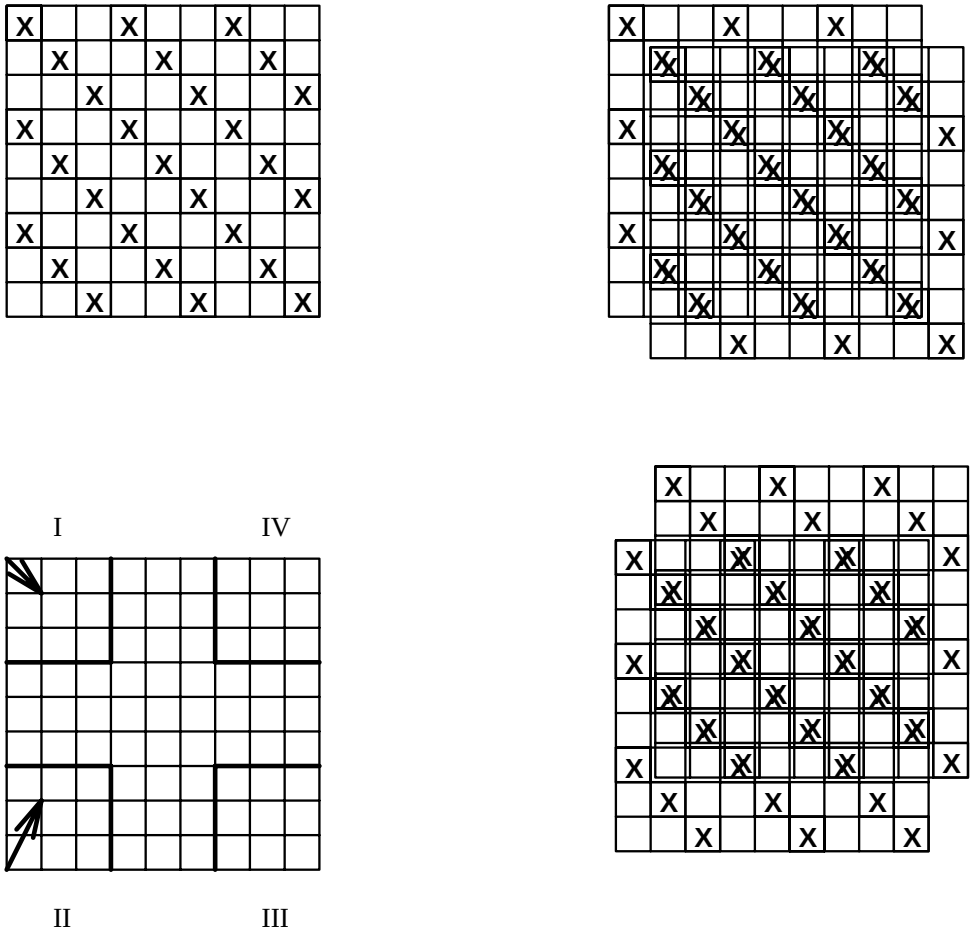

FIG. 4. *Lattice-periodic array.*

$A[m-1+\hat{\imath}r_1+\hat{\jmath}r_2, \hat{\imath}c_1+\hat{\jmath}c_2]$ for integers $\hat{\imath}, \hat{\jmath}$.

- *line periodic* — the array has a periodic vector in only one quadrant and the sources in that quadrant all fall on one line.
- *radiant periodic* — this category is identical to the line periodic category, except that in the quadrant with the periodic vector, the sources fall on several lines which all radiate from the quadrant's corner. We do not describe the exact location of the sources for this class; see [GP-92] for a detailed analysis of the source locations.

Next, we prove some theorems about the properties of the classes. All the theorems are stated in terms of square arrays for clarity. At the end of the theorems we explain how they can be modified to apply to any $n \times m$ rectangular array.

In Lemmas 3.4–3.6, we establish the fact that if we have symmetry vectors for both quadrants I and II, and they meet a pair of constraints on the sum of their coefficients, then every linear combination of the vectors defines another symmetry vector.

LEMMA 3.4. *If* (r_1, c_1) *and* (r_2, c_2) *are symmetry vectors from quadrants* I *and* II*, respectively, and* $c_1 + c_2 < m$ *and* $r_1 + |r_2| < m$*, then* $(r_1 + r_2, c_1 + c_2)$ *is either a*

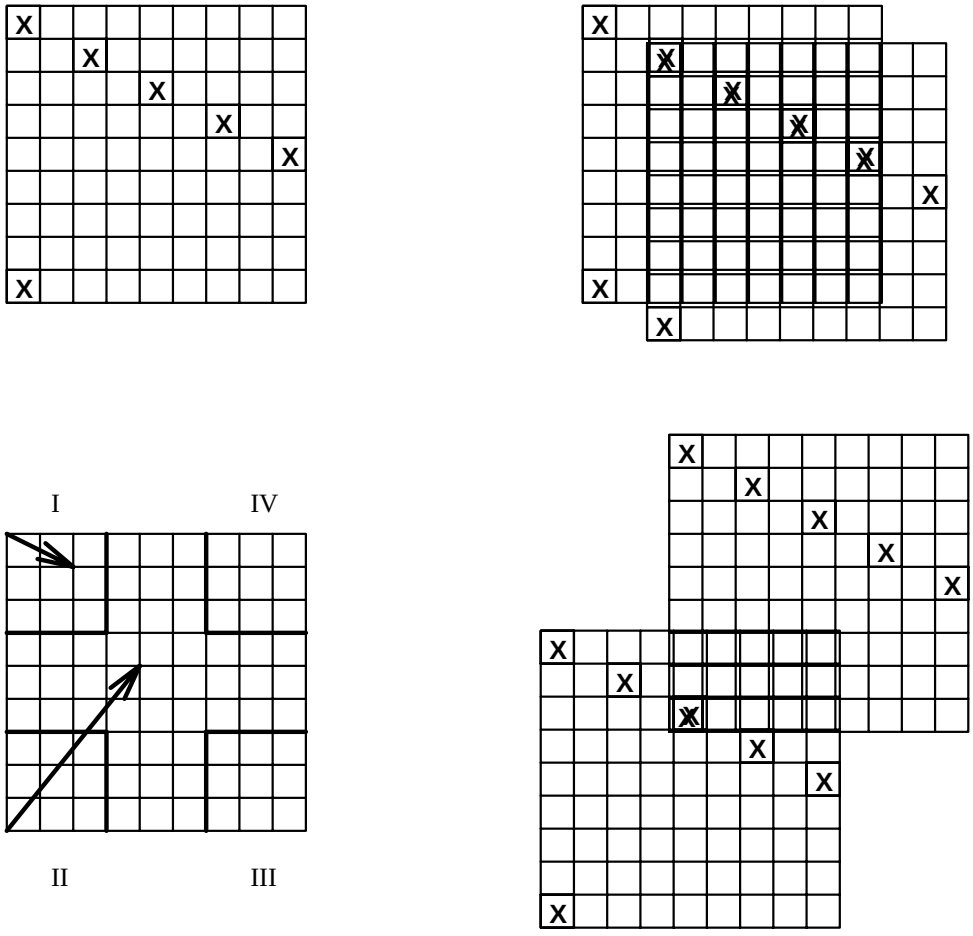

FIG. 5. *Line-periodic array.*

quadrant I *symmetry vector* $(r_1 \geq |r_2|)$ *or a quadrant* II *symmetry vector* $(r_1 < |r_2|)$.

Proof. We prove for the case $r_1 \geq |r_2|$. The proof for the other case is similar. We show that $S = (r_1 + r_2, c_1 + c_2)$ is a quadrant I source. First, by the constraint on the c_i, the fact that r_2 is negative and the assumption that $r_1 \geq |r_2|$, S is an element of A. Next, we show via two pairs of mappings that the quadrant I prefix block $A[0 \ldots m - r_1 - r_2 - 1, 0 \ldots m - c_1 - c_2 - 1]$ is identical to the suffix block $A[r_1 + r_2 \ldots m - 1, c_1 + c_2 \ldots m - 1]$.

First pair: (r_1, c_1) maps block $A[0 \ldots m - r_1 - 1, 0 \ldots m - c_1 - c_2 - 1]$ to block $A[r_1 \ldots m - 1, c_1 \ldots m - c_2 - 1]$. (r_2, c_2) maps the resultant block to block $A[r_1 + r_2 \ldots m + r_2 - 1, c_1 + c_2 \ldots m - 1]$.

Second pair: (r_2, c_2) maps block $A[m - r_1 \ldots m - r_1 - r_2 - 1, 0 \ldots m - c_1 - c_2 - 1]$ to $A[m - r_1 + r_2 \ldots m - r_1 - 1, c_1 \ldots m - c_2 - 1]$. (r_1, c_1) maps the resultant block to $A[m + r_2 \ldots m - 1, c_1 + c_2 \ldots m - 1]$. □

LEMMA 3.5. *If* (r_1, c_1) *and* (r_2, c_2) *are two quadrant* k *symmetry vectors* ($k =$ I, II) *and* $|r_1| + |r_2| < m$ *and* $c_1 + c_2 < m$, *then* $(r_1 + r_2, c_1 + c_2)$ *is also a quadrant* k *symmetry vector.*

Proof. We prove for quadrant I. The proof for the other quadrant is similar. We

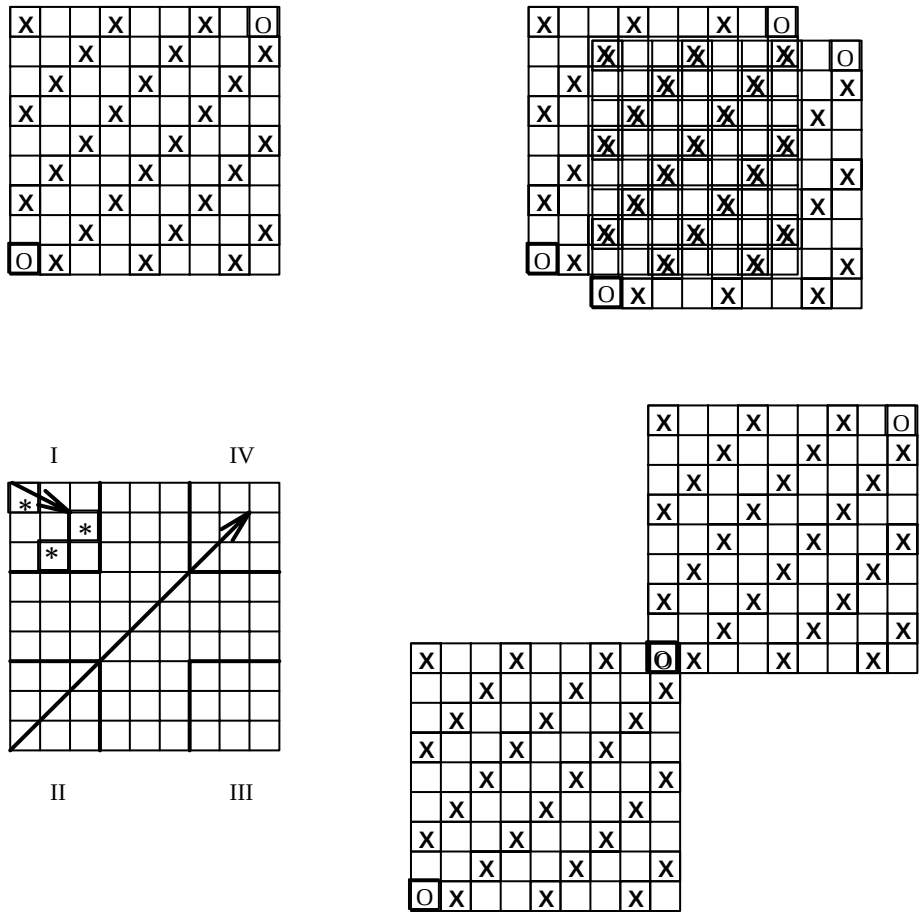

FIG. 6. *Radiant-periodic array. Three noncolinear sources are starred.*

show that $S = (r_1 + r_2, c_1 + c_2)$ is a quadrant I source. First, by the restraints on the r_i and the c_i, S is an element of A. Next, by a pair of mappings, we show that the quadrant I prefix block $A[0 \ldots m - r_1 - r_2 - 1, 0 \ldots m - c_1 - c_2 - 1]$ is identical to the suffix block $A[r_1 + r_2 \ldots m - 1, c_1 + c_2 \ldots m - 1]$. Recall that both r_1 and r_2 are positive.

First mapping: (r_1, c_1) maps the block $A[0 \ldots m - r_1 - r_2 - 1, 0 \ldots m - c_1 - c_2 - 1]$ to the block $A[r_1 \ldots m - r_2 - 1, c_1 \ldots m - c_2 - 1]$. Second mapping: (r_2, c_2) maps the resultant block to the block $A[r_1 + r_2 \ldots m - 1, c_1 + c_2 \ldots m - 1]$. □

LEMMA 3.6. *If* $\vec{v}_1 = (r_1, c_1)$ *and* $\vec{v}_2 = (r_2, c_2)$ *are symmetry vectors from quadrants* I *and* II*, respectively, and* $c_1 + c_2 < m$ *and* $r_1 + |r_2| < m$*, then for all integers* i, j *such that* $A[ir_1 + jr_2, ic_1 + jc_2]$ *is an element of* A*,* $(ir_1 + jr_2, ic_1 + jc_2)$ *is a quadrant* I *symmetry vector. Similarly, for all* $\hat{\imath}, \hat{\jmath}$ *such that* $A[m - 1 + \hat{\imath}r_1 + \hat{\jmath}r_2, \hat{\imath}c_1 + \hat{\jmath}c_2]$ *is an element of* A*,* $(\hat{\imath}r_1 + \hat{\jmath}r_2, \hat{\imath}c_1 + \hat{\jmath}c_2)$ *is a quadrant* II *symmetry vector.*

Proof. We prove for vector $(ir_1 + jr_2, ic_1 + jc_2)$, equivalent to source $S_{i,j} = A[ir_1 + jr_2, ic_1 + jc_2]$. The proof for the other vector is similar. Consider the lattice of elements in A defined by the quadrant I and II vectors and with one element at

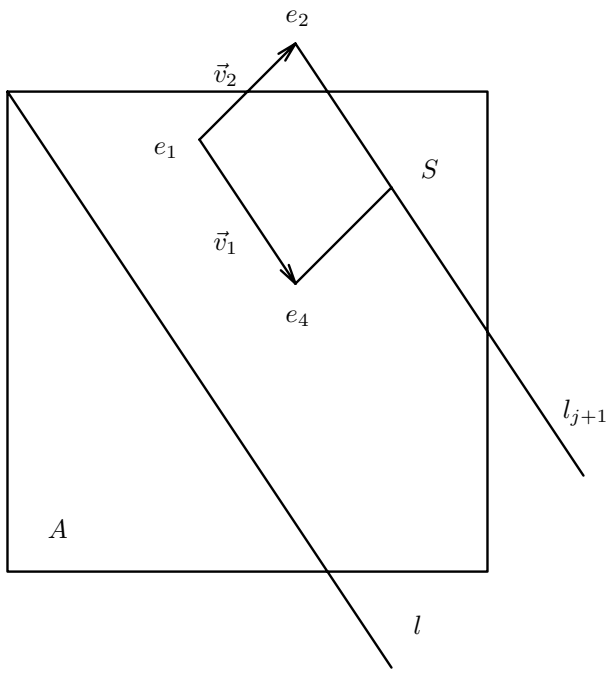

FIG. 7. *A candidate source S in Lemma* 3.6. *Here* $|r_1| \geq |r_2|$.

$A[0,0]$. (The lattice elements correspond exactly to the elements $S_{i,j}$.) Consider the line l that extends from element $A[0,0]$ through elements $S_{i,0} = A[ir_1, ic_1]$. We prove the lemma only for those lattice elements on or to the right of l. The remaining elements are treated similarly.

Case 1. $S_{i,0}$ is on line l. For $S_{1,0}$, $i = 1$ and (r_1, c_1) is a symmetry vector by hypothesis. Now, by induction on i, assume that (ir_1, ic_1) is a symmetry vector. Since (r_1, c_1) and (ir_1, ic_1) are both quadrant I symmetry vectors, by Lemma 3.5 $((i+1)r_1, (i+1)c_1)$ is a quadrant I symmetry vector.

Case 2. $S_{i,j}$ $j \geq 1$ to the right of line l. Elements $S_{i,j}$ fall on lines l_j which are parallel to line l. We show that the *uppermost* element $S_{i,j}$ is a source. By application of Lemma 3.5, as in Case 1, the remaining sources on l_j are established.

Consider a *cell* of the lattice with sides (r_1, c_1) and (r_2, c_2) and corners

$$\begin{aligned} e_1 &= A[ir_1 + jr_2, ic_1 + jc_2], \\ e_2 &= A[ir_1 + (j+1)r_2, ic_1 + (j+1)c_2], \\ e_4 &= A[(i+1)r_1 + jr_2, (i+1)c_1 + jc_2], \\ S &= A[(i+1)r_1 + (j+1)r_2, (i+1)c_1 + (j+1)c_2], \end{aligned}$$

where S is the uppermost lattice element on line l_{j+1} (Figure 7). The following are always true:

- e_2 is **not** an element of A. Otherwise e_2—not S—is the top element on its line.
- e_4 **is** an element of A. Otherwise S is not in A, S is not to the right of line l or $r_1 + |r_2| \geq m$.

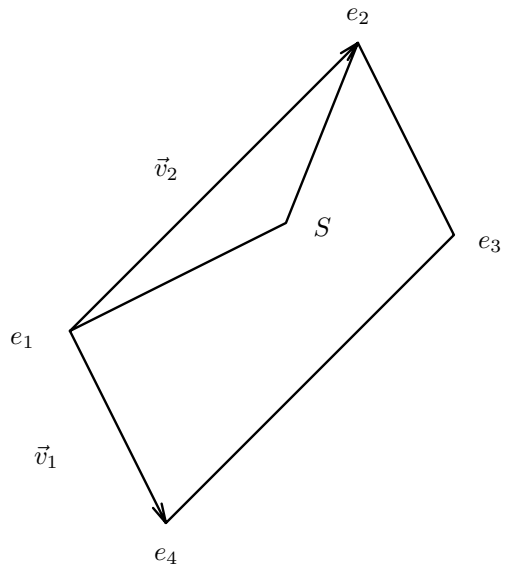

FIG. 8. *One of the vectors from e_1 to S or S to e_2 is a quadrant* II *vector shorter than $\vec{v}_2$.*

Two possibilities remain. Either e_1 is an element of A or it is not. Our proof is by induction on i and j. For the base cases we use $\vec{v}_1$ $(i = 1, j = 0)$, $\vec{v}_2$ $(i = 0, j = 1)$, and $\vec{v}_3 = \vec{v}_1 + \vec{v}_2$ which is either a quadrant I vector $(r_1 \geq |r_2|)$ or a quadrant II vector $(r_1 < |r_2|)$ by Lemma 3.4.

Subcase A. $r_1 \geq |r_2|$.

- e_1 is not an element of A. By the induction hypothesis, $\vec{v}_{e_4} = (i+1)\vec{v}_1 + j\vec{v}_2$ is a symmetry vector. Since e_1 is not on A, $r_{e_4} < r_1$. That is, the row coefficient in $\vec{v}_{e_4}$ is smaller than the row coefficient in $\vec{v}_1$. Apply Lemma 3.4 to $\vec{v}_{e_4}$ and $\vec{v}_2$ and S is a source.
- e_1 is an element of A. By the induction hypothesis, $\vec{v}_{e_1} = i\vec{v}_1 + j\vec{v}_2$ is a quadrant I symmetry vector. From the base case, $\vec{v}_3 = \vec{v}_1 + \vec{v}_2$ is a quadrant I symmetry vector. Apply Lemma 3.5 to $\vec{v}_{e_1}$ and $\vec{v}_3$ and S is a source.

Subcase B. $r_1 < |r_2|$.

- e_1 is not an element of A. It is impossible, else S is not in A or S is not right of l.
- e_1 is an element of A. Note that S is above row r_1 or else e_2 is on the array. The vector $\vec{v}_{e_2} = i\vec{v}_1 + (j+1)\vec{v}_2$ is a quadrant II symmetry vector (because r_{e_2} is negative) by application of Subcase A to quadrant II. Now, $r_{e_2} + r_1 =$(the row index of S)≥ 0, so $r_1 \geq -r_{e_2}$ or $|r_{e_2}| \leq r_1$. By hypothesis, $r_1 < |r_2|$ and therefore $|r_{e_2}| < |r_2|$. Apply Lemma 3.5 to $\vec{v}_1$ and $\vec{v}_{e_2}$ and S is a source. □

The proof of Theorem 3.9 is simplified by the following easily proven observation.

OBSERVATION 3.7. *Let (r_1, c_1) and (r_2, c_2) be symmetry vectors from quadrants* I *and* II*, respectively, and $c_1 + c_2 < m$ and $r_1 + |r_2| < m$, and let L be an infinite lattice of points on the xy-plane also with basis vectors (r_1, c_1) and (r_2, c_2). If we put one copy of A on each lattice point by aligning element $A[0, 0]$ with the lattice point, then the copies are in register and completely cover the plane.*

The next lemma establishes that for a given lattice of elements in A, an element

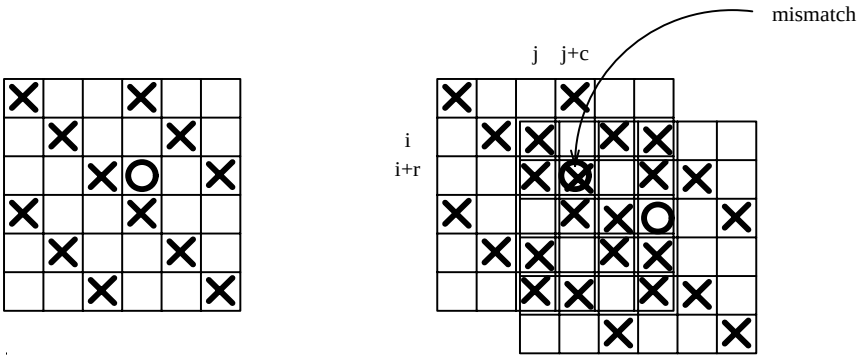

FIG. 9. *The witness table gives the location of a mismatch (if one exists) for two overlapping patterns:* $Witness[i, j] = [r, c]$.

not on the lattice has a shorter vector to some lattice point than the corresponding basis vector for the lattice. (Note that a simplified version of the proof appeared in [GP-92], and we use essentially that same proof here.)

LEMMA 3.8. *Let L be an infinite lattice in the xy-plane with basis vectors $\vec{v}_1 = (r_1, c_1)$ and $\vec{v}_2 = (r_2, c_2)$ (quadrants* I *and* II *symmetry vectors, respectively), where all the r_i and c_i are integers. Then, for any point $S = (x, y)$ that is not a lattice element, where x and y are integers, there exists a lattice point e such that the vector $\vec{v}$ from e to S (or S to e) is a quadrant* I *vector shorter than $\vec{v}_1$ or a quadrant* II *vector shorter than $\vec{v}_2$.*

Proof. Let S be an element that does not fall on a lattice point. Consider the unit cell of the lattice containing S (Figure 8) with nodes labeled e_1, e_2, e_3, and e_4, where

$$\begin{aligned} e_4 &= e_1 + \vec{v}_1, \\ e_2 &= e_1 + \vec{v}_2, \\ e_3 &= e_1 + \vec{v}_1 + \vec{v}_2. \end{aligned}$$

Connect S to the four corners of the unit cell to get four triangles. At least one of these triangles has a right or obtuse angle. W.l.o.g., let the triangle be on points e_1, e_2, and S. Then both the vector from e_1 to S and the vector from e_2 to S is shorter than the vector from e_1 to e_2. Since at least one of the two is a quadrant II vector, we have a quadrant II vector shorter than $\vec{v}_2$. □

Our first main result is the following theorem. It establishes that if an array has basis vectors in both quadrants, then in a certain block of the array, which depends on the coefficients of the basis vectors, all symmetry vectors are linear combinations of the basis vectors. We state the theorem in terms of quadrant I for simplicity. Since the array can be rotated so that any quadrant becomes quadrant I, it applies to all quadrants.

THEOREM 3.9. *Let A be an array with basis vectors (r_1, c_1) and (r_2, c_2) in quadrants* I *and* II*, respectively, with $c_1 + c_2 < m$ and $r_1 + |r_2| < m$. Let L be an infinite lattice with the same basis vectors and containing the element $A[0, 0]$. Then, in the block $A[0 \ldots m - r_1 - |r_2|, 0 \ldots m - c_1 - c_2]$, an element is a quadrant* I *source iff it is a lattice element.*

Proof. By Lemma 3.6, if $S = A[r, c]$ is a lattice element, then it is a source. Suppose that S is not a lattice element, but that it is a quadrant I source. We will

show that S cannot occur within block $A[0 \ldots m - r_1 - |r_2|, 0 \ldots m - c_1 - c_2]$.

By way of contradiction, assume S does occur in prefix block $A[0 \ldots m - r_1 - |r_2|, 0 \ldots m - c_1 - c_2]$. There is a quadrant I vector $\vec{v}$ associated with S that is not a linear combination of $\vec{v}_1$ and $\vec{v}_2$. By Observation 3.7, copies of A can be aligned with the points of lattice L and the copies will be in register and cover the plane. Let $A' = A[r \ldots m-1, c \ldots m-1]$, i.e., the suffix block originating at element $A[r, c]$. Because S is a source, $\vec{v}$ maps $A[0 \ldots m - r - 1, 0 \ldots m - c - 1]$ to A'. For each copy of A, remove all but A'. The copies of A' are in register. Since A' has dimensions at least $r_1 + |r_2|$ by $c_1 + c_2$, it is at least as large as a unit cell of the lattice and therefore, the copies of A' also cover the plane. Now every element of the plane is mapped by $\vec{v}$ from an identical element, and there is a complete copy of A at S. S falls within some cell of lattice L. By Lemma 3.8, there is a quadrant I or quadrant II vector $\vec{v}_3$ from S to some corner e of the cell (or from e to S) which is *shorter* than the corresponding basis vector of L. Since there are complete copies of A at S and e, $\vec{v}_3$ is a symmetry vector and therefore, $\vec{v}_1$ and $\vec{v}_2$ are not both basis vectors of A as assumed. □

Since our quadrants are of size $\lceil \frac{m}{3} \rceil \times \lceil \frac{m}{3} \rceil$, they are no greater in size than the smallest block that can contain only lattice point sources. The region that contains only lattice point sources can be larger than the block described in Theorem 3.9 (see [GP-92]). Next, we prove the following important trait about radiant-periodic arrays that facilitates their handling in matching applications [AB-92b, **?**, KR-94]. Origins ($A[0, 0]$) of complete copies of a radiant-periodic array A that overlap without mismatch can be *ordered monotonically*.

DEFINITION 3.10. *A set of elements of an array B can be* ordered monotonically *if the elements can be ordered so that they have column index nondecreasing and row index nondecreasing (ordered monotonically in quadrant* I*) or row index nonincreasing (ordered monotonically in quadrant* II*).*

Our theorem is stated in terms of quadrant I, but generalizes to quadrant II.

THEOREM 3.11. *Let A be a radiant-periodic array with periodic vector in quadrant* I*. Let $S_1, \ldots, S_j$ be quadrant* I *sources occurring within quadrant* I*. On each source, place one copy of A by aligning $A[0, 0]$ with the source. If every pair of copies is in register, then the sources can be ordered monotonically in quadrant* I*.*

Proof. Suppose two sources $A[c_1, r_1]$ and $A[c_2, r_2]$ cannot be ordered monotonically. That is, $c_1 < c_2$ but $r_2 < r_1$. If there is no mismatch in the copies of A at these sources, then by the fact that $c_2 - c_1 < \frac{m}{3}$ and $r_1 - r_2 < \frac{m}{3}$, $\vec{v} = (r_2 - r_1, c_2 - c_1)$ is a periodic, quadrant II symmetry vector and by definition, A is lattice periodic, which is a contradiction. □

As stated earlier, our classification scheme applies to any rectangular array. The major modification is a new definition of length.

DEFINITION 3.12. *The length of a symmetry vector of a rectangular array is the maximum of the absolute values of its coefficients* scaled to the dimensions of the array*. Let A be n rows by m columns with $m \geq n$. Let $\vec{v} = (r, c)$ be a symmetry vector in A. Then the length of $\vec{v}$ scaled to the dimensions of the array is* $\max(r \cdot \frac{m}{n}, c)$.

4. Periodicity and witness algorithms. In this section, we present two algorithms, one serial and one parallel for finding all sources in an array A. In addition, for each location in A which is not a source, our algorithms find a *witness* that proves that the overlapping copies of A are not in register.

We want to fill out an array $Witness[-m - 1 \ldots m - 1, 0 \ldots m - 1]$. For each location $A[i, j]$ that is a quadrant I source, $Witness[i, j] = [m, m]$. Otherwise, $Witness[i, j] = [r, c]$ where $[r, c]$ identifies some mismatch. Specifically, $A[r, c] \neq$

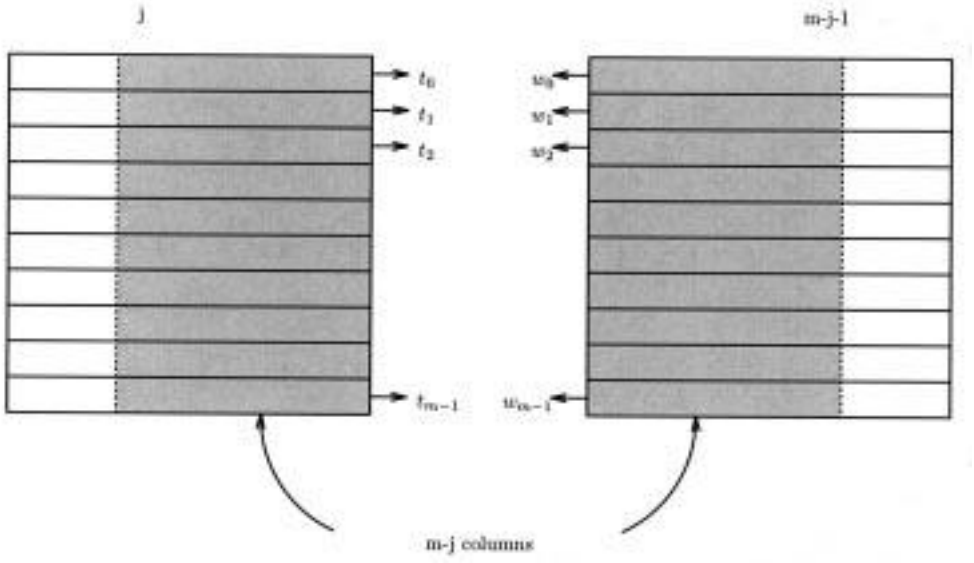

FIG. 10. *Representing a block of the array by a string.* $T_j = t_0 \dots t_{m-1}$ *is the text and* $W_j = w_0 \dots w_{m-1}$ *is the pattern.*

$A[i + r, j + c]$ (Figure 9). For each location $A[i, j]$ that is a quadrant II source, $Witness[i - (m - 1), j] = [m, m]$, otherwise $Witness[i - (m - 1), j] = [r, c]$, where $A[r, c] \neq A[i - (m - 1) + r, j + c]$.

4.1. The serial algorithm. Our serial algorithm (Algorithm A) makes use of two algorithms (Algorithms 1 and 2) from [ML-84] which are themselves variations of the KMP algorithm [KMP-77] for string matching. Algorithm 1 takes as input a pattern string w of length m and builds a table $lppattern[0 \dots m-1]$ where $lppattern[i]$ is the length of the longest prefix of w starting at w_i. Algorithm 2 takes as input a text string t of length n and the table produced by Algorithm 1 and produces a table $lptext[0 \dots n-1]$ where $lptext[i]$ is the length of the longest prefix of w starting at t_i.

The idea behind Algorithm A is the following: we convert the two-dimensional problem into a problem on strings (Figure 10). Let the array A be processed column by column and suppose we are processing column j. Assume we can convert the suffix block $A[0 \dots m-1, j \dots m-1]$ into a string $T_j = t_0 \dots t_{m-1}$ where t_i represents the suffix of row i starting in column j. This will serve as the text string. Assume also that we can convert the prefix block $A[0 \dots m-1, 0 \dots m-j-1]$ into a string $W_j = w_0 \dots w_{m-1}$, where w_i represents the prefix of row i of length $m - j$. This will serve as the pattern string. Now, use Algorithm 1 to produce the table *lppattern* for W_j and Algorithm 2 to produce the table *lptext* for T_j. If a copy of the pattern starting at t_i matches in every row to t_{m-1}, then $lptest[i] = m - i$ and $A[i, j]$ is a source. If the pattern doesn't match and the first pattern row to mismatch is row $k < m-i$, then $lptext[i] = k$ and $A[i, j]$ is not a source. The mismatch occurs between the prefix of pattern row k and the suffix of text row $i + k$. We need merely locate the mismatch to obtain the witness.

In order to treat the suffix and prefix of a row as a single character, we will build a *suffix tree* for the array. A suffix tree is a compacted trie of suffixes of a string $S = s_1 \cdots s_n$ [W-73]. Each node v has associated with it the indices [a,b] of some

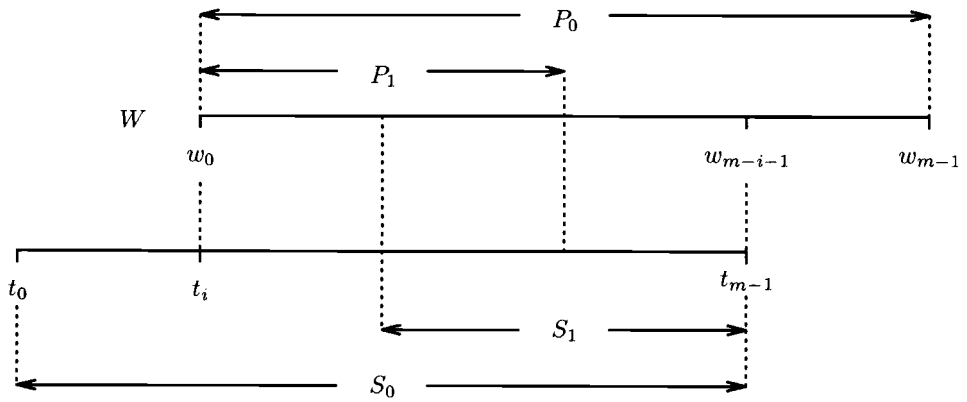

FIG. 11. *P_1 is a prefix of $t_i \dots t_{m-1}$ and S_1 is a suffix of $w_0 \dots w_{m-i-1}$.*

substring $S(v) = s_a \cdots s_b$ of S. If u is the least common ancestor (LCA) of two nodes v and w, then $S(u)$ is the longest common prefix of $S(v)$ and $S(w)$ [LV-85]. A tree can be preprocessed in linear time to answer LCA queries in constant time [HT-84]. Thus, we can answer questions about the length of $S(u)$ in constant time.

ALGORITHM A. *Serial algorithm for building a witness array and deciding periodicity class.*

Step A.1: Build a suffix tree by concatenating the rows of the array. Preprocess the suffix tree for least common ancestor queries in order to answer questions about the length of the common prefix of any two suffixes.

Step A.2: For each column j, fill out $Witness[0 \dots m-1, j]$ (quadrant I):

Step A.2.1: Use Algorithm 1 to construct the table *lppattern* for $W_j = w_0 \dots w_{m-1}$. Character w_i is the *prefix* of row i of length $m - j$. We can answer questions about the equality of two characters by consulting the suffix tree. If the common prefix of the two characters has length at least $m - j$ then the characters are equal.

Step A.2.2: Use Algorithm 2 to construct table *lptext* for $T_j = t_0 \dots t_{m-1}$. Character t_i is the *suffix* of row i starting in column j (also of length $m-j$). Again we test for equality by reference to the suffix tree.

Step A.2.3: For each row i, if $lptext[i] = m - i$ then we have found a quadrant I source and $Witness[i, j] = [m, m]$; otherwise, using the suffix tree, compare the suffix of text row $i + lptext[i]$ starting in column j with the prefix of pattern row $lptext[i]$. The length l of the common prefix will be less than $m - j$, and $Witness[i, j] = [lptext[i], l + 1]$.

Step A.3: Repeat Step A.2 for $Witness[-m+1 \dots 0, j]$ (quadrant II) by building the automata and processing the columns from the bottom up.

Step A.4: Select quadrant I and quadrant II basis vectors from $Witness$ if they exist.

Step A.5: Use the basis vectors to decide to which of four periodicity classes the pattern belongs.

THEOREM 4.1. *Algorithm A is correct and runs in time $O(m^2 \log |\Sigma|)$.*

Proof. The correctness of Algorithm A follows from the correctness of Algorithms 1 and 2 of [ML-84]. The suffix tree construction [W-73] takes time $O(m^2 \log |\Sigma|)$ while the preprocessing for least common ancestor queries [HT-84] can be done in

time linear in the size of the tree. Queries to the suffix tree are processed in constant time. The tables *lppattern* and *lptext* can be constructed in time $O(m)$ [ML-84]. For each of m columns, we construct two tables so the total time for Steps A.2 and A.3 is $O(m^2)$. Step A.4 can be done in one scan through the witness array and Step A.5 requires comparing all vectors to the basis vectors in order to distinguish between the radiant- and line-periodic classes, so the time for Steps A.4 and A.5 is $O(m^2)$. The total complexity of the pattern preprocessing is therefore $O(m^2 \log |\Sigma|)$. □

Recently, [GP-92] gave an $O(m^2)$ (linear time) serial algorithm for the witness computation.

4.2. The parallel algorithm. Our parallel algorithm (Algorithm B) makes use of the parallel string matching algorithm (Algorithm 3) from [V-85]. Algorithm 3 takes as input a pattern string w of length m and a text string t of length n and produces a boolean table $match[0 \ldots n-m-1]$, where $match[i] = true$ if a *complete* copy of the pattern starts at t_i. Algorithm 3 first preprocesses the pattern and then processes the text.

First, for a text of length m, we show how to modify Algorithm 3 to compute $match[0 \ldots m-1]$, where $match[i] = true$ if $t_i \ldots t_{m-1}$ is a prefix of the pattern. For simplicity, we assume m is a power of 2.

Let

$$\begin{aligned} P_k &= w_0 \ldots w_{\lfloor \frac{m-1}{2^k} \rfloor}, \\ S_k &= t_{m-1-\lfloor \frac{m-1}{2^k} \rfloor} \ldots t_{m-1}, \\ k &= 0, 1, \ldots, \log m. \end{aligned}$$

For example, P_1 is the prefix of w of length $\frac{m}{2}$ and S_1 is a suffix of t of the same length. The following observation embodies the key idea (Figure 11).

OBSERVATION 4.2. *If $t_i \ldots t_{m-1}$ is a prefix of w of length between m and $\frac{m}{2}$, then P_1 is a prefix of $t_i \ldots t_{m-1}$ and S_1 is a suffix of $w_0 \ldots w_{m-i-1}$. Similarly, if $t_i \ldots t_{m-1}$ is a prefix of w of length between $\frac{m}{2}$ and $\frac{m}{4}$, then the prefix and suffix are P_2 and S_2, etc.*

Now, for each $k \geq 1$, we attempt to match P_k in S_{k-1} and S_k in P_{k-1}. If a matched prefix begins at t_i and a matched suffix ends at w_{m-i-1} then $t_i \ldots t_{m-1}$ is a prefix of w.

Using Algorithm 3, we first preprocess the P_k and S_k as patterns and then use these to process the appropriate segments as text. We can additionally modify Algorithm 3 so that at every index where a prefix or suffix does not match, we obtain the location of a mismatch. Since the sum of the lengths of the P_i and S_i are no more than a linear multiple of the length of w, the modification does not increase the complexity of the algorithm and therefore the time complexity of the modified Algorithm 3 is $O(\log m)$ using $O(\frac{m}{\log m})$ CRCW processors—the same as the unmodified algorithm [V-85]. In our parallel algorithm, only Step 2 differs from the serial algorithm.

ALGORITHM B. *Parallel algorithm for finding sources and building a witness array.*

Step B.2: For each column j, fill out $Witness[0 \ldots m-1, j]$ (quadrant I):
  Step B.2.1: For each $k = 1, \ldots, \log m$:
    Step B.2.1.1: Use W_j to form P_k and P_{k-1} and T_j to form S_k and S_{k-1}. Use modified Algorithm 3 to match P_k in S_{k-1} and S_k in P_{k-1}. As in the serial algorithm, use the suffix tree to answer questions about equality.

Step B.2.1.2: For each row i for $m-1-\frac{m-1}{2^{k-1}} \leq i < m-1-\frac{m-1}{2^k}$. If P_k matches beginning at t_i and S_k matches ending at w_{m-i-1}, then $Witness[i,j] = [m,m]$. Otherwise, using the row r of mismatch from modified Algorithm 3, refer to the suffix tree to find the column c of mismatch and set $Witness[i,j] = [r,c]$.

THEOREM 4.3. *Algorithm B is correct and runs in time $O(\log m)$ using $O(m^2)$ CRCW processors.*

Proof. The suffix tree construction [AILSV-87] and preprocessing for LCA queries [SV-88] are done in time $O(\log m)$ using $O(m^2)$ CRCW processors. Step B.2 is done in time $O(\log m)$ using $O(\frac{m^2}{\log m})$ CRCW processors [V-85]. Finding the basis vectors is done by prefix minimum [LF-80] in time $O(\log m)$ using $O(\frac{m^2}{\log m})$ processors. Distinguishing the line and radiant periodic cases can be done in constant time using $O(m^2)$ processors. The total complexity is therefore $O(\log m)$ time using $O(m^2)$ CRCW processors. □

A FAST DISCRETE APPROXIMATION ALGORITHM FOR THE RADON TRANSFORM*

MARTIN L. BRADY†

Abstract. This paper addresses fast parallel methods for the computation of the Radon (or Hough) transform. The Radon transform of an image is a set of projections of the image taken at different angles. Its computation is important in image processing and computer vision for problems such as pattern recognition and reconstruction of medical images. A unique new method for combining partial results is presented, from which an algorithm is constructed that computes a provably good approximation to the discrete Radon transform. The approximate discrete Radon transform (ADRT) algorithm computes $4N-4$ projections through an $N \times N$ image in time $O(N^2 \lg N)$ (the majority of previous algorithms are $O(N^3)$). The method is quite simple and easy to parallelize. A parallel version of the ADRT requires only $O(\lg N)$ parallel steps on $O(N^2)$ processors, ignoring communication time. An additional property of the algorithm is that it can be applied directly to compute the backprojection step of the inverse RT.

Key words. Radon transform, Hough transform, approximation algorithms, image processing, image reconstruction

1. Introduction.

The problem of computing projections of two-dimensional data arises in numerous applications in image processing and computer graphics. The Radon transform (RT) of an image is a set of projections of the image along lines taken at different angles (i.e., a mapping from image space to projection space, or "Radon space"). For discrete image data, a projection is computed by summation of all data points that lie within specified unit-width strips. The Hough transform is a restricted form of the discrete RT (DRT) in which the input is taken to be discrete binary data [9]. The Hough transform is an essential component of many methods for pattern recognition and parameter extraction [12], and it has been applied to problems such as line and curve detection [5], [1].

The standard computation of the RT of an $N \times N$ image at M different angles requires time $O(N^2 M)$. In this paper, we present a new approach to the problem and develop an algorithm that computes a good *approximation* to the DRT. This algorithm computes the RT for a specific set of $4N-4$ projection angles in only $O(N^2 \lg N)$ time.[1] The algorithm is extremely simple, and the approximation is very good even for large images. The maximum sampling error grows only as $\lg N$ times a small constant (< 1).

The inversion of the RT is also of importance in image processing. It is essential in reconstructing images collected by projective techniques; for instance, it is used in computer tomography to reconstruct medical images from data collected with X rays (e.g., computed tomography (CT), or magnetic resonance imaging (MRI)); (see [11]). The inversion (reconstruction of an image from its projections) of the RT can be achieved by a fixed convolution, followed by backprojection (the inversion formula

[1]In this paper "lg" denotes a base 2 logarithm.

was discovered by J. Radon [15]). Backprojection is similar to the RT projection computation, except that the projections do not usually follow straight lines. However, our algorithm produces nonuniformly sampled *linogram* Radon data. A consequence is that data, sampled as in our forward RT algorithm, can be backprojected using the same algorithm. As a result, our algorithm for the DRT is also useful in computing the inverse DRT.

In the next section we give some definitions and describe previous work done in the area. Section 3 contains the description of our new algorithm. In section 4 we describe the application of the algorithm to the computation of the inverse of the RT. In section 5 we conclude with a summary of the results as well as observations about other problems to which our method can be applied.

2. Description of the RT. The two-dimensional RT of an image defined in (x, y) coordinate space is a set of projections of the image taken by integrating along the set of lines defined by $x\cos\theta + y\sin\theta = d$ for $0 \le \theta < \pi$. Parameterized in this way, θ is the angle of the line with respect to the positive y-axis and d represents its distance from the origin. An image in (x, y) space is thus transformed into "Radon space" (d, θ).

When working with digital images, a discretized form of the RT is required. A digital image $I(x, y)$ is an $N \times N$ array of *pixels* $(x, y) \in \mathbb{Z}^2$, $0 \le x, y \le N-1$, each representing the average gray level of a unit square in the image.[2] The gray levels can be taken to be nonnegative reals $I(x, y)$: $\mathbb{R}^2 \to \mathbb{R}_{>0}$ (although in practice gray levels are often restricted to eight bit integers, $0 \le I(x, y) \le 255$). A line integral along $x\cos\theta + y\sin\theta = d$ is approximated by a summation of the pixels lying in the one-pixel-wide *strip* $d - \frac{1}{2} \le x\cos\theta + y\sin\theta < d + \frac{1}{2}$ (see Figure 1). Since strips have unit width, d can be restricted to integer values, and for a given θ at most $\sqrt{2}N$ strips are needed. The number of angles is defined to be M, and we assume here that $M = \Theta(N)$. The set of M angles is often defined to be uniformly distributed between 0 and π (however, we will explore the benefits of a nonuniform distribution in this paper).

The DRT can be computed as follows. For any given angle θ, each of the pixels lies in exactly one strip. Therefore, for each pixel we simply determine the strip to which it belongs (d relative to θ) and add the pixel's value to the current total for strip (d, θ). This procedure is repeated for each value of θ. A simple pseudocode description of this algorithm is given in Algorithm 1. The complexity of this method is $O(N^2M)(= O(N^3)$ under the assumption that $M = \Theta(N))$.

ALGORITHM 1. *Standard DRT calculation.*

Initialization:
$R(d, \theta) = 0$ for all (d, θ);

DRT computation:

for $\theta = 0$ **to** $\frac{(M-1)\pi}{M}$ **step** $\frac{\pi}{M}$
{ **for** $x = 0$ **to** $N-1$
{ **for** $y = 0$ **to** $N-1$

[2] Actually, the image can be more generally defined as an $N_1 \times N_2$ array of pixels, where N_1 is not necessarily equal to N_2. However, the discussion is greatly simplified by limiting it to square arrays. The extension to nonsquare images could most easily be handled by zero-padding the image in the smaller dimension.

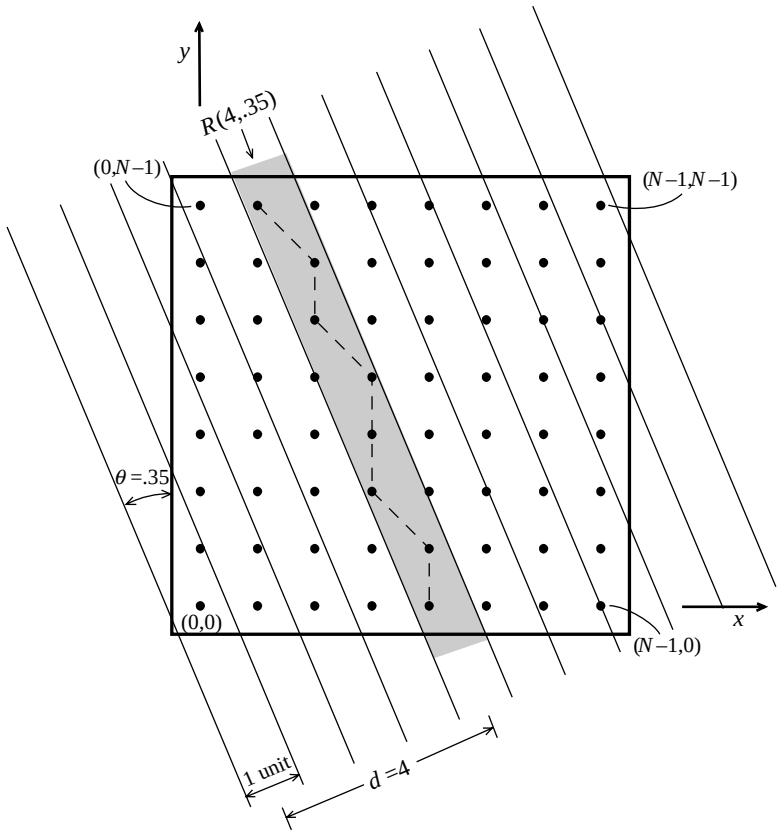

FIG. 1. *Representation of the set of strips for summation along a single direction, θ. Each strip represents a single Radon data point (the sum of the pixels in the shaded strip represents Radon data point $(d, \theta) = (4, .35)$).*

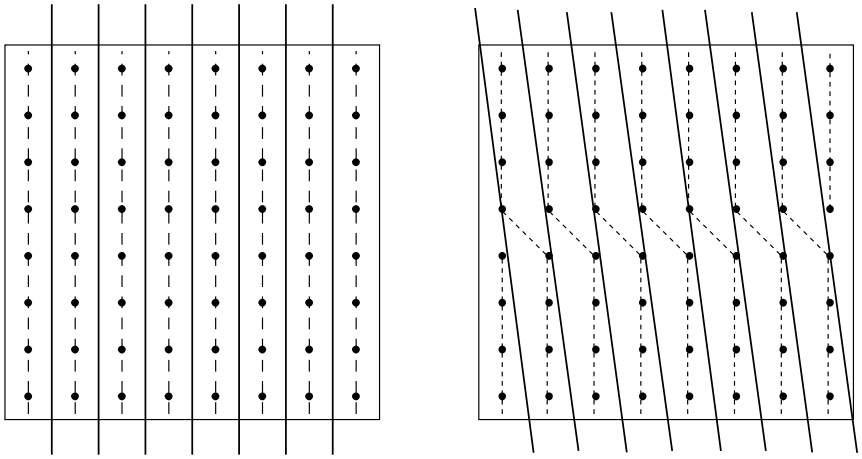
```
            {     d = ⌊x cos θ + y sin θ + 1/2⌋;
                  R(d, θ) = R(d, θ) + I(x, y);
            }
      }
}
```

Due to the complexity of computing the RT and its importance in image processing and other fields, much research has been devoted to speeding it up by mapping the problem into parallel processing architectures. Implementations that require $O(N)$ time on an $N \times N$ mesh-connected array of processors were discovered independently by Cypher, Sanz, and Snyder [4] and Guerra and Hambrush [8]. Pan and Chuang [14] give an $O(\lg N)$ time algorithm for a hypercube with $O(N^4)$ processors, and Jenq and Sahni [10] presented a collection of algorithms for reconfigurable meshes. Many special-purpose parallel architectures have also been proposed; e.g., a pipeline architecture solution was given by Sanz and Hinkle [17].

Our new approach is to construct a simple sequential *approximation* algorithm that is both asymptotically and practically more efficient than the standard algorithm. It requires only $O(N^2 \lg N)$ time to compute projections along $4N - 4$ angles in an $N \times N$ image—a sequential speedup of $\Theta(N/\lg N)$. This large speedup is obtained at



(a) Angle θ_1. (b) Angle θ_2.

FIG. 2. *The large amount of overlap between strips at neighboring angles is illustrated. Dashed lines trace out the sets of points that compose individual strips. Notice that groups of four points are common to one strip at each of the two angles.*

the cost of computing only a fixed, nonuniformly distributed set of angles and computing only an approximation to the desired strip sums. We describe our approximate discrete Radon transform (ADRT) algorithm in section 3.

3. The ADRT algorithm. In Algorithm 1, each point (d, θ) in Radon space is computed independently by summing the pixels within each strip (d, θ). However, the computation can be sped up by observing that *for discrete images*, the computations for different points in the discrete Radon space are not entirely independent; specifically, observe that for neighboring angles, large subsets of pixels may be shared by different strips, as illustrated in Figure 2. Thus, one could potentially save time by computing such shared partial sums only once for use in two or more lines. One approach is to attempt to derive the optimal ordering of computations for a given problem size to make maximum use of partial terms. Unfortunately, there does not appear to be much structure to these sets of partial sums, and it may be more difficult to calculate the proper subsets and order the computations accordingly than to simply calculate the DRT data independently. Instead, we construct an algorithm to compute an *approximation* to the DRT which is designed to take maximum advantage of intermediate terms in a structured manner. We define a specific set of angles and distances and define a set of approximate discrete lines which make full use of partial sums. The number of sample points (d, θ) that we compute is sufficiently dense so that arbitrary data points in Radon space can be extracted by interpolation, if desired. (The accuracy of this approximation is discussed in section 3.3.)

In order to simplify the discussion, let N be a power of two. The extension to arbitrary N can be achieved by either zero-padding the data or by complicating the algorithm's handling of image boundaries, without increasing the asymptotic run time.

3.1. General strategy. We first describe the general strategy of our algorithm. Partial sums of the gray levels of consecutive pixels, representing short discrete line segments, will be computed. We refer to these sets of pixels as *segments* and to the

sum of the gray levels of the pixels in a segment as the *value* of the segment. In the first pass, the values of a large set of two-point segments are computed. Next, pairs of two-point segments are combined to form a set of four-point segments. In successive passes, the values of 2^i-point segments are computed using only the values of the 2^{i-1}-point segments from the previous pass. After $\lg N$ passes, the values of N-point segments have been computed, each representing the sum of a strip of N pixels from the original image. These sums constitute the approximate DRT data.

The computation is divided into four parts which correspond to four equal-sized ranges of angles $\frac{\pi}{4}r \le \theta \le \frac{\pi}{4}(r+1)$ for $r = 0, 1, 2, 3$. Within a range of 45 degrees, the angles are similar enough to derive benefit from sharing intermediate terms. The algorithm will be described for a single group of angles $0 \le \theta \le \pi/4$; each of the other three ranges can be computed symmetrically.

Central to our method is the specification of a set of segments which are simply defined yet closely approximate straight lines. Let the two end points of a segment be labeled (x_1, y_1) and (x_2, y_2). The *x-displacement* of the segment is defined as $|x_1 - x_2|$ (the *y-displacement* is defined analogously). First, we specify the set of segments computed in each pass i by their end points. We then explain how the segments in pass $i+1$ are approximated using the pass i segments. The segments computed as pass i have the following properties.

1. Both end points of each segment lie on pixels in the image space (i.e., the end points have integral (x, y) values).

2. The value of each segment computed in pass i represents the sum of 2^i pixels. One pixel is taken from each of 2^i consecutive rows. Thus, the y-displacement of each segment is $2^i - 1$ and the x-displacement determines the segment's angle.

3. The number of different angles represented by the segments computed in pass i is 2^i. As noted above, a segment's angle depends solely on its x-displacement. Since the angles are between 0 and $\pi/4$, the x-displacements are between 0 and $2^i - 1$. All end points are integer, and therefore the set of x-displacements at pass i is $\{0, 1, 2, \ldots, 2^i - 1\}$. The set of angles for pass i can be calculated as follows:

$$\theta = \tan^{-1}\left(\frac{a}{2^i - 1}\right) \quad \text{for } a = 0, 1, 2, \ldots, 2^i - 1. \tag{1}$$

4. In the y-direction, segments start only on every 2^ith row, i.e., rows y such that $y \equiv 0 \pmod{2^i}$. Within this set of rows, all pixels are valid starting points. Thus, the lowest set of segments spans rows 0 through $2^i - 1$, the next set spans 2^i through $2^{i+1} - 1$, etc. More specifically, the set of segments computed in pass i begins at $y = j(2^i)$ and ends at $y = (j+1)(2^i) - 1$, for $j = 0, 1, 2, \ldots, (N/2^i) - 1$, and spans all x-values. The segments constructed in the first three passes of the algorithm are illustrated for an 8×8 portion of an image in Figure 3.

The properties given above describe the situation for strips that have their lower and upper end points at the bottom and top rows of the image, respectively. However, some strips "fall off" the left or right boundaries of the image and therefore do not sum an entire set of N pixels. A simple way to handle these boundary conditions is to pad the image with zeros and construct the segments in cyclic fashion. Specifically, the image is padded with zeros in the range $N \le x < 2N$, $0 \le y < N$ into an $N \times 2N$ image, and all x-values are taken modulo $2N$. Strips that "fall off" of the left side of the image wrap around to sum zeros from the padded right half, and some of the strips that begin in the zero-padded right half of the image eventually enter the left half and complete the sum for a line that falls off of the right half. As a result, all of

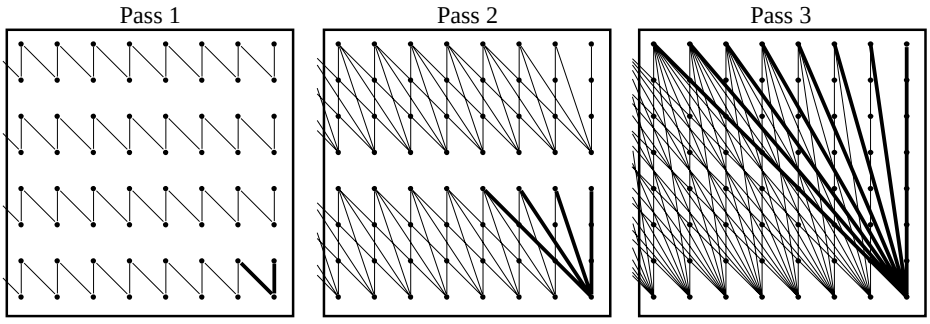


FIG. 3. *Illustration of the segments computed in the first three passes of the ADRT algorithm.*

the strips in the cyclically defined image consist of exactly N pixels. Strips that fall off of an edge take the balance of their N pixels from the set of padded zeros. Since the maximum x-displacement is $N-1$, a strip that moves into the padded zeros never passes all the way through to reenter the image from the other side.

3.2. Algorithm specification. In pass i, two segments of the same angle, $\tan^{-1}(\frac{\lfloor a/2 \rfloor}{2^{i-1}-1})$, are adjoined to create a segment that is about twice as long whose angle is $\tan^{-1}(\frac{a}{2^i-1})$. Let $R_i(x,y,a)$ represent the value of the segment constructed in pass i with lower end point at (x,y) and x-displacement a. Then $R_i(x,y,a)$ is computed as the sum of the values of two (2^{i-1})-point segments from pass $i-1$ as follows (recall that x is taken modulo $2N$):

$$R_i(x,y,a) = R_{i-1}(x,y,\lfloor a/2 \rfloor) + R_{i-1}(x-\lceil a/2 \rceil, y+2^{i-1}, \lfloor a/2 \rfloor) \tag{2}$$

for $x = 0,1,2,\ldots,2N-1$, for $y = j(2^i)$ such that $j = 0,1,2,\ldots,(N/2^i)-1$, and for $a = 0,1,2,\ldots,2^i-1$. Note that the ranges of both y and a are dependent on i. Their product is exactly N, for all i, and therefore within each pass a total of exactly $2N^2$ data values are maintained. At each consecutive pass, the number of different starting point y-values is halved, but the number of different angles per starting point doubles.

The ADRT algorithm is summarized below in Algorithm 2. The image $I(x,y)$ is represented as $R_0(x,y,0)$. After $\lg N$ passes, the DRT data $R(d,\theta)$ are obtained from $R_{\lg N}(x,0,a)$, i.e., $R(d,\theta) = R_{\lg N}(x,0,a)$ for $\theta = \tan^{-1}(\frac{a}{N-1})$ and $d = x\cos\theta$.

ALGORITHM 2. *ADRT computation for* $0 \le \theta \le \pi/4$.

Initialize R_0:

$R_0(x,y,0) = I(x,y)$ for $0 \le x,y < N$
$R_0(x,y,0) = 0$ for $N \le x < 2N, 0 \le y < N$

Approximate DRT computation:

```
for i = 1 to lg N
{    for a = 0 to 2^i - 1
     {    for y = 0 to N - 2^i step 2^i
          {    for x = 0 to 2N - 1
               {    R_i(x,y,a) = R_{i-1}(x,y,⌊a/2⌋) + R_{i-1}(x - ⌈a/2⌉, y + 2^{i-1}, ⌊a/2⌋)
               }
          }
     }
}
```

A total of $O(N^2 \lg N)$ simple arithmetic calculations dominate the computation time in Algorithm 2. Three more applications of symmetric variations of Algorithm 2 are performed to calculate the DRT data for angles in the range $\pi/4$ through π. The basic computation at a single step is extremely simple, requiring only a few additions and divisions by 2. All of the $2N^2$ segment sums in a given pass i can be performed independently, so a PRAM implementation on $2N^2$ processors would require $O(\lg N)$ time. Hence, this algorithm is both asymptotically and practically fast and should yield efficient sequential and parallel implementations. (References [16] and [13] describe sequential and parallel ADRT implementations, respectively; mappings into various parallel architectures are discussed in [3].)

3.3. Analysis of the ADRT. By their construction, the segments computed by Algorithm 2 are "crooked" approximations of the desired strips. Each pass of Algorithm 2 introduces some deviation, and these errors may be compounded in each pass. In this section, we derive an upper bound on the deviation of a pixel that is used to compute $R(d, \theta)$ from the line (d, θ). (Recall that in the standard DRT specified in Algorithm 1, all pixels used to compute a line (d, θ) are within $\frac{1}{2}$ unit of the line.)

Consider the construction of a *parent* segment S in pass i by adjoining two *child* segments S_1 and S_2. Assume for now that S_1 and S_2 are exactly represented, i.e., that all samples lie on the child segments. Observe that each child segment intersects the parent at one of its end points and reaches its maximum distance from S near the parent's center (see Figure 4). We refer to the maximum separation between two line segments taken in the x-direction as their *horizontal separation*.

LEMMA 1. *The horizontal separation of a segment S constructed by Algorithm 2 from either of the two subsegments S_1 and S_2 used to construct it is less than $\frac{1}{2}$ unit.*

Proof. Consider w.l.o.g. a segment S with a lower end point at $(0, 0)$ and x-displacement a, constructed in pass i. Its children S_1 and S_2 are adjoined either diagonally or vertically, depending upon whether a is odd or even, as shown in Figure 4.

Case 1. *a odd (diagonally joined).* This case is illustrated in Figure 4a. The coordinates of the upper end point of S_1 are $(-(a-1)/2, 2^{i-1}-1)$. Since the slope of S is $-\frac{2^i-1}{a}$, at $y = 2^{i-1}-1$ segment S has x-coordinate $x = \frac{-a(2^{i-1}-1)}{2^i-1}$. The horizontal separation of S_1 and S is therefore

$$-\frac{a-1}{2} - \frac{-a(2^{i-1}-1)}{2^i-1} = -\frac{a}{2} + \frac{1}{2} + a\left(\frac{2^{i-1}-1}{2^i-1}\right) < -\frac{a}{2} + \frac{1}{2} + a\frac{1}{2} = \frac{1}{2}.$$

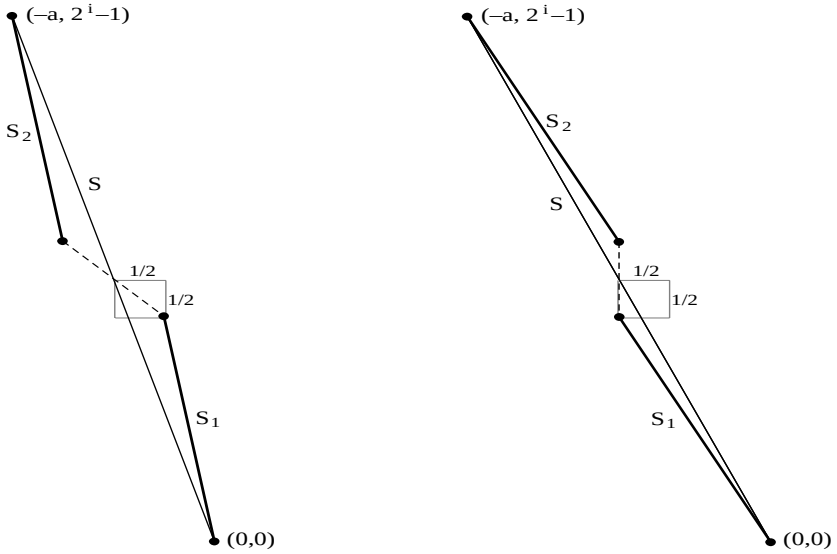
Since S_1 and S_2 are symmetric, the horizontal separation of S_2 and S is also less than $1/2$.

Case 2. *a even (vertically joined).* This case is illustrated in Figure 4b. Here the upper end point of S_1 is at $(-a/2, 2^{i-1}-1)$ and the x-coordinate of S at $y = 2^{i-1}-1$ is again $x = \frac{-a(2^{i-1}-1)}{2^i-1}$. The horizontal separation of S_1 and S is

$$\frac{-a(2^{i-1}-1)}{2^i-1} - \left(-\frac{a}{2}\right) = -\frac{a}{2(2^i-1)}.$$

At pass i, $a \le 2^i - 1$ in general, and since a is even, $a \ne 2^i - 1$, so the horizontal separation is strictly less than $\frac{2^i-1}{2(2^i-1)} = \frac{1}{2}$. (Again S_1 and S_2 are symmetric, so the bound holds for S_2 as well.) □

Lemma 1 bounds the error between a parent segment and two exactly represented child segments used to construct it. But in the ADRT, the children are approximations



(a) S_1 and S_2 adjoined diagonally when a is odd.

(b) S_1 and S_2 adjoined vertically when a is even.

FIG. 4. *The values of two 2^{i-1}-point segments S_1 and S_2 of x-displacement $\lfloor a/2 \rfloor$ are added to create a 2^i-point segment of x-displacement a starting at $(0,0)$. When a is odd, S_2 starts one unit above and one unit to the left of the upper end point of S_2; if a is even, S_2 starts just one unit above the upper end point of S_2.*

themselves and contain some error in their constructions and so forth. The maximum total horizontal error (the horizontal distance of the N-point line segment S from the *points* used to construct it) can be bounded by repeated application of Lemma 1. In the first pass, simple two-point segments are created, incurring no error. Next, these segments are combined to form four-point segments, whose points lie within $\frac{1}{2}$ unit in the x-direction from the intended line. In the next pass, these four-point segments are combined to form eight-point segments, and an additional error of less than $\frac{1}{2}$ unit in the x-direction is incurred. That is, the maximum horizontal separation of the eight-point segments from the (exactly represented) child four-point segments is at most $\frac{1}{2}$, and the separation of these four-point segments from the two-point segments used to construct them is an additional $\frac{1}{2}$. The $\frac{1}{2}$-unit horizontal error bound is invoked for each pass of the algorithm from 2 to $\lg N$. Some of the errors may offset each other, but in the worst case all horizontal errors could be incurred in the same direction, so the maximum total horizontal distance of a pixel from one of the lines to which it contributes is $\frac{1}{2}$ $(\lg\ N - 1)$. The total perpendicular distance is therefore $\frac{1}{2}$ $(\lg\ N - 1)\cos\theta \leq \frac{1}{2}(\lg\ N - 1)$.

The following theorem summarizes the performance of Algorithm 2.

THEOREM 1. *Algorithm 2 produces a set of approximate DRT data points (d, θ) for $\theta = \tan^{-1}(a/(N-1))$, $a = 0, 1, 2, \ldots, N-1$, and $d = d_x \cos\theta$, $d_x = 0, 1, 2, \ldots, 2N-1$, such that all pixels used to generate (d, θ) are within $\frac{1}{2}(\lg N - 1)\cos\theta$ units of the line parameterized by (d, θ). The algorithm requires $O(N^2 \lg N)$ time on a sequential machine, and $O(\lg N)$ parallel steps using $O(N^2)$ processors on an EREW PRAM.*

Note that the error bound is somewhat pessimistic; no single error actually reaches

TABLE 1
Calculated maximum horizontal and perpendicular sampling errors in the ADRT.

N	Maximum horizontal error	Maximum perpendicular error
4	0.333	0.316
8	0.429	0.424
16	0.667	0.632
32	0.774	0.764
64	1.000	0.949
128	1.110	1.095
256	1.333	1.265
512	1.444	1.425
1024	1.667	1.581
2048	1.778	1.754
4096	2.000	1.897

$\frac{1}{2}$ unit, and it is not possible for a single point to receive the maximum error at every iteration. Numerical calculations suggest that the maximum horizontal error may in fact be bounded by $\frac{\lg N}{6}$ (see Table 1).

Notice that the Radon data produced by Algorithm 2 are not uniformly distributed in either d or θ. However, the $2N^2$ data points are extremely dense for an $N \times N$ image. Spacing between adjacent lines ranges from one pixel (for $\theta = 0$) to $1/\sqrt{2}$ pixels (for $\theta = \pi/4$). These lines are as densely spaced as the individual pixels; there is little to be gained by increasing their density without resorting to interpolation. Furthermore, the line spacings are optimized to the geometry of the data points, in that line segments start and end centered on pixels and become more dense at angles in which pixels appear more densely distributed. Similarly, the angles are not uniformly distributed but are dense. For example, the consecutive angles 0 and $\tan^{-1}(\frac{1}{N-1})$ (i.e., $a = 0$ and $a = 1$) with the same starting point share 50% of their data points. It is therefore unlikely that the Radon data computed by Algorithm 2 is too sparse.

It may be the case that specific data points are desired. In this case, it would be reasonable to calculate the desired points from the Algorithm 2 data by interpolation, or to simply select the nearest ADRT data points. There is always an ADRT line within $\frac{1}{2}$ unit of horizontal separation of the desired line. Consider the range $0 \le \theta \le \pi/4$, for example. Since all integer x-coordinates on $y = 0$ and $y = N - 1$ are valid starting and ending points for ADRT lines, one can always select an ADRT sample whose end points are both within $\frac{1}{2}$ unit in the x-direction of the desired line. The maximum horizontal separation will be at one of the end points and is thus bounded by $\frac{1}{2}$. Thus, the ADRT data can be used to approximate *any* Radon data point with a maximum perpendicular error of $\frac{1}{2} \lg N$ units.

3.4. Reducing the approximation error. The maximum error in the data points used to compute the ADRT grows very slowly with the size of the image. This fact can be used to further reduce the error with only a small factor increase in computation time. The general method is as follows. First, the image is *expanded* by a factor k in both dimensions (k must be a power of 2), and then the ADRT is applied. The maximum error incurred for the $kN \times kN$ image is $\frac{1}{2}(\lg kN)$—only $\frac{1}{2}(1 + \lg k)$ units greater than that of an $N \times N$ image. When the RT data is *contracted* back to its original size, the effective error is reduced by nearly a factor of k.

Define an *expanded* image $\hat{\mathrm{I}}(x, y)$ of size $kN \times kN$ as follows:

$$\hat{\mathrm{I}}(x,y) = \begin{cases} I(\lfloor (x/k) + 1/2 \rfloor, \lfloor y/k \rfloor) & \text{if } y \equiv 0 \pmod{k}, \\ 0 & \text{otherwise.} \end{cases} \tag{3}$$

The expanded image is stretched horizontally so that each data point is repeated in k consecutive columns. Vertically every kth row contains image data, while the rest are padded with zeros. Consider the application of the ADRT to this expanded image. Since each line sum uses exactly one data point from each row, the line sums $\hat{\mathrm{R}}(d, \theta)$, computed for $\hat{\mathrm{I}}(x, y)$, involve exactly one element from each row of the original image.

To complete the transform, we contract the Radon data by selecting every kth distance coordinate $d = j \cdot k, j = 0, 1, 2, \ldots, 2N - 1$. In addition, we must discard all but N different angles, selecting those which most closely match the ones produced by the algorithm on the original $N \times N$-sized images. Note that the angles computed on the expanded image do not, in general, contain those that would be computed in the initial image. Consider a line in I with x-displacement a. The slope of the corresponding line in $\hat{\mathrm{I}}$ should be approximately $-\frac{N-1}{a}$. Thus the line's x-displacement $\hat{\mathrm{a}}$ in $\hat{\mathrm{I}}$ should be such that $-\frac{kN-1}{\hat{\mathrm{a}}} = -\frac{N-1}{a}$, i.e., $\hat{\mathrm{a}} = \frac{kN-1}{N-1} \cdot a = (k + \frac{k-1}{N-1})a$. The closest such x-displacement available in $\hat{\mathrm{R}}$ is $(k + \lfloor \frac{k-1}{N-1} + \frac{1}{2} \rfloor)a$. Thus, if the lines are parameterized by their x-intercept d_x and x-displacement a, then contraction is defined as

$$\tilde{\mathrm{R}}(d_x, a) = \hat{\mathrm{R}}\left(kd, \left(k + \left\lfloor \frac{k-1}{N-1} + \frac{1}{2} \right\rfloor\right) a\right) \tag{4}$$

for $d_x = 0, 1, 2, \ldots, 2N - 1$, $a = 0, 1, 2, \ldots, N - 1$. The horizontal separation of this line from one of slope $-\frac{N-1}{a}$ is at most $1/2$ unit in $\hat{\mathrm{I}}$.

THEOREM 2. *Algorithm* 2 *can be used to produce a set of DRT data points* (d, θ) *for* $\theta = \tan^{-1}(a/(N-1))$, $a = 0, 1, 2, \ldots, N - 1$, *and* $d = d_x \cos\theta$, $d_x = 0, 1, 2, \ldots, 2N - 1$, *such that all pixels used to generate* (d, θ) *are within* $\frac{\lg kN}{k} + \frac{1}{2}$ *units of the line parameterized by* (d, θ). *The algorithm requires* $O(N^2k^2 \lg kN)$ *time on a sequential machine and* $O(\lg kN)$ *parallel steps using* $O(N^2k^2)$ *processors on an EREW PRAM.*

Proof. Consider a line L, parameterized by (d_x, a), to be sampled using the expand-ADRT-contract procedure described above with an expansion of factor k. We want to bound the horizontal distance between a point (x, y) on L from the corresponding sample point used in the ADRT. L corresponds to an "ideal" line $\hat{\mathrm{L}}$ of the same slope in the expanded image, parameterized by $(kd_x, (k + \frac{k-1}{N-1})a)$, and corresponding point (kx, ky) lies on $\hat{\mathrm{L}}$. From Theorem 1, the ADRT sample point for (kx, ky) in the expanded image is $\hat{\mathrm{I}}(kx + e, ky)$, where $|e| < \lg kN$. This is the value $I(\lfloor \frac{kx+e}{k} + \frac{1}{2} \rfloor, y)$ from the original image (see equation (3)). Therefore, the maximum possible error in the x-direction is bounded by $e/k + \frac{1}{2} \leq \frac{\lg kN}{k} + \frac{1}{2}$.

The time is dominated by the ADRT computation on the $kN \times kN$ expanded image. This is obtained by substituting kN for N in Theorem 1. ∎

Note that many of the computations in the expanded image are obviously unnecessary (e.g., segments consisting of padded zeroes, segments that will be discarded), and a careful implementation might greatly reduce the actual amount of computation. Furthermore, one might obtain a better approximation by interpolating the image data during the expansion rather than simply replicating it.

4. Approximate inverse of the DRT. The inverse of the RT is used in the reconstruction of medical images. A discrete version of Radon's inversion formula is as follows:

$$I(x,y) = \frac{\pi}{M} \sum_{i=1}^{M} Q(x\cos\theta_i + y\sin\theta_i, \theta_i). \tag{5}$$

$Q(d,\theta)$ represents the *filtered projection data*, which is computed from the Radon data $R(d,\theta)$ by convolving each row of data $R(d,\theta_i)$ with a filter $h(t)$, whose impulse response is $|\omega|$ in the frequency domain, where ω represents the frequency. A row of Q for fixed angle θ_i can be computed in the Fourier domain by

$$Q(d,\theta_i) = \text{FFT}^{-1}(\text{FFT}(R(d,\theta_i)) \cdot |\omega|). \tag{6}$$

This first step, which computes $Q(d,\theta)$, is called *filtering*, and the second step, represented by equation (5), is called *backprojection*. The computation of a single image pixel, $I(x,y)$, is done by summing the values of the M lines (one at each different angle) which pass through (x,y). This amounts to selecting one data point from each row, θ_i, whose d value is the closest to $x\cos\theta_i + y\sin\theta_i$. If both d and θ are uniformly sampled, then the M pixels used to compute $I(x,y)$ trace out a curve $d = x\cos\theta + y\sin\theta$ in discrete Radon space. To compute the complete image, we must sum along the family of sinusoidal curves $\{d = x\cos\theta + y\sin\theta\}$ for $x, y = 0, 1, 2, \ldots, N-1$.

Notice that the backprojection step is quite similar to the computation of the forward RT, except that points in image space trace out sinusoids in uniform Radon space rather than lines. Recall, however, that the data produced by the ADRT is not uniformly distributed in d or θ. (Angles in the range $0 - \pi/4$ are sampled at $\tan^{-1}(\frac{a}{N-1})$ for $a = 0, 1, 2, \ldots, N-1$, and distances are taken at $x\cos\theta_i$ for $x = 0, 1, 2, \ldots, N-1$.) It turns out that for Radon data sampled in this manner, points (x,y) trace out lines in the discrete Radon space. (More precisely, (x,y) traces out four separate lines corresponding to the ranges $\frac{\pi}{4}r \le \theta \le \frac{\pi}{4}(r+1)$, $r = 0, 1, 2, 3$.) Furthermore, the set of image points (x,y), when x and y are integers between 0 and $N-1$, trace out exactly the set of lines that are computed by the ADRT algorithm. Therefore, the ADRT algorithm can be used to compute an approximation to the backprojection of $Q(d,\theta)$. The algorithm is applied separately to each of the four groups of N angles, and the four resulting arrays are added to produce $I(x,y)$. (Note that angles $0, \pi/4$, $\pi/2$, and $3\pi/4$ are necessarily doubly represented in the set of four ranges of Radon data. One must therefore zero their values in one of the two ranges in which each appears before performing backprojection.) The following theorem summarizes the application of the ADRT to the group of angles $0 \le \theta \le \pi/4$.

THEOREM 3. *Given a set of filtered RT data points $Q(d,\theta)$ for $\theta = \tan^{-1}(a/(N-1))$, $a = 0, 1, 2, \ldots, N-1$, and $d = x\cos\theta$, $x = 0, 1, 2, \ldots, N-1$, Algorithm 2 can be used to produce the backprojection of the data $I(x,y), x, y = 0, 1, 2, \ldots, N-1$, such that all RT data points used to reconstruct pixel (x,y) are within $\frac{1}{2}(\lg N - 1)$ units of the line $d = x\cos\theta + y\sin\theta$. The algorithm requires $O(N^2 \lg N)$ time on a sequential machine and $O(\lg N)$ parallel steps using $O(N^2)$ processors on an EREW PRAM.*

Proof. The maximum error and execution times follow from the forward RT description in section 3; we must show that the lines computed by the ADRT correspond to the curves traced out by (x,y) in the nonuniformly sampled Radon space. First we show that the set of Radon space points (d,θ) corresponding to lines which pass through (x,y) is collinear. Recall that the angles are taken at $a = 0, 1, 2, \ldots, N-1$, where $\theta = \tan^{-1}(\frac{a}{N-1})$, so the angles are uniform in the x-displacement variable a.

Similarly, the distances are sampled at unit intervals horizontally. Letting h represent the horizontal distance from the origin of line (d, θ), we have $d = h \cos\theta$. Thus, in the (h, a) coordinate system, the samples represent $h, a = 0, 1, 2, \ldots, N-1$. Consider the pixel (x, y), which traces out the curve $d = x \cos\theta + y \sin\theta$ in the Radon data. Substituting for d, we obtain

$$h \cos\theta = x \cos\theta + y \sin\theta, \tag{7}$$

$$h = x + y\left(\frac{\sin\theta}{\cos\theta}\right) = x + y \tan\theta. \tag{8}$$

Since $\tan\theta = (\frac{a}{N-1})$, we have

$$h = x + \left(\frac{y}{N-1}\right) a, \tag{9}$$

which implies a line in (h, a) space (since x, y, and N are constant for a given image pixel).

Finally, we show that the lines defined in equation (9) are exactly the ones computed by the ADRT, by demonstrating that all such lines begin and end on grid points in (h, a). We need to show that in the top and bottom rows, $a = 0$ and $a = N-1$, the necessary h is an integer. Substituting into equation (9), at $a = 0$ we have $h = x$, and thus h is an integer in the range 0 to $N-1$. At $a = N-1$, $h = x + y$, so we have h an integer in the range 0 to $2N-1$. □

The quality of the approximation can be improved as before, by expanding and then contracting the Radon data set, as explained in section 3.4.

COROLLARY 1. *Given a set of filtered RT data points $Q(d, \theta)$ for $\theta = \tan^{-1}(a/(N-1))$, $a = 0, 1, 2, \ldots, N-1$, and $d = x \cos\theta$, $x = 0, 1, 2, \ldots, N-1$, Algorithm 2 can be used to produce the backprojection of the data $I(x, y), x, y = 0, 1, 2, \ldots, N-1$, such that all RT data points used to reconstruct pixel (x, y) are within $(\lg kN/k) + 1/2$ units of the line $d = x \cos\theta + y \sin\theta$. The algorithm requires $O(N^2k^2 \lg kN)$ time on a sequential machine and $O(\lg kN)$ parallel steps $O(N^2k^2)$ processors on an EREW PRAM.*

5. Conclusions. This paper presents a fundamentally new approach to computing the DRT and HT, taking advantage of the overlap in discrete lines to reduce the total number of computations. The ADRT algorithm yields an asymptotic factor of $N/\lg N$ speedup and due to its simplicity should lead to faster practical implementations as well. While the algorithm computes only an approximation to the desired transform, for realistic-sized images the maximum error is only a few units. This small error can be further reduced, with only a small factor increase in running time, by the expand/contract method described.

For appropriately sampled data (i.e., linograms), the ADRT can be directly applied to approximate the backprojection step of image reconstruction with $\Theta(N/lgN)$ speedup over standard methods. Since the filtering step can already be computed in $O(N^2 \lg N)$ time (in the Fourier domain, using the fast Fourier transform (FFT)), the entire image reconstruction computation time is reduced to $O(N^2 \lg N)$. An entirely different method which computes the image reconstruction from linograms in $O(N^2 \lg N)$ time has recently been discovered (see [6], [7]).

It is important to note that the general strategy of taking advantage of the overlap of near-parallel lines through discrete data can be applied to other important problems. For instance, three-dimensional volume visualization utilizes projections along

lines to compute two-dimensional views, and rotation of the views requires repeated computations along lines at neighboring angles. We are currently extending these ideas to develop fast approximation algorithms for volume visualization [18], [2].

Acknowledgments. The author has benefited from helpful discussion with Raghu Raghayan, Dave Swanson, and Tony Ticknor of Lockheed Missiles and Space Co., Inc., Palo Alto, California, during the course of this research.

VALUE SETS OF SOME POLYNOMIALS OVER FINITE FIELDS $GF(2^{2m})$*

THOMAS W. CUSICK†

Abstract. This paper shows that there is a connection between the crosscorrelation functions of certain binary m-sequences and the value sets of the polynomials $x^k(1+x)^{2^m-1}$ for $k \in \{\pm 1, \pm 2, 4\}$, where x is in the finite field $GF(2^{2m})$. In particular, the size of such value sets is determined by using finite field theory and known results about crosscorrelation functions.

Key words. finite field, polynomial, value set

AMS subject classifications. 68Q40, 11T06, 12E20

1. Introduction.

Let $GF(q)$ denote the finite field with q elements, and let $f(x)$ be a polynomial of degree n in the ring $GF(q)[x]$. Define the value set $V(f)$ of $f(x)$ by

$$V(f) = \{f(x) : x \in GF(q)\}.$$

The problem of estimating the number of elements $|V(f)|$ in the value set was first given prominence by Chowla [2].

A polynomial $f(x)$ for which $|V(f)| = q$ is called a permutation polynomial, and such polynomials have been studied extensively (see Lidl and Niederreiter [6, pp. 347–368] for references up to 1983 and Mullen [7] for a survey of more recent work).

Birch and Swinnerton-Dyer [1] defined "general" polynomials over $GF(q)$ and proved that if $f(x)$ is such a polynomial of degree n, then

$$|V(f)| = q\left(\sum_{j=1}^{n} \frac{(-1)^{j-1}}{j!}\right) + 0\ (q^{1/2}).$$

Uchiyama [10] proved that if the degree n is at least 4 and $f(x)$ satisfies certain mild conditions, then $|V(f)| > \frac{1}{2}q$. Recent work on value sets develops these ideas (see Gomez-Calderon [3], Knopfmacher and Knopfmacher [5], Voloch [11], and von zur Gathen [12]), but the number of results on value sets is still relatively small.

The purpose of this paper is to show that for various values of k, the value sets of the special polynomials

$$f_m^{(k)}(x) = x^k(1+x)^{2^m-1}, \qquad x \in GF(2^{2m}),$$

can be counted for all positive integers m. If $k = 1$ or 2, use of the theory of the finite fields $GF(2^n)$ is enough to give the results. For other values of k, we also use known results on the crosscorrelation functions of certain binary m-sequences, which will be explained later. On the other hand, it turns out that results about certain value sets can be used to deduce new information about some crosscorrelation functions. This issue will be discussed in another paper.

†Department of Mathematics, State University of New York–Buffalo, Buffalo, NY 14214-3093 (cusick@acsu.buffalo.edu).

The polynomials considered in this paper have a special form, which is dictated by the methods of proof used below. However, there is reason to believe that the polynomials studied here are worthy of special attention, apart from the fact that their value sets can be counted. The case $k = 1$ (Theorem 1 below) provides the first examples of polynomials of arbitrarily large degree which attain an upper bound due to Wan [13] on the size of the value set of a polynomial which is not a permutation polynomial. Wan proved that if $f(x)$ is a polynomial of degree n over $GF(q)$ which is not a permutation polynomial, then

$$|V(f)| \le [q - n^{-1}(q-1)]$$

(here $[x]$ denotes the greatest integer not exceeding x). It follows from Theorem 1 that the polynomials $f_m^{(1)}(x)$ meet this bound when $q = 2^{2m}$.

We begin with the simplest cases, $k = 1$ and 2, where only finite field theory is used. It is convenient to define

$$S_m^{(k)} = \{x^k(1+x)^{2^m-1} : x \neq 0 \text{ or } 1, x \in GF(2^{2m})\}.$$

Of course this is just the value set $V(f_m^{(k)})$ with 0 omitted. We take $f_m^{(k)}(0) = 0$ even if k is negative, since $x^k = x^{2^n-1+k}$ in $GF(2^n)$.

2. Cases $k = 1$ and 2. For $k = 1$ and 2, we obtain not only a count of $S_m^{(k)}$ but also detailed information about the elements of these sets. We shall often use the fact that

$$(1+x)^{2^m-1} = \sum_{j=0}^{2^m-1} x^j \quad \text{for } x \in GF(2^{2m}), \tag{1}$$

which is true since all of the binomial coefficients $\binom{2^m-1}{j}$ are odd.

THEOREM 1. *Let τ generate the multiplicative group of nonzero elements of $GF(2^{2m})$. The sequence*

$$a_j = \tau^j(1+\tau^j)^{2^m-1}, \qquad 1 \le j \le 2^{2m} - 2,$$

is made up of 2^m elements 1, which occur when $2^m - 1$ divides j, and one occurrence of each of the $2^{2m} - 2^m - 2$ elements of $GF(2^{2m})$ which are nonzero and are not (2^m+1)st roots of one.

COROLLARY. *For each $m \ge 1$, $|S_m^{(1)}| = 2^{2m} - 2^m - 1$.*

Proof. First we show that for nonzero x and y in $GF(2^{2m})$, we can have

$$x(1+x)^{2^m-1} = y(1+y)^{2^m-1}, \qquad x \neq y, \tag{2}$$

only if x and y are (2^m+1)st roots of one. Taking the (2^m+1)st power in (2) gives

$$x^{2^m+1} = y^{2^m+1}. \tag{3}$$

Now (1), (2), and (3) imply

$$x + x^2 + \cdots + x^{2^m+1} = y + y^2 + \cdots + y^{2^m+1}$$

or (if $x \neq 1$ and $y \neq 1$)

$$x(x^{2^m+1}+1)(x+1)^{-1} = y(y^{2^m+1}+1)(y+1)^{-1}. \tag{4}$$

By (3), if $x^{2^m+1} \neq 1$ then (4) implies $x = y$.

Hence if (2) holds, then both x and y are (2^m+1)st roots of one. In that case we have (for $x \neq 1$)

$$x(1+x)^{2^m-1} = x(x^{2^m}+1)(x+1)^{-1} = (x^{2^m+1}+x)(x+1)^{-1} = 1.$$

Thus a 1 occurs in the sequence a_j exactly when τ^j is a (2^m+1)st root of one, i.e., when 2^m-1 divides j.

Finally, it is easy to see that if x is not a (2^m+1)st root of one, then neither is $x(1+x)^{2^m-1}$. This completes the proof of Theorem 1.

THEOREM 2. *Let τ generate the multiplicative group of nonzero elements of $GF(2^{2m})$. The sequence*

$$a_j = \tau^{2j}(1+\tau^j)^{2^m-1}, \quad 1 \le j \le 2^{2m}-2,$$

is made up of one occurrence of each of the 2^m (2^m+1)st roots of one other than 1; one occurrence of each of the 2^m-2 elements of $GF(2^m)$ other than 0 or 1; and two occurrences of those $2^{2m-1}-2^m$ elements of $GF(2^{2m})$ which are values of $f_m^{(2)}(x)$ for x not in $GF(2^m)$ and not a (2^m+1)st root of 1. In these last cases we have

$$f_m^{(2)}(x) = f_m^{(2)}(y) \quad \text{for } y = (x^{2^m+1}+x)(x+1)^{-1} \neq x.$$

COROLLARY. *For each $m \ge 1$, $|S_m^{(2)}| = 2^{2m-1}+2^m-2$.*

Proof. We must analyze the consequences of assuming

$$x^2(1+x)^{2^m-1} = y^2(1+y)^{2^m-1}, \qquad x \neq y. \tag{5}$$

Taking the (2^m+1)st power in (5) gives $x^{2(2^m+1)} = y^{2(2^m+1)}$ and so

$$x^{2^m+1} = y^{2^m+1}. \tag{6}$$

Now (1), (5), and (6) imply

$$x^2 + x^3 + \cdots + x^{2^m} = y^2 + y^3 + \cdots + y^{2^m}$$

or $(x^{2^m+1}+x^2)(x+1)^{-1} = (y^{2^m+1}+y^2)(y+1)^{-1}$. Crossmultiplying in this last equation and using (6) give

$$x^2 + y^2 = (x+y)x^{2^m+1} + (x+y)xy.$$

Now dividing by $x+y$ gives $x+y = x^{2^m+1}+xy$, so for $x \neq 1$ we have

$$y = (x^{2^m+1}+x)(x+1)^{-1} = x(x^{2^m}+1)(x+1)^{-1}. \tag{7}$$

Equation (7) is inconsistent with our assumption that $x \neq y$ if and only if $(x^{2^m}+1)(x+1)^{-1} = 1$, which is equivalent to $x^{2^m} = x$, i.e., $x \in GF(2^m)$. Since

$$f_m^{(2)}(x) = x^2(x^{2^m}+1)(x+1)^{-1} = x^2 \quad \text{for } x \in GF(2^m),$$

this shows that the 2^m-2 elements of $GF(2^m)$ other than 0 and 1 each occur once as values of a_j, when τ^j is in $GF(2^m)$.

We have assumed that (5) and (7) hold with $x \neq 1$, which implies $y \neq 1$. Thus the cases where $x^{2^m+1} = 1$ (and so $y = 1$ in (7)) are not covered. In these cases

$$f_m^{(2)}(x) = x(x^{2^m+1}+x)(x+1)^{-1} = x,$$

so the 2^m solutions $x \neq 1$ of $x^{2^m+1} = 1$ each occur once as values of a_j. This completes the proof of the assertions in Theorem 2.

To prove our results for other values of k, we use some known results on the cross-correlation functions for some binary m-sequences. The facts we need are developed in the next section.

3. Known results on crosscorrelation functions. A binary sequence generated by a linear recursion of order n and having the maximum period 2^n-1 is called a binary m-sequence (here "m" stands for "maximum period"). Crosscorrelation properties of such sequences have been studied extensively because of their importance in communications applications. In 1980, a survey of results in this area was given by Sarwate and Pursley [9].

It is well known that if $\{a_j : j = 1, 2, \ldots\}$ and $\{b_j : j = 1, 2, \ldots\}$ are two binary m-sequences with period 2^n-1, then there exists an integer d relatively prime to 2^n-1 and an integer t such that $b_{j+t} = a_{dj}$ for all j. Thus the study of the crosscorrelation between two binary m-sequences involves the functions

$$C_d(t) = \sum_{j=0}^{2^n-2} (-1)^{a_{j+t}+a_{dj}} \qquad (0 \le t \le 2^n - 2). \tag{8}$$

It will be convenient for us to define the crosscorrelation function $F_{d,n}(t) = F_d(t)$ of order n by

$$F_d(t) = C_d(t) + 1 \qquad (0 \le t \le 2^n - 2).$$

The set of values taken on by $F_d(t)$ for $0 \le t \le 2^n - 2$, together with a count of the number of times each values occurs, is called the crosscorrelation spectrum. It is well known (see [9, p. 602]) that the crosscorrelation spectrum depends only on d and not on the choice of the m-sequence $\{a_j\}$.

For later use, we introduce the trace function Tr_1^n from $GF(2^n)$ to $GF(2)$ by

$$Tr_1^n(x) = x + x^2 + x^{2^2} + \cdots + x^{2^{n-1}},$$

where $x \in GF(2^n)$. If the field $GF(2^n)$ is understood, we may write Tr in place of Tr_1^n. We remark that the crosscorrelation function is given by

$$F_{d,n}(t) = \sum_{x \in GF(2^n)} (-1)^{Tr(x\tau^t + x^d)}, \tag{9}$$

where τ generates the multiplicative group of nonzero elements of $GF(2^n)$ (to see this, take $a_j = Tr(\tau^j)$ in (8) and let $x = \tau^j$).

We prepare for the proof of our first theorem on crosscorrelation functions by giving three elementary lemmas.

LEMMA 1. *If α is an element of $GF(2^n)$, then*

$$\sum_{x \in GF(2^n)} (-1)^{Tr(\alpha x)} = \begin{cases} 0 & \text{if } \alpha \ne 0, \\ 2^n & \text{if } \alpha = 0. \end{cases}$$

Proof. The result follows from the fact that half of the elements of $GF(2^n)$ have trace 0 and the other half have trace 1.

LEMMA 2. *Every nonzero element x in $GF(2^{2m})$ can be represented uniquely as $x = \alpha\beta$, where α is in $GF(2^m)$ and β is a (2^m+1)st root of one in $GF(2^{2m})$.*

Proof. We let $\alpha = x^{2^{m-1}(2^m+1)}$ and $\beta = x^{2^{m-1}(2^m-1)}$.

LEMMA 3. *If α is in $GF(2^m)$ and β is in $GF(2^{2m})$, then*

$$Tr_1^{2m}(\alpha\beta) = Tr_1^m(\alpha(\beta + \beta^{2^m})).$$

Proof. We have

$$Tr_1^{2m}(\alpha\beta) = \sum_{j=0}^{2m-1} (\alpha\beta)^{2^j} = \sum_{j=0}^{m-1} (\alpha\beta)^{2^j} + \sum_{j=0}^{m-1} (\alpha\beta)^{2^{m+j}}$$
$$= \sum_{j=0}^{m-1} (\alpha(\beta+\beta^{2^m}))^{2^j} = Tr_1^m(\alpha(\beta+\beta^{2^m})).$$

The following theorem and proof are given in the thesis of Niho [8, pp. 40–41] under the supervision of L. R. Welch. Apparently the theorem was never published, so we repeat the proof here for the reader's convenience.

THEOREM 3. *Let τ generate the multiplicative group of nonzero elements of $GF(2^{2m})$. If $n = 2m$, d is relatively prime to $2^n - 1$, $d \equiv 2^r \bmod 2^m - 1$ for some $r (0 \le r \le m-1)$ and $d \equiv s \bmod 2^m + 1$, then*

$$F_{d,n}(t) = 2^m(N(\mu) - 1), \tag{10}$$

where $\mu = \tau^t$ and $N(\mu)$ is the number of distinct solutions x in $GF(2^{2m})$ to the system of equations

$$\mu x + x^{2^{-r}s} + \mu^{2^m} x^{-1} + x^{-2^{-r}s} = 0, \qquad x^{2^m+1} = 1. \tag{11}$$

Proof. Given $x \neq 0$ in $GF(2^{2m})$, let $x = \alpha\beta$ be the representation in Lemma 2; then we can write (9) as

$$F_{d,n}(t) = 1 + \sum_{\substack{\beta \in GF(2^{2m}) \\ \beta^{2^m+1}=1}} \sum_{\substack{\alpha \in GF(2^m) \\ \alpha \neq 0}} (-1)^{Tr(\alpha\beta\mu + \alpha^d \beta^d)}. \tag{12}$$

By our hypotheses, we have (using $Tr(x^2) = Tr(x)$)

$$Tr(\alpha\beta\mu + \alpha^d\beta^d) = Tr(\alpha\beta\mu + (\alpha^{2^r}\beta^s)^{2^{2m-r}}) = Tr(\alpha\beta\mu + \alpha\beta^{2^{-r}s}).$$

Substituting this into (12) and introducing terms with $\alpha = 0$ into the inner sum gives

$$F_{d,n}(t) = -2^m + \sum_{\substack{\beta \in GF(2^{2m}) \\ \beta^{2^m+1}=1}} \sum_{\alpha \in GF(2^m)} (-1)^{Tr(\alpha\beta\mu + \alpha\beta^{2^{-r}s})}. \tag{13}$$

By Lemma 3, the trace in (13) is

$$Tr_1^{2m}(\alpha(\beta\mu + \beta^{2^{-r}s})) = Tr_1^m(\alpha(\beta\mu + \beta^{2^{-r}s} + \mu^{2^m}\beta^{-1} + \beta^{-2^{-r}s})).$$

Substituting this into (13) and applying Lemma 1 to the inner sum give the desired formula (10).

LEMMA 4. *If d and d_1 are positive integers which satisfy $dd_1 \equiv 2^r \bmod 2^n - 1$ for some $r \ge 0$, then the functions $F_{d,n}(t)$ and $F_{d_1,n}(t)$ have the same crosscorrelation spectra.*

Proof. A computation gives $F_{d,n}(t) = F_{d_1,n}(-dt)$.

Later we shall require the following theorems which evaluate particular crosscorrelation spectra. For these theorems, it is convenient to extend the domain of $F_{d,n}(t)$ to all of $GF(2^n)$ by defining

$$F_{d,n}(-\infty) = 0.$$

TABLE 1

$N(\mu)$	Value of $F_d(t)$	Number of times given value occurs: m odd	m even
4	$3 \cdot 2^m$	$\frac{1}{3}\,(2^{2m-3} - 2^{m-2})$	$\frac{1}{3}\,(2^{2m-3} - 2^{m-1})$
3	2^{m+1}	2^{m-1}	2^{m-1}
2	2^m	$2^{2m-2} - 2^{m-1}$	2^{2m-2}
1	0	$\frac{1}{3}\,(2^{2m} + 5 \cdot 2^{m-1})$	$\frac{1}{3}\,(2^{2m} + 2^{m-1})$
0	-2^m	$3(2^{2m-3} - 2^{m-2})$	$3 \cdot 2^{2m-3} - 2^{m-1}$

TABLE 2

$N(\mu)$	Value of $F_d(t)$	Number of times given value occurs
3	2^{m+1}	$\frac{1}{3}\,(2^{2m-1} - 2^{m-1})$
2	2^m	2^m
1	0	$2^{2m-1} - 2^{m-1}$
0	-2^m	$\frac{1}{3}\,(2^{2m} - 2^m)$

THEOREM 4. *Let $n = 2m$ with $m \geq 2$, and let $d = 2^m + 3$. Then the crosscorrelation spectrum for $F_{d,n}(t)$ is given by Table* 1. *Here $N(\mu)$ is the number of solutions of the system* (11) *with $r = 2 = s$.*

Proof. Niho [8, Thm. 3.8, p. 51] proved that when $d = 2^m+3$, $N(\mu) \leq 4$ must hold in Theorem 3 above. Niho [8, p. 55] also conjectured the crosscorrelation spectrum as given above, and Helleseth [4, Thm. 4.8, pp. 221–222] proved this conjecture. Note that for $m = 2$, $F_d(t) = 12$ occurs zero times. In every other case $F_d(t)$ actually takes on five different values.

THEOREM 5. *Let $n = 2m$ with m even and $m \geq 2$. Let $d = 2^{m+1} - 1$. Then the crosscorrelation spectrum for $F_{d,n}(t)$ is given by Table* 2. *Here $N(\mu)$ is the number of solutions of the system* (11) *with $r = 0$ and $s = -3$.*

Proof. This is a result of Niho [8, Thm. 3.6, p. 43].

We remark that the proofs of Theorems 4 and 5 involve detailed analyses of the solutions of certain equations over finite fields.

4. The cases $k = -2$ and 4. For $k = -2$ and 4, we are unable to obtain the kind of specific information about the elements of the sets $S_m^{(k)}$ that was achievable for $k = 1$ and 2 (see section 2 above); however, we can obtain an exact count for these sets $S_m^{(k)}$.

THEOREM 6. *For $k = -2$ and 4, we have for each $m \geq 2$*

$$|S_m^{(-2)}| = |S_m^{(4)}| = 5 \cdot 2^{2m-3} + 2^{m-1} - 2 \quad \textit{if } m \textit{ is even}$$

and

$$|S_m^{(-2)}| = |S_m^{(4)}| = 5 \cdot 2^{2m-3} + \frac{1}{3}(2^{m-2} - 2) - 1 \quad \textit{if } m \textit{ is odd.}$$

For later reference, it is convenient to have the following trivial lemma.

LEMMA 5. *If $\beta \in GF(2^{2m})$ and $\beta^{2^m+1} = 1$, then $\beta(1+\beta)^{2^m-1} = 1$.*

Proof. We have

$$\beta(1+\beta)^{2^m-1} = \beta(\beta^{2^m}+1)(\beta+1)^{-1} = 1,$$

where the first equality follows from (1).

In proving Theorem 6, we shall deal first with the case $k = 4$. We take $d = 3\cdot 2^m - 1$ in Theorem 3, so $r = 1$, $s = -4$, and the system (11) becomes

$$\mu x + x^{-2} + \mu^{2^m} x^{-1} + x^2 = 0, \qquad x^{2^m+1} = 1$$

or

$$x^4 + \mu x^3 + \mu^{2^m} x + 1 = 0, \qquad x^{2^m+1} = 1. \tag{14}$$

Suppose that (14) has a solution $x = \beta$ for a given μ, and define γ by $\mu = \beta\gamma$. Then, provided that $\gamma \neq 1$, the first equation in (14) gives, using (1),

$$\beta^4 = (\gamma^{2^m}+1)(\gamma+1)^{-1} = (1+\gamma)^{2^m-1},$$

so

$$\mu^4 = \beta^4\gamma^4 = \gamma^4(1+\gamma)^{2^m-1} \in S_m^{(4)}.$$

Conversely, given $\gamma \in GF(2^{2m})$ we can define μ by

$$\mu^4 = \gamma^4(1+\gamma)^{2^m-1} \in S_m^{(4)}$$

and β by $\beta = \mu/\gamma$. Then, provided $\gamma \neq 1$,

$$\beta^4 = (1+\gamma)^{2^m-1} = (\gamma^{2^m}+1)(\gamma+1)^{-1},$$

and the system (14) is satisfied by $x = \beta$, because $(1+\gamma)^{2^m-1}$ (and hence its unique fourth root β) is clearly a (2^m+1)st root of 1 in $GF(2^{2m})$. If we define

$$H_m = \{\mu : \mu \in GF(2^{2m}) \text{ and the system (14) has at least one solution}\},$$

then we can establish the following lemma.

LEMMA 6. *For each $m \geq 2$,*

$$|H_m| - |S_m^{(4)}| = 2 \quad \textit{if } m \textit{ is even}$$

and

$$|H_m| - |S_m^{(4)}| = \frac{1}{3}(2^{m+1}+2) + 1 \quad \textit{if } m \textit{ is odd}.$$

Proof. By the argument in the paragraph preceding the lemma, there is a one-to-one correspondence between H_m and $S_m^{(4)}$ except that 0, and possibly some elements $\mu = \beta\gamma$ in H_m which have $\gamma = 1$, are missing from $S_m^{(4)}$. In fact we have shown that, apart from the missing elements just mentioned, $S_m^{(4)}$ is made up of fourth powers of elements of H_m. Thus, the elements of H_m that are not in $S_m^{(4)}$ are 0 and also those (2^m+1)st roots of 1 which are not in $S_m^{(4)}$.

If β is a (2^m+1)st root of 1 and $f_m^{(4)}(x) = \beta$, then x is also a (2^m+1)st root of 1. Also, by Lemma 5

$$\beta^{2^m+1} = 1 \text{ implies } \beta^4(1+\beta)^{2^m-1} = \beta^3.$$

Hence

$$S_m^{(4)} \cap \{\beta : \beta^{2^m+1} = 1\} = \{\beta^3 : \beta^{2^m+1} = 1\}. \tag{15}$$

Since the set on the right-hand side in (15) is $\{\beta : \beta^{(2^m+1)/3} = 1\}$, this proves Lemma 6 for m odd (the elements of H_m not in $S_m^{(4)}$ are 0 and the $(2^{m+1}+2)/3$ (2^m+1)st roots of 1 which are not in the set just mentioned). For m even, it is clear that 1 is not in $S_m^{(4)}$, so the set on the left-hand side of (15) is simply the set of all (2^m+1)st roots of 1 except 1. This proves Lemma 6 for m even (the elements of H_m not in $S_m^{(4)}$ are just 0 and 1).

The system (14) was obtained by taking $d = 3 \cdot 2^m - 1$ in Theorem 3. Since

$$(3 \cdot 2^m - 1)(2^m + 3) \equiv 2^{m+3} \bmod 2^{2m} - 1,$$

it follows from Lemma 4 that Table 1 is also valid for $d = 3 \cdot 2^m - 1$. Hence $|H_m|$ in Lemma 6 is simply 2^{2m} minus the entry for $N(\mu) = 0$ in Table 1. If we plug in those values for $|H_m|$, Lemma 6 immediately gives Theorem 6 for $k = 4$.

Now we turn to the case $k = -2$ of Theorem 6. We take $d = 2^m + 3$ in Theorem 3, so $r = 2$, $s = 2$, and the system (11) becomes

$$\mu x + x^{\frac{1}{2}} + \mu^{2m} x^{-1} + x^{-\frac{1}{2}} = 0, \qquad x^{2^m+1} = 1$$

or (squaring the first equation and changing notation by replacing μ^2 by μ)

$$\mu x^4 + x^3 + x + \mu^{2^m} = 0, \qquad x^{2^m+1} = 1. \tag{16}$$

Suppose that (16) has a solution $x = \beta$ for a given μ, and define γ by $\mu = \beta^{-1}\gamma$. Then, provided that $\gamma \neq 1$, the first equation in (16) gives, using (1),

$$\beta^2 = (\gamma^{2^m} + 1)(\gamma + 1)^{-1} = (1 + \gamma)^{2^m - 1},$$

so

$$\mu^{-2} = \beta^2 \gamma^{-2} = \gamma^{-2}(1 + \gamma)^{2^m - 1} \in S_m^{(-2)}.$$

If we define

$$G_m = \{\mu : \mu \in GF(2^{2m}) \text{ and the system (16) has at least one solution}\},$$

then by the above remarks there is a one-to-one correspondence between G_m and $S_m^{(-2)}$ except that 0, and possibly some elements $\mu = \beta^{-1}\gamma$ in G_m which have $\gamma = 1$, are missing from $S_m^{(-2)}$. In fact apart from the missing elements, $S_m^{(-2)}$ is made up of squares of reciprocals of elements of G_m. This enables us to prove the following lemma.

LEMMA 7. *For each $m \geq 2$,*

$$|G_m| - |S_m^{(-2)}| = 2 \quad \textit{if } m \textit{ is even}$$

and

$$|G_m| - |S_m^{(-2)}| = \frac{1}{3}\,(2^{m+1} + 2) + 1 \quad \textit{if } m \textit{ is odd}.$$

Proof. The argument is very similar to the proof of Lemma 6. By Lemma 5,

$$\beta^{2^m+1} = 1 \text{ implies } \beta^{-2}(1+\beta)^{2^m-1} = \beta^{-3}.$$

Hence (15) holds with $S_m^{(-2)}$ in place of $S_m^{(4)}$. Now the proof of Lemma 7 is completed as in the proof of Lemma 6.

The system (16) was obtained by taking $d = 2^m + 3$ in Theorem 3. Hence, as before we can evaluate G_m by using Theorem 4 and we see that $|G_m| = |H_m|$. Therefore, by Lemmas 6 and 7 we have $|S_m^{(-2)}| = |S_m^{(4)}|$ for $m \geq 2$ and the proof of Theorem 6 is complete.

5. The cases $k = -1$ and 3. We are able to get an exact count of $S_m^{(-1)}$ when m is even. The corresponding problem with m odd seems to be more difficult, for reasons which we will examine below.

THEOREM 7. *For each even $m \geq 2$, we have*

$$|S_m^{(-1)}| = \frac{1}{3}\,(2^{2m+1} + 2^m) - 2.$$

To begin the proof of Theorem 7, we take $d = 2^{m+1} - 1$ in Theorem 3 (note d is relatively prime to $2^{2m} - 1$ since m is even), so $r = 0$, $s = -3$, and the system (11) becomes

$$\mu x + x^{-3} + \mu^{2^m} x^{-1} + x^3 = 0, \qquad x^{2^m+1} = 1$$

or (multiplying the first equation by x^3, changing notation by replacing μ by μ^2, and taking the square root of the first equation)

$$x^3 + \mu x^2 + \mu^{2^m} x + 1 = 0, \qquad x^{2^m+1} = 1. \tag{17}$$

We define

$$g_\mu(x) = g(x) = x^3 + \mu x^2 + \mu^{2^m} x + 1 \qquad (\mu \in GF(2^{2m}))$$

and

$$h_\xi(x) = h(x) = \xi x^3 + x^2 + x + \xi^{2^m} \qquad (\xi \in GF(2^{2m})).$$

Our next lemma shows that when m is even, the system (17) involving $g_\mu(x)$ and the system

$$\xi x^3 + x^2 + x + \xi^{2^m} = 0, \quad x^{2^m+1} = 1 \tag{18}$$

involving $h_\xi(x)$ have identical patterns of numbers of solutions. To state the lemma, we define

$$N_j^{(g)}(m) = N_j^{(g)} = |\{\mu \in GF(2^{2m}) : (17) \text{ has exactly } j \text{ solutions } x \in GF(2^{2m})\}|$$

and

$$N_j^{(h)}(m) = N_j^{(h)} = |\{\xi \in GF(2^{2m}) : (18) \text{ has exactly } j \text{ solutions } x \in GF(2^{2m})\}|.$$

LEMMA 8. *If m is even, then $N_j^{(g)}(m) = N_j^{(h)}(m)$ for all j, and $N_j^{(g)}(m)$ is nonzero if and only if $0 \leq j \leq 3$.*

Proof. If we let $x = \mu^{2^m-1}y$ ($\mu \neq 0$) in $g_\mu(x)$, then we obtain

$$\mu^{2^m-2}y^3 + y^2 + y + \mu^{-2^{m+1}+1} = 0.$$

Since $(\mu^{2^m-2})^{2^m} = \mu^{-2^{m+1}+1}$, we can define $\xi = \mu^{2^m-2}$ and get

$$h_\xi(y) = \xi y^3 + y^2 + y + \xi^{2^m} = 0.$$

Since $x^{2^m+1} = (\mu^{2^m-1}y)^{2^m+1} = y^{2^m+1}$ and

$$gcd(2^m - 2, 2^{2m} - 1) = \begin{cases} 1, m \text{ even}, \\ 3, m \text{ odd}, \end{cases}$$

for m even $\xi = \mu^{2^m-2}$ gives a one-to-one correspondence between ξ and μ, and the systems (17) and (18) have exactly the same number of solutions except possibly when $\mu = 0$ or $\xi = 0$. It is easy to see that for m even, (17) and (18) each have exactly one solution ($x = 1$) when $\mu = \xi = 0$. Thus $N_j^{(g)}(m) = N_j^{(h)}(m)$ holds for all j when m is even.

For the final assertion in the lemma we appeal to Theorem 5, which says that $N_j^{(g)}(m)$ is nonzero for m even if and only if $0 \leq j \leq 3$.

Now we can complete the proof of Theorem 7. Suppose that (18) has a solution $x = \beta$ for a given ξ, and define γ by $\xi = \beta^{-1}\gamma$. Then, provided that $\gamma \neq 1$, the first equation in (18) gives, using (1),

$$\beta = (\gamma^{2^m} + 1)(\gamma + 1)^{-1} = (1 + \gamma)^{2^m-1},$$

so

$$\xi^{-1} = \beta\gamma^{-1} = \gamma^{-1}(1 + \gamma)^{2^m-1} \in S_m^{(-1)}.$$

If we define

$$I_m = \{\xi : \xi \in GF(2^{2m}) \text{ and the system (18) has at least one solution}\},$$

then by the above remarks there is a one-to-one correspondence between I_m and $S_m^{(-1)}$ except that 0, 1, and possibly some other elements $\xi = \beta^{-1}\gamma$ in I_m which have $\gamma = 1$, are missing from $S_m^{(-1)}$. In fact, we can prove in our next lemma that the only missing elements are 0 and 1.

LEMMA 9. *For each $m \geq 1$,*

$$|I_m| - |S_m^{(-1)}| = 2.$$

Proof. The argument is very similar to the proofs of Lemmas 6 and 7. Here there is no distinction between m even and m odd, because Lemma 5 gives

$$\beta^{2^m+1} = 1 \text{ implies } \beta^{-1}(1 + \beta)^{2^m-1} = \beta^{-2};$$

hence for all m, $S_m^{(-1)}$ contains all of the $(2^m + 1)$st roots of 1 except 1.

We know from Theorem 5 that for m even

$$|I_m| = 2^{2m} - N_0^{(g)}(m) = 2^{2m} - \frac{1}{3}\,(2^{2m} - 2^m).$$

TABLE 3

i	$N_i^{(g)}(m)$	$N_i^{(h)}(m)$
3	$\frac{1}{3}\,(2^{2m-1}-2^{m-1}+2)$	$\frac{1}{3}\,(2^{2m-1}-2^{m-1}-1)$
2	2^m-2	2^m
1	$2^{2m-1}-2^{m-1}+2$	$2^{2m-1}-2^{m-1}+1$
0	$\frac{1}{3}\,(2^{2m}-2^m-2)$	$\frac{1}{3}\,(2^{2m}-2^m-2)$

Now Lemma 9 gives Theorem 7.

We make the following conjecture.

CONJECTURE 1. *For each odd $m \geq 1$, we have Table 3.*

By Lemma 9, Conjecture 1 implies the following conjecture.

CONJECTURE 2. *For each odd $m \geq 1$, we have*

$$|S_m^{(-1)}| = \frac{1}{3}\,(2^{2m+1}+2^m-4).$$

Of course, to prove Conjecture 2 it would be enough to prove the formula for $N_0^{(g)}(m)$ given in Conjecture 1; we would not need the rest of Conjecture 1. Unfortunately, we can prove only the following lemma.

LEMMA 10. *For each odd $m \geq 1$, we have*

$$N_2^{(g)}(m) = 2^m - 2 \quad \textit{and} \quad N_2^{(h)}(m) = 2^m.$$

Proof. Niho [8, pp. 44–46] proved $N_2^{(g)}(m) = 2^m$ for even $m \geq 2$ by a direct count of the number of μ for which $g_\mu(x) = 0$ can have a repeated root of multiplicity 2. Analogous arguments suffice to prove Lemma 10. We omit the rather tedious details.

We can also prove that if m is odd, then 3 divides $N_3^{(g)}(m) - 1$ and $N_i^{(g)}(m)$ for $i = 0, 1, 2$ (all this follows from Conjecture 1); we omit the details since we make no use of the result.

Now we turn to the case $k = 3$, where we have the following conjecture.

CONJECTURE 3. *For each odd $m \geq 1$, $|S_m^{(3)}| = |S_m^{(-1)}|$.*

We show how this conjecture can be reduced to

$$N_0^{(g)}(m) = N_0^{(h)}(m) \quad \text{for odd } m \geq 1, \tag{19}$$

which is part of Conjecture 1.

Suppose that (17) has a solution $x = \beta$ for a given μ and define γ by $\mu = \beta\gamma$. Then, provided that $\gamma \neq 1$, the first equation in (17) gives, using (1),

$$\beta^3 = (\gamma^{2^m}+1)(\gamma+1)^{-1} = (1+\gamma)^{2^m-1},$$

so

$$\mu^3 = \beta^3\gamma^3 = \gamma^3(1+\gamma)^{2^m-1} \in S_m^{(3)}.$$

If we define

$$J_m = \{\mu : \mu \in GF(2^{2m}) \text{ and the system (17) has at least one solution } x\},$$

then we can prove

$$|J_m| - |S_m^{(3)}| = 2 \quad \text{for odd } m \geq 1. \tag{20}$$

This follows because for m odd, $\mu^3 = \beta^3\gamma^3$ has a unique cube root $\mu = \beta\gamma$ in $GF(2^{2m})$. Therefore (as in the proofs of Lemmas 6 and 7) there is a one-to-one correspondence between J_m and $S_m^{(3)}$ (made up of cubes of elements of J_m), except that 0 and 1 are in J_m but not in $S_m^{(3)}$.

If (19) is true, then $|I_m| = |J_m|$ for odd $m \geq 1$. Now Conjecture 3 follows from (20) and Lemma 9.

Conjecture 3 is certainly false for even m, since then 3 divides $2^m - 1$ and the one-to-one correspondence used to prove (20) is certainly false. For m even, every element $\gamma^3(1+\gamma)^{2^m-1}$ of $S_m^{(3)}$ is a $\frac{1}{3}(2^{2m}-1)$st root of 1 in $GF(2^{2m})$. It is reasonable to conjecture that all of these roots of 1 are actually in $S_m^{(3)}$, which gives our last conjecture.

CONJECTURE 4. *For each even $m \geq 2$, $|S_m^{(3)}| = \frac{1}{3}(2^{2m} - 1)$.*

OPTIMAL UPWARD PLANARITY TESTING OF SINGLE-SOURCE DIGRAPHS*

PAOLA BERTOLAZZI†, GIUSEPPE DI BATTISTA‡, CARLO MANNINO§, AND ROBERTO TAMASSIA¶

Abstract. A digraph is upward planar if it has a planar drawing such that all the edges are monotone with respect to the vertical direction. Testing upward planarity and constructing upward planar drawings is important for displaying hierarchical network structures, which frequently arise in software engineering, project management, and visual languages. In this paper we investigate upward planarity testing of single-source digraphs; we provide a new combinatorial characterization of upward planarity and give an optimal algorithm for upward planarity testing. Our algorithm tests whether a single-source digraph with n vertices is upward planar in $O(n)$ sequential time, and in $O(\log n)$ time on a CRCW PRAM with $n \log\log n / \log n$ processors, using $O(n)$ space. The algorithm also constructs an upward planar drawing if the test is successful. The previously known best result is an $O(n^2)$-time algorithm by Hutton and Lubiw [*Proc. 2nd ACM–SIAM Symposium on Discrete Algorithms*, SIAM, Philadelphia, 1991, pp. 203–211]. No efficient parallel algorithms for upward planarity testing were previously known.

1. Introduction.

The upward planarity of digraphs is a fundamental issue in the area of graph drawing and has been extensively investigated. A digraph is upward planar if it has a planar upward drawing, i.e., a planar drawing such that all the edges are monotone with respect to the vertical direction (see Figure 1a). Planarity and acyclicity are necessary but not sufficient conditions for upward planarity, as shown in Figure 1b.

Testing upward planarity and constructing upward planar drawings are important for displaying hierarchical network structures, which frequently arise in a wide variety of areas. Key areas of application include software engineering, project management, and visual languages. Especially significant in a number of applications are single-source digraphs, such as subroutine-call graphs, is-a hierarchies, and organization charts. Also, upward planarity of single-source digraphs has deep combinatorial

*Received by the editors December 6, 1994; accepted for publication (in revised form) January 4, 1996. An extended abstract of this paper was presented at the *First European Symposium on Algorithms* (ESA '93), Bonn, Germany, Lecture Notes in Comput. Sci. 726, Springer-Verlag, New York, 1993, pp. 37–48. This research was performed in part while Roberto Tamassia was visiting IASI–CNR. implications in the theory of ordered sets. Namely, the orders defined by the transitive closure of upward planar single-source digraphs have bounded dimension [34] so that they can be compactly represented.

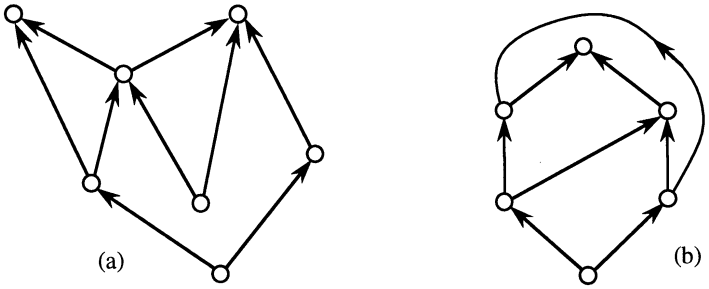

FIG. 1. *Examples of planar acyclic digraphs:* (a) *upward planar;* (b) *not upward planar.*

A survey on algorithms for planarity testing and graph drawing can be found in [7]. Previous work on upward planarity is as follows.

Combinatorial results on upward planarity for covering digraphs of lattices were first given in [22, 26]. Further results on the interplay between upward planarity and ordered sets are surveyed by Rival [30]. Lempel, Even, and Cederbaum [23] relate the planarity of biconnected undirected graphs to the upward planarity of st-digraphs. A combinatorial characterization of upward planar digraphs is provided in [21, 9]; namely, a digraph is upward planar if and only if it is a subgraph of a planar st-digraph.

Di Battista, Tamassia, and Tollis [9, 12] give algorithms for constructing upward planar drawings of st-digraphs and investigate area bounds and symmetry display. Tamassia and Vitter [32] show that the above drawing algorithms can be efficiently parallelized. Upward planar drawings of trees and series-parallel digraphs are studied in [29, 31, 6, 13, 15] and [1, 2], respectively.

In [8] it is shown that for the special case of bipartite digraphs, upward planarity is equivalent to planarity. In [3, 4] a polynomial-time algorithm is given for testing the upward planarity of digraphs with a prescribed embedding. Thomassen [33] characterizes the upward planarity of single-source digraphs in terms of forbidden circuits. Hutton and Lubiw [19] combine Thomassen's characterization with a decomposition scheme to test the upward planarity of an n-vertex single-source digraph in $O(n^2)$ time. Very recently, Papakostas [25] has given a polynomial-time algorithm for upward planarity testing of outerplanar digraphs, and Garg and Tamassia [16] have shown that upward planarity testing is NP-complete for general digraphs.

In this paper we investigate upward planarity testing of single-source digraphs. Our main results are summarized as follows:

- We provide a new combinatorial characterization of upward planarity within a given embedding in terms of a forest embedded in the face-vertex incidence graph.
- We reduce the upward planarity testing problem to that of finding a suitable orientation of a tree that synthetically represents the decomposition of a graph into its triconnected components.
- We show that the above combinatorial results yield an optimal $O(n)$-time upward planarity testing algorithm for single-source digraphs. The algorithm also constructs an upward planar drawing if the test is successful. Our algorithm is an improvement over the previously known best result [19] by an $O(n)$ factor in the time

complexity. Our algorithm is easy to implement and does not require any complex data structure.

- We efficiently parallelize the above algorithm to achieve $O(\log n)$ time on a CRCW PRAM with $n \log\log n / \log n$ processors. Hence, we provide the first efficient parallel algorithm for upward planarity testing. Our parallel time complexity is the same as that of the best parallel algorithm for planarity testing [28, 27].
- Finally, as a side effect we provide an optimal parallel algorithm for testing acyclicity of a planar n-vertex single-source digraph in $O(\log n)$ time with $n/\log n$ processors on an EREW PRAM.

Open problems include the following:

- devising efficient dynamic algorithms for upward planarity testing of single-source digraphs;
- exploring the area requirements of upward planar drawings of single-source digraphs;
- reducing the time complexity of upward planarity testing of planar digraphs with a prescribed embedding; and
- identifying additional classes of planar digraphs for which upward planarity can be tested in polynomial time.

The remainder of this paper is organized as follows. Section 2 contains preliminary definitions and results. The problem of testing upward planarity for planar single-source digraphs with a prescribed embedding is investigated in section 3. A combinatorial characterization of upward planarity for single-source digraphs is given in sections 4, 5, and 6. The complete upward planarity testing algorithm for single-source digraphs is presented in section 7. Also in section 7, two examples of application of the algorithm are illustrated. In the first example the considered digraph is not upward drawable; in the second example an upward drawable digraph is considered.

2. Preliminaries. In this section we recall some terminology and basic results on upward planarity. We also review the SPQR-tree, introduced in [10, 11], and the combinatorial characterization of upward planarity for embedded planar digraphs, shown in [3, 4]. We assume the reader's familiarity with planar graphs.

2.1. Drawings and embeddings. A drawing of a graph maps each vertex to a distinct point of the plane and each edge (u, v) to a simple Jordan curve with endpoints u and v. A *polyline* drawing maps each edge into a polygonal chain. A *straight-line* drawing maps each edge into a straight-line segment.

A drawing is planar if no two edges intersect except, possibly, at common endpoints. A graph is planar if it has a planar drawing. Two planar drawings of a planar graph G are equivalent if, for each vertex v, they have the same circular clockwise sequence of edges incident on v. Hence, the planar drawings of G are partitioned into equivalence classes. Each such class is called an *embedding* of G. An embedded planar graph is a planar graph with a prescribed embedding. A triconnected planar graph has a unique embedding up to a reflection. A planar drawing divides the plane into topologically connected regions delimited by circuits, called faces. The external face is the boundary of the unbounded region. Two drawings with the same embedding have the same faces. Hence, one can speak of the faces of an embedding.

Let G be a digraph, i.e., a directed graph. A *source* of G is a vertex without incoming edges. A *sink* of G is a vertex without outgoing edges. An *internal vertex* of G has both incoming and outgoing edges. An *sT-digraph* is an acyclic digraph with exactly one source.

Let f be a face of planar drawing (or embedding) of a digraph. A *source-switch* (*sink-switch*) of f is a source (sink) of f. Note that a *source-switch* (*sink-switch*) is not necessarily a source (sink) of G.

An *upward* drawing of a digraph is such that all the edges are represented by directed curves increasing monotonically in the vertical direction. A digraph has an upward drawing if and only if it is acyclic. A digraph is *upward planar* if it admits a planar upward drawing. Note that a planar acyclic digraph does not necessarily have a planar upward drawing, as shown in Fig. 1b. An upward planar digraph also admits a planar upward straight-line drawing [21, 9]. A planar st-digraph is a planar digraph with exactly one source s and one sink t, connected by edge (s,t). A digraph is upward planar if and only if it is a subgraph of a planar st-digraph [21, 9].

A planar embedding of a digraph is *candidate* if the incoming (outgoing) edges around each vertex are consecutive. The planar embedding underlying an upward drawing is candidate.

An *upward embedding* of a digraph G is an embedding of G such that

- each source- and sink-switch of each face of G is labeled *small* or *large*;
- there exists a planar straight-line upward drawing of G where each switch labeled *small* corresponds to an angle with measure $< \pi$, and each switch labeled *large* has measure $> \pi$.

Finally, the following lemma is due to Hutton and Lubiw.

LEMMA 1 (see [19]). *If a digraph has a single source, then it is upward planar if and only if its biconnected components are upward planar.*

Due to this result, in the remainder of the paper we will consider only biconnected digraphs.

2.2. SPQR-trees. In the following we summarize SPQR-trees. For more details see [10, 11]. SPQR-trees are closely related to the classical decomposition of biconnected graphs into triconnected components [17].

Let G be a biconnected graph. A *split pair* of G is either a separation pair or a pair of adjacent vertices. A *split component* of a split pair $\{u,v\}$ is either an edge (u,v) or a maximal subgraph C of G such that C contains u and v, and $\{u,v\}$ is not a split pair of C. Note that a vertex w distinct from u and v belongs to exactly one split component of $\{u,v\}$.

Let $\{s,t\}$ be a split pair of G. A *maximal split pair* $\{u,v\}$ of G with respect to $\{s,t\}$ is a split pair of G distinct from $\{s,t\}$ such that, for any other split pair $\{u',v'\}$ of G, there exists a split component of $\{u',v'\}$ containing vertices u, v, s, and t.

Let $e(s,t)$ be an edge of G, called *reference edge*. The *SPQR-tree* $\mathcal{T}$ of G with respect to e describes a recursive decomposition of G induced by its split pairs. Tree $\mathcal{T}$ is a rooted ordered tree whose nodes are of four types: S, P, Q, and R. Each node μ of $\mathcal{T}$ has an associated biconnected multigraph, called the *skeleton* of μ, and denoted by *skeleton*(μ). Also, it is associated with an edge of the skeleton of the parent ν of μ, called the *virtual edge* of μ in *skeleton*(ν). Tree $\mathcal{T}$ is recursively defined as follows.

Trivial case. If G consists of exactly two parallel edges between s and t, then $\mathcal{T}$ consists of a single Q-node whose skeleton is G itself.

Parallel case. If the split pair $\{s,t\}$ has at least three split components $G_1,\ldots,G_k$ ($k \geq 3$), the root of $\mathcal{T}$ is a P-node μ. Graph *skeleton*(μ) consists of k parallel edges between s and t, denoted $e_1,\ldots,e_k$, with $e_1 = e$.

Series case. Otherwise, the split pair $\{s,t\}$ has exactly two split components, one of them is the reference edge e, and we denote with G' the other split component. If G' has cutvertices $c_1,\ldots,c_{k-1}$ ($k \geq 2$) that partition G into its blocks

$G_1, \ldots, G_k$, in this order from s to t, the root of $\mathcal{T}$ is an S-node μ. Graph *skeleton*(μ) is the cycle $e_0, e_1, \ldots, e_k$, where $e_0 = e$, $c_0 = s$, $c_k = t$, and e_i connects c_{i-1} with c_i $(i = 1, \ldots, k)$.

Rigid case. If none of the above cases applies, let $\{s_1, t_1\}, \ldots, \{s_k, t_k\}$ be the maximal split pairs of G with respect to $\{s, t\}$ $(k \geq 1)$, and for $i = 1, \ldots, k$, let G_i be the union of all the split components of $\{s_i, t_i\}$ except for the one containing the reference edge e. The root of $\mathcal{T}$ is an R-node μ. Graph *skeleton*(μ) is obtained from G by replacing each subgraph G_i with the edge e_i between s_i and t_i.

Except for the trivial case, μ has children $\mu_1, \ldots, \mu_k$ in this order such that μ_i is the root of the SPQR-tree of graph $G_i \cup e_i$ with respect to reference edge e_i $(i = 1, \ldots, k)$. Edge e_i is said to be the *virtual edge* of node μ_i in *skeleton*(μ) and of node μ in *skeleton*(μ_i). Graph G_i is called the *pertinent graph* of node μ_i, and of edge e_i.

The tree $\mathcal{T}$ so obtained has a Q-node associated with each edge of G, except the reference edge e. We complete the SPQR-tree by adding another Q-node, representing the reference edge e, and making it the parent of μ so that it becomes the root. Observe that we are defining SPQR-trees of graphs; however, the same definition can be applied to digraphs. An example of SPQR-tree is shown in Figure 2.

Let μ be a node of $\mathcal{T}$. We have the following:

- if μ is an R-node, then *skeleton*(μ) is a triconnected graph;
- if μ is an S-node, then *skeleton*(μ) is a cycle;
- if μ is a P-node, then *skeleton*(μ) is a triconnected multigraph consisting of a bundle of multiple edges;
- if μ is a Q-node, then *skeleton*(μ) is a biconnected multigraph consisting of two multiple edges.

The skeletons of the nodes of $\mathcal{T}$ are homeomorphic to subgraphs of G. The SPQR-trees of G, with respect to different reference edges, are isomorphic and are obtained one from the other by selecting a different Q-node as the root. Hence, we can define the *unrooted SPQR*-tree of G without ambiguity.

The SPQR-tree $\mathcal{T}$ of a graph G with n vertices and m edges has m Q-nodes and $O(n)$ S-, P-, and R-nodes. Also, the total number of vertices of the skeletons stored at the nodes of $\mathcal{T}$ is $O(n)$.

A graph G is planar if and only if the skeletons of all the nodes of the SPQR-tree $\mathcal{T}$ of G are planar. An SPQR-tree $\mathcal{T}$ rooted at a given Q-node represents all the planar drawings of G having the reference edge (associated with the Q-node at the root) on the external face (see Figure 2). Namely, such drawings can be constructed by the following recursive procedure:

- construct a drawing of the skeleton of the root ρ with the reference edge of the parent of ρ on the external face;
- for each child μ of ρ
  - let e be the virtual edge of μ in *skeleton*(ρ), and let H be the pertinent graph of μ plus edge e;
  - recursively draw H with the reference edge e on the external face;
  - in *skeleton*(ρ), replace virtual edge e with the above drawing of H minus edge e.

2.3. Upward planarity testing of embedded digraphs. In the remainder of this section we recall the combinatorial characterization of upward planarity for planar digraphs with a fixed embedding, given in [3, 4], which will be used extensively in this paper.

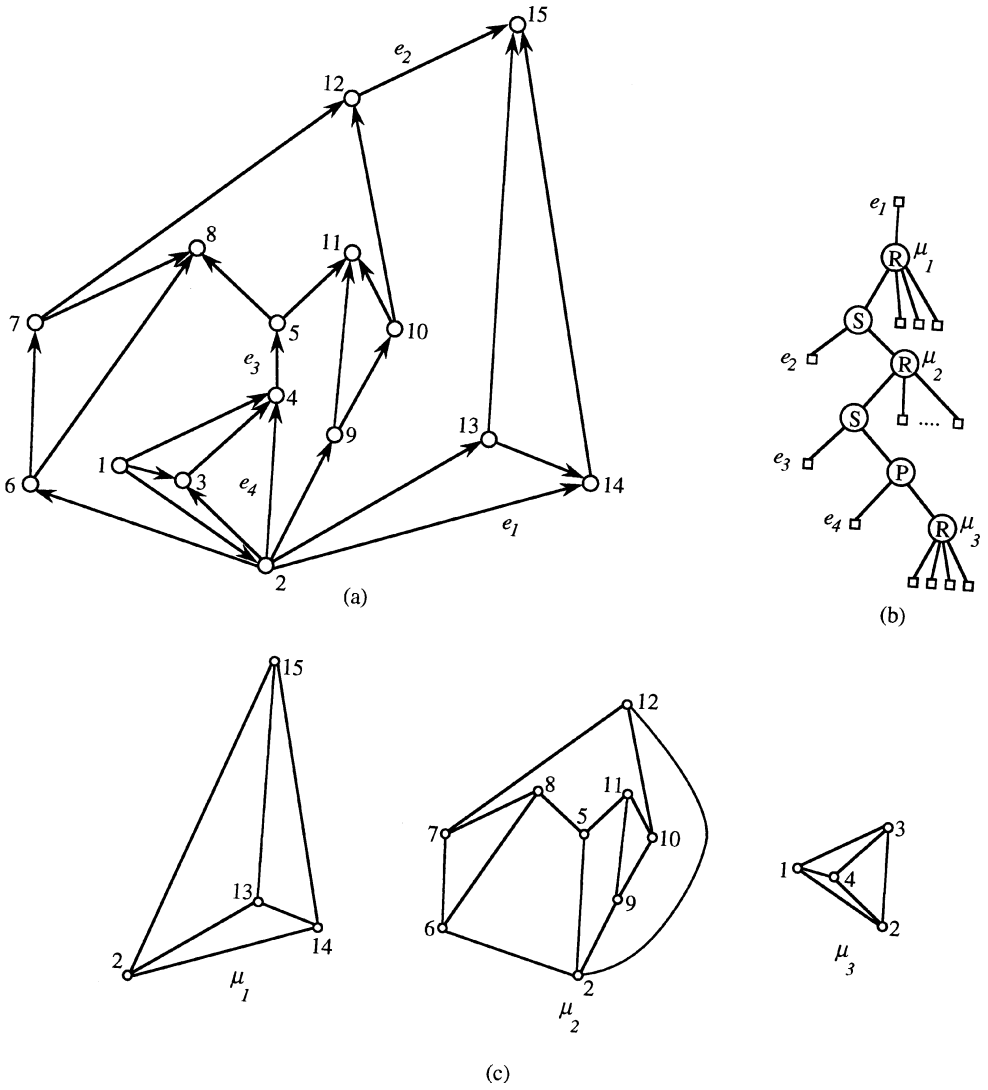

FIG. 2. (a) *A planar biconnected digraph G.* (b) *SPQR-tree $\mathcal{T}$ of G, where the* Q*-nodes are represented by squares.* (c) *Skeletons of the* R*-nodes.*

In [3, 4], the problem of testing whether an embedded planar digraph G admits a planar upward drawing is formulated as a perfect c-matching problem on a bipartite graph derived from G. To introduce this formulation we need some notation and definitions.

Let Γ be a planar straight-line upward drawing of an embedded upward planar digraph G. (As shown in [21, 9], every upward planar digraph admits a planar upward straight-line drawing.) We say that a sink t (source s) of G is *assigned* to a face f of Γ if the angle defined by the two edges of f incident on t (s) is greater than π. Informally speaking, t (s) is assigned to f if it "penetrates" into face f. Clearly, each sink (source) can be assigned only to one face, while an internal vertex is not assigned to any face. In [3, 4], it is shown that the number of vertices assigned to a face f in

any upward drawing is equal to the capacity $c(f)$ of the face itself, which is defined as follows. Let n_f be the number of sink-switches of f (n_f is also equal to the number of source-switches of f). We set $c(f) = n_f - 1$ if f is an internal face and $c(f) = n_f + 1$ if f is the external face. In the following, we associate to each vertex x and each face f the quantity $Z(x, f)$, where $Z(x, f) = 1$ if x is a switch of f, $Z(x, f) = 0$ otherwise. Clearly, we have that $2n_f = \sum_{x \in f} Z(x, f)$.

This intuitive idea of assignment of vertices to faces can be formally expressed as a perfect c-matching problem [24]. Namely, given a planar digraph G with a candidate planar embedding Ψ, we associate with G and Ψ the bipartite network $N(L_1, L_2, E_N)$ with vertex set $L_1 \cup L_2$ and edge-set E_N, where (i) the vertices of L_1 represent the sources and sinks of G; (ii) the vertices of L_2 represent the faces of Ψ; and (iii) E_N has an edge (v, f) if and only the vertex of G represented by $v \in L_1$ lies on the face of Ψ represented by $f \in L_2$. The c-matching problem for G and Ψ is described by the following equations:

$$\sum_{(v,f) \in E_N} x_{vf} = c(f), \quad \forall f \in L_2,$$

$$\sum_{(v,f) \in E_N} x_{vf} = 1, \quad \forall v \in L_1,$$

where $x_{vf} = 1$ indicates that vertex v is *assigned* to face f and $x_{vf} = 0$ indicates otherwise. A solution of this c-matching problem is called an *upward consistent assignment* of the variables x_{vf} and is denoted by $\mathcal{A}$. The equations of the first set are called *capacity equations*.

LEMMA 2 (see [3, 4]). *Let G be a digraph with a candidate planar embedding Ψ. Then Ψ is an upward embedding of G if and only if the c-matching problem associated with G and Ψ admits an upward consistent assignment.*

If $\mathcal{A}$ is an upward consistent assignment for Ψ, and f is a face of Ψ, we denote by $A(f)$ the set of vertices of G assigned to f in $\mathcal{A}$.

3. Embedded digraphs. In this section we give a new combinatorial characterization of upward planarity for planar single-source digraphs with a prescribed embedding. This characterization yields an optimal algorithm for testing whether an embedded planar single-source digraph has an upward planar drawing that preserves the embedding.

Given a planar single-source digraph G and an upward embedding Γ of G, from the first condition on the capacity equations of the perfect matching problem and from the fact that G has a unique source, the following properties can be easily derived (see Figure 3).

FACT 1. *The source of G is the bottommost vertex of Γ.*

FACT 2. *For the external face h of Γ, all the sink-switches are sinks of G and are assigned to h. (See Figure* 3a.*)*

FACT 3. *For each internal face f, at most one sink-switch (the topmost vertex of f in Γ) is not a sink of G and all but one sink switches are assigned to f. (See Figure* 3b.*)*

We shall also use the following result about cycles in planar single-source digraphs.

LEMMA 3. *Let G and G' be planar single-source digraphs such that G' is obtained from G by means of one of the following operations:*

- *adding a new vertex v and a new edge (u, v) or (v, u), connecting v to a vertex u of G;*

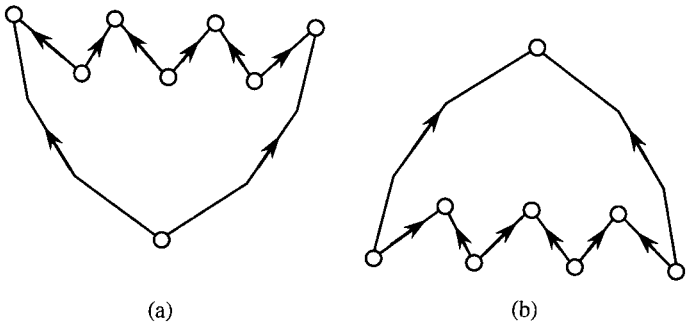

FIG. 3. *Schematic illustration of* (a) *the external face;* (b) *an internal face of an upward planar drawing of a planar single-source digraph.*

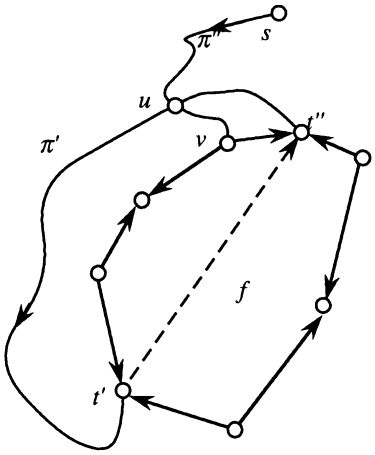

FIG. 4. *Illustration of the proof of Lemma* 3.

- *adding a directed edge between the source and a sink on the same face in some embedding of G;*
- *adding a directed edge between two sink-switches on the same face in some embedding of G.*

Then G is acyclic if and only if G' is acyclic.

Proof. The acyclicity is trivially preserved by the first two operations. Regarding the third operation, consider an embedding of G with the source on the external face, and assume, for a contradiction, that G is acyclic and that adding the edge (t', t'') between sink-switches t' and t'' of face f causes the resulting graph G' to have a cycle γ (see Figure 4). Cycle γ must consist of edge (t', t'') and a directed path π' in G from t'' to t'. Let v be the neighbor of t'' in f inside γ, and let π'' be a directed path from the source of G to v. Since the source is external to cycle γ, path π'' must have at least a vertex in common with path π'. Let u be the last vertex of π'' that is also on π'. We have that G has a cycle consisting of edge (v, t''), the subpath of π' from t'' to u, and the subpath of π'' from u to v, which is a contradiction. □

Given an embedded planar single-source digraph G, the *face-sink graph* F of G is the incidence graph of the faces and the sink-switches of G (see Figures 5a and 6).

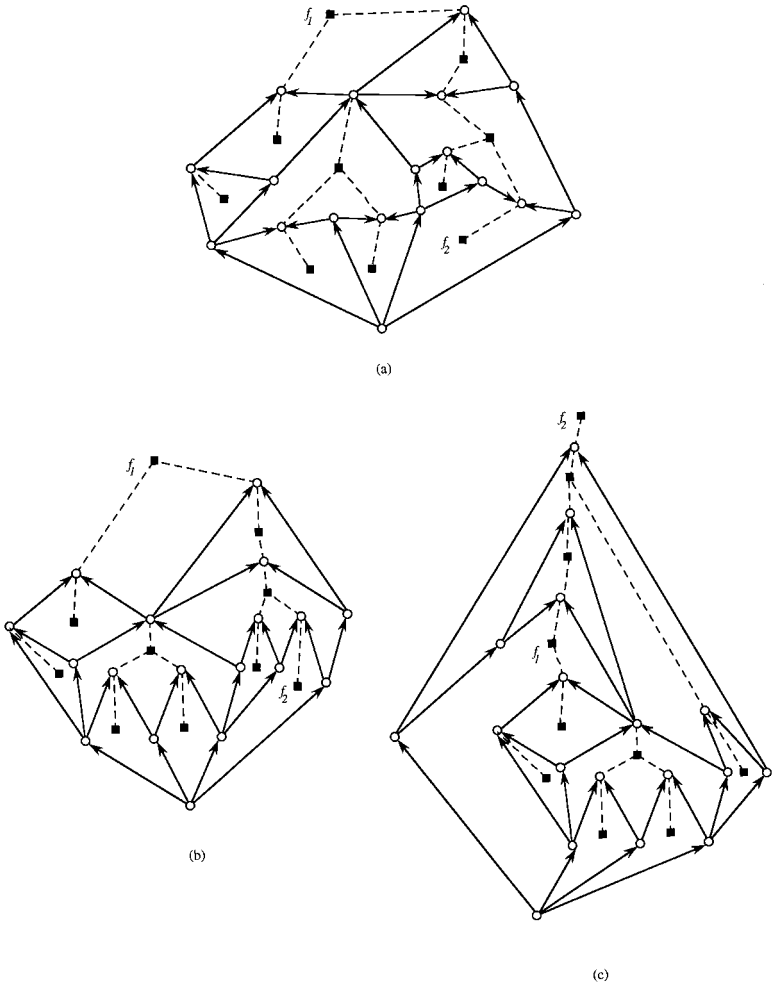

FIG. 5. (a) *An embedded planar single-source digraph G and its face-sink graph.* (b)–(c) *Upward drawings of G that preserve the embedding, with different external faces.*

Namely,

- the vertices of F are the faces and the sink-switches of G;
- graph F has an edge (f, v) if v is a sink-switch on face f.

THEOREM 1. *Let G be an embedded planar single-source digraph and let h be a face of G. Digraph G has an upward planar drawing that preserves the embedding with external face h if and only if all of the following conditions are satisfied:*

1. *graph F is a forest;*

2. *there is exactly one tree T of F with no internal vertices of G, while the remaining trees have exactly one internal vertex;*

3. *h is in tree T; and*

4. *the source of G is in the boundary of h.*

Also, if the above conditions are satisfied, then an embedded planar st-digraph G' containing G as an embedded subgraph is obtained as follows:

1. *root tree T at h and each remaining tree of F at its (unique) internal vertex;*

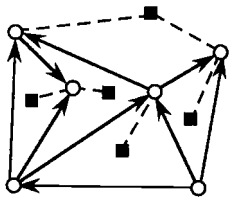

FIG. 6. *An embedded planar single-source digraph that does not have an upward drawing that preserves the embedding.*

2. *orient F by directing edges toward the roots;*
3. *prune the leaves from every tree of F; and*
4. *add the resulting forest $\hat{F}$ and the edge (s, h) to G.*

Proof. Only if. Let Γ be any planar upward drawing of G that preserves the original planar embedding and has external face h. By Fact 1, condition 4 is verified. Orient the face-sink graph F of G by directing edge (v, f) from v to f if v is a sink assigned to face f, and from f to v otherwise. By Facts 2–3, each vertex of F has at most one outgoing edge. Specifically, each internal face and each sink has exactly one outgoing edge, while each internal vertex and the external face have no outgoing edges. Now, label the vertices of F as follows: the label of a sink-switch is its y-coordinate in Γ; the label of an internal face f is $y(v) - \epsilon$, where v is the sink-switch not assigned to f, and ϵ is a suitably small positive real value, and the label of the external face h is $+\infty$. Since Γ is an upward drawing, the edges of F are directed by increasing labels. We conclude that F is a forest of sink-trees. One tree is rooted at h, while the other trees are rooted at internal vertices. This shows conditions 1–2. Condition 3 follows from Fact 1.

If. We show that, if F satisfies the conditions of the theorem, then G is a subgraph of a planar st-digraph G', which is obtained as the union of G and $\hat{F}$. This implies that G is upward planar. Planarity is preserved since a star is inserted in each face. Also, G' has exactly one source (s) and one sink (h) connected by a directed edge. It remains to be shown that G' is acyclic. By the construction of G' and Lemma 3, we have that G' is acyclic if and only if G is acyclic. Assume, for a contradiction, that G is not acyclic. Let γ be a cycle of G that does not enclose any other cycle. Note that the source s must be outside γ. If γ is a face of G, then F has an isolated vertex associated with face γ, which is a contradiction. Otherwise (γ is not a face of G), the subgraph $\hat{F}'$ of $\hat{F}$ enclosed by γ consists of a forest of trees, each with exactly one internal vertex. Let H be the digraph obtained from the subgraph of G enclosed by γ by removing the edges of γ, and adding a new vertex s' together with edges from s' to all the vertices of γ. By our choice of cycle γ, H is a planar single-source digraph. Adding $\hat{F}'$ to H yields a planar single-source digraph without sinks, and hence a digraph with cycles. By Lemma 3, H must also have cycles, which is again a contradiction. □

Theorem 1 is illustrated in Figures 5–6. The following algorithm tests whether an embedded planar single-source digraph G is upward planar, and reports all the faces of G that can be external in an upward planar drawing of G with the prescribed embedding.

ALGORITHM. *Embedded-Test.*

1. Construct the face-sink graph F of G.
2. Check conditions 1 and 2 of Theorem 1. If these conditions are not verified,

then return "not-upward-planar" and stop.

3. Report the set of faces of G that contain vertex s in their boundaries and are associated with nodes of tree T. If such a set of faces is empty, then return "not-upward-planar"; else return "upward-planar."

For the example of Figure 5, Algorithm *Embedded-Test* returns "upward-planar" and reports two faces.

THEOREM 2. *Let G be an embedded planar single-source digraph with n vertices. Algorithm* embedded test *determines whether G has an upward planar drawing that preserves the embedding and reports all the admissible external faces. It runs in $O(n)$ sequential time and in $O(\log n)$ time on a CRCW PRAM with $n \cdot \alpha(n)/\log n$ processors, using $O(n)$ space.*

Proof. The correctness of the algorithm follows directly from Theorem 1. All the steps can be performed sequentially in $O(n)$ time with straightforward methods.

Regarding the parallel complexity, steps 1 and 3 take $O(\log n)$ time on a CREW PRAM with $n/\log n$ processors, using list-ranking [5]. Step 2 can be executed by computing a spanning forest of the face-sink graph, which takes $O(\log n)$ time on a CRCW PRAM with $n \cdot \alpha(n)/\log n$ processors [5], and thus determines the parallel time complexity. □

4. Upward planarity and SPQR-trees. Let G be a biconnected single-source digraph. In this section we give a combinatorial characterization of the upward planarity of G using SPQR-trees.

4.1. Basic definitions and main result. A digraph is *expanded* if each internal vertex has exactly one incoming edge or one outgoing edge. The *expansion* of a digraph is obtained by replacing each internal vertex v with two new vertices v_1 and v_2, which inherit the incoming and outgoing edges of v, respectively, and the edge (v_1, v_2). Observe that a digraph is acyclic if and only if its expansion is acyclic. A planar embedding of an expanded digraph is candidate. In the remainder of this section we consider only expanded digraphs because of the following property.

FACT 4. *A digraph is upward planar if and only if its expansion is upward planar.*

Let $G' = (V', E')$ and $G'' = (V'', E'')$ be two digraphs. The *union* of G' and G'', denoted by $G' \cup G''$, is a digraph $G = (V, E)$ with $V = V' \cup V''$ and $E = E' \cup E''$, i.e., G is obtained from G' and G'' by identifying the vertices in V' and V'' with common labels.

Let $\{u, v\}$ be a separation pair of G that decomposes G into p split components $J_1, \ldots, J_p$. We call a *component separated by* $\{u, v\}$ or simply a *component* any digraph obtained as the union of q of the split components in $\{J_1, \ldots, J_p\}$, with $0 < q < p$.

We call *peak* a digraph consisting of three vertices a, b, and t, and two directed edges (a, t) and (b, t). See Figure 7b.

Let K be a component of G with respect to the separation pair $\{u, v\}$. In the following, we denote with $G - K$ the digraph obtained from G by deleting every vertex belonging to K, except for the vertices u and v, and by K° the digraph obtained from K by deleting vertices u and v. Also, for simplicity we write $G - K_1 - K_2 - \cdots - K_m$ instead of $(\cdots((G - K_1) - K_2) \cdots - K_m)$.

Finally, we associate with a component K of G either a directed edge or a peak (see Figures 7a–b) according to the following rules.

Rule 1. u and v are sources of K: a peak with $a \equiv u$ and $b \equiv v$.

Rule 2. u is a source of K and v is a sink of K.

(a) $s \notin K^\circ$: a directed edge (u, v).

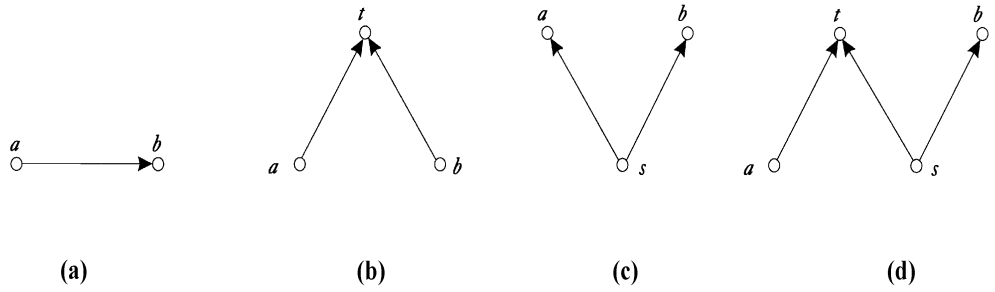

FIG. 7. (a) *Directed edge;* (b) *peak;* (c) *valley;* (d) *zig-zag.*

(b) $s \in K^\circ$: a peak with $a \equiv u$ and $b \equiv v$.

Rule 3. u is a source of K and v is an internal vertex of K.

(a) v is a source of $G - K$ and $s \notin K^\circ$: a directed edge (u, v).

(b) v is not a source of $G - K$ or $s \in K^\circ$: a peak with $a \equiv u$ and $b \equiv v$.

Rule 4. u and v are not sources of K.

(a) u is a source of $G - K$: a directed edge (u, v).

(b) u is not a source of $G - K$: a directed edge (v, u).

The digraph associated to K by the above rules is called *directed-virtual-edge* and will be denoted by $d(K, G - K)$. Observe that the choice of the directed-virtual-edge depends, in general, both on K and on $G - K$.

We call *minor* of G either G itself or the digraph

$$G - K_1 - \cdots - K_m \cup d(K_1, G - K_1) \cup \cdots \cup d(K_m, G - K_m),$$

where $K_1, \ldots, K_m, m \geq 1$, are components of G with the property that no two components share a common edge. In other words, the digraph $G - K_1 - \cdots - K_m \cup d(K_1, G - K_1) \cup \cdots \cup d(K_m, G - K_m)$ is obtained from G by replacing $K_1, \ldots, K_m$ with the corresponding directed-virtual-edges (see Figure 8). Observe that, in general, a minor of a minor of G is not a minor of G.

Let G be a planar single-source digraph, and let $\mathcal{T}$ be its SPQR-unrooted tree. The *sT-skeleton* of a node μ of $\mathcal{T}$, denoted by sT-skeleton(μ), is the minor of G obtained from the skeleton of μ by replacing each virtual edge with the directed-virtual-edge associated to its pertinent digraph. The *reference directed-virtual-edge* is the directed-virtual-edge associated with the pertinent digraph of the reference edge of μ. Examples of sT-skeletons are shown in Figure 9.

The main result of this section is summarized in the following theorem.

THEOREM 3. *A biconnected acyclic single-source digraph G is upward planar if and only if there exists a rooting of the SPQR-tree $\mathcal{T}$ of the expansion of G at a reference edge containing the source, such that the sT-skeleton of each node μ of $\mathcal{T}$ has a planar upward drawing with the reference directed-virtual-edge on the external face.*

The proof of Theorem 3 is given in the next two sections. Section 5 shows the *only-if* part, while section 6 shows the *if* part. Here we give some preliminary lemmas that will be used in the next sections.

4.2. Preliminary lemmas. In the following, S_G, T_G, and I_G will denote the set of sources, sinks, and internal vertices of G, respectively. If G has exactly one source, we denote such source by $s(G)$ (or simply by s, when no confusion arises).

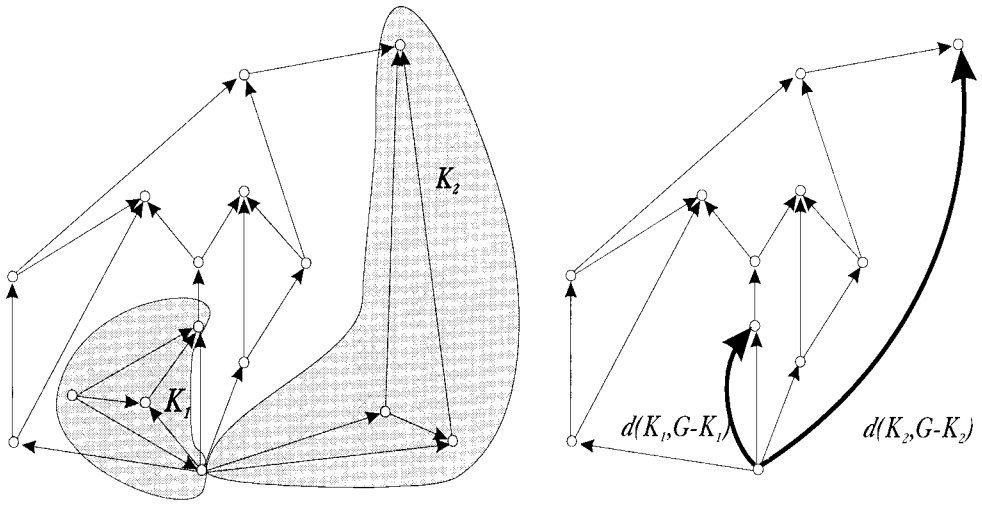

FIG. 8. *Construction of a minor.*

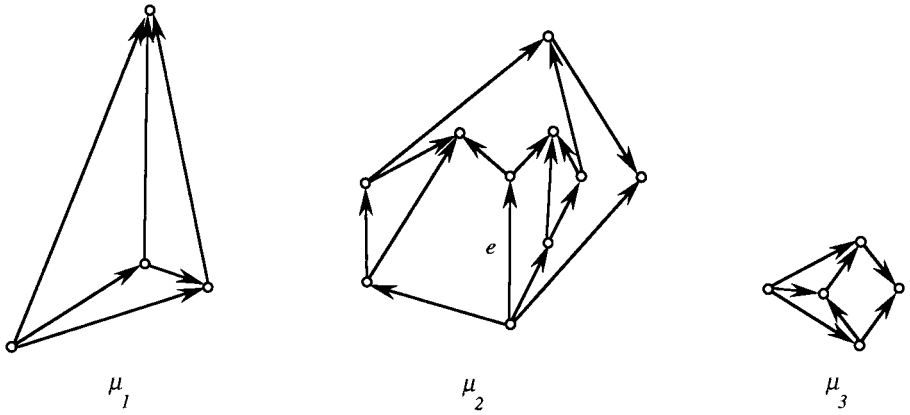

FIG. 9. *The sT-skeletons of the* R*-nodes of the digraph of Figure* 2.

We will make use of the following operations defined on an edge $e = (x, y)$ of a digraph G:

- *Contraction* (denoted by G/e) transforms G into a digraph G' obtained from G by removing edge e and by identifying vertices x and y.
- *Direct subdivision* transforms G into a digraph G' obtained from G by removing edge e and by adding a vertex z and edges (x, z) and (z, y).

We say that digraphs G_1 and G_2 are *homeomorphic* if both can be obtained by performing a finite number of direct subdivisions of a digraph G. Observe that we can have $G_1 = G$ or $G_2 = G$.

We call *valley* a digraph consisting of three vertices s', a, and b, and two directed edges (s', a) and (s', b) (see Figure 7c). Also, we call *zig-zag* a digraph consisting of four vertices s', t, a, and b, and three directed edges (s', t), (s', b), and (a, t) (see Figure 7d).

We denote by $x \to y$ a path from vertex x to vertex y. A vertex u is said to be *dominated* by vertex v if there is a path $v \to u$. We say that vertices x and y are

incomparable in G, denoted by $x \parallel y$, if there exists in G neither a path $x \to y$ nor a path $x \to y$.

FACT 5. *Let G be an sT-digraph. Then every vertex of G is dominated by s.*

FACT 6. *Let G be an acyclic digraph. G contains a source.*

LEMMA 4 (see [19]). *If G is an sT-digraph with $u \parallel v$ in G, then there exists in G a subgraph homeomorphic to a valley, with $a \equiv u$ and $b \equiv v$.*

LEMMA 5 (see [19]). *Let G be a connected acyclic digraph with exactly two sources u and v. Then there exists in G a subgraph homeomorphic to a peak, with $a \equiv u$ and $b \equiv v$.*

FACT 7. *Let G be a biconnected digraph and let $\{u, v\}$ be a separation pair of G. Neither u nor v is a cut-vertex of any component of G with respect to $\{u, v\}$.*

LEMMA 6. *Let G be an sT-digraph and let $\{u, v\}$ be a separation pair of G. Let K be a component with respect to $\{u, v\}$ such that $v \in I_K$ and K has exactly one source u. Then digraph K contains a subgraph homeomorphic to a peak, with $a \equiv u$ and $b \equiv v$.*

Proof. Let w be a vertex of K such that there exist two vertex disjoint directed paths $u \to w$ and $v \to w$ contained in K. The subgraph of K consisting of all edges and vertices belonging to the two paths is homeomorphic to a peak. Suppose w does not exist. Let V_v be the set of all vertices dominated by v in K (except v).

Let $\bar{V}_v$ be the set of all vertices not dominated by v in K. Observe that both V_v and $\bar{V}_v$ are nonempty and disjoint. Also, $V_v \cup \bar{V}_v \cup \{v\}$ is the set of vertices of K. Since v is not a cut-vertex of K, there is an edge connecting a vertex x of V_v with a vertex y of $\bar{V}_v$. If such an edge is (x, y), then y belongs to V_v, which is a contradiction. If such an edge is (y, x), then x is dominated by both v and u, and $x = w$, which is a contradiction. □

Finally, the following fact and lemmas concerning the embeddings of G will be used in the proof of the main theorem.

FACT 8. *Let G be a digraph and let G' be a digraph homeomorphic to a subgraph G'' of G. We have that*

(i) *if G is acyclic, then G' is acyclic.*
(ii) *if G is expanded, then G' is expanded.*
(iii) *if G is upward planar, then G' is upward planar.*
(iv) *if G'' is an sT-digraph, then G' is an sT-digraph.*

LEMMA 7 (see [19]). *Let G be a digraph, let (u, v) be an edge of G, and let vertex $u(v)$ have out-degree (in-degree) 1 in G. Let $G' = G/(u, v)$. We have that*

(i) *if G is acyclic then G' is acyclic.*
(ii) *if G is upward planar, then G' is upward planar.*

LEMMA 8. *Let G be an upward planar sT-digraph, and let Ψ_G be an upward embedding of G. Let $e = (s, u)$ be an edge of G embedded on the external face α of Ψ_G. Let $G' = G - e \cup P$ where P is a valley, i.e., P is the path $\{(s', s), (s', u)\}$. Then G' is an sT-digraph and has an upward embedding $\Psi_{G'}$, with P embedded on the external face.*

Proof. From Ψ_G we simply derive a candidate planar embedding $\Psi_{G'}$ of G' by replacing the edge (s, u) of G with the path P (see Figure 10).

We now show that $\Psi_{G'}$ is an upward embedding. This is done by deriving an upward consistent assignment $\mathcal{A}'$ associated to $\Psi_{G'}$ from the upward consistent assignment $\mathcal{A}$ associated to Ψ_G.

Let β be the internal face of Ψ_G containing the edge (s, u). We denote by $\gamma_1, \ldots, \gamma_p$ the faces of Ψ_G different from α and β.

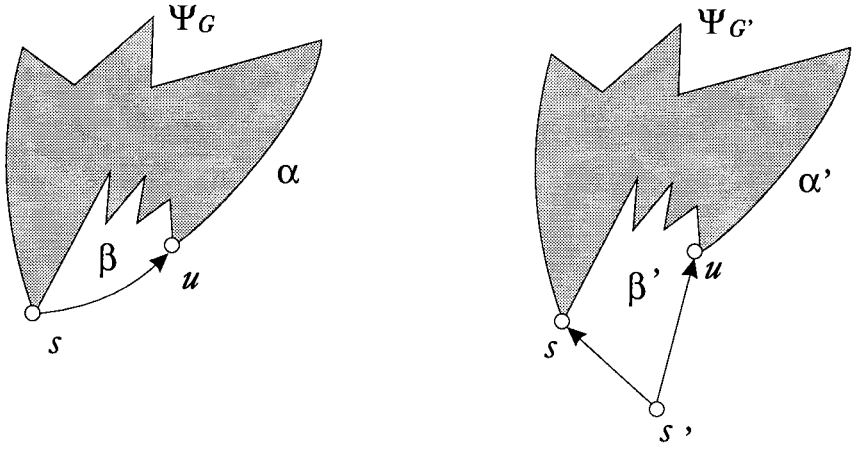

FIG. 10. *Construction of* $\Psi_{G'}$.

Clearly, there is a one-to-one correspondence between the faces of Ψ_G and the faces of $\Psi_{G'}$. We denote by α', β', $\gamma'_1, \ldots, \gamma'_p$ the faces of $\Psi_{G'}$ corresponding to $\alpha, \beta, \gamma_1, \ldots, \gamma_p$.

Also, it is $\gamma'_i = \gamma_i$, for $i = 1, \ldots, p$, and thus $c(\gamma'_i) = c(\gamma_i)$, for $i = 1, \ldots, p$. We show that $c(\alpha') = c(\alpha)$ and $c(\beta') = c(\beta)$.

Following the notation introduced in section 2.3, we have that $2n_{\alpha'} = 2n_\alpha - Z(s, \alpha) + Z(s, \alpha') - Z(u, \alpha) + Z(u, \alpha') + Z(s', \alpha')$. Since the edge (s, u) of α has been replaced by the edge (s', u) of α', it is $Z(u, \alpha') = Z(u, \alpha)$. It is easy to see that $Z(s, \alpha) = 1$, $Z(s, \alpha') = 0$, and $Z(s', \alpha') = 1$. Thus, $2n_{\alpha'} = 2n_\alpha$ and then $c(\alpha') = c(\alpha)$. In the same fashion, we can prove that $c(\beta') = c(\beta)$.

Let S (S') and T (T') be the set of sources and sinks of G (G'), respectively. Clearly $S' = S - \{s\} \cup \{s'\}$, and $T' = T$. Observe that, by Theorem 1, $s \in A(\alpha)$. $\mathcal{A}'$ is derived from $\mathcal{A}$ in the following way:

- $A'(\gamma'_i) = A(\gamma_i)$ for $i = 1, \ldots, p$;
- $A'(\alpha') = A(\alpha) - \{s\} \cup \{s'\}$; and
- $A'(\beta') = A(\beta)$.

It is straightforward to prove that $|A'(f)| = c(f)$ for each face $f \in \Psi_{G'}$. Since $\Psi_{G'}$ is a candidate embedding and $\mathcal{A}'$ is upward consistent, by Lemma 2, G' is upward planar. □

5. Proof of necessity for Theorem 3.

LEMMA 9. *Let G be a planar expanded sT-digraph G, $\{u, v\}$ a separation pair of G, and K a component with respect to $\{u, v\}$. Let $H = G - K$ and let $d_K = d(K, H)$ be the directed-virtual-edge associated to K with respect to G. Finally, let H' be the minor $H \cup d_k$. We have that*

(i) *H' is an expanded, acyclic sT-digraph.*

(ii) *if G is upward planar, then H' is upward planar.*

(iii) *if G is upward planar and $s(G) \in K^\circ$, then H' has an upward embedding with d_k on the external face.*

Proof. The following cases are possible, each corresponding to one of Rules 1–4 (in each case, the proof of (iii) is trivial and thus omitted).

1. u and v are sources of K.

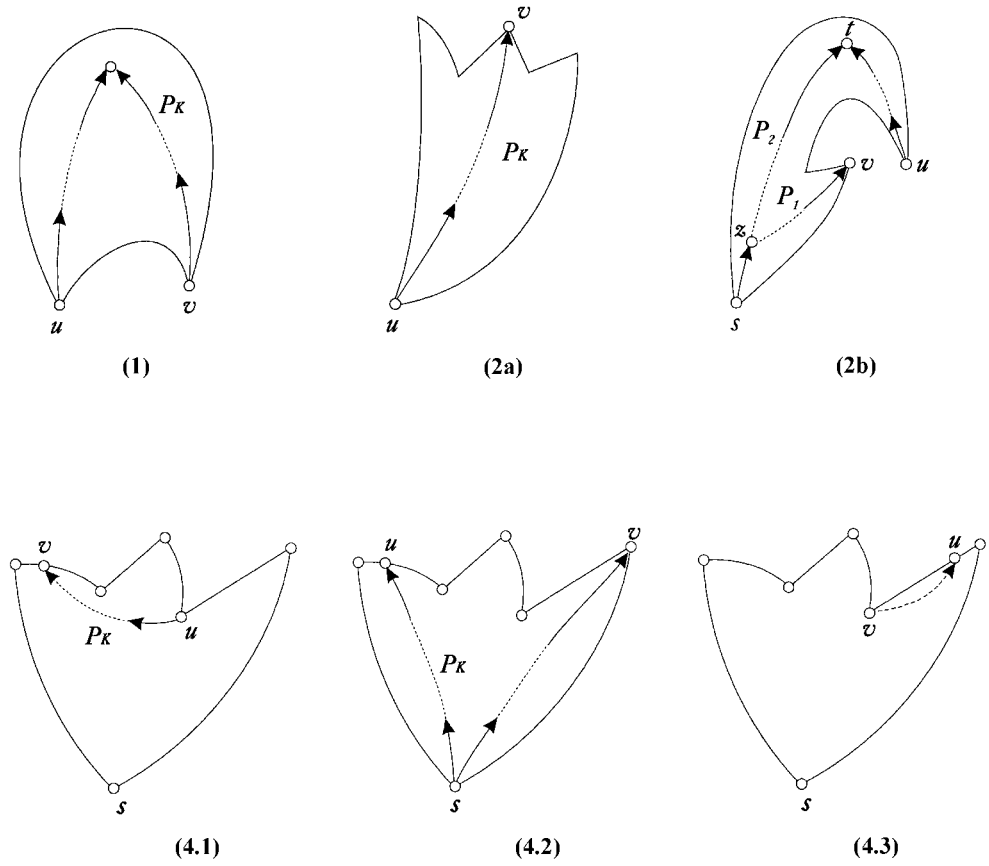

FIG. 11. *Various cases in the proof of Lemma* 9.

By Lemma 5, there is in K a path P_K homeomorphic to a peak, with $a \equiv u$ and $b \equiv v$ (see Figure 11). Thus, $H' = H \cup d_K$ is homeomorphic to a subgraph of G.

(i) By Fact 8, H' is an expanded acyclic digraph. We show now that it contains only one source. Vertices u and v are not both sources in H; otherwise G would contain two sources. Suppose one of u, v (say, u) is a source of H. Then $u \equiv s(G)$ and $u \equiv s(H')$; thus u is the only source of H'. Suppose neither u nor v is a source in H; then $s(G) \in H^\circ$ and s is the only source of H'.

(ii) By Fact 8, H' is upward planar.

2(a) u is a source of K and v is a sink of K and $s \notin K^\circ$.

Since $s \notin K^\circ$, u is the only source of K and there exists in K a path $u \to v$. Thus there is in K a path P_K homeomorphic to the directed edge (u, v), and then there is in G a subgraph homeomorphic to $H' = H \cup d_K$ (see Figure 11).

(i) By Fact 8, H' is an acyclic expanded digraph. Because of the existence of edge (u, v), v is not a source of H'. If $u \in S_H$, then $s(G) \equiv u$; thus u is the only source of H'. If $u \notin S_H$, $s(G) \in H^\circ$, and $s(G) \equiv s(H')$.

(ii) By Fact 8, H' is upward planar.

2(b) u is a source of K and v is a sink of K and $s \in K^\circ$.

Since $s \in K^\circ$, $s \neq u$ and, by Lemma 5, there is a vertex t distinct from s and u,

and two vertex disjoint paths $s \to t$ and $u \to t$. Note that u is not a source of H; otherwise u is a source of G, which is a contradiction. So v is the only source of H and since there is in G a path $s \to v$, we have that there is a path $s \to v$ in K. Moreover, since v is the only source of H, there is a path $v \to u$ in H and thus there is a path $v \to u$ in G. This implies that the path $s \to v$ and the path $u \to t$ are node-disjoint; otherwise there would be a path $u \to v$ and G would contain a cycle, which is a contradiction.

Let P_1 and P_2 be a path $s \to v$ and a path $s \to t$, respectively. Let z be the last vertex common to paths P_1 and P_2. Note that $z \neq t$, since P_1 and any path $u \to t$ are disjoint. Thus there exists in K a path P_K homeomorphic to a zig-zag, and then there is in G a subgraph homeomorphic to $H'' \equiv H \cup (z, v) \cup (z, t) \cup (u, t)$ (see Figure 11).

Observe that in H'', vertex v has in-degree 1. If we contract the edge (z, v) we obtain $H''/(z, v) \equiv H \cup d_K = H'$.

(i) By Fact 8 H'' is acyclic and expanded; thus, by Lemma 7 H' is acyclic. Note that every vertex except v has the same in- and out-degrees in H'' and H'. Since H'' is expanded and v is a source of H', H' is an expanded digraph. Moreover, since v is the only source of H, v is the only source of H'.

(ii) By Fact 8 H'' is upward planar; thus, by Lemma 7 H' is upward planar.

3(a) u is a source of K and v is an internal vertex of K; v is a source of $G - K$ and $s \notin K^\circ$.

Since u is the only source of K, there is a path $u \to v$ in K and the proof is analogous to that of case 2(a).

3(b) u is a source of K and v is an internal vertex of K; v is not a source of $G - K$ or $s \in K^\circ$.

1. If $s \in K^\circ$, then $s \neq u$ and K contains two sources; the proof is as in case 2(b).

2. If $s \notin K^\circ$, then u is the only source of K and, by Lemma 6, K contains a path P_K homeomorphic to a peak, with $u \equiv a$ and $v \equiv b$. Then $H' = H \cup d_K$ is homeomorphic to a subgraph of G.

(i) By Fact 8 H' is an expanded, acyclic digraph. If $u = s(G)$, then vertex u is the only source of H'. If $u \neq s(G)$, then u is not a source of H (otherwise G contains two sources, which is a contradiction), and $s(G)$ is the only source of H'. Thus, H' is an sT-digraph.

(ii) By Fact 8 H' is upward planar.

4. u and v are not sources of K.

Since u and v are not sources of K, we have that $s(G) \in K^\circ$. Then either u or v (or both) is a source of H. We discuss only the case where u is a source of H and Rule 4(a) is applied. In fact, if u is not a source of H, then v is a source of H and Rule 4(b) is applied; that is, the roles of u and v are interchanged. Three cases are possible.

1. If there exists a path $u \to v$ in K, then there is in K a path P_K homeomorphic to the directed edge (u, v) (see Figure 11).

(i) By Fact 8 H' is an expanded, acyclic digraph. Because of the existence of the edge (u, v), u is the only source of H'.

(ii) By Fact 8 H' is upward planar.

2. If u and v are incomparable in K, by Lemma 4 there exists in K a path P_K homeomorphic to a valley with $a \equiv u$ and $b \equiv v$ (see Figure 11). Thus, $H'' \equiv H \cup (s, v) \cup (s, u)$ is homeomorphic to a subgraph of G. Observe that in H'', vertex u has in-degree 1. If we contract the edge (s, u) we obtain $H''/(s, u) \equiv H \cup d_K = H'$.

(i) By Fact 8 H'' is acyclic and expanded; thus by Lemma 7 H' is acyclic. Note that all vertices except u have the same in- and out-degrees in H'' and H'. Since H'' is expanded and u is a source of H', then H' is an expanded digraph. Moreover, since $s(G) \in K^\circ$, u is the only source of H'.

(ii) By Fact 8 H'' is upward planar; thus, by Lemma 7 H' is upward planar.

3. If there exists a path P_K from v to u in K, then v is also a source of H (see Figure 11). Otherwise u would be the only source of H, so there would be a path $u \to v$ in H and thus a path $u \to v$ in G, which is a contradiction. So both u and v are sources of H.

(i) Since H is an expanded, acyclic digraph, and since both vertices u and v are sources of H, $H' = H \cup (u, v)$ is expanded and acyclic. Furthermore, it contains only one source u.

(ii) Let H'' be the digraph $H \cup (v, u)$. Digraph H'' is homeomorphic to a subgraph of G and thus, by Fact 8, there exists an upward embedding $\Psi_{H''}$ of H'', with (v, u) on the external face. Furthermore, v is the only source of H'', and H'' is an expanded sT-digraph.

H' can be obtained from H'' by the means of the following operations:

1. Construct $\bar{H}$ from H'' by adding a vertex s' and replacing the edge (v, u) with the valley $\{(s', v), (s', u)\}$.

2. Construct H' from $\bar{H}$ by contracting the edge (s', u).

By Lemma 8, $\bar{H}$ has an upward embedding with the valley $\{(s', v), (s', u)\}$ on the external face. By Lemma 7, H' has an upward embedding with the edge (u, v) on the external face. □

Following the developments of the previous proof, for each case a particular path P_K is detected in the component K. These paths and the corresponding cases will play a central role in the next section.

The previous lemma refers to a particular minor of G obtained by replacing exactly one component, but it can be easily extended to any minor of G. Before proving the next lemma, we must observe a property of sources in minors. Suppose u is a source of G. Then u is a source in every component of G that contains u. By a simple inspection of Rules 1–4 we have the following.

FACT 9. *Let G be a digraph and K be a component of G with respect to the separation pair $\{u, v\}$. Let G' be a minor of G such that $K \subset G'$. If u is a source of $G - K$, then u is a source in $G' - K$.*

LEMMA 10. *Let G be an expanded sT-digraph and let $\tilde{H}' = G - K_1 - \cdots - K_m \cup d_{K_1} \cdots \cup d_{K_m}$ be a minor of G, where $d_{K_i} = d(K_i, G - K_i)$. Then*

(i) *$\tilde{H}'$ is an expanded sT-digraph.*

(ii) *if G is upward planar, then $\tilde{H}'$ is upward planar.*

(iii) *if G is upward planar and $s(G) \in K_i^\circ$, $1 \le i \le m$, then H' has an upward embedding with d_{K_i} on the external face.*

Proof. The proof is by induction. When $m = 1$, the minor is $\tilde{H}' = G - K_1 \cup d(K_1, G - K_1)$, and by Lemma 9 the basis of the induction holds. Now, suppose that the minor $\tilde{G} = G - K_1 - \cdots - K_{l-1} \cup d_{K_1} \cup \cdots \cup d_{K_{l-1}}$ is an expanded sT-digraph and is upward planar. We show that the minor $\tilde{J}' = G - K_1 - \cdots - K_l \cup d_{K_1} \cup \cdots \cup d_{K_l}$ is an expanded sT-digraph and is upward planar.

Note first that $\tilde{J}' = \tilde{G} - K_l \cup d_{K_l}$. If we can prove that $d_{K_l} = d(K_l, G - K_l)$ is equal to $d(K_l, \tilde{G} - K_l)$, then the thesis follows by Lemma 9. In other words, we have to prove that the directed-virtual-edge which substitutes K_l remains the same when Rules 1–4 are applied to the pair $(K_l, \tilde{G} - K_l)$ rather than to the pair $(K_l, G - K_l)$.

When Rules 1 and 2 are applied, the directed-virtual-edge depends only on the component K_l, and $d_K = d(K_l, G - K_l) = d(K_l, \tilde{G} - K_l)$. Hence we have to consider only Rules 3 and 4.

3(a) u is a source of K_l and v is an internal vertex of K_l, v is a source of $G - K_l$ and $s(G) \notin K_l^\circ$.

By Fact 9, v is a source in $\tilde{G} - K_l$. Moreover, since $s(G) \notin K_l^\circ$ we have that $s(\tilde{G}) \notin K_l^\circ$, and Rule 3(a) must be applied to the pair $(K_l, \tilde{G} - K_l)$.

3(b) u is a source of K_l and v is an internal vertex of K_l; v is not a source of $G - K_l$ or $s(G) \in K_l^\circ$.

If $s \in K_l^\circ$, Rule 3(b) must be applied to the pair $(K_l, \tilde{G} - K_l)$.

Suppose that v is not a source of $G - K_l$ and $s \notin K_l^\circ$. Note that v is a sink in $G - K_l$ (v cannot be internal in $G - K_l$ since v is internal in K_l and G is expanded).

If v is not a source of $\tilde{G} - K_l$ then Rule 3(b) must be applied to the pair $(K_l, \tilde{G} - K_l)$.

Suppose v is a source of $\tilde{G} - K_l$; then there exists a component K_q of $G - K_l$, with $0 < q < l$, with $K_q \notin \tilde{G} - K_l$, having v and u_q as poles, whose directed-virtual-edge is either a peak or the edge (v, u_q). Observe that v is a sink of K_q. If $s \notin K_q^\circ$ then u_q is the only source of K_q. Hence Rule 2(a) is applied to the pair $(K_q, G - K_q)$ and $d(K_q, G - K_q)$ is the edge (u_q, v), which is a contradiction.

If $s \in K_q^\circ$ then u_q is a source of $G - K_q$ (since v is internal in $K_l \in G - K_q$). Thus u_q is not a source of K_q; otherwise G contains two sources. Then Rule 4(a) is applied to the pair $(K_q, G - K_q)$ and $d(K_q, G - K_q)$ is the edge (u_q, v), which is a contradiction.

4(a) u and v are not sources of K_l; u is a source of $G - K_l$. By Fact 9, u is a source of $\tilde{G} - K_l$ and Rule 4(a) can be applied to the pair $(K_l, \tilde{G} - K_l)$.

4(b) u and v are not sources of K_l; u is a not a source of $G - K_l$. Since u is not a source in $G - K_l$ and $s(G) \in K_l$, then v is a source in $G - K_l$ and v is a source in $\tilde{G} - K_l$. So Rule 4(a) can be applied to the pair $(K_l, \tilde{G} - K_l)$, with v and u interchanged. □

The proof of the necessity of Theorem 3 is now a simple corollary of Lemma 10. In fact, for each node μ of tree $\mathcal{T}$, the sT-skeleton of μ is a minor of G.

6. Proof of sufficiency for Theorem 3.

LEMMA 11. *Let G be a planar expanded sT-digraph, $\{u, v\}$ a separation pair of G, and K a component with respect to $\{u, v\}$ such that $s(G) \in K$. Let $H = G - K$ and let $d_K = d(K, H)$ and $d_H = d(H, K)$ be the directed-virtual-edges associated to K and H (with respect to G), respectively. Finally, let H' be the minor $H \cup d_K$ and K' be the minor $K \cup d_H$. If K' is upward planar and H' has an upward embedding with d_K on the external face, then G is upward planar.*

Before proving the above lemma, we need some preliminary results, namely, the following Lemmas 12–16.

We remind the reader that in the proof of Lemma 9, in correspondence with each case of the proof, a path P_K is detected in the component K. Such a path P_K will be used in the following lemma (see Figure 12).

LEMMA 12. *Let G be a planar expanded sT-digraph G, $\{u, v\}$ a separation pair of G, and K a component with respect to $\{u, v\}$. Let $H = G - K$ and let $d_K = d(K, H)$ be the directed-virtual-edge associated to K with respect to G. Let H' be the minor $H \cup d_K$ and let $\bar{H} = H \cup P_K$. Suppose H' has an upward embedding $\Psi_{H'}$, with d_K embedded on the external face if $s(G) \in K^\circ$. Denote by $\Psi_H \subset \Psi_{H'}$ the upward embedding of H contained in $\Psi_{H'}$ and let α_H be the face of Ψ_H in which d_K is embedded. We have that*

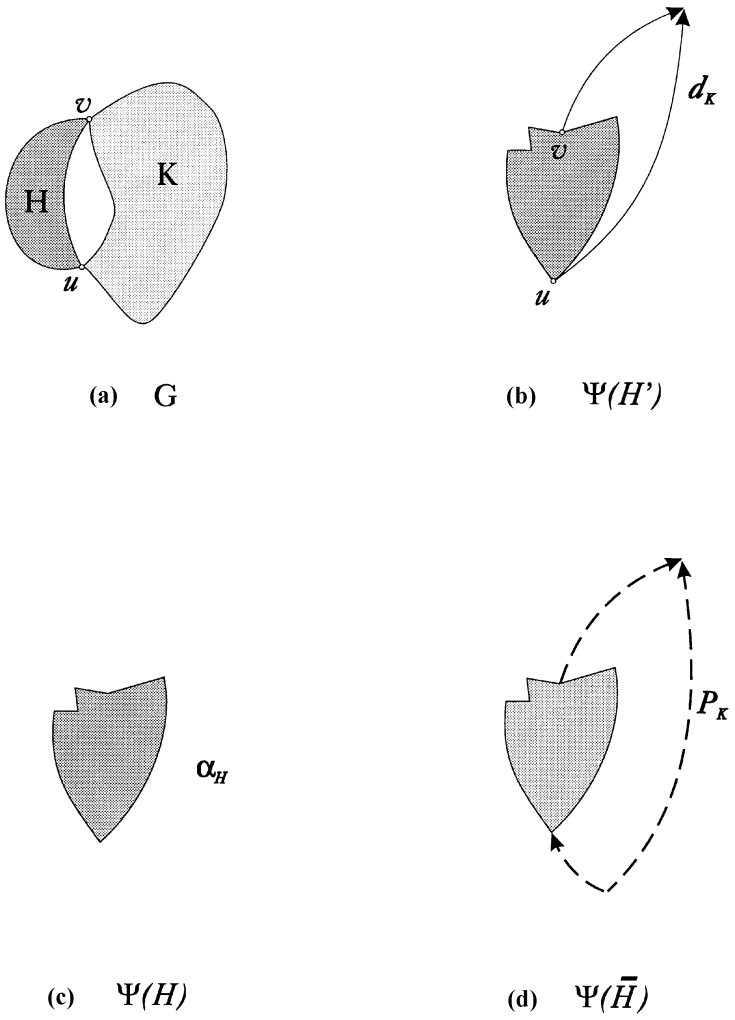

FIG. 12. *Illustration of the statement of Lemma* 12.

(i) $\bar{H} = H \cup P_K$ *is an expanded, acyclic digraph.*

(ii) $\bar{H}$ *is an sT-digraph and has an upward embedding* $\Psi_{\bar{H}}$*, with* $\Psi_H \subset \Psi_{\bar{H}}$ *and* P_K *embedded in face* α_H *of* Ψ_H*.*

Proof. Since $\bar{H}$ is a subgraph of G then it is expanded and acyclic and (i) holds.

We now prove (ii). Since both d_K and P_K depend on the component K, we distinguish the following four cases, each corresponding to the cases of the proof of Lemma 9.

1. P_K is homeomorphic to d_K; hence $\bar{H}$ is homeomorphic to H'. By Fact 8, the lemma holds.

2.(a) P_K is homeomorphic to d_K; hence $\bar{H}$ is homeomorphic to H'. By Fact 8, the lemma holds.

(b) Since $s \in K^\circ$, d_K is embedded on the external face of $\Psi_{H'}$. Observe that $\bar{H}$ can be obtained from H' substituting the edge (v, t) with a path homeomorphic to a valley. Thus, by Lemma 8 and by Fact 8, the lemma holds.

3.(a) P_K is homeomorphic to d_K; hence $\bar{H}$ is homeomorphic to H'. By Fact 8, the lemma holds.

(b) If $s \in K^\circ$ then the proof is as in case 2(b). If $s \notin K^\circ$ then P_K is homeomorphic to d_K; hence $\bar{H}$ is homeomorphic to H'. By Fact 8, the lemma holds.

4. (1) P_K is homeomorphic to d_K; hence $\bar{H}$ is homeomorphic to H'. By Fact 8, the lemma holds.

(2) Since $s \in K^\circ$, d_K is embedded on the external face of $\Psi_{H'}$. Observe that $\bar{H}$ can be obtained from H' substituting the edge (u, v) with a path homeomorphic to a valley. Thus, by Lemma 8 and by Fact 8, the lemma holds.

(3) Observe that $\bar{H}$ can be obtained from H' by reversing edge (u, v) and by direct subdivision. Thus, following the proof of case 4.3 of Lemma 9, and by Fact 8, the lemma holds.

Suppose K, H, K', and H' satisfy the conditions of Lemma 11. Let P_K and P_H be the paths associated with d_K and d_H, respectively (see Figures 13(a), (b)). Except for the common endpoints u and v, P_K and P_H are disjoint paths of G, since they lie in different components. Thus, $C = P_K \cup P_H$ is a simple (undirected) cycle of G.

Let $\bar{K} = K \cup P_H$ and $\bar{H} = H \cup P_K$ (see Figures 13(c), (d)). Since K' and H' are upward planar, by the previous lemma, $\bar{K}$ and $\bar{H}$ are upward planar. Let $\Psi_{\bar{K}}$ and $\Psi_{\bar{H}}$ be two upward embeddings of $\bar{K}$ and $\bar{H}$, respectively, and let $\alpha_{\bar{K}}$ and $\alpha_{\bar{H}}$ be the corresponding external faces. Now, let $K^*(H^*)$ be the subgraph of $\bar{K}(\bar{H})$ embedded inside C in $\Psi_{\bar{K}}(\Psi_{\bar{H}})$ (see Figures 13(e), (f)). We have the following lemma.

LEMMA 13. *Let s^* be a source of K^* (H^*). Then $s^* \in C$.*

Proof. Suppose $s^* \notin C$. Then s^* is a source of $\bar{K}$ embedded inside C in $\Psi_{\bar{K}}$. Since $\bar{K}$ is an sT-digraph, s^* is the only source of $\bar{K}$ and is embedded on the external face of every upward embedding of $\bar{K}$, and thus cannot be embedded inside C in $\Psi_{\bar{K}}$, which is a contradiction. □

LEMMA 14. *The digraph K^* (H^*) is an expanded sT-digraph.*

Proof. Since K^* is a subgraph of G, then it is acyclic and expanded. By Lemma 13, all of the sources of K^* belong to $C = P_K \cup P_H$. In order to prove the existence of a single source, we have to consider the "shapes" of P_K and P_H. Observe that P_K (P_H) can be homeomorphic to an edge, a peak, a valley, or a zig-zag. If both P_K and P_H are homeomorphic to the edge (u, v) $((v, u))$, then $s(K^*)$ is either u or v. Suppose now that P_K is not homeomorphic to an edge. We consider the following cases.

1. P_K is homeomorphic to a peak. Clearly, if P_H is homeomorphic to (u, v) or (v, u) or a valley, then C has only one source. We now show that P_H is not homeomorphic to a peak or to a zig-zag. Since P_K is a peak, then K is in case 1 or in case 3b.2 of the proof of Lemma 9.

Suppose P_H is a peak. Then H is in case 1 or in case 3b.2.

(a) P_K as in case 1. If H is in case 1, then G contains two sources, which is a contradiction. If H is in case 3b.2, then v is not a source of K, which is a contradiction.

(b) P_K as in case 3b.2. If H is in case 1, then the proof is as above. If H is in case 3b.2, then v is internal both in H and in K, which is a contradiction.

Suppose P_H is homeomorphic to a zig-zag. Then H is in case 2.b or in case 3b.1.

(a) P_K as in case 1. If H is in case 2.b or in case 3b.1, then $s(G) \in H^\circ$. Since u is source both in K and in H then G contains two sources, which is a contradiction.

(b) P_K as in case 3b.2. The proof is as above.

2. P_K homeomorphic to a zig-zag (w.l.o.g., we can suppose $a \equiv u$ and $b \equiv v$). Clearly, if P_H is homeomorphic to (v, u), then C has only one source. If P_H is

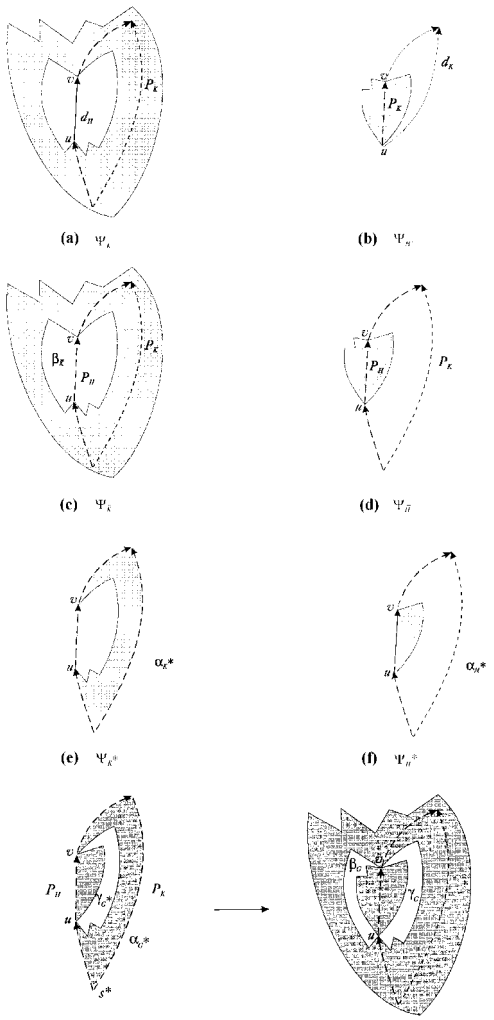

FIG. 13. *Construction of* Ψ_G.

homeomorphic to a peak, the proof is as for the case P_H homeomorphic to a zig-zag and P_K homeomorphic to a peak. We now show that P_H is not homeomorphic to the edge (u, v), to a valley, or to a zig-zag. Since P_K is a zig-zag, then K is in case 2(b) or case 3b.1; thus $s(G) \in K^\circ$ and u is a source of K.

Suppose P_H is homeomorphic to the edge (u, v). Then H is in case 2(a) or case 3(a) or case 4.1. If H is in case 2(a) or case 3(a), then u is a source of G and G contains two sources, which is a contradiction. If H is in case 4.1, then $s(G) \in H^\circ$, which is a contradiction.

Suppose P_H is homeomorphic to a valley. Then H is in case 4.2 and $s(G) \in H^\circ$, which is a contradiction.

Suppose P_H is homeomorphic to a zig-zag. Then H is in cases 2(b) and 3b.1 and $s(G) \in H^\circ$, which is a contradiction.

3. P_K is homeomorphic to a valley. Clearly, if P_H is homeomorphic to the edge (u, v), to the edge (v, u), or to the peak, then C has only one source. If P_H is

homeomorphic to a zig-zag, the proof is as for the case where P_H is homeomorphic to a valley and P_K is homeomorphic to a zig-zag. We now show that P_H is not homeomorphic to a valley.

Since both P_K and P_H are homeomorphic to a valley, then both K and H are in case 4.2; thus $s(G) \in K^\circ$ and $s(G) \in H^\circ$, which is a contradiction. □

The proof of the next lemma can be found in [3, 4].

LEMMA 15. *Let G be digraph, let Ψ_G be a candidate planar embedding of G, and let face $\delta \in \Psi_G$. Finally, let $\mathcal{A}$ be an assignment of the sinks and the sources of G to the faces of Ψ_G. If $|A(f)| = c(f)$ for each face $f \in \Psi_G$, with $f \neq \delta$, then $|A(\delta| = c(\delta)$.*

Suppose G, K, H, K', and H' satisfy the conditions of Lemma 11. In the following we give a constructive procedure to derive an embedding Ψ_G of G from two upward embeddings $\Psi_{H'}$ and $\Psi_{K'}$ of H' and K', respectively. We then show Ψ_G to be upward.

Let $\bar{K}$, $\bar{H}$, K^*, H^*, Ψ_{K^*}, Ψ_{H^*} be as defined for Lemmas 13 and 14 and let $\Psi_{K^*} \subseteq \Psi_{\bar{K}}(\Psi_{H^*} \subseteq \Psi_{\bar{H}})$ be the upward embedding of K^* (H^*) contained in $\Psi_{\bar{K}}$ ($\Psi_{\bar{H}}$). Denote by α_{K^*} and α_{H^*} the external faces of Ψ_{K^*} and Ψ_{H^*}, respectively (see Figures 13(e), (f)). Recall that $\alpha_{K^*} = \alpha_{H^*} = C$.

Let $G^* = K^* \cup H^*$ (see Figure 13(g)). Ψ_{G^*} is a planar embedding of G^* such that $\Psi_{K^*} \subset \Psi_{G^*}$, $\Psi_{H^*} \subset \Psi_{G^*}$, and P_K and P_H lie on the external face α_{G^*} of Ψ_{G^*} (i.e., $\alpha_{G^*} = C$).

We denote by γ_{G^*} the other face of Ψ_{G^*} (besides α_{G^*}) containing both edges of K^* and edges of H^*.

LEMMA 16. *Let G^* and Ψ_{G^*} be defined as above. Then*

(i) *G^* is an expanded sT-digraph.*

(ii) *Ψ_{G^*} is an upward embedding.*

Proof. (i) Since G^* is a subgraph of G, then G^* is expanded and acyclic. Since G^* is acyclic, it contains at least one source. Suppose G^* contains two sources s_1 and s_2. Since K^* (H^*) is an sT-digraph, both s_1 and s_2 cannot belong to K^* (H^*). Thus, w.l.o.g., $s_1 \in K^*$ and $s_2 \in H^*$. Furthermore, by Lemma 13, s_1 and s_2 lie on cycle C, so they are both contained in K^* and H^*, which is a contradiction. In the following, we denote by s^* the source of G^*.

(ii) We derive an upward consistent assignment $\mathcal{A}_{G^*}$ from the upward consistent assignments $\mathcal{A}_{K^*}$ and $\mathcal{A}_{H^*}$ associated with Ψ_{K^*} and Ψ_{H^*}.

First note that $A_{K^*}(\alpha_{K^*}) = A_{H^*}(\alpha_{H^*})$. In fact, let T^* be the set of sink-switches of $C = \alpha_{K^*} = \alpha_{H^*}$. Since Ψ_{K^*} and Ψ_{H^*} are upward embeddings of sT-digraphs, by Fact 2, each sink-switch on α_{K^*} and α_{H^*} is a sink of K^* and H^*, respectively, and they are all assigned to α_{H^*} and α_{K^*}. We have that $A_{K^*}(\alpha_{K^*}) = A_{H^*}(\alpha_{H^*}) = T^* \cup \{s^*\}$.

For each face $f \in \Psi_{G^*}$, with $f \neq \gamma_{G^*}$ and $f \neq \alpha_{G^*}$, we have that f belongs to Ψ_{K^*} or f belongs to Ψ_{H^*}, but not both. It is trivial to see that the following assignment to the faces of $\Psi_{G^*} - \{\gamma_{G^*}\}$ is feasible (i.e., the number of vertices assigned to each face equals the capacity of the face):

- $A_{G^*}(\alpha_{G^*}) = A_{K^*}(\alpha_{K^*}) = A_{H^*}(\alpha_{H^*})$;
- $A_{G^*}(f) = A_{K^*}(f)$, for $f \neq \alpha_{G^*}$ and $f \in \Psi_{K^*}$;
- $A_{G^*}(f) = A_{H^*}(f)$, for $f \neq \alpha_{G^*}$ and $f \in \Psi_{H^*}$.

Observe that all the sinks of Ψ_{G^*} not assigned by the above assignment lie on face γ_{G^*}, and so they can be assigned to it in $\mathcal{A}^*_G$. Since Ψ_{G^*} is a candidate embedding and, for each face $f \in \Psi_{G^*} - \{\gamma_{G^*}\}$, it is $|A_{G^*}(f)| = c(f)$, by Lemma 15 we have that $A_{G^*}(\gamma_{G^*}) = c(\gamma_{G^*})$. Thus, A_{G^*} is an upward consistent assignment and G^* is

upward planar. □

We are now able to give the proof of Lemma 11.

Proof of Lemma 11. A planar embedding Ψ_G of G can be obtained from the upward embeddings $\Psi_{\bar{K}}$ and $\Psi_{\bar{H}}$ in such a way that $\Psi_{G^*} \subseteq \Psi_G$. Each face of Ψ_G belongs either to $\Psi_{\bar{K}}$ or to $\Psi_{\bar{H}}$, except for two faces which share edges both of $\bar{K}$ and $\bar{H}$. One of these two faces coincides with face γ_{G^*} of Ψ_{G^*}, and thus it is internal in Ψ_{G^*}; we denote it by γ_G and denote the other face by β_G (see Figure 13(h)). Conversely, all the faces of $\Psi_{\bar{K}}$ ($\Psi_{\bar{H}}$), except for the two faces sharing P_H (P_K), belong to Ψ_G.

We now derive an assignment $\mathcal{A}_G$ from the upward consistent assignments $\mathcal{A}_{\bar{K}}$, $\mathcal{A}_{\bar{H}}$, and $\mathcal{A}_{G^*}$ in the following way:

- $A_G(\gamma_G) = A_{G^*}(\gamma_{G^*})$;
- $A_G(f) = A_{\bar{K}}(f)$, for $f \in \Psi_{\bar{K}}$;
- $A_G(f) = A_{\bar{H}}(f)$, for $f \in \Psi_{\bar{H}}$;
- it is easy to see that all remaining sinks and (eventually) the source of G stay on face β_G and so they are assigned to β_G in $\mathcal{A}_G$.

In order to prove that $\mathcal{A}_G$ is upward consistent we have to show that

(i) every sink and the source of G is assigned to exactly one face of Ψ_G;
(ii) every internal vertex of G is not assigned to any face of Ψ_G;
(iii) the number of vertices assigned to each face equals the capacity of the face.

Observe first that since P_K is embedded in the external face $\alpha_{\bar{H}}$ of $\Psi_{\bar{H}}$, $\alpha_{\bar{H}}$ is not a face of Ψ_G. Moreover, since γ_{G^*} is not the external face of Ψ_{G^*}, u and v are not assigned to it in $\mathcal{A}_{G^*}$ (they both lie on the external face) and, in turn, in $\mathcal{A}_G$.

We first prove (i). It is easy to see that each sink (source) of G is assigned to at least one face. We have to prove that each sink (source) of G is assigned to at most one face. Let x be a vertex assigned to two faces f_1 and f_2 in $\mathcal{A}_G$ ($f_1 \neq f_2$). From the definition of $\mathcal{A}_G$, $f_1 \in \Psi_{\bar{K}}$ and $f_2 \in \Psi_{\bar{H}}$. This is not possible if $x \neq u$ or $x \neq v$. If $x = u$ ($x = v$) then it is assigned to the external face $\alpha_{\bar{H}} = f_2$ of $\Psi_{\bar{H}}$ in $\mathcal{A}_{\bar{H}}$ and thus $f_2 \notin \Psi_G$, which is a contradiction.

(ii) Let x be an internal vertex of G and suppose it is assigned to a face f of Ψ_G. Again $x = u$ or $x = v$. Assume, w.l.o.g., $x = v$. Observe that f is not a face of $\Psi_{\bar{H}}$ (v is eventually assigned to its external face, which is not a face of Ψ_G). Furthermore, $f \neq \gamma_G$, since neither u nor v is assigned to it in $\mathcal{A}_G$. So f is a face of $\Psi_{\bar{K}}$.

Let us denote by $\beta_{\bar{K}}$ the face of $\Psi_{\bar{K}}$ sharing the path P_K and not embedded inside cycle C (see Figure 13(c)). Face $\beta_{\bar{K}}$ is not a face of Ψ_G, and thus $f \neq \beta_{\bar{K}}$. Since v is not assigned to $\beta_{\bar{K}}$ in $\mathcal{A}_{\bar{K}}$, $\beta_{\bar{K}}$ is internal in $\Psi_{\bar{K}}$. So, both $\beta_{\bar{K}}$ and $\gamma_{\bar{K}}$ are internal faces of $\Psi_{\bar{K}}$ and hence Ψ_H is embedded in a face of Ψ_K in Ψ_G. This implies that $s(\bar{K}) = s(G) \in \bar{K}$.

Suppose now that $x = v$ is a sink in $\bar{K}$ and v is not a sink in G.

Since v is a sink of $\bar{K}$, then P_H has an incoming edge into v, and P_H is homeomorphic to the edge (u, v) or to a zig-zag or to a valley. If P_H is homeomorphic to edge (u, v), then H is in case 2(a), 3(a), or 4.1 of the proof of Lemma 9. In case 2(a), v is a sink of H and thus u is a sink of G, which is a contradiction. In case 3(a), v is a source of K and thus it is not a sink in $\bar{K}$, which is a contradiction. If H is in case 4.1 then $s \in H^\circ$, which is a contradiction.

If P_H is homeomorphic to a valley, then H is in case 4.2 and $s(G) \in H^\circ$, which is a contradiction.

If P_H is homeomorphic to a zig-zag, then H is in case 2(b) or 3b.2. In both cases, $s(G) \in H^\circ$, which is a contradiction.

(iii) Since G is an expanded digraph, every planar embedding is candidate. By Lemma 15, the capacity equation for face β_G is satisfied, and $\mathcal{A}_G$ is upward consistent. □

Lemma 11 refers to digraph G. We extend the result to a minor $\tilde{G}$ of G. This is done by showing that, under certain restrictions, the directed-virtual-edges substituting components can be chosen independently one from another. In particular, this is true if the source s of G belongs to its minor. Note that in this case a minor of a minor of G is a minor of G.

LEMMA 17. *Let $\tilde{G}$ be a minor of G such that $s(\tilde{G}) = s(G)$. Let $\{u, v\}$ be a split pair of $\tilde{G}$ such that $\{u, v\}$ is also a split pair of G. Let $\tilde{K}$ be a component of $\tilde{G}$ w.r.t. $\{u, v\}$ and let K be the corresponding component of G, i.e., K is obtained from $\tilde{K}$ by replacing each directed-virtual-edge of $\tilde{K}$ with its associated component of G. Then it is $d(\tilde{K}, \tilde{G} - \tilde{K}) = d(K, G - K)$.*

Proof. In the following we denote by H the digraph $G - K$ and by $\tilde{H}$ the digraph $\tilde{G} - \tilde{K}$. Observe that, for each component J of G such that $J \notin \tilde{G}$ (i.e., J is substituted by its directed-virtual-edge), since $s(G) \in \tilde{G}$, then $s(G) \notin J^\circ$.

We examine the following four cases corresponding to the substitution Rules 1–4 applied to components K and $\tilde{K}$.

1. Since u and v are sources of K, by Fact 9, u and v are sources of $\tilde{K}$. Then $d(\tilde{K}, \tilde{H})$ is a peak and the lemma holds.

2(a) u is a source of K, v is a sink of K, and $s(G) \notin K^\circ$. By Fact 9, u is a source of $\tilde{K}$. Since $s(\tilde{G}) = s(G)$ then $s(G) \notin K^\circ$. We now show that v is a sink of $\tilde{K}$. In fact, v is a sink of all the components having v as a pole. By the substitution rules, whenever a component $J \in K$ has v as a sink then the associated directed-virtual-edge has an edge incoming into v except for Rules 2(b) and 4(b). But, in both cases, $s(G) \in J^\circ$, contradicting that $s \notin K_\circ$. Then Rule 2(a) is applied to $\tilde{K}$ and $d(\tilde{K}, \tilde{H})$ is the edge (u, v).

2(b) u is a source of K, v is a sink of K, and $s(G) \in K^\circ$. By Fact 9, u is a source of $\tilde{K}$. Furthermore, $s(\tilde{G}) \in \tilde{K}^\circ$.

If v is a sink of $\tilde{K}$, then Rule 2(b) is applied to $\tilde{K}$ and $d(\tilde{K}, \tilde{H})$ is a peak.

If v is internal of $\tilde{K}$, then Rule 3(b) is applied to $\tilde{K}$ and $d(\tilde{K}, \tilde{H})$ is a peak.

If v is a source of $\tilde{K}$, then $\tilde{K}$ has three sources and the minor $\tilde{G}$ is not an sT-digraph (it contains at least two sources), which is a contradiction.

3(a) u is a source of K, v is internal of K, $s(G) \in H$, and v is a source of H. By Fact 9, u is a source of $\tilde{K}$ and v is a source of $\tilde{H}$.

If v is internal in $\tilde{K}$, then Rule 3(a) is applied to $\tilde{K}$ and $d(\tilde{K}, \tilde{H})$ is the edge (u, v).

If v is a sink of $\tilde{K}$, then Rule 2(a) is applied to $\tilde{K}$ and $d(\tilde{K}, \tilde{H})$ is the edge (u, v).

If v is a source of $\tilde{K}$, then v is a source of $\tilde{G}$. Since $s(\tilde{G}) = s(G) \neq v$, then $\tilde{G}$ has two sources, which is a contradiction.

3(b) u is a source of K and v is internal in K, $s(G) \in K^\circ$ or v is not a source of H.

By Fact 9, u is a source of $\tilde{K}$. Two cases are possible.

(i) $s(G) \in K^\circ$. Then v is the only source of H. In fact, if u is a source of H, then u is a source of G, which is a contradiction. By Fact 9, v is a source of $\tilde{H}$.

If v is internal in $\tilde{K}$, then Rule 3(b) is applied to $\tilde{K}$ and $d(\tilde{K}, \tilde{H})$ is a peak.

If v is a sink of $\tilde{K}$, then Rule 2(b) is applied to $\tilde{K}$ and $d(\tilde{K}, \tilde{H})$ is a peak.

If v is a source of $\tilde{K}$, then v is a source of $\tilde{G}$. Since $s(\tilde{G}) = s(G) \neq v$, then $\tilde{G}$ has two sources, which is a contradiction.

(ii) v is not a source of H and $s(G) \in H$. Since G is expanded, v is a sink of H.

If v is a source of $\tilde{K}$, then Rule 1 is applied to $\tilde{K}$ and $d(\tilde{K}, \tilde{H})$ is a peak.

If v is internal in $\tilde{K}$ and v is not a source of $\tilde{H}$, then Rule 3(b) is applied to $\tilde{K}$ and $d(\tilde{K}, \tilde{H})$ is a peak. If v is a source of $\tilde{H}$, there exists a component J of H, with $J \notin \tilde{H}$, having v and u_J as poles, whose directed-virtual-edge is either a peak or the edge (v, u_J). Observe that v is a sink of J and u_J is the source of J (since $s(G) \notin J^\circ$). But in this case, Rule 2(a) is applied to J and $d(J, G - J)$ is the edge (u_J, v), which is a contradiction.

If v is a sink of $\tilde{K}$, since v is internal in K, there exists a component J, with $J \in K$ and $J \notin \tilde{K}$, having v and u_J as poles, whose directed-virtual-edge is the edge (u_J, v). Furthermore, v is an internal vertex or a source of J. If v is a source of J then $d(J, G - J)$ is not the edge (u_J, v). If v is internal in J, then Rules 3(a) or 4(b) must be applied in order to have $d(J, G - J) = (u_J, v)$. Rule 3(a) implies that v is a source of $G - J$; hence v is a source of K, which is a contradiction. Rule 4(a) implies that $s(G) \in J^\circ$, which is a contradiction.

4. u and v are not sources of K. $s \in K^\circ$. Either u or v (or both) is a source of H. Suppose, w.l.o.g., that u is a source of H. u is not a source of $\tilde{K}$; otherwise the minor $\tilde{G}$ has two sources. By Fact 9, u is a source of $\tilde{H}$.

If v is not a source of $\tilde{K}$, Rule 4(a) can be applied and $d(\tilde{K}, \tilde{H})$ is the edge (u, v).

If v is a source of $\tilde{K}$, there exists a component J of K, with $J \notin \tilde{K}$, having v and u_J as poles, such that v is a nonsource of J, and its directed-virtual-edge is either a peak or the edge (v, u_J). Observe that, since $s(G) \notin J^\circ$, u_J is the source of J. If v is a sink of J, Rule 2(a) is applied to J and $d(J, G - J)$ is the edge (u_J, v), which is a contradiction. If v is internal in J, Rule 3(b) is applied and, since $s(G) \notin J^\circ$, v is a sink of $G - J$ and hence it is a sink in all components of $K - J$. Now, v is a source in the digraph $\tilde{K} - d(J, G - J)$. Then there exists a component Z of K, with $Z \neq J$ and $Z \notin \tilde{K}$, having v and u_Z as poles, such that v is a source in $d(Z, G - Z)$. Since v is a sink of Z and $s(G) \notin Z^\circ$ (since $s(G) \in \tilde{K}$), u_Z is a source of Z and then Rule 2(a) is applied. But then $d(Z, G - Z)$ is the edge (u_Z, v), which is a contradiction. □

We are now able to prove the sufficiency part of Theorem 3.

Proof of sufficiency of Theorem 3. Let $\mathcal{T}$ be the rooted *SPQR*-tree associated with the graph G, and let $\mu_1, \ldots, \mu_m$ be the sequence of nodes of $\mathcal{T}$ deriving from a depth-first-search (DFS) visit of $\mathcal{T}$, starting at its root. Let $Skel(\mu_i), i = 1, \ldots, m$ be the sT-skeleton associated with $\mu, \ldots, \mu_m$.

For each node μ_i, let d_i^c be the directed virtual edge of μ_i in the skeleton associated with the parent of μ_i, and let d_i^p be the directed-virtual-edge of the parent of μ_i in $Skel(\mu_i)$. Clearly, if $\mu_i = \mu_1$ is the root, then $d_i^p = d_1^p = \{\emptyset\}$. Finally, let $\tilde{G}_i = Skel(\mu_1) - d_2^c \cup (Skel(\mu_k) - d_2^p) - d_3^c \cup (Skel(\mu_3) - d_3^p) - \cdots - d_i^c \cup (Skel(\mu_i) - d_i^p)$.

We show that $\tilde{G}_i$ is a minor of G, with $s(G) \in \tilde{G}_i$, and that $\tilde{G}_i$ is upward planar.

For $i = 1$ we have that $\tilde{G}_1 = Skel(\mu_1)$ and the claim trivially holds. Suppose that $\tilde{G}_{l-1}$ is a minor of G with $s(G) \in \tilde{G}_{l-1}$, and that $\tilde{G}_{l-1}$ is upward planar. We show that $\tilde{G}_l$ is a minor of G, with $s(G) \in \tilde{G}_l$, and that $\tilde{G}_l$ is upward planar.

Let H be the pertinent graph of d_l^c and K be the pertinent graph of d_l^p. Recall that $K \cup H = G$ and that K and H share exactly two vertices. Moreover $d_l^p = d(K, H)$ and $d_l^c = d(H, K)$.

Let $J_1, \ldots, J_q$ be components of G contained in K, such that

$$\begin{aligned}\tilde{G}_{l-1} &= G - H - J_1 - \cdots - J_q \cup d(H, K) \cup d(J_1, G - J_1) \cup \cdots \cup d(J_q, G - J_q) \\ &= K - J_1 - \cdots - J_q \cup d(H, K) \cup d(J_1, G - J_1) \cup \cdots \cup d(J_q, G - J_q),\end{aligned}$$

and let $Z_1, \ldots, Z_r$ be split components of G contained in H, such that

$$\begin{aligned} \mathit{Skel}(\mu_l) &= G - K - Z_1 - \cdots - Z_r \cup d(K,H) \cup d(Z_1, G - Z_1) \cup \cdots \cup d(Z_r, G - Z_r) \\ &= H - Z_1 - \cdots - Z_q \cup d(K,H) \cup d(Z_1, G - Z_1) \cup \cdots \cup d(Z_r, G - Z_r). \end{aligned}$$

The digraph $\tilde{G}_l = K \cup H - J_1 - \cdots - J_q - Z_1 - \cdots - Z_q \cup d(J_1, G - J_1) \cup \cdots \cup d(J_q, G - J_q) \cup d(Z_1, G - Z_1) \cup \cdots \cup d(Z_r, G - Z_r)$ is a minor of G. In fact, since $J_i \in K$, $i = 1, \ldots, q$, and $Z_t \in H$, $t = 1, \ldots, r$, it follows that J_i and Z_t do not share any edge, for $i = 1, \ldots, q$ and $t = 1, \ldots, r$.

Since $s(G) \in \tilde{G}_{l-1}$, then $s(G) \in \tilde{G}_l$.

Let $\tilde{K} = \tilde{G}_{l-1} - d_l^c$ and $\tilde{H} = \mathit{Skel}(\mu_l) - d_l^p$. Clearly $\tilde{G}_l = \tilde{K} \cup \tilde{H}$. By Lemma 17, $d(\tilde{K}, \tilde{H}) = d(K,H) = d_l^p$ and $d(\tilde{H}, \tilde{K}) = d(H,K) = d_l^c$. Since $\tilde{K} \cup d(\tilde{H}, \tilde{K}) = \tilde{G}_{l-1}$ is upward planar and $\tilde{H} \cup d(\tilde{K}, \tilde{H}) = \mathit{Skel}(\mu_l)$ is upward planar with $d(\tilde{K}, \tilde{H}) = d_l^p$ embedded on the external face, then by Lemma 11, $\tilde{G}_l$ is upward planar.

We now show that $\tilde{G}_m = G$. By induction $\tilde{G}_m$ is a minor of G. Suppose $\tilde{G}_m \neq G$; then there exists a component J of G such that $J \notin \tilde{G}_m$ and $d(J, G - J) \in \tilde{G}_m$. Let μ_j be the node of $\mathcal{T}$ such that $d(J, G - J) \in \mathit{Skel}(\mu_j)$. $d(J, G - J)$ is associated with either the parent of μ_j or one of the children of μ_j. Since the tree $\mathcal{T}$ has been entirely visited then $d(J, G - J)$ has been substituted, and thus $d(J, G - J) \notin \tilde{G}_m$, which is a contradiction. □

7. Algorithm for general single-source digraphs. Let G be a biconnected single-source digraph. In this section we present an algorithm for testing whether G is upward planar.

ALGORITHM. *Test.*

1. Construct the expansion G' of G.

2. Test whether G' is planar. If G' is not planar, then return "not-upward-planar" and stop; else, construct an embedding for G'.

3. Test whether G' is acyclic. If G' is not acyclic, then return "not-upward-planar" and stop.

4. Construct the SPQR-tree $\mathcal{T}$ of G' and the skeletons of its nodes.

5. For each virtual edge e of a skeleton, classify each endpoint of e as a source, sink, or internal vertex in the pertinent digraph of e. Also, determine if the pertinent digraph of e contains the source.

6. For each node μ of $\mathcal{T}$, compute the sT-skeleton of μ.

7. For each R-node μ of $\mathcal{T}$

(a) test whether the sT-skeleton of μ is upward planar by means of algorithm *Embedded-Test*. If *Embedded-Test* returns "not-upward-planar," then return "not-upward-planar" and stop.

(b) mark the virtual edges of the skeleton of μ whose endpoints are on the external face in some upward drawing of the sT-skeleton of μ.

(c) for each unmarked virtual edge e of the skeleton of μ, constrain the tree edge of $\mathcal{T}$ associated with e to be directed towards μ.

(d) if the source is not in $\mathit{skeleton}(\mu)$, let ν be the node neighbor of μ whose pertinent digraph contains the source, and constrain the tree edge (μ, ν) to be directed towards ν.

8. Determine whether $\mathcal{T}$ can be rooted at a Q-node in such a way that orienting edges from children to parents satisfies the constraints of steps 7(c)–(d). If such a rooting exists then return "upward-planar"; else return "not-upward-planar."

For single-source digraphs that are not biconnected we apply the above algorithm to each biconnected component.

THEOREM 4. *Upward planarity testing of a single-source digraph with n vertices can be done in $O(n)$ time using $O(n)$ space.*

Proof. Steps 1 and 3 can be trivially performed in $O(n)$ time. Planarity testing in step 2 can also be done in $O(n)$ time [18]. The construction of the SPQR-tree and the skeletons of its nodes (step 4) takes time $O(n)$ using a variation of the algorithm of [17]. The preprocessing of step 5 consists essentially of a visit of $\mathcal{T}$ and can be done in $O(n)$ time. Let n_μ be the number of vertices of the skeleton of μ. The information collected in step 5 allows us to perform step 6 in $O(n)$ time and step 7(d) in $O(n_\mu)$ time. By Theorem 2, step 7(a) takes $O(n_\mu)$ time. The output of step 7(a) allows us to perform steps 7(b)–(c) in $O(n_\mu)$ time. Since $\sum_\mu n_\mu = O(n)$, the total complexity of step 7 is $O(n)$. Finally, step 8 consists of a visit of $\mathcal{T}$ and takes $O(n)$ time. □

To parallelize Algorithm *Test*, we need an efficient way of testing in parallel whether a planar single-source digraph with n vertices is acyclic. For this purpose, we can use the algorithm of [20], which runs in $O(\log^3 n)$ time on a CRCW PRAM with n processors. However, the particular structure of planar single-source digraphs allows us to perform this test optimally. The following characterization is inspired by some ideas in [20].

Let G be an embedded, expanded, planar single-source digraph. The *clockwise subgraph* of G is obtained by taking the first incoming edge of each internal vertex, in clockwise order. The *counterclockwise subgraph* of G is similarly obtained by taking the first incoming edge of each internal vertex, in counterclockwise order. Such subgraphs of G have all vertices with in-degree 1 or 0.

THEOREM 5. *An embedded, expanded single-source digraph G is acyclic if and only if both the clockwise and counterclockwise subgraphs of G are acyclic.*

Proof. The only-if part is trivial. For the if part, assume for contradiction that G is not acyclic, and consider an arbitrary drawing of G with the prescribed embedding and with the source on the external face. We will show the existence of a cycle in either the clockwise or counterclockwise subgraph. Let γ be a cycle of G that does not enclose any other cycle. Since the source of G must be outside γ, all the edges incident on vertices of γ and inside γ must be outgoing edges. Hence, γ is contained in the clockwise or counterclockwise subgraph depending on whether it is a clockwise or counterclockwise cycle. □

The structure of each connected component of the clockwise and counterclockwise subgraphs is either a source tree, or a collection of source trees with their roots connected in a directed cycle. Hence, one can test whether such subgraphs are acyclic using standard parallel techniques. Since expansion preserves acyclicity, we have the following theorem.

THEOREM 6. *Given an embedded planar single-source digraph G with n vertices, one can test if G is acyclic in $O(\log n)$ time with $n/\log n$ processors on an EREW PRAM.*

By applying the result of Theorem 6 and various parallel techniques (in particular [14, 28, 27]) we can efficiently parallelize algorithm *Test*.

THEOREM 7. *Upward planarity testing of a single-source digraph with n vertices can be done in $O(\log n)$ time on a CRCW PRAM with $n \log\log n/\log n$ processors using $O(n)$ space.*

As a consequence of Theorems 1 and 3, algorithm *Test* can be easily extended such that if the n-vertex digraph G is found to be upward planar, a planar st-digraph

G' with $O(n)$ vertices is constructed that contains G as a subdigraph. Hence, by applying the planar polyline upward drawing algorithm of Di Battista, Tamassia, and Tollis [12] to G' and then removing the vertices and edges of G' that are not in G, we obtain a planar polyline upward drawing of G.

THEOREM 8. *Algorithm* Test *can be extended so that it constructs a planar polyline upward drawing if the digraph is upward planar. The complexity bounds stay unchanged.*

7.1. Examples of application of algorithm *Test*. In this subsection we use two examples to illustrate the behavior of algorithm *Test* in performing the upward planarity testing. In the first example, the algorithm is applied to a graph which is not upward drawable; in the second example, the algorithm is applied to an upward drawable graph.

Example 1. In this example we consider the graph G of Figure 2a. We apply algorithm *Test* step by step.

1. The expansion graph G' of G is shown in Figure 14.

2. By a simple inspection it is possible to verify that G' is planar.

3. Again, by a simple inspection, it is possible to verify that G' is acyclic.

4. The SPQR-tree $\mathcal{T}$ of G' is shown in Figure 15. The skeletons of the nodes of $\mathcal{T}$ are shown in Figure 16 (the skeletons of the Q nodes are omitted).

5. Consider, for example, the virtual edge (2, 15) in skeleton μ_1 of Figure 16, which is the virtual edge of μ_4. The pertinent graph of μ_4 is subgraph G'_4 of G' induced by the node set $V(G') - \{13, 14, 24, 25\}$. By simple inspection, it is possible to verify that node 2 is internal in G'_4, while node 15 is a sink in G'_4. In addition, the source 1 of G' is contained in G'_4. In the same way, all other endnodes of virtual edges can be classified.

6. The sT-skeletons corresponding to the skeletons of Figure 16 are shown in Figure 17. Consider, for example, the sT-skeleton of μ_2. The pertinent graph G'_1 associated with the virtual edge (2, 13) of the skeleton of μ_2 (Figure 16) is the subgraph of G' induced by the node set $V(G') - \{24\}$. Using the classification performed in the preceding step, it is easy to verify that: (i) 2 is internal in G'_1 and 13 is a source in G'_1. In addition, the source 1 of G' belongs to G'°_1, hence, by Rule 3b the directed-virtual-edge associated with G'_1 is a peak. The pertinent graph associated with the virtual edge (2, 24) of μ_2 is the directed edge (2, 24). If is easy to see that the directed-virtual-edge associated with an edge u, v, is the edge (u, v) (Rule 3a). Thus, the directed-virtual-edge associated with the directed edge 2, 24 is again (2, 24). The same holds for edge (24, 13).

7. Now we perform Steps 7(a)–7(d) on all the R-nodes of $\mathcal{T}$.

(a) In Figure 18 we show the face-sink graphs associated with the sT-skeletons of the R-nodes μ_1, μ_5, and μ_{12} (the vertices associated with the faces are represented by squares). It is easy to verify that they all satisfy the conditions of Theorem 1; thus the algorithm *Embedded Test* will return "upward-planar" for every R-node. It also returns, for each R-node, the set of faces that can be external faces in an upward drawing of the associated sT-skeleton. In the figure, the nodes associated with these faces are indicated by black squares.

(b) By inspection of Figure 18, the unmarked edges are the following:

- μ_1: $\{(13, 14)\}$.
- μ_5: $\{(2, 5), (5, 8), (5, 11), (6, 8), (7, 8), (9, 11), (10, 11)\}$.
- μ_{12}: $\{(1, 3), (2, 3), (3, 4)\}$.

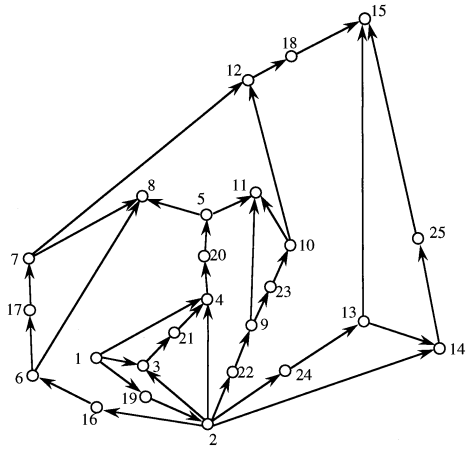

FIG. 14. *Expansion graph of graph G of Figure* 2a.

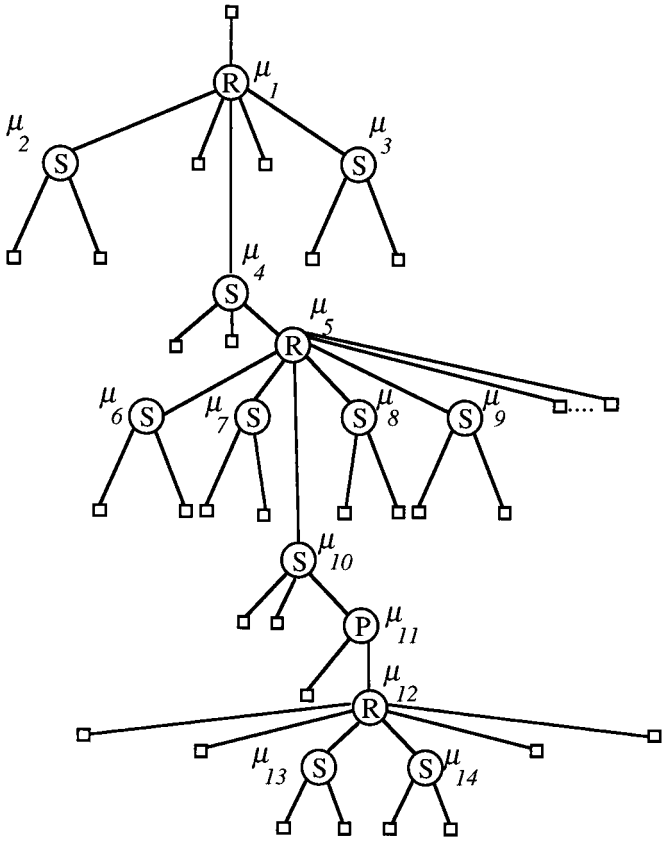

FIG. 15. *The SPQR-tree* $\mathcal{T}$ *of* G'.

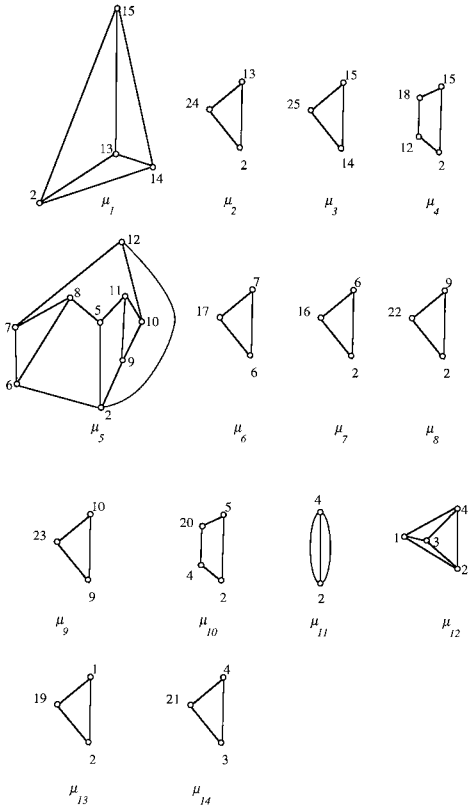

FIG. 16. *The skeletons of the nodes of* $\mathcal{T}$.

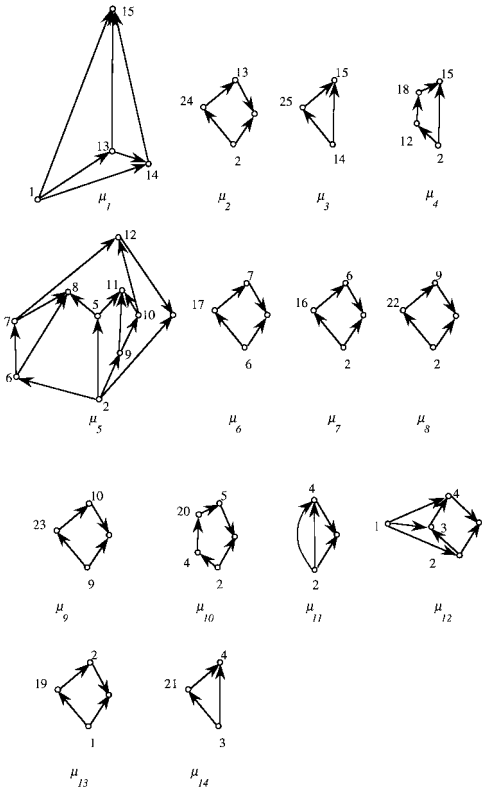

FIG. 17. *The sT-skeletons of the nodes of* $\mathcal{T}$.

(c) In Figure 19, the edges of the SPQR-tree $\mathcal{T}$ associated with unmarked virtual edges are oriented. For example, the tree-edge associated with the directed virtual edge (13, 14) of the sT-skeleton of μ_1 is oriented toward μ_1. Analogously, the tree-edge (μ_5, μ_{10}) associated with the directed-virtual-edge (2, 5) of sT-skeleton of μ_5 is directed toward μ_5.

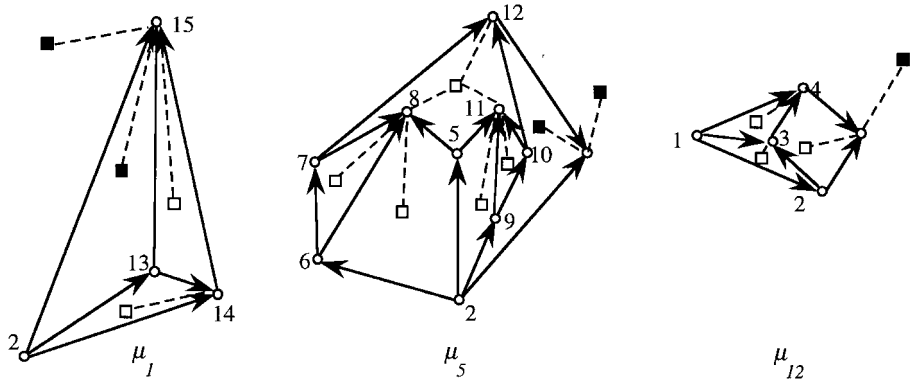

FIG. 18. *The face-sink graphs of the sT-skeletons of the* R*-nodes of* $\mathcal{T}$.

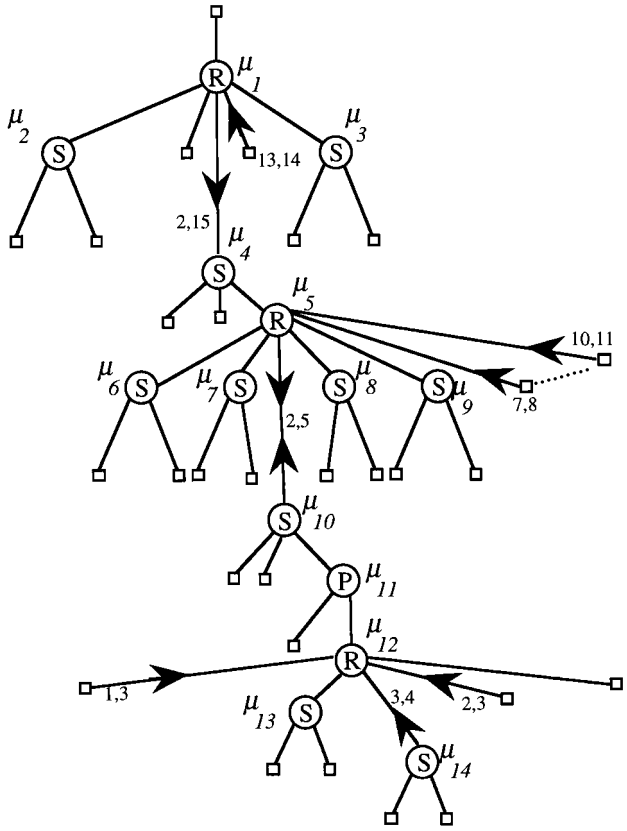

FIG. 19. *Partial orientation of* $\mathcal{T}$.

(d) Since the skeleton of μ_1 does not contain the source 1 of G', and the pertinent graph G'_4 associated with μ_4 contains the source 1, then the tree-edge μ_1, μ_4 is oriented toward μ_4. Analogously, the tree-edge μ_5, μ_{10} is oriented towards μ_{10}.

8. Since the tree-edge (μ_5, μ_{10}) is constrained to be oriented in both directions, it follows that it is not possible to find a rooting of $\mathcal{T}$ at a Q-node containing the source. Hence algorithm *Test* returns "not-upward-planar."

Example 2. In this example, we consider a graph H obtained from graph G of Figure 2a by contracting edge (12, 15).

1. In Figure 20 we show the expansion graph H' of H.

2. By a simple inspection it is possible to verify that H' is planar.

3. By a simple inspection it is possible to verify that H' is acyclic.

4. In Figure 21 we show the SPQR-tree $\mathcal{T}_H$ of H' and in Figure 22 the skeletons of the nodes of $\mathcal{T}_H$ (the skeletons of the Q-nodes are omitted).

5. In the same way as in step 5 of the previous example, all the endnodes of the virtual edges can be classified.

6. The sT-skeletons corresponding to the skeletons of Figure 22 are shown in Figure 23.

7. (a) In Figure 24 we show the face-sink graphs associated with the sT-skeletons of the R-nodes μ_1, μ_4, and μ_{11} (the vertices associated with the faces are represented by squares). It is easy to verify that they all satisfy the conditions of Theorem 1;

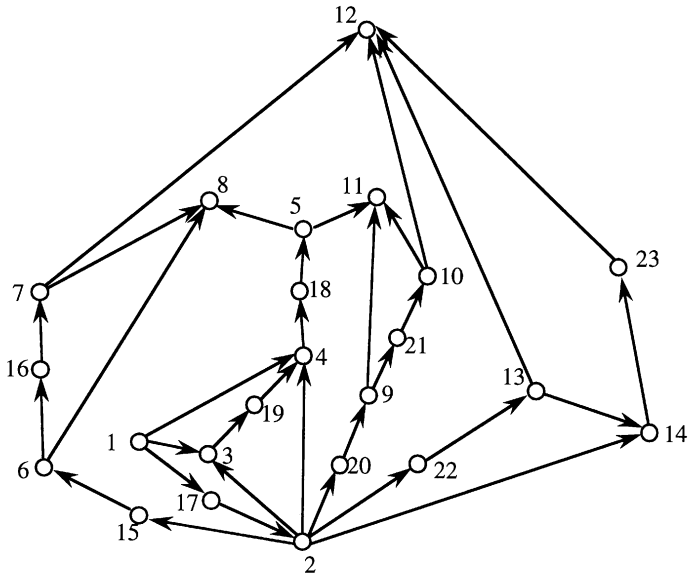

FIG. 20. *Expansion graph of graph H.*

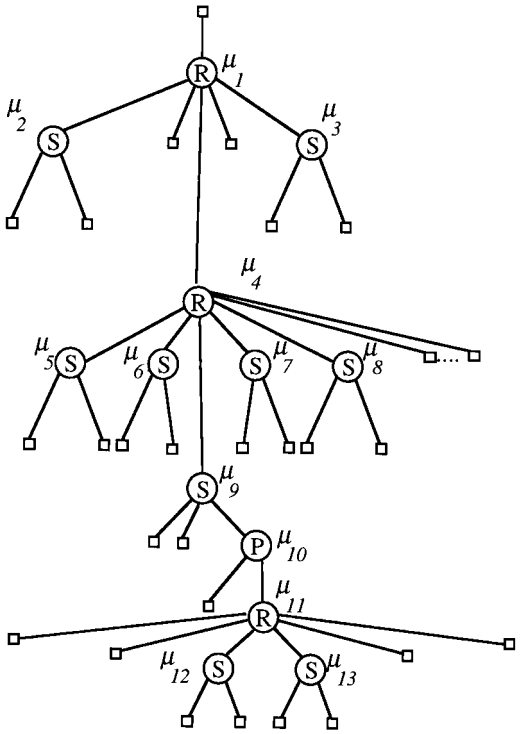

FIG. 21. *The SPQR-tree $\mathcal{T}_H$ of H'.*

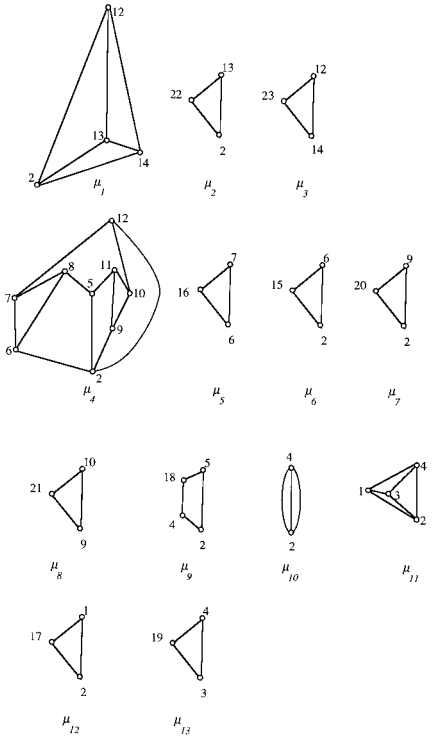

FIG. 22. *The skeletons of the nodes of* $\mathcal{T}_H$.

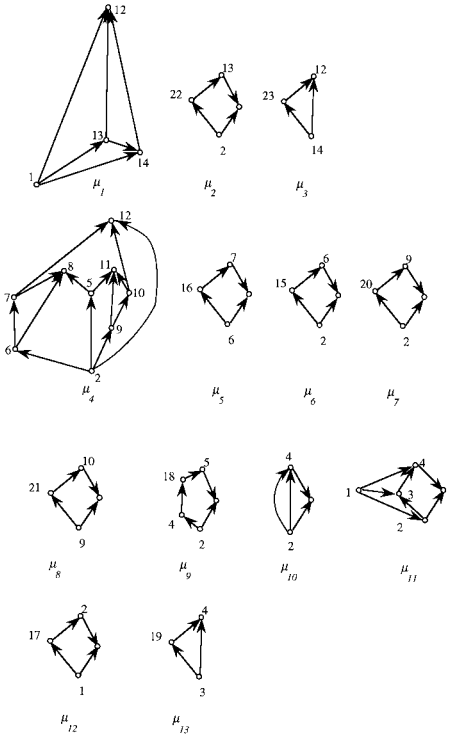

FIG. 23. *The* sT*-skeletons of the nodes of* $\mathcal{T}_H$.

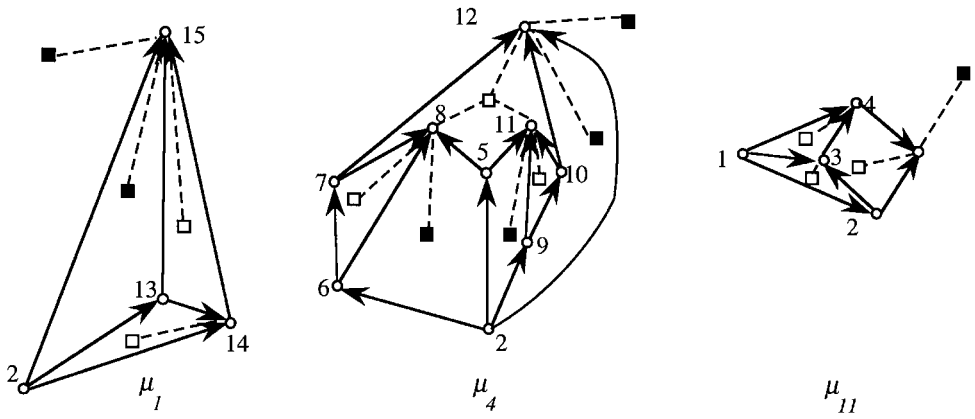

FIG. 24. *The face-sink graphs of the sT-skeletons of the* R*-nodes of* $\mathcal{T}_H$.

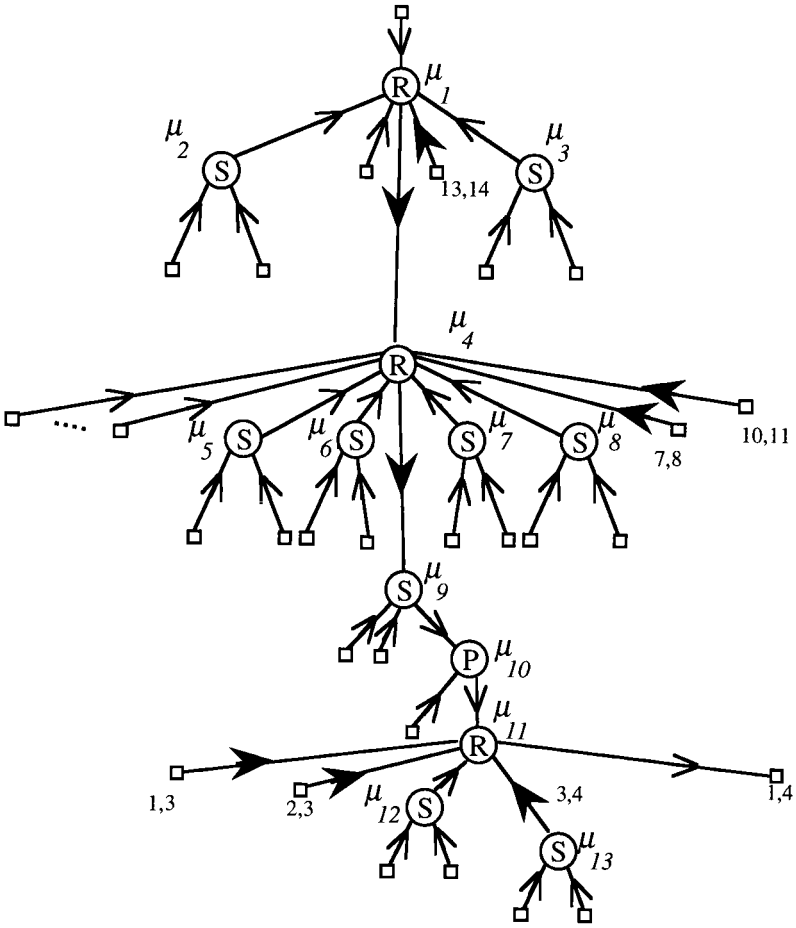

FIG. 25. *Orientation of* $\mathcal{T}_H$.

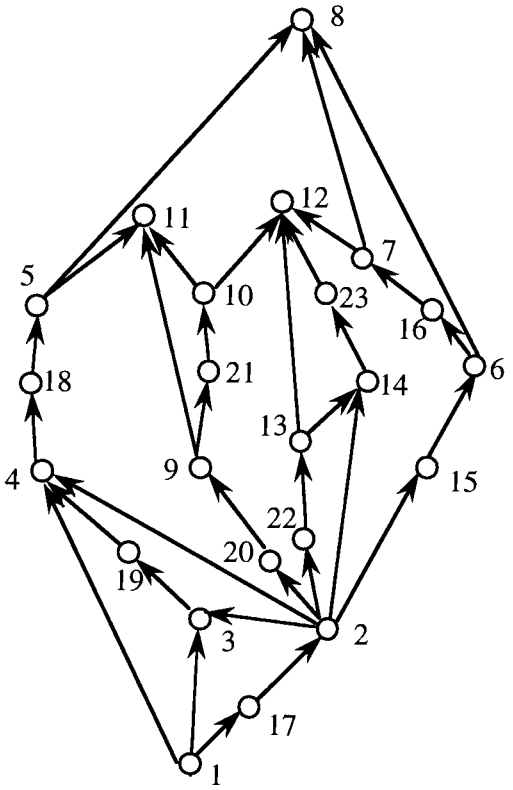

FIG. 26. *Upward drawing of H'.*

thus the algorithm *Embedded Test* will return "upward-planar" for every R-node. It also returns, for each R-node, the set of faces that can be external faces in an upward drawing of the associated sT-skeleton. In the figure, the nodes associated with these faces are indicated by black squares.

(b) By inspection of Figure 24, the unmarked edges are the following:

- μ_1: $\{(13, 14)\}$.
- μ_4: $\{(7, 8), (10, 11)\}$.
- μ_{11}: $\{(1, 3), (2, 3), (3, 4)\}$.

(c) In Figure 25, the edges of the SPQR-tree $\mathcal{T}_H$ associated with unmarked virtual edges are oriented; their orientations are represented by bold arrows.

(d) Since the skeleton of μ_1 does not contain the source 1 of H', and the pertinent graph H'_4 associated with μ_4 contains the source 1, then the tree-edge (μ_1, μ_4) is oriented toward μ_4. Analogously, the tree-edge (μ_4, μ_9) is oriented toward μ_9. Again, in Figure 25 these fixed orientations are represented by bold arrows.

8. By simple inspection, it is possible to find a rooting of $\mathcal{T}_H$ at the Q-node associated with the edge (1, 4) (see Figure 25). Hence algorithm *Test* returns "upward-planar."

An upward drawing of the expansion H' of graph H is shown in Figure 26.

LINEAR AND $O(n \log n)$ TIME MINIMUM-COST MATCHING ALGORITHMS FOR QUASI-CONVEX TOURS*

SAMUEL R. BUSS† AND PETER N. YIANILOS‡

Abstract. Let G be a complete, weighted, undirected, bipartite graph with n red nodes, n' blue nodes, and symmetric cost function $c(x, y)$. A maximum matching for G consists of $\min\{n, n'\}$ edges from distinct red nodes to distinct blue nodes. Our objective is to find a minimum-cost maximum matching, i.e., one for which the sum of the edge costs has minimal value. This is the weighted bipartite matching problem or, as it is sometimes called, the assignment problem.

We report a new and very fast algorithm for an abstract special case of this problem. Our first requirement is that the nodes of the graph are given as a "quasi-convex tour." This means that they are provided circularly ordered as $x_1, \ldots, x_N$, where $N = n + n'$, and that for any x_i, x_j, x_k, x_ℓ, not necessarily adjacent but in tour order, with x_i, x_j of one color and x_k, x_ℓ of the opposite color, the following inequality holds:

$$c(x_i, x_\ell) + c(x_j, x_k) \leq c(x_i, x_k) + c(x_j, x_\ell).$$

If $n = n'$, our algorithm then finds a minimum-cost matching in $O(N \log N)$ time. Given an additional condition of "weak analyticity," the time complexity is reduced to $O(N)$. In both cases only linear space is required. In the special case where the circular ordering is a line-like ordering, these results apply even if $n \neq n'$.

Our algorithm is conceptually elegant, straightforward to implement, and free of large hidden constants. As such we expect that it may be of practical value in several problem areas.

Many natural graphs satisfy the quasi-convexity condition. These include graphs which lie on a line or circle with the canonical tour ordering, and costs given by any concave-down function of arclength — or graphs whose nodes lie on an arbitrary convex planar figure with costs provided by Euclidean distance.

The weak-analyticity condition applies to points lying on a circle with costs given by Euclidean distance, and we thus obtain the first linear-time algorithm for the minimum-cost matching problem in this setting (and also where costs are given by the L_1 or L_∞ metrics).

Given two symbol strings over the same alphabet, we may imagine one to be red and the other blue and use our algorithms to compute string distances. In this formulation, the strings are embedded in the real line and multiple independent assignment problems are solved, one for each distinct alphabet symbol.

While these examples are somewhat geometrical, it is important to remember that our conditions are purely abstract; hence, our algorithms may find application to problems in which no direct connection to geometry is evident.

Key words. assignment problem, bipartite weighted matching, computational geometry, concave penalty function, convexity, linear time, Monge property, quadrangle inequality, string comparison

matching. We shall consider graphs G which have N nodes; the nodes are partitioned into a set of n red nodes and n' blue nodes with $N = n + n'$. G is *balanced* if it has equal numbers of red and blue nodes. There is a symmetric cost function $c(x, y)$, which gives the cost of an edge from node x to node y, with x and y of distinct colors. A matching is a set of edges with no endpoints in common that match all the nodes of one color with the same number of nodes of the opposite color. The cost of a matching is the sum of the costs of its edges. The problem of finding a minimal-cost matching for a general bipartite graph is known to have an $O(N^3)$ time algorithm (see Lawler [18] for this and other background on matching), and for graphs with nodes in the plane with the Euclidean distance as cost function, there is a $O(N^{2.5} \log N)$ time algorithm due to Vaidya [22].

The minimum-cost matching problem is substantially easier in the case where the nodes are in line-like order or are circularly ordered. The simplest versions of line-like/circular orderings are where the points lie on a line or lie on a curve homeomorphic to a circle, and the cost $c(x, y)$ of an edge between x and y is equal to the shortest arclength distance between the nodes. The matching problem for this arclength cost function has been studied by Karp and Li [14], Aggarwal et al. [1], Werman et al. [23], and others, and is the "skis and skiers" problem of Lawler [18]. Karp and Li have given linear time algorithms for this matching problem; Aggarwal et al. have generalized the linear time algorithm to the transportation problem.

A more general version of the matching problem for graphs in line-like order has been studied by Gilmore and Gomory [10] (see [18]). In this version, the cost of an edge from a red node x forward to a blue node y is defined to equal $\int_x^y f$, and from a blue node x forward to a red node y to equal $\int_x^y g$, for some functions f and g. This matching problem has a linear time algorithm provided $f + g \geq 0$.

Another version of the matching problem for line-like graphs is considered by Aggarwal et al. [1]; they use graphs which satisfy a "Monge" property which states that the inequality (1.1) below holds except with the inequality sign's direction reversed. They give a linear time algorithm for the matching problem for (unbalanced) Monge graphs.

In the prior work most closely related to this paper, Marcotte and Suri [20] consider the matching problem for a circularly ordered, balanced tour in which the nodes are the vertices of a convex polygon and the cost function is equal to Euclidean distance. This matching problem is substantially more complicated than the comparatively simple "skis and skiers" type problems; nonetheless, Marcotte and Suri give an $O(N \log N)$ time algorithm which solves this minimum-cost matching problem. For the case where the nodes are the vertices of a simple polygon and the cost function is equal to the shortest Euclidean distance *inside* the polygon, they give an $O(N \log^2 N)$ time algorithm.

The main results of this paper apply to all of the above matching problems on circularly ordered or line-like tours, with the sole exception of unbalanced, Monge graphs. For the "skis and skiers" and the problems of Gilmore and Gomory, Theorem 1.9 gives new linear time algorithms that find minimum-cost matchings which are different than the traditional minimum-cost matchings (and our algorithms are more complicated than is necessary for these simple problems). Our algorithms subsume those of Marcotte and Suri and give some substantial improvements. First, with the weak analyticity condition, we have linear time algorithms for many important cases, whereas Marcotte and Suri's algorithm takes $O(N \log N)$ time. Second, our assumption of quasi convexity is considerably more general than their planar geometrical

setting and allows diverse applications. Third, our algorithms are conceptually simpler than the divide-and-conquer methods used by Marcotte and Suri, and we expect that our algorithms are easier to implement.

All of our algorithms have been implemented as reported in [5]; a brief overview of this implementation is given in section 3.4.

We list some sample applications of our algorithms in the examples numbered 1–8 below. One example of a matching problem solution is shown in Figure 1.1. For this figure, a 74-node bipartite graph was chosen with nodes on the unit circle. For this matching problem, the cost of an edge is equal to the Euclidean distance between its endpoints. The edges shown form a minimum-cost matching.

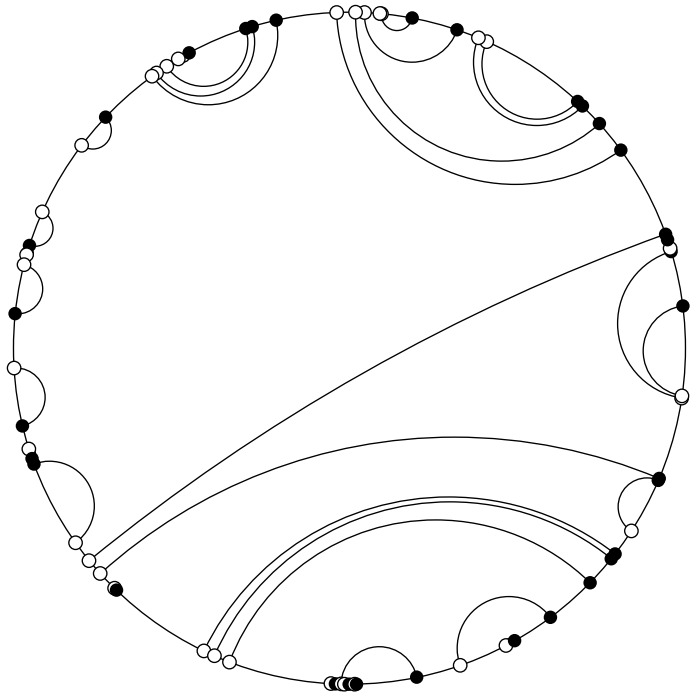

FIG. 1.1. *The minimum-cost matching for a* 74*-node graph on the circle with Euclidean distance as the cost function.*

Our quasi-convex property is equivalent to the "inverse quadrangle inequality" used, for instance, by [8] but is weaker than the similar "inverse Monge property" of [4]. In fact, we show below that any Monge matching problem may be trivially transformed into a quasi-convex matching problem, but not vice-versa.

Dynamic programming problems based on cost functions which satisfy the (inverse) quadrangle inequality, and some closely related matrix-search problems, have been studied by many authors including [2, 3, 4, 7, 8, 9, 12, 15, 16, 17, 19, 24, 25]. However, we have discovered no direct connection between our quasi-convex matching problem and the problems solved by these authors.

The notion of a *Monge array* [13] is related to that of quasi convexity, but the Monge condition is stronger (i.e., quasi convexity is strictly more general). Because of the similarity between the definitions of both properties, we take the time to illustrate this point in detail. To understand the Monge property in our bipartite setting, imagine the cost function to be an array, and impose the restriction that its first

argument select a red point and the second a blue point. The array is Monge provided that for all i, j, k, ℓ satisfying $1 \le i < j \le n$ and $1 \le k < \ell \le n'$, we have

$$c(R_i, B_k) + c(R_j, B_\ell) \le c(R_i, B_\ell) + c(R_j, B_k).$$

Now given a graph with a Monge cost array, we convert it (in linear time) to a quasi-convex tour by simply visiting the red vertices first, in Monge order, followed by the blue vertices, in reverse Monge order. The quasi-convexity inequality is then an immediate consequence of the Monge property and our reverse ordering of the blue vertices. This reversal is necessary because the sense of the Monge inequality is opposite that of quasi convexity.

However, not every quasi-convex tour can be rearranged to form a Monge array. We will now exhibit such a quasi-convex tour. Its nodes lie along the real line, and costs are given by the square root of internode distance; tour order is from left to right. Given a subtour of the form $R_iR_jB_aB_b$, then it is easily shown that in any Monge reordering, $B_a \prec B_b$ iff $R_j \prec R_i$. Similarly, given a tour of the form $R_jB_aB_bR_i$, $B_a \prec B_b$ iff $R_j \prec R_i$. Our counterexample then consists of any tour having a subtour of the form $RBBRRBB$. To understand why, we attach subscripts resulting in $R_iB_aB_bR_jR_kB_cB_d$ and proceed to apply the two rules above to get the implications

$$B_a \prec B_b \implies R_i \prec R_j \implies B_d \prec B_c \implies R_j \prec R_k.$$

Also,

$$B_a \prec B_b \implies R_k \prec R_j,$$

which is a contradiction. Symmetrically the same conclusion is reached if one begins instead with $B_b \prec B_a$, whence no Monge rearrangement exists.

We now give the definitions necessary to state the main results of this paper. We think of the nodes of the graph G as being either a line-like or circular tour of the graph; in the case of a circular tour, we think of the node x_1 as following again after x_N.

DEFINITION 1.1. *A sequence of nodes $x_{i_1}, x_{i_2}, \ldots, x_{i_\ell}$ are* in input order *if and only if $i_1 < i_2 < \cdots < i_\ell$. The nodes are defined to be* in tour order *if and only if there exists a k such that the sequence $x_{i_k}, \ldots, x_{i_\ell}, x_{i_1}, \ldots, x_{i_{k-1}}$ is in input order.*

DEFINITION 1.2. *The nodes $x_1, \ldots, x_N$ form a* quasi-convex *tour if and only if, whenever x_i, x_j, x_k, x_ℓ are in tour order, with x_i and x_j of one color and x_k and x_ℓ of the other color, then*

$$c(x_i, x_\ell) - c(x_i, x_k) \le c(x_j, x_\ell) - c(x_j, x_k). \tag{1.1}$$

Reordering terms in (1.1) gives

$$c(x_i, x_\ell) + c(x_j, x_k) \;\le\; c(x_i, x_k) + c(x_j, x_\ell).$$

To give a geometric intuition to quasi convexity, note that when x_i, x_j, x_k, x_ℓ are the vertices of a quadrilateral, the inequality states that the sum of the lengths of diagonals is greater than or equal to the sum of the lengths of two of the sides.

DEFINITION 1.3. *The tour $x_1, \ldots, x_N$ of G is* line-like *if and only if the following holds: For all $i < j < k$, we have*

$$c(x_i, x_j) \le c(x_i, x_k)$$

if x_i is of opposite color from x_j and x_k, and we have

$$c(x_i, x_k) \geq c(x_j, x_k)$$

if x_k is of opposite color from x_i and x_j.

The property of quasi convexity is defined independently of the starting point of the tour; i.e., the nodes of the tour can be "rotated" without affecting quasi convexity. Obviously, the definition of line-like tours is sensitive to the choice of starting point of the tour.

Our main theorems give either $O(N \log N)$ or $O(N)$ time algorithms for all of the following examples, with the exception of example 7:

1. Let the nodes $x_1, \ldots, x_N$ be sequentially ordered points on a line (e.g., they are real numbers indicating points on the x-axis), and let $||x_j - x_i||$ be the Euclidean distance from x_i to x_j. Let f be any concave-down function, so $f''(x) \leq 0$ for all x. If the cost function is defined by

$$c(x_i, x_j) \;=\; f(||x_j - x_i||), \tag{1.2}$$

then $x_1, \ldots, x_N$ form a quasi-convex tour. Prior work for examples 1 and 2 gave linear time matching algorithms *only* for the case where $f(x)$ is a linear function [14, 1].

2. Now let the points $x_1, \ldots, x_N$ lie on a smooth curve C which is homeomorphic to a circle, with the points listed in, say, counterclockwise order. And let $||x_j - x_i||$ equal the shortest arclength along C from x_i to x_j. Again let $f(x)$ be any concave down function. With the cost function given by equation (1.2), the nodes $x_1, \ldots, x_N$ form a quasi-convex tour.

3. Suppose $x_1, \ldots, x_N$ lie, in that order, on a circle. Let $c(x_i, x_j)$ equal the Euclidean distance from x_i to x_j. Since Euclidean distance is a concave-down function of the circular arclength, this is a special case of example 2 and the nodes form a quasi-convex tour. In this case, the weak analyticity condition always holds and Main Theorem 1.9 gives an $O(N)$ time algorithm. The best prior algorithm was $O(N \log N)$ time [20].

4. More generally, if $x_1, \ldots, x_N$ are the vertices of a convex polygon listed in, say, counterclockwise order, and if the cost function is equal to Euclidean distance, then the nodes form a quasi-convex tour. The prior algorithm for this case was $O(N \log N)$ time [20] and our algorithms are either $O(N)$ or $O(N \log N)$ time depending on whether the weak analyticity condition holds.

5. Some nonconvex polygons also have vertices which form a quasi-convex tour. For example, in a polygon shaped as in Figure 1.2, the vertices A, B, C, D will form a quasi-convex tour, provided the angle θ not too large. (This is why we use "quasi-convex" instead of "convex" to describe tours which satisfy equation (1.1).)

6. Examples 4 and 5 are also quasi-convex under other distance metrics such as the L_1 and L_∞ metrics.

7. Marcotte and Suri consider graphs where the nodes are the vertices of a simple polygon and the cost function is equal to the length of the shortest connecting path inside the polygon. The nodes of such a polygon form a quasi-convex tour. The prior algorithm and the algorithm of this paper are $O(N \log^2 N)$ time for this example, since the cost function requires $O(\log N)$ time to compute.

8. In string matching algorithms, the cost of shifting a character's position is specified as a function of the distance shifted. The authors have worked in the past on string matching algorithms [26, 27] in which the cost function is a linear function

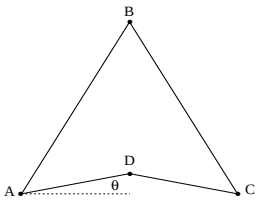

FIG. 1.2. *A quasi-convex polygon which is not geometrically convex.*

of distance. These prior algorithms have been quite successfully used in commercial applications, especially natural language search, and we expect that the use of a concave-down distance function will significantly improve the matching quality. As we discuss in section 5, the setting of example 1 above is precisely what is needed to allow (near) linear time string matching algorithms with concave-down cost functions. A number of authors, including [7, 8], have studied concave-down cost functions for string matching; their string matching algorithms are based on least-edit-distance and, in this regard, are quite different from ours. Least-edit-distance string matching algorithms are widely used because they provide rich and flexible string comparison functions; on the other hand, the best general algorithms for computing least-edit-distance require $O(N^2)$ time (see [21]). Our string matching algorithms are not as flexible but can be tailored to work well for many applications; they have the advantage of being linear time computable.

MAIN THEOREM 1.4.

(i) *There is an $O(N \log N)$ time algorithm for the minimum-cost matching problem for line-like quasi-convex tours.*

(ii) *There is an $O(N \log N)$ time algorithm for the minimum-cost matching problem for balanced quasi-convex tours.*

Remark. The running times of the algorithms are given in terms of the number N of nodes, even though the input size may in some cases need to be $\Omega(N^2)$ to fully specify the values of the cost function. However, in all the examples above, the input size is $O(N)$ since the cost function is specified by the nodes' positions on a line, on a curve, or in the plane. In any event, our runtime analysis assumes that any value $c(x_i, x_j)$ of the cost function can be computed in constant time. If this is not the case, then the runtimes are to be multiplied by the time needed to compute a value of the cost function; this is the situation in example 7 above.

We next define a "weak analyticity" condition which will allow even faster algorithms.

DEFINITION 1.5. *Suppose that x_i and x_j are red (blue) nodes, that $\delta \geq 0$, and that there is a blue (respectively, red) node x_k such that*

$$c(x_i, x_k) - c(x_j, x_k) < \delta.$$

The δ-crossover point *of x_i and x_j is defined to be the first such x_k, where "first" means in tour order starting from x_j and ending at x_i. If no such x_k exists, then the δ-crossover point does not exist.*

It is not hard to see that the property of quasi convexity implies that, if the δ-crossover point x_k exists, then $c(x_i, x_\ell) - c(x_j, x_\ell) \geq \delta$ whenever x_i, x_j, x_ℓ, x_k are in tour order and $c(x_i, x_\ell) - c(x_j, x_\ell) < \delta$ whenever x_i, x_j, x_k, x_ℓ are in tour order. Thus binary search provides an $O(\log N)$ time procedure which, given x_i, x_j, and δ, will determine if x_k exists and, if so, which node is x_k. This is the approach taken in

the algorithms of Theorem 1.4 and is the source of the $\log N$ factor in the runtime. However, in some cases, x_k can be found in constant time and we define the following.

DEFINITION 1.6. *A quasi-convex tour satisfies the* strong analyticity condition *provided there is a constant-time algorithm which can determine if the δ-crossover point of x_i and x_j exists and, if so, can determine which node it is.*

A quasi-convex tour satisfies the analyticity condition *provided there is a constant-time algorithm which can answer the following question (as a function of similarly colored nodes x_i, x_j, x_k in tour order and of $\epsilon, \delta > 0$, where the δ-crossover of x_i and x_j is known to exist):*

> *"Do x_j and x_k have an ϵ-crossover point which either equals or precedes in tour order the δ-crossover point of x_i and x_j?"*

Even the analyticity condition is too strong to be satisfied in many situations, so we also define a "weak analyticity condition" as follows.

DEFINITION 1.7. *Let x be a node and y and z be denotations of nodes. We write $y \prec_x z$ to denote that either* (i) *y and z exist and are distinct and y precedes z in the tour order beginning at x, or* (ii) *y exists and z does not.*

A relative crossover procedure *is a procedure Ω such that, given ϵ, δ, x_i, x_j, and x_k as input, and letting y be the δ-crossover of x_i and x_j, and z be the ϵ-crossover of x_j and x_k, then*

(i) *If $y \prec_{x_j} z$, then Ω outputs "Yes."*
(ii) *If $z \prec_{x_j} y$, then Ω outputs "No."*
(iii) *Otherwise Ω may output either answer.*

Note that Ω is not required to determine y and z. The difference between weak analyticity and ordinary analyticity is that when condition (iii) *holds, Ω may output either answer.*

DEFINITION 1.8. *The* weak analyticity condition *is said to hold provided there is a constant-time relative crossover procedure.*

Clearly the strong analyticity condition implies the analyticity condition, which in turn implies the weak analyticity condition. In most applications, we do not have the analyticity or strong analyticity conditions, but the weak analyticity condition does hold in many natural situations. In particular, examples 1, 2, 3, and 4 do satisfy the weak analyticity condition provided that the concave-down function is sufficiently natural. Consider, for instance, example 1 with the concave-down function $f(x) = x$, $f(x) = \sqrt{x}$, or $f(x) = \log x$, etc. For example 1, the input nodes $x_1, \ldots, x_N$ are given with a sequence of real numbers $r_1 \leq r_2 \leq \cdots \leq r_N$ which are the positions of the nodes on the real line. Given nodes x_i, x_j and $\delta > 0$, the first possible position for the δ-crossover of x_i and x_j can be found by solving the equation $f(y - r_i) = \delta + f(y - r_j)$ for y; since we assume that arithmetic operations take constant time, the solution y can be found in constant time. Note that y is only the *theoretical* crossover point; the actual crossover is the first node x_k such that $y \leq r_k$. Unfortunately, even after y is known, it will not be possible to determine x_k in constant time unless some additional information is given about the distribution of the nodes on the real line. Thus, the analyticity condition and strong analyticity conditions do not hold in general for example 1. The reason the analyticity condition does not hold is that, if the theoretical ϵ-crossover point occurs after the theoretical δ-crossover point, then the analyticity algorithm must output "No" if there is a node after the theoretical δ-crossover point and before or at the theoretical ϵ-crossover point, and must output "Yes" otherwise (because in the latter case the two actual crossover points coincide). Unfortunately, there is no general way to decide this in constant time, so the analyticity condition

is false. However, the weak analyticity condition does hold, since the function Ω may operate by computing the theoretical δ-crossover of x_i and x_j and the theoretical ϵ-crossover of x_j and x_k and outputting "Yes" if the former is less than the latter.

For similar reasons, example 3 satisfies the weak analyticity condition; in this case, since the nodes lie on a circle and the cost function is Euclidean distance, the theoretical crossover position is computed (in constant time) as the intersection of a hyperbola and the circle. Likewise, the weak analyticity condition also holds for example 2 if the concave-down function is sufficiently nice, and it holds for example 6, where nodes lie on a circle under the L_1 and L_∞ metrics. Example 4, where the nodes form the vertices of a convex polygon, does not seem to satisfy the weak analyticity condition in general; however, some important special cases do. For example, if the vertices of the convex polygon are known to lie on a polygon with a bounded number of sides, on an oval, or on a branch of a hyperbola, then the weak analyticity condition does hold.

The analyticity condition has been implicitly used by Hirschberg and Larmore [12] who defined a *Bridge* function which is similar to our Ω function. They give a special case in which *Bridge* is constant-time computable and thus the analyticity condition holds. Later, Galil and Giancarlo [8] defined a "closest zero property" which is equivalent to our strong analyticity condition.[1] As we illustrated above, the analyticity and strong analyticity conditions rarely hold. Thus it is interesting to note that the algorithms of Hirschberg and Larmore and of Galil and Giancarlo will still work, with only minor modifications, if only the weak analyticity condition holds.

Our second main theorem implies that these examples which satisfy the weak analyticity condition have linear time algorithms for minimum-cost matching.

MAIN THEOREM 1.9.

(i) *There is an $O(N)$ time algorithm for the minimum-cost matching problem for line-like quasi-convex tours which satisfy the weak analyticity condition.*

(ii) *There is an $O(N)$ time algorithm for the minimum-cost matching problem for balanced quasi-convex tours which satisfy the weak analyticity condition.*

Remark. In order to achieve the linear time algorithms, it is necessary that nodes of the graph be input in their tour order. This assumption is necessary, since without it, it is possible to give a linear time reduction of sorting to the matching problem for line-like tours.

Our main theorems also apply to minimum-cost matchings for some nonbipartite quasi-convex tours. If a nonbipartite graph G has N nodes and cost function c, then a matching for G is a set of $\lfloor \frac{1}{2}N \rfloor$ edges with all endpoints distinct. Part (i) of Main Theorems 1.4 and 1.9 hold also for nonbipartite graphs which are line-like quasi-convex tours. And part (ii) of Main Theorems 1.4 and 1.9 hold also for nonbipartite graphs which are quasi-convex tours with an even number of nodes. The nonbipartite cases are discussed in section 4; the algorithms are simple modifications of the algorithms for the bipartite tours.

It is apparent that our algorithms can be parallelized, but we have not investigated the precise runtime and processor count that is needed for a parallel implementation. He [11] has given a PRAM implementation of Marcotte and Suri's algorithm which uses N processors and $O(\log^2 N)$ time and it is clear that our algorithm can be

[1] The definition of the "closest zero property" is misstated in [8]; it should be defined as saying that it is possible to find the first r such that $w(l,r) - w(k,r) - a \leq 0$ (note their w corresponds to our cost function c, and a is a real). However, their algorithm explicitly uses the correct definition of "closest zero property" (see their Fact 2).

computed with the same number of processors with the same time bounds using He's methods.

Our algorithms apply to unbalanced tours only if they are line-like. This is because in the line-like case the leveling process, described in the next section, induced by choosing the first node as starting point, is guaranteed to decompose the problem into alternating color subproblems, which may be independently solved and reassembled to produce an overall solution. Now, some of these subproblems may be unbalanced, but again using the line-like property, we are able to force balance by adding a dummy node when necessary. These then are two different uses of the line-like property.

In balanced, unimodal tours[2] such as the circle, the leveling concept of section 2 holds in a weaker form. However, we have been unable to extend our results to the unbalanced unimodal case. As an example of the difficulty of this, consider the highly eccentric ellipse of Figure 1.3; the bipartite tour containing its four nodes is unbalanced and is neither line-like nor unimodal. Notice that no starting point induces a leveling which places R_2 and B_1 at the same level, despite the fact that the minimum-cost matching consists of an edge between them. The path to extending our methods to such cases is therefore less clear.

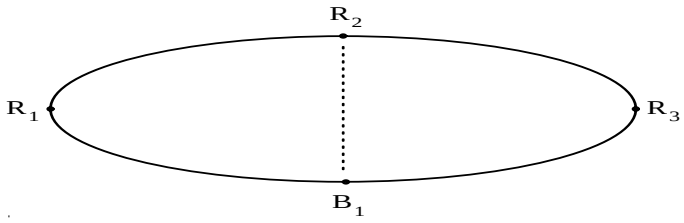

FIG. 1.3. *A bipartite, unbalanced, unimodal tour for which no leveling process works.*

2. Reductions and lemmas.

2.1. Reduction to tours of alternating colors. The first step to giving our minimum-cost matching algorithms is to reduce to the special case of tours in which the colors of the nodes alternate. In other words, we will be able to assume w.l.o.g. that $x_1, x_3, x_5, \ldots$, are red and that $x_2, x_4, x_6, \ldots$, are blue.

DEFINITION 2.1. *Let x_i and x_j be nodes. We write $[x_i, x_j]$ to denote the sequence of nodes obtained by starting with x_i and advancing in tour order to x_j. We write $(x_i, x_j]$, $[x_i, x_j)$, and (x_i, x_j) for this sequence minus the starting node, the ending node, or both.*

If x is a node, let $d(x)$ denote the number of red nodes in $[x_1, x)$ minus the number of blue nodes in $[x_1, x)$. The level *of x, $level(x)$, is equal to $d(x)$ if x is blue and is equal to $d(x) + 1$ if x is red. We write $x \sim y$ to mean that $level(x) = level(y)$; obviously, $\sim$ is an equivalence relation. It is easy to see that if y is the first node after x in input order such that $x \sim y$, then x and y are of opposite colors. Also, if $x \sim y$ and x, y are in input order and are of opposite colors, then (x, y) contains equal number of red and blue nodes. For balanced tours, the $\sim$-equivalence relation is invariant under circular rotation of the nodes in the tour.*

Given a matching on the nodes of a graph, we write $x_i \leftrightarrow x_j$ to indicate the presence of an edge between x_i and x_j in the matching. We say that x_j immediately

[2] In unimodal tours, the cost function from any node rises and then falls as the tour is traversed.

follows x_i *in tour order if* $j = i + 1$ *or if* $i = N$ *and* $j = 1$. *Two nodes* x_i *and* x_j *are* adjacent *if and only if one of them immediately follows the other. An edge* $x_i \leftrightarrow x_j$ *is called a* jumper *if* x_i *and* x_j *are not adjacent. Two jumpers are said to* cross *if they are of the form* $x_i \leftrightarrow x_k$ *and* $x_j \leftrightarrow x_\ell$ *with* x_i, x_j, x_k, x_ℓ *in tour order.*

LEMMA 2.2. *Let* G *be either a line-like quasi-convex tour or a balanced quasi-convex tour. Then* G *has a minimum-cost matching in which every edge* $x_i \leftrightarrow x_j$ *satisfies* $x_i \sim x_j$. *In other words, some minimum-cost matching for* G *can be obtained as a union of minimum-cost matchings on the* $\sim$*-equivalence classes of* G.

To prove Lemma 2.2 we use the following lemma.

LEMMA 2.3. *G has a minimum-cost matching in which no jumpers cross.*

Sketch of proof. If a minimum-cost matching does have a pair of jumpers which cross, the quasi-convexity property allows them to be "uncrossed" without increasing the total cost. Repeatedly uncrossing jumpers will eventually yield a minimum-cost matching with no crossing jumpers. (See Lemma 1 of [1] for a detailed proof of this.)

Lemma 2.2 is proved by noting that a minimum-cost matching with no crossing jumpers must respect the $\sim$-equivalence classes. This is because, if a jumper $x_i \leftrightarrow x_j$ is in a crossing-free matching with $i < j$, then the nodes in the interval (x_i, x_j) must be matched with each other and thus (x_i, x_j) must have equal numbers of red and blue nodes. In the unbalanced, line-like case, this also depends on the fact that, w.l.o.g., there is no jumper which crosses an unmatched node (this is an immediate consequence of the line-like condition). □

By Lemma 2.2, in order to find a minimum-cost matching, it suffices to extract the $\sim$-equivalence classes and find minimum-cost matchings for each equivalence class independently. It is an easy matter to extract the $\sim$-equivalence classes in linear time by using straightforward counting. Each equivalence class consists of an alternating color subtour; in the balanced case, there are an even number of nodes in each equivalence class, and in the line-like condition case, there may be an even or odd number of nodes. Thus, to give (near) linear time algorithms for finding matchings, it will suffice to restrict our attention to tours in which the nodes are of alternating colors.

In view of Lemma 2.3, we may restrict our attention to matchings which contain no crossing jumpers. Such a matching will be called *crossing-free*.

Finally, we can assume w.l.o.g. that the tour is balanced. To see why we can assume this, suppose that $x_1, \ldots, x_N$ is an unbalanced, line-like tour of alternating colors. This means that x_1 and x_N are the same color, say red. We can add a new node x_{N+1} to the end of the tour, label it blue, and let $c(x_i, x_{N+1}) = 0$ for all red x_i. These $N + 1$ nodes no longer form a line-like tour; however, they do form a balanced quasi-convex tour. Solving the matching problem for the $N + 1$ nodes immediately gives a solution to the matching problem on the original N nodes.

2.2. Some important lemmas. Since we are now working only with balanced quasi-convex tours of alternating colors, we shall often change the names of the nodes to $R_1, B_1, \ldots, R_M, B_M$; so R_i and B_j refer to the ith red node and the jth blue node in the tour, respectively. (So x_{2i-1} is the same as R_i and x_{2i} is the same as B_i.) Note that this means $N = 2M$. To simplify notation, we define

$$c_i \;=\; c(R_i, B_i) \qquad \text{and} \qquad c'_i \;=\; c(B_i, R_{i+1}).$$

A *greedy* matching is a matching which contains no jumpers, i.e., every node is matched to an adjacent node. There are two greedy matchings, namely, the one containing all edges $R_i \leftrightarrow B_i$ and the one containing all edges $B_{i-1} \leftrightarrow R_i$ and the edge $B_M \leftrightarrow R_1$. For x_i and x_j nodes of opposite color, a matching σ is said to

be *greedy on* (x_i, x_j) provided it contains as a submatching the unique matching of adjacent nodes contained in the interval (x_i, x_j). We similarly define the notion of σ being greedy on a balanced interval I, where I is one of the intervals $[x_i, x_j)$, $[x_i, x_j]$, or $(x_i, x_j]$, but with the additional provisos that $x_i \leftrightarrow x_{i+1}$ is in σ in the first two cases and that $x_{j-1} \leftrightarrow x_j$ is in σ in the second two cases.[3]

The notation $[R_i, B_j]$ has already been defined. In addition, the notation $[i, j]$ denotes the interval of integers $i, i+1, \ldots, j$ if $i < j$, or the (circular) interval $i, i+1, \ldots, M, 1, 2, \ldots, j$ if $j < i \leq M$. We also use the notations $(i, j]$, $[i, j)$, and (i, j) for the intervals with one or both of the endpoints omitted.

DEFINITION 2.4. *Let R_i and B_j be nodes; we write $R_i \rightarrow B_j$ to denote a* directed *edge going from R_i forward (in tour order) to B_j. That is, we think of $R_i \rightarrow B_j$ jumping over the nodes $R_i, B_i, R_{i+1}, \ldots, R_j, B_j$. We say that $R_i \rightarrow B_j$ is a* candidate *(meaning, a candidate for a jumper), if*

$$c(R_i, B_j) + \sum_{\ell \in [i,j)} c'_\ell \;<\; \sum_{\ell \in [i,j]} c_\ell.$$

The intuitive meaning of $R_i \rightarrow B_j$ being a candidate is that it would be of lower cost to use the jumper $R_i \leftrightarrow B_j$, plus the greedy matching of adjacent nodes in (R_i, B_j), in place of just the greedy matching of adjacent nodes in $[R_i, B_j]$.

A similar definition is used to define what it means for an edge $B_i \rightarrow R_j$ to be a candidate; namely, $B_i \rightarrow R_j$ is a candidate if and only if

$$c(B_i, R_j) + \sum_{\ell \in (i,j)} c_i \;<\; \sum_{\ell \in [i,j)} c'_i.$$

Candidates always have endpoints of opposite colors and are directed. It is possible to have both $R_i \rightarrow B_j$ and $B_j \rightarrow R_i$ be (distinct) candidates or to have one or neither of them candidates.

It is an easy observation that if there are no candidates, then the greedy assignment(s) are minimum-cost matchings. To prove this, suppose σ is a minimum-cost matching which contains a jumper; by Lemma 2.3, σ may be picked to contain no crossing jumpers. Since there are no crossing jumpers, σ must contain a jumper $x_i \leftrightarrow x_j$ such that σ is greedy on (x_i, x_j) (namely, pick the jumper so as to minimize the tour-order distance from x_i to x_j). Let σ' be the matching which is the same as σ except greedy on $[x_i, x_j]$. Clearly σ' has one fewer jumper than σ, and since $x_i \rightarrow x_j$ is not a candidate, σ' has cost no greater than σ. Iterating this construction shows that at least one of the jumperless greedy matchings must be minimum-cost. To show they are both minimum-cost, let σ_0 and σ_1 be the greedy matchings which contain the edges $x_1 \leftrightarrow x_2$ and $x_1 \leftrightarrow x_N$, respectively. Then σ_0 cannot have cost lower than (respectively, higher than) the cost of σ_1 since otherwise, $x_2 \rightarrow x_1$ ($x_1 \rightarrow x_N$, respectively) would be a candidate.

DEFINITION 2.5. *A candidate $x_i \rightarrow x_j$ is a* minimal *candidate if and only if there is no other candidate $x_k \rightarrow x_\ell$ in its interior; that is to say, there is no candidate $x_k \rightarrow x_\ell$ with $[x_k, x_\ell]$ a proper subset of $[x_i, x_j]$.*

LEMMA 2.6. *Consider a balanced quasi-convex tour of alternating colors.*

[3]Note that, of the two greedy matchings for G, one is greedy on $[x_1, x_N]$ and the other is greedy on $[x_2, x_1]$.

(i) *Suppose $R_a \to B_b$ is a minimal candidate. Then every minimum-cost, crossing-free matching is greedy on the interval (R_a, B_b). That is to say, every minimum-cost, crossing-free matching contains the edges $B_{\ell-1} \leftrightarrow R_\ell$ for all $\ell \in (a, b]$.*

(ii) *Suppose $B_a \to R_b$ is a minimal candidate. Then every minimum-cost, crossing-free matching is greedy on the interval (B_a, R_b). That is to say, every minimum-cost, crossing-free matching contains the edges $R_\ell \leftrightarrow B_\ell$ for all $\ell \in (a, b)$.*

Note that Lemma 2.6 says only that the edges connecting adjacent nodes in the *interior* of the minimal candidate are in every minimum-cost matching; it does not say that the minimal candidate itself is a jumper in any minimum-cost matching. The proof of Lemma 2.6 is fairly involved and we postpone it until section 2.3. Lemma 2.6 also holds for line-like tours with alternating colors for candidates $x \to y$ with x, y in input order.

Lemma 2.6 suggests an algorithm for finding a minimum-cost matching. Namely, if there is a minimal candidate, greedily assign edges in its interior according to Lemma 2.6. This induces a matching problem on the remaining unassigned nodes, and it is clear that any minimum-cost matching on this smaller problem will lead to a minimum-cost matching for the original problem. Iterating this, one can continue removing nodes in the interiors of minimal candidates and reducing the problem size. Eventually a matching problem with no candidates will be reached; in this case, it suffices to greedily match the remaining nodes.

Unfortunately, this algorithm suggested by Lemma 2.6 is not linear time (yet); thus we need to refine Lemma 2.6 somewhat with the following definition.

DEFINITION 2.7. *We define*

$$\mathsf{Bnft}[R_a, B_b] = \left(\sum_{i \in [a,b]} c_i - \sum_{i \in [a,b)} c'_i \right) - c(R_a, B_b),$$

$$\mathsf{Bnft}[B_a, R_b] = \left(\sum_{i \in [a,b)} c'_i - \sum_{i \in (a,b)} c_i \right) - c(B_a, R_b),$$

and, for x and y the same color, $\mathsf{Bnft}[x, y] = -\infty$.

It is immediate that $\mathsf{Bnft}[x, y] > 0$ if and only if $x \to y$ is a candidate; in fact, $\mathsf{Bnft}[x, y]$ measures the benefit (i.e., the reduction in cost) of using $x \leftrightarrow y$ as a minimal jumper instead of the greedy matching on $[x, y]$.

The next lemma forms the basis for the correctness of the algorithm given in section 3 for the serial transitive closure problem. The general idea is that the algorithm will scan the nodes in tour order until at least one candidate is found and then, according to Lemma 2.8, the algorithm will choose an interval (x_ℓ, x_k) to greedily match. Once the interval (ℓ, k) has been greedily matched, the algorithm need only solve the induced matching problem on the remaining nodes.

LEMMA 2.8. *Let G be a balanced quasi-convex tour matching problem. Let $1 < k \le N$ and suppose $\mathsf{Bnft}[x_i, x_j] \le 0$ for all $1 \le i < j < k$. Further suppose that $m \stackrel{\text{def}}{=} \max\{\mathsf{Bnft}[x_i, x_k] : i < k\} > 0$ and let $\ell \stackrel{\text{def}}{=} \max\{i < k : \mathsf{Bnft}[x_i, x_k] = m\}$. Then every minimum-cost, crossing-free matching is greedy on (x_ℓ, x_k).*

Proof. The proof is, in essence, an iteration of Lemma 2.6. We argue by induction on k. Let G, k, m, and ℓ satisfy the hypothesis of the lemma. Let $s = \max\{i < k : \mathsf{Bnft}[x_i, x_k] > 0\}$, so $x_s \to x_k$ is a minimal candidate. By Lemma 2.6, any minimum-cost, crossing-free solution for G is greedy on the interval (x_s, x_k).

Hence, it will suffice to let G' be the matching problem obtained from G by discarding the nodes $x_{s+1}, \ldots, x_{k-1}$ and prove that any minimum-cost, crossing-free solution for G' is greedy on $(x_\ell, x_s]$. If $\ell = s$, there is nothing to prove, so we assume $\ell < s$. Note that x_k is now the $(s+1)$st node in the G' tour order. We use Bnft' to denote the Bnft function for G'.

We claim the following:

(i) If $1 \le i < j \le s$, $\mathsf{Bnft}'[x_i, x_j] = \mathsf{Bnft}[x_i, x_j]$.

(ii) If $1 \le i \le s$, $\mathsf{Bnft}'[x_i, x_k] = \mathsf{Bnft}[x_i, x_k] - \mathsf{Bnft}[x_s, x_k]$.

Claim (i) is immediate from the definition of Bnft. The intuitive meaning of (ii) is that the benefit of using the jumper $x_i \leftrightarrow x_k$ is reduced by the benefit already obtained from the jumper $x_s \leftrightarrow x_k$. We formally prove (ii) for the case that x_i and x_s are red and x_k is blue; the opposite colored case has a similar proof. Assume $x_i = R_a$, $x_s = R_b$, and $x_k = B_c$. Then

$$\mathsf{Bnft}'[R_a, B_c] = \sum_{\ell \in [a,b)} c_i + c(R_b, B_c) - \sum_{\ell \in [a,b)} c'_i - c(R_a, B_c),$$

$$\mathsf{Bnft}[R_a, B_c] = \sum_{\ell \in [a,c]} c_i - \sum_{\ell \in [a,c)} c'_i - c(R_a, B_c),$$

$$\mathsf{Bnft}[R_b, B_c] = \sum_{\ell \in [b,c]} c_i - \sum_{\ell \in [b,c)} c'_i - c(R_b, B_c).$$

From these three equations claim (ii) follows immediately.

Now let $m' = \max\{\mathsf{Bnft}'[x_i, x_k] : i < s\}$. By claim (ii), $m' = m - \mathsf{Bnft}[x_s, x_k]$; since $\ell < s$, $m' > 0$. Likewise, $\ell = \max\{i < s : \mathsf{Bnft}'[x_i, x_k] = m'\}$. Thus, by the induction hypothesis, any minimum-cost solution for G' is greedy on $(x_\ell, x_s]$ and Lemma 2.8 is proved. □

DEFINITION 2.9. *The Δ function is defined by*

$$\Delta[R_a, R_b] = \sum_{\ell \in [a,b)} c_\ell - \sum_{\ell \in [a,b)} c'_\ell,$$

$$\Delta[B_a, B_b] = \sum_{\ell \in [a,b)} c'_\ell - \sum_{\ell \in (a,b]} c_\ell.$$

LEMMA 2.10.

(i) $\mathsf{Bnft}[R_a, B_c] > \mathsf{Bnft}[R_b, B_c]$ *if and only if* $c(R_a, B_c) - c(R_b, B_c) < \Delta[R_a, R_b]$.

(ii) $\mathsf{Bnft}[B_a, R_c] > \mathsf{Bnft}[B_b, R_c]$ *if and only if* $c(B_a, R_c) - c(B_b, R_c) < \Delta[B_a, B_b]$.

Lemma 2.10 follows immediately from the definitions.

LEMMA 2.11. *Let u, v, x, y be in tour order with nodes u and v of one color and x and y of the other color. Then*

$$\mathsf{Bnft}[u, x] > \mathsf{Bnft}[v, x] \quad \Rightarrow \quad \mathsf{Bnft}[u, y] > \mathsf{Bnft}[v, y].$$

Proof. By Lemma 2.10, $\mathsf{Bnft}[u, x] > \mathsf{Bnft}[v, x]$ is equivalent to $c(u, x) - c(v, x) < \Delta[u, v]$, and $\mathsf{Bnft}[u, y] > \mathsf{Bnft}[v, y]$ is equivalent to $c(u, y) - c(v, y) < \Delta[u, v]$. Now, by quasi convexity, $c(u, x) - c(v, x) \ge c(u, y) - c(v, y)$, which suffices to prove the lemma. □

Let R_a and R_b be distinct red nodes. The previous two lemmas show that if there is any node B_c (with R_a, R_b, and B_c in tour order) such that $\mathsf{Bnft}[R_a, B_c]$ is greater than $\mathsf{Bnft}[R_b, B_c]$, then the first such B_c is the $\Delta[R_a, R_b]$-crossover point of

R_a and R_b. We shall denote this first B_c, if it exists, by $\chi[R_a, R_b]$; if it does not exist, then $\chi[R_a, R_b]$ is said to be undefined. Similarly, $\chi[B_a, B_b]$ is defined to the be the $\Delta[B_a, B_b]$-crossover point of B_a and B_b, and, if defined, is the first R_c where $\mathsf{Bnft}[B_a, R_c]$ is greater than $\mathsf{Bnft}[B_b, R_c]$.

We now assume that we have a procedure $\Omega(x, y, z)$, which, given nodes x, y, z in tour order, returns "True" if $\chi[x, y] \prec_y \chi[y, z]$ and returns "False" if $\chi[y, z] \prec_y \chi[x, y]$. (If neither condition holds, then $\Omega(x, y, z)$ may return an arbitrary truth value.) If the weak analyticity condition holds, then Ω is constant-time computable. Without this assumption, Ω is $O(\log N)$ time computable since Lemma 2.11 allows $\chi[-, -]$ to be computable by binary search.

The general idea of the algorithm given in section 3 below is that it will scan the nodes in tour order searching for candidates. Whenever a node is reached that is the head of a candidate, the algorithm will take the candidate specified in Lemma 2.8 (the one that was denoted $x_\ell \to x_k$) and greedily match the nodes in its interior. The greedily matched nodes are then dropped from consideration and the algorithm resumes its search for a candidate. Suppose the u and v are two nodes already scanned in this process that are being remembered as potential endpoints of candidates. Lemma 2.10 tells us that if a node x is found where $\mathsf{Bnft}[u, x] > \mathsf{Bnft}[v, x]$, then at all succeeding nodes y, $\mathsf{Bnft}[u, y] > \mathsf{Bnft}[v, y]$. By the criterion of Lemma 2.8, this means that after the node x is found, there is no further reason to consider candidates that begin at node v, since any candidate $v \to y$ would be subsumed by the better candidate $u \to y$.

To conclude this section we describe the algorithm in very general terms; in section 3 we give the precise specification of the algorithm. The algorithm scans nodes (starting with node x_1, say) and maintains three lists. The first list, $\mathcal{M}$, contains the nodes in tour order which have been examined so far. The second list, $\mathcal{L}^{-1}$, contains all the red nodes that need to be considered as potential endpoints of candidates (so $\mathcal{L}^{-1}$ is guaranteed to contain all the nodes satisfying the criterion of Lemma 2.8). The third list, $\mathcal{L}^1$, similarly contains all the blue nodes that need to be considered as potential endpoints of candidates. At any point during the scan, the lists will be of the form

$$\mathcal{M} = x_1, \ldots, x_{r-1},$$
$$\mathcal{L}^{-1} = R_{a_1}, \ldots, R_{a_p},$$
$$\mathcal{L}^{1} = B_{b_1}, \ldots, B_{b_q},$$

with $\mathcal{L}^{-1}$ and $\mathcal{L}^1$ subsequences of $\mathcal{M}$. The following five conditions will be maintained during execution:

(i) $x_1, \ldots, x_{r-1}$ are the nodes scanned but not matched and are in tour order, and there are no candidates $x_i \to x_j$ with $1 \le i < j < r$.

(ii) x_{r-1} precedes $\chi[R_{a_{p-1}}, R_{a_p}]$ in tour order.

(iii) For all $1 \le i \le p-2$, $\Omega(R_{a_i}, R_{a_{i+1}}, R_{a_{i+2}})$ is false.

(iv) For all $1 \le i \le q-2$, $\Omega(B_{b_i}, B_{b_{i+1}}, B_{b_{i+2}})$ is false.

(v) At any possible future node x_k following x_{r-1} such that x_k is the first point where a candidate is discovered; if the x_ℓ which satisfies Lemma 2.8 is among $x_1, \ldots, x_{r-1}$ then it is already on the list $\mathcal{L}^{-1}$ or $\mathcal{L}^1$ (depending on which color it is).

When scanning the next node x_r, the algorithm must do the following (we assume x_r is blue; similar actions are taken for red nodes):

(β) While $p \ge 2$ and $\mathsf{Bnft}[R_{a_{p-1}}, x_r] > \mathsf{Bnft}[R_{a_p}, x_r]$, pop R_{a_p} from $\mathcal{L}^{-1}$ and decrement p.

(γ) If $\mathsf{Bnft}[R_{a_p}, x_r] > 0$, greedily match nodes in the interval (R_{a_p}, x_r). The matched nodes are discarded from the lists $\mathcal{M}$, $\mathcal{L}^{-1}$, and $\mathcal{L}^1$ (the remaining nodes are to be implicitly renumbered at this point).

(δ) While $q \geq 2$ and $\Omega(B_{a_{q-1}}, B_{a_q}, x_r)$, pop B_{a_q} from $\mathcal{L}^1$ and decrement q. Then push x_r onto the end of $\mathcal{L}^1$ (and increment q).

Step (β) is justified by recalling that if x_r is past $\chi[R_{a_{p-1}}, R_{a_p}]$, then R_{a_p} may be removed from consideration as an endpoint of a candidate (by Lemma 2.8).

Step (δ) is justified as follows: suppose $R_i = \chi[B_{a_{q-1}}, B_{a_q}]$ equals or precedes $R_j = \chi[B_{a_q}, x_r]$ (using tour order, beginning at B_{a_q}). Then at any future candidate endpoint x_k, either x_k follows or equals R_i, in which case $\mathsf{Bnft}[B_{a_{q-1}}, x_k]$ is greater than $\mathsf{Bnft}[B_{a_q}, x_k]$, or x_k precedes R_j, in which case, $\mathsf{Bnft}[x_r, x_k]$ is greater than $\mathsf{Bnft}[B_{a_q}, x_k]$. Thus B_{a_q} will never be the starting endpoint of a candidate satisfying the criteria of Lemma 2.8, and we may drop it from consideration.

To justify step (γ) we must show that the candidate $R_{a_p} \to x_r$ satisfies the criteria from Lemma 2.8; in view of the correctness of the rest of the algorithm, for this it will suffice to show that $\mathsf{Bnft}[R_{a_i}, x_r] \leq \mathsf{Bnft}[R_{a_p}, x_r]$ for all $1 \leq i < p$. For this, note that step (β) and condition (iii) above ensure that x_r precedes $\chi[R_{a_i}, R_{a_{i+1}}]$ for all $1 \leq i < p$. This, in turn, implies $\mathsf{Bnft}[R_{a_i}, x_r] \leq \mathsf{Bnft}[R_{a_{i+1}}, x_r]$ for all i, which proves the desired inequality.

After the algorithm has scanned all the nodes once, it will have found and processed all candidates $x_i \to x_j$ where $i < j$. However, since the tour is circular, it is necessary to process candidates $x_i \to x_j$ with $i > j$. At the end of the first scan, the list $\mathcal{M}$ consists of all nodes $x_1, \ldots, x_n$ which have not been matched yet and $\mathcal{L}^{-1}$ and $\mathcal{L}^1$ contain nodes $R_{a_1}, \ldots, R_{a_p}$ and $B_{b_1}, \ldots, B_{b_q}$, as usual. During the second scan, the algorithm is searching for any candidates of the form $R_{a_i} \to B_j$ with $j < a_i$ or of the form $B_{a_i} \to R_j$ with $j \leq a_i$ (and only for such candidates). To process a node during the second scan, the algorithm pops x_1 off the left end of $\mathcal{M}$, implicitly renames x_1 to x_n and the rest of the nodes x_i to x_{i-1}, sets $r = n$, and does step (α) (still assuming x_r is blue):

(α) If x_r equals B_{b_1}, then pop B_{b_1} from the list $\mathcal{L}^1$ and implicitly renumber $\mathcal{L}^1$, decrementing q.

It then does steps (β)–(δ), except that in step (δ), the node x_r is not added to the end of $\mathcal{L}^1$. The reason for step (α) is that once a node B_{b_i} is encountered on the second scan, B_{b_i} is no longer a possible starting endpoint for a candidate. The reason for not adding x_r to the end of $\mathcal{L}^1$ in step (δ) is that it cannot be the starting endpoint of a candidate, because any such candidate would have already been found earlier.

The second scan will stop as soon as both $\mathcal{L}$ lists become empty. At this point no candidates remain and a greedy matching may be used for the remaining nodes in the $\mathcal{M}$ list.

The actual description of the algorithm with an efficient implementation is given in section 3, and it is there proved that the algorithm is linear time with the weak analyticity condition and $O(N \log N)$ time otherwise. Although we described steps (α)–(δ) only for blue x_r above, the algorithm in section 3 uses a toggle ψ to handle both colors with the same code. Finally, one more important feature of the algorithm is the way in which it computes the values of the Bnft function and of the $\Delta[x, y]$ function; it uses intermediate values $I[x]$ which are defined as follows.

DEFINITION 2.12. *The $I[x]$ function is defined by*

$$I[R_a] = \Delta[R_1, R_a],$$

$$I[B_a] = I[R_a] + c(R_a, B_a).$$

Note that $I[R_{a+1}] = I[B_a] - c(B_a, R_{a+1})$.

It is immediate from the definitions that, if x, y are tour order (starting from x_1), then

$$\begin{aligned}
\Delta[x,y] &= I[y] - I[x] && \text{for } x \text{ and } y \text{ red},\\
\Delta[x,y] &= I[x] - I[y] && \text{for } x \text{ and } y \text{ blue},\\
\mathsf{Bnft}[x,y] &= I[y] - I[x] - c(x,y) && \text{for } x \text{ red}, y \text{ blue},\\
\mathsf{Bnft}[x,y] &= I[x] - I[y] - c(x,y) && \text{for } x \text{ blue}, y \text{ red}.
\end{aligned}$$

These equalities permit the values of Δ and Bnft to be computed in constant time from the values of $I[-]$. Also, it is important to note that only the relative $I[-]$ values are needed; in other words, it is OK if the $I[-]$ values are shifted by a constant additive constant, since we always use the difference between two $I[-]$ values.

The $I[-]$ function is not only easy to compute but also provides an intuitive graphical means of understanding the above lemmas and algorithm description. For example, in Figure 2.1, $R_1 \to B_3$ is a (minimal) candidate whereas $R_1 \to B_1$ and $R_1 \to B_2$ are not candidates. In Figure 2.2(a), the node B_3 is the relative crossover, $\chi[R_1, R_2]$, of R_1 and R_2; on the other hand, in Figure 2.2(b), the relative crossover does not exist. Figure 2.3(a) shows an example where $\Omega(R_1, R_2, R_3)$ is true and Figure 2.3(b) shows an example where $\Omega(R_1, R_2, R_3)$ is false.

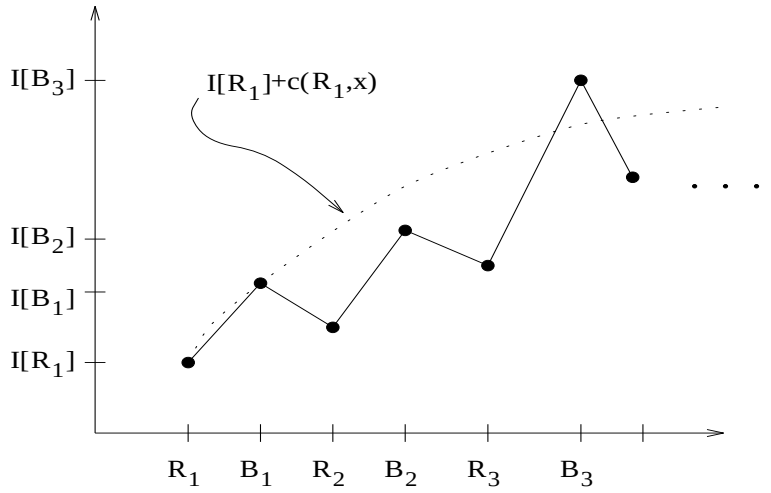

FIG. 2.1. *$R_1 \to B_3$ is a candidate as $I[R_1] + c(R_1, B_3) < I[B_3]$, which is equivalent to $\mathsf{Bnft}[R_1, B_3] > 0$.*

2.3. Proof of Lemma 2.6. By symmetry it will suffice to prove part (i). Since the lemma is trivial in case $a = b$, we assume $a \neq b$. Let σ be a crossing-free minimum-cost matching; we must prove that σ is greedy on (R_a, B_b). By the crossing freeness of σ and by the fact that $R_a \to B_b$ is a *minimal* candidate, σ does not contain any jumper with both endpoints in $[R_a, R_b]$, except possibly $R_a \leftrightarrow B_b$ itself. If $R_a \leftrightarrow B_b$ is in σ, then the same reasoning shows that σ is greedy on (R_a, B_b); so we suppose that $R_a \leftrightarrow B_b$ is not in σ. Since we are dealing (w.l.o.g.) with balanced tours, we may assume that $b = N$, by renumbering nodes if necessary.

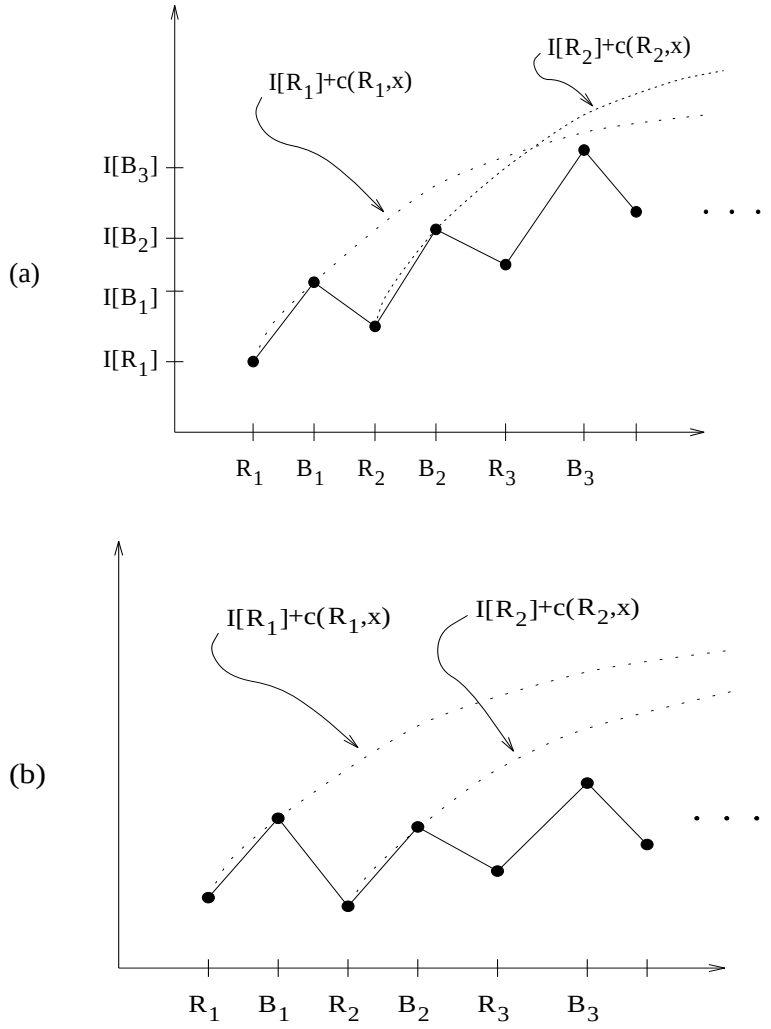

FIG. 2.2. *Illustrations of the relative crossover, $\chi[R_1.R_2]$, of R_1 and R_2. In* (a)*, B_3 is $\chi[R_1, R_2]$, since it is the first node x to satisfy $I[R_2]+c(R_2, x) > I[R_1]+c(R_1, x)$. In* (b)*, the relative crossover does not exist.*

Claim (i). $R_a \leftrightarrow B_a$ is not in σ.

Suppose, for a contradiction, that $R_a \leftrightarrow B_a$ is in σ. Let v be the least value such that $R_v \leftrightarrow B_q$ is in σ for some $q < a < v$. Note that such a v, $a < v \leq N$, must exist since there are no jumpers in $[R_a, B_N]$ and since σ is not greedy on $[R_a, B_N]$ (it cannot be greedy on $[R_a, B_N]$, since $R_a \rightarrow B_N$ is a candidate). By choice of v, σ is greedy on $[R_a, R_v)$. These edges in the matching σ are represented by edges drawn above the line in Figure 2.4(a). Since $R_a \rightarrow B_N$ is a minimal candidate, $\mathsf{Bnft}[R_a, B_N] > \mathsf{Bnft}[R_v, B_N]$, so Lemma 2.10 implies

$$\sum_{i\in[a,v)} c_i - \sum_{i\in[a,v)} c'_i > c(R_a, B_N) - c(R_v, B_N).$$

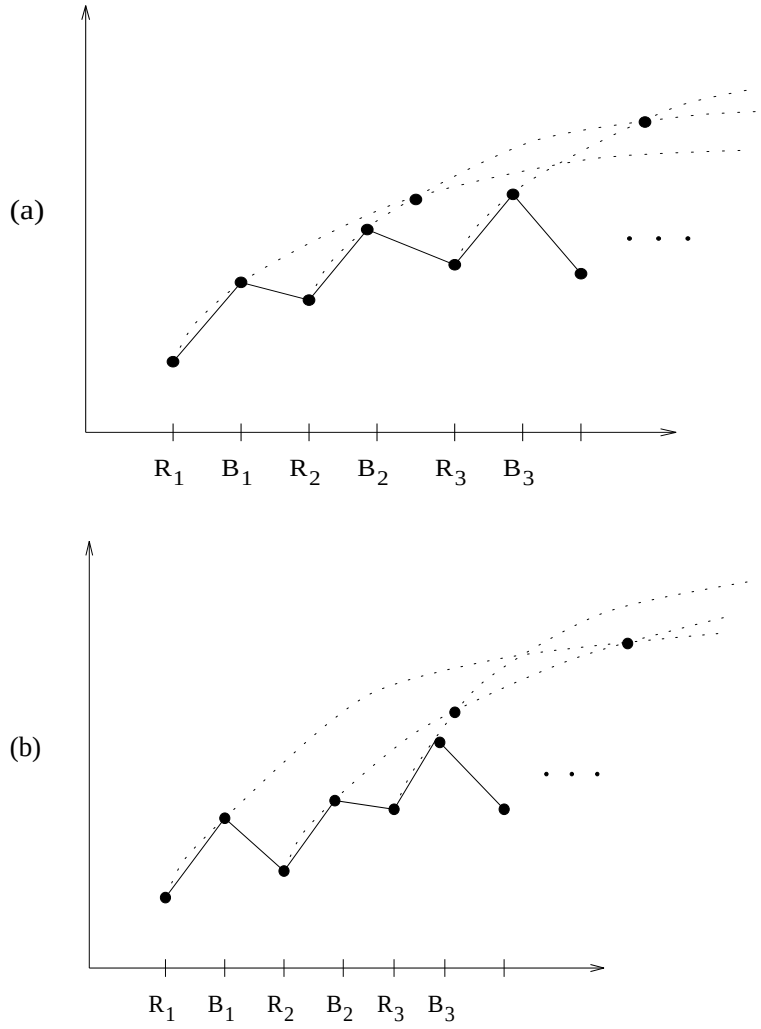

FIG. 2.3. $\Omega(R_1, R_2, R_3)$ *is true in* (a) *and false in* (b).

Since R_a, R_v, B_N, and B_q are in tour order, quasi convexity implies

$$c(R_a, B_N) - c(R_v, B_N) \geq c(R_a, B_q) - c(R_v, B_q).$$

Combining these inequalities yields

$$\sum_{i \in [a,v)} c_i + c(R_v, B_q) > \sum_{i \in [a,v)} c'_i + c(R_a, B_q). \tag{2.1}$$

Let σ' be the matching obtained from σ by replacing the jumper $B_q \leftrightarrow R_v$ and the greedy matching on $[R_a, R_v)$ with the edge $B_q \leftrightarrow R_a$ and the greedy matching on $(R_a, R_v]$. The new edges in σ' are drawn below the line in Figure 2.4(a). By (2.1), σ' has cost strictly less than the cost of σ, which is a contradiction.

Claim (ii). $R_N \leftrightarrow B_N$ is not in σ.

Claim (ii) is proved by an argument similar to Claim (i). Alternatively, reverse the colors and the tour order and Claim (ii) is a version of Claim (i).

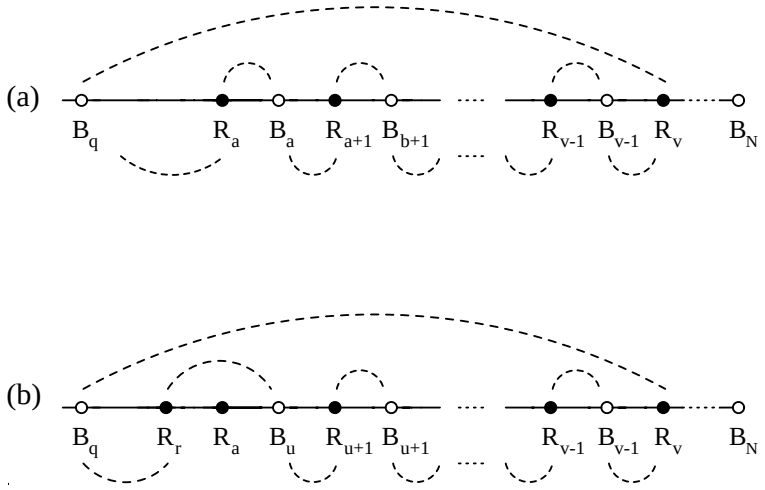

FIG. 2.4. *Illustrations of Claims* (i) *and* (iii) *from the proof of Lemma* 2.6. *The edges above the lines represent edges in the presumed minimum-cost matching σ; these are replaced by the edges below the line in the lower-cost matching σ'.*

Claim (iii). The matching σ is greedy on (R_a, B_b).

Suppose for a contradiction that σ is not greedy on (R_a, B_b). In view of Claims (i) and (ii) and since σ has no jumpers in $[R_a, B_N]$, this means that there exist u and v such that u is the least value, such that σ contains $B_u \leftrightarrow R_r$ with $r < a \leq u$, and v is the least value, such that σ contains $R_v \leftrightarrow B_q$ with $q < a \leq v$. Namely, let u be the least value $\geq a$ such that $B_u \leftrightarrow R_{u+1}$ is not in σ and v be the least value $> u$ such that $R_v \leftrightarrow B_v$ is not in σ. For these choices of u and v, it must be that $q < r < a \leq u \leq v \leq N$ and that σ is greedy on $[B_a, R_u]$ and $[R_{u+1}, B_{v-1}]$. These edges in the matching σ are represented by edges drawn above the line in Figure 2.4(b).

Since $R_a \rightarrow B_N$ is a candidate,

$$\sum_{i\in[a,N]} c_i > c(R_a, B_N) + \sum_{i\in[a,N)} c'_i.$$

And since it is minimal, neither $R_a \rightarrow B_u$ nor $R_v \rightarrow B_N$ are candidates; i.e.,

$$\sum_{i\in[a,u]} c_i \leq c(R_a, B_u) + \sum_{i\in[a,u)} c'_i,$$

$$\sum_{i\in[v,N]} c_i \leq c(R_v, B_N) + \sum_{i\in[v,N)} c'_i.$$

Combining these three inequalities gives

$$\sum_{i\in(u,v)} c_i + c(R_a, B_u) + c(R_v, B_N) > \sum_{i\in[u,v)} c'_i + c(R_a, B_N). \tag{2.2}$$

Since R_a, R_v, B_N, B_q and R_r, R_a, B_u, B_q are in tour order, quasi convexity implies the two inequalities

$$c(R_a, B_q) + c(R_v, B_N) \leq c(R_a, B_N) + c(R_v, B_q),$$

$$c(R_r, B_q) + c(R_a, B_u) \le c(R_r, B_u) + c(R_a, B_q)$$

which combine to yield

$$\begin{aligned} c(R_a, B_N) - c(R_a, B_u) - c(R_v, B_N) \\ \ge c(R_r, B_q) - c(R_r, B_u) - c(R_v, B_q). \end{aligned} \tag{2.3}$$

Using (2.2) and (2.3) gives the inequality

$$\sum_{i \in (u,v)} c_i + c(R_r, B_u) + c(R_v, B_q) > \sum_{i \in [u,v)} c'_i + c(R_r, B_q).$$

Let σ' be the matching obtained from σ by replacing the jumpers $R_r \leftrightarrow B_u$, $R_v \leftrightarrow B_q$, and the greedy matching on (B_u, R_v) with the edge $R_r \leftrightarrow B_q$ and the greedy matching on $[B_u, R_v]$. The new edges in σ' are drawn below the line in Figure 2.4(b). The last inequality above says that σ' has cost strictly less than the cost of σ, which is a contradiction. □

3. The algorithm. In this section, we give the actual algorithm for the main theorems. The correctness of the algorithm follows from the development in section 2.2. With Kanzelberger and Robinson, we have developed efficient implementations in ANSI-C of all the algorithms described below [5].[4]

3.1. Preliminaries. As mentioned above, the algorithm maintains three lists of nodes called deques (for "double ended queues," since we will have to access both ends of the lists). The three deques are the "main" deque $\mathcal{M}$ and two "left" deques $\mathcal{L}^1$ and $\mathcal{L}^{-1}$. The latter two are called "left deques" since they contain possible left endpoints for candidates. The deques will be updated by *push-right* operations which add a new node to the right end, by *pop-right* operations which pop the rightmost node off the deque, and by *pop-left* operations. However, *push-left* operations are never required. Deque operations can be efficiently implemented by using contiguous memory locations to store the deque elements and maintaining pointers to the left and right endpoints; each deque operation can then be performed in constant time. For our algorithm, it will suffice to reserve enough space for $2N$ deque elements (with no possibility that a deque will grow leftward since push-left's are not used).

Subscripts R, L, and $R-1$ are used to select the rightmost item, leftmost item, and the item preceding the rightmost, respectively. So $\mathcal{L}^{-1}_L$ refers to the leftmost element of $\mathcal{L}^{-1}$, $\mathcal{M}_{R-1}$ refers to the item just before the rightmost member of $\mathcal{M}$, etc. Each deque element is actually a pair, for example, $\mathcal{M}_R = (X, I)$; the first entry X of the pair is a node and the second entry I is a numerical value, namely $I = I[X]$ as defined in section 2.2. To simplify notation, we shall use the same notation for a deque element as for the node which is its first component. Thus, $\mathcal{M}_L$ also denotes the node which is its first component. We write $I[\mathcal{M}_L]$ to denote its second (numerical) component. Similar conventions apply to the $\mathcal{L}^{\pm 1}$ deques. To simplify our presentation of the algorithm, we deal with boundary effects by augmenting the definition of primitive operations as necessary. For example, accessing a nonexistent deque element will return an *undefined* indicator $\emptyset$ and, in general, functions of undefined operands are false or zero (in particular, the cost function $c(-,-)$ and the $I[-]$ functions return zero if they have $\emptyset$ as an argument).

[4]These C implementations are also available electronically from the authors or can currently be obtained by anonymous ftp from `math.ucsd.edu` or `ftp.nj.nec.com`

Function Input() returns the next vertex from an imagined input tape, which moves in the forward direction only and is assumed to hold a balanced alternating color tour. When the tape's end is reached, "*undefined*" is returned. Procedure Output() is used to write an individual matching to an imagined output tape. They are written as discovered but can easily be output in tour order (with only an extra $O(N)$ time computation).

To use the same code for red nodes and blue nodes, a variable ψ tracks vertex color by toggling between -1 and 1. Our convention is that $\psi = 1$ corresponds to blue and $\psi = -1$ to red.

3.2. Narrative description of the algorithm. Initialization consists of setting the three deques to be empty and setting the color toggle $\psi := -1$.

The algorithm first reads nodes from the input and pushes them onto the right end of the $\mathcal{M}$ deque, and then twice scans the nodes in tour order. During the two scans, nodes are popped from the left end of $\mathcal{M}$ and then pushed onto its right end.[5] In addition, while processing a node some nodes may be popped off the right end of $\mathcal{M}$ to be matched. It will always be the case that $\mathcal{M}$ contains a sequence of contiguous nodes in tour order and that the node currently being scanned immediately follows the (formerly) rightmost element of $\mathcal{M}$.

The variable ψ will be maintained as a color toggle, so that ψ is equal to -1 if the node currently being processed is red and to 1 if the current node is blue. The algorithm used for pushing an element onto the right end of $\mathcal{M}$ follows.

ALGORITHM 3.1. *This procedure pushes a vertex X onto the right of the $\mathcal{M}$ deque and computes the corresponding $I[X]$ value which is pushed along with X.*

procedure *Push_Main* (X)
    I:= $I[\mathcal{M}_R] + \psi \cdot c(\mathcal{M}_R, X)$
    push-right (X,I) *onto* $\mathcal{M}$
    return ()

Algorithm 3.1 merely computes the $I[-]$ value for a node X and pushes the node and its $I[-]$ value on the right end of M. To justify the computation of the value of $I[X]$, note that if X is blue, then $\psi = 1$ and $I[X]$ was defined to equal $I[\mathcal{M}_R] - c(\mathcal{M}_R, X)$; whereas, if X is red then $\phi = -1$ and $I[X]$ equals $I[\mathcal{M}_R] + c(\mathcal{M}_R, X)$. (Unless $\mathcal{M}$ is empty, in which case, $I[X] = 0$.)

Once the current node has been pushed onto the right end of $\mathcal{M}$, the following code implements step (β) from section 2.2:

while $c(\mathcal{L}_{R-1}^{\text{-}\psi}, \mathcal{M}_R) - c(\mathcal{L}_R^{\text{-}\psi}, \mathcal{M}_R) < \psi \cdot (I[\mathcal{L}_R^{\text{-}\psi}] - I[\mathcal{L}_{R-1}^{\text{-}\psi}])$
    pop-right $\mathcal{L}^{\text{-}\psi}$

To justify the correctness of the **while** condition, suppose that the currently scanned node is red, so $\phi = -1$. By Lemma 2.10, $\mathsf{Bnft}[\mathcal{L}_{R-1}^{\text{-}\psi}, \mathcal{M}_R] > \mathsf{Bnft}[\mathcal{L}_R^{\text{-}\psi}, \mathcal{M}_R]$ if and only if $c(\mathcal{L}_{R-1}^{\text{-}\psi}, \mathcal{M}_R) - c(\mathcal{L}_R^{\text{-}\psi}, \mathcal{M}_R) < \Delta[\mathcal{L}_{R-1}^{\text{-}\psi}, \mathcal{L}_R^{\text{-}\psi}]$. Furthermore, $\Delta[\mathcal{L}_{R-1}^{\text{-}\psi}, \mathcal{L}_R^{\text{-}\psi}]$ is equal to $\psi \cdot (I[\mathcal{L}_R^{\text{-}\psi}] - I[\mathcal{L}_{R-1}^{\text{-}\psi}])$ since $\mathcal{L}^{\text{-}\psi}$ contains blue nodes and $\psi = -1$ (by the equalities at the end of section 2.2). In this case, $\mathcal{M}_R$ is past the crossover point of $\mathcal{L}_{R-1}^{\text{-}\psi}$ and $\mathcal{L}_R^{\text{-}\psi}$, so $\mathcal{L}_R^{\text{-}\psi}$ may be discarded from consideration as a left endpoint of a candidate. A similar calculation justifies the case when the current node is blue.

[5] For line-like tours, only the first scan is needed; however, we treat only the more general (circular) case.

To implement step (γ), the following code is used:

if $c(\mathcal{M}_R, \mathcal{L}_R^{\neg\psi}) < \psi \cdot (I[\mathcal{M}_R] - I[\mathcal{L}_R^{\neg\psi}])$
  X := *pop-right* $\mathcal{M}$
  while $\mathcal{M}_R \neq \mathcal{L}_R^{\neg\psi}$
    Match_Pair()
  Push_Main(X)

where Match_Pair is defined below. The above **if** statement checks whether $\mathcal{L}_R^{\neg\psi} \rightarrow \mathcal{M}_R$ is a candidate; if so, the algorithm greedily assigns edges to nodes in the interior of the candidate (where "greedily" means with respect to the nodes that have not already been assigned). Before the greedy assignment is started, the rightmost entry is popped from $\mathcal{M}$ and is saved as X to pushed back on the right end afterwards. There are two reasons for this: first, this gets the current node X out of the way of Match_Pair's operation, and second, and more importantly, when X is pushed back onto $\mathcal{M}$, the $I[-]$ value for the current node is recomputed so as to be correct for the reduced matching problem in which the greedily matched nodes are no longer present. Match_Pair is the following procedure:

procedure *Match_Pair*()
  Output ("$\mathcal{M}_{R-1} \leftrightarrow \mathcal{M}_R$")
  pop-right $\mathcal{M}$
  if $\mathcal{M}_R = \mathcal{L}_R^{\psi}$
    pop-right $\mathcal{L}^{\psi}$
  pop-right $\mathcal{M}$
  return()

The procedure Match_Pair assigns a jumper $\mathcal{M}_{R-1} \leftrightarrow \mathcal{M}_R$ and discards a matched node from the deque $\mathcal{L}^{\psi}$ if it appears there. Because of the **while** condition controlling calls to Match_Pair, it is not possible for a matched node to occur in $\mathcal{L}^{\neg\psi}$, so we do not check for this condition.

To implement step (δ), the following code is used:

while $\Omega(\mathcal{L}_{R-1}^{\psi}, \mathcal{L}_R^{\psi}, \mathcal{M}_R) =$ "Yes"
  pop-right $\mathcal{L}^{\psi}$
push-right $\mathcal{M}_R$ onto $\mathcal{L}^{\psi}$ (without popping $\mathcal{M}_R$)

That completes the description of how nodes are processed during the first scan. As mentioned earlier, the last instruction (the *push-right*) is omitted from step (δ) during the second scan. Other than this, the processing for steps (β)–(δ) is identical in the two scans.

One potentially confusing aspect of the second scan is that the $I[-]$ values are no longer actually the correct $I[-]$ values; for example, it is no longer the case that $I[\mathcal{M}_L]$ is necessarily equal to zero. Strictly speaking, the $I[-]$ values all shift by an additive constant when an entry is popped from the left end of $\mathcal{M}$; however, it is not necessary to implement this shift, since the algorithm only uses differences between $I[-]$ values. The end result is that nothing special needs to be done to the I values when we pop-left $\mathcal{M}$.

After both scans are completed, any remaining nodes may be greedily matched. As discussed above, there are two possible greedy matchings and both have the same (optimal) cost. Thus either one may be used; the algorithm below just calls

Match_Pair repeatedly to assign one of these greedy matchings.

ALGORITHM 3.2. *This is the matching algorithm for balanced quasi-convex tours. All variables are global.*

"Initialization"
$\mathcal{M}, \mathcal{L}^{-1}, \mathcal{L}^{1} := \emptyset$
ψ := *-1*

  $\psi := -\psi$
"Windup Processing"
while $\mathcal{M}$ *is not empty*
  Match_Pair()
Exit.
procedure *Process_Node*()
  Push_Main(X)
  while $c(\mathcal{L}^{\bar{\psi}}_{R-1}, \mathcal{M}_R) - c(\mathcal{L}^{\bar{\psi}}_{R}, \mathcal{M}_R) < (I[\mathcal{L}^{\bar{\psi}}_{R}] - I[\mathcal{L}^{\bar{\psi}}_{R-1}]) \cdot \psi$
    pop-right $\mathcal{L}^{\bar{\psi}}$
  if $c(\mathcal{M}_R, \mathcal{L}^{\bar{\psi}}_{R}) < \psi \cdot (I[\mathcal{M}_R] - I[\mathcal{L}^{\bar{\psi}}_{R}])$
    $X :=$ *pop-right* $\mathcal{M}$
    while $\mathcal{M}_R \neq \mathcal{L}^{\bar{\psi}}_{R}$
      Match_Pair()
    Push_Main(X)
  while $\Omega(\mathcal{L}^{\psi}_{R-1}, \mathcal{L}^{\psi}_{R}, \mathcal{M}_R)$
    pop-right $\mathcal{L}^{\psi}$
  return

The complete matching algorithm is shown as Algorithm 3.2. When interpreting Algorithm 3.2, it is necessary to recall our convention that any predicate of undefined arguments is to be false. This situation can occur in the four **while** and **if** conditions of Process_Node. If $\mathcal{L}^{\bar{\psi}}$ is empty, then $\mathcal{L}^{\bar{\psi}}_{R}$ is undefined and the two **while** conditions and the first **if** condition are to be false. Similarly, if $\mathcal{L}^{\bar{\psi}}$ has < 2 elements, then the first **while** condition is to be false; and if $\mathcal{L}^{\psi}$ has < 2 elements, then the final **while** condition is to be false.

The runtime of Algorithm 3.2 is either $O(N)$ or $O(N \log N)$ depending on whether the weak analyticity condition holds. To see this, note that the initialization and the windup processing both take $O(N)$ time. The loops for each of the two scans are executed $\leq N$ times. Except for the **while** loops, each call to Process_Node takes constant time. The second **while** loop (which calls Match_Pair) is executed more than once only when edges are being output. If the first or third **while** loop is executed more than once, then vertices are being popped from the L stacks. Since $\lfloor \frac{1}{2}N \rfloor$ edges are output and since $O(N)$ vertices are pushed onto the L stacks, each of these **while** loops are executed only $O(N)$ times during the *entire* execution of the algorithm. An iteration of the first or second **while** loop takes constant time, while an iteration of the third **while** loop takes either constant time or $O(\log N)$ time, depending on whether the weak analyticity property holds.

When the weak analyticity condition holds, the Ω predicate typically operates in constant time by computing two theoretical relative crossovers and comparing their positions. This happens, for example, when the tour consists of points lying on a circle, with the cost function equal to Euclidean distance; section 3.3 outlines a constant-time algorithm for this example. Without the weak analyticity condition, the Ω-predicate runs in logarithmic time, by using a binary search of the $\mathcal{M}$ deque. This general (not weakly analytic) case is handled by the generic Ω algorithm discussed in section 3.3.

There are a couple of improvements that can be made to the algorithm which will increase execution speed by a constant factor. First, the calls to Match_Pair made during the "Windup Processing" do not need to check if $\mathcal{M}_R = \mathcal{L}_R^\psi$, since $\mathcal{L}^\psi$ is empty at this time. Second, if computing the cost function $c(-,-)$ is more costly than simple addition, then it is possible for Push_Main() to use an alternative method during the two scans to compute the cost $c(\mathcal{M}_R, X)$ for nodes X which have just been popped from the left of $\mathcal{M}$ (except for the first one popped from the left in the first scan). Namely, the algorithm can save the old $I[X]$ value for the node X as it is left-popped off the deque $\mathcal{M}$. Then the cost function can be computed by computing the difference between the $I[-]$ value of X and the $I[-]$ of the previous node left-popped from $\mathcal{M}$. This second improvement applies only to the first Push_Main call in Process_Node.

3.3. Algorithms for Ω. During the first scan, the procedure Ω is called (repeatedly) by Process_Node to determine whether $\mathcal{L}_R^\psi$ should be popped before the current node $\mathcal{M}_R$ is pushed onto the right end of the $\mathcal{L}^\psi$ deque. During the second scan, $\mathcal{M}_R$ is never pushed onto the $\mathcal{L}^\psi$ deque; however, using the procedure Ω can allow the $\mathcal{L}^\psi$ deque to be more quickly emptied, thus speeding up the algorithm's execution. (However, the use of the Ω could be omitted during the second scan without affecting the correctness of the algorithm.)

When Ω is called, $\mathcal{L}_{R-1}^\psi$, $\mathcal{L}_R^\psi$, and $\mathcal{M}_R$ are distinct nodes, in tour order, and of the same color. Let $\delta = (I[\mathcal{L}_{R-1}^\psi] - I[\mathcal{L}_R^\psi]) \cdot \psi$ and $\epsilon = (I[\mathcal{L}_R^\psi] - I[\mathcal{M}_R]) \cdot \psi$. Let Y denote the δ-crossover point of $\mathcal{L}_{R-1}^\psi$ and $\mathcal{L}_R^\psi$, and let Z denote the ϵ-crossover point of $\mathcal{L}_R^\psi$ and $\mathcal{M}_R$ (note Y and/or Z may not exist). By definition, Y and Z are both opposite in color from the other three nodes. The procedure Ω must return *True* if Y exists and Z does not, must return *False* if Y does not exist, and, if both exist, must return *True* if $\mathcal{L}_R^\psi, Y, Z$ are in tour order, must return *True* if $\mathcal{L}_R^\psi, Z, Y$ are in tour order, and may return either value if $Y = Z$.

In this section, we discuss two algorithms for Ω. We first discuss a "generic" algorithm that works for any cost function, regardless of whether the weak analyticity condition holds. This generic Ω procedure is shown as Algorithm 3.3 below. The

generic Ω executes a binary search for a node which is at or past one of the crossover points but is not at or past the other. Obviously, if the crossover Y exists, then it exists in the range $(\mathcal{L}_R^\psi, \mathcal{L}_{R-1}^\psi)$, and if the crossover Z exists, it is in the range $(\mathcal{M}_R, \mathcal{L}_R^\psi)$. Furthermore, Y cannot exist in the range $(\mathcal{L}_R^\psi, \mathcal{M}_R)$, since otherwise it would have been popped when Y was reached (by the first **while** loop in an earlier call to Match_Pair). Hence, the binary search may be confined to the range $(\mathcal{M}_R, \mathcal{L}_{R-1}^\psi)$, provided that *True* is returned in the event that the binary search is unsuccessful.

In Algorithm 3.3, a new notation $\mathcal{M}_k$ is used. This presumes that the $\mathcal{M}$ deque is implemented as an array; the elements of $\mathcal{M}$ fill a contiguous block of the array elements. When we write $\mathcal{M}_k$, we mean the kth entry of the array. The L deques can contain pointers to $\mathcal{M}$ deque entries; in fact, in our preferred implementation, the L deque entries contain only an index for an $\mathcal{M}$ deque entry. Thus the value h can be found in constant time for Algorithm 3.3.

The generic Ω algorithm shown in Algorithm 3.3 takes $O(\log N)$ time since it uses a binary search.

ALGORITHM 3.3. *This is the generic Ω algorithm which works with any tour, regardless of weak analyticity. Past_Xover_A and Past_Xover_B are boolean-valued variables.*

procedure $\Omega(\mathcal{L}_{R-1}^\psi, \mathcal{L}_R^\psi, \mathcal{M}_R)$

"Nodes $\mathcal{L}_{R-1}^\psi$, $\mathcal{L}_R^\psi$ and $\mathcal{M}_R$ are the same color."

Let h be the index so that $\mathcal{M}_{h-1}$ is $\mathcal{L}_{R-1}^\psi$.
Let ℓ be the index so that $\mathcal{M}_\ell$ is $\mathcal{M}_R$.

$\delta := (I[\mathcal{L}_{R-1}^\psi] - I[\mathcal{L}_R^\psi]) \cdot \psi$
$\epsilon := (I[\mathcal{L}_R^\psi] - I[\mathcal{M}_R]) \cdot \psi$

"Do binary search of opposite color nodes from $\mathcal{M}_\ell$ to $\mathcal{M}_{h-2}$"

while $h > \ell + 1$
  $k := \ell + 2\lfloor (h-\ell)/4 \rfloor$
  Past_Xover_A:= $(c(\mathcal{L}_{R-1}^\psi, \mathcal{M}_k) - c(\mathcal{L}_R^\psi, \mathcal{M}_k)) < \delta$
  Past_Xover_B:= $(c(\mathcal{L}_R^\psi, \mathcal{M}_k) - c(\mathcal{M}_R, \mathcal{M}_k)) < \epsilon$
  if *Past_Xover_A*
    if *Past_Xover_B*
      $h := k$
    else
      return(TRUE)
  else
    if *Past_Xover_B*
      return(FALSE)
    else
      $\ell := k + 2$
return (TRUE)

Next we describe an example of a linear time algorithm for Ω where the weak analyticity condition holds. For this example, we assume that the nodes of the quasiconvex tour lie on the unit circle in the xy plane, the cost function is equal to straight-line Euclidean distance, and the tour proceeds in counterclockwise order around the circle. The Ω algorithm either is given, or computes, the xy coordinates of the three nodes $\mathcal{L}_{R-1}^\psi$, $\mathcal{L}_R^\psi$, and $\mathcal{M}_R$. It then uses a routine Circle_Crossover to find the **theoretical**

δ-crossover Y of $\mathcal{L}_{R-1}^{\psi}$ and $\mathcal{L}_R^{\psi}$ and the **theoretical** ϵ-crossover of $\mathcal{L}_R^{\psi}$ and $\mathcal{M}_R$. If the theoretical crossover Y exists, it will be in the interval $[\mathcal{L}_R^{\psi}, \mathcal{L}_{R-1}^{\psi}]$, and if Z exists, Z will be in the interval $[\mathcal{M}_R, \mathcal{L}_R^{\psi}]$. When Y and Z both exist, the Ω procedure returns *True* if $\mathcal{L}_R^{\psi}, Y, Z$ are in tour order or any two of these nodes are equal; otherwise the procedure returns *False*.

ALGORITHM 3.4. *This is the algorithm which computes the δ-theoretical crossover point for two nodes lying on the unit circle with cost function equal to Euclidean distance. The inputs are δ and two points (x_1, y_1) and (x_2, y_2) lying on the unit circle. The procedure returns TRUE or FALSE to indicate whether the crossover point exists; if it does exist, it sets (x_3, y_3) equal to the crossover point. There is a possibility that roundoff errors will lead to spurious "FALSE" answers, so the values of (x_3, y_3) are set even when FALSE is returned.*

```
procedure Circle_Crossover(x1,y1,x2,y2,δ)
    a := δ/2
    hip := (x1 · x2 + y1 · y2)/2
    if hip > 0.5                    "two checks to avoid roundoff errors"
        hip := 0.5
    else if hip < −0.5
        hip := −0.5
    csqr := .5 − hip
    c := √csqr
    d := √(.5 + hip)
    if −x2 · y1 + x1 · y2 < 0
        d := −d
    asqr := a · a
    if asqr > csqr
        if a < 0
            x3 := x1
            y3 := y1
        else
            x3 := x2
            y3 := y2
        return(FALSE)
    u := −(1 + d)(1 − (asqr/csqr))
    if asqr = csqr
        v := a
    else
        v := a√(1 + (u²)/(csqr − asqr))
    if hip > 0
        α := (x1 + x2)/(2d)
        β := (y1 + y2)/(2d)
    else
        α := (y2 − y1)/(2c)
        β := (x1 − x2)/(2c)
    x3 := (u + d)α − vβ
    y3 := vα + (u + d)β
    return (TRUE)
```

Of course, the crucial implementation difficulty for the procedure Ω is the algorithm for Circle_Crossover; this is shown as Algorithm 3.4. Circle_Crossover takes two points (x_1, y_1) and (x_2, y_2) lying on the unit circle in the xy-plane and a real

value δ. The theoretical δ-crossover point of (x_1, y_1) and (x_2, y_2) is found as an intersection point of the unit circle and the hyperbola consisting of those points which have distance from (x_1, y_1) equal to δ plus their distance from (x_2, y_2) (namely, the intersection which is not between (x_1, y_1) and (x_2, y_2) in tour order). Letting the "half inner product" hip equal $(x_1x_2+y_1y_2)/2$, the distance between the two points is equal to $2c$, where $c = \sqrt{\frac{1}{2} - hip}$. And, the midpoint of the line segment between the two points is distance $\sqrt{\frac{1}{2} + hip}$ from the origin. To conveniently express the equation for the hyperbola, we set up uv-axes as a rigid translation of the xy-axes, positioned so that the points (x_1, y_1) and (x_2, y_2) have uv-coordinates $(0, -c)$ and $(0, c)$, respectively. This makes the origin have uv-coordinates $(d, 0)$, where $d = \pm\sqrt{\frac{1}{2} + hip}$ with the sign being + if and only if the angle from (x_1, y_1) to (x_2, y_2) is ≤ 180 deg. In the uv-plane, the hyperbola has equation

$$\frac{v^2}{a^2} - \frac{u^2}{c^2 - a^2} = 1$$

where $a = \delta/2$, and the unit circle has equation

$$(u + d)^2 + v^2 = 1.$$

Eliminating v^2 from these equations and solving for u, and then for v, shows that the desired intersection point of the circle and the hyperbola has uv-coordinates

$$u = (1 - d)\left(1 - \frac{a^2}{c^2}\right),$$
$$v = a\sqrt{1 + \frac{u^2}{c^2 - a^2}}.$$

Given the uv-coordinates, it is an easy matter to find values α, β which allow the corresponding xy-coordinates to be computed. Algorithm 3.4 show two equivalent calculations of α, β; the algorithm chooses the one which avoids division by zero or division by a number close to zero. Algorithm 3.4, as shown, also checks for some error conditions that can arise from roundoff errors. In particular, it makes sure that $|hip| \leq \frac{1}{2}$, and that $a^2 < c^2$. Amazingly enough, we found, during extensive testing with randomly generated tours of points on the unit circle, that roundoff error occasionally caused these conditions to be violated, even for points on the unit circle and for $|a| < |c|$.

3.4. An ANSI-C implementation. An efficient and highly portable ANSI-C implementation of our algorithms is described in [5], which includes complete source code, test programs for several interesting cases, benchmark results, and software to produce postscript graphical representations of the matchings found. To help ensure the correctness of our implementation, a straightforward $O(n^3)$ dynamic programming solution was also implemented, and the results compared for 4,000,000 pseudo-randomly drawn problems. Figure 1.1 shows an example of a matching produced by our software.

Benchmark results for a variety of RISC processors produced nearly identical results when normalized by clock rate. So timing results in [5] are given in units of RISC cycles. Graphs of up to 20,000 nodes are included in this study.

Recall that $O(\log N)$ time is a worst case bound for generic Ω. One interesting experimental result is that over the range of graph sizes considered, for the specific settings implemented in the test programs, and given the uniform pseudorandom manner in which problem instances were generated, the generic Ω implementation exhibits very nearly linear time performance. In other words, the experimentally observed runtime of Ω was nearly constant. We suspect that this is primarily a consequence of the uniform random distribution from which problems were drawn, and that it should be possible to demonstrate expected time results better than $O(\log N)$ for more structured settings.

The benchmarks included one line-like and two circular settings. Solving pseudorandomly drawn matching problems of size n required on average between 2,000 and 16,000 RISC cycles per node depending on the setting and on whether a constant-time or generic Ω was employed. It is interesting to note that, in all cases, the constant-time Ω performed better by a factor ranging from roughly 1.5 to slightly over 3. Thus, for some problems, the linear time result of this paper may be of practical interest.

Despite our focus on efficiency, further code improvements and cost function evaluation by table lookup may contribute to significant performance improvement.

4. Nonbipartite, quasi-convex tours. In this section we show how the earlier algorithms can be applied to nonbipartite, quasi-convex tours. The principal observation is that nonbipartite tours may be made bipartite by the simple construction of making the nodes alternate in color. This is already observed by Marcotte and Suri [20] in a more restrictive setting; we repeat the construction here for the sake of completeness.

First, it is apparent that the proof of Lemma 2.3 still works in the nonbipartite case, and thus any nonbipartite, quasi-convex tour has a minimum-cost matching in which no jumpers cross. This fact implies the following two lemmas.

LEMMA 4.1. *Let $x_1, \ldots, x_N$ be a nonbipartite, quasi-convex tour with N even. Then there exists a minimum-cost matching such that every edge in the tour is of the form $x_i \leftrightarrow x_j$ with i even and j odd.*

Proof. It will suffice to show that any crossing-free matching has this property. Suppose $x_i \leftrightarrow x_j$ is a jumper in a crossing-free matching, with $i < j$. Since N is even, the matching is complete in that every node is matched. The crossing-free property thus implies that the nodes in (x_i, x_j) are matched with each other, so there are an even number of such nodes, i.e., one of i and j is even and the other is odd. □

LEMMA 4.2. *Let $x_1, \ldots, x_N$ be a nonbipartite line-like quasi-convex tour. Then there exists a minimum-cost matching such that every edge in the tour is of the form $x_i \leftrightarrow x_j$ with i even and j odd.*

Proof. If N is even then this lemma is just a special case of the former lemma. If N is odd, then add an additional node x_{N+1} to the end of the tour, with $c(x_i, x_{N+1}) = 0$ for all i. The resulting tour is again quasi-convex and of even length; so the lemma again follows immediately from the former lemma. □

When Lemmas 4.1 and 4.2 apply, we may color the even nodes red and the odd nodes blue and reduce the nonbipartite matching problem to a bipartite matching problem. As an immediate corollary, we have that the two main theorems also apply in the nonbipartite setting; namely, for nonbipartite, quasi-convex tours of even length and for nonbipartite, line-like, quasi-convex tours, the matching problem can always be solved in $O(N \log N)$ time and it can be solved in $O(N)$ time if the weak analyticity condition holds.

We do not know whether similar algorithms exist for the case of general (i.e.,

nonline-like) quasi-convex tours of odd length. Similarly, we do not know any linear or near-linear time algorithms for bipartite, quasi-convex tours which are neither balanced nor line-like.

We conclude this section by mentioning a tantalizing connection between our work and the work of Yao [25]. Yao gave a quadratic runtime algorithm for solving the dynamic programming problem

$$d(i,j) \;=\; c(i,j) + \min\{d(i,k-1) + d(k,j) : i < k \le j\}$$

for line-like quasi-convex tours with cost function c (improving on the obvious cubic-time algorithm). Our nonbipartite matching problem can be stated as a similar dynamic programming problem; namely, the minimum-cost, $MC(i,j)$, of a complete matching on the nodes in $[x_i, x_j]$ can be recursively defined to equal

$$\min\{c(i,k) + MC(i+1,k-1) + MC(k+1,j) : i < k \le j\}.$$

(A similar dynamic programming algorithm can be given for the bipartite matching problem.) The obvious naive algorithm for computing $MC(-,-)$ is cubic-time; however, our main results give (near)-linear time algorithms for line-like quasi-convex tours. This raises the possibility that the dynamic programming problem considered by Yao may also have a near-linear time solution.

5. Applications to string matching. As a final topic we briefly discuss the application of our matching results to string comparison. A full treatment is beyond the scope of this paper, but additional details and related algorithms may be found in [6]. Given two symbol strings $v = a_1 a_2 \cdots a_n$ and $w = b_1 b_2 \cdots b_n$, our goal is to measure a particular notion of *distance* between them. Intuitively, distance acts as a measure of similarity; i.e., strings that are highly similar (highly dissimilar) are to have a small (large) distance between them. The purpose of such formulations is usually to approximate human similarity judgments within a pattern classification or information retrieval system.

Suppose $f(x)$ is a monotonely increasing, concave-down function with $f(0) = 0$. Let symbols $a_1, \ldots, a_n$ in v be a graph's red nodes and $b_1, \ldots, b_n$ in w be its blue nodes, and consider bipartite matchings of these $2n$ symbols. In the simplest formulation, we define the cost of an edge $a_i \leftrightarrow b_j$ as $f(|j-i|)$ if a_i and b_j are the same symbol and as $f(n)$ if a_i and b_j are distinct symbols. The cost of matching unequal characters can also be set to be any other fixed value instead of $f(n)$. Our *distance*, $\sigma(v,w)$, between strings v and w is then the minimum cost of any such bipartite matching.

As an example, consider the two strings "delve" and "level" and let $f(x) = \sqrt{x}$. Then the distance between these two strings is $\sqrt{5} + \sqrt{0} + \sqrt{2} + \sqrt{1} + \sqrt{1} \approx 5.65$.

As we have set up our problem above, the computation of $\sigma(v,w)$ is not directly an instance of the quasi-convex matching problem. However we can compute the σ function by considering each alphabet symbol α separately, and solving the quasi-convex matching problem σ_α which results from restricting attention to occurrences of a single alphabet symbol at a time. To make this clear, we introduce a special symbol "-" which indicates the absence of an alphabet symbol. The value of $\sigma($"delve," "level"$)$ can be expressed as the sum

$$\begin{aligned}&\sigma_d(\text{“}d\text{----”},\text{“-----”}) + \sigma_e(\text{“-}e\text{--}e\text{”},\text{“-}e\text{-}e\text{-”})\\ &\quad +\sigma_l(\text{“--}l\text{--”},\text{“}l\text{---}l\text{”}) + \sigma_v(\text{“---}v\text{-”},\text{“--}v\text{--”}).\end{aligned}$$

To make the summed σ_α terms equal σ as originally defined, each σ_α is defined to be the subproblem's minimum matching cost plus $f(n)/2$ times the number of unmatched symbols.

We will loosely refer to distance functions that result from this kind of formulation as σ-distances. Assuming that $f(x)$ satisfies the weak analyticity condition, it is not too difficult to show that it is possible to compute $\sigma(v, w)$ in linear time. If the weak analyticity condition does not hold, then our results give an $O(n \log n)$ time algorithm.

A novel feature of our σ-distances is that distinct alphabet symbols are treated independently. This is in contrast to most prior work which has used "least edit distance" for string comparison (see [21] for a survey). As an illustration of the difference between our distance measure and the "edit distance" approach, consider comparing the word "abcde" with its mirror image "edcba." Our approach recognizes some similarity between these two forms, while the most standard "edit distance" approach sees only that the two strings have "c" in common—in essence substituting the first two and last two symbols of the string without noticing the additional occurrences of the same symbols at the other end of the other string.

A special form of our σ-distance measure in which $f(x) = x$, and the optimal matching is only approximated, was introduced earlier by the authors and shown to have a simple linear time algorithm [26, 27]. Its relationship to σ-distances is described in [6]. This earlier algorithm has been successfully used in commercial applications, especially for spelling correction in word processing software, typewriters, and handheld dictionary devices (we estimate that over 15,000,000 such software/hardware units have been sold by Proximity Technology, Franklin Electronic Publishers, and their licensees). Other less prominent commercial applications include database field search (e.g., looking up a name or address), and the analysis of multifield records such as mailing addresses, in order to eliminate near-duplicates. In both of these applications, the strict global left-right ordering imposed by $O(n^2)$ time "edit distance" methods can be problematic. On the other hand, very local left-right order preservation seems to be an important part of similarity perception in humans. One simple adaptation of our σ-distance methods which goes a long way toward capturing this characteristic consists of extending the alphabet beyond single symbols to include digraphs or multigraphs. The result is increased sensitivity to local permutation. Another effective alphabet extension technique involves the addition of *feature symbols* to the alphabet to mark events such as likely phonetic transitions. We expect that the use of general concave-down distance functions (as opposed to $f(x) = x$) will improve the quality of the similarity judgments possible within the σ-distance framework.

The development above considers strings of equal length only. The unequal length case is not a difficult generalization but considering it does highlight the issue of *embedding*. By this we mean that it is implicit in our formulation that the two strings are in a sense embedded into the real line. The particular, rather natural embedding we've assumed so far maps a_i and b_i to value i on the real line, but others are possible.

A detailed comparison of our methods with "edit distance" approaches is beyond the scope of this paper. But we must point out that the "edit distance" formulation is in several senses richer than ours. First, the cost of matching different alphabet members need not be fixed. Also, our distance formulation depends on a designated embedding while the "edit distance" method requires no such specification. Finally, for some problems left-right order preservation may be desirable. On the other hand, even the simplest "edit distance" approach is $O(n^2)$ compared with the $O(n)$ or $O(n \log n)$ complexity of our method. We therefore feel that additional work

is needed to better understand the applications of our approach—and perhaps extend it.

Acknowledgments. We wish to thank Dina Kravets, Dave Robinson, and Warren Smith for helpful discussions and Dave Robinson and Kirk Kanzelberger for implementing and testing the algorithms described above.

SPACE-EFFICIENT SCHEDULING OF MULTITHREADED COMPUTATIONS*

ROBERT D. BLUMOFE† AND CHARLES E. LEISERSON‡

Abstract. This paper considers the problem of scheduling dynamic parallel computations to achieve linear speedup without using significantly more space per processor than that required for a single-processor execution. Utilizing a new graph-theoretic model of multithreaded computation, execution efficiency is quantified by three important measures: T_1 is the time required for executing the computation on a 1 processor, T_∞ is the time required by an infinite number of processors, and S_1 is the space required to execute the computation on a 1 processor. A computation executed on P processors is time-efficient if the time is $O(T_1/P + T_\infty)$, that is, it achieves linear speedup when $P = O(T_1/T_\infty)$, and it is space-efficient if it uses $O(S_1 P)$ total space, that is, the space per processor is within a constant factor of that required for a 1-processor execution.

The first result derived from this model shows that there exist multithreaded computations such that no execution schedule can simultaneously achieve efficient time and efficient space. But by restricting attention to "strict" computations—those in which all arguments to a procedure must be available before the procedure can be invoked—much more positive results are obtainable. Specifically, for any strict multithreaded computation, a simple online algorithm can compute a schedule that is both time-efficient and space-efficient. Unfortunately, because the algorithm uses a global queue, the overhead of computing the schedule can be substantial. This problem is overcome by a decentralized algorithm that can compute and execute a P-processor schedule online in expected time $O(T_1/P + T_\infty \lg P)$ and worst-case space $O(S_1 P \lg P)$, including overhead costs.

1. Introduction.

In the course of investigating schemes for general-purpose MIMD-style parallel computation, many diverse research groups have agreed on multithreading as a dominant paradigm. As an example, modern dataflow systems [16, 19, 25, 33, 34, 35, 40, 41] partition the dataflow instructions into fixed groups called threads and arrange the instructions of each thread into a fixed sequential order at compile time. At run time, a scheduler dynamically orders execution of the threads. Other systems employ schedulers that dynamically order threads based on the availability of data in shared-memory multiprocessors [1, 10, 23] or message arrivals in message-passing multicomputers [2, 17, 29, 44].

Rapid execution of a multithreaded computation on a parallel computer requires exposing and exploiting parallelism in the computation by keeping enough threads concurrently alive to keep the processors of the computer busy. If processors are busy most of the time, the P-processor execution schedule $\mathcal{X}$ of the computation exhibits

linear speedup: the running time $T(\mathcal{X})$ is order P times faster than the optimal running time T_1 with 1 processor, that is, $T(\mathcal{X}) = O(T_1/P)$.

In attempting to expose parallelism, however, schedulers often end up exposing more parallelism than the computer can actually exploit, and since each living thread requires the use of a certain amount of memory, such schedulers can easily overrun the memory capacity of the machine [15, 22, 24, 39, 43]. To date, the space requirements of multithreaded computations have been managed with heuristics or not at all [14, 15, 22, 24, 26, 32, 39, 43]. In this paper, we use algorithmic techniques to address the problem of managing storage for multithreaded computations. Our goal is to develop scheduling algorithms that expose sufficient parallelism to obtain linear speedup but without exposing so much parallelism that the space requirements become excessive.

We compare the total space $S(\mathcal{X})$ required by a P-processor execution schedule $\mathcal{X}$ with the space S_1 used by a space-optimal 1-processor execution. We wish to use as little space as possible, and we argue that a space-efficient P-processor execution schedule $\mathcal{X}$ exhibits at most linear expansion of space, that is, $S(\mathcal{X}) = O(S_1 P)$.

Our first result shows that, in general, it is not possible to achieve both linear speedup and linear expansion of space. We exhibit a multithreaded computation such that any execution schedule $\mathcal{X}$ that achieves a factor of ρ speedup, that is, execution time $T(\mathcal{X}) \leq T_1/\rho$, must use space at least $S(\mathcal{X}) \geq (1/4)(\rho - 1)\sqrt{T_1} + S_1$. For such a computation, even achieving a factor of 2 speedup ($\rho = 2$) requires space that grows as a function of the serial execution time.

In order to cope with this negative result, we restrict our attention to the class of "strict" multithreaded computations. Intuitively, a strict computation is one in which no subroutine is called until all its parameters are available, although the parameters may be evaluated in parallel. Computations such as parallel divide-and-conquer, backtrack search, branch-and-bound, and game-tree search are all strict.

We show that for any strict multithreaded computation and any number P of processors, there exists a P-processor execution schedule $\mathcal{X}$ that achieves time $T(\mathcal{X}) \leq T_1/P + T_\infty$, where T_∞ is the optimal execution time on an infinite number of processors, and space $S(\mathcal{X}) \leq S_1 P$. Such a schedule exhibits linear expansion of space and linear speedup, $T(\mathcal{X}) = O(T_1/P)$, provided the average available parallelism, which we define as T_1/T_∞, is at least proportional to P, that is, $T_1/T_\infty = \Omega(P)$. We prove such schedules exist by exhibiting a simple centralized algorithm to compute them. We give a second, somewhat more efficient algorithm that computes equally good execution schedules; this algorithm is online and should be practical for moderate numbers of processors, but its use of a centralized queue makes it inefficient for large numbers of processors.

To demonstrate an algorithm that is efficient even for large machines, we give a randomized, distributed, and online scheduling algorithm that achieves space expansion proportional to $P \lg P$ for any strict computation and linear expected speedup for any strict computation with average available parallelism $T_1/T_\infty = \Omega(P \lg P)$.

We also show that some nonstrictness can be allowed in an otherwise strict computation in a way that may improve performance but does not adversely affect the time and space bounds.

The remainder of this paper is organized as follows. Section 2 develops a formal model of multithreaded computation and execution schedules. In section 3, we characterize multithreaded computations with three parameters and state some basic bounds relating these parameters to execution time and space. The lower bound for general multithreaded computations is presented in section 4. The upper bound

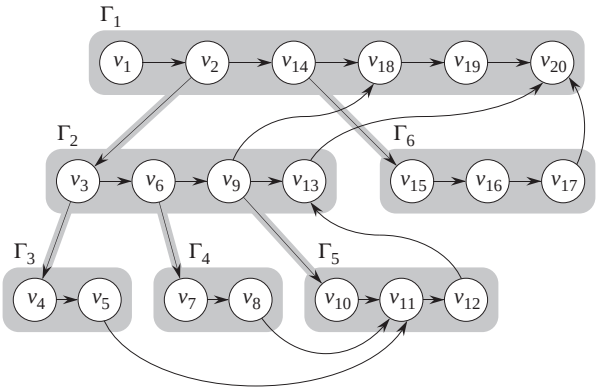

FIG. 2.1. *A multithreaded computation. This computation contains* 20 *tasks* $v_1, v_2, \ldots, v_{20}$ *and six threads* $\Gamma_1, \Gamma_2, \ldots, \Gamma_6$.

for strict computations and the technique for handling limited nonstrictness are presented in section 5. Section 6 presents a distributed scheduling algorithm for strict computations. Finally, in section 7 we conclude with a discussion of related and future work.

2. A model for multithreaded computation. This section defines the model of multithreaded computation that we use in this paper. We also define what it means for a parallel computer to execute a multithreaded computation.

A multithreaded computation is composed of a set of threads, each of which is a sequential ordering of unit-size tasks. In Figure 2.1, for example, each shaded block is a thread with circles representing tasks and the horizontal edges, called *continue* edges, representing the sequential ordering. Thread Γ_5 of this example contains three tasks: v_{10}, v_{11}, and v_{12}. The tasks of a thread must execute in this sequential order from the first (leftmost) task to the last (rightmost) task. In order to execute a thread, we allocate for it a chunk of memory, called an *activation frame*, that the tasks of the thread can use to store the values on which they compute.

A P-processor *execution schedule* for a multithreaded computation determines which processors of a P-processor parallel computer execute which tasks at each step. In any given step of an execution schedule, each processor either executes a single task or sits idle. A 3-processor execution schedule for our example computation (Figure 2.1) is shown in Figure 2.2. At step 3 of this example, processors p_1 and p_2 each execute a task while processor p_3 sits idle.

During the course of its execution, a thread may create, or *spawn*, other threads. Spawning a thread is like a subroutine call except that the spawning thread can operate concurrently with the spawned thread. We consider spawned threads to be children of the thread that did the spawning, and a thread may spawn as many children as it desires. In this way, threads are organized into a *spawn tree* as indicated in Figure 2.1 by the downward-pointing, shaded edges, called *spawn* edges, that connect threads to their spawned children. The spawn tree is the parallel analogue of a call tree. In our example computation, the spawn tree's *root* thread Γ_1 has two children, Γ_2 and Γ_6, and thread Γ_2 has three children, Γ_3, Γ_4, and Γ_5. Threads Γ_3, Γ_4, Γ_5, and Γ_6, which have no children, are *leaf* threads.

Each spawn edge goes from a specific task—the task that actually does the spawn operation—in the parent thread to the first task of the child thread. An execution

step	living threads						processor activity p_1	p_2	p_3

10	Γ_1	$\mathbf{\Gamma_2}$							v_{13}
11	$\mathbf{\Gamma_1}$								v_{20}

FIG. 2.2. *A 3-processor execution schedule for the computation of Figure* 2.1. *This schedule lists the living threads at the start of each step and the task (if any) executed by each of the three processors, p_1, p_2, and p_3, at each step. Living threads that are ready are listed in bold. The other living threads are stalled.*

schedule must obey this edge in that no processor may execute a task in a spawned child thread until after the spawning task in the parent thread has been executed. In our example computation (Figure 2.1), due to the spawn edge (v_6, v_7), task v_7 cannot be executed until after the spawning task v_6. Consistent with our unit-time model of tasks, a single task may spawn at most one child. When the spawning task executes, it allocates an activation frame for the new child thread. Once a thread has been spawned and its frame has been allocated, we say the thread is *alive* or *living*. When the last task of a thread executes, it deallocates its frame and the thread *dies*. In our 3-processor execution schedule (Figure 2.2), thread Γ_5 is spawned at step 5 and dies at step 9. Therefore, it is living at steps 6, 7, 8, and 9.

An execution schedule must respect one more kind of dependency. Consider a task that produces a data value that is consumed by another task. Such a producer/consumer relationship precludes the consuming task from executing until after the producing task. To enforce such orderings, we introduce *data-dependency* edges, as shown in Figure 2.1 by the curved edges. If the execution of a thread arrives at a consuming task before the producing task has executed, execution of the consuming thread cannot continue; the thread *stalls*. Once the producing task executes, the data dependency is *resolved*, which *enables* the consuming thread to resume with its execution; the thread becomes *ready*. For example, at step 4 of our 3-processor execution schedule (Figure 2.2), thread Γ_1 is stalled at task v_{18} because task v_9 has not yet been executed. At step 5 task v_9 is executed by processor p_2, thereby enabling thread Γ_1. At step 6, thread Γ_1 is ready at task v_{18}. A multithreaded computation does not model the mechanism by which data dependencies get resolved or unresolved dependencies get detected.

An execution schedule must obey the constraints given by the data-dependency, spawn, and continue edges of the computation. These edges form a directed graph of tasks, and no processor may execute a task until after all of the task's predecessors in this graph have been executed. So that execution schedules exist, this graph must be acyclic. That is, it must be a directed acyclic graph, or *dag*. At any given step of an execution schedule, a task is *ready* if all of its predecessors in the dag have been executed. Only ready tasks may be executed.

We make the simplifying assumption that a parent thread remains alive until all its children die, and thus, a thread does not deallocate its activation frame until all its children's frames have been deallocated. Although this assumption is not strictly necessary, it gives the execution a natural structure, and it will simplify our analyses of space utilization. We also assume that the frames hold all the values used by the computation; there is no global storage available to the computation outside the frames. Therefore, the space used at a given time in executing a computation is the total size of all frames used by all living threads at that time, and the total space used in executing a computation is the maximum such value over the course of the execution.

To summarize, a multithreaded computation can be viewed as a dag of tasks connected by continue, spawn, and data-dependency edges. The tasks are connected by continue edges into threads, and the threads form a spawn tree with the spawn edges. When a thread is spawned, an activation frame is allocated and this frame remains allocated as long as the thread remains alive. A living thread may be either ready or stalled due to an unresolved data dependency.

The notion of an execution schedule is independent of any real machine characteristics. An execution schedule simply requires that no processor executes more than one task per time step and every task is executed at a time step after all of its predecessor tasks (which connect to it via continue, spawn, or data-dependency edges) have been executed. A given execution schedule may not be viable for a real machine, since the schedule may not account for properties such as communication latency. For example, in our 3-processor execution schedule (Figure 2.2), task v_{11} is executed at step 8 by processor p_3 exactly one step after v_8 is executed by processor p_1, even though there is a data dependency between them that surely requires some latency to be resolved.

It is important to note the difference between what we are calling a multithreaded computation and a program. A multithreaded computation is the "parallel task stream" resulting from the execution of a multithreaded program with a given set of inputs. Unlike a serial computation in which the task stream is totally ordered, a multithreaded computation only partially orders its tasks. In general, a multithreaded computation is not a statically determined object; rather, the computation unfolds dynamically during execution as determined by the program and the input data. For example, a program may have conditionals, and therefore, the order of tasks (or even the set of tasks) executed in a thread may not be known until the thread is actually executed. We can think of a multithreaded computation as encapsulating both the program and the input data. The computation then reveals itself dynamically during execution.

3. Time and space. We shall characterize the time and space of an execution of a multithreaded computation in terms of three fundamental parameters: work, computation depth, and activation depth. We first introduce work and computation depth, which relate to the execution time, and then we focus on activation depth, which relates to the storage requirements.

The two time parameters are based on the underlying graph structure of the multithreaded computation. If we ignore the shading in Figure 2.1 that organizes tasks into threads, our multithreaded computation is just a dag of tasks. We define the *work* of the computation to be the total number of tasks and the *computation depth* to be the length of a longest directed path in the dag.

We quantify and bound the execution time of a computation on a P-processor

parallel computer in terms of the computation's work and depth. For a given computation, let $T(\mathcal{X})$ denote the time to execute the computation using P-processor execution schedule $\mathcal{X}$, and let

$$T_P = \min_{\mathcal{X}} T(\mathcal{X})$$

denote the minimum execution time with P processors—the minimum being taken over all P-processor execution schedules for the computation. Then T_1 is the work of the computation, since a 1-processor computer can only execute one task at each step, and T_∞ is the computation depth, since, even with arbitrarily many processors, each task on a path must execute serially.

Still viewing the computation as a dag, we borrow some basic results on dag scheduling to bound T_P. A computer with P processors can execute at most P tasks per step, and since the computation has T_1 tasks, we have $T_P \geq T_1/P$. Of course, we also have $T_P \geq T_\infty$. Early work by Graham [20, 21] and independently by Brent [11, Lemma 2] yields the bound $T_P \leq T_1/P + T_\infty$. The following theorem extends these results minimally to show that this upper bound on T_P can be obtained by *greedy schedules*, i.e., those in which at each step of the execution, if at least P tasks are ready, then P tasks execute, and if fewer than P tasks are ready, then all execute.

THEOREM 3.1 (the greedy-scheduling theorem). *For any multithreaded computation with work T_1 and computation depth T_∞, and for any number P of processors, every greedy P-processor execution schedule $\mathcal{X}$ achieves $T(\mathcal{X}) \leq T_1/P + T_\infty$.*

Proof. Let $G = (V, E)$ denote the underlying dag of the computation. Thus we have $|V| = T_1$, and a longest directed path in G has length T_∞. Consider a greedy P-processor execution schedule $\mathcal{X}$ where the set of tasks executed at time i, for $i = 1, 2, \ldots, k$, is denoted $\mathcal{V}_i$, with $k = T(\mathcal{X})$. The $\mathcal{V}_i$ form a partition of V.

We shall consider the progression $\langle G_0, G_1, G_2, \ldots, G_k \rangle$ of dags, where $G_0 = G$, and for $i = 1, 2, \ldots, k$, we have $V_i = V_{i-1} - \mathcal{V}_i$, and G_i is the subgraph of G_{i-1} induced by V_i. In other words, G_i is obtained from G_{i-1} by removing from G_{i-1} all the tasks that are executed by $\mathcal{X}$ at step i and all edges incident on these tasks. We shall show that each step of the execution either decreases the size of the dag or decreases the length of the longest path in the dag.

We account for each step i according to $|\mathcal{V}_i|$. Consider a step i with $|\mathcal{V}_i| = P$. In this case, $|V_i| = |V_{i-1}| - P$, so since $|V| = T_1$, there can be at most $\lfloor T_1/P \rfloor$ such steps. Now, consider a step i with $|\mathcal{V}_i| < P$. In this case, since $\mathcal{X}$ is greedy, $\mathcal{V}_i$ must contain every vertex of G_{i-1} with in-degree 0. Therefore, the length of a longest path in G_i is one less than the length of a longest path in G_{i-1}. Since the length of a longest path in G is T_∞, there can be no more than T_∞ steps i with $|\mathcal{V}_i| < P$.

Consequently, the time it takes schedule $\mathcal{X}$ to execute the computation is $T(\mathcal{X}) \leq \lfloor T_1/P \rfloor + T_\infty \leq T_1/P + T_\infty$. □

The greedy-scheduling theorem (Theorem 3.1) can be interpreted in two important ways. First, the time bound given by the theorem says that any greedy schedule yields an execution time that is within a factor of 2 of an optimal schedule, which follows because $T_1/P + T_\infty \leq 2\max\{T_1/P, T_\infty\}$ and $T_P \geq \max\{T_1/P, T_\infty\}$. Second, the greedy-scheduling theorem tells us when we can obtain *linear parallel speedup*, that is, when we can find an execution schedule $\mathcal{X}$ such that $T(\mathcal{X}) = \Theta(T_1/P)$. Specifically, when the number P of processors is no more than the *average available parallelism* T_1/T_∞, then $T_1/P \geq T_\infty$, which implies that for a greedy schedule $\mathcal{X}$, we have $T(\mathcal{X}) \leq 2T_1/P$. We shall be especially interested in the regime where $P = O(T_1/T_\infty)$

and linear speedup is possible, since outside this regime, linear speedup is impossible to achieve because $T_P \geq T_\infty$.

These results on dag scheduling have been known for years. A multithreaded computation, however, adds further structure to the dag: the partitioning of tasks into threads. This additional structure allows us to quantify the space used in executing a multithreaded computation. Once we have quantified space usage, we will look back at the greedy-scheduling theorem and consider whether there exist execution schedules that achieve similar time bounds while also making efficient use of space. Of course, we will have to quantify a space bound to capture what we mean by "efficient use of space."

We shall focus on a space parameter for a multithreaded computation which is based on the tree structure of threads. If we collapse each thread into a single node and consider just the spawn edges, the multithreaded computation is just a spawn tree of threads. We define the *activation depth* of a thread to be the sum of the sizes of the activation frames of all its ancestors, including itself. The *activation depth* of a multithreaded computation is the maximum activation depth of any thread.

We shall denote the space required by a P-processor execution schedule $\mathcal{X}$ of a multithreaded computation by $S(\mathcal{X})$. Recall that $S(\mathcal{X})$ is just the maximum, over all steps in $\mathcal{X}$, of the sum of the sizes of the activation frames of the living threads at that step. Since we can always simulate a P-processor execution with a 1-processor execution that uses no more space, we have $S_1 \leq S(\mathcal{X})$, where $S_1 = \min_{\mathcal{X}} S(\mathcal{X})$ denotes the minimum space used by a 1-processor execution.

The following simple theorem shows that the activation depth of a computation is a lower bound on the space required to execute it.

THEOREM 3.2. *Let $\mathcal{A}$ be the activation depth of a multithreaded computation, and let $\mathcal{X}$ be a P-processor execution schedule of the computation. Then we have $S(\mathcal{X}) \geq \mathcal{A}$, and more specifically, we have $S_1 \geq \mathcal{A}$.*

Proof. In any schedule, the leaf thread with greatest activation depth must be alive at some time step. Since we assume that if a thread is alive, its parent is alive, when the deepest leaf thread is alive, all its ancestors are alive, and hence, all its ancestors' frames are allocated. However, the sum of the sizes of its ancestors' activation frames is just the activation depth. Since $S(\mathcal{X}) \geq \mathcal{A}$ holds for all P-processor schedules $\mathcal{X}$ and all P, it holds for the minimum-space execution schedule, and hence, $S_1 \geq \mathcal{A}$. □

Given the lower bound of activation depth on the space used by a P-processor schedule, it is natural to ask whether the activation depth can be achieved as an upper bound. In general, the answer is no, since all the threads in a computation may contain a cycle of data dependencies that force all of them to be simultaneously living in any execution schedule. For the class of "depth-first" computations, however, space equal to the activation depth can be achieved by a 1-processor schedule.

A *depth-first* computation is a multithreaded computation in which a left-to-right depth-first search of tasks in the spawn tree always visits all the tasks on which a given task depends before it visits the given task. In the example computation of Figure 2.1, the left-to-right depth-first search order is $v_1, v_2, \ldots, v_{20}$, and this computation is depth-first. In fact, this depth-first search produces a 1-processor execution schedule which is just the familiar stack-based execution: the serial depth-first execution begins with the root thread and executes its tasks until it either spawns a child thread or dies. If the thread spawns a child, the parent thread is put aside to be resumed only after the child thread dies; the scheduler then begins work on the child, executing the

child until it either spawns a child or dies.

THEOREM 3.3. *For any depth-first computation, we have* $S_1 = \mathcal{A}$.

Proof. At any time in a serial depth-first execution of the computation, the set of living threads always forms a path from the root. Therefore, the space required is just the activation depth of the computation. By Theorem 3.2, $S_1 \geq \mathcal{A}$, and thus the the space used is the minimum possible. □

The remainder of this paper considers only depth-first computations, and we shall use S_1 to denote a computation's activation depth.

We now turn our attention to determining how much space $S(\mathcal{X})$ a P-processor execution schedule $\mathcal{X}$ can use and still be considered efficient with respect to space usage. Our strategy is to compare the space used by a P-processor schedule with the space required by an optimal 1-processor schedule. Of course, we can always ignore $P - 1$ of the processors to match the single-processor space bounds, and therefore, our goal is to use small space while obtaining linear speedup.

Even for depth-first computations, a P-processor schedule may use nearly P times the space of a 1-processor schedule. Consider, for example, a computation in which the root thread is a loop that spawns a child thread for each iteration. A single processor executing this computation uses only the space needed for a single iteration (plus the space used by the root), since upon completion of an iteration, all the memory can be freed and then reused for the next iteration. A natural P-processor execution, however, might execute P iterations concurrently, thereby requiring the memory of P iterations. Such a P-processor execution schedule $\mathcal{X}$ uses space $S(\mathcal{X}) = \Theta(S_1 P)$.

In fact, a P-processor schedule that uses only P times the space of a single processor is arguably efficient, since on average, each of the P processors only needs as much memory as is used by the 1 processor. We would, of course, like to do better, but an expansion in space that is linear in the number of processors, while achieving linear speedup, is quite good, since the time-space product is bounded by a value independent of P:

$$\begin{aligned} T(\mathcal{X})S(\mathcal{X}) &= O(T_1/P) \cdot O(S_1 P) \\ &= O(T_1 S_1) \ . \end{aligned}$$

We shall show in section 4 that achieving linear speedup and linear expansion of space simultaneously is impossible in general, even for depth-first computations. For the class of strict computations, however, section 5 shows that one can achieve both.

4. Lower bound. In this section we show that there exist multithreaded computations for which no execution schedule can achieve both linear speedup and linear expansion of space. In particular, for any amount of serial space S_1 and any (reasonably large) serial execution time T_1, we can exhibit a depth-first multithreaded computation with work T_1 and activation depth S_1 but with provably bad time/space tradeoff characteristics. Being depth-first, we know from Theorem 3.3 that our computation can be executed using serial space S_1. Furthermore, we know from the greedy-scheduling theorem (Theorem 3.1) that for any number P of processors, any greedy P-processor execution schedule $\mathcal{X}$ achieves $T(\mathcal{X}) \leq T_1/P + T_\infty$. Our computation has computation depth $T_\infty \approx \sqrt{T_1}$, and consequently, for $P = O(\sqrt{T_1})$, a greedy P-processor schedule $\mathcal{X}$ yields $T(\mathcal{X}) = O(T_1/P)$, i.e., linear speedup. We show, however, that any P-processor schedule $\mathcal{X}$ achieving $T(\mathcal{X}) = O(T_1/P)$ must use space $S(\mathcal{X}) = \Omega(\sqrt{T_1}(P-1))$. Of course, $\sqrt{T_1}$ may be much larger than S_1, and hence, this space bound is nowhere near linear in its space expansion.

THEOREM 4.1. *For any amount of serial space $S_1 \geq 4$ and serial time $T_1 \geq 16S_1^2$, there exists a depth-first multithreaded computation with work T_1, computation depth $T_\infty \leq 8\sqrt{T_1}$, and activation depth S_1 with the following property: for any number P of processors and any value ρ in the range $1 \leq \rho \leq (1/8)T_1/T_\infty$, if $\mathcal{X}$ is a P-processor execution schedule that achieves speedup ρ—that is, $T(\mathcal{X}) \leq T_1/\rho$— then the schedule requires space $S(\mathcal{X}) \geq (1/4)(\rho - 1)\sqrt{T_1} + S_1$.*

Proof. To exhibit a depth-first multithreaded computation with work T_1, computation depth T_∞, and activation depth S_1, we first ignore the partitioning of tasks into threads and consider just the dag structure of the computation. Minus a few tasks and dependencies, the dag appears as in Figure 4.1(a). The tasks are organized into

$$m = \sqrt{T_1}/8$$

separate components $\mathcal{C}_0, \mathcal{C}_1, \ldots, \mathcal{C}_{m-1}$ that we call *chains*.[1] Each chain begins with

$$\lambda = \sqrt{T_1}/S_1$$

tasks that we call *headers* (vertical hashed in Figure 4.1(a)). After the headers, each chain contains

$$\nu = 6\sqrt{T_1}$$

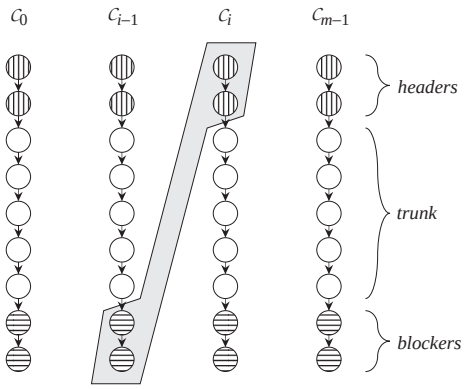
tasks (plain white in Figure 4.1(a)) that form the *trunk*. At the end of each chain, there are λ *blockers* (horizontal hashed in Figure 4.1(a)). Each chain, therefore, consists of $2\lambda + \nu = 2(\sqrt{T_1}/S_1) + 6\sqrt{T_1}$ tasks. Since there are $m = \sqrt{T_1}/8$ chains, the total number of tasks accounted for by the m chains is $(2\sqrt{T_1}/S_1 + 6\sqrt{T_1})\sqrt{T_1}/8 = (3/4)T_1 + (1/4)T_1/S_1$, and this number is no more than $(13/16)T_1$ since $S_1 \geq 4$. The remaining (at least) $(3/16)T_1$ tasks form the parts of the computation not shown in Figure 4.1(a).

There are no dependencies between different chains, so the average available parallelism T_1/T_∞ is at least $m = \sqrt{T_1}/8$ and the computation depth T_∞ is no more than $8\sqrt{T_1}$ as promised.

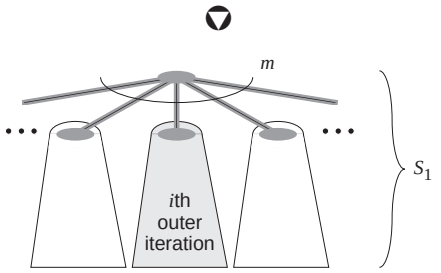
Now, consider the partitioning of the tasks from each chain into the actual threads. As alluded to in Figure 4.1(b), the root thread has m child threads, each of which is the root of a subcomputation that we call an *outer iteration*. (The outer iterations contain *inner iterations* that will be discussed later.) Each of these outer iterations contains $\sqrt{T_1}/2$ threads. As illustrated by the shading in Figure 4.1, the ith outer iteration for $i = 1, 2, \ldots, m-1$ contains both the header tasks of chain $\mathcal{C}_i$ and the blocker tasks of chain $\mathcal{C}_{i-1}$. These tasks are organized into the threads of the outer iteration so as to ensure that chain $\mathcal{C}_i$ cannot begin executing its trunk tasks until all $\sqrt{T_1}/2$ of the outer iteration's threads have been spawned, and none of these threads can die until chain $\mathcal{C}_{i-1}$ begins executing its blocker tasks. (We will exhibit this organization later.) Thus, if chain $\mathcal{C}_i$ begins executing its trunk tasks before chain $\mathcal{C}_{i-1}$ finishes its, then the execution will require at least $\sqrt{T_1}/2$ space.

For any number P of processors, consider any valid P-processor execution schedule $\mathcal{X}$. For each chain $\mathcal{C}_i$, let $t_i^{(s)}$ denote the time step at which $\mathcal{X}$ executes the first

[1] In what follows, we refer to a number x of objects (such as tasks) when x may not be integral. Rounding these quantities to integers does not affect the correctness of the proof. For ease of exposition, we shall not consider the issue.



(A) *Chains of tasks.*



(B) *Outer iterations.*

FIG. 4.1. *Constructing a computation with no efficient execution schedule. The header tasks of chain $\mathcal{C}_i$ and the blocker tasks of chain $\mathcal{C}_{i-1}$ are both placed in the threads of the ith outer iteration.*

trunk task of $\mathcal{C}_i$, and let $t_i^{(\mathrm{f})}$ denote the first time step at which $\mathcal{X}$ executes a blocker task of $\mathcal{C}_i$. Since the trunk has length ν and no blocker task of $\mathcal{C}_i$ can execute until after the last trunk task of $\mathcal{C}_i$, we have $t_i^{(\mathrm{f})} - t_i^{(\mathrm{s})} \geq \nu$.

Now consider two chains, $\mathcal{C}_i$ and $\mathcal{C}_{i-1}$, and suppose $t_i^{(\mathrm{s})} < t_{i-1}^{(\mathrm{f})}$; this is the scenario we described as using at least $\sqrt{T_1}/2$ space. In this case, we consider the time interval from $t_i^{(\mathrm{s})}$ (inclusive) to $t_{i-1}^{(\mathrm{f})}$ (exclusive) during which we say that chain $\mathcal{C}_i$ is *exposed*, and we let $\tau_i = t_{i-1}^{(\mathrm{f})} - t_i^{(\mathrm{s})}$ denote the amount of time chain $\mathcal{C}_i$ is exposed. See Figure 4.2. If $t_i^{(\mathrm{s})} \geq t_{i-1}^{(\mathrm{f})}$ then chain $\mathcal{C}_i$ is never exposed and we let $\tau_i = 0$. As we have seen, over the time interval during which a chain is exposed, it uses at least $\sqrt{T_1}/2$ space. We will show that in order to achieve speedup ρ—that is $T(\mathcal{X}) \leq T_1/\rho$—there must be some time step during the execution at which at least $\lceil (3/4)\rho \rceil - 1$ chains are exposed.

If schedule $\mathcal{X}$ is such that $T(\mathcal{X}) \leq T_1/\rho$, then we must have $t_{m-1}^{(\mathrm{f})} - t_0^{(\mathrm{s})} \leq T_1/\rho$. We can expand this inequality to yield

$$\begin{aligned} T_1/\rho &\geq t_{m-1}^{(\mathrm{f})} - t_0^{(\mathrm{s})} \\ &= \sum_{i=0}^{m-1} \left(t_i^{(\mathrm{f})} - t_i^{(\mathrm{s})} \right) - \sum_{i=1}^{m-1} \left(t_{i-1}^{(\mathrm{f})} - t_i^{(\mathrm{s})} \right) . \end{aligned} \tag{4.1}$$

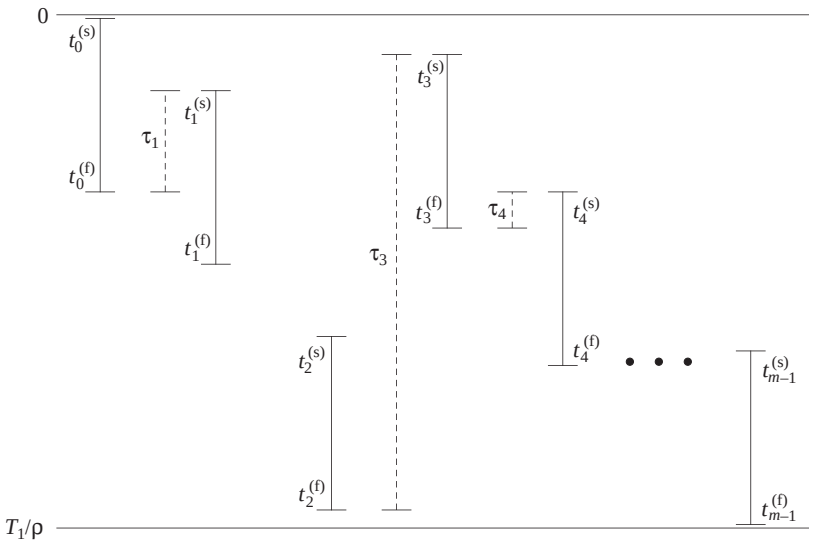


FIG. 4.2. *Scheduling the execution of the chains. A solid vertical interval from* $t_i^{(s)}$ *to* $t_i^{(f)}$ *indicates the time during which the trunk of chain* $\mathcal{C}_i$ *is being executed. When* $t_i^{(s)} < t_{i-1}^{(f)}$*, we can define an interval, shown dashed, of length* $\tau_i = t_{i-1}^{(f)} - t_i^{(s)}$*, during which chain* $\mathcal{C}_i$ *is exposed.*

Considering the first sum, we recall that $t_i^{(f)} - t_i^{(s)} \geq \nu$, hence,

$$\sum_{i=0}^{m-1} \left(t_i^{(f)} - t_i^{(s)} \right) \geq m\nu \ . \tag{4.2}$$

Considering the second sum of inequality (4.1), when $t_{i-1}^{(f)} t_i^{(s)}$ (so $\mathcal{C}_i$ is exposed), we have $\tau_i = t_{i-1}^{(f)} - t_i^{(s)}$, and otherwise, $\tau_i = 0 \geq t_{i-1}^{(f)} - t_i^{(s)}$. Therefore,

$$\sum_{i=1}^{m-1} \left(t_{i-1}^{(f)} - t_i^{(s)} \right) \leq \sum_{i=1}^{m-1} \tau_i \ . \tag{4.3}$$

Substituting inequalities (4.2) and (4.3) back into inequality (4.1), we obtain

$$\sum_{i=1}^{m-1} \tau_i \geq m\nu - T_1/\rho \ .$$

Let *exposed*(t) denote the number of chains exposed at time step t, and observe that

$$\sum_{t=1}^{T_1/\rho} \mathit{exposed}(t) = \sum_{i=i}^{m-1} \tau_i \ .$$

Then the average number of exposed chains per time step is

$$\frac{1}{T_1/\rho} \sum_{t=1}^{T_1/\rho} \mathit{exposed}(t) = \frac{1}{T_1/\rho} \sum_{i=1}^{m-1} \tau_i$$

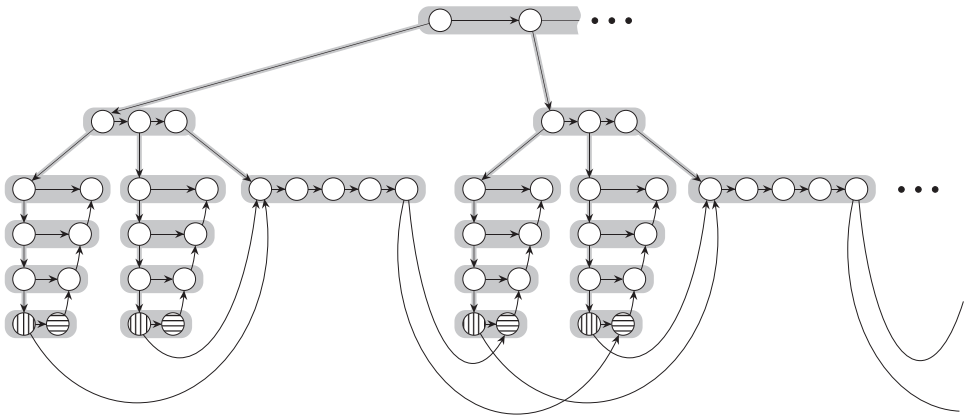

FIG. 4.3. *Laying out the chains into the threads of a multithreaded computation. As before, the header tasks are vertical hashed, and the blocker tasks are horizontal hashed. In this example, each activation frame has unit size so* $S_1 = 6$. *Also, in this example* $\lambda = 2$, $\nu = 5$, *and only the first* 2 *out of the* m *tasks in the root thread are shown. Each task of the root thread spawns a child (an outer iteration), and each child thread contains* $\lambda + 1 = 3$ *tasks; the first* λ *of these spawn a child thread which is the root of an inner iteration with activation depth* $S_1 - 2 = 4$, *and the last one spawns a leaf thread with the* $\nu = 5$ *trunk tasks of a single chain.*

$$\begin{aligned} &\geq \frac{1}{T_1/\rho}\left(m\nu - T_1/\rho\right) \\ &= \frac{3}{4}\rho - 1, \end{aligned}$$

since $m = \sqrt{T_1}/8$ and $\nu = 6\sqrt{T_1}$. There must be some time step t^* for which $\mathit{exposed}(t^*)$ is at least the average, and consequently,

$$\mathit{exposed}(t^*) \geq \left\lceil \frac{3}{4}\rho \right\rceil - 1 \ .$$

Now, recalling that each exposed chain uses space $\sqrt{T_1}/2$, we have

$$\begin{aligned} S(\mathcal{X}) &\geq \left(\left\lceil \frac{3}{4}\rho \right\rceil - 1\right)\frac{1}{2}\sqrt{T_1} \\ &\geq \frac{1}{4}(\rho - 1)\sqrt{T_1} + S_1 \end{aligned}$$

for $S_1 \leq \sqrt{T_1}/4$ (which is true since we have $T_1 \geq 16S_1^2$).

All that remains is exhibiting the organization of the tasks of each chain into a depth-first multithreaded computation with work T_1, computation depth $T_\infty \leq 8\sqrt{T_1}$, and activation depth S_1 in such a way that each exposed chain uses $\sqrt{T_1}/2$ space. There are actually many ways of creating such a computation. One such way, which uses unit-size activation frames for each thread, is shown in Figure 4.3.

For the multithreaded computation of Figure 4.3, the root thread contains m tasks, each of which spawns a child thread (an outer iteration). Each child thread contains $\lambda + 1$ tasks; the first λ of these spawn a child thread which is the root of a subcomputation that we call an *inner iteration*. Each inner iteration has activation depth $S_1 - 2 \geq S_1/2$ (since $S_1 \geq 4$), and the last one spawns a leaf thread with the ν

trunk tasks of a single chain. Each of these inner iterations contains a single header from one chain and a single blocker from the previous chain (except in the case of the first group of λ) as shown in Figure 4.3. The header and blocker in an inner iteration are organized such that in order to execute the header, all $S_1 - 2$ of the threads in the inner iteration must be spawned, and none of them can die until the blocker executes. Thus, when a chain is exposed, all λ of these inner iterations have all of their threads living, thereby using space $\lambda(S_1 - 2) \geq (\sqrt{T_1}/S_1)(S_1/2) = \sqrt{T_1}/2$.

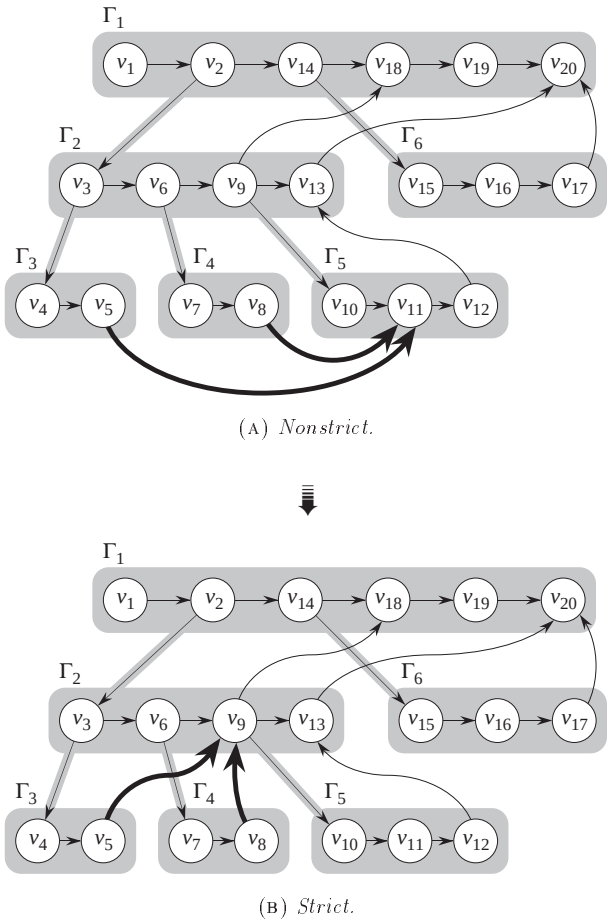
We can verify from Figure 4.3 and from the given values of m, λ, and ν that this construction actually has work slightly less than T_1; in order to make the work equal to T_1 we can just add the extra tasks evenly among the threads that contain the trunk of each chain (thereby increasing ν by a bit). Also, we can verify that $T_\infty \leq 8\sqrt{T_1}$. Finally, looking at Figure 4.3 we can see that this computation is indeed depth-first. □

The construction of a multithreaded computation with provably bad time/space characteristics as just described can be modified in various ways to accommodate various restrictions to the model while still obtaining the same result. For example, some real multithreaded systems require limits on the number of tasks in a thread, data dependencies that only go to the first task of a thread, limited fan-in for data dependencies, or a limit on the number of children a thread can have. Simple changes to the construction just described can produce multithreaded computations that accommodate any or all of these restrictions and still have the same provably bad time/space tradeoff. Thus, the lower bound of Theorem 4.1 holds even for multithreaded computations with any or all of these restrictions.

5. Scheduling algorithms for strict multithreaded computations. In the view of negative results from section 4, we consider scheduling algorithms for a specific class of depth-first multithreaded computations called "strict" computations. In this section, we show that for any strict multithreaded computation and any number P of processors, there exists a P-processor execution schedule $\mathcal{X}$ that achieves time $T(\mathcal{X}) \leq T_1/P + T_\infty$. We give two algorithms to compute such a schedule. We conclude this section by showing how some nonstrictness can be allowed in an otherwise strict computation in a way that may improve performance, but which does not adversely affect our asymptotic time and space bounds.

Given a multithreaded computation, a scheduling algorithm for a P-processor parallel computer must compute a P-processor execution schedule. In computing such a schedule, the algorithm does not know the entire computation; the computation actually unfolds dynamically during the course of execution, and consequently, the scheduling algorithm must be online. At any given time during the execution, the scheduler has a set of living threads, some of which are ready and some of which are stalled. There might be some extra information attached to each thread that the scheduling algorithm can use in deciding which ready threads get executed by which processors, but the scheduler cannot know about the structure of the portion of the computation not yet executed.

To cope with the lower bound from Theorem 4.1, we now restrict our attention to those multithreaded computations in which every data dependency goes from a thread to one of its ancestors in the spawn tree. It turns out that requiring all data dependencies to go from a thread to one of its ancestors can be viewed as requiring that all function invocations (in a functional language) be strict, and therefore, we refer to this class of computations as *strict* multithreaded computations. For example, the computation shown in Figure 5.1(a) is not strict since the bold data dependencies



(A) *Nonstrict.*

(B) *Strict.*

FIG. 5.1. (A) *This multithreaded computation (the same as Figure* 2.1*) is nonstrict since it has nonstrict data dependencies (shown bold) that go to nonancestor threads.* (B) *If we replace the nonstrict data dependencies with new strict ones (shown bold) we obtain a strict computation since all data dependencies go from a child thread to an ancestor thread.*

violate the strictness condition just stated, but by promoting these dependencies we obtain the strict computation shown in Figure 5.1(b).

Strict multithreaded computations are depth-first computations, since no data dependency can go between two distinct subcomputations of a thread. Once a thread Γ has been spawned in a strict computation, a single processor can complete the execution of Γ and all of its descendant threads by using a depth-first schedule, even if no other progress is made on other parts of the computation. In other words, from the time the thread Γ is spawned until the time Γ dies, there is always at least one thread from the subtree rooted at Γ that is ready. This property allows us to derive algorithms to schedule the execution of these computations with efficient use of both time and space.

Algorithm GDF (which stands for *global depth-first*) maintains all living threads in a global queue prioritized by activation depth, i.e., the deepest threads get highest priority. At each step of the algorithm, the scheduler removes from the queue the P deepest ready threads (if there are fewer than P ready threads, it just removes them

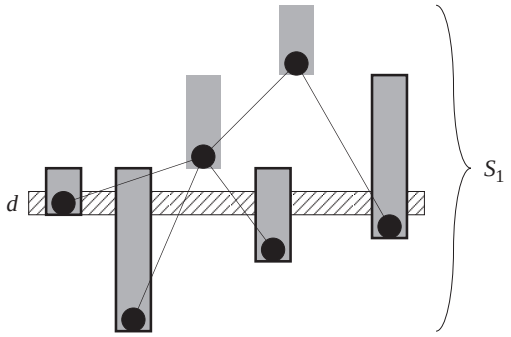


FIG. 5.2. *The spawn tree corresponding to the example computation of Figure* 2.1. *The bold outlined threads span depth d.*

all) and assigns them arbitrarily to the P processors so that each processor receives at most one thread. Each processor that has an assigned thread then executes one task from that thread. To complete the step, all surviving threads and all newly spawned threads are placed back into the global queue.

THEOREM 5.1. *For any number P of processors and any strict multithreaded computation with work T_1, computation depth T_∞, and activation depth S_1, Algorithm* GDF *computes a P-processor schedule $\mathcal{X}$ that uses space $S(\mathcal{X}) \le S_1 P$ and time $T(\mathcal{X}) \le T_1/P + T_\infty$.*

Proof. The time bound follows immediately from the greedy-scheduling theorem (Theorem 3.1), since GDF always produces a greedy schedule.

To prove the space bound, we show that the queue never contains more than P threads (ready or otherwise) that span any activation depth. A thread Γ *spans* an activation depth d, if Γ has activation depth $\mathcal{A}(\Gamma) \ge d$, and either Γ is the root or the parent thread Γ' of Γ has activation depth $\mathcal{A}(\Gamma') < d$. For example, Figure 5.2 depicts the spawn tree corresponding to the computation of Figure 2.1. Each thread has height equal to the size of its activation frame and is located so that the top of its activation frame is aligned with the bottom of its parent's activation frame. In this way, each black node is located at its thread's activation depth, and the bold outlined threads span depth d. For any time step t during the execution and any activation depth d, let $s(t, d)$ denote the number of living threads that span d at the start of step t. Then the total space $s(t)$ being used at the start of time step t is

$$s(t) = \sum_{d=1}^{S_1} s(t, d) \ . \tag{5.1}$$

By induction on the number of steps, we shall show that for all t, every activation depth d has $s(t, d) \le P$. With this bound, equation (5.1) shows that $s(t) \le S_1 P$ for all time t, from which the space bound follows.

The algorithm begins with just one living thread (the root), so for every activation depth d, we have $s(1, d) \le 1 \le P$. Now, consider any activation depth d, and suppose that for time step t, the induction hypothesis $s(t, d) \le P$ holds. The computation being strict means that for each of the $s(t, d)$ living threads that span d at the start of step t, there is at least one ready thread with activation depth greater than or equal to d; remember, this is the crucial property that we get by having all data dependencies go from a child thread to an ancestor thread. Therefore, step t begins

with at least $s(t,d)$ ready threads at or deeper than d. The depth-first ordering then ensures that no more than $P - s(t,d)$ threads with depth less than d can execute at step t. Then, since the only way to increase the number of threads that span d is to execute a thread shallower than d that spawns a child thread at or deeper than d, step t ends with at most $s(t,d) + (P - s(t,d)) = P$ living threads that span activation depth d. Therefore, $s(t+1,d) \leq P$, and the induction is complete. □

Algorithm GDF′ is a refinement of Algorithm GDF that achieves greater efficiency by reducing the number of accesses to the global queue. Algorithm GDF′ begins with the root thread assigned to some arbitrary processor and the global queue empty. On subsequent steps, GDF′ has completed a "previous" step and must schedule threads for a "current" step. Suppose the previous step ends with P' out of the P processors not having a thread. To start the current step, the scheduler removes from the queue the P' deepest ready threads, or, if there are fewer than P' ready threads, it removes them all. It assigns these threads arbitrarily to the P' idle processors so that each idle processor receives at most one thread. The current step is now ready to proceed. Each of the P processors that has an assigned thread executes one task from that thread. Unless that thread spawns, dies, or stalls, the processor will have a thread at the end of the current step. If the thread stalls, then the processor must return it to the global queue, and consequently, the processor will not have a thread at the end of the current step. Similarly, if the thread dies, then the processor will not have a thread at the end of the step. Lastly, if the thread spawns a child, then the processor returns the parent thread (the one it was working on) to the global queue and keeps the child thread; in this case, the processor will still have a thread at the end of the current step.

Algorithm GDF′ achieves the same performance bounds as proved in Theorem 5.1, but it requires access to the global queue only when threads spawn, die, or stall.

THEOREM 5.2. *For any number P of processors and any strict multithreaded computation with work T_1, computation depth T_∞, and activation depth S_1, Algorithm* GDF′ *computes a P-processor schedule $\mathcal{X}$ that uses space $S(\mathcal{X}) \leq S_1 P$ and time $T(\mathcal{X}) \leq T_1/P + T_\infty$.*

Proof. This proof follows the proof of Theorem 5.1, but we add the following assertion to the induction hypothesis: for any activation depth d, if a step t begins with $s(t,d) \leq P$ living threads that span depth d, then step t begins with no more than $P - s(t,d)$ processors that have a thread with activation depth less than d. □

This algorithm may be feasible for a modest number of processors, but for a large number of processors, the cost of synchronization at the global queue becomes prohibitive. To derive a truly scalable and distributed algorithm, we need to split the global queue into P local queues, one for each processor. The next section presents and analyzes such a distributed algorithm.

We have been able to relate resource requirements to nonstrictness in the computation by characterizing two extremes. At one end, we have shown that arbitrary uses of nonstrictness make efficient execution impossible. At the other end, purely strict computations allow near optimally efficient executions. We now mention two minor results that begin to characterize resource requirements for limited uses of nonstrictness.

Given an arbitrary depth-first computation, any of the scheduling algorithms for strict computations can be employed by first adding data-dependency edges to make the computation strict. This transformation, known as *strictifying* (see Figure 5.1),

is always valid for depth-first computations. Of course, strictifying may dramatically reduce the average available parallelism, and therefore, we would like some way of exploiting the parallelism available through nonstrict spawns. Suppose we could execute the computation as if it were strictified, but at each step, if there is an idle processor and a thread that is stalled (due only to the strictness condition) at a task that wants to spawn, we let the processor go ahead and execute that task, thereby performing a nonstrict spawn. Unfortunately, the naive application of this rule can actually result in an execution that takes longer than the purely strict execution.

With due care, however, we can modify this rule to allow some nonstrict spawns while still guaranteeing the time and space bounds of a purely strict execution. For example, we can restrict the application of this rule to a set of threads designated by the programmer. If the programmer can designate this set of threads so as to ensure that, during execution, at most x nonstrictly spawned threads simultaneously span a given depth, then Algorithm GDF can achieve space bounded by $S_1(P + x)$ and linear speedup as in Theorem 5.1; similar results apply for Algorithm GDF$'$ and for the distributed algorithm that will be presented in the next section. Alternatively, by "sequestering" the nonstrictly spawned threads, the scheduler itself can budget the nonstrict spawns and achieve these same time and space bounds; details can be found in [4].

6. Distributed scheduling algorithms. In a distributed thread-scheduling algorithm, each processor works depth-first out of its own local priority queue. Specifically, to get a thread to work on, a processor removes the deepest ready thread from its local queue. Ideally, we would like the processor to then continue working on that thread until it either stalls, dies, or spawns, and when the processor does need to enqueue a thread (as in the case when the thread stalls or spawns) or dequeue a new thread, it does so by accessing only its local queue. Of course, this approach could result in processors with empty queues sitting idle while other processors have large queues. Thus, we require each processor to have some access to nonlocal queues in order to facilitate some type of load balancing.

The technique of Karp and Zhang [28] suggests a randomized algorithm in which threads are located in random queues in order to achieve some balance. We can show, however, that the naive adoption of this technique does not work. In particular, threads must migrate occasionally and some degree of synchronization is needed to avoid the large deviations that result if this random process is run over a long period of time. Further discourse on these problems can be found in [4]. In order to achieve the desired result, we modify the Karp and Zhang technique by incorporating a new mechanism to enforce a modest degree of synchrony among the processors.

Algorithm LDF (which stands for *local depth-first*) operates in iterations, with each iteration consisting of a synchronization phase followed by a computation phase and ending with a communication phase. In a synchronization phase, we compute a *cutoff depth* D which is a global value made available to all processors. During the following computation phase, only those threads with activation depth greater than or equal to D can execute. Finally, the communication phase redistributes threads to random locations.

The operation of each phase is governed by a *synchronization parameter* r that affects both the time and space performance of the algorithm. Let LDF(r) denote Algorithm LDF with synchronization parameter r.

In a synchronization phase of LDF(r), we use the synchronization parameter r to compute the cutoff depth D. Each processor p_i, for $i = 1, \ldots, P$, computes the

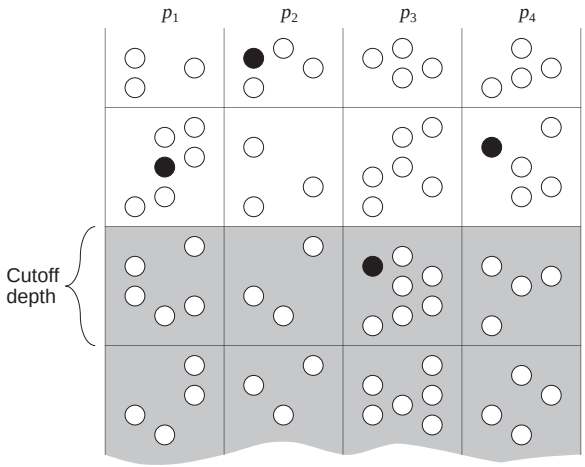

FIG. 6.1. *Computing the cutoff depth. Each column represents the local priority queue of a processor, and each row represents an activation depth with depth increasing in the downward direction. We depict each ready thread by a circle located in its processor's queue and at its activation depth. (Within a processor's queue, the horizontal ordering of threads is irrelevant.) The ready threads in each queue are ordered by activation depth with ties broken arbitrarily—this tie breaking is depicted by the vertical ordering of threads within an activation depth. In this example, the synchronization parameter* $r = 12$*, and the* 12*th deepest ready thread for each processor is shown in black (just count up from the bottom). The deepest of these black threads determines the cutoff depth. Only the ready threads at or deeper than the cutoff depth—those in the shaded region—can execute during the following computation phase.*

activation depth d_i of its rth deepest ready thread. In other words, d_i is the activation depth for which processor p_i has fewer than r ready threads deeper than d_i but at least r ready threads at or deeper than d_i. Cutoff depth D is then computed simply by

$$D = \max_{1 \le i \le P} d_i$$

as illustrated in Figure 6.1.

During the computation phase of LDF(r), each processor executes at least one task from each ready thread with activation depth greater than or equal to the cutoff depth D in its local queue. We further forbid each processor from executing more than r spawns; if a processor has more than r threads at or deeper than D that want to spawn, it may only execute r of them.

The iteration ends with a communication phase during which each processor must move each ready thread with activation depth greater than or equal to D (as determined at the beginning of the iteration) and each newly spawned thread from its local queue to a queue selected uniformly at random, independently for each thread.

By using the synchronization parameter r to compute the cutoff depth and then ensuring that each processor executes only tasks from threads at or deeper than the cutoff depth, while allowing at most r spawns, we get a guaranteed space bound.

LEMMA 6.1. *For any number* P *of processors and any strict multithreaded computation with activation depth* S_1*, Algorithm* LDF(r) *computes a* P*-processor schedule* $\mathcal{X}$ *such that* $S(\mathcal{X}) \le 2rS_1P$.

Proof. We show by induction on the number of iterations that no activation depth ever has more than $2rP$ living threads that span it. Specifically, recalling the

notation used in the proof of Theorem 5.1, we show that for every activation depth d and every iteration t of the execution, $s(t,d) \leq 2rP$. The result then follows from equation (5.1). As before, the base case is straightforward.

For any activation depth d and any iteration t of the execution, we consider two cases. In the first case, suppose iteration t begins with $rP \leq s(t,d) \leq 2rP$ living threads spanning depth d. Due to the strictness of the computation, there must be at least rP ready threads with activation depth greater than or equal to d, and by pigeonholing, some processor's local queue must have at least r of them. Therefore, the cutoff depth D will be set with $D \geq d$. Consequently, during the computation phase of iteration t, no thread with activation depth less than d can execute and the iteration ends with no more living threads spanning depth d than it started with. Now, suppose iteration t begins with $s(t,d) < rP$ living threads spanning depth d. In this case, during the computation phase, since each processor is only allowed r spawns, the number of living threads that span depth d can increase by at most rP, and therefore, the iteration ends with no more than $2rP$ living threads spanning depth d. In either case, $s(t+1,d) \leq 2rP$, which completes the induction. □

In order to achieve speedup in the execution time, we must ensure that during the computation phase of each iteration, each processor has some ready threads at or deeper than the cutoff depth. To ensure that the cutoff depth is not set too deep, we must use a large enough synchronization parameter r. On the other hand, the space bound of Lemma 6.1 is directly proportional to r. By setting $r = 6 \lg P$, the space bound of Lemma 6.1 becomes $S(\mathcal{X}) \leq 12 S_1 P \lg P$, and with high probability, most computation phases take $O(\lg P)$ time and get at least $P \lg P$ tasks executed as we now show.

To analyze the running time, we say that each iteration either *succeeds* or *fails* depending on how many tasks execute. An iteration that begins with at least $P \lg P$ ready threads fails if fewer than $P \lg P$ of the ready threads get a task executed. An iteration that begins with fewer than $P \lg P$ ready threads fails if not all of them get a task executed.

We now show that with the synchronization parameter set to $r = 6 \lg P$, it is highly likely that each iteration succeeds.

LEMMA 6.2. *For any number P of processors and any iteration of Algorithm* LDF$(6 \lg P)$*, the iteration fails with probability no more than P^{-5}.*

Proof. Suppose that when two threads have the same activation depth, we give each thread a unique identifier to break the tie so we can uniquely identify the $P \lg P$ deepest ready threads. If no local queue contains more than $6 \lg P$ of the $P \lg P$ deepest ready threads, then the synchronization phase sets the cutoff depth so that all $P \lg P$ of these deepest threads are at or are deeper than the cutoff depth. Therefore, an iteration succeeds if no local queue contains more than $6 \lg P$ of the $P \lg P$ deepest ready threads.

Consider a particular processor p_i, and let the random variable Z_i denote how many of the $P \lg P$ deepest ready threads start the iteration in the local queue of processor p_i. Each thread is located independently at random, and hence, the random variable Z_i has a binomial distribution with $P \lg P$ trials and success probability $1/P$. Therefore,

$$\Pr\{Z_i > 6 \lg P\} \leq \binom{P \lg P}{6 \lg P} \left(\frac{1}{P}\right)^{6 \lg P} .$$

Then, from the bound

$$\binom{x}{y} \leq \left(\frac{ex}{y}\right)^y \tag{6.1}$$

and the fact that $6 \geq 2e$, we can upper bound $\Pr\{Z_i > 6 \lg P\}$ by

$$\begin{aligned}\Pr\{Z_i > 6 \lg P\} &\leq \left(\frac{eP \lg P}{6 \lg P}\right)\left(\frac{1}{P}\right)^{6 \lg P} \\ &= \left(\frac{e}{6}\right)^{6 \lg P} \\ &\leq P^{-6}.\end{aligned}$$

Now, let $Z = \max_{1 \leq i \leq P} Z_i$. For an iteration that begins with at least $P \lg P$ ready threads, the probability of failure is no more than $\Pr\{Z > 6 \lg P\}$. We can use Boole's inequality to upper bound $\Pr\{Z > 6 \lg P\}$ by adding the individual probabilities, yielding

$$\begin{aligned}\Pr\{Z > 6 \lg P\} &\leq P \cdot \Pr\{Z_i > 6 \lg P\} \\ &\leq P^{-5} \ . \qquad \square\end{aligned}$$

We now show that iterations fail independently of each other. Specifically, we show that knowing whether an iteration t fails provides no information about whether any future iteration fails. The failure of an iteration depends only on how the ready threads are distributed among the processors. Therefore, we need to show that knowing whether iteration t fails provides no information about the distribution of threads at the end of the iteration. Suppose iteration t has cutoff depth D. No matter if iteration t fails or not, the iteration ends with a communication phase in which every ready thread at or deeper than D gets moved to a random location. Thus, iteration t provides no information about the distribution of threads at or deeper than the cutoff depth. Now, consider the threads less deep than D. The only part of an iteration that even considers the threads shallower than the cutoff depth is the synchronization phase. Therefore, we need to show that computing the cutoff depth provides no information about the distribution of threads with activation depth less than D. Consider an alternative method for computing the cutoff depth. Let all the processors work in synchrony from the bottom up. First each processor counts the number of ready threads it has with activation depth S_1. Then each processor adds on the number of ready threads it has with activation depth $S_1 - 1$. We continue in this manner until some processor reaches a count of r (the synchronization parameter). At this depth we stop and set the cutoff depth. In this way the synchronization phase can compute the cutoff depth with the exact same result but without ever considering threads shallower than D. Thus, computing the cutoff depth provides no information about the distribution of threads shallower than the cutoff depth.

With iterations failing independently of each other, we can bound the number of failed iterations, thereby bounding the total number of iterations taken.

LEMMA 6.3. *For any number P of processors and any strict multithreaded computation with work T_1 and computation depth T_∞, for any $\epsilon > 0$, with probability at least $1 - \epsilon$, Algorithm* LDF$(6 \lg P)$ *computes a P-processor schedule $\mathcal{X}$ that takes $O(T_1/(P \lg P) + T_\infty + \log_P(1/\epsilon))$ iterations.*

Proof. First we consider the failed iterations. Let the random variable f denote the number of failed iterations. We will show that for any $\epsilon > 0$, the probability that

$f \geq eT_1/(P \lg P) + b$ is no more than ϵ when $b = (1/3)\log_P(1/\epsilon)$. There are at most T_1 iterations, since each iteration always results in at least one task being executed, and each iteration fails independently with probability P^{-5}. Therefore, f is bounded by a binomial distribution with T_1 trials and success probability P^{-5}, from which we obtain

$$\Pr\left\{f \geq e\frac{T_1}{P\lg P} + b\right\} \leq \binom{T_1}{e\frac{T_1}{P\lg P} + b}\left(\frac{1}{P^5}\right)^{e\frac{T_1}{P\lg P}+b}.$$

Then, using inequality (6.1), we get

$$\begin{aligned}\Pr\left\{f \geq e\frac{T_1}{P\lg P} + b\right\} &\leq \left(\frac{eT_1}{e\frac{T_1}{P\lg P} + b}\cdot\frac{1}{P^5}\right)^{e\frac{T_1}{P\lg P}+b} \\ &\leq \left(\frac{P\lg P}{P^5}\right)^{e\frac{T_1}{P\lg P}+b} \\ &\leq \left(\frac{1}{P^3}\right)^{b} \\ &= P^{-3b},\end{aligned}$$

and $P^{-3b} = \epsilon$ for $b = (1/3)\log_P(1/\epsilon)$. Thus, with probability at least $1 - \epsilon$, we have $f = O(T_1/(P \lg P) + \log_P(1/\epsilon))$.

Now consider the successful iterations. We can think of each successful iteration as a step in a greedy schedule with $P \lg P$ processors. Then, as in the proof of the greedy-scheduling theorem (Theorem 3.1), we know that there can be no more than $T_1/(P \lg P) + T_\infty$ successful iterations.

Adding together the number of successful iterations and the number of failed iterations completes the proof. □

Now, if we let the random variable X_i denote the time taken by the ith computation phase of Algorithm LDF$(6 \lg P)$, we can give the total time in computation phases as the random variable $X = X_1 + X_2 + \cdots + X_Y$, where Y is the random variable denoting the number of iterations. The time taken by the ith computation phase is proportional to the maximum number of ready threads with activation depth greater than or equal to the cutoff depth in any processor. There can be a total of at most $18P \lg P$ ready threads at or deeper than the cutoff depth—$r = 6P \lg P$ deeper than the cutoff depth and $12P \lg P$ at the cutoff depth (from Lemma 6.1 with synchronization parameter $r = 6 \lg P$)—and each of these threads is located independently at random. Thus, we can bound each X_i as the size of the largest bin when throwing $18P \lg P$ balls at random into P bins. Furthermore, by the independence argument the X_i's are independent. We can now bound the random variable X.

LEMMA 6.4. *Let the random variable X denote the sum of Y mutually independent random variables, $X = X_1 + X_2 + \cdots + X_Y$ with each X_i, for $i = 1, \ldots, Y$, distributed as the number of balls in the fullest bin when throwing $P \ln P$ balls independently at random into $P \geq 2$ bins. Then, for any $\epsilon > 0$, we have $X = O(Y \ln P + \lg(1/\epsilon))$ with probability at least $1 - \epsilon$.*

Proof. We have

$$\begin{aligned}\Pr\{X \geq aY \ln P + b\} &= \Pr\left\{e^{X/e} \geq e^{(aY \ln P + b)/e}\right\} \\ &\leq \mathrm{E}\left[e^{X/e}\right] e^{-(aY \ln P + b)/e} \qquad (6.2)\end{aligned}$$

by Markov's inequality. By the independence of the X_i's,

$$\mathrm{E}\left[e^{X/e}\right] = \prod_{i=1}^{Y} \mathrm{E}\left[e^{X_i/e}\right]. \tag{6.3}$$

From the definition of expectation,

$$\mathrm{E}\left[e^{X_i/e}\right] = \sum_{j=\ln P}^{P\ln P} \Pr\{X_i = j\}\, e^{j/e}.$$

To bound $\mathrm{E}\left[e^{X_i/e}\right]$, we break this sum into pieces. First we break out the terms from $j = \ln P$ to $j = e^3 \ln P - 1$, which yields

$$\mathrm{E}\left[e^{X_i/e}\right] = \sum_{j=\ln P}^{e^3 \ln P - 1} \Pr\{X_i = j\}\, e^{j/e} + \sum_{j=e^3 \ln P}^{P\ln P} \Pr\{X_i = j\}\, e^{j/e}. \tag{6.4}$$

The first of these sums we bound by factoring out the largest term and upper-bounding the sum of probabilities by 1 as follows:

$$\begin{aligned}
\sum_{j=\ln P}^{e^3 \ln P - 1} \Pr\{X_i = j\}\, e^{j/e} &\le \sum_{j=\ln P}^{e^3 \ln P - 1} \Pr\{X_i = j\}\, e^{e^2 \ln P} \\
&= e^{e^2 \ln P} \sum_{j=\ln P}^{e^3 \ln P - 1} \Pr\{X_i = j\} \\
&\le e^{e^2 \ln P}. \qquad (6.5)
\end{aligned}$$

To bound the second sum in equation (6.4), we further break the range of the index variable j into smaller pieces indexed by $k = 3, \ldots, \lceil \ln P \rceil - 1$, with piece k going from $j = e^k \ln P$ to $j = e^{k+1} \ln P - 1$ as follows:

$$\begin{aligned}
\sum_{j=e^3 \ln P}^{P\ln P} \Pr\{X_i = j\}\, e^{j/e} &= \sum_{k=3}^{\lceil \ln P \rceil - 1} \left(\sum_{j=e^k \ln P}^{e^{k+1} \ln P - 1} \Pr\{X_i = j\}\, e^{j/e} \right) \\
&\le \sum_{k=3}^{\lceil \ln P \rceil - 1} \left(e^{e^k \ln P} \sum_{j=e^k \ln P}^{e^{k+1} \ln P - 1} \Pr\{X_i = j\} \right) \\
&\le \sum_{k=3}^{\lceil \ln P \rceil - 1} e^{e^k \ln P} \Pr\left\{X_i \ge e^k \ln P\right\} \\
&= \sum_{k=3}^{\lceil \ln P \rceil - 1} P^{e^k} \Pr\left\{X_i \ge e^k \ln P\right\}. \qquad (6.6)
\end{aligned}$$

Now we can bound $\Pr\left\{X_i \ge e^k \ln P\right\}$ by the same technique as in Lemma 6.2, since X_i has the same distribution as the random variable Z considered in the proof of Lemma 6.2:

$$\begin{aligned}
\Pr\left\{X_i \ge e^k \ln P\right\} &\le P \binom{P \ln P}{e^k \ln P} \left(\frac{1}{P}\right)^{e^k \ln P} \\
&\le P e^{-(k-1)e^k \ln P} \\
&= P^{-(k-1)e^k + 1}.
\end{aligned}$$

Substituting this bound into inequality (6.6) yields

$$\begin{aligned}\sum_{j=e^3 \ln P}^{P \ln P} \Pr\{X_i = j\}\, e^{j/e} &\le \sum_{k=3}^{\lceil \ln P \rceil - 1} P^{e^k} P^{-(k-1)e^k+1} \\ &\le \sum_{k=3}^{\infty} P^{-(k-2)e^k+1} \\ &\le 1, \qquad (6.7)\end{aligned}$$

since the sum is bounded by the geometric sum $\sum_{k=1}^{\infty} 2^{-k} = 1$. Now we can substitute inequalities (6.5) and (6.7) back into equation (6.4), producing

$$\begin{aligned}\mathrm{E}\left[e^{X_i/e}\right] &\le e^{e^2 \ln P} + 1 \\ &\le e^{(e^2+1)\ln P}.\end{aligned}$$

Finally, by substituting this bound into equation (6.3) and then substituting into inequality (6.2), we obtain

$$\begin{aligned}\Pr\{X \ge aY \ln P + b\} &\le e^{((e^2+1)\ln P)Y} e^{-(aY \ln P + b)/e} \\ &= \exp\left(-\left(\frac{a}{e} - e^2 - 1\right) Y \ln P - \frac{b}{e}\right) \\ &\le \exp\left(-\frac{b}{e}\right)\end{aligned}$$

for $a \ge e^3 + e$. Thus, with $b = e\ln(1/\epsilon)$, we obtain

$$\Pr\left\{X \ge (e^3 + e)Y \ln P + e\ln(1/\epsilon)\right\} \le \epsilon. \qquad \square$$

We can now characterize the time and space usage for execution schedules computed by the LDF algorithm with synchronization parameter $r = 6 \lg P$.

THEOREM 6.5. *For any number $P \ge 2$ of processors and any strict multithreaded computation with work T_1, computation depth T_∞, and activation depth S_1, Algorithm* LDF$(6 \lg P)$ *computes a P-processor schedule $\mathcal{X}$ that uses space $S(\mathcal{X}) = O(S_1 P \lg P)$, and for any $\epsilon > 0$, with probability at least $1 - \epsilon$, the schedule uses time $T(\mathcal{X}) = O(T_1/P + T_\infty \lg P + \lg(1/\epsilon))$.*

Proof. The space bound follows directly from Lemma 6.1 with synchronization parameter $r = 6 \lg P$. The time $T(\mathcal{X})$ is the total time taken in computation phases. Let the random variable Y denote the number of iterations. Then we can decompose $T(\mathcal{X})$ as a sum of Y mutually independent random variables, $T(\mathcal{X}) = X_1 + X_2 + \cdots + X_Y$, with each X_i distributed as the size of the fullest bin when throwing $18P \lg P$ balls independently at random into P bins. Using $\epsilon/2$ as the value of ϵ in Lemma 6.3, we obtain $Y = O(T_1/(P \lg P) + T_\infty + \log_P(1/\epsilon))$ with probability at least $1 - \epsilon/2$. Then, using $\epsilon/2$ as the value of ϵ in Lemma 6.4, we obtain $T(\mathcal{X}) = O(Y \lg P + \lg(1/\epsilon))$ with probability at least $1 - \epsilon/2$ (using $18P \lg P$ instead of $P \ln P$ only affects the constant). Thus, with probability at least $1 - \epsilon$, the total time taken in computation phases is $T(\mathcal{X}) = O(T_1/P + T_\infty \lg P + \lg(1/\epsilon))$. $\square$

COROLLARY 6.6. *For any number $P \ge 2$ of processors and any strict multithreaded computation with work T_1 and computation depth T_∞, Algorithm* LDF$(6 \lg P)$

computes a P-processor schedule $\mathcal{X}$ with expected execution time $\mathrm{E}[T(\mathcal{X})] = O(T_1/P + T_\infty \lg P)$.

Proof. Just use $\epsilon = 1/P$ in Theorem 6.5 to get $T(\mathcal{X}) = O(T_1/P + T_\infty \lg P)$ with probability at least $1 - 1/P$. Then we have

$$\begin{aligned}\mathrm{E}[T(\mathcal{X})] &\le \left(1 - \frac{1}{P}\right) O\left(\frac{T_1}{P} + T_\infty \lg P\right) + \frac{1}{P} T_1 \\ &= O\left(\frac{T_1}{P} + T_\infty \lg P\right). \qquad \square\end{aligned}$$

This algorithm achieves linear expected speedup when the computation has average available parallelism $T_1/T_\infty = \Omega(P \lg P)$.

We can view the $\lg P$ factors in the space bound and the average available parallelism required to achieve linear speedup as the computational slack required by Valiant's bulk-synchronous model [42]. The space bound $S(\mathcal{X}) = O(S_1 P \lg P)$ indicates that Algorithm LDF$(6 \lg P)$ requires memory to scale sufficiently to allow each *physical* processor enough space to simulate $\Theta(\lg P)$ *virtual* processors. Given this much space, the time bound $\mathrm{E}[T(\mathcal{X})] = O(T_1/P + T_\infty \lg P)$ then demonstrates linear expected speedup provided the computation has $\lg P$ slack in the average available parallelism.

The space bound of Theorem 6.5 is an aggregate bound, but in a distributed memory machine, we may want to bound the space associated with each individual processor's queue. In the LDF algorithm, each living thread is located in the local queue of a processor chosen at random, so we assume that each activation frame is located in the local memory of the same randomly chosen processor as its associated living thread. Since the aggregate space used by Algorithm LDF(r) is bounded by $2rS_1P$, we would like some way to ensure that each individual processor requires space bounded by $O(rS_1)$.

If we consider any given processor p and any given iteration t of the algorithm, then we can let W denote the total space being used by activation frames located in the memory of processor p. We can decompose W as a weighted sum of independent indicator random variables and show that $\mathrm{E}[W] \le 2rS_1$. Then, using a theorem due to Raghavan [36, Theorem 1], we can show that with probability at least $1 - e^{-2r}$, we have $W \le 2erS_1$.

With this probabilistic bound on the space used by a given processor at a given iteration, we can show that with appropriate choice of the synchronization parameter r, we can bound the per-processor memory by simply rerandomizing thread locations any time a processor's memory fills up. In particular, if we choose $r = \Theta(\lg P + \lg S_1)$, then the total time spent rerandomizing is $O(T_1/P)$ and the per-processor storage bound is $O(S_1(\lg P + \lg S_1))$. Details can be found in [4].

7. Related and future work. Although the work we have presented here provides some theoretical underpinnings for understanding the resource requirements of multithreaded computations, much remains to be done. In this section, we review some of the related work, both theoretical and empirical, on scheduling dynamic computations. We discuss the class of "thread-stealing" algorithms and present some of our preliminary research on this kind of scheduling algorithm.

Substantial research has been reported in the theoretical literature concerning dynamic computations. In contrast to our research on multithreaded computations, however, other theoretical research has tended to treat the aggregate resource requirements of a computation as a given, rather than as a quantity that depends on the

execution schedule. Thus, the relevant issue in this work is how to balance the load across processors. Important work in this area includes a randomized work-stealing algorithm for load balancing [38]; dynamic tree-embedding algorithms [3, 31]; and algorithms for backtrack search [27, 37, 45], which can be viewed as a multithreaded computation with no data-dependency edges. Although this work ignores aggregate space requirements, it is interesting to note that Zhang's work-stealing algorithm for backtrack search [45] actually gives at most linear expansion of space, but he does not mention this fact.

The problem of storage management for multithreaded computations has been a growing concern among practitioners [13, 22]. To date, most existing techniques for controlling storage requirements have consisted of heuristics to either bound storage use by explicitly controlling storage as a resource or reduce storage use by modifying the scheduler's behavior. We are aware of no prior scheduling algorithms for multithreaded computations for which simultaneously good time and space bounds have been proved.

The storage management problem can often be quite pronounced under the execution of a *fair* scheduler. By executing threads in round-robin fashion, a fair scheduler gives each ready thread a fair portion of the execution time. A fair scheduler aggressively exposes parallelism, often resulting in excessive space requirements. In order to curb the excessive use of space exhibited by fair scheduling, researchers from the dataflow community have developed heuristics to explicitly manage storage [15, 39]. The effectiveness of these heuristics is documented with encouraging empirical evidence but no provable time bounds.

In contrast with these heuristic techniques, we have chosen to develop an algorithmic foundation that manages storage by allowing programmers to leverage their knowledge of storage requirements for serially executed programs.

Other researchers have also addressed the storage issue by attempting to relate parallel storage requirements to serial storage requirements. Burton and Sleep [12] and Halstead [22], for example, considered unfair scheduling policies based on *thread stealing*. In these thread-stealing strategies, each processor works depth-first—just like a serial execution—but when a processor runs out of ready threads, it *steals* threads from other processors. In many cases, this scheduling policy results in each processor using no more space than that used by a single processor, but a problem arises as to what to do when all threads in a processor have stalled. If the processor goes out to steal a thread from another processor, greater-than-linear space expansion may result. If the processor goes idle, however, linear speedup is not guaranteed. For these unfair scheduling policies, characterizing the performance analytically is difficult.

Thread stealing has also been employed in two parallel chess-playing programs. Zugzwang [18] is a program in which processors steal subcomputations of a chess tree using a parallel alpha-beta search algorithm. StarTech [30] is another parallel program organized along similar lines but with a parallel scout-search algorithm. Although the authors make no guarantees of performance for their algorithms, the empirical results of these programs are good; both have won prizes in international chess competitions.

In recent work, we have obtained some preliminary results on thread stealing. We have devised a new global algorithm that forms the basis of a randomized, distributed, thread-stealing algorithm. Our new global algorithm is like GDF$'$ except for two changes. First, the global queue is not organized by activation depth; when a processor removes a ready thread from the queue, any ready thread suffices. Second, when a thread dies, the thread's processor must locate the parent thread in the global queue

and check to see if the parent has any surviving children. If the parent no longer has any surviving children, then the processor must commence work on the parent thread. Otherwise, the processor is free to take any ready thread from the global queue. It can be proved by simple induction that this algorithm satisfies the same time and space bounds as Algorithms GDF and GDF′ . In our distributed thread-stealing algorithm, we replace the global queue with local queues, one per processor. By making some generous modeling assumptions, we have been able to analyze this algorithm and to obtain bounds similar to those for Algorithm LDF. We are currently working on improving these results.

Appendix. During the time between our results becoming publicly known [7] and this journal publication, we have explored multithreaded computing more fully. We have been able to characterize the performance of a distributed thread-stealing algorithm [5, 8]. For the class of "fully strict" (well-structured) computations, this randomized algorithm achieves execution space bounded by S_1P and expected execution time bounded by $O(T_1/P+T_\infty)$, including scheduling overheads. Additionally, in contrast to Algorithm LDF, this thread-stealing algorithm is efficient with respect to communication. We have implemented this thread-stealing algorithm in the runtime system for *Cilk* [5, 6], a parallel multithreaded extension of the C language. By employing a provably efficient scheduler, Cilk is able to deliver efficient and predictable performance, guaranteed. Moreover, structure in the Cilk programming model facilitates the implementation of "adaptive parallelism" and transparent fault tolerance in a runtime system for Cilk on networks of workstations [5, 9]. More information about Cilk is available online at `http://theory.lcs.mit.edu/~cilk`.

SIMULATING THRESHOLD CIRCUITS BY MAJORITY CIRCUITS*

MIKAEL GOLDMANN† AND MAREK KARPINSKI‡

Abstract. We prove that a single threshold gate with arbitrary weights can be simulated by an explicit polynomial-size, depth-2 majority circuit. In general we show that a polynomial-size, depth-d threshold circuit can be simulated uniformly by a polynomial-size majority circuit of depth $d+1$. Goldmann, Håstad, and Razborov showed in [*Comput. Complexity*, 2 (1992), pp. 277–300] that a nonuniform simulation exists. Our construction answers two open questions posed by them: we give an explicit construction, whereas they use a randomized existence argument, and we show that such a simulation is possible even if the depth d grows with the number of variables n (their simulation gives polynomial-size circuits only when d is constant).

Key words. threshold circuits, majority circuits, circuit complexity

1. Introduction.

A threshold gate is a fairly simple device that computes a weighted sum of its inputs, compares it to a threshold value, and outputs 1 or 0 depending on the outcome of the comparison. A threshold circuit is an acyclic network of threshold gates. The *size* of a circuit is the number of wires in it.

Small-weight threshold gates are a restricted type of threshold gates. In this case the magnitude of the (integer) weights of the gate is bounded by a polynomial in the number of inputs to the gate. The corresponding circuits are called small-weight threshold circuits. In this case the magnitude of the weights in the circuit is bounded by a polynomial in the total number of inputs to the circuit. It is easy to see that a majority gate can simulate a small weight threshold gate by simply duplicating input wires and adding some constant inputs. This leads only to a polynomial increase in the number of wires. Hence, depth-d, polynomial-size majority circuits are equivalent to depth d polynomial-size, small-weight threshold circuits.

Threshold circuits have been shown to be surprisingly powerful. It is implicit in work by Beame, Cook, and Hoover [4] that integer division can be carried out by polynomial-size threshold circuits of constant depth. Allender [1] (inspired by Toda [29]) shows that any function in AC^0 can be computed by depth-3 majority circuits of quasi-polynomial size. Yao [34] extends this to all of ACC^0 (see also [5]).

There are some strong lower bounds for majority circuits of very small depth. Hajnal et al. [11] prove exponential lower bounds on the size of depth-2 majority circuits computing "inner product mod 2." These results were extended in [13] to depth-3 majority circuits where the gates on the bottom level have very small fan-in, and recently superpolynomial bounds were proved for depth-3 majority circuits where the gates on the bottom level are arbitrary gates of fan-in $n^{1-\epsilon}$ [23]. For depth-3 majority circuits with no extra restrictions, no superpolynomial lower bounds are

known. Siu, Roychowdhury, and Kailath proved superlinear lower bounds on the number of wires in constant-depth majority circuits computing parity [28]. Recently Impagliazzo, Paturi, and Saks extended the results of [28] to constant-depth threshold circuits (with large weights) computing parity [15].

If one considers threshold circuits with arbitrary weights, even less is known. There is no superpolynomial lower bound for depth-2 threshold circuits computing some function in NP. As we mentioned above, such bounds exist for majority circuits [11]. It is therefore interesting to explore the power of large weights in threshold circuits.

It has long been known that a single threshold gate is strictly more powerful than a single small-weight threshold gate. For instance, Myhill and Kautz showed in 1961 that there are functions computable by a single threshold gate that require weights of size $\Omega(2^n/n)$, where n is the number of inputs [17]. Also, it was recently shown that depth-2, polynomial-size threshold circuits are more powerful than depth-2, polynomial-size, small-weight threshold circuits [10].

On the other hand, it was proved by Chandra, Stockmeyer, and Vishkin [8] that addition of n binary encoded integers can be performed by constant depth majority circuits (see also [21]). This implies that depth-d, polynomial-size threshold circuits can be simulated by depth $O(d)$, polynomial-size, small-weight threshold circuits.

In [25] Siu and Bruck gave a nonconstructive proof that polynomial-size, depth-d threshold circuits can be simulated by polynomial-size, depth-$2d+1$ majority circuits. Alon and Bruck gave a uniform construction in [3] achieving this. Goldmann, Håstad, and Razborov showed in [10] that any function computed by a depth-d, polynomial-size threshold circuit is computable by a depth-$d+1$, polynomial-size majority circuit (note that for $d = 1, 2$ this is optimal). Two open questions were posed in [10]: can one make an explicit construction, and can one make it work also for nonconstant depth? (Reference [10] uses a probabilistic argument, and the blowup in size is superpolynomial if the depth grows with the number of variables.) We give positive answers to both questions.

For a thorough survey of complexity theoretic results on threshold circuits, see [22].

2. Preliminaries. It will be convenient to work over $\{1, -1\}$ rather than $\{0, 1\}$. An n-variable Boolean function thus maps $\{1, -1\}^n$ to $\{1, -1\}$. This is a simple transformation that does not affect the power of threshold gates. A threshold gate computes its output as the sign of a linear form:

$$g(x) = \operatorname{sign}\left(w_0 + \sum_{i=1}^{n} w_i x_i\right),$$

where the w_i are the *weights*, and the sign function takes a real-valued input and is defined by

$$\operatorname{sign}(x) = \begin{cases} -1 & \text{if } x < 0, \\ 0 & \text{if } x = 0, \\ 1 & \text{if } x > 0. \end{cases}$$

Since g is to be ± 1-valued, the argument to the sign function is required to be nonzero for all $x \in \{1, -1\}^n$. The following well-known result by Muroga [16] gives a bound on the magnitude of the weights.

THEOREM 2.1 (see [16, Theorem 9.3.2.1]). *Let $f(x)$ be an arbitrary n-variable threshold function. Then $f(x)$ can be written as*

$$f(x) = \operatorname{sign}\left(w_0 + \sum_1^n w_i x_i\right),$$

where for all $i = 0, \ldots, n$,

$$w_i \in \mathbb{Z} \quad \textit{and} \quad |w_i| \leq 2^{-n}(n+1)^{(n+1)/2}.$$

Remark 1. A recent result by Håstad [12] gives a lower bound on the weights required for a particular threshold function. The lower bound nearly matches the upper bound in Theorem 2.1.

A threshold circuit is a directed acyclic graph the nodes of which are either threshold gates or input variables. We allow multiple output nodes, and a circuit is evaluated in topological order. For a given circuit C, f_C is the function computed by C. The size of a circuit is the number of wires in it.

A family of circuits $\{C_n\}$ is said to compute a function $f\colon \{1,-1\}^* \to \{1,-1\}^*$ provided $f \restriction_{\{1,-1\}^n} = f_{C_n}$ for all n.

DEFINITION 2.2. *We use the following notation from* [6].

- *LT_d is the class of functions computable by depth-d, polynomial-size threshold circuits.*
- *$\widehat{LT}_d$ is the class of functions computable by depth-d, polynomial-size threshold circuits with polynomially bounded integer weights.*

Note that if we allow a gate to have multiple wires from an input (i.e., the underlying structure is a *multi*-graph), then depth-d, polynomial-size majority circuits can compute any function in $\widehat{LT}_d$.

We introduce also uniform classes of threshold circuits. In doing so we can use the threshold circuit descriptions, e.g., similar to the "direct connection language" of Ruzzo [24] (see also [9]).

Let BIN be the set of binary encodings of the positive integers. A threshold circuit C_n with n inputs is described by a labeled multigraph (V_n, E_n). $V_n = I_n \dot\cup G_n$, where $I_n = \{1, x_1, \ldots, x_n\}$ is the set of inputs (note that the constant "1" is included in I_n), and $G_n = \{g_1, \ldots, g_s\}$ is the set of gate labels. The edges in E_n are tuples $(e, v, g, k, \delta) \in V_n \times BIN \times G_n \times BIN \times \{1, -1\}$ with the following interpretation: the edge with label e goes from v to g (where e is a unique edge label), and the weight of the edge is $\delta \cdot 2^k$. There is no need to assign a threshold value to the gates in G_n. We give them all threshold 0 and by having an appropriate weight assigned to the constant input 1 any threshold can be achieved. Also, an edge with weight w can be split into about $\log w$ edges the weights of which are powers of 2. We use $\overline{C_n}$ to denote the description of C_n.

We use the same syntax when describing small-weight threshold circuits, but k in an edge-tuple (n, e, v, g, k, δ) is interpreted as the weight having magnitude k rather than 2^k.

A circuit-family has *polynomial-size descriptions* if there is a constant c such that

- for each $n \in \mathbb{N}$ and each $g \in G_n$ it holds that $|g| \leq c(1 + \log(n+1))$.
- for each $n \in \mathbb{N}$ and each edge $(e, v, g, k, \delta) \in E_n$ it holds that $|e| \leq c(1 + \log(n+1))$ and that $|k| \leq c(1 + \log(n+1))$.

Note that given the above constraints both V_n and E_n have size polynomial in n.

To define uniformity, let $\mathcal{C} = \{C_n\}$ be a sequence of circuits, and for each C_n let G_n and E_n be the corresponding gates and edges. $\mathcal{C}$ defines the language $L_{\mathcal{C}} = L_G \cup L_E$, where $L_G = \{ (n, g) \mid g \in G_n \}$ and $L_E = \{ (n, e, v, g, k, \delta) \mid (e, v, g, k, \delta) \in E_n \}$.

DEFINITION 2.3. *A function is in L-uniform LT_d if there is a sequence $\mathcal{C}$ of depth-d threshold circuits with polynomial-size descriptions, such that there is a Turing machine that accepts $L_{\mathcal{C}}$ in linear space.*

A function is in L-uniform $\widehat{LT}_d$ if there is a sequence $\mathcal{C}$ of depth-d small-weight threshold circuits with polynomial-size descriptions, such that there is Turing machine that accepts $L_{\mathcal{C}}$ in linear space.

The reason for the terminology "L-uniform" is that the description of a circuit of the above type can be generated in space that is logarithmic in the size of the description.

We call a sequence of circuits P-uniform if the description of the nth circuit can be generated in polynomial time on input 1^n (cf., for example, [9]).

We define the following operator.

DEFINITION 2.4. *The operator* rem *is defined as follows. For integers a and b,*

$$a \text{ rem } b = c,$$

where c is the unique integer such that

$$a \equiv c \pmod{b} \quad \textit{and} \quad -b/2 < c \leq b/2.$$

3. The idea behind the construction. Let f be an arbitrary threshold gate given by

$$f(x) = \operatorname{sign}(F(x)),$$

where

$$F(x) = w_0 + \sum_{i=1}^{n} w_i x_i.$$

Since we have integer weights, and we require that the argument of 'sign' is nonzero, we have $|F(x)| \geq 1$ for all x.

In the next section we will build a parametrized *approximator* for f. For a fixed input, the approximator is good for randomly chosen parameters. To show the intuition behind the construction, we build an approximator φ for f that computes correctly for a random input.

In the construction it will be convenient to use rational weights. All the weights in the circuits we construct are of the form $w/2$, where w is an integer. By multiplying all weights in the circuit by 2 we get integer weights, and the increase in the magnitude of the weights is just a factor 2.

To describe the construction we need a couple of parameters that we call W and m. Let $w_{\max}(f)$ be the largest magnitude of a weight of the gate f. It will be convenient to assume the following:

$$W \geq \max\{w_{\max}(f), 2^n\}, \tag{1}$$

$$10n \leq m \leq W. \tag{2}$$

The parameter m controls the quality of the approximator. In the circuit that implements the approximator the weights will have magnitude about m^2. To have small-weight circuits, clearly m must be kept small. On the other hand, intuitively it seems that allowing larger weights allows a more accurate approximator. The parameter m reflects this trade-off.

The construction uses the following function of one integer variable y:

$$\begin{aligned} M^m(y) = &\frac{1}{2}\operatorname{sign}\left(y - m + \frac{1}{2}\right) \\ &-\frac{1}{2}\operatorname{sign}\left(y - 2m + \frac{1}{2}\right) \\ &+\frac{1}{2}\operatorname{sign}\left(y + m - \frac{1}{2}\right) \\ &-\frac{1}{2}\operatorname{sign}\left(y + 2m - \frac{1}{2}\right). \end{aligned}$$

The function $M^m(y)$ has the following useful property, which is immediate from the definition of M^m.

LEMMA 3.1. *If $m \le |y| < 2m$, then $M^m(y) = \operatorname{sign}(y)$, and otherwise $M^m(y) = 0$.*

Let us look at a fixed input x. Assume that $2^l \le |F(x)| < 2^{l+1}$. Given this information, we can use less precision in the weights w_i. Set

$$F_{(l)}(x) = \lfloor w_0 m/2^l \rfloor + \sum_{i=1}^{n} \lfloor w_i m/2^l \rfloor x_i.$$

If we disregard the error introduced by the floor operation, we will have

$$m \le |F_{(l)}(x)| < 2m.$$

It is plausible that for most inputs x the truncation error will not matter, and then $\operatorname{sign}(F(x)) = \operatorname{sign}\big(F_{(l)}(x)\big)$. To get the weights small, we just look at $F_{(l)}(x)$ modulo some small prime $p > m^2$.

We are now ready to construct a small gadget $\varphi^{(l)}(x)$ that implements the computation described above.

$$\begin{aligned} w_i^{(l)} &= \lfloor w_i m/2^l \rfloor \operatorname{rem} p, \\ \Phi_{(l)}(x) &= w_0^{(l)} + \sum_{i=1}^{n} w_i^{(l)} x_i, \\ \varphi_{(l)}(x) &= \sum_{j=-\lfloor (n+1)/2 \rfloor}^{\lceil (n+1)/2 \rceil} M^m\big(\Phi_{(l)}(x) + jp\big). \end{aligned} \tag{3}$$

Let us establish some properties of $\varphi_{(l)}$ as defined by (3).

PROPOSITION 3.2. *For $p > 4m$ the following holds.*

1. *For any x, $\big|\varphi_{(l)}(x)\big| \in \{0, 1\}$.*
2. *If $\big|F_{(l)}(x) \operatorname{rem} p\big| \notin [m, 2m)$, then $\varphi_{(l)}(x) = 0$.*
3. *If $m \le \big|F_{(l)}(x)\big| < 2m$, then $\varphi_{(l)}(x) = \operatorname{sign}\big(F_{(l)}(x)\big)$.*

Proof. All statements follow from Lemma 3.1.

1. Each term $M^m\left(\Phi_{(l)}(x)+jp\right)$ is either 0, 1, or -1, and since $p>4m$ there is at most one j for which $\left|\Phi_{(l)}(x)+jp\right|<2m$, and thus at most one nonzero term $M^m\left(\Phi_{(l)}(x)+jp\right)$.
2. By Lemma 3.1, $M^m(y)\neq 0$ implies that $|y|<2m$, and since $p>4m$ this in turn implies $y=y \text{ rem } p$. Thus, the only term that might be nonzero is the term $M^m\left(\Phi_{(l)}(x)+jp\right)$ for which $\Phi_{(l)}(x)+jp=\Phi_{(l)}(x) \text{ rem } p$. Now just observe that $F_{(l)}(x)\equiv\Phi_{(l)}(x)(\text{mod } p)$.
3. For the third statement we have the following. Assume that $m\leq\left|F_{(l)}(x)\right|<2m$. We then have $\Phi_{(l)}(x) \text{ rem } p=F_{(l)}(x)$.
   Let j_0 be the integer that satisfies $\Phi_{(l)}(x) \text{ rem } p=\Phi_{(l)}(x)+j_0p$.
   Since $\left|\Phi_{(l)}(x)\right|\leq(n+1)(p-1)/2$, j_0 occurs in the sum in (3). The third statement now follows from Lemma 3.1. □

It is tempting to set

$$\varphi(x)=\sum_l \varphi_{(l)}(x) \tag{4}$$

and hope that $\varphi(x)=\text{sign}\,(F(x))=f(x)$. The idea is that there is always an l such that $2^l\leq|F(x)|<2^{l+1}$. If there was no error introduced by the floor operations, we would have $m\leq\left|F_{(l)}(x)\right|<2m$ and $\text{sign}\left(F_{(l)}(x)\right)=\text{sign}\,(F(x))$. By Proposition 3.2, $\varphi_{(l)}(x)=\text{sign}\left(F_{(l)}(x)\right)$, and for all other l we would probably have $\varphi_{(l)}(x)=0$. Then we would have $\varphi(x)=\varphi_{(l)}(x)=\text{sign}\,(F(x))=f(x)$.

Remark 2. We know that $|F(x)|\leq(n+1)W$. Thus, it is sufficient to sum over l such that $0\leq l\leq\log((n+1)W)$ in (4).

The problems with (4) are of course that the floor operation sometimes introduces *truncation errors* (e.g., when $2^l\leq F(x)$ but $F_{(l)}(x)<m$), and sometimes the "wrong" l gives a nonzero contribution to the sum (a *modular error*). Equation (4) is not such a bad idea though, because it works for most x.

4. The approximator. To get an approximator based on the ideas of the previous section we want to spread the value $F(x)$ in some random fashion. This was done in [10] by considering $\text{sign}\,(\alpha F(x))$ for a randomly chosen integer $\alpha\in\{1,2,\ldots,2^{2n}\}$, and since $\alpha>0$, one has $\text{sign}\,(F(x))=\text{sign}\,(\alpha F(x))$. It was shown that for any x, the approximator would compute $\text{sign}\,(\alpha F(x))$ correctly with high probability. By taking many independent α's and taking the sign of the average, one gets an approximator that behaves well on all inputs. If the range of α was smaller, we could get an explicit approximator by taking the average over all α's.

We will modify the construction. Our approximator will depend on two parameters, and for any input, the approximator will be good with high probability if the parameters are chosen at random. In our case the probability space is small enough that we may take the average over all possible choices of parameter values. Just like in [10] we will use a multiplier α, but it will be much smaller. For a random α, the probability of a truncation error is small. To handle the modular errors, we will also choose the prime p, used in the construction, randomly, and the probability that we get a modular error for a random p is small.

DEFINITION 4.1. *We define the following sets. Let*

$$[m]=\{1,2,\ldots,m\},$$

$\mathcal{PR}^m$ *is the set of the first* m^2 *primes that are greater than* m^2.

When α *and* p *are chosen randomly, they are picked as a pair* $(\alpha,p)\in[m]\times\mathcal{PR}^m$ *according to the uniform distribution.*

Instead of looking at the weights w_i, we make the approximator for weights αw_i. Thus, instead of looking at $F(x)$ we look at $\alpha F(x)$, but this works since $\operatorname{sign}(\alpha F(x)) = \operatorname{sign}(F(x)) = f(x)$. We call the corresponding truncated linear form $F^{\alpha}_{(l)}(x)$; that is,

$$F^{\alpha}_{(l)}(x) = \lfloor \alpha w_0 m/2^l \rfloor + \sum_{i=1}^{n} \lfloor \alpha w_i m/2^l \rfloor x_i.$$

Now we are ready to define the parametrized approximator $\varphi^{\alpha,p}(x)$.

$$\begin{aligned} w_i^{(l)} &= \left\lfloor \alpha w_i m/2^l \right\rfloor \operatorname{rem} p, \\ \Phi^{\alpha,p}_{(l)}(x) &= w_0^{(l)} + \sum_{i=1}^{n} w_i^{(l)} x_i, \\ \varphi^{\alpha,p}_{(l)}(x) &= \sum_{j=-\lfloor (n+1)/2 \rfloor}^{\lceil (n+1)/2 \rceil} M^m(\Phi^{\alpha,p}_{(l)}(x) + jp), \qquad (5) \\ \varphi^{\alpha,p}(x) &= \sum_{l=0}^{\lfloor 3 \log W \rfloor + 1} \varphi^{\alpha,p}_{(l)}(x), \end{aligned}$$

where the upper bound of the last summation follows from an argument analogous to Remark 3, assumptions (1) and (2), and the fact that $\alpha \le m$.

The following proposition is the (α, p)-version of Proposition 3.2. The proof is completely analogous.

PROPOSITION 4.2. *For $p > m^2$ the following hold.*

1. *For any x, $\left|\varphi^{\alpha,p}_{(l)}(x)\right| \in \{0, 1\}$.*
2. *If $\left|F^{\alpha}_{(l)}(x) \operatorname{rem} p\right| \notin [m, 2m)$ then $\varphi^{\alpha,p}_{(l)}(x) = 0$.*
3. *If $m \le \left|F^{\alpha}_{(l)}(x)\right| < 2m$ then $\varphi^{\alpha,p}_{(l)}(x) = \operatorname{sign}\big(F^{\alpha}_{(l)}(x)\big)$.*

COROLLARY 4.3. *If we assume* (1) *and* (2)*, then for all $x \in \mathbb{Z}^n$ we have $\varphi^{\alpha,p}(x) \in \mathbb{Z}$ and $|\varphi^{\alpha,p}(x)| \le 2 + 3 \log W$.*

Proof. It is not hard to see that statement 4.2 of Proposition 4.2 holds even for $x \in \mathbb{Z}^n$. The corollary follows since we sum over at most $2 + 3 \log W$ different l in (5). □

For any x there are usually α's and p's such that we get truncation errors or modular errors. We will show that for any fixed x most pairs (α, p) do not give such errors.

DEFINITION 4.4.

1. *We say that α is* bad *for x if there is some l such that $\big||\alpha F(x)| - 2^l\big| \le 2^{l+1} n/m$. Otherwise α is* good *for x.*
2. *We say that p is* bad *for x and α if there is an l such that $\left|F^{\alpha}_{(l)}(x)\right| \ge 2m$ but $\left|F^{\alpha}_{(l)}(x) \operatorname{rem} p\right| < 2m$. Otherwise p is* good *for x and α.*
3. *We call a pair (α, p)* bad *for x if α is bad for x or if p is bad for x and α. Otherwise (α, p) is* good *for x.*

We will show that when a pair (α, p) is good for x, then $\varphi^{\alpha,p}(x) = f(x)$. We will also show that for any fixed x, a random pair (α, p) is likely to be good.

First we show that $\varphi^{\alpha,p}(x) = f(x)$ when (α, p) is good.

PROPOSITION 4.5. *Let x be an arbitrary fixed input. If (α, p) is good for x, then $\varphi^{\alpha,p}(x) = f(x)$.*

Proof. Let x be a fixed input and assume that (α, p) is a good pair for x. Without loss of generality, we assume that $F(x) > 0$.

First we will show that there are no truncation errors that matter in this case. Let l_0 be the integer such that

$$2^{l_0} \leq \alpha F(x) < 2^{l_0+1}.$$

Since $F(x) \leq (n+1)W$ and $\alpha \leq m$ we have $\alpha F(x) \leq m(n+1)W \leq 2W^3$, and thus $l_0 \leq \lfloor 3 \log W \rfloor + 1$.

For any l

$$\left| F^{\alpha}_{(l)}(x) - \frac{\alpha F(x) m}{2^l} \right| < n+1, \tag{6}$$

since the floor operation makes an error less than 1 for each weight of the gate.

Equation (6) immediately tells us that

$$m < F^{\alpha}_{(l_0)}(x) < 2m.$$

This implies that the term $\varphi^{\alpha,p}_{(l_0)}(x)$ will be equal to 1.

For $l \neq l_0$ we have the following. Let $l < l_0$ be an arbitrary integer. Since α is good for x we have

$$2^{l+1}\left(1 + \frac{2n}{m}\right) < \alpha F(x),$$

and from (6) it follows that

$$2m < F^{\alpha}_{(l)}(x).$$

A completely analogous argument shows that for any $l > l_0$ one has

$$m > F^{\alpha}_{(l)}(x).$$

Thus, no error is introduced due to truncation.

We still need to show that there are no modular errors, that is, when we do the computation modulo p we do not get a contribution from some $l > l_0$ for which $F^{\alpha}_{(l)}(x) > 2m$. However, this would mean that for some l one has $F^{\alpha}_{(l)}(x) > 2m$ but $\left|F^{\alpha}_{(l)}(x) \text{ rem } p\right| < 2m$, and this implies by definition that p is bad for x and α contrary to our assumption. □

It remains to show that for any fixed x most α's are good, and for any fixed x and α most p's are good.

LEMMA 4.6. *If W and m satisfy* (1) *and* (2), *then for any x*

$$\Pr\alpha \textit{ is bad for } x < (16 \log^2 \mathrm{W})/m.$$

Proof. Let $r = |F(x)|$. We want to show that for most α we have $\left|2^l - \alpha r\right| > 2^{l+1} n/m$ for all l.

Look at a fixed l. If there is any α which is bad with respect to l, then r must satisfy the following equations.

$$r \leq 2^l\left(1 + \frac{2n}{m}\right) < 2^{l+1}, \tag{7}$$

$$r \geq \frac{2^l}{m}\left(1 - \frac{2n}{m}\right) > 2^{l-1}/m. \tag{8}$$

The bad interval for α has length $2^{l+2}n/(rm)$. If r and l do not satisfy (8), then all α's are too small to be bad. On the other hand, if r and l satisfy (8), there are at most $8n$ different α's that fit in the bad interval.

For any r, there are less than $2\log m$ different l that satisfy (7) and (8). Thus, any x has at most $16n\log m$ bad α. The lemma follows by our assumption that (1) and (2) hold. □

LEMMA 4.7. *If W and m satisfy* (1) *and* (2)*, then for any x and α*

$$\Pr p \text{ is bad for } x \text{ and } \alpha < (16\log^2 W)/m.$$

Proof. Once again consider a fixed l first, and assume that for input x and multiplier α we have $|F^{\alpha}_{(l)}(x)| \geq 2m$ but $|F^{\alpha}_{(l)}(x) \operatorname{rem} p| < 2m$ for $4m\log W$ of the primes. By the pigeon hole principle we must have more than $\log W$ primes that give the same remainder k, such that $|k| < 2m$. By the Chinese remainder theorem, $F^{\alpha}_{(l)}(x)$ is uniquely determined modulo the product of those primes. That product is greater than $m^{2\log W}$. Since we assume (1) and (2),

$$\begin{aligned}\left|F^{\alpha}_{(l)}(x)\right| &\leq |m\alpha F(x)| \\ &\leq m^2(n+1)W \\ &\ll m^{2\log W}.\end{aligned}$$

This implies that $k = F^{\alpha}_{(l)}(x)$, which means that $\left|F^{\alpha}_{(l)}(x)\right| < 2m$, and we have a contradiction. Since there are at most $2 + 3\log W < 4\log W$ different l, the lemma follows. □

Lemmas 4.6 and 4.7 imply the following lemma.

LEMMA 4.8. *If W and m satisfy* (1) *and* (2)*, then for an arbitrary fixed input x,*

$$\Pr(\alpha, p) \text{ is bad for } x \leq (32\log^2 W)/m.$$

We conclude this section by showing how the approximator allows us to simulate a single threshold gate (with large weights) by a depth-2, small-weight, threshold-circuit. This is a constructive version of Theorem 7.8 from [10].

THEOREM 4.9. $LT[1] \subsetneq \widehat{LT}[2]$.

Proof. We will prove the inclusion. That it is strict follows from the fact that parity is in $\widehat{LT}[2] \setminus LT[1]$. Assume $n \geq 100$; smaller inputs are handled by writing the function in disjunctive normal form.

We are given a threshold gate

$$f(x) = \operatorname{sign}\left(w_0 + \sum_{i=1}^{n} w_i x_i\right).$$

Let $W = \max\{w_{\max}(f), 2^n\}$ be the bound used in the construction, and set the parameter $m = 128\log^3 W$ (observe that W and m satisfy (1) and (2)). Consider the following function:

$$g(x) = \operatorname{sign}\left(\sum_{(a,p)} \varphi^{\alpha,p}(x)\right).$$

We claim two things: $f(x) = g(x)$ for all $x \in \{1,-1\}^n$, and $g(x)$ can be computed by a depth-2, polynomial-size, threshold circuit with polynomially bounded weights.

The correctness of the construction follows from

$$E[f(x)\varphi^{\alpha,p}(x)] > 0, \tag{9}$$

where x is arbitrary and fixed, and we take expectation over the uniform distribution on pairs (α, p). Let us prove (9).

$$\begin{aligned} &E[f(x)\varphi^{\alpha,p}(x)] \\ &\quad \geq \Pr(\alpha,p) \text{ good} \\ &\qquad -(2+3\log W)\Pr(\alpha,p) \text{ bad} \\ &\quad \geq 1 - \frac{1}{4\log W} - \frac{2+3\log W}{4\log W} \\ &\quad > 0, \end{aligned}$$

where the first inequality follows from Corollary 4.3 and the second inequality follows from Lemma 4.8. This shows that $f(x) = g(x)$ for all x.

Now, to implement $g(x)$ as a circuit, let us look at what $g(x)$ does.

$$g(x) = \operatorname{sign}\left(\sum_{\alpha,p,l,j} \frac{1}{2}\operatorname{sign}\left(\Phi_{(l)}^{\alpha,p}(x) + jp - m + \frac{1}{2}\right) - \frac{1}{2}\operatorname{sign}\left(\Phi_{(l)}^{\alpha,p}(x) + jp - 2m + \frac{1}{2}\right)\right.$$
$$\left. + \frac{1}{2}\operatorname{sign}\left(\Phi_{(l)}^{\alpha,p}(x) + jp + m - \frac{1}{2}\right) - \frac{1}{2}\operatorname{sign}\left(\Phi_{(l)}^{\alpha,p}(x) + jp + 2m - \frac{1}{2}\right)\right).$$

$\Phi_{(l)}^{\alpha,p}(x)$ is simply a weighted sum of the inputs. Hence, we only have two levels of sign-functions, and one is the outmost operator, so $g(x)$ can be computed by a depth-2 threshold circuit. The size is the total number of terms in the summations (recall that each $\Phi_{(l)}^{\alpha,p}(x)$ depends on $n \leq \log W$ variables). There are $m^3 = O\left(\log^9 W\right)$ pairs (α, p), and $O(\log W)$ different l. This gives a total size of $O(\log^{12} W)$.

As for the weights, they are not necessarily integers, but if we multiply them by 2 they are. The only weights that are not ± 1 are of the form $2w_j^{(l)}$, $2(w_0^{(l)} + jp \pm m)$, or $2(w_0^{(l)} + jp \pm 2m)$. All the $w_i^{(l)}$ are reduced modulo some prime p that is among the first $2m^2 = O(\log^6 W)$ primes. This implies that $p \leq O(\log^7 W)$. Since $-\lfloor (n+1)/2 \rfloor \leq j \leq \lceil (n+1)/2 \rceil$, the weights are all of magnitude $O(\log^8 W)$.

If we assume Muroga's bound on weights to hold for the original threshold gate f, then $\log W \leq O(n \log n)$, and hence we have a polynomial-size, polynomial-weight threshold circuit of depth 2 that computes $f(x)$. Actually, we need only to have $\log W$ polynomial in n. □

5. Extending the construction to circuits. In the previous section we showed that a single threshold gate can be simulated by a polynomial-size majority circuit. We will now generalize this to show that a depth-d, polynomial-size threshold circuit can be simulated by a depth-$d+1$, polynomial-size majority circuit.

In [10] Goldmann, Håstad, and Razborov introduced a circuit class that mixes small and large weights.

DEFINITION 5.1. *$\widetilde{LT}_d$ is the class of functions computable by depth-d, polynomial-size circuits where the top gate has polynomially bounded weights.*

We will show the following theorem.

THEOREM 5.2. *For any depth d, possibly depending on n, $\widetilde{LT}_d = \widehat{LT}_d$. Moreover, given an $\widetilde{LT}_d$ circuit, for input size n, with weights bounded by $2^{p(n)}$ for some polynomial p, there is an explicit $\widehat{LT}_d$ circuit that computes the same function.*

COROLLARY 5.3. *For any depth d, possibly depending on n, $LT_d = \widehat{LT}_d + 1$. Moreover, given an LT_d circuit, for input size n, with weights bounded by $2^{p(n)}$ for some polynomial p, there is an explicit $\widehat{LT}_d + 1$ circuit that computes the same function.*

Proof. Make the LT_d circuit into an $\widetilde{LT}_d + 1$ circuit by adding a dummy gate with the output-gate of the LT_d circuit as its only input and give this input weight 1. By Theorem 5.2 the $\widetilde{LT}_d + 1$ circuit can be turned into an $\widehat{LT}_d + 1$ circuit. □

It remains to prove the theorem.

Proof of Theorem 5.2. Let us look at a circuit C for an $\widetilde{LT}_d$-function. For simplicity, assume that the weights at the top gate are all 1. Let the top gate be given by

$$g(x) = \operatorname{sign}\left(\sum_{i=1}^{t} C_i(x)\right),$$

where the C_i are depth-$d-1$ threshold circuits. Let s be the size of C. For each circuit C_i we construct an approximator $\Gamma_i^{\alpha,p}$. Below we describe how this is done.

Let $w_{\max}(C)$ be the largest magnitude of a weight of the circuit C, and let $W = \max\{w_{\max}(C), 2^s\}$. Let C_k be one of the subcircuits of g. Let the gates of C_k be $f_1, \ldots, f_r$, where $r \le s$. The fan-in of any f_i is trivially bounded by $\log W$, and all gates have their weights bounded by W. Set the parameter m of the previous section as follows:

$$m = 256 s\, t \log^3 W.$$

For $(\alpha, p) \in [m] \times \mathcal{PR}^m$, construct a gate approximator $\varphi_i^{\alpha,p}$ for each gate f_i. Now, connect the approximators in the same way as the gates. That is, if the output of f_i is the kth input to f_j, then the output of $\varphi_i^{\alpha,p}$ is the kth input to $\varphi_j^{\alpha,p}$. We call the constructed "circuit" $\Gamma_k^{\alpha,p}$. Note that for any fixed input x, if (α, p) is simultaneously good for x in all $\varphi_i^{\alpha,p}$ of $\Gamma_k^{\alpha,p}$, then $\Gamma_k^{\alpha,p}(x) = C_k(x)$.

LEMMA 5.4. *For any fixed input x, if (α, p) is chosen uniformly at random from $[m] \times \mathcal{PR}^m$, then* $\mathrm{Pr}\Gamma_{\mathrm{k}}^{\alpha,\mathrm{p}}(\mathrm{x}) \neq \mathrm{C_k(x)} \le (8\mathrm{t}\log \mathrm{W})^{-1}$.

Proof. We know that each gate f_i of C_k has fan-in bounded by $\log W$, and will give the correct output if (α, p) is good. By Lemma 4.8, the probability that (α, p) is bad is $(8s\,t \log W)^{-1}$ by the choice of m. Since there are at most s gates in C_k, the lemma follows. □

We say that (α, p) is good for x and $\Gamma_k^{\alpha,p}$ if it is good for all gate approximators $\varphi_i^{\alpha,p}$ of $\Gamma_k^{\alpha,p}$ simultaneously.

What happens when (α, p) is bad for $\Gamma_k^{\alpha,p}$? The magnitude of the output of $\Gamma_k^{\alpha,p}$ is bounded by the maximum output of the approximator of the top gate of C_k. Using Corollary 4.3, we have for all x and all (α, p),

$$|\Gamma_k^{\alpha,p}(x)| \le 2 + 3 \log W. \tag{10}$$

Since the corollary holds even when the inputs to the top gate are integers, this bound holds even when some other approximator in $\Gamma_k^{\alpha,p}$ fails.

If we combine Lemma 5.4 and (10) we get the following lemma.

LEMMA 5.5. *For any fixed input x, if (α, p) is chosen uniformly at random from $[m] \times \mathcal{PR}^m$, then $|\mathrm{E}[\Gamma_{\mathrm{k}}^{\alpha,\mathrm{p}}(\mathrm{x})] - \mathrm{C_k(x)}| \leq \frac{1}{2t}$.*

Do the same for all the circuits C_i to get approximators $\Gamma_i^{\alpha,p}$. Consider the following function:

$$h(x) = \operatorname{sign}\left(\sum_{i=1}^{t} \sum_{(\alpha,p)} \Gamma_i^{\alpha,p}(x)\right).$$

Observe that this is equivalent to

$$h(x) = \operatorname{sign}\left(E\left[\sum_{i=1}^{t} \Gamma_i^{\alpha,p}(x)\right]\right). \tag{11}$$

We claim the following.

PROPOSITION 5.6. *For all inputs x, $h(x) = g(x)$.*

Proof. By (11) and the fact that $\left|\sum_{i=1}^{t} C_i(x)\right| \geq 1$, it is sufficient to show that

$$\left|\mathrm{E}\left[\sum_{i=1}^{t} \Gamma_i^{\alpha,p}(x)\right] - \sum_{i=1}^{t} C_i(x)\right| \leq 1/2.$$

This inequality follows by straightforward application of Lemma 5.5. □

An argument analogous to that in the previous section shows that $g(x)$ can be implemented as a depth-d threshold circuit. We call the circuit $\widehat{C}$. It is not hard to see that each wire in C corresponds to polynomially (in $\log W$) many wires in $\widehat{C}$.

To get integer weights in the circuit it is sufficient to multiply all weights by 2. The weights all have magnitude bounded by order of the largest prime used multiplied by s. The largest prime in $\mathcal{PR}^m$ has size $O(m^2 \log m)$, so the weights are all $O(s^3 t^2 \log^6 W(\log(st) + \log\log W))$. This completes the proof of Theorem 5.2.

Just as before, the construction is polynomial in n as long as $\log W$ is polynomial in n. By Theorem 2.1, this is always possible. □

6. Uniform computations. In addition to being explicit, the constructions given in this paper also preserve the uniformity conditions of the classes of circuits. The constructions of sections 4 and 5 yield the following.

THEOREM 6.1. *Given any q-uniform class of threshold circuits $\{C_n\}$ of depth d and polynomial size, $q \in \{L, P\}$. There exists an algorithm running in logspace that, given a description of a circuit C_n of depth d and polynomial size, will output the description of a small-weight threshold circuit C'_n of depth $d+1$ and a polynomial size such that $f_{C_n} = f_{C'_n}$ for all $n \geq 0$.*

We have also the following corollary.

COROLLARY 6.2.

$$L\text{-uniform } LT_d \subseteq L\text{-uniform } \widehat{LT}_{d+1},$$
$$P\text{-uniform } LT_d \subseteq P\text{-uniform } \widehat{LT}_{d+1}.$$

Proof. For P-uniformity the proof is very simple: generate the large-weight circuit and then translate it to a small-weight circuit using Theorem 6.1.

To prove the result for L-uniformity we use the following lemma.

LEMMA 6.3. *A family of circuits is L-uniform if and only if there is a Turing machine that on input n outputs $\overline{C}_n$ using space $O(\log n)$.*

Proof. Assume that we have an L-uniform family of circuits $\mathcal{C}$, that is, we have a machine M that recognizes the language $L_{\mathcal{C}}$. Let $\overline{C}_n$ be the description of the circuit for input size n.

There are constants c and c' such that each $(n, g) \in L_G$ has at most $c(1+\log(n+1))$ bits, and each $(n, e, v, g, k, \delta) \in L_E$ has at most $c'(1 + \log(n + 1))$ bits. Consider the machine M' that, given n, runs through all possible tuples with n as the first component and outputs those that belong to $L_{\mathcal{C}}$. This will output $\overline{C}_n$. The space required is $O(\log n)$ plus the space used by M and the time is polynomial in n times the time used by M. Thus, we have proved the "only if" part of the lemma.

Next we consider the case when there is a machine M that on input n generates $\overline{C}_n$. Let us construct a machine M' that works as follows. When given an input tuple, say (n, g) for instance, it checks if $|(n, g)| > c(1 + \log(n + 1))$ and, if so, it rejects; otherwise it runs M on input n and checks the output of M "on-line," and if (n, g) is produced then M' accepts; otherwise it rejects. Clearly, M' recognizes $L_{\mathcal{C}}$. Also, M uses space $O(\log n)$ plus the space used by M and time polynomial in n plus the time used by M. We have now proved the "if" part of both statements and the proof of the lemma is complete. □

The following argument completes the proof of the corollary. If a family of (large-weight) threshold circuits is L-uniform, then by Lemma 6.3 there is a machine that generates $\overline{C}_n$ in space $O(\log n)$. By Theorem 6.1 this description can be translated to a description of an equivalent small-weight circuit in space $O(\log n)$. Applying the lemma again, in the other direction, we see that the family of small-weight circuits is also L-uniform. □

It remains to prove Theorem 6.1. Below we explain how, given a polynomial-size description of a large-weight threshold circuit, one can construct a description of an equivalent small-weight threshold circuit with one extra level of gates. It will be clear that all the necessary computations can be carried out in space $O(\log n)$. In order to conform with the notation used so far, we allow weights of the form $w/2$, where w is an integer. However, as stated before, if all weights in the circuit are multiplied by 2, then the circuit has integral weights.

In what follows

- α ranges over $[m]$,
- p ranges over $\mathcal{PR}^m$,
- l ranges from 0 to $\lfloor 3 \log W \rfloor + 1$,
- j ranges from $-\lfloor (n+1)/2 \rfloor$ to $\lceil (n+1)/2 \rceil$,
- β ranges over $\{-1, 1\}$,
- γ ranges over $\{1, 2\}$,
- g is a gate label in a large-weight circuit,
- and e is an edge label in a large-weight circuit.

The parameters α through γ correspond to the threshold gates in an approximator for a large-weight gate, since the approximator can be written on the following form (for fixed α and p):

$$\sum_{l,j,\beta,\gamma} \frac{3 - 2\gamma}{2} \operatorname{sign}\left(\Phi_{(l)}^{\alpha,p} + jp + \beta\gamma m - \frac{\gamma}{2}\right). \tag{12}$$

Note that the summation over β and γ corresponds to the four terms in the function M^m. The idea now is that for each (large-weight) gate in the original circuit, we

construct the collection of gates in (12), and for each edge between two gates in the original circuit we construct edges between the corresponding sets of small-weight gates in the new (small-weight) circuit.

We use g and e for gate labels and edge labels of the large-weight circuit, and we use $\hat{g}$ and $\hat{e}$ to denote labels in the small-weight circuit. To describe the construction it is convenient to define *labeling functions*. We have functions $\lambda_g(n, g, \alpha, p, l, j, \beta, \delta)$ (to generate new gate labels), $\lambda_e(n, e, \hat{g}', \hat{g})$ (to generate new edge labels), $\lambda_1(n, \hat{g})$, and $\lambda_t(n, \hat{g})$ (which also generate edge labels). We also use $\hat{g}_t$ as the label of the top gate of the new circuit. We will assume that

1. the functions are linear space computable (i.e., space $O(\log n)$),
2. the size of the output is linear in the size of the input (i.e., size $O(\log n)$),
3. the functions λ_e, λ_1, and λ_t have pairwise disjoint images,
4. the set I_n is disjoint from the image of λ_g,
5. $\hat{g}_t$ is not in I_n or in the image of λ_g,
6. the functions are one-to-one.

Such functions are easy to find and we will not concern ourselves with the exact implementation of them.

The translation works as follows:

1. Compute the size s of the large-weight circuit and find the largest k-value of any edge and call this $k_{\max}$.
2. Compute $L = \max\{s, k_{\max}\}$ (note that $W = 2^L$).
3. Compute $m = 256sL^3$.
4. Output $(n, \hat{g}_t)$.
5. For each gate (n, g) we output a collection of gates that corresponds to the threshold functions of (12) for each value of α and p:

```
for each (α, p) ∈ [m] × PR^m
    for each l ∈ {0, 1, ..., 3L + 1}
        for each j ∈ {−⌊(n + 1)/2⌋, ..., ⌈(n + 1)/2⌉}
            for each (β, γ) ∈ {−1, 1} × {1, 2}
                ĝ ← λ_g(n, g, α, p, l, j, β, γ)
                output (n, ĝ)
                ê ← λ_1(n, ĝ)
                w ← jp + βγm − β/2
                output (n, ê, 1, ĝ, |w|, sign(w))
```

6. For each edge (n, e, v, g, k, δ) construct a collection of new edges. How this is done depends on whether v is an input or a gate.
   If v is an input, then it must be fed, with the appropriate weight, to all of the gates that are constructed from g in the previous step.

```
for each (α, p) ∈ [m] × PR^m
    for each l ∈ {0, 1, ..., 3L + 1}
        for each j ∈ {−⌊(n + 1)/2⌋, ..., ⌈(n + 1)/2⌉}
            for each (β, γ) ∈ {−1, 1} × {1, 2}
                ĝ ← λ_g(n, g, α, p, l, j, β, γ)
                ê ← λ_e(n, e, v, ĝ)
                w ← ⌊αγδm2^{k−l}⌋ rem p
                output (n, ê, v, ĝ, |w|, sign(w))
```

   If, on the other hand, we have an edge (n, e, g', g, k, δ) between two gates, the situation is quite similar, except that many of the gates that g' gives rise to are connected to many of the gates that g gives rise to.

```
for each (α, p) ∈ [m] × PR^m
```

```
for each (l, l') ∈ {0, 1, ..., 3L + 1}^2
    for each (j, j') ∈ {−⌊(n + 1)/2⌋, ..., ⌈(n + 1)/2⌉}^2
        for each (β, β', γ, γ') ∈ {−1, 1}^2 × {1, 2}^2
            ĝ ← λ_g(n, g, α, p, l, j, β, γ)
            ĝ' ← λ_g(n, g', α, p, l', j', β', γ')
            ê ← λ_e(n, e, ĝ', ĝ)
            w ← ⌊α(3 − 2γ)γδm2^{k−l−1}⌋ rem p
            output (n, ê, ĝ', ĝ, |w|, sign(w))
```

7. Finally, let g_t be the top gate of the original circuit. Each gate that is produced from g_t in step 5 is to be fed with weight 1 to $\hat{g}_t$, the top gate of the new circuit.

```
for each (α, p) ∈ [m] × PR^m
    for each l ∈ {0, 1, ..., 3L + 1}
        for each j ∈ {−⌊(n + 1)/2⌋, ..., ⌈(n + 1)/2⌉}
            for each (β, γ) ∈ {−1, 1} × {1, 2}
                ĝ ← λ_g(n, g_t, α, p, l, j, β, γ)
                ê ← λ_t(n, ĝ)
                output (n, ê, ĝ, ĝ_t, 1, 1)
```

Except for the calculation of w in step 6 it is immediately clear that the computations involved can be carried out in space $O(\log n)$. This is true also for the weight computation. For $\lfloor \alpha\gamma\delta m 2^{k-l} \rfloor$ rem p, note that $\alpha\gamma m$ can be represented with $O(\log n)$ bits, and that when $k < l$ then so can $\lfloor \alpha\gamma\delta m 2^{k-l} \rfloor$. When $k \geq l$, then $\alpha\gamma\delta m 2^{k-l}$ is an integer, and computing 2^{k-l} rem p is easily done in space $O(p + k + l) = O(\log n)$.

7. Conclusions and open problems. Our results entail the first explicit constructions for the optimal-depth, polynomial-size majority circuits for the number of basic functions including, among others, *powering* (depth 3), *integer multiplication* and *integer division* (depth 3); see [27] and [4].

More generally, our results entail the *uniformity* of the classes of majority circuits simulating the corresponding classes of *threshold circuits*. We look at the following functions.

ADDITION: given two n-bit numbers, compute their sum.

MULTIPLE ADDITION: given n n-bit numbers, compute their sum.

MULTIPLICATION: given two n-bit numbers, compute their product.

MULTIPLE MULTIPLICATION: given n n-bit numbers, compute their product.

DIVISION: given a $2n$-bit numbers x and an n-bit number y, compute $\lfloor x/y \rfloor$.

SQUARING: given an n-bit number x, compute x^2.

POWERING: given an n-bit number x and a $\log n$-bit number y, compute x^y.

COMPARISON: given two n-bit numbers x and y, decide if $x \geq y$.

MAXIMUM: given n n-bit numbers, output the largest one.

SORTING: given n n-bit numbers, output them in sorted order.

The following table surveys the uniform upper bounds known before and stemming from the present paper and compares them with the best-known (nonuniform) lower bounds. Most of the constructions follow from nonuniform versions in [27] and [26] (see also [22]). The uniform constructions for ADDITION, COMPARISON, and SORTING follow from [3].

Function	Uniform Depth Upper Bound	Lower Bound
ADDITION	2,L-uniform	2
MULTIPLE ADDITION	2,L-uniform	2
MULTIPLICATION	3,L-uniform	3 [11]
MULTIPLE MULTIPLICATION	4,L-uniform	3 [11]
DIVISION	3,P-uniform	3 [33]
SQUARING	3,L-uniform	3 [33]
POWERING	3,P-uniform	2 [33]
COMPARISON	2,L-uniform	2 [25]
MAXIMUM	3,L-uniform	2
SORTING	3,L-uniform	3 [26]

We conclude with a list of open problems:

1. If the original circuit is monotone, our construction yields a nonmonotone majority circuit. It is an open question if an arbitrary monotone threshold gate can be simulated by constant-depth monotone majority circuits of polynomial size.
2. Alternating Turing machines are closely connected to circuits with AND-gates and OR-gates, and counting Turing machines are connected to majority circuits. Is there a reasonable machine model that has such a relationship to threshold circuits? If so, what would be the corresponding notion of uniformity, and would our simulation still work?
3. Are there any strong lower bounds for depth-2 threshold circuits or depth-3 majority circuits computing some explicit function?

Acknowledgments. We are grateful to Johan Håstad and Ingo Wegener for many valuable comments on earlier versions of this paper. We also thank Jens Lagergren, Sasha Razborov, and Avi Wigderson for several helpful discussions on the topic of this paper. Finally, we thank the referees for careful reading and for numerous helpful suggestions and comments.

FULLY POLYNOMIAL BYZANTINE AGREEMENT FOR $n > 3t$ PROCESSORS IN $t + 1$ ROUNDS*

JUAN A. GARAY† AND YORAM MOSES‡

Abstract. This paper presents a polynomial-time protocol for reaching Byzantine agreement in $t + 1$ rounds whenever $n > 3t$, where n is the number of processors and t is an a priori upper bound on the number of failures. This resolves an open problem presented by Pease, Shostak, and Lamport in 1980. An early-stopping variant of this protocol is also presented, reaching agreement in a number of rounds that is proportional to the number of processors that actually fail.

Key words. Byzantine agreement, consensus, distributed computing, fault tolerance, computer security

1. Introduction.

The Byzantine agreement (BA) problem, introduced by Pease, Shostak, and Lamport in [22], is recognized as a fundamental problem in fault-tolerant distributed computing. Over the last decade or more, the problem has received a great deal of attention in the literature, and has become a testbed for a variety of models for distributed computing (see [15] for an early survey on the subject). While BA has been studied extensively over the years, the original model in which faulty processors can act in arbitrarily malicious ways has continued to withstand a complete analysis. In [22], the authors presented a protocol that solves the problem (then still referred to as the *interactive consistency problem*) in $t + 1$ rounds whenever $n > 3t$. Here n is the total number of processors and t is an a priori upper bound on the number of faulty processors possible. They also proved that no solution for $n \leq 3t$ exists, while Fischer and Lynch later showed that $t + 1$ rounds were necessary in the worst-case run of any BA protocol [16]. The protocol presented in [22], however, required the processors to send exponentially long messages and perform exponentially many steps of computation. The design of more efficient protocols is presented in [22] as an open problem, and has been the subject of many subsequent papers. This paper presents a BA protocol for $n > 3t$ that halts in $t+1$ rounds and uses only a polynomial amount of communication and computation.

This work is based on a long sequence of papers whose goal was to reduce the complexity of the protocol while maintaining good performance in terms of the number of rounds necessary for agreement. Polynomial-time BA protocols for $n > 3t$ that halt in more than $2t$ rounds (see, e.g., [11, 24]) have been known as of 1982. In 1985 Coan presented a family of BA protocols for $n > 4t$ that, for every d, halt in $t + t/d$ rounds, and require messages of size $O(n^d)$ [8]. However, Coan's protocols require ex-

ponential local computation. Bar-Noy, Dolev, Dwork, and Strong later improved on this result, providing protocols with essentially the same round and communication behavior, but requiring only polynomial computation [2]. These protocols thus provide a tradeoff between the number of rounds required and the size of messages used, and prove that $2t$ rounds are not necessary for polynomial-time BA protocols. $(t+1)$-round polynomial-time BA protocols for $n = \Omega(t^2)$ were presented in 1986 by Dolev, Reischuk, and Strong [13]. In 1988 Moses and Waarts presented the first polynomial $(t+1)$-round protocol with linear resilience. It required only that $n > 8t$ and was later improved to handle $n > 6t$ [21]. In 1989 Berman and Garay presented a polynomial protocol for $n > 4t$ [3], which they improved in 1991 to handle $n > (3+\epsilon)t$ for any $\epsilon > 0$ [4]. At the cost of requiring more processors ($\Omega(t \log t)$), Coan and Welch developed a polynomial protocol that uses one-bit messages and asymptotically optimal total bit transfer [10]. Table 1 presents a summary of these and related results.

Our work starts out using observations and techniques developed in [2, 21, 3]. In particular, we start from the formulation by Bar-Noy et al. of the exponential protocol for $n > 3t$ in terms of a two-stage process. In the first stage, processors exchange information for $t+1$ rounds, and each processor stores the information it receives in a treelike data structure. In the second stage, each processor computes *resolved* values for each node in a bottom-up fashion, where the resolved value of a node is a function of the resolved values of its children in the tree. The resolved value of the root of the tree is the value the processor decides on. In order to obtain our result, we need to develop new techniques to handle the great powers that faulty processors have when $n > 3t$. In particular, we study the class of functions that can serve in the second stage of the algorithm for computing resolved values for the nodes. We present a new class of *admissible* resolve functions, that alternate between favoring the value 0 at one level of the tree and favoring 1 at the next level. By extending the methods for fault detection and fault masking used, we are able to present a particular admissible resolve function, which restricts the freedom of faulty processors. Given these methods, this function forces the number of processors that are detected as faulty by all nonfaulty processors to be large in runs in which the processors' trees grow exponential. This in turn makes it possible to apply a monitor voting technique along the lines of the cloture votes technique of Berman and Garay [3] to obtain a polynomial BA protocol.

A few comments are in order regarding the related *randomized* Byzantine agreement problem. Rabin showed that a shared coin can be used to attain randomized

agreement in a constant number of rounds [23]. Later, Feldman and Micali presented an algorithm for constructing such a coin, thereby providing an optimal protocol for this problem [17]. In the protocol of [17], however, the decision property was guaranteed only with probability 1, and the protocol has runs in which no processor ever reaches a decision. Moreover, there is no finite bound K, such that the processors that do decide, do so in K rounds. Indeed, there is no obvious way to transform such a probabilistic protocol into a polynomial protocol in which nonfaulty processors never violate the conditions of Byzantine agreement (agreement and validity), and yet they all decide in fewer than $t+1$ rounds with probability 1. A very close approximation of this was obtained by Goldreich and Petrank [19]. They presented a probabilistic Byzantine agreement protocol with a constant expected number of rounds that is guaranteed to always halt in $t + O(\log t)$. Their protocol is based on a sequential combination of a probabilistic protocol with a deterministic $(t+1)$-round protocol. Before our paper, their scheme, when applied to the case of $n > 3t$, would yield a protocol with an exponential worst-case complexity in terms of both computation and communication. Using our protocols in their scheme, it is now possible to obtain such a probabilistic protocol for $n > 3t$ with polynomial-time worst-case complexity. Using different techniques, Zamsky has recently improved to $t+1$ the worst-case running time of [19], while maintaining linear, but nonoptimal, resiliency [27].

The remainder of the paper is organized as follows. In section 2 we describe the model and formally define the problem. In section 3 we review EIG, the exponential information gathering protocol of Bar-Noy et al. In section 4 we review the techniques that made polynomial-time protocols possible for $n > 4t$. Section 5 is the first step towards a polynomial solution for $n > 3t$. We introduce a general, radically different class of resolve functions. This class of functions is then used in section 6 as the basis of a protocol for a slightly generalized version of Byzantine agreement. In section 7 we present the concrete function of our choice, while in section 8 we present `Sliding-flip`, the polynomial-time protocol for $n > 3t$. Finally, in section 9 we modify the protocol so as to terminate in $\min\{t+1, f+3\}$ rounds, where $f < t$ is the actual number of failures that occur in the run.

2. Preliminary definitions. For ease of exposition of our protocols we shall be concentrating on the following variant of Byzantine agreement, sometimes also called the *consensus* problem, which is defined as follows: given are n processors, at most t of which might be faulty. Each processor i has an initial value $v_i \in \{0,1\}$. Required is a protocol with the following properties:

(i) Decision: Every nonfaulty processor i eventually irreversibly "decides" on a value $d_i \in \{0,1\}$.

(ii) Agreement: The nonfaulty processors all decide on the same value.

(iii) Validity: If the initial values v_i of all nonfaulty processors are identical, then $d_i = v_i$ for all nonfaulty processors i.

In the other common variant of Byzantine agreement there is a distinguished leader with a single initial value v. The agreement and decision conditions remain the same, while the validity condition requires that if the leader is nonfaulty, all nonfaulty processors should decide on the leader's value v. Protocols for both variants are practically identical, and everything we say here applies to the single leader case with only minor modifications.

Throughout the paper we use t to denote an upper bound on the number of faulty processors. We assume the standard model for Byzantine agreement, in which processors may fail in arbitrarily malicious ways (see, for example, [16]). Each proces-

sor can communicate directly with every other processor via a reliable point-to-point channel. Finally, the processors are synchronous and their communication proceeds in synchronous rounds. In a round, a processor can send one message to each of the other processors, and all messages are received in the round in which they are sent.

3. Exponential information gathering protocols. We start by describing the exponential protocol due to Bar-Noy et al. [2] (Exponential Information Gathering (EIG)), which is closely related to the original protocol of Pease, Shostak, and Lamport [22]. Our final protocol will be obtained by a sequence of transformations to this protocol, based on distinct observations. Our description of the EIG protocol below is essentially taken from Bar-Noy et al. [2].

In the first round of the EIG protocol for Byzantine agreement, each processor broadcasts its initial value v_i to all other processors. In each of the following t rounds, every processor broadcasts all of the information it received in the latest round. At the end of $t+1$ rounds each processor computes a decision value based on the information it has gathered, decides on this value, and halts.

We now describe the protocol in greater detail. Each processor incrementally constructs a tree-based data structure which we will call an EIG *tree*. We consider the root of the tree to be a node of *depth* 0, and inductively define the depth of a node to be greater by one than the depth of its parent. We will only be interested in EIG trees of depth at most $t+1$. In the EIG tree, a node of depth r has $n-r$ children. Thus, in particular, the root has n children. The edges of the EIG tree are labelled with processor names as follows. The outgoing edges of the root are labelled $1, \ldots, n$, respectively. A node of depth $r \geq 1$ has an edge labelled i for every processor name i that does not appear on the path leading from the root to the node. Notice that with this definition no label appears twice on a path from the root to a leaf. It follows that the sequence of labels on the path from the root to a given node uniquely determines this node. Moreover, there is a 1–1 correspondence between strings σ of up to $t+1$ distinct processor names and the nodes in an EIG tree of depth $t+1$. We will thus regard such a string as the *name* of the corresponding node, and refer to nodes by such names. The root is named by λ, which stands for the empty string. Notice that the length of the string σ, which we shall denote by $|\sigma|$, coincides with the depth of σ.

We shall ultimately associate two values with each node σ in a processor i's tree: a *stored value*, denoted by $\mathtt{tree}(\sigma)$, and a *resolved value* denoted by $\mathtt{res}(\sigma)$. When we need to specify the particular processor i in whose tree these values appear, we denote them by $\mathtt{tree}_i(\sigma)$ and $\mathtt{res}_i(\sigma)$, respectively. The stored values are assigned during the $t+1$ rounds of information exchange between the processors, while the resolved values are computed at the end, in order to determine the decision value. The manner in which these values are arrived at is described below. A node σj is said to *correspond* to the processor j whose name labels the edge leading to the node from its parent σ. We call a node of the EIG tree *correct* if it corresponds to a nonfaulty processor.

Each processor i initially stores its initial value v_i in $\mathtt{tree}_i(\lambda)$—at the root of its EIG tree. In the first round of the EIG protocol a processor will send the value stored in its root to all n processors (including itself, although of course this message need not actually be sent). For every processor j, the value that j sends to i in the first round will be stored in the node $\langle j \rangle$ of $\mathtt{tree}_i$ (a default value of 0 will be stored in $\mathtt{tree}_i(\langle j \rangle)$ in case processor j does not receive a legitimate message with a value from j). In each subsequent round every processor sends to all other processors the level of its tree most recently filled in. (Note that a faulty processor may of course send

different values than the ones it should send, and also may send conflicting messages to different processors in the same round.) The messages received are broken up and used to form a new level in the processor's tree as follows: If j's message reports the value v for the node σ, and j does not appear in σ, then the value v will be stored at the node σj. Again, we store a default value of 0 in σj in case j did not report a legitimate value for σ (that is, if j did not send a message that is in the syntax appropriate for messages sent in this round). Intuitively, the node σj in $\texttt{tree}_i$ stores the value that j claims in its message to i to have stored in $\texttt{tree}_j(\sigma)$. Notice that the single message received by i from j in a given round reports on the values of many nodes in j's tree, and will be used to update many different nodes in $\texttt{tree}_i$.

We consider a node to be *created* in the round in which a value is stored in the node. In the first stage of the EIG protocol, information is gathered for $t+1$ rounds, until all nodes of depth up to $t+1$ are created. At that point each processor computes a value for the tree by applying the recursive computation of $\texttt{res}_i(\cdot)$ to the root λ. The processor then "decides" on the value of $\texttt{res}(\lambda)$, and halts. For the purpose of the current section and the next one, the particular function used for $\texttt{res}(\cdot)$ is *recursive majority voting*, defined as follows:

$$\texttt{res}_i(\sigma) = \begin{cases} \texttt{tree}_i(\sigma) & \text{if } \sigma \text{ is a leaf;} \\ 1 & \text{if majority of } \texttt{res}_i(\sigma j) \text{ are 1;} \\ 0 & \text{otherwise.} \end{cases}$$

Thus, $\texttt{res}_i(\sigma)$ computes the value of the recursive majority of the descendants of the node σ in $\texttt{tree}_i$. This completes the description of the EIG protocol. Bar-Noy et al. prove the following theorem.

THEOREM 3.1 (see Bar-Noy et al. [2]). *Protocol* EIG *solves the Byzantine agreement problem for* $n > 3t$.

4. Polynomial protocols for $n > 4t$. While the EIG protocol is a correct $(t+1)$-round BA protocol for $n > 3t$, it has a major drawback in requiring messages and local memory of exponential size. In fact, *every* run of this protocol is exponential. Nevertheless, the clean structure provided by the EIG tree will allow us to apply a sequence of transformations to this protocol, and to finally arrive at a polynomial protocol. In this section we shall present the basic observations that lead to a polynomial protocol in the case of $n > 4t$. In section 5 we shall highlight the problems and discuss the modifications required in the case of $n > 3t$. This will require a careful analysis and new techniques. In particular, we shall introduce a new class of resolve functions, which are instrumental in achieving a polynomial protocol for $n > 3t$.

4.1. Predicting resolved values. The first step is based on an observation due to Moses and Waarts in [21]. A processor i can often determine early on what the value of $\texttt{res}_i(\sigma)$ in the EIG protocol will be. This is commonly called *prediction*. Roughly speaking, once i is able to predict the resolved value of σ, it can stop gathering information about the whole subtree of $\texttt{tree}_i$ rooted at σ. One basis for prediction is the following lemma that is used in the proof of Theorem 3.1.

LEMMA 4.1 (see Bar-Noy et al. [2]). *Let $n > 3t$, let i and j be nonfaulty processors, and let σ be a node of depth $|\sigma| \leq t$ such that j does not appear in σ. Then at the end of round $t+1$ we have $\texttt{res}_i(\sigma j) = \texttt{tree}_i(\sigma j) = \texttt{tree}_j(\sigma)$.*

As discussed in [21] if, for example, *majority* $+t-1$ children of σ store the same value v in $\texttt{tree}_i$, then i knows that at least majority of children of σ are correct and store v. Hence, by Lemma 4.1 we get that the majority of $\texttt{res}_i(\sigma j)$ values will be v. The definition of the resolve function now implies that we will end up with

$\texttt{res}_i(\sigma) = v$. Following [21], we will say in this case that the value of σ is *fixed to* v *for* i once σ's children in $\texttt{tree}_i$ have been created. Another case in which the resolved value of a node can be predicted is when a majority of its children become fixed to the same value. We also define a node σ to be *closed* in $\texttt{tree}_i$ at the end of round r if either σ or one of its ancestors is fixed in $\texttt{tree}_i$ at that time. The properties of prediction in the case of $n > 4t$ are described in the following two statements.

LEMMA 4.2 (see Moses and Waarts [21]). *Assume $n > 4t$, let σ be a correct node with $|\sigma| \leq t$, and let i be a nonfaulty processor. Then σ is closed in $\texttt{tree}_i$ by the end of round $|\sigma| + 1$.*

COROLLARY 4.3 (see Moses and Waarts [21]). *Assume $n > 4t$ and let i and j be nonfaulty processors. In the* EIG *protocol, if σ is fixed for i at the end of round r, then σ is closed in $\texttt{tree}_j$ at the end of round $r + 1$ at the latest.*

An immediate implication of Corollary 4.3 is that a nonfaulty processor need report on descendants of a node for at most one round after it can determine that the node is fixed to some value. No further information it can send about the subtree of that node will help anyone determine its final resolved value. In particular, once the root becomes fixed in $\texttt{tree}_i$, processor i knows the decision value and needs to send information for at most one more round. Moses and Waarts [21] use this to devise an early-stopping BA protocol for $n > 4t$. This protocol is still exponential, although it is significantly more efficient than the one that constructs the full EIG tree. Moreover, there are many cases in which the tree is polynomial in size. In fact, in the common case in which no failures arise, the protocol ends after two rounds, and the amount of communication sent by a processor is $O(n)$ in the case of single-source BA and $O(n^2)$ in the consensus case.

Lemma 4.2 provides some insight into the relationship between the size of the EIG trees (and hence the complexity of computation and communication) in a given run of the early-stopping BA algorithm and the behavior of the faulty processors during that run. Let us call a node σ *corrupted in* $\texttt{tree}_i$ if σ is not closed in $\texttt{tree}_i$ by the end of round $|\sigma| + 1$. Clearly, a noncorrupted node can have at most n children in the tree. In addition, it is not hard to check that a corrupted node can account for the need to store its grandchildren, but not for any later descendants. The total size of an EIG tree thus becomes roughly $O(n^2 C)$, where C denotes the number of corrupted nodes in the tree. It follows that if we are able to reduce the number of corrupted nodes, then the trees will shrink, and hence also the communication. (Indeed, the protocol of [21] managed, for $n > 8t$, to ensure that no processor is able to corrupt more than one node overall, and thus in all trees $C \leq t$.) A central tool in reducing the number of corrupted nodes turns out to be the detection and masking of faulty processors, which we now turn to discuss.

4.2. Detecting and masking failures. Lemma 4.2 implies that if σj is corrupted in $\texttt{tree}_i$, then processor i can detect that j is faulty immediately after it receives values for σj's children. Indeed, we shall see later on some other instances in which a processor i can detect another processor as faulty. Detecting failures is useful because of the following observation, which was first made by Dolev, Reischuk, and Strong [13] and later used in various ways in [8, 2, 21, 3] and others. Since faulty processors can send arbitrary messages, once we detect a processor as being faulty, we can act as if it sends us particular messages that may be to our advantage, ignoring what it actually sends us. This is called *fault masking*. One particularly simple form of fault masking is to regard a processor detected as faulty to send us a fixed value (e.g., 0) for all nodes of interest. As we shall see, this can help reduce the number

of corrupted nodes. Once all nonfaulty processors mask a given processor z, we say that z is *disabled*. Notice, in particular, that once z is disabled, nodes of the form σz can no longer be corrupted. They become fixed to the value being used for masking at the end of round $|\sigma z| + 1$.

Corollary 4.3 implies that unless σj is corrupted in all of the correct processors' trees, it will become closed (in all trees) at the end of round $|\sigma j| + 2$. It follows that in order for the subtree of σj to grow to a substantial size in some processor's tree, the node σj must be corrupted in *all* nonfaulty processors' trees. We will call a node *universally corrupted* if it is corrupted in all nonfaulty processors' trees. Another consequence of Corollary 4.3 is that the final size of an EIG tree is polynomial if and only if the number of universally corrupted nodes in the tree is polynomial. This follows from the fact that if the subtree of a universally corrupted node has more than n^3 nodes, at least one of the node's children must also be universally corrupted. If a node σj is universally corrupted, then everyone detects j as faulty at the end of round $|\sigma j| + 1$, and j becomes disabled from that point on. It cannot corrupt nodes in later rounds. It follows that when $n > 4t$, fault masking allows a faulty processor to universally corrupt nodes only during a single round. Moreover, Lemma 4.2 implies that if neither the node σj nor any of its ancestors is fixed in $\texttt{tree}_i$ by the end of round $|\sigma j|$, then all processor names appearing in the string σ denote faulty processors. This implies that once we employ early stopping and fault masking in the case of $n > 4t$, at least $3t$ of the children of any node of interest are nonfaulty. Moreover, at most $t - |\sigma|$ children of a node σj can be faulty. As a result, if processor i finds more than $t - |\sigma|$ values among the children of σj that differ from $\texttt{tree}_i(\sigma j)$, it can detect that j is faulty.

If no faulty processor universally corrupts a node in a given round r, then all nonfaulty processors decide by the end of round $r+1$. If only one processor universally corrupts nodes in each round (and we employ early stopping and fault masking), then the total size of the tree is polynomial. Following [3], we shall call ESFM (early stopping with fault masking) the protocol resulting from the combined application of the prediction and fault masking techniques to EIG. The ESFMprotocol significantly reduces the size of the EIG tree processors construct.[1] However, as discussed in [21], the trees may still grow exponential in general because (i) more than one processor can corrupt nodes in a given round, and (ii) a processor can corrupt many nodes in a given round. The final observation that will yield a polynomial protocol, at least in the case of $n > 4t$, is that when many processors universally corrupt nodes in a given round, it is possible for the nonfaulty processors to detect that something "fishy" is going on, and to decide to stop. How to do so is the subject of our next subsection.

4.3. Monitor voting. An important new idea was introduced by Berman and Garay in [3]. They proposed to have each processor observe the size of its tree, and when the size exceeds a certain threshold, to "vote" to stop the whole agreement procedure. Thus, roughly speaking, they started a new instance of Byzantine agreement in every round, in which a processor's initial value reflects whether or not the processor is in favor of stopping the process (and deciding on a default value). In order for any processor's tree to become exponential, all processors' trees must grow beyond any polynomial threshold. Should this happen, all nonfaulty processors would vote in favor of stopping and deciding on the default, and this instance of the agree-

[1] Using both techniques—prediction and fault masking—simultaneously reduces the tree from size $O(n^t)$ to $O(c^t)$ (see [21]). In [4] a more sophisticated masking technique yields a similar result for $n > 3t$.

ment protocol would stop in two rounds. In the [3] protocol, once such an agreement is attained, every nonfaulty processor decides on the default and halts, terminating its participation in all Byzantine agreement instances underway.[2] We think of the agreement instances initiated in every round of the [3] protocol as processes that *monitor* the run, ensuring that trees do not grow too much. Indeed, Berman and Garay showed that when performed in a careful way, the monitor voting technique yields the following theorem.

THEOREM 4.4 (see Berman and Garay [3]). *By applying monitor voting to the* ESFM *tree, it is possible to obtain a* $(t+1)$*-round polynomial-time BA algorithm for* $n > 4t$.

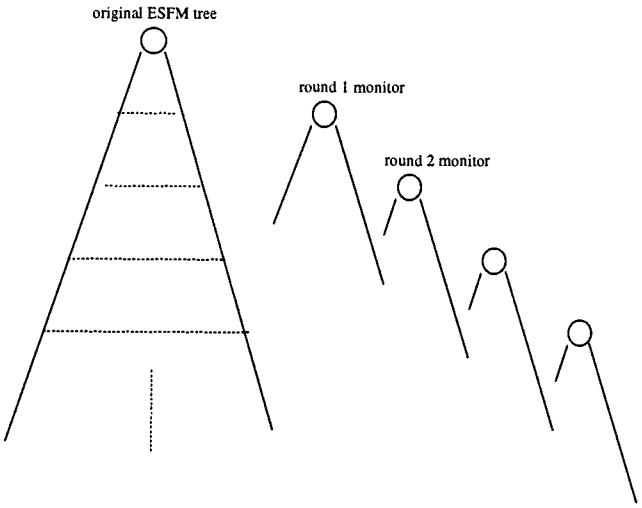

FIG. 1. *The monitor voting technique.*

The technique is illustrated in Figure 1. Monitor voting introduces a number of new subtleties.

(i) Once there are a number of agreement processes underway, we must be careful to ensure that processors use the individual agreements' values in a consistent way when determining their ultimate decision value. If, for example, one processor may decide 0 because its original information gathering tree stopped with value 0, while the other decides 1 because one of the monitors stopped with value 1, we are in trouble.

(ii) As monitor processes are initiated in different rounds of the execution, we need to take action to ensure that they all halt by time $t+1$. Otherwise, we may run into consistency problems as described above, when we are forced to decide at time $t+1$.

(iii) It may seem desirable to exclude faulty processors from participating in a monitor, in order to ensure the monitor halts in time. However, deciding that a given processor is faulty is as hard as Byzantine agreement itself. Techniques of [12] can be used to show that we cannot exclude processors "on the fly," as a result of failures being detected.

[2] This technique was called *cloture votes* by the authors, since it resembles a procedure in the U.S. Senate in which a vote can be called on whether the discussion on a given topic has been going on for too long.

The main tool that can be used to limit the damage caused by faulty processors is to use information about failures that a processor has gained in one agreement process to mask faulty processors in all agreement processes. It is crucial, however, to ensure that sufficiently many processors are *disabled* before a processor can vote in favor of stopping in a monitor agreement process. In fact, we shall use the following rule for determining the initial value of processor i in monitor process $\mathtt{M}^r$, which is the monitor agreement process initiated in round r:

Monitor-vote: Processor i will vote 1 on $\mathtt{M}^r$ if it has detected that $r-1$ faulty processors have corrupted nodes and are disabled by the end of round $r-1$; it will vote 0 on $\mathtt{M}^r$ otherwise.

In the case of $n > 4t$, it is possible to show that for the information gathering trees to grow large, the number of disabled processors must grow sufficiently fast to cause every nonfaulty processor to eventually vote 1 using this rule. This is the basis of the solution for $n > 4t$ given in [3]. Extending this idea to $n > 3t$, however, seems to be problematic, because the faulty processors have greater powers to corrupt nodes when $4t \geq n > 3t$.

5. Deriving a polynomial protocol for $n > 3t$. Our goal in this paper is to describe a polynomial BA protocol for $n > 3t$ that is guaranteed to terminate in $t+1$ rounds. Intuitively, the protocol follows the monitor voting approach presented in the previous section. In the case of $n > 3t$, however, most of the properties used when $n > 4t$ no longer hold. First of all, using the resolve function defined in section 4, the analogues of Lemma 4.2 and Corollary 4.3 fail, i.e., it is possible to show that when $n < 4t$ the majority function does not guarantee quick prediction of the value $\mathtt{res}(\sigma)$ even for correct nodes σ. (Indeed, we know of no constant number of generations of descendants for which `res` guarantees prediction of correct nodes.) In [25] Waarts presented prediction rules for a resolve function introduced by Bar-Noy et al. [2], and showed that they guarantee prediction in two rounds. In the case of $n > 4t$ we had the property that exponential size of trees requires many faulty processors to expose themselves (and hence become disabled) early in the run. Intuitively, we say that some faulty processors must be "wasted" for the adversary to be able to cause trees to grow exponential. This was crucial for the monitor voting scheme to succeed in keeping the trees polynomial. As we shall see, the fact that it sometimes takes nodes two rounds to fix when $n > 3t$ implies that there are often cases in which the tree can grow without requiring such waste to occur. The function used by Waarts in [25] is ternary, and it occasionally provides an "undecided" value for an internal node. This introduces enough "slack" into the information conveyed by the resolve function, that we were unable to use it successfully in the case of $n > 3t$. It seems possible for the adversary to cause the trees to grow exponential when that resolve function is used, without the number of disabled processors ever becoming large enough to be "caught" via monitor voting. A major focus of this paper is on deriving a resolve function and corresponding prediction and fault detection rules that will guarantee that exponential growth of the agreement trees will require sufficient waste to enable monitor voting to detect the problem and halt.

In the rest of this section we introduce a radically different class of resolve functions. This class of functions is then used in section 6 as the basis of a protocol for a slightly generalized version of Byzantine agreement. We end up chosing the precise function from this class in such a way that it guarantees that for the size of the EIG trees to grow beyond a polynomial bound, faulty processors must be disabled at a rate that is greater than one per round. This is the key point that enables us to perform

monitor voting for the case of $n > 3t$ in the spirit of the monitor voting we performed for $n > 4t$.

5.1. A general class of resolve functions. Let us denote the set $\{0, \ldots, j\}$ by $[j]$. For every function $F : [t] \to [n]$, we define a resolve function $\texttt{res}^F$ as follows:

$$\texttt{res}^F(\sigma) = \begin{cases} \texttt{tree}(\sigma) & \text{if } \sigma \text{ is a leaf;} \\ 1 & \text{if at least } F(|\sigma|) \text{ of } \texttt{res}^F(\sigma j) \text{ are 1;} \\ 0 & \text{otherwise.} \end{cases}$$

Notice that $\texttt{res}^F(\sigma) = 0$ if and only if $\#\{j : \texttt{res}^F(\sigma j) = 0\} \geq n - |\sigma| + 1 - F(|\sigma|)$. Moreover, notice that the original res function of [2] is simply $\texttt{res}^M$, where M is the majority function. Let us now turn to a straightforward observation regarding functions of this type. Let a *cut* through the EIG tree be a set C of nodes that intersects every path from the root to a leaf exactly once. One important property of resolve functions is that the values of a resolve function on the nodes of a cut uniquely determine its values on all nodes above it.

LEMMA 5.1. *Let C be a cut of the* EIG *tree, and let $F : [t] \to [n]$. Then the values of $\texttt{res}^F$ on the nodes of C uniquely determine the values of $\texttt{res}^F(\sigma)$, for all nodes σ that are ancestors of nodes in C.*

Proof. Notice that because C is a cut, if a node σ is an ancestor of a node in C, then every one of σ's children is either in C or an ancestor of a node in C. The proof is by induction on the height of σ above C. Assume that σ is an ancestor of a node in C and that the values of $\texttt{res}^F$ on the nodes of C uniquely determine the values of all of σ's children σj. Since $\texttt{res}^F(\sigma)$ depends only on the values of $\texttt{res}^F$ on σ's children, and their values are uniquely determined by the values of $\texttt{res}^F$ on C, we are done. □

This lemma has an immediate corollary that we shall find most useful in the sequel.

COROLLARY 5.2. *Let $F : [t] \to [n]$. If, for all nodes σ of some cut C it is the case that $\texttt{res}^F(\sigma)$ has the same value in all correct processors' trees, then the values of $\texttt{res}^F$ on every node above C are the same in all trees. In particular, this applies to $\texttt{res}^F(\lambda)$, the resolved value for the root.*

We are now in a position to identify a large class of functions F that can serve as resolve functions for Byzantine agreement protocols. We say that F is a *sound* resolve function for Byzantine agreement if applying $\texttt{res}^F$ to the complete EIG trees of nonfaulty processors is guaranteed to fulfill the requirements of BA. (Notice that decision is trivial in this case, since it is assumed that a processor decides on $\texttt{res}^F(\lambda)$; thus, the claim actually concerns the agreement and validity properties).

LEMMA 5.3. *If $F : [t] \to [n]$ satisfies $t + 1 \leq F(r) \leq n - t - r$, then $\texttt{res}^F$ is a sound resolve function for Byzantine agreement for $n > 3t$.*

Proof. The proof proceeds along the lines of the proof of $\texttt{res}^M$ (the majority resolve function) from [2]. First notice that we are only interested in applying this rule for depths r satisfying $r \leq t$. In this case, if $n > 3t$ then indeed $n - t - r \geq t + 1$, so such functions $F(r)$ exist.

Let $h_L(\sigma) = t + 1 - |\sigma|$ be the height of the node σ above the leaves. First, we show by induction on $h_L(\sigma)$ that every correct node σ is resolved to $\texttt{tree}(\sigma)$. For a leaf σ ($h_L = 0$) this is immediate from the definition of $\texttt{res}^F$. Assume the claim is true for all children of σ, and that σ is a correct node with $h_L(\sigma) \geq 1$. It follows that at least $n - t - |\sigma|$ of σ's children j are correct. Moreover, since σ is correct, all correct processors $j \notin \sigma$ receive and echo an identical value for σ, so that $\texttt{tree}(\sigma j) = \texttt{tree}(\sigma)$.

By the inductive hypothesis, we thus have $\#\{j : \mathtt{res}^F(\sigma j) = \mathtt{tree}(\sigma)\} \geq n - t - |\sigma|$. The claim is obtained by observing that $n - t - |\sigma| \geq F(|\sigma|)$, which covers the case $\mathtt{tree}(\sigma) = 1$, and $n - t - |\sigma| = n - |\sigma| + 1 - (t + 1) \geq n - |\sigma| + 1 - F(|\sigma|)$, which covers the case of $\mathtt{tree}(\sigma) = 0$. This completes the inductive argument.

To complete the proof, notice that a tree of depth $t + 1$ has at least one correct node on every path from the root to the leaves. It follows that there is a cut C through the tree consisting of correct nodes only. For correct nodes σ (and, in particular, all nodes $\sigma \in C$) we have just shown that $\mathtt{res}^F(\sigma)$ is the same in all correct processors' trees. It follows by Corollary 5.2 that $\mathtt{res}^F(\lambda)$ is the same in all trees, and we are done. □

Notice that Lemma 5.3 allows a wide range of functions $F(r)$, including the natural function M (majority). Our quest to lower the complexity of the algorithm requires that we do not expand the whole EIG tree. Rather, we wish to use information we gather incrementally in order to be able to predict the resolved values of nodes, and thereby hopefully be able to avoid expanding their subtrees. Once every processor is able to predict the resolved values of nodes on a cut of the tree, we shall be done. Indeed, as shown in [21], when $n > 4t$ the function $\mathtt{res}^M$ guarantees that the resolved values of correct nodes can always be predicted once values of their children are stored. Unfortunately, when $n < 4t$ majority does not guarantee quick prediction of the value of $\mathtt{res}^M(\sigma)$ even for correct nodes σ. We shall thus seek other functions that will allow effective prediction.

We shall be most interested in a particular type of resolve function satisfying the conditions of Lemma 5.3 which, roughly speaking, will alternate between favoring the value 0 and favoring the value 1 in consecutive rounds.[3] (Intuitively, a favored value is one that requires a minimal amount of support in a given round in order to force a parent to be resolved to this value, while the opposite value requires a substantial amount of support.) A major consequence of this "flipping" function will be that the resolved values of correct nodes can be predicted in two rounds at the latest. More specifically, the alternating behavior will be controlled by the *parity* of the round. We let $\mathtt{par}(r)$ denote the parity of r. Thus, $\mathtt{par}(0) = 0$, $\mathtt{par}(1) = 1$, $\mathtt{par}(2) = 0$, etc.

Another important property of our function is that it will only be defined for an appropriate portion of the EIG tree, and not for the complete tree. More specifically, let us define a node σ to be *righteous* if σ is a correct node, and all of its ancestors are faulty. (In other words, a righteous node is the first correct node on some path from the root to a leaf.) Clearly, the identity of the faulty processors in a given run completely determines which nodes of the tree are righteous. An important property of the EIG tree is that given any choice of up to t faulty processors, the set of righteous nodes forms a cut in the EIG tree. Given a set B of up to t faulty processors, we define the *righteous subtree* of the EIG tree (with respect to B) to be the tree whose leaves are the righteous nodes, and whose internal nodes consist of the ancestors of righteous nodes. Clearly, different choices for B yield different righteous subtrees. (In the sequel, the set B will be implicit, and will consist of the faulty processors in the run under discussion.) Our goal will be to devise a mechanism by which, roughly speaking, righteous nodes will be resolved to their stored values in all nonfaulty processors' trees. Since the righteous nodes are, in particular, correct nodes, this means that they will be resolved to the same value in all trees. Once

[3] A protocol that similarly alternates between favoring 0 and favoring 1, albeit in a different setting, has previously been used by Attiya et al. in [29]. In our setting, alternation has been used for fault masking by Berman and Garay in [4].

righteous nodes resolve to the same values, we can use them in the role of leaves in the definition of a new resolve function. We thus define a resolve function $\texttt{right}^F$ on nodes σ of the righteous subtree as follows:

$$\texttt{right}_i^F(\sigma) = \begin{cases} \texttt{tree}_i(\sigma) & \text{if } \sigma \text{ is righteous;} \\ \texttt{par}(|\sigma|) & \text{if } \texttt{right}_i^F(\sigma j) = \texttt{par}(|\sigma|) \text{ for at least } F(|\sigma|) \text{ nodes } \sigma j\text{; and} \\ 1 - \texttt{par}(|\sigma|) & \text{otherwise.} \end{cases}$$

Notice that $\texttt{right}_i^F(\sigma)$ is undefined for nodes σ outside the righteous subtree. Since, for a righteous node σ, we are guaranteed that $\texttt{tree}_i(\sigma) = \texttt{tree}_j(\sigma)$ holds for all (nonfaulty) i and j, it is the case that $\texttt{right}_i^F = \texttt{right}_j^F$. Since the righteous nodes form a cut in the tree, it follows by Lemma 5.1 that $\texttt{right}_i^F$ is independent of i. Therefore, we shall henceforth drop the subscript and refer to this function by $\texttt{right}^F$. We now have the following proposition.

PROPOSITION 5.4. *$\texttt{right}^F$ satisfies the agreement and validity conditions of Byzantine agreement for every resolve function $F : [t] \to [n]$.*

The definition of $\texttt{right}^F$ seems to have a drawback. Processors are, in general, unable to tell a righteous node from a nonrighteous one. So how can $\texttt{right}^F$ be used by the processors? Intuitively, our plan is to present "fixing" rules that would predict the $\texttt{right}^F$ value of a node, provided the node is in the righteous subtree. For nodes outside the righteous subtree the $\texttt{right}^F$ value is undefined, and we give no guarantee on what values our fixing rules may give. This will not cause problems because our rules will have the property that for every righteous node σ, either σ or one of its ancestors will be fixed by the time values for σ's grandchildren are stored in the tree (i.e., by the end of round $\min(t+1, |\sigma|+2)$. Thus, our scheme will guarantee that all nodes of the righteous subtree, including the root, become fixed in all trees by the end of round $t+1$, if not earlier. Moreover, the nodes of the righteous subtree, when fixed to a value, will be fixed to their $\texttt{right}^F$ value. We shall now turn to formalize this intuition.

6. Δ-agreement. The monitor processes we talk about are agreement protocols that closely resemble ordinary Byzantine agreement, except for the following differences. (a) A monitor process is initiated in a state in which each nonfaulty processor i has a set $\mathcal{F}_i$ of processors that i has already detected as faulty, and is masking throughout the monitor. (b) The set of faulty processors used by processor i in each of the monitors is obtained based on fault detection performed by i in *all* active agreement processes. (c) Finally, we will associate with a monitor $\texttt{M}$ a parameter $\Delta < t$ which, roughly speaking, is a lower bound on the number of initially disabled faulty processors. This gives rise to a slight generalization of Byzantine agreement, that we shall call Δ-agreement.

We define Δ-agreement more formally as follows. As in Byzantine agreement, in an instance of Δ-agreement, each nonfaulty processor i starts out with an initial value $v_i \in \{0,1\}$. In addition, every nonfaulty processor i starts out with a set $\mathcal{F}_i$ of faulty processes. If all nonfaulty processors start out with an initial vote of 0, the parameter Δ plays no role. If, however, at least one nonfaulty processor votes 1, then at least Δ faulty processors are initially disabled. Let $\mathcal{D} \stackrel{\text{def}}{=} \bigcap_i \mathcal{F}_i$ denote the set of initially disabled processors. In Δ-agreement, we are guaranteed that if at least one nonfaulty processor votes 1, then $\#\mathcal{D} \geq \Delta$. (Thus, if all nonfaulty processors vote 0, no guarantee about the size of $\mathcal{D}$ is given.) Strictly speaking, an instance

of Δ-agreement has two additional parameters, n and t, where as usual n is the total number of processors, and t is an upper bound on the total number of faulty processors (including the ones in $\mathcal{D}$ and in the $\mathcal{F}_i$'s). Rather than working explicitly with (n, t, Δ)-agreement, we shall continue to talk about Δ-agreement, keeping n and t implicit and assuming that n and t satisfy $n \geq 3t + 1$, while $\Delta < t$. The decision, agreement, and validity requirements are as in the case of Byzantine agreement defined in section 2. Notice that the standard variant of Byzantine agreement that we have been considering can be viewed as an instance of Δ-agreement, where $\Delta = 0$ and $\mathcal{F}_i = \emptyset$ for every nonfaulty processor i.

6.1. Basic structure of the Δ-EIG protocol. Our purpose in this section will be to describe a protocol for Δ-agreement, which we shall call the Δ-EIG protocol. In later sections we shall discuss how to combine a number of these protocols via monitor voting to obtain an efficient solution to Byzantine agreement.

Our Δ-EIG protocol for a single instance of Δ-agreement will be based on a number of components. We now discuss some of them. First of all, the Δ-EIG protocol will operate on an EIG tree of depth $t + 1 - \Delta$ (as opposed to depth $t + 1$ in the standard EIG protocol). This will be essential, as we want to be able to complete a run of this protocol within $t+1-\Delta$ rounds. In addition, we shall have every processor i maintain a set of processors it has detected as faulty. Let $\mathcal{F}_i(r)$ denote the set of faulty processors detected by i in the first r rounds. Thus, in particular, $\mathcal{F}_i(0) = \mathcal{F}_i$ and the sets $\mathcal{F}_i(r)$ grow monotonically over time (i.e., $\mathcal{F}_i(r + 1) \supseteq \mathcal{F}_i(r)$). These sets will be used by the processors both for masking values in their own trees and for reporting on masked nodes. Rather than processor i sending in round $r + 1$ separate reports of masked values for each node τz corresponding to processors $z \in \mathcal{F}_i(r)$, we shall have i send a report of the form $\texttt{mask}(i, z)$ in the first round following the one in which it detects z to be faulty. All processors that receive this report will, from then on, act as if i actually sends separate masked reports for such nodes. In fact, we shall abuse the language slightly, and consider a processor i that issues a $\texttt{mask}(i, z)$ report in round r as if it "reports" masked values for all nodes σz with $|\sigma z| \geq r$. A processor will keep track of $\texttt{mask}(i, z)$ reports it receives and will store masked values in nodes accordingly on i's behalf, as specified below. In addition to saving in communication, this will allow a processor to detect failures based on reports its receives, and will, later on, make it easier for i to estimate the number of disabled processors.

Formally, processors will send messages according to the following rule.

- Sending: In a given round $r + 1$, a processor i sends all other processors a message consisting of two components. In the first component, the message contains reports $\texttt{mask}(i, z)$ on the processors $z \in \mathcal{F}_i(r) \setminus \mathcal{F}_i(r - 1)$ that i has just discovered as faulty. For completeness, we formally define $\mathcal{F}_i(-1) = \emptyset$, so that in the first round i reports that it is masking the processors in $\mathcal{F}_i(0) = \mathcal{F}_i$. The second component of the message consists of pairs $\langle \sigma j; v \rangle$, where $v = \texttt{tree}_i(\sigma j)$, for all nodes σj of depth r such that $j \notin \mathcal{F}_i(r)$.

Upon receiving the messages sent to it in round r, processor i will record and mask values as follows.

- Recording and masking:

1. Processor i appends every $\texttt{mask}(z, j)$ report it receives in round r to a list of mask reports that it maintains;

2. Processor i records values in $\texttt{tree}_i$ according to the following:

a. If $j \notin \mathcal{F}_i(r-1)$, then $\texttt{tree}_i(\tau j)$, for a node τj of depth r, is the value reported by j for τ in round r. In particular, if $\tau = \sigma z$ for some z such that i has received a

$\texttt{mask}(j, z)$ report from j in one of the first r rounds, then $\texttt{tree}_i(\tau j) = \texttt{par}(|\tau j|)$.

b. If $z \in \mathcal{F}_i(r-1)$ and τz is a node of depth r, then $\texttt{tree}_i(\tau z) = \texttt{par}(|\tau|)$.

In particular, this means that values of nodes corresponding to initially detected failures are always masked.

The set $\mathcal{F}_i$ is updated in the following manner.

- Fault detection: $\mathcal{F}_i(r)$ is obtained by adding to $\mathcal{F}_i(r-1)$ any new processor failure discovered by applying the fault detection rules FD0–FD3 described in section 6.3 to $\texttt{tree}_i$ after the recording and masking steps have taken place. Since, as discussed later on, the fault detection rules will be computable in a fairly efficient manner, this whole step is feasible. We remark that it would be possible to use the new failures detected in the last step in order to mask additional nodes, and then perhaps perform the fault detection step again. Indeed, this process could be repeated until no new failures would be discovered. For the sake of simplicity, we choose not to do so. The failures discovered in round r will affect processors' messages and processing from round $r+1$ on.

Faulty processors will be assumed to be discovered according to a set of sound fault discovery rules. The only thing we require of this set of rules is that it should include the rules FD0–FD3 described in section 6.3. The soundness of the rules implies that one invariant of our algorithm will be the following.

- Soundness: If i and j are nonfaulty, then $j \notin \mathcal{F}_i(r)$ holds for all rounds r.

Given the soundness invariant, the sending and the recording and masking rules guarantee that $\texttt{tree}_i(\sigma) = \texttt{tree}_j(\sigma)$ will hold for every correct node σ of depth at most $t + 1 - \Delta$, and nonfaulty processors i and j. It follows that the values of the function $\texttt{right}^F$ will continue to be independent of the tree in which they are computed.

Prediction will be handled by a set of fixing rules Fx1–Fx3 described in section 6.2. These rules will determine when a node σ is said to be *fixed to value v in* $\texttt{tree}_i$. Recall that we defined a node σ to be *closed in* $\texttt{tree}_i$ at the end of round r if either σ or one of its ancestors is fixed in $\texttt{tree}_i$ at that point.

Finally, we shall use a simple rule for deciding on a value and for halting in the basic Δ-EIG protocol.

- Deciding: When the root λ becomes fixed to a value v in $\texttt{tree}_i$, processor i decides on value v.
- Halting: Processor i continues to record information, perform fault detection, and report on values until the end of round $t + 1 - \Delta$, at which point it halts.

We shall show in Lemma 6.7 and Corollary 6.9 that the root cannot be fixed both to 0 and to 1, and that the root is guaranteed to be fixed by the end of round $t+1-\Delta$. As a result, the decision rule given above is well defined and will guarantee that i will decide on a value.

To complete the description of Δ-EIG, we need to describe the rules by which nodes are fixed to values, and the manner in which processors perform fault discovery. This will be the subject of the next two subsections.

6.2. Fixing nodes to values. We now define when a node σ is *fixed* in $\texttt{tree}_i$ to a value v. This will be a major component in our protocol, and the properties of fixing, which we discuss below, will be instrumental in the development of the algorithm. We start with a fairly abstract definition of the fixing rules, relative to a function $F : [t] \to [n]$. We shall call such a function F *admissible* if it satisfies that

(i) $F(0) = F(1) = t + 1$, and

(ii) $t + r - 1 \geq F(r) \geq t - r + 2$ for $r \geq 2$.

In the sequel, we shall restrict our attention to admissible functions. A considerable amount of our analysis will be valid for admissible functions in general. Only in section 7 will we choose a particular admissible function to be used in our final protocol. We remark that admissible functions do not necessarily conform to the conditions of Lemma 5.3. As we shall see, the fact that we shall be fixing values of nodes before the full tree is developed will allow us to go beyond the bounds of Lemma 5.3. The role of Lemma 5.3 is in motivating the development of admissible functions and our fixing rules. It will not play a role in the correctness of our protocol in the end.

The bounds used in the definition of admissible functions were chosen so that they would match the following fixing rules. Formally, a node σ becomes *fixed in* $\texttt{tree}_i$ *to value* v at the end of round r if σ was not closed at the end of round $r-1$, and one of the following rules applies:

Fx1: $r = |\sigma| = t + 1 - \Delta$ and $\texttt{tree}_i(\sigma) = v$.

Fx2: $r = |\sigma| + 1$, $\texttt{par}(|\sigma|) = v$ and

$$\texttt{tree}_i(\sigma j) = v \text{ for at least } \begin{cases} n - t \text{ nodes } \sigma j & \text{if } \sigma = \lambda; \\ n - t - 1 \text{ nodes } \sigma j & \text{if } |\sigma| = 1; \text{ and} \\ n - t - 2 \text{ nodes } \sigma j & \text{if } |\sigma| \geq 2. \end{cases}$$

Fx3: Rules Fx1 and Fx2 do not apply, and either

(a) $\texttt{par}(|\sigma|) = v$ and at least $F(|\sigma|)$ of the σj's are fixed to v; or

(b) $\texttt{par}(|\sigma|) = 1 - v$ and at least $n - |\sigma| - F(|\sigma|) + 1$ (i.e., all but at most $F(|\sigma| - 1)$ of the σj's are fixed to v.

We remark that a naive bottom-up computation based on Fx1–Fx3 can be used to determine all of the fixed nodes and the values they are fixed to in a given EIG tree. Such a computation requires a number of steps at most linear in the size of the tree. The properties of the fixing rules Fx1–Fx3 will play a major role in the correctness of our ultimate protocol. We now consider some of these properties.

One immediate consequence of the definition of the above fixing rules is the following.

LEMMA 6.1. *Let F be admissible and let i be a nonfaulty processor. If all nonfaulty processors vote* 0*, then the root λ is fixed to* 0 *in* $\texttt{tree}_i$ *by the end of round* 1*. Similarly, if all nonfaulty processors vote* 1*, then the root λ is fixed to* 1 *in* $\texttt{tree}_i$ *by the end of round* 2*.*

Proof. Recall that $\texttt{par}(|\lambda|) = 0$. First assume that all nonfaulty processors vote 0. It follows that at least $n - t$ correct children of λ in $\texttt{tree}_i$ store 0 at the end of round 1, and as a result, by rule Fx2, the root is fixed to 0 at that point. Now assume that all nonfaulty processors vote 1. The root λ has at least $n - t$ correct children. Let σ denote a correct child of the root λ. Thus, at the end of round 1 we have that $\texttt{tree}_i(\sigma) = 1$. The root is not fixed yet. At the end of round 2, however, $\texttt{tree}_i(\sigma j) = 1$ for at least $n - t - 1$ children of σ. Since $\texttt{par}(|\sigma|) = 1$, it follows from the second clause of Fx2 that σ will be fixed to 1 at the end of round 2. We thus obtain that at least $n - t$ children of λ are fixed to 1 by the end of round 2. Recall that if F is admissible, then $F(0) = t + 1$. Hence, by rule Fx3 we now have that the root becomes fixed to 1 at the end of round 2, since that $F(|\lambda|) = F(0) = t + 1$, and $n - |\lambda| - F(|\lambda|) + 1 = n - (t + 1) + 1 = n - t$. □

Lemma 6.1 essentially takes care of the validity problem for Δ-agreement in the case in which all nonfaulty processors have initial votes of 0. The lemma states that in this case the root in all nonfaulty processors' trees will fix to 0 by the end of round 1, and by the decision clause of the Δ-EIG protocol, all nonfaulty processors

will decide 0 at that point. In the sequel, we shall therefore concern ourselves with the case in which at least one nonfaulty processor votes 1. Hence, we will be able to assume that the number of initially disabled processors is at least Δ.

We now wish to use the fixing rules to show that they guarantee that nodes of the righteous subtree end up being fixed to the desirable values. In Δ-agreement, however, we have processors that are initially disabled, that resemble nonfaulty processors in the fact that they cannot corrupt nodes or otherwise misbehave. As a result, finding a node corresponding to an initially disabled processor on a path from the root is quite analogous to finding a correct node. Following this observation, we shall therefore replace the definition of the righteous subtree with the analogous tree (which we shall call the *safe subtree*), and perform our analysis with respect to the new tree. Formally, we proceed as follows. Let $\mathcal{D}$ denote the set of initially disabled processors. We call a node σ *safe* if (i) σ is either righteous or corresponds to a processor in $\mathcal{D}$, and (ii) none of σ's ancestors are righteous, and none of them correspond to processors in $\mathcal{D}$. Since $\#\mathcal{D} \geq \Delta$ by definition of Δ-agreement, at most $t - \Delta$ processors labelling edges on a path from the root can be faulty but not from $\mathcal{D}$. It follows that every path of $t+2-\Delta$ nodes leading from the root must contain a safe node. In particular (since $|\lambda| = 0$), if σ is safe, then $|\sigma| \leq t + 1 - \Delta$. Since, by definition, there can be at most one safe node on every path from the root to leaves of the EIG tree, we obtain that the safe nodes form a cut in the tree. Let us denote this cut by C_s. We define the *safe subtree* of an EIG tree in an execution of Δ-EIG to consist of C_s and all ancestors of nodes in C_s. We remark that $|\sigma| = t + 1 - \Delta$ can hold for a node of the safe subtree only if σ is a safe node, and hence is either righteous or (initially) disabled. Finally, we shall use $h_s(\sigma)$, for a node σ of the safe subtree, to denote the length of the maximal path from the node σ to some node in C_s. More formally, for nodes σ in the safe subtree, we define

$$h_s(\sigma) \stackrel{\text{def}}{=} \begin{cases} 0 & \text{if } \sigma \in C_s; \text{ and} \\ 1 + \max_j h_s(\sigma j) & \text{otherwise.} \end{cases}$$

One somewhat technical property that will serve us in the sequel is the following. (In this and all other statements in this paper, references to EIG trees such as $\texttt{tree}_i, \texttt{tree}_j$ and $\texttt{tree}_z$ are made only for nonfaulty processors; the assumption that i, j, or z is nonfaulty will be implicit.)

LEMMA 6.2. *Let F be an admissible function, and let σ be a node of the safe subtree such that $0 < |\sigma| < t+1-\Delta$, and all nonfaulty processors that do not appear in σ report the value v for σ. Then*

(a) *If $v = \texttt{par}(|\sigma|)$ then σ is closed in $\texttt{tree}_i$ by the end of round $|\sigma| + 1$ at the latest*; *while*

(b) *If $v \neq \texttt{par}(|\sigma|)$ then σ is closed in $\texttt{tree}_i$ by the end of round $\min(|\sigma|+2, t+1-\Delta)$ at the latest.*

Moreover, if σ is fixed in $\texttt{tree}_i$, then it is fixed to v.

Proof. We prove the claim separately for different depths of $|\sigma|$.

(i) For $t - \Delta > |\sigma| \geq 1$: We argue by cases depending on whether or not $v = \texttt{par}(|\sigma|)$.

(a) Assume $v = \texttt{par}(|\sigma|)$. If σ is closed by the end of round $|\sigma|$ then σ does not become fixed in $\texttt{tree}_i$ and we are done. Otherwise, σ has at least $n - t - 1$ correct children all of which store v by the end of round $|\sigma| + 1$. By rule Fx2 we thus obtain that σ is fixed to v at the end of round $|\sigma| + 1$.

(b) Now assume $v \neq \texttt{par}(|\sigma|)$. The node σ cannot be fixed to $v \neq \texttt{par}(|\sigma|)$ by rule Fx2, since this rule only allows fixing to $\texttt{par}(|\sigma|)$. If σ is closed by the end of

round $|\sigma|+1$, then σ does not become fixed in $\texttt{tree}_i$ and we are done. We shall show that if σ is not closed by the end of round $|\sigma|+1$ then σ becomes fixed to v by the end of round $|\sigma|+2$. Let σj be a correct child of σ. In particular, $\texttt{tree}_i(\sigma j) = v$, and all correct children of σj store v in $\texttt{tree}_i$ as well. Notice that $\texttt{par}(|\sigma j|) = v$ and $|\sigma j| \geq 2$. In addition, since σ is a node of the safe subtree and $|\sigma| < t - \Delta$, the node σj has at least $n - t - 2$ correct children, and they all store v. It follows that Fx1 does not apply to σj, and σj becomes fixed to v at the end of round $|\sigma|+2$ for all correct nodes σj. Recall that there are at least $n - t - 1$ such correct nodes σj. Let $r = |\sigma|$, and recall that we are assuming that $F(r) \geq t - r + 2$.[4] Thus, in particular, $n - r - F(r) + 1 \leq n - r - t + r - 2 + 1 = n - t - 1$. It now follows by Fx3(b) that σ is fixed to v in $\texttt{tree}_i$ by the end of round $|\sigma|+2$.

(ii) For $t - \Delta = |\sigma|$: If σ is closed at the end of round $|\sigma| = t - \Delta$, then σ does not become fixed in $\texttt{tree}_i$ and we are done. Otherwise, if $v = \texttt{par}(|\sigma|)$ then σ becomes fixed by rule Fx2 to v as in the case of $t - \Delta > |\sigma|$ described above. If $v \neq \texttt{par}(|\sigma|)$ then all of σ's children are fixed in $\texttt{tree}_i$ at the end of round $|\sigma|+1$. Moreover, at least $n - t - 1$ correct children σj of σ are fixed to v. As in the case of $|\sigma| > t - \Delta$ and $v \neq \texttt{par}(|\sigma|)$ we have that σ is fixed to v in $\texttt{tree}_i$ by rule Fx3(b). □

Lemma 6.2 immediately provides us with a number of useful corollaries. Essentially, Lemma 6.2 implies that nodes corresponding to initially disabled processors and righteous nodes are guaranteed to close quickly given our fixing rules.

COROLLARY 6.3. *Let F be admissible, and let $\sigma = \tau z$ be a node of the safe subtree such that $|\sigma| < t + 1 - \Delta$ and z is disabled by the end of round $|\sigma|$. Then σ is closed in $\texttt{tree}_i$ by the end of round $|\sigma|+1$ at the latest. Moreover, if σ becomes fixed to a value v in $\texttt{tree}_i$, then $v = \texttt{par}(|\sigma|) = \texttt{right}^F(|\sigma|)$.*

Proof. Since $|\sigma| < t + 1 - \Delta$, rule Fx1 does not apply to fixing σ. If σ is closed in $\texttt{tree}_i$ by the end of round $|\sigma|$, we are done. Otherwise, since we have that z is disabled by the end of round $|\sigma|$ and $\sigma = \tau z$, all nonfaulty processors j issue a $\texttt{mask}(j, z)$ report by round $|\sigma|+1$ at the latest. As a result, all nonfaulty processors are considered to be reporting $v = \texttt{par}(|\sigma|)$ for $\sigma = \tau z$. Lemma 6.2 now implies that σ is closed in $\texttt{tree}_i$ by the end of round $|\sigma|+1$, and, if it is fixed in $\texttt{tree}_i$, it is fixed to $v = \texttt{par}(|\sigma|)$. Since at least $n - t > n - t - 1 \geq F(|\sigma|)$ righteous children of τz in $\texttt{tree}_i$ store the value $\texttt{par}(|\sigma|)$, we obtain that $\texttt{par}(|\sigma|) = \texttt{right}^F(\sigma)$ and we are done. □

In particular, Corollary 6.3 implies that all nodes corresponding to initially disabled processors become closed within one round, and can fix only to their masked value. A similar situation holds with respect to righteous nodes as shown in the following corollary.

COROLLARY 6.4. *Let F be admissible, and let σ be a safe node (and hence a leaf of the safe subtree). Then σ is closed in $\texttt{tree}_i$ by the end of round $\min(|\sigma|+2, t+1-\Delta)$. Moreover, if σ becomes fixed to a value v in $\texttt{tree}_i$, then $v = \texttt{tree}_i(\sigma) = \texttt{right}^F(\sigma)$.*

Proof. First notice that if $|\sigma| = t + 1 - \Delta$ and σ is not closed by the end of round $t - \Delta$, then σ is fixed in $\texttt{tree}_i$ by rule Fx1 to $\texttt{tree}_i(\sigma) = \texttt{right}^F(\sigma)$ and we are done. If $|\sigma| = t + 1 - \Delta$ and σ is closed in $\texttt{tree}_i$ by the end of round $t - \Delta$, then σ is not fixed in $\texttt{tree}_i$ and we are done. Otherwise, we have that $|\sigma| < t+1-\Delta$. Let $\sigma = \tau z$, and assume that σ is not closed by the end of round $|\sigma|$. If σ is safe because $z \in \mathcal{D}$, then all processors report $\texttt{par}(|\sigma|)$ for σ in round $|\sigma|+1$ and we are done by Lemma 6.2. We may thus assume that σ is righteous, then every nonfaulty processor j reports $\texttt{tree}_j(\sigma)$ for σ. Since we are assuming that z is nonfaulty, then, by

[4] This is where we use the lower bound specified in the definition of admissible functions.

soundness of the fault detection module and the recording condition, every nonfaulty processor j would store the value that z reports for τ in $\texttt{tree}_j(\sigma) = \texttt{tree}_j(\tau z)$. Moreover, a nonfaulty processor z would report the same value for τ to all nonfaulty processors j. Thus, we have that $\texttt{tree}_i(\sigma) = \texttt{tree}_j(\sigma)$ for every nonfaulty processor j, and we obtain that all nonfaulty processors report the value $\texttt{tree}_i(\sigma) = \texttt{right}^F(\sigma)$ for σ. The claim now follows by Lemma 6.2. □

An immediate consequence of Corollaries 6.3 and 6.4 follows.

LEMMA 6.5. *A node σ that is not closed in $\texttt{tree}_i$ by the end of round $|\sigma|+1$ is in the safe subtree.*

Proof. Corollaries 6.3 and 6.4 imply that every node τ on the safe cut C_s is closed by the end of round $|\tau|+2$. Since these nodes form a cut in the EIG tree, every node σ that is not in the safe subtree has an ancestor τ in C_s; moreover, $|\sigma|+1 \geq |\tau|+2$. It follows that a node σ that is not in the safe subtree must be closed by the end of round $|\sigma|+1$ at the latest, and the claim follows. □

The fixing rule Fx3 has the property that once all children of a node are fixed, so is the node itself. As a result, we obtain the following lemma.

LEMMA 6.6. *For each nonfaulty i, every node σ of the safe subtree is closed in $\texttt{tree}_i$ by the end of round $t+1-\Delta$.*

Proof. We prove the claim by induction on $h_s(\sigma)$ for nodes σ of the safe subtree. Recall that we have defined $h_s(\sigma)$ to be the height of σ in the safe subtree. In particular, we clearly have that $h_s(\sigma) \leq t+1-\Delta$ for every node σ of the safe subtree. If $h_s(\sigma) = 0$, then σ is a safe node, by definition of h_s. The claim now follows from Corollary 6.4. Now assume $h_s(\sigma) = k > 0$, and assume the claim holds for all nodes τ satisfying $h_s(\tau) < k$. In particular, every child σj of σ is in the safe subtree and satisfies $h_s(\sigma j) < h_s(\sigma) = k$. Thus, the inductive assumption implies that all of σ's children are closed by the end of round $t+1-\Delta$. If this is because σ or one of its ancestors are fixed, we are done. Otherwise, all of σ's children are fixed by the end of round $t+1-\Delta$. Recall that the number of σ's children is $n-|\sigma|$. If rule Fx3(a) does not apply, then fewer than $t+2-|\sigma|$ of the children of σ are fixed to the value $\texttt{par}(|\sigma|)$. It then follows that at least $n-|\sigma|-(t+1-|\sigma|) = n-t-1$ of the children of σ are fixed to $1-\texttt{par}(|\sigma|)$, so that σ is fixed to $1-\texttt{par}(|\sigma|)$ in $\texttt{tree}_i$ by rule Fx3(b). In either case we obtain that σ must also be fixed in $\texttt{tree}_i$, and we are done. □

A crucial property of our fixing rules is that a node σ can be fixed to at most one value in $\texttt{tree}_i$, as we now prove in the following lemma.

LEMMA 6.7. *If a node σ of the safe subtree is fixed to value v in $\texttt{tree}_i$, then σ is not fixed to $1-v$ in $\texttt{tree}_i$.*

Proof. We prove the claim by induction on $h_s(\sigma)$. The case $h_s(\sigma) = 0$ follows from Corollary 6.4. Assume that $h_s(\sigma) \geq 1$ and that the claim holds for all nodes τ of the safe subtree with $h_s(\tau) < h_s(\sigma)$. Hence, in particular, rule Fx1 does not apply to σ, and the claim holds for σ's children in $\texttt{tree}_i$. Assume σ is fixed by Fx2. The only value to which σ can be fixed by Fx2 is $\texttt{par}(|\sigma|)$. Moreover, by the definition of these rules, if Fx2 applies to σ in $\texttt{tree}_i$ then neither Fx1 nor Fx3 do. It follows that if σ is fixed by rule Fx2, then it is fixed to a unique value. Finally, assume σ becomes fixed in $\texttt{tree}_i$ by rule Fx3. In particular, Fx1 and Fx2 do not apply in the case of σ. The node σ has exactly $n-|\sigma|$ children σj. By definition, $h_s(\sigma j) < h_s(\sigma)$. Thus, by the inductive hypothesis, each of these children is fixed to at most one value. The total number of fixed children of σ that would be necessary for both Fx3(a) and Fx3(b) to apply is $t+2-|\sigma|+n-t-1 = n-|\sigma|+1$, which is more than the number of children of σ. It follows that only one of these rules can apply, so that σ can be fixed to at

most one value in $\texttt{tree}_i$. □

We are now ready to prove that nodes of the safe subtree can become fixed only to their $\texttt{right}^F$ values.

THEOREM 6.8. *If F is admissible and a node σ of the safe subtree is fixed to value v in $\texttt{tree}_i$, then $v = \texttt{right}^F(\sigma)$.*

Proof. We prove the claim by induction on $h_s(\sigma)$. The case of $h_s(\sigma) = 0$ follows directly from Corollary 6.4.

Assume that $h_s(\sigma) > 0$ and the claim holds for all children σj of σ. (By definition of h_s we have that $h_s(\sigma) > h_s(\sigma j) \geq 0$.) Notice that the rule Fx1 cannot apply to σ since Fx1 deals with nodes τ satisfying $|\tau| = t + 1 - \Delta$, and such a node is in the safe subtree only if it is a safe node, in which case $h_s(\tau) = 0$. Thus, $h_s(\sigma) > 0$, and only rules Fx2 and Fx3 can apply for fixing σ. Since σ is an internal node of the safe subtree, σ and all of its ancestors are incorrect nodes. As a result, at least $n-t$ of σ's children are correct, while at most $t - |\sigma|$ of them are faulty. Moreover, every correct child of σ is righteous. We now consider the ways in which σ can become fixed due to Fx2 and Fx3.

(i) Assume that $|\sigma| \geq 2$ and σ becomes fixed in $\texttt{tree}_i$ to value $v = \texttt{par}(\sigma)$ by rule Fx2. The definition of Fx2 implies that $\texttt{tree}_i(\sigma j) = v$ for at least $n - t - 2$ nodes σj. Since at most $t - |\sigma|$ of these may be incorrect, we obtain that at least $n-t-2-t+|\sigma| = n-2t+|\sigma|-2 \geq t+|\sigma|-1$ of these nodes are correct. For each such correct child σj we have that $\texttt{right}^F(\sigma j) = v$. Since F is admissible, we have that $F(|\sigma|) \leq t+|\sigma|-1$, and it follows from the definition of $\texttt{right}^F$ that $\texttt{right}^F(\sigma) = v$.[5] A similar argument applies for the cases of $|\sigma| \leq 1$. In these cases, $F(|\sigma|) = t + 1$, at least $n - t - |\sigma|$ of the children are fixed to v, and at most $t - |\sigma|$ of the children are incorrect. In both cases $n - t - |\sigma| - t + |\sigma| = n - 2t \geq t + 1 = F(|\sigma|)$ and we are done.

(ii) If σ is fixed in $\texttt{tree}_i$ to v by rule Fx3(a), then $\texttt{par}(|\sigma|) = v$ and we have by the inductive hypothesis for the $F(|\sigma|) \geq t + 2 - |\sigma|$ nodes of the form σj that are fixed to v in $\texttt{tree}_i$ that $\texttt{right}^F(\sigma j) = v$. Thus, by the definition of $\texttt{right}^F$ we have that $\texttt{right}^F(\sigma) = v$ as well. An analogous argument works for fixing based on Fx3(b). □

COROLLARY 6.9. *The root λ of $\texttt{tree}_i$ is fixed to value $\texttt{right}^F(\lambda)$ by the end of round $t + 1 - \Delta$.*

Proof. Lemma 6.6 implies that λ is closed in $\texttt{tree}_i$ by the end of round $t+1-\Delta$. Since λ has no ancestors, it must be fixed at that time. Theorem 6.8 implies that λ is fixed to $\texttt{right}^F(\lambda)$. □

THEOREM 6.10. *For any sound fault-detection module and admissible function F, the Δ-EIG protocol satisfies the decision, agreement, and validity properties.*

Proof. Decision follows immediately from Corollary 6.9 and Lemma 6.7. Recall from our discussion of $\texttt{right}^F$ that if σ is in the righteous subtree, then the value of $\texttt{right}^F(\sigma)$ is independent of the tree in which it is computed. Corollary 6.9 implies that every nonfaulty processor decides on $\texttt{right}^F(\lambda)$, and since λ is in the righteous subtree, we obtain agreement. We now argue why validity holds. All correct children of λ are righteous. If all nonfaulty processors j have the same initial value $v_j = v$, then $\texttt{right}^F(\sigma) = v$ for all $n - t$ righteous children σ of λ. By definition of $\texttt{right}^F$, this implies that $\texttt{right}^F(\lambda) = v$, and since $\texttt{right}^F(\lambda)$ is the value decided on, we obtain validity. □

[5] This is where we use the upper bound specified in the definition of admissible functions.

6.3. Fault detection in Δ-EIG. We now turn to describing the fault discovery rules we shall use in the instances of Δ-agreement for the purposes of our final protocol. Notice that all of the results regarding fixing that we have seen above depend only on the masking and soundness rules, which state that initially detected failures must be masked to the favored value, and nonfaulty processors are not masked by other nonfaulty processors. Thus, we have a considerable amount of freedom in introducing fault discovery rules without affecting the correctness of the protocol.

We find it convenient to consider the notion of a node σ being *committed to value* v *in* $\texttt{tree}_i$. Intuitively, $\sigma = \tau z$ will be committed to v in $\texttt{tree}_i$ only if i has a proof that at least one nonfaulty processor either has received a report of v for τ from z, or is masking z. Formally, we say that a node $\sigma \neq \lambda$ is committed to v in $\texttt{tree}_i$ if one of the following holds:

C1: $\texttt{tree}_i(\sigma) = v$;

C2: $\texttt{tree}_i(\sigma j) = v$ for at least $\min(t+1, t+3-|\sigma|)$ nodes σj;

C3: σ is not closed in $\texttt{tree}_i$ at the end of round $|\sigma|+1$ and σ is not fixed to $1-v$ at the end of round $|\sigma|+2$.

As in the case of fixing, a naive linear-time computation based on C1, C2, and C3 is easily seen to suffice for determining all of the commitments of nodes to values in a given EIG tree. We remark that these rules will only be applied to nodes of the safe subtree. For such nodes, the bound of C2 guarantees that one of the children σj with $\texttt{tree}_i(\sigma j) = v$ is correct.

The main use we have for the notion of commitment is captured in the following lemma.

LEMMA 6.11. *Let τ be a node of the safe subtree. If a child τz of τ is committed to v in $\texttt{tree}_i$ by the end of round r, then, for at least one nonfaulty processor j, either $z \in \mathcal{F}_j(|\tau z|)$ or j received a report of v from z for τ.*

Proof. If τz is committed to v in $\texttt{tree}_i$ by C1, then the claim holds trivially for $j = i$, since $\texttt{tree}_i(\tau z) = v$ only if either i received a report of v for τ from z, or $v = \texttt{par}(|\tau|)$ and i is masking z in round $|\tau z|$. Assume that τz is committed to v in $\texttt{tree}_i$ by C2. Since τ is a node of the safe subtree, all, except possibly for the last, members of the sequence τ are faulty processors. It follows that the number of incorrect children of τz is at most $t - |\tau| + 1$ $(= t + 2 - |\tau z|)$. We thus obtain that if C2 applies, then at least one of the children $\tau z j$ of τz with $\texttt{tree}_i(\tau z j) = v$ must be a correct node. But $\texttt{tree}_i(\tau z j) = v$ for a correct node $\tau z j$ only if either $z \in \mathcal{F}_j(|\tau z|)$ (in which case j sends a $\texttt{mask}(j, z)$ message no later than in round $|\tau z| + 1$), or if j received a report of v for τ from z. We are left with the case of commitment to v due to C3. First notice that if τz is righteous and committed to v in $\texttt{tree}_i$ by C3, then it is already committed to v in $\texttt{tree}_i$ by C2. This is because if τz is not closed in $\texttt{tree}_i$ at the end of round $|\tau z| + 1$, then it is committed in $\texttt{tree}_i$ to value $w = \texttt{tree}_i(\tau z)$, and by Corollary 6.4, it will not not be committed to $1 - w$ by C3. Thus, we may assume that τz is not righteous. In particular, it has at least $n - t$ righteous children. It suffices to show that at least one nonfaulty processor j reports v for τz. Assume not. Then all nonfaulty processors report $1 - v$ for τz. It now follows by Lemma 6.2 that τz must be fixed to $1 - v$ by the end of round $|\tau z| + 2$ if it was not closed by the end of round $|\tau z| + 1$. This contradicts the assumption that τz is committed to v in $\texttt{tree}_i$ by C3. □

LEMMA 6.12. *Assume that $t \geq 3$. If a node $\sigma \neq \lambda$ of the safe subtree is ever fixed to value v in $\texttt{tree}_i$, then σ is committed to v in $\texttt{tree}_i$ by the end of round $|\sigma| + 2$.*

Proof. Assume σ is fixed to v in $\texttt{tree}_i$ by the end of round $|\sigma| + 2$. If σ is fixed

by rule Fx1, then by C1 it is also committed to v in $\texttt{tree}_i$. If it is fixed by Fx2, then it is committed to v by C2, since Fx2 implies that $\texttt{tree}_i(\sigma j) = v$ for at least $n-t-2$ nodes σj. Given that $t \geq 3$ and $|\sigma| \geq 1$, we have

$$n - t - 2 \geq 2t + 1 - 2 = 2t - 1 \geq t + 3 - 1 = t + 2 \geq t + 3 - |\sigma|.$$

Finally, assume that σ is fixed to v by Fx3. In particular, σ is not closed in $\texttt{tree}_i$ by the end of round $|\sigma| + 1$, and it becomes fixed to v no earlier than the end of round $|\sigma| + 2$. Lemma 6.7 implies that σ can be fixed to at most one value in $\texttt{tree}_i$, so that σ is not fixed to $1 - v$ at the end of round $|\sigma| + 2$, and by C3 it is committed to v in $\texttt{tree}_i$ at that point. □

Notice that for every node $\sigma \neq \lambda$ of the safe subtree, there must be at least one value $v \in \{0, 1\}$ such that at least $t + 1$ (and hence $\geq t + 2 - |\sigma|$) nonfaulty processors report v for σ. We say that σ is then *publicly committed* to such a value v. If σ is publicly committed to v, then σ becomes committed by C2 to v in $\texttt{tree}_i$ for all trees $\texttt{tree}_i$ in which values of children of σ are stored. A variant of Lemma 6.12 that applies to public commitment and will be useful in the sequel is the following lemma.

LEMMA 6.13. *Let σ be a node of the safe subtree of depth $2 \leq |\sigma| \leq t - \Delta$, let $v = \texttt{par}(|\sigma|)$, and let σ be fixed in $\texttt{tree}_i$ to $1 - v$ (the "disfavored" value). Then σ is publicly committed to $1 - v$.*

Proof. By Theorem 6.8, a node σ of the safe subtree can be fixed only to $\texttt{right}^F(\sigma)$. Given our definition of publicly committed, we have that a node must be publicly committed to at least one value among $0, 1$. However, if σ were publicly committed to $v = \texttt{par}(|\sigma|)$, then by definition of $\texttt{right}^F$ we would have that $\texttt{right}^F(\sigma) = \texttt{par}(|\sigma|) \neq 1 - v$. It follows that σ must be publicly committed to $1 - v$. □

We are now ready to present our fault detection rules. Intuitively, a nonfaulty processor i discovers that a processor is faulty when there is "enough" evidence that the processor has sent conflicting values to other correct processors. This evidence may be gathered when the messages of the children of a node corresponding to the faulty processor are received. Formally, processor i will detect z at the end of round as being faulty if one of the following holds:

FD0: z sends i an ill-formatted message in round r.

FD1: By the end of round r, processor i has received $\texttt{mask}(j, z)$ reports from at least $t + 1$ distinct processors j.

FD2: By the end of round r, some node τz that was not closed in $\texttt{tree}_i$ by the end of round $|\tau z|$ is committed both to 0 and to 1 in $\texttt{tree}_i$.

FD3: By the end of round r, for some node $\tau a z$ and value v such that (a) $r = |\tau a z| + 1$, and (b) $\tau a z$ is not closed in $\texttt{tree}_i$ by the end of round r; we have that

(i) $\tau a z$ is committed to v in $\texttt{tree}_i$;

(ii) at least $2(t + 1 - |\tau a|) + 1$ of the nodes $\tau a j$ are committed to $1 - v$ in $\texttt{tree}_i$ by the end of round r; and

(iii) z does not mask a in round $|\tau a z| + 1$. (Namely, z did not send a $\texttt{mask}(z, a)$ report to i in the first r rounds.)

The motivation for the first three rules FD0–FD2 is fairly intuitive and straightforward. Similar rules have appeared in earlier work in the literature. The fourth rule, FD3, is of a new type. It is tailor made for handling a specific type of corruption, called cross corruption, that we will consider in detail in section 7. Intuitively, FD3 can be thought of as detecting a *crime of omission*. It applies when the detecting processor i has a proof that, had z been nonfaulty, then z would have detected another processor a as being faulty due to FD2 in round $r - 1$. As a result, z should have

issued a $\texttt{mask}(z, a)$ report no later than in round r. By rule FD3, i discovers z as being faulty once z fails to issue a $\texttt{mask}(z, a)$ in time. Figure 2 illustrates this scenario.

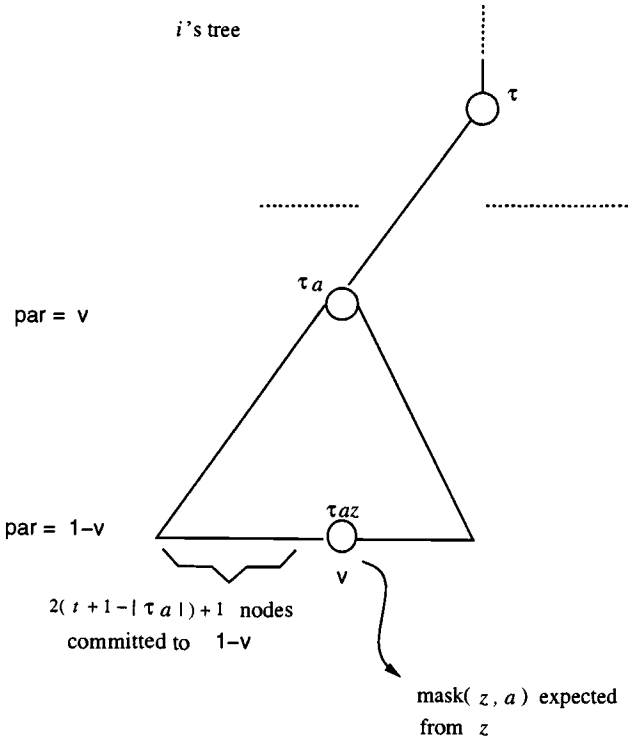

FIG. 2. *Discovering a fault using* FD3.

LEMMA 6.14. *The rules* FD0–FD3 *are sound. That is, if the fault detection module is sound for all nonfaulty processors through the end of round* $r - 1$*, then every processor that is added to* $\mathcal{F}_i(r)$ *according to one of these rules is faulty.*

Proof. The soundness of FD0 is trivial, since a processor that sends an ill-formatted message is deviating from the protocol, and hence is faulty. If rule FD1 applies, then at least one of the $t + 1$ processors that report to i that they are masking z must be nonfaulty. The soundness of the rule now follows from our assumption about the soundness of the fault detection module in the first $r - 1$ rounds. We now turn to FD2. Notice that this rule cannot apply with respect to a node τz before the end of round $|\tau z| + 1$, since only one commitment value can be obtained in $\texttt{tree}_i$ before values for the children of τz are stored. By Lemma 6.5, if τz is not closed at the end of round $|\tau z|$, then τ is a node of the safe subtree. Since τz is committed both to 0 and to 1, Lemma 6.11 implies that either at least one nonfaulty processor is masking z in round $|\tau z|$, or z sent conflicting reports of both 0 and 1 for τ to two different nonfaulty processors. Having assumed that the fault detection module was sound in the first $r - 1$ rounds we obtain that, in either case, z must be faulty, and hence FD2 is sound.

Finally, let us consider FD3. Roughly speaking, the soundness of FD3 is based on FD2 and the fact that if (i) and (ii) hold, then i can determine that z must have had enough information for detecting a as faulty using FD2 in round $|\tau a z|$. If z did not

react accordingly, then it must be faulty. We now formalize this intuition. Assume that z is nonfaulty, and conditions (i) and (ii) apply. Moreover, assume that z does not issue a $\texttt{mask}(z, a)$ report by the end of round $|\tau az|$. Since τaz is not closed by the end of round $|\tau az| + 1$, then by Lemma 6.5 the node τaz is in the safe subtree, and hence all of the processors in the sequence τa are faulty. It follows that at most $t - |\tau a|$ of the nodes τaj that are committed to $1 - v$ in $\texttt{tree}_i$ by the end of round $|\tau az| + 1$ can be incorrect. $t - |\tau a|$ can be incorrect. Since their total number is, by assumption, at least $2(t + 1 - |\tau a|) + 1$, it follows that at least

$$2(t + 1 - |\tau a|) + 1 - (t - |\tau a|) = t + 3 - |\tau a|$$

of these nodes are correct, and, in particular, must appear in $\texttt{tree}_z$. It thus follows by rule C2 that τa must be committed to $1 - v$ in $\texttt{tree}_z$ by the end of round $|\tau az|$. However, since τaz is committed to v in $\texttt{tree}_i$, (and z is nonfaulty) it must be the case that τa is committed to v in $\texttt{tree}_z$ as well by the end of round $|\tau az|$. Thus, by rule FD2 we obtain that z must detect a as faulty in round $|\tau az|$. Moreover, by the masking behavior rule, in round $|\tau az|+1$, processor z must report that it is masking a, if it has not done so in an earlier round. If z fails to do so, then z must be faulty as determined by FD3. □

Given these fault discovery rules, we can now turn to study the conditions under which nodes can be corrupted in instances of Δ-EIG. In addition, we shall be interested in the relationship between the corrupted nodes and the size of the EIG tree constructed.

6.4. Corrupting nodes in Δ-EIG. Formally, in an execution of the Δ-EIG protocol we define a node σ to be *corrupted in* $\texttt{tree}_i$ if σ is not closed in $\texttt{tree}_i$ by the end of round $|\sigma| + 2$.

A node σ is said to be *universally corrupted* if it is corrupted in $\texttt{tree}_i$ for all nonfaulty processors i. The following three lemmas show that, in order to cause lasting trouble, a node must be universally corrupted.

LEMMA 6.15. *Let i and j be nonfaulty processors, and let σ be a node of the safe subtree. If σ is fixed in $\texttt{tree}_i$ by rule Fx2, then σ is closed in $\texttt{tree}_j$ by the end of round $|\sigma| + 3$.*

Proof. The claim follows immediately for righteous nodes σ by Corollary 6.4. We shall henceforth consider the case in which σ is not righteous, so that at most $t - |\sigma|$ of its children are faulty. We prove the claim for $|\sigma| \geq 2$; the modifications for the cases $|\sigma| = 0$ and $|\sigma| = 1$ are simple and left for the reader. Assume that σ is fixed in $\texttt{tree}_i$ by rule Fx2, and that σ is not closed in $\texttt{tree}_j$ by the end of round $|\sigma| + 2$. Since σ is fixed to v in $\texttt{tree}_i$ by Fx2 in round $|\sigma| + 1$, we have that at least $n - t - 2 - (t - |\sigma|) = n - 2t + |\sigma| - 2 \geq t + |\sigma| - 1$ of σ's children in $\texttt{tree}_j$ are righteous children that store v. If σ is not closed in $\texttt{tree}_j$ beforehand, then Corollary 6.4 implies that these nodes will all be fixed to v in $\texttt{tree}_j$ by the end of round $|\sigma| + 3$. Since $F(|\sigma|) \leq t + |\sigma| - 1$ we have that σ becomes fixed to v in $\texttt{tree}_j$ by Fx3(a) at the end of round $|\sigma| + 3$. □

As a consequence of Lemma 6.15, a straightforward induction yields the following.

COROLLARY 6.16. *Let i and j be nonfaulty processors, and let σ be a node of the safe subtree. If σ is closed in $\texttt{tree}_i$ by the end of round r, then it is closed in $\texttt{tree}_j$ by the end of round $r + 2$.*

COROLLARY 6.17. *Let i be a nonfaulty processor, and let τ be a node that is not universally corrupted. Then τ is closed in $\texttt{tree}_i$ by the end of round $|\tau| + 4$.*

Proof. By definition of corruption, a node τ that is not universally corrupted must be closed in $\texttt{tree}_j$ for some nonfaulty j by the end of round $|\tau|+2$. By Corollary 6.16 we have that τ is closed in $\texttt{tree}_i$ by the end of round $|\tau|+4$. □

As in the case of $n > 4t$, there is a close relationship between corrupted nodes and failure detection. Indeed, an immediate consequence of the fault discovery rule FD2 and the commitment rule C3 is the fact that a processor that corrupts a node in $\texttt{tree}_i$ is discovered by i as being faulty. Formally, we have the following lemma.

LEMMA 6.18. *If a node τz is corrupted in $\texttt{tree}_i$, then $z \in \mathcal{F}_i(|\tau z|+2)$.*

Given Lemmas 6.2 and 6.18, we obtain the following relationship between universal corruption and disabled processors.

COROLLARY 6.19. *If a node τz is universally corrupted, then processor z is disabled from the end of round $|\tau z|+2$ on.*

Since corruption is determined within at most two rounds, Corollary 6.19 implies that a faulty processor can universally corrupt nodes in at most two different rounds. Thus, our situation resembles that of the $n > 4t$ case with majority, except that now the faulty processors are able to corrupt nodes in two consecutive rounds in some cases. This will force us to consider the possibility of cross corruption in section 7.

6.4.1. Waste. One consequence of Corollary 6.17 is that if no node σ of depth r is universally corrupted, then all such nodes are closed by the end of round $r+4$. Moreover, it is easy to see that if all nodes of depth r are closed, then so are all of their ancestors including the root. We thus have the following lemma.

LEMMA 6.20. *If no node σ of depth $|\sigma| = r$ is universally corrupted, then the root λ is closed in all processors' trees by the end of round $r+4$.*

We say that a processor z *universally corrupts a node τz at depth r* if the node τz is universally corrupted, and $|\tau z| = r$. Notice that whether z universally corrupts τz might depend on events that take place after round $r = |\tau z|$, such as what values other faulty processors report for τz, and who is masking z in round $r+1$. Intuitively, we can figure out whether z universally corrupted τz only in round $r+2$. Corollary 6.19 states that at most two rounds after a processor universally corrupts a node, this processor is disabled. Corollary 6.3 implies that a disabled processor cannot universally corrupt nodes. It follows that a processor can universally corrupt nodes in at most two (consecutive) rounds. However, it is not hard to see that a processor z cannot be the only processor universally corrupting nodes in a pair of consecutive rounds r and $r+1$.

LEMMA 6.21. *Assume that z universally corrupts nodes at depth r. If there are universally corrupted nodes at depth $r+1$, then there must be at least one processor $z' \neq z$ corrupting nodes either at depth r or at depth $r+1$.*

Proof. Assume that τxy is a node of depth $|\tau xy| = r+1$ that is universally corrupted. If no processor other than z universally corrupts nodes at depth $r+1$, we must have that $y = z$. By definition of the EIG tree, a node is a sequence of processor names without repetitions, and hence $x \neq z$. Since τxy is universally corrupted, it is not closed in any processor's tree by the end of round $|\tau|+4$. It follows that τx is also not closed in any processor's tree at that point. We conclude that τx was not closed in any tree at the end of round $|\tau|+3 = |\tau x|+2$, and hence was universally corrupted. Thus, $x \neq z$ universally corrupted nodes at depth r, and the claim follows. □

Lemma 6.20 implies that in order to keep the trees from closing, at least one processor must universally corrupt nodes at every depth. Moreover, Lemma 6.21 implies that at least two different processors must universally corrupt nodes in consecutive rounds. Finally, by Corollary 6.19, we know that two rounds after a processor universally corrupts nodes, this processor is disabled. It follows that, roughly speaking,

in order to keep the root from closing, at least one processor per round must become disabled. We now make a few definitions that will allow us to make this intuition into a precise statement, and will later help us in the analysis of monitor voting.

Let us denote by $\mathcal{D}(r)$ the set of processors that are disabled at the end of round r. We define the *deficit* at r, denoted $\texttt{deficit}(r)$, to be the number of processors that universally corrupt nodes at depth $r-1$, but are not disabled by the end of round r. Recall that every processor that universally corrupts a node at depth $r-1$ is detected by all nonfaulty processors as faulty (and hence disabled) by the end of round $r+1$. We thus have $\#\mathcal{D}(r+1) \geq \#\mathcal{D}(r) + \texttt{deficit}(r)$. We are almost ready to define the *waste* at r. Roughly speaking, the term *waste* comes from the idea that the nonfaulty processors are playing against an adversary.[6] This adversary is trying to enlarge the size of processors' trees without spending more than one disabled processor per round. The waste measures the extent by which the adversary has exceeded this allowance. Intuitively, the waste should be a measure, stated in terms of the number of disabled processors and the deficit, that will have the following properties:

1. As long as at least one node is universally corrupted in every round, the waste should be nondecreasing;

2. an appropriate form of monitor voting will guarantee that if the waste exceeds a certain constant threshold, then the agreement process will be halted; and

3. as long as the waste does not exceed the threshold of (2), then the number of universally corrupted nodes in the tree is polynomial.

To obtain this, we define the *waste* at the end of round r, denoted by $\texttt{Waste}(r)$, as follows:

$$\texttt{Waste}(r) \;=\; \#\mathcal{D}(r) - r + \texttt{deficit}(r) - \texttt{correction}(r).$$

The last term, $\texttt{correction}(r)$, is technically needed in order to compensate for cases in which the processors that form the deficit are able to corrupt nodes at depth r in addition to round $r-1$. In this case, we want to account one of these processors to the following round. Formally, we define $\texttt{correction}(r)$ as follows:

$$\texttt{correction}(r) = \begin{cases} 0 & \text{if } \texttt{deficit}(r) = 0; \\ 0 & \text{if } \texttt{deficit}(r) = 1 \text{ and only one processor universally} \\ & \qquad\qquad \text{corrupts nodes at depth } r-1; \quad \text{and} \\ 1 & \text{otherwise.} \end{cases}$$

In other words, the correction is 1 if either $\texttt{deficit}(r) \geq 2$, or if $\texttt{deficit}(r) = 1$, provided there is at least one processor universally corrupting nodes at depth $r-1$ in addition to the processor forming the deficit at r. In either case, we deduct a cost of 1 for the fact that some processor in the deficit had the option of causing harm at depth r as well as at depth $r-1$. The following lemma makes this claim precise.

LEMMA 6.22. *If* $\texttt{correction}(r) = 0$ *then no processor universally corrupts nodes both at depth* $r-1$ *and at depth* r.

Proof. We consider the two cases in which $\texttt{correction}(r) = 0$. For the first case, if $\texttt{deficit}(r) = 0$, then all processors that universally corrupt nodes in round $r-1$ are disabled by the end of round r, and hence cannot corrupt nodes at depth r. For the other case, assume that $\texttt{deficit}(r) = 1$ and let z be the processor forming the deficit at r. By definition, if $\texttt{correction}(r) = 0$ then z is the only processor that

[6] The notion of *waste* used here is close in spirit to, though technically quite different from, a similar notion introduced in the work of Dwork and Moses [12].

universally corrupts nodes at depth $r-1$. By Lemma 6.21, z cannot also universally corrupt nodes at depth r. □

We can now prove the following theorem.

THEOREM 6.23. *Let $r \geq 2$. If $\texttt{Waste}(r+1) < \texttt{Waste}(r)$ then no node of depth r is universally corrupted.*

Proof. We prove the contrapositive: assume that there is at least one universally corrupted node at depth r, and we shall show that $\texttt{Waste}(r+1) \geq \texttt{Waste}(r)$. Recall from the discussion above that $\#\mathcal{D}(r+1) \geq \#\mathcal{D}(r) + \texttt{deficit}(r)$. In addition, notice that, by definition of `correction`, we are guaranteed that $\texttt{deficit}(r') - \texttt{correction}(r') \geq 0$ for all r', and in particular we will have that $\texttt{deficit}(r+1) - \texttt{correction}(r+1) \geq 0$. We consider three cases:

(i) At least one processor universally corrupting nodes at depth $r-1$ also universally corrupts nodes at depth r. In this case, we have by Lemma 6.22 that $\texttt{correction}(r) = 1$. We thus have:

$$\begin{aligned}\texttt{Waste}(r+1) &= \#\mathcal{D}(r+1) - (r+1) + \texttt{deficit}(r+1) - \texttt{correction}(r+1) \geq \\ &\#\mathcal{D}(r+1) - (r+1) \geq \#\mathcal{D}(r) + \texttt{deficit}(r) - r - 1 = \\ &\#\mathcal{D}(r) - r + \texttt{deficit}(r) - \texttt{correction}(r) = \texttt{Waste}(r).\end{aligned}$$

(ii) The assumption of case (i) does not hold, and at least one processor z that universally corrupts nodes at depth r is disabled by the end of round $r+1$. Clearly, $z \notin \mathcal{D}(r)$, and by assumption we have that z is not one of the processors forming a deficit at r. Since z is disabled by the end of round $r+1$, we have that $\#\mathcal{D}(r+1) \geq \#\mathcal{D}(r) + \texttt{deficit}(r) + 1$, and hence we are guaranteed that $\texttt{Waste}(r+1) \geq \texttt{Waste}(r)$ by:

$$\begin{aligned}&\texttt{Waste}(r+1) \geq \#\mathcal{D}(r+1) - (r+1) \geq \#\mathcal{D}(r) + \texttt{deficit}(r) + 1 - (r+1) = \\ &\#\mathcal{D}(r) + \texttt{deficit}(r) - r \geq \#\mathcal{D}(r) - r + \texttt{deficit}(r) - \texttt{correction}(r) = \texttt{Waste}(r).\end{aligned}$$

(iii) The assumptions of cases (i) and (ii) do not hold. Thus, no processor universally corrupts nodes both at depth $r-1$ and at depth r, and no processor that universally corrupts nodes at depth r is disabled by the end of round $r+1$. It follows that only processors forming the deficit at $r+1$ universally corrupt nodes at depth r. In this case, if $\texttt{deficit}(r+1) \geq 2$, then $\texttt{deficit}(r+1) - \texttt{correction}(r+1) \geq 1$, and we have that that $\texttt{Waste}(r+1) \geq \#\mathcal{D}(r) + \texttt{deficit}(r) + 1 - (r+1)$ and hence $\texttt{Waste}(r+1) \geq \texttt{Waste}(r)$ as in the previous case. Finally, if $\texttt{deficit}(r+1) = 1$ then the assumptions imply that the processor forming the deficit at $r+1$ is the only processor universally corrupting nodes at depth r. By the definition of `correction` we thus have that $\texttt{correction}(r+1) = 0$, and we again obtain that $\texttt{deficit}(r+1) - \texttt{correction}(r+1) \geq 1$, so that $\texttt{Waste}(r+1) \geq \texttt{Waste}(r)$ and we are done. □

Theorem 6.23 will be instrumental in the correctness of our ultimate algorithm. We shall design the monitor voting scheme in such a way that once the waste becomes large enough (which in our case will mean at least two), an appropriate monitor decision process will "fire," thereby causing the processors all to decide on a default value and halt.

In section 7.3 we shall demonstrate how it is possible to stop interacting about a subtree of the EIG tree after it becomes closed. As a result, a fundamental parameter determining the size of the processors' trees will be the number of universally corrupted nodes in the tree. Theorem 6.23 allows us to formalize the idea that there is a close relationship between the waste of an execution and the number of universally

corrupted nodes in the tree. Recall, for example, that if there is only one processor universally corrupting nodes at any given depth, then the total number of universally corrupted nodes is no greater than t. In order for this number to grow, it is necessary for there to be levels of the tree at which two or more processors universally corrupt nodes. Notice, however, that if three or more processors universally corrupt nodes at depth r, then Corollary 6.19 implies they all will be disabled by the end of round $r+2$, and as a result we would have that $\texttt{Waste}(r+2) > \texttt{Waste}(r)$. As we are going to start with a waste at $r = 2$ of at least -1, it will follow that after a constant number of such rounds, the monitors will detect a problem and stop the growth of the EIG tree.

The only situation in which the number of universally corrupted nodes can grow more than in a linear fashion, and the waste need not increase, is in the case of *cross corruption*. This is a situation in which two processors, say a and b, universally corrupt nodes at depth r, and they continue to be the only processors to universally corrupt nodes at depth $r+1$. Specifically, if a corrupted a node τa at depth r and b corrupted τb, then at depth $r+1$ we will find b universally corrupting τab, while a corrupts τba. See Figure 3 for an illustration of this situation. In this fashion, it is possible to double the number of universally corrupted nodes of depth $r+1$ compared to the number of corrupted nodes of depth $r-1$, without increasing the waste.[7]

The next section is devoted to cross corruption. In particular, we shall devise an admissible resolve function that will restrict the number of times at which cross corruption need not increase the waste.

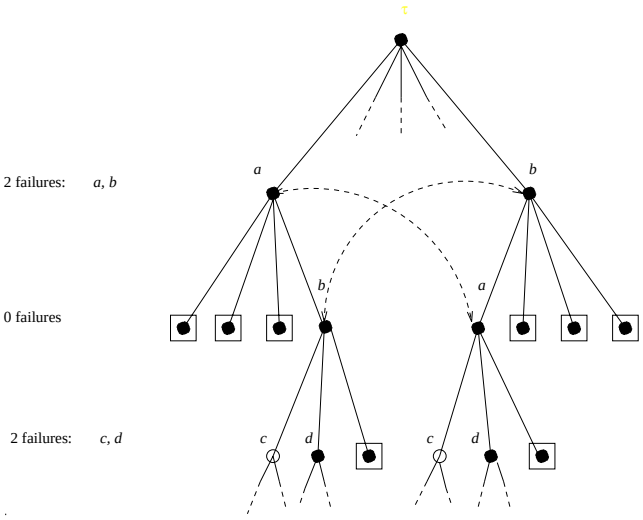

FIG. 3. *Cross corruption.*

7. Cross corruption. As discussed in the last section, in order for the number of universally corrupted nodes to grow significantly without the waste growing at the same time, pairs of faulty processors need to cross corrupt nodes in consecutive rounds. In this section, we perform a careful analysis of the conditions that must be met for cross corruption to succeed. We then use this analysis to fine tune the

[7] Indeed, Berman and Garay [5] have shown that for the resolve function of [2] for $n > 3t$, it is possible to construct an exponential tree this way, despite fault masking, early stopping, and monitor voting.

function F we use for fixing nodes, to limit the number of times that a cross corruption can take place without the waste increasing. This analysis will yield essentially all of the necessary ingredients for our final protocol.

The first property of cross corruption we shall use is the fact that in cross corruption, each universally corrupted node τa in the first of the two rounds has at most one universally corrupted child τab. As a result, if the node τa is not closed in a small number of rounds, then all of its children other than τab must be fixed in all trees. Moreover, since τa is not closed after these nodes become fixed, the number of its children fixed to $\mathtt{par}(|\tau a|)$ and the number fixed to its complement are uniquely determined. More specifically, we have the following lemma.

LEMMA 7.1. *In a* Δ-EIG *protocol with admissible function* F*, let* $v = \mathtt{par}(|\tau a|)$ *and let* τa *be a universally corrupted node whose only universally corrupted child is* τab*. For every nonfaulty processor* i*, if* τa *is not closed in* $\mathtt{tree}_i$ *by the end of round* $|\tau| + 6$*, then all of its children other than* τab *are fixed in* $\mathtt{tree}_i$ *at that point. Moreover, let* A *denote the set of processors* x *for which the node* τax *is fixed to* v *in* $\mathtt{tree}_i$*, and let* B *denote the set of processors* y *such that* τay *is fixed to* $1 - v$*. Then* $\#A = F(|\tau a|) - 1$ *and* $\#B = n - |\tau a| - F(|\tau a|)$.

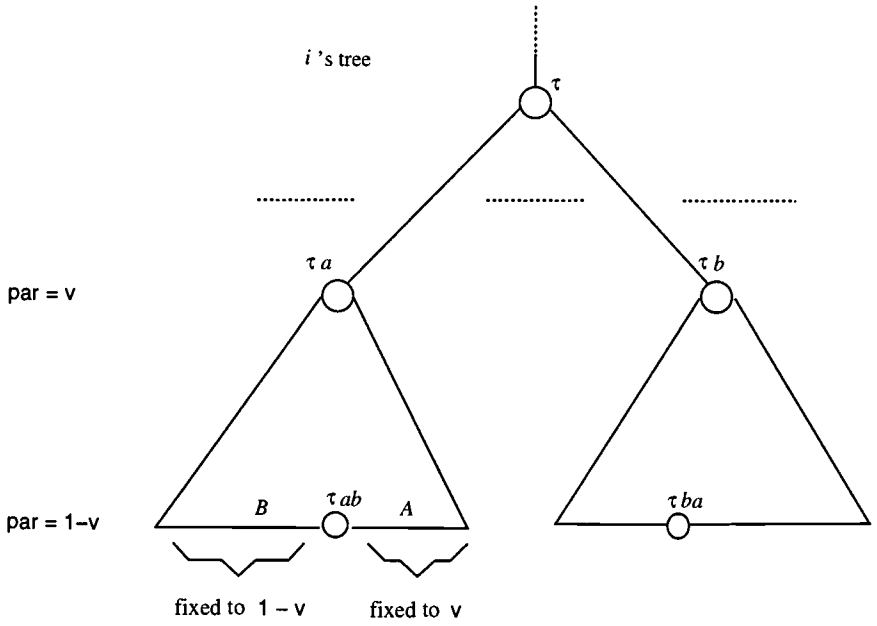

FIG. 4. *Two universally corrupted nodes.*

Proof. The scenario described in the statement of the lemma is depicted in Figure 4. Corollary 6.17 implies that a node τax that is not universally corrupted must be closed in all trees by the end of round $|\tau ax| + 4 = |\tau| + 6$. Since we are assuming that τa is not closed in $\mathtt{tree}_i$ at that point, it follows that every such node τax will necessarily be fixed in $\mathtt{tree}_i$ by the end of round $|\tau| + 6$. Since τab is the only universally corrupted child of τa, we obtain that all other children of τa must be fixed in $\mathtt{tree}_i$ by the end of round $|\tau| + 6$. Let A be set of processors x such that the node τax is fixed to v in $\mathtt{tree}_i$ (by the end of round $|\tau| + 6$), and let B the set of processors y such that the node τay is fixed to $1 - v$. This is depicted in Figure 4.

Since τa is not closed in $\texttt{tree}_i$ by the end of round $|\tau|+6$ we are guaranteed that $\#A < F(|\tau a|)$ and $\#B < n - |\tau a| + 1 - F(|\tau a|)$. However, the fact that only one of τa's children is universally corrupted implies that $\#A + \#B = n - |\tau a| - 1$. It follows that $\#A = F(|\tau a|) - 1$ and $\#B = n - |\tau a| - F(|\tau a|)$. □

Another observation regarding cross corruption is the following. Recall that every node of the safe subtree must be publicly committed either to 0 or to 1. If a node τac is publicly committed to v and then becomes fixed to $1-v$, then by rule FD2 everybody will discover that c is faulty by the end of round $|\tau ac|+2 = |\tau|+4$, and c will become disabled by then. As a result, we obtain the following lemma.

LEMMA 7.2. *Under the conditions and notation of Lemma* 7.1*, let $C \subseteq B$ consist of the processors c such that τac is publicly committed to v. Then $C \subseteq (\mathcal{D}(|\tau|+5) \setminus \mathcal{D}(|\tau|+2))$.*

Proof. By definition of C, for every nonfaulty processor j we have that each node τac with $c \in C$ is committed to v in $\texttt{tree}_j$. In addition, since $C \subseteq B$, we have that τac is fixed to $\texttt{right}^F(\tau ac) = 1 - v$ in $\texttt{tree}_i$ by the end of round $|\tau| + 6$. As a result, we have by Theorem 6.8 and Lemma 6.7 that τac cannot become fixed to v in $\texttt{tree}_j$. Moreover, since, by assumption, τa is not closed in $\texttt{tree}_i$ by the end of round $|\tau| + 6$, we have by Corollary 6.16 that τa is not closed in $\texttt{tree}_j$ by the end of round $|\tau| + 4 = |\tau ac| + 2$. Hence, τac can be closed in $\texttt{tree}_j$ at the end of round $|\tau ac|+2$ only if it is fixed (to $1-v$) in $\texttt{tree}_j$ at that point. If it is indeed fixed to $1 - v$ in $\texttt{tree}_j$ at the end of round $|\tau| + 4$, then τac is committed at that point to $1 - v$ in $\texttt{tree}_j$ by Lemma 6.12. If not, then it is committed to $1 - v$ at that point by C3. Since τa is not closed in $\texttt{tree}_j$ by the end of round $|\tau| + 4|$, we have that τac is not closed in $\texttt{tree}_j$ by the end of round $|\tau ac|$. Thus, in either case, rule FD2 implies that j detects c as faulty by the end of round $|\tau| + 4$. Since this argument applies for every nonfaulty processor j, we have that c is disabled at the end of round $|\tau| + 4$. Notice, however, that c could not have been disabled at the end of round $|\tau| + 2$, for if it had been disabled at that point, then, by Lemma 6.2, τac would not be publicly committed to v: all nonfaulty processors would be reporting $1 - v$ for τac by masking c. By definition of B, this contradicts the assumption that $c \in C \subseteq B$. We conclude that $C \subseteq (\mathcal{D}(|\tau| + 4) \setminus \mathcal{D}(|\tau| + 2))$. Since $\mathcal{D}(|\tau| + 5) \supseteq \mathcal{D}(|\tau| + 4)$, we obtain that $C \subseteq (\mathcal{D}(|\tau| + 5) \setminus \mathcal{D}(|\tau| + 2))$ and we are done. □

Lemma 7.2 implies that, in order to avoid having the waste grow in an instance of cross corruption, the size of the set C must remain small. Specifically, as we shall see later on, it is necessary that $\#C \leq 2$. When this is the case, then the vast majority of nodes τay with $y \in B$ must be publicly committed to $1 - v$. As a result, if B is large enough, we can use the fault-detection rule FD3 to force the processors in A to mask a in round $|\tau| + 3$. More specifically, we have the following lemma.

LEMMA 7.3. *Under the conditions and notation of Lemma* 7.1*, let $B' \subseteq B$ consist of the processors $y' \in B$ such that the node $\tau ay'$ is publicly committed to $1-v$. Assume $\#B' \geq 2(t+1-|\tau a|)+1$. If the node τba is not closed in $\texttt{tree}_i$ at the end of round $|\tau|+7$, then every processor $x \in A$ for which τbax is not fixed to $1-v$ in $\texttt{tree}_i$ by the end of round $|\tau| + 7$ is disabled by the end of round $|\tau| + 5$.*

Proof. Consider the following two cases.

(i) τbax is not closed in $\texttt{tree}_i$ by the end of round $|\tau| + 7$: In this case, by Corollary 6.17 we have that τbax is universally corrupted, and by Corollary 6.19 we obtain that x is disabled by the end of round $|\tau bax| + 2 = |\tau| + 5$.

(ii) τbax is closed in $\texttt{tree}_i$ by the end of round $|\tau| + 7$: Since, by assumption, τba is not closed in $\texttt{tree}_i$ by the end of round $|\tau|+7$, if τbax is closed in $\texttt{tree}_i$ at that

point, then it must be fixed in $\texttt{tree}_i$. Moreover, since we have assumed that τbax is not fixed to $1-v$, it must be fixed to v in $\texttt{tree}_i$ by the end of round $|\tau|+7$. As a result, for every nonfaulty processor j, the node τbax does not become fixed to $1-v$ in $\texttt{tree}_j$. We now show that every nonfaulty processor j must have detected x as faulty no later than in round $|\tau|+5$.

Let j be an arbitrary nonfaulty processor. Recall that every node τax with $x \in A$ is fixed in $\texttt{tree}_i$ to $v \neq \texttt{par}(|\tau ax|)$ by the end of round $|\tau|+6$. By Lemma 6.13 we thus have that every node τax with $x \in A$ is publicly committed to v. If x does not send j a $\texttt{mask}(x,a)$ message by the end of round $|\tau|+3$ then the conditions of the fault detection rule FD3 hold for j with respect to x:

(i) τax is committed to v in $\texttt{tree}_j$; and

(ii) since all nodes τay with $y \in B'$ are publicly committed to $1-v$, at least $\#B' \geq 2(t+1-|\tau a|)+1$ such nodes τay are committed to $1-v$ in $\texttt{tree}_j$ by the end of round $|\tau ax|+1$. It follows that j will detect x as faulty in round $|\tau|+3$.

If $x \in \mathcal{F}_j(|\tau|+3)$ then we are done. Otherwise, x sent j a $\texttt{mask}(x,a)$ message by the end of round $|\tau|+3$, and hence by the masking rule we have that $\texttt{tree}_j(\tau bax) = 1-v$, so that τbax is committed to $1-v$ in $\texttt{tree}_j$ by C1. In addition, since

(i) τbax is not closed in $\texttt{tree}_j$ by the end of round $|\tau bax|+1$; and

(ii) τbax is not fixed to $1-v$ by the end of round $|\tau bax|+2 = |\tau|+5$,

we have that τbax is committed in $\texttt{tree}_j$ to v by C3 by the end of round $|\tau|+5$. Given that τba is not closed in $\texttt{tree}_i$ by the end of round $|\tau|+7$, Corollary 6.16 implies that τba is not closed in $\texttt{tree}_j$ by the end of round $|\tau|+5$. It follows that τbax is not closed in $\texttt{tree}_j$ by the end of round $|\tau bax|+2 = |\tau|+5$. Hence, by fault discovery rule FD2, we obtain that $x \in \mathcal{F}_j(|\tau|+5)$ and we are done. □

Roughly speaking, Lemma 7.3 implies that in a successful cross corruption, most members of A must mask a when reporting on τba. The ones that do not will become disabled by the end of round $|\tau|+5$. As a result, if $F(|\tau|) \geq F(|\tau|+1)+3$, then for τba not to close by the end of round $|\tau|+7$, at least three members of A must become disabled by the end of round $|\tau|+5$. As we shall see, this will be sufficient to guarantee that a cross corruption in these rounds must increase the waste by at least 1.

7.1. A concrete admissible function. Lemmas 7.2 and 7.3 motivate us to seek an admissible function F with the following two properties:

1. $F(r) \leq t+r-4$ for all $2 \leq r \leq t$, and
2. $F(r) \geq F(r+1)+3$ for all $2 \leq r \leq t$.

In the notation of the above lemmas, the first property guarantees, for nodes τ satisfying $|\tau| \geq 2$, that if $\#B' \leq 2(t+1-|\tau a|)$ then $\#C \geq 3$. As we shall see, a combination of both properties implies that a cross corruption must necessarily cause an increase in the waste. Unfortunately, an admissible function with both properties does not exist. We now turn to define a function that will have the first property, and will approximate the second property. This property will hold for all but a small number of rounds r.

Recall that, for F to be admissible, it must satisfy $t+r-1 \geq F(r) \geq t-r+2$ for $2 \leq r \leq t$. Intuitively, we divide the execution into "phases" consisting of many rounds each. In each phase we start with $F(r)$ being close to $t+r$, and we reduce the threshold by steps of 3 from one round to the next until we come close to $t-r$. A new phase then begins. Rather than at $t+r-1$, a phase will start with the threshold no greater that $t+r-4$, to guarantee the first property described above. Thus, both desired properties are maintained during a phase, but they are violated in the

transition between phases. Luckily, the number of such transitions will be shown to be logarithmic in n.

We define $\mathsf{rem}(k)$ to be the difference between k and the largest power of 2 that is smaller than k. More precisely stated,

$$\mathsf{rem}(k) \stackrel{\text{def}}{=} k - 2^{\lfloor \log_2 k \rfloor}.$$

Notice that $\mathsf{rem}(k) = 0$ for $k \geq 1$ precisely if k is a power of 2. Moreover, one property of rem that we shall use in the sequel is that, for all natural numbers $k \geq 1$ we have $0 \leq \mathsf{rem}(k) \leq \frac{k+1}{2} - 1$, so that, in particular, we have $0 \leq 4\mathsf{rem}(k) \leq 2k - 2$.

Our threshold function F^* is defined as follows:

$$F^*(r) = \begin{cases} t+1 & \text{for } 0 \leq r \leq 4; \text{ and} \\ t + r - 4 - 4\mathsf{rem}(r-3) & \text{for } r \geq 5. \end{cases}$$

A few essential properties of the function F^* that we shall find useful in the sequel are as follows.

LEMMA 7.4. *If $r \geq 5$ then*

$$t + r - 4 \;\geq\; F^*(r) \;\geq\; t - r + 4.$$

Proof. Since $0 \leq 4\mathsf{rem}(k) \leq 2k-2$ for $k \geq 2$, we have that $0 \leq 4\mathsf{rem}(r-3) \leq 2r-8$ for $r \geq 5$. It follows that $t+r-4 \geq F^*(r) \geq t+r-4-(2r-8) = t+r-4-2r+8 = t-r+4$ for $t+1 \geq r \geq 5$ and we are done. □

LEMMA 7.5. *The function F^* is an admissible resolve function.*

Proof. Recall that a function F is admissible if it satisfies $F(0) = F(1) = t+1$ and $t + r - 1 \geq F(r) \geq t - r + 2$ for $r \geq 2$. For $r = 0, 1$ we have $F^*(r) = t+1$ as desired. For $2 \leq r \leq 4$ we have $F^*(r) = t+1$ and $t + r - 1 \geq t + 1 \geq t - r + 2$. For $r \geq 5$, Lemma 7.4 states that $t + r - 4 \geq F^*(r) \geq t - r + 4$. We thus have $t + r - 1 \geq t + r - 4 \geq F^*(r) \geq t - r + 4 \geq t - r + 2$ and we are done. □

LEMMA 7.6. *Let $r \geq 5$ and assume that $r - 2$ is not a power of 2. Then $F^*(r) - F^*(r+1) = 3$.*

Proof. Since $r \geq 5$, we have that $F^*(r) = t + r - 4 - 4\mathsf{rem}(r-3)$, while $F^*(r+1) = t + r - 3 - 4\mathsf{rem}(r-2)$. The fact that $r-2$ is not a power of 2 implies that $\mathsf{rem}(r-2) = \mathsf{rem}(r-3)+1$. It follows that $F^*(r) = t+r-3+1-4(\mathsf{rem}(r-2)-1) = F^*(r+1) - 1 + 4 = F^*(r+1) + 3$ and we are done. □

Obviously, the number of rounds $r \leq t$ for which $r-2$ is a power of 2 is roughly $\log_2 t$.

7.2. The main lemma. We are now in a position to prove that, given our fixing and fault detection rules, the price of cross corruption is high. In other words, that for cross corruption to take place, many faulty processors must become disabled. As a result, cross corruption will no longer be a problem for monitor voting. We now have the following.

LEMMA 7.7. *Let τa and τb be universally corrupted nodes, such that*

(i) *$|\tau| \geq 4$ and $|\tau| - 1$ is not a power of 2;*

(ii) *the only universally corrupted child of τa is τab and the only universally corrupted child of τb is τba; and*

(iii) *for some i, both of the nodes τa and τb are not closed in $\mathtt{tree}_i$ by the end of round $|\tau| + 7$.*

Then

$$\#(\mathcal{D}(|\tau|+5) \setminus \mathcal{D}(|\tau|+2)) \ \geq \ 5.$$

Proof. The situation considered in this lemma is partly illustrated by Figure 4. We first prove the following about a and b.

CLAIM 7.8. $a, b \in (\mathcal{D}(|\tau|+5) \setminus \mathcal{D}(|\tau|+2))$.

Proof. The fact that τa and τb are not closed in $\texttt{tree}_i$ by the end of round $|\tau|+7$ implies, by Corollary 6.17, that these nodes are universally corrupted. By Corollary 6.19 we thus obtain that both a and b must be disabled no later than at the end of round $|\tau a|+2 = |\tau|+3$. However, if either of them were disabled by the end of round $|\tau|+2$, then all nonfaulty processors would be masking them in round $|\tau|+3$, and by Lemma 6.2 we would have that τba and τab would not be corrupted in any nonfaulty processor's tree, contradicting our assumption about a and b. It follows that

$$a, b \in (\mathcal{D}(|\tau|+3) \setminus \mathcal{D}(|\tau|+2)) \subseteq (\mathcal{D}(|\tau|+5) \setminus \mathcal{D}(|\tau|+2)). \qquad \square$$

Given Claim 7.8, we need to show that, under the conditions of the lemma, at least three additional faulty processors must become disabled between rounds $|\tau|+3$ and $|\tau|+5$.

We shall perform our analysis based on the subtree rooted at τa. Assume the conditions of the lemma hold, and without loss of generality let $\texttt{par}(|\tau a|) = v$. Since τab is the only universally corrupted child of τa, it follows by Corollary 6.17 that all other children of τa must be fixed in $\texttt{tree}_i$ by the end of round $|\tau|+6$. Let A denote the set of processors x such that the node τax is fixed to v in $\texttt{tree}_i$ (by the end of round $|\tau|+6$), and let B the set of processors y such that the node τay is fixed to $1-v$. This is depicted in Figure 4. The conditions of Lemma 7.1 are satisfied, and as a result we have that $\#A = F^*(|\tau a|) - 1$ and $\#B = n - |\tau a| - F^*(|\tau a|)$.

As in Lemma 7.2, let C denote the subset of B consisting of processors c such that τac is publicly committed to v.

Let us denote $B' \stackrel{\text{def}}{=} B \setminus C$. By definition, every node $\tau ay'$ with $y' \in B'$ is publicly committed to $1-v$, and is hence committed to $1-v$ in every nonfaulty processor's tree. We now show that, if B' is "small" (namely, $\#B' \leq 2(t+1-|\tau a|)$), then C is large enough (i.e., $\#C \geq 3$) to yield the lemma. If B' is not small, however, we shall use Lemma 7.3 to show that sufficiently many processors, this time members of A, must be disabled. Thus, either way we obtain that at least three processors in addition to a and b become disabled in rounds $|\tau|+3$ through $|\tau|+5$.

As described above, we consider two cases:

(i) $\#B' \leq 2(t+1-|\tau a|)$: In this case, we claim that $\#C \geq 3$. This follows from the fact that $\#B = n - |\tau a| - F^*(|\tau a|)$ and $\#C = \#B - \#B'$. The calculation is as follows:

$$\begin{aligned}
\#C &\geq n - |\tau a| - F^*(|\tau a|) - 2(t+1-|\tau a|) \\
&= n - 2t + |\tau a| - 2 - F^*(|\tau a|) \\
&\geq n - 2t + |\tau a| - 2 - (t + |\tau a| - 4) \\
&= n - (3t+1) + 3 \geq 3.
\end{aligned}$$

Lemma 7.2 implies that $C \subseteq (\mathcal{D}(|\tau|+5) \setminus \mathcal{D}(|\tau|+2))$. In the claim above we showed that $a, b \in (\mathcal{D}(|\tau|+5) \setminus \mathcal{D}(|\tau|+2))$. Since $a \notin C$ and $b \notin C$, we obtain that $\#(\mathcal{D}(|\tau|+5) \setminus \mathcal{D}(|\tau|+2) \geq 5$.

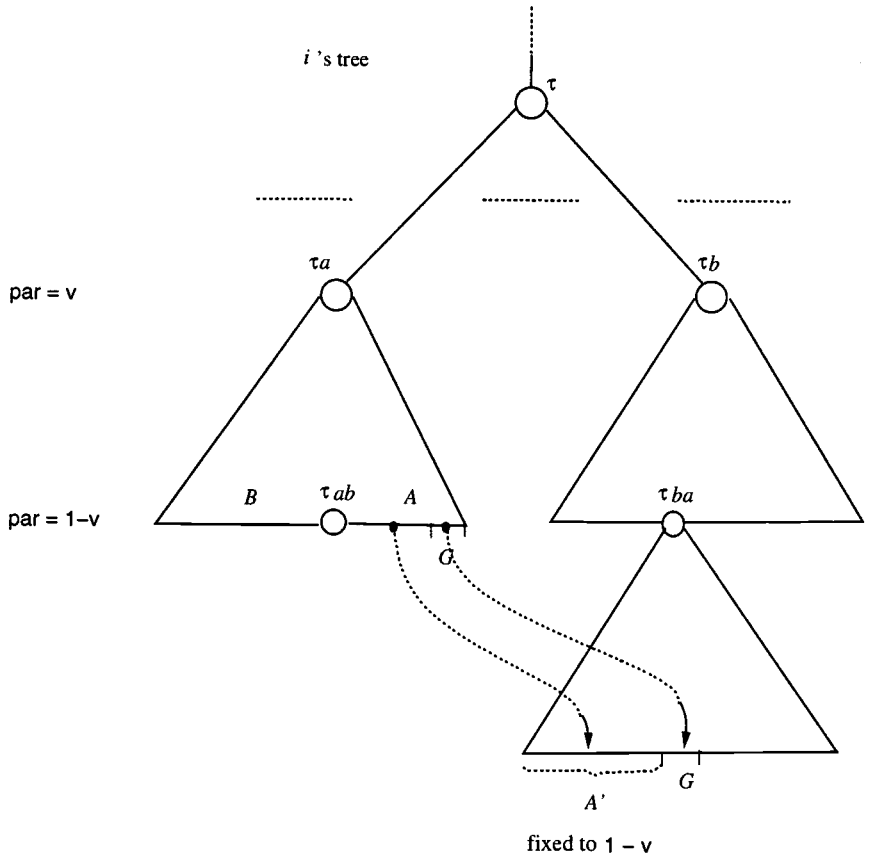

FIG. 5. *A set G of newly disabled processors.*

(ii) $\#B' \geq 2(t+1-|\tau a|)+1$: Since we are assuming that $|\tau| \geq 4$ we have $|\tau a| \geq 5$. By Lemma 7.6 we thus have that $F^*(|\tau a|) - F^*(|\tau ba|) = 3$. Let A' consist of the processors x' such that $\tau bax'$ is fixed to $1-v$ in $\texttt{tree}_i$ by the end of round $|\tau|+7$. Since τb is not closed in $\texttt{tree}_i$ by the end of round $|\tau|+7$ and τba is the only universally corrupted child of τb, we have that τba is also not closed in $\texttt{tree}_i$ at that point. It follows that $\#A' \leq F^*(|\tau ba|) - 1 = F^*(|\tau a|) - 4 = \#A - 3$. Define $G \stackrel{\text{def}}{=} (A \setminus A')$ (see Figure 5). In particular, we obtain that $\#G \geq 3$. Moreover, if a processor $z \in A$ is disabled by the end of round $|\tau|+3$, then Lemma 6.2 and the masking rules imply that τbaz is fixed in $\texttt{tree}_i$ to $\texttt{par}(|\tau ba|) = 1-v$ by the end of round $|\tau|+4$. It follows that no processor $x \in G$ is disabled by the end of round $|\tau|+3$. The conditions of Lemma 7.3 are satisfied with respect to every $x \in G$, and hence by Lemma 7.3 we have that $G \subseteq (\mathcal{D}(|\tau|+5) \setminus \mathcal{D}(|\tau|+2))$. Notice that $a, b \notin G$. Thus, we again obtain that $\#(\mathcal{D}(|\tau|+5) \setminus \mathcal{D}(|\tau|+2)) \geq 5$, and we are done. □

As a consequence of Lemma 7.7 and the definition of `Waste` we obtain the following.

COROLLARY 7.9. *If the conditions of Lemma* 7.7 *hold with respect to τ, then* $\texttt{Waste}(|\tau|+5) > \texttt{Waste}(|\tau|+1)$.

Proof. We have defined $\texttt{Waste}(r)$ by:

$$\texttt{Waste}(r) \;=\; \#\mathcal{D}(r) - r + \texttt{deficit}(r) - \texttt{correction}(r).$$

By definition, we have that $\texttt{correction}(r) \geq 0$, and $\texttt{deficit}(r) - \texttt{correction}(r) \geq 0$. It thus follows that

$$\#\mathcal{D}(r) + \texttt{deficit}(r) \geq \texttt{Waste}(r) + r \geq \#\mathcal{D}(r). \tag{1}$$

In particular, we have that $\texttt{Waste}(|\tau|+5) + |\tau| + 5 \geq \#\mathcal{D}(|\tau|+5)$. Recall that the deficit at $|\tau|+1$ corresponds to processors that have universally corrupted nodes at depth $|\tau|$ but are not yet disabled at time $|\tau|+1$. All of these processors are discovered as faulty by all nonfaulty processors, and are hence disabled, by time $|\tau|+2$. Thus, we have that $\#\mathcal{D}(|\tau|+2) \geq \#\mathcal{D}(|\tau|+1) + \texttt{deficit}(|\tau|+1)$. By equation (1) above we thus obtain that $\#\mathcal{D}(|\tau|+2) \geq \texttt{Waste}(|\tau|+1) + |\tau| + 1$.

By Lemma 7.7 we have that $\#(\mathcal{D}(|\tau|+5) \setminus \mathcal{D}(|\tau|+2)) \;\geq\; 5$. Since the set $\mathcal{D}$ grows monotonically, $\mathcal{D}(|\tau|+5) \supseteq \mathcal{D}(|\tau|+2)$, and we can therefore conclude that $\#\mathcal{D}(|\tau|+5) \geq \#\mathcal{D}(|\tau|+2) + 5$. In summary, we have

$$\texttt{Waste}(|\tau|+5) + |\tau| + 5 \geq \#\mathcal{D}(|\tau|+5) \geq \#\mathcal{D}(|\tau|+2) + 5 \geq \texttt{Waste}(|\tau|+1) + |\tau| + 1 + 5.$$

Deducting $|\tau|+5$ from both sides, we obtain that $\texttt{Waste}(|\tau|+5) \geq \texttt{Waste}(|\tau|+1) + 1$, so that $\texttt{Waste}(|\tau|+5) > \texttt{Waste}(|\tau|+1)$ and we are done. □

Lemma 7.7 implies that from round five on, the only rounds in which cross corruption can take place without increasing the waste of the run are pairs of rounds $r, r+1$ such that $r-1$ is a power of 2. In particular, since $r \leq t$, this can happen no more than $\log_2 t + O(1)$ times. These rounds can increase the number of universally corrupted nodes at any given depth in the tree by a factor of at most $O(t)$.

7.3. Early stopping in Δ-agreement. A crucial property of the Δ-EIG protocol is captured by Corollary 6.16. It states that two rounds after a node σ is closed in one nonfaulty processor's tree, it will be closed in all processors' trees. Obviously, once σ is closed in $\texttt{tree}_i$, processor i has no use for the descendants of σ. Nevertheless, it might still need to record values and perform fault detection, in order to continue reporting on nodes in order to allow σ to close in the trees of other processors. What Corollary 6.16 implies, then, is that i needs to relay values in the subtree rooted at σ for at most two rounds after σ is closed in $\texttt{tree}_i$. This suggests that we can modify the Δ-EIG protocol to obtain an early-stopping protocol as follows.

(a) Rather than reporting on all internal nodes in the Δ-EIG tree, processor i will report on a node σ in round $|\sigma|+1$ only if σ was not closed in $\texttt{tree}_i$ by the end of round $|\sigma|-2$. (Recall that a node can be closed before any value is stored in it; all that is needed for it to be closed is that one of its ancestors should be fixed to a value.) To implement this rule, all that is needed is for i to handle and report only on the children and grandchildren of nodes that fix by rule Fx2.

(b) We modify the halting condition for a processor i to:

- *Halting′:* Processor i continues to record information, perform fault detection, and report on values for two rounds after the root λ is closed in $\texttt{tree}_i$. At the end of these two rounds (and no later than at the end of round $t+1-\Delta$), it halts.

(c) There are a couple of details we need to take care of once we modify the protocol as described above. They result from the fact that it is now possible not to receive a message from a *nonfaulty* processor. This can only happen, however, in cases in which these values are of no use to the receiver. This leads to modifications

of the recording and masking rule, and to a modification of the definition of an ill-formatted message, which in turn affects the process of fault detection. We start by describing the latter. We shall extend the notion of an ill-formatted message as follows: If node σ is not closed in $\texttt{tree}_i$ by the end of round $|\sigma|$, and processor j's message in round $|\sigma|+1$ does not report values for all children of σ, then the message is considered ill formatted and i will detect j as faulty by rule FD0. One consequence of this definition is that if j sends no message to i in round $r+1$ and the root λ is not closed in $\texttt{tree}_i$ by the end of round r, then i detects j as being faulty.

Finally, the recording and masking rule is modified for the case in which the root λ is fixed in $\texttt{tree}_i$ at the end of round r and i receives no message in round $r+1$ from some processor $j \notin \mathcal{F}_i(r)$. Since i needs to continue to report on values in round $r+2$ by the halting$'$ rule, it acts as follows. For nodes that correspond to processors z for which j has issued $\texttt{mask}(j,z)$ reports in the first r rounds, there is no problem. For all other nodes, we choose to have i consider j as reporting the same values that i has reported, for all depth r nodes that i reports on in round $r+1$. This is related to the reconstruction method advanced by Zamsky [26, 28], and by Berman, Garay, and Perry [7]. One feature of this choice is that it keeps the fault detection rule FD2 from ever causing i to mistakenly "detect" j as faulty. (While such a mistaken detection would not change i's decision in the agreement process being executed, it becomes problematic when we run a number of agreement processes in parallel, and use a common fault-detection module as will be described in section 8.1.)

We call the resulting protocol the Δ-ES protocol (the ES stands for *early stopping*). Despite possibly reporting on much fewer nodes in a run of Δ-ES than in similar runs of Δ-EIG, the processors' behavior in Δ-ES maintains an important invariant: If a node σ is not closed in $\texttt{tree}_i$ at the end of round $|\sigma|$ and none of σ's ancestors is closed in $\texttt{tree}_i$ by the end of round $|\sigma|+1$, then all nonfaulty processors report a value for σ in round $|\sigma|+1$, as well as performing fault detection for all of σ's children in round $|\sigma|+1$, and reporting on them in round $|\sigma|+2$. This ensures the following:

(i) For every nonfaulty i and j, the first node to close in $\texttt{tree}_j$ along any path from the root, is guaranteed to close in $\texttt{tree}_i$ at most two rounds after it does in $\texttt{tree}_j$. Hence, the information that processor i would receive in Δ-EIG but does not receive in Δ-ES does not affect i's decision.

(ii) The commitment rules operate in Δ-ES as they do in Δ-EIG, since they depend only on the values stored in a node (C1), its children (C2), and grandchildren (C3). The fault detection rule FD2 remains sound, since it depends solely on these commitment rules.

(iii) The soundness of fault detection rule FD3 is maintained: If the node τaz is not closed in $\texttt{tree}_i$ by the end of round $|\tau az|+1$, then all processors are guaranteed to store the children of τa in the previous round, perform failure detection at the end of round $|\tau az|$, and report on nodes in round $|\tau az|+1$. Hence, a processor that does not mask the culprit processor a of FD3 in the designated round, must be faulty.

As a result, all of the properties proven for Δ-EIG in the previous sections hold once we move to the Δ-ES protocol in the following proposition.

PROPOSITION 7.10. *All of the statements from Lemma* 6.7 *through Lemma* 7.7 *hold for the* Δ*-ES protocol.*

The main aim of the protocol Δ-ES is to allow us to refrain from having to construct exponential-size EIG trees and hence from having to send an exponential amount of communication. At this point, we are able to prove a polynomial relation

between the number of universally corrupted nodes and the size of trees. This will reduce our problem to keeping the number of universally corrupted nodes polynomial, which will be done in the later sections. We thus have the following corollary.

COROLLARY 7.11. *Assume that the last nonfaulty processor halts by the end of round r, and let the number of universally corrupted nodes σ of depth $|\sigma| \leq r-6$ be T. Then, for every nonfaulty processor i, the total number of nodes in $\texttt{tree}_i$ is bounded by $O(n^6 T)$.*

Proof. Let σ be a universally corrupted node. The node σ has $O(n)$ children σj that are not universally corrupted. Corollary 6.17 implies that each such child is closed in $\texttt{tree}_i$ by the end of round $|\sigma j|+4$. It follows that σj has at most $O(n^4)$ descendants in $\texttt{tree}_i$ by the time it is closed. By definition of the Δ-ES protocol, processor i will need to store one level of nodes, beyond these $O(n^4)$ nodes, in the subtree rooted in σj. It follows that σ can have at most $O(n^6)$ descendants in $\texttt{tree}_i$ that are not themselves descendants of a universally corrupted child of σ. By accounting each node of $\texttt{tree}_i$ to its closest ancestor that is universally corrupted, the claim follows. □

8. The `Sliding-flip` protocol. We now have all of the ingredients necessary to define the final combined protocol. Intuitively, the protocol will be a variant of monitor agreement in which the monitors will be instances of Δ-agreement. We remark that in such a setting, there is a distinction between the *global* round number, which is counted from the start of the original agreement process, and the *local* round number of a specific instance of Δ-ES, which is counted from the start of this instance. The *global depth* and *local depth* of a node are defined analogously. The definition of Δ-ES and our analysis of Δ-ES use local round numbers. In our protocol, one instance of Δ-agreement is spawned in every round, for rounds $1 \leq r \leq t$. In round r, the agreement process that is generated will be a Δ-ES for $\Delta = r-1$. Since, by the Halting′ property, such an instance will complete in $t+1-\Delta = t+2-r$ rounds, we obtain that every such process will be complete by the end of (global) round $r-1+t+2-r = t+1$. We call such a process *$(t+1)$-bounded*. Before we provide the details of the voting rules and properties of these instances of Δ-agreement, we now describe a general method by which such agreement processes can be combined. This will be used when we come to combine the agreement processes in the final description of the combined protocol.

8.1. Preempt-on-one. In our combined protocol, we initiate one Δ-agreement process $\texttt{M}^r$ in every round r, where the parameter $\Delta = r-1$ is used in $\texttt{M}^r$. In this section we describe the method by which we combine the different agreement processes. This method is stated in slightly more general terms than we need, as it applies elsewhere as well. We call a set of agreement processes being executed concurrently with respect to a single fault detection module (FDM) an *ensemble*, and denote ensembles by $\mathcal{E}$. Different agreement processes are said to use a single FDM if for all nonfaulty processor i and (global) round r, the set $\mathcal{F}_i(r)$ used by one agreement process is the same as that used by the others.

We now define an operation that takes an ensemble and turns it into a single protocol. In executing $\texttt{Preempt-on-One}(\mathcal{E})$, a nonfaulty protocol concurrently executes all of the processes in $\mathcal{E}$. It decides and halts according to the following rule:

`Dec0`. Processor i decides 0 on $\texttt{Preempt-on-One}(\mathcal{E})$ and halts once i has halted with a decision of 0 on all processes in $\mathcal{E}$.

`Dec1`. Processor i decides 1 on $\texttt{Preempt-on-One}(\mathcal{E})$ and halts (preempting all agreement processes underway) once i has halted with a decision of 1 on

some process in $\mathcal{E}$.

The following property of `Preempt-on-One`$(\cdot)$ is fairly immediate, and will turn out useful.

LEMMA 8.1. *Let $\mathcal{E}$ be an ensemble of agreement processes. If all processes in $\mathcal{E}$ are $(t+1)$-bounded and satisfy the agreement property, then* `Preempt-on-One`$(\mathcal{E})$ *is $(t+1)$-bounded and satisfies the agreement property.*

Proof. We start by showing that `Preempt-on-One`$(\mathcal{E})$ is an agreement protocol. Assume that some processor i decides 0 on `Preempt-on-One`$(\mathcal{E})$ in a given run. It follows from `Dec0` that i decides 0 on all processes in $\mathcal{E}$ in this run. Since the instances all satisfy the agreement property, no other nonfaulty processor j will decide 1 on any of the processes in $\mathcal{E}$. In addition, since the processes in $\mathcal{E}$ are all $(t+1)$-bounded, it follows that j will actually decide 0 on every process in $\mathcal{E}$ no later than in round $t+1$. We conclude that every nonfaulty processor will halt in `Preempt-on-One`$(\mathcal{E})$ with a decision of 0 by the end of round $t+1$. Assume now that i decides 1 on `Preempt-on-One`$(\mathcal{E})$ in a given run. Let $\mathtt{M} \in \mathcal{E}$ be the process that triggers i's decision. In particular, it follows that processor i decides 1 and then halts on `M` at the end of some round $r_i \leq t+1$. Let $j \neq i$ be any other nonfaulty processor. There are two possibilities: (i) Processor j decides and halts on `Preempt-on-One`$(\mathcal{E})$ before it has a chance to decide and halt on the process `M`. By rule `Dec0` in the definition of `Preempt-on-One`$(\mathcal{E})$, a decision of 0 can only be taken after j has decided and halted on all processes in $\mathcal{E}$. It follows that j could only have decided 1, so its decision is in agreement with processor i's decision. Moreover, since `M` was $(t+1)$-bounded, and j decided before it had a chance to decide on `M`, we obtain that j decides before round $t+1$. (ii) The other possibility is that j does manage to decide and halt on `M`. Here again because `M` satisfies the agreement property, j will decide 1 on `Preempt-on-One`$(\mathcal{E})$. In addition, since `M` was $(t+1)$-bounded, j decides no later than in round $t+1$. In summary, we have that in all cases, `Preempt-on-One`$(\mathcal{E})$ satisfies the agreement property and is $(t+1)$-bounded, and we are done. □

8.2. Putting it all together. As described above, the ensemble generated in the combined protocol consists of instances of Δ-ES protocols, initiated one per round, in rounds $1 \leq R \leq t$. We use R in this section to refer to global round numbers. In round R, a monitor process initiated in global round K will have its own local round number $r = R + 1 - K$. All the instances of Δ-ES protocols invoked use the function F^* defined in section 7.1. Notice that the function F^* is applied, for every instance of Δ-ES, relative to the local round count. Thus, in the same global round, each agreement process has its own local round number. The combined protocol will be `Preempt-on-One`$(\mathcal{E})$, for the ensemble thus generated. We now describe how to determine a processor's initial vote in any given monitor process.

Clearly, in round $R = 1$, the value a processor i uses as its initial value is its original initial value v_i. In later rounds $R > 1$, the initial value of processor i in monitor process $\mathtt{M}^R$, is essentially the same as the one we mentioned in section 4.3 for $n > 4t$. For the purpose of this voting rule, we say that processor i has *detected* another processor z *as being disabled* by the end of round K if i has received `mask`(j, z) reports from at least $2t + 1$ processors j by that point. The following lemma justifies this terminology.

LEMMA 8.2. *If i has detected z as being disabled by the end of round K, then z is disabled at the end of round K.*

Proof. By definition, i can detect z as being disabled only once i has received at least $2t+1$ `mask`(j, z) reports. At least $t+1$ of these reports are from nonfaulty proces-

sors j. The sending rule implies that a nonfaulty processor sends identical messages to all processors in every round. It thus follows that every nonfaulty processor i' must have received at least $t+1$ $\texttt{mask}(j,z)$ reports by the end of round K. As a result, the fault detection rule FD1 implies that each such processor i' must detect z as being faulty by the end of round K. It follows that z is disabled at that point, and we are done. □

The voting rule on a monitor $\texttt{M}^R$ with $R > 1$ is:

Monitor vote: Processor i will vote 1 on $\texttt{M}^R$ if

(i) at least one node at (global) depth $R-1$ in one of i's trees is not closed; and

(ii) i has detected at least $R-1$ faulty processors as being disabled by the end of round $R-1$.

It will vote 0 on $\texttt{M}^R$, otherwise.

We define the `Sliding-flip` protocol to be the protocol that results from performing `Preempt-on-One` on the ensemble consisting of the original agreement tree together with the monitor agreement processes $\texttt{M}^R$, for $2 \leq R \leq t$, where the votes of the nonfaulty processes are obtained according to the monitor-vote rule above. These agreements processes are all instances of Δ-ES, based on the threshold function F^* defined in section 7.1. For ease of exposition, we shall consider the original agreement process to be $\texttt{M}^1$.

The role of part (i) in the monitor-vote rule is to guarantee that if all initial values are 0, then a decision of 0 will be reached. The role of part (ii) is to guarantee that the monitors satisfy the initial conditions of Δ-agreement: A nonfaulty process votes 1 on a monitor agreement process only if a sufficient number of processors are disabled. In fact, an immediate consequence of Lemma 8.2 is the following corollary.

COROLLARY 8.3. *If at least one nonfaulty processor votes* 1 *in a monitor* $\texttt{M}^{R+1}$*, then* $\#\mathcal{D}(R) \geq R$.

Corollary 8.3 formally shows that the monitors that are initiated in the combined protocol are "legal" instances of Δ-agreement. We can now prove the following proposition.

PROPOSITION 8.4. *The* `Sliding-flip` *protocol is a correct* $(t+1)$*-round Byzantine agreement protocol.*

Proof. Theorem 6.10 and Corollary 8.3 imply that all of the agreement processes initiated in `Sliding-flip` are $(t+1)$-bounded instances of Byzantine agreement. We therefore obtain by Lemma 8.1 that the `Sliding-flip` protocol satisfies the decision and agreement conditions. We need to show that it also satisfies validity. If all initial values are 1, then the root of the initial tree will fix to 1 at the end of round two for all of the nonfaulty processors, so by the definition of `Preempt-on-One` they will all decide 1. Assume that all initial values are 0. In particular, the initial values of all nonfaulty processors are 0. It follows that, for every nonfaulty processor i, at least $2t+1$ of the root's children in the initial tree will store 0 at the end of round one. Since 0 is the preferred value in this round, the root will fix to 0. As a result, all nodes at global depth 1 will be closed for every nonfaulty processor, and by the monitor-vote rule, every such processor i will vote 0 on $\texttt{M}^2$. A straightforward induction on R now shows that all nonfaulty processors vote 0 on all monitors $\texttt{M}^R$, so that all monitors decide 0, and by definition of `Preempt-on-One` every nonfaulty processor i will end up deciding 0 at time $t+1$. □

It remains to show that the protocol is efficient. As a partial converse of Lemma 8.2 we have the following.

LEMMA 8.5. *If z is disabled at the end of round R and no nonfaulty processor has halted by the end of round R, then every nonfaulty processor i will have detected z as being disabled by the end of round $R+1$.*

Proof. If no nonfaulty processor has halted by the end of round R, then they all send messages in round $R+1$. If z is disabled at the end of round R, then every nonfaulty processor j must send a $\texttt{mask}(j,z)$ message to i no later than in round $R+1$. It follows that i is guaranteed to receive at least $2t+1$ such messages by the end of round $R+1$, and we are done. □

Recall that the `Waste` was defined with respect to a given instance of Δ-ES. The parameter r of $\texttt{Waste}(r)$ in a given instance of Δ-ES is a local round number. When we run many instances of Δ-ES concurrently, as in the `Sliding-flip` protocol, we wish to reason about an overall notion of waste. Let us define the global waste at time K, denoted by $\texttt{G\_Waste}(K)$, to be the maximum value of $\texttt{Waste}(K-R)$ in monitor $\texttt{M}^R$, over all $R < K$. Thus, $\texttt{G\_Waste}(K)$ is the maximal value that the waste obtains at global time K. As a consequence of Lemma 8.5 and the monitor voting rule, we now have the following lemma.

LEMMA 8.6. *If $\texttt{G\_Waste}(R) \geq 2$ and some node is universally corrupted, then all nonfaulty processors are guaranteed to halt by the end of round $R+6$.*

Proof. If $R+6 \geq t+1$ the claim is immediate from the definition of the combined protocol, which is guaranteed to halt for every processor by the end of (global) round $t+1$. Assume $R+6 < t+1$. It follows that processors can halt by the end of round $\leq R+6$ only due to their deciding 1 on some monitor. First assume that some nonfaulty processor i halts by the end of round $R+4$, based on deciding 1 on a monitor $\texttt{M}^{R'}$ for some $R' < R+3$ by the end of round $R+2$. It follows from Corollary 6.16 and Proposition 7.10 that all processors will have decided 1 on $\texttt{M}^{R'}$ by the end of round $R+4$ and will halt by the end of round $R+6$. Assume now that no nonfaulty processor has halted by the end of round $R+4$ due to a monitor $\texttt{M}^{R'}$ with $R' < R+3$. The fact that $\texttt{G\_Waste}(R) \geq 2$ implies that $\#\mathcal{D}(R+1) \geq R+2$. Lemma 8.5 states that every nonfaulty processor i detects all members of $\mathcal{D}(R+1)$ as being disabled by the end of round $R+2$. As a result, i will have detected at least $R+2$ disabled processors by the end of round $R+2$. Finally, the fact that some node is universally corrupted implies that, for every nonfaulty processor i, one of i's trees has survived the first round. The monitor voting rule now states that i will vote 1 on $\texttt{M}^{R+3}$. Since all of the processors vote 1 on $\texttt{M}^{R+3}$ and are active until the end of round $R+4$, it follows that they all decide 1 on $\texttt{M}^{R+3}$ at the end of round $R+4$ and will thus halt by the end of round $R+6$. □

Given Lemma 8.6 and Theorem 6.23, we can now prove the following lemma.

LEMMA 8.7. *Choose L such that the last nonfaulty processor halts by the end of round $L+6$. Then, for every nonfaulty i and every monitor $\texttt{M}^R$ with $R \leq L$, the number of universally corrupted nodes in $\texttt{tree}_i$ for $\texttt{M}^R$ is $O(t^2)$.*

Proof. If, for some nonfaulty processor i, none of i's trees survives the first round, then no node is universally corrupted, and we are done. We shall therefore assume from now on that at least one node is universally corrupted. By Lemma 8.6, the waste cannot reach 2 before round L, or all processors would halt before round $L+6$. We thus reason about the rounds preceding L, assuming the waste never reaches 2 in those rounds. We claim that if any node of (global) depth $K \geq 2$ is universally corrupted, then $\texttt{G\_Waste}(K) \geq -2$. Since, for every monitor it is guaranteed by definition that $\texttt{deficit}(r) - \texttt{correction}(r) \geq 0$ for every r, it suffices to show that $\#\mathcal{D}(K) - K \geq -1$. Assume that σ is a node of depth K in a monitor $\texttt{M}^R$ (and hence

$|\sigma| = K-(R-1)$). Since there is a universally corrupted node in $\mathtt{M}^R$, we know that at least one nonfaulty processor voted 1 on this monitor, and hence by the monitor-vote rule and by Lemma 8.2 we have that $\#\mathcal{D}(R-1) - (R-1) \geq 0$. If $|\sigma| \leq 2$ we are clearly done. If, however, $|\sigma| \geq 3$, then the path from the root to σ consists of nodes all of which are universally corrupted. Clearly, by the end of round K, all processors universally corrupting nodes at depths smaller than $K-1$ are disabled. It follows that $|\sigma|-2$ of σ's ancestors contribute fresh disabled processors that were not in $\mathcal{D}(R-1)$. We thus obtain that $\mathcal{D}(K) \geq R-1+|\sigma|-2 = R-1+K-(R-1)-2 = K-2$, and hence $\mathcal{D}(K) - K \geq -2$ and the claim is proven. We conclude that `G_Waste` can vary within a small constant range without causing a monitor to halt the protocol.

It is straightforward to check that if $k \geq 3$ processors universally corrupt nodes at (global) depth R, then $\mathtt{G\_Waste}(R+1) - \mathtt{G\_Waste}(R-1) \geq k-2$. It follows that this can happen only a constant number of times. A round with no universal corruption whatsoever will cause all of the active monitors to close in two rounds. As argued in section 7.2 following Corollary 7.9, the only case in which two processors can corrupt nodes at a given depth in the same tree without increasing the waste is when cross corruption takes place in a pair of rounds $r, r+1$ such that $r-1$ is a power of 2. The number of such rounds $r \leq t+1$ is $\log t + O(1)$. It follows that the number of universally corrupted nodes at any particular level of $\mathtt{tree}_i$ for a monitor $\mathtt{M}^R$ is $O(t)$. Hence, the total number of universally corrupted nodes created by the end of round L in $\mathtt{tree}_i$ for $\mathtt{M}^R$ is bounded by $O(t^2)$. □

As a consequence of Lemma 8.7 and Lemma 7.11 we obtain the following lemma.

LEMMA 8.8. *For every nonfaulty processor i, the total size of each of the t* EIG *trees that i ever constructs is polynomial.*

Finally, as a result of Lemma 8.8 and Corollary 7.11, we obtain the following theorem.

THEOREM 8.9. *The* `Sliding-flip` *protocol is a correct Byzantine agreement protocol that halts in $t+1$ rounds in the worst case, and is polynomial in both communication and computation.*

9. Early stopping. The `Sliding-flip` protocol consists of an ensemble of agreement processes running concurrently. They are initiated one per round, and are combined using the `Preempt-on-One` scheme: a local decision of 1 in any instance causes a global decision of 1 coupled with preemption of all decision processes. A decision of 0 can be reached only at time $t+1$, in case all agreement processes turn out to have decided 0. (Recall that the agreement processes in the ensemble are all guaranteed to reach a local decision by the end of round $t+1$.) In particular, even in runs with no failures, a decision of 0 cannot take place before round $t+1$. Thus, while `Sliding-flip` is a polynomial protocol that is guaranteed to halt in $t+1$ rounds, it is not guaranteed to stop early in runs in which few processors actually fail. In this section we discuss how to modify the `Sliding-flip` protocol to obtain a protocol that does stop early when few failures actually occur. The concept of *early stopping* is due to [13], who showed that no protocol for Byzantine agreement can be guaranteed to halt in fewer than $\min\{t+1, f+2\}$ rounds in the worst case, where f is the number of failures that occur in the run in question. Our goal will be to obtain a protocol that is guaranteed to halt in $\min\{t+1, f+c\}$ rounds for a small constant c.

The `Preempt-on-One` scheme already takes care of stopping quickly when the decision is 1. Early decision on 1 was of crucial importance to the `Sliding-flip` protocol, because that was the way the protocol keeps trees from growing beyond a polynomial bound. What remains, therefore, is to allow early stopping on a decision

of 0 without hindering the correctness of the early decision on 1. Our basic strategy will be to maintain the basic `Preempt-on-One` rules for deciding on 1. Early stopping on 0 will then depend on our ability to predict at an early stage that all agreement processes that have been initiated, as well as all those that are due to be initiated in the future, are bound to decide 0. It is safe to decide 0 when this happens, rather than wait until the end of round $t+1$ to do so. The following lemma describes a fairly general condition that guarantees that all future monitors will decide 0.

LEMMA 9.1. *In the protocol* `Sliding-flip`*, if all monitors* $\mathtt{M}^R$ *with* $R \leq K$ *are closed on* 0 *for all nonfaulty processors at the end of round* K*, then every monitor* $\mathtt{M}^R$ *with* $R > K$ *that is initiated in the protocol closes on* 0 *at the end of its first round* R*.*

Proof. Assume that all monitors $\mathtt{M}^R$ with $R \leq K$ are closed on 0 for all nonfaulty processors at the end of round K. Part (i) of the monitor-vote rule implies that all nonfaulty processors will vote 0 on the monitor $\mathtt{M}^R$ for the first $R > K$. This monitor will close on 0 in its first round for all nonfaulty processors, and the same argument can now be applied inductively to show that all later monitors will do the same. □

The problem in trying to apply the condition of Lemma 9.1 is that this condition is not one that can be detected by an individual processor. We now discuss a way of making a similar condition detectable. In order to do so, we consider a variant `Sliding-flip`$'$ of the `Sliding-flip` protocol that differs from the original only in that, instead of initiating a new monitor agreement process $\mathtt{M}^R$ in every round, such a process is initiated once in five rounds. Specifically, $\mathtt{M}^R$ monitors are initiated for every integer R of the form $R = 5k+1$, for $1 \leq k \leq \lfloor \frac{t-1}{5} \rfloor$. (The agreement tree based on the processors' original initial values is, of course, initiated in round one.) First notice that `Sliding-flip`$'$ has all of the desired qualities of `Sliding-flip`: It halts in at most $t+1$ rounds, and is guaranteed to be polynomial. The proof of correctness of `Sliding-flip`$'$ is the same as that for `Sliding-flip`. The only changes required in order to prove the complexity bounds for `Sliding-flip`$'$ are in Corollary 7.11, Lemma 8.6, and Lemma 8.7. In Lemma 8.6 we are now guaranteed only that if $\mathtt{G\_Waste}(R) \geq 6$ then a monitor issued no later than round $R+7$ closes with value 1. Without any fine tuning, this will cause an increase of $O(n^4)$ in the complexity of the protocol. The analogue of Corollary 7.11 will replace $r-6$ by $r-10$ and n^6T by $n^{10}T$. The proof of the analogue of Lemma 8.7 goes through essentially without change, when we assume $\mathtt{G\_Waste}(R) \leq 6$ instead of assuming that $\mathtt{G\_Waste}(R) \leq 2$.

Define $\Phi_i(K)$ to hold if (i) $K \equiv 1 \bmod 5$, (ii) no node of (global) depth K is corrupted in any of i's trees, and (iii) no agreement process initiated in a round $R \leq K$ either has or will close with the root fixed to value 1. Intuitively, we will use $\Phi_i(K)$ to determine a condition for early stopping on 0. We can show the following lemma.

LEMMA 9.2. *If* $\Phi_i(K)$ *holds for some* K*, then all monitors* $\mathtt{M}^R$ *for* $R > K$ *that will ever be initiated in* `Sliding-flip`$'$ *will close with value* 0 *in round* R*, for all nonfaulty processors.*

Proof. Let $K \equiv 1 \bmod 5$, and assume that no node of (global) depth K is corrupted in any of i's trees. Notice that because $K \equiv 1 \bmod 5$, no monitors are initiated in the rounds $K+1, \ldots, K+4$. By definition of corruption, the fact that no node of (global) depth K is corrupted for i implies that all depth K nodes in all of i's trees are closed by the end of round $K+2$. Corollary 6.16 implies that all depth K nodes in the trees of all nonfaulty processors are closed by the end of round $K+4$. It follows that all trees corresponding to existing agreement processes close for all nonfaulty processors by that time. As a result, by part (i) of the monitor-vote rule, all

nonfaulty processors will vote 0 on $\mathtt{M}^R$ for $R = K+5$, and a straightforward inductive argument shows that they will all vote 0 on every monitor initiated thereafter. □

The condition $\Phi_i(K)$ used in Lemma 9.2 is easily detectable by process i. Moreover, Lemma 9.2 implies that if Φ_i holds, then Φ_j will hold soon thereafter.

COROLLARY 9.3. *Let i and j be nonfaulty processors. If $\Phi_i(K)$ holds in a run of* `Sliding-flip′`*, then $\Phi_j(K+5)$ holds at the end of round $K+5$.*

Proof. Assume that $\Phi_i(K)$ holds. The argument given in the proof of Lemma 9.2 shows that the trees corresponding to all monitors initiated in rounds $R \leq K$ will be closed for all nonfaulty processors by the end of round $K+4$. By the monitor-vote rule, all nonfaulty processors vote 0 on the monitor initiated in round $K+5$. As a result, this monitor is closed at the end of round $K+5$, for all nonfaulty processors. It follows that $\Phi_j(K+5)$ holds, for all nonfaulty processors j. □

Notice that if $\Phi_i(K)$ holds, then i will detect that $\Phi_i(K)$ holds no later than by the end of round $K+2$. Moreover, the proof of Corollary 9.3 shows that $\Phi_j(K+5)$ will be detectable by j no later than by the end of round $K+5$. It follows that once i detects that $\Phi_i(K)$ holds, it can essentially decide 0. The only thing it needs to do in order to guarantee that Φ_j will hold for all j is to continue to participate in the existing agreement processes (all of which, by Corollary 6.17, are guaranteed to terminate by the end of round $K+4$), and send its vote in the monitor initiated in round $K+5$. This provides an early-stopping method for deciding 0.

We define the `ES-Sliding-flip` protocol to consist of `Sliding-flip′` with the following modifications: (i) we add the rule that once a processor i first detects that $\Phi_i(K)$ holds, it decides 0 and it halts once all of its monitors initiated in rounds $R \leq K$ halt according to Δ-ES; and (ii) we add the default that sending no value as a vote on a monitor amounts to sending a vote of 0 (and is not regarded an ill-formed message). The purpose of point (ii) is to enable a processor that detects that $\Phi_i(K)$ holds to halt before round $K+5$. Its silence in round $K+5$ will be interpreted as a vote of 0, which will suffice to ensure that the necessary conditions of $\Phi_j(K+5)$ will hold. We can now summarize the properties of the protocol `ES-Sliding-flip` as follows.

THEOREM 9.4. *The* `ES-Sliding-flip` *protocol is a correct Byzantine agreement protocol that is polynomial in both communication and computation. It halts in* $\min\{t+1, f+5\}$ *rounds in the worst case, where f is the number of failures that actually take place.*

Proof. Correctness of the protocol `ES-Sliding-flip` is inherited from that of `Sliding-flip′` and Corollary 9.3, which guarantees that if one of the nonfaulty processors decides 0, then all of them will. The polynomial complexity and $(t+1)$-boundedness of `ES-Sliding-flip` are also inherited from `Sliding-flip′`. It remains to show that the protocol halts in no more than $f+5$ rounds. First notice that for a node of global depth K to be corrupted, at least K distinct processors must fail. This is obvious in the initial agreement process, and is true for arbitrary monitors $\mathtt{M}^R$ based on Lemma 6.1 and part (ii) of the monitor-vote rule. Assume that exactly f processors fail in a given run. It follows that no more than f processors can ever be disabled, and no node of depth greater than f can be corrupted. It follows that by the end of round $f+3$ all monitors ever initiated are closed in all nonfaulty processors' trees. Since exactly f processors fail, if a node of depth f is corrupted, no nonfaulty processor can detect f processors as being disabled before round $f+2$, because an additional round in which `mask` messages are sent is necessary for the detection. This implies that the last monitor on which some nonfaulty processor votes 1 can

be initiated in a round $K \leq f$. Let $F = \min\{K : K \equiv 1 \bmod 5 \,\&\, K > f\}$. Notice that $F \leq f + 5$. Let i be an arbitrary nonfaulty processor. If $\Phi_i(K)$ holds for some $K < F$, then we have seen that i detects $\Phi_i(K)$ no later than time $K + 2$, and halts no later than time $K + 4$, and $K + 4 < F \leq f + 5$. Assume that $\Phi_i(K)$ did not hold for $K < F$. It follows that $\Phi_i(F)$ will hold at the end of round $f + 3$. Processor i will be able to decide 0 at the end of round $f + 3$, and halt at the end of round $f + 5$. It follows that all processors decide and halt by the end of round $f + 5$ and we are done. □

A few remarks are in order: (i) It is possible to use the reconstruction method of [26, 28, 7] in order to avoid the need for the additional two rounds in which nonfaulty processors "echo" values to ensure that the others reach the same decision in an instance of Δ-ES. A variant of `ES-Sliding-flip` based on such a modified version of Δ-ES will halt in $\min\{t + 1, f + 3\}$ rounds.

(ii) To obtain an early-stopping protocol halting within $f + 2$ rounds, what is needed is to extend the fixing rule `Fx2` in order to allow fixing in round $|\sigma| + 1$ to the nonfavored value $1 - \mathtt{par}(|\sigma|)$ if an overwhelming majority of σ's children store this value. The current version allows fixing only to $\mathtt{par}(|\sigma|)$. The current choice was made in order to simplify the statements of the various lemmas in this paper, and to shorten their proofs. We believe that with this extension and using reconstruction, it should be possible to obtain an early stopping protocol that halts in the optimal bounds of $\min\{t + 1, f + 2\}$ rounds.

(iii) In runs with no failures, our protocol decides in at most three rounds and halts in five. Only a single agreement tree is ever constructed, and the protocol acts just like a simple straightforward protocol. With reconstruction the protocol would halt in three rounds, and with an extended `Fx2` rule both decision and termination would be obtained in two rounds.

Acknowledgments. The authors would like to thank Café Ka'ze in Tel Aviv for providing the ambiance and hospitality during critical stages of this work. Special thanks to Cynthia Dwork, Arkady Zamsky, and to an anonymous referee for comments and suggestions that improved this paper. The first author is also thankful to Piotr Berman for innumerable discussions on the subject, and the second author is similarly thankful to Orli Waarts.

AN $O(\log k)$ APPROXIMATE MIN-CUT MAX-FLOW THEOREM AND APPROXIMATION ALGORITHM*

YONATAN AUMANN† AND YUVAL RABANI‡

Abstract. It is shown that the minimum cut ratio is within a factor of $O(\log k)$ of the maximum concurrent flow for k-commodity flow instances with arbitrary capacities and demands. This improves upon the previously best-known bound of $O(\log^2 k)$ and is existentially tight, up to a constant factor. An algorithm for finding a cut with ratio within a factor of $O(\log k)$ of the maximum concurrent flow, and thus of the optimal min-cut ratio, is presented.

Key words. approximation algorithms, cuts, sparse cuts, network flow, multicommodity flow

1. Introduction.

1.1. Multicommodity flow. Consider an undirected graph $G = (V, E)$ with an assignment of nonnegative capacities to the edges, $c : E \to \mathbb{R}^+$. A *multicommodity flow* instance on G is a set of ordered pairs of vertices $(s_1, t_1), (s_2, t_2), \ldots, (s_k, t_k)$. Each pair (s_i, t_i) represents a *commodity*, with *source* at s_i and *destination* or *target* at t_i. The s_i's and t_i's are also called *terminals*. The objective is to maximize the amount of *flow* traveling from the sources to the corresponding destinations, subject to the capacity constraints. The problem comes in two flavors. In the first, called the *maximum throughput* problem, the total flow, summed over all commodities, is to be maximized. The second is called the *maximum concurrent flow* problem. Here, for each commodity (s_i, t_i) a nonnegative demand D_i is specified. The objective is to maximize the *fraction* of the demand that can be shipped simultaneously for all commodities. A maximum concurrent flow instance is *uniform* if the set of commodities is the set of all ordered pairs of vertices and all demands are equal. Both the maximum throughput problem and the maximum concurrent flow problem can be solved in polynomial time using linear programming.

Given a multicommodity flow instance (together with demands) the *minimum cut ratio* is defined. A *cut* $(S, \overline{S})$ is a partition of the vertices, with $S \cup \overline{S} = V$ and $S \cap \overline{S} = \emptyset$. The *capacity* of the cut $(S, \overline{S})$ is the sum of capacities of the edges with one endpoint in S and the other in $\overline{S}$. The *cut ratio* is this capacity divided by the sum of demands of commodities with one terminal in S and the other terminal in $\overline{S}$. Finally, the minimum cut ratio R is the minimum of cut ratios taken over all cuts $(S, \overline{S})$,

$$R = \min_{S \subset V} \frac{\sum_{e \in E \cap (S \times \overline{S})} c(e)}{\sum_{(s_i, t_i) \in (S \times \overline{S}) \cup (\overline{S} \times S)} D_i} .$$

In general, determining the minimum cut ratio is an NP-hard problem [9]. The maximum concurrent flow is a lower bound on the minimum cut ratio.

For the maximum throughput problem a different notion is useful—that of the *minimum multicut*. A *multicut* is a subset of edges $F \subseteq E$ whose removal disconnects all source-destination pairs. The *capacity* of a multicut F is the sum of capacities of the edges in F. Determining the value of the minimum multicut is an NP-hard and a MAX-SNP-hard problem [11]. The maximum throughput is a lower bound on the capacity of the minimum multicut.

Our results. In this paper, we study the problem of determining the worst-case ratio between the minimum cut ratio and the maximum concurrent flow. We establish that for any k commodity instance, the ratio is $O(\log k)$. The bound holds for instances involving arbitrary capacities and demands, thus improving upon the best previously known bound of $O(\log^2 k)$ [27]. We also consider the related question of finding a cut whose ratio approximates the minimum cut ratio. Finding such a cut is a basic step in approximation algorithms for many NP-hard problems (see [20, 16]). We give an algorithm that produces a cut whose ratio is within an $O(\log k)$ factor of the maximum concurrent flow, and thus within at most this factor of the minimum cut ratio.

We now give a brief overview of the proof method and the procedure for obtaining the cut. Starting with the linear programming formulation of the maximum concurrent flow problem, a solution to the dual program is an assignment of points in $\mathbb{R}^k$ to the vertices of the graph. The *value* of the solution is the sum of L_∞ distances spanned by the edges, scaled by the capacities. The constraints of the dual program dictate that the sum of distances between source-destination pairs, scaled by the demands, equals one. Thus, we first solve the (dual) linear program and obtain an embedding of the graph in $\mathbb{R}^k$. Next, we wish to produce the cut by placing a hyperplane in the space, where the two sides of the hyperplane determine the cut. Suppose that a random hyperplane would have the property that for each pair of vertices x, y, the hyperplane separates x from y with probability proportional to the distance between the two. Then, the expected amount of demands separated by a random hyperplane would be 1 (the sum of source-destination distances scaled by the demands). The expected capacity of the cut, induced by the random hyperplane, would be the sum of edge distances scaled by the capacities, which is exactly the *value* of the solution to the dual, which, in turn, equals the optimal value of the primal, which is the max-flow. Given these expectation, we could then try and find a hyperplane which maintains the expected ratio. Such a cut would have cut ratio equal to the max-flow. Clearly, this procedure fails. This is because in L_∞ norm the necessary distribution over hyperplanes does not necessarily exist. As it turns out, L_1 is the natural norm under which to produce such a distribution. In particular, in L_1 norm a random hyperplane perpendicular to one of the axes has exactly the necessary property (i.e., it separates any two nodes with probability proportional to the distance between the two).

With this intuition in mind, we use small distortion embeddings of finite metric spaces into ℓ_1 [3, 21]. Once the (solution) graph is embedded in ℓ_1, we show how to find (deterministically) a good cut. The factor of $O(\log k)$ is lost in the distortion of the embedding. We also show that similar ideas are applicable to bounding the min-multicut max-flow ratio for the maximum throughput problem, though the bounds derived are inferior to the best-known bounds. Finally, as a consequence of known instances of graphs with a high min-cut max-flow ratio, we derive tight (up to a constant factor) lower bounds on the best possible distortion of embeddings into ℓ_1

and into ℓ_2, thus improving the lower bound of [3].

Related work. One of the most celebrated theorems in combinatorial optimization is the min-cut max-flow theorem of Ford and Fulkerson and of Elias, Feinstein, and Shannon [8, 7], which states that for a single commodity, the maximum flow is equal to the minimum cut (here the two flavors of the problem coincide). Early on it had been noted that this is not the case for multicommodity flow.

Early work on multicommodity flow concentrated on characterizing instances where the maximum flow equals the minimum cut ratio. Equality has been established for instances where the *support* (i.e., the graph created by connecting source-destination pairs) is either the union of two stars, or the clique K_4, or the cycle C_5, through the consecutive works of Hu [14], Rothschild and Whinston [28], Dinits (see [1]), Seymour [29], and Lomonosov [23]. Seymour [30] shows that equality holds when the union of the network and the support is planar. Okamura and Seymour [26] establish equality for instances on planar graphs where all terminals reside on the boundary of a single face. For more on this vein of work see [18].

In their groundbreaking work, Leighton and Rao [20] introduce the notion of an approximate min-cut max-flow theorem. They show that for uniform multicommodity flow, the min-cut ratio is within a factor of $O(\log n)$ of the maximum concurrent flow, where n is the number of nodes in the network. Klein et al. [16] extend their techniques to show an $O(\log C \log D)$ approximate min-cut max-flow theorem for general concurrent flow, where C is the sum of capacities and D is the sum of demands. This ratio has been improved to $O(\log^2 k)$, where k is the number of commodities, through the works of Tragoudas [32], Garg, Vazirani, and Yannakakis [12], and Plotkin and Tardos [27]. The prevalent method in these papers is the use of graph partitions (see [17]). The last paper in the sequence overcomes the dependency on the values of the demands by applying a scaling argument and combining flows. We note that while in [20, 16] the primal program considered is the problem of minimizing the capacity utilization (i.e., the factor by which edge capacities need to be multiplied to allow all the demand through; see also Shahrokhi and Matula [31]), in [12] the primal program considered is that of maximizing the throughput. This latter view is the one taken in this paper.

Multicuts have been considered by Garg, Vazirani, and Yannakakis [11, 12]. The first paper gives a 2-approximate min-multicut max-flow bound and approximation algorithm for maximum throughput instances on arbitrary capacitated trees. The second paper gives an $O(\log k)$-approximate min-multicut max-flow bound and approximation algorithm for arbitrary maximum throughput instances. Dahlhaus et al. [5] consider the problem of *multiway cuts*, i.e., multicuts for maximum throughput instances defined by listing all pairs among a subset of k vertices. They show a $2 - \frac{2}{k}$ approximation algorithm.

Of related interest is the beautiful approximate max-cut algorithm given by Goemans and Williamson [13]. They use semidefinite programming to optimize distances among vertices of a graph. When embedded into the unit ball in $\mathbb{R}^n$ with distances determined by the L_2 norm, the original distances do not shrink too much (but they may have an unbounded increase). It is easy to cut the embedded graph by a hyperplane. Similar ideas have been exploited by Karger, Motwani, and Sudan to give an improved approximation algorithm for vertex coloring [15]. We note that these techniques seem to fail when it is required to minimize a cut rather than to maximize it.

The relation between ℓ_1-embeddability and multicommodity flow has been noted

by Avis and Deza [2]. They show that Lomonosov's min-cut-equals-max-flow result (and its predecessors for two commodities, etc.) is related directly to the ℓ_1-embeddability of certain fixed metric spaces.

A central tool in our proof is the small distortion embedding of a given metric space into ℓ_1. For this we use a result of Linial, London, and Rabinovich. In a fundamental work, they study algorithmic and other applications of embeddings of graphs into low-dimensional normed spaces, introducing techniques from functional analysis. In particular, they consider a theorem of Bourgain [3] which asserts that any n-point metric space can be embedded into ℓ_1 (and also into ℓ_2) with logarithmic distortion. Bourgain's original proof is existential. Linial, London, and Rabinovich present an algorithmic version of the proof which also bounds the dimension by $O(\log^2 n)$ (see also Matoušek [25]). Following their initial work, Linial, London, and Rabinovich have obtained independently similar results to the ones reported here. A full account of their work, which also includes the earlier results, appears in [21]. We note that, while the derivation in [21] is very similar to ours, we generate the cut by cutting with a hyperplane, whereas in [21] the cut is generated by a different procedure.

Subsequent to this work, Linial, London, and Rabinovich (in the journal version of their paper [22]), and independently Garg [10], have come up with modified algorithms that can be effectively derandomized.

2. Min-cut-ratio max-concurrent-flow. Let $G = (V, E)$ be a graph. Let $c : E \to \mathbb{R}^+$ be an assignment of nonnegative capacities to the edges of G. Consider a maximum concurrent flow problem on G, with demand D_i from source s_i to destination t_i, $i = 1, \ldots, k$. For each i, let $\{q_1^i, q_2^i, \ldots\}$ be an enumeration of the paths from s_i to t_i. Let $q_j^i(e)$ denote the characteristic function of the predicate $e \in q_j^i$. Let f_j^i be the amount of commodity i flowing along the path q_j^i, and let f be the minimum fraction of any of the demands which is transmitted in the system in total. We formulate the maximum concurrent flow problem as the following linear program:

$$\text{(P1)} \qquad \begin{array}{lll} \text{maximize} & f & \text{subject to} \\ & D_i f - \sum_j f_j^i \le 0 & \forall i \in \{1, 2, \ldots, k\}, \\ & \sum_{i,j} q_j^i(e) f_j^i \le c(e) & \forall e \in E, \\ & f_j^i \ge 0 & \forall i, j. \end{array}$$

The first set of constraints requires that the total flow of commodity i be at least an f fraction of the demand D_i. The second set of constraints prevents the edge capacities from being violated.

The dual is

$$\text{(D1)} \qquad \begin{array}{lll} \text{minimize} & \sum_e c(e) d(e) & \text{subject to} \\ & \sum_i D_i h_i = 1, & \\ & \sum_e q_j^i(e) d(e) - h_i \ge 0 & \forall i, j, \\ & h_i \ge 0 & \forall i, \\ & d(e) \ge 0 & \forall e. \end{array}$$

The dual has a pictorial physical interpretation. Imagine that the edges of the graph represent a network of pipes. The "cross-section" area of pipe e is $c(e)$, and $d(e)$ denotes the length of the pipe. Thus, the objective is to minimize the total volume of the network. The variable h_i corresponds to the distance between the terminals of commodity i (i.e., the minimum length of a path q_j^i). Now suppose that the network supports a flow such that for each commodity i, the rate at which this

commodity is transmitted from source to destination is an f fraction of the demand of the commodity. Then, at any given time the total *volume* of flow in the network is at least $\sum_i fD_ih_i$. Clearly, the volume of flow cannot be greater than the total volume of the pipes, which is $\sum_e c(e)d(e)$. The first constraint in the dual scales $\sum_i D_ih_i = 1$. Thus we have $f \leq \sum_e c(e)d(e)$, which is precisely the statement of weak duality in this case.

The program (D1) may be of exponential size. Using the above interpretation, we convert it to an equivalent program of polynomial size. The purpose of this step is to allow the solution of the linear program in polynomial time. We consider the vertices of G as points in $\mathbb{R}^k$ with L_∞ norm. The distances between the vertices are the distances assigned to the corresponding edges. For each $i = 1, \ldots, k$, the ith coordinate of the location of the vertex represents the distances of the vertex from the source s_i. Thus, we obtain the following equivalent, polynomial size, linear program:

$$
\begin{array}{lllll}
\text{minimize} & \sum_e c(e)d(e) & & \text{subject to} & \\
(\mathrm{D}') & \begin{array}{rcl} d(e) & \geq & u_i^x - u_i^y \\ & \geq & u_i^y - u_i^x \end{array} & & \forall e = (x,y),\ \forall i \in \{1,2,\ldots,k\}, \\
& \sum_i D_ih_i = 1, & & & \\
& h_i \leq u_i^{t_i} - u_i^{s_i} & & \forall i, & \\
& u_i^{t_i} \geq 0,\ u_i^{s_i} \leq 0 & & \forall i. &
\end{array}
$$

Here, vertex x is mapped to the point $u^x = (u_1^x, \ldots, u_k^x) \in \mathbb{R}^k$.

LEMMA 2.1. *The optimal solutions to* D1 *and* D′ *are equal.*

Proof. Consider a feasible solution to D′. The same $d(e)$'s and h_i's also constitute a feasible solution for D1. To see this we only have to show that $\sum_e q_j^i(e)d(e) \geq h_i$ for all i, j. Indeed,

$$\sum_e q_j^i(e)d(e) \geq \sum_{e=(x,y)} q_j^i(e)\,|u_i^x - u_i^y| = u_i^{t_i} - u_i^{s_i} \geq h_i\ .$$

The equality holds because q_j^i is a path from s_i to t_i and thus the summation is telescopic. Thus, any feasible solution to D′ is also a solution to D1. Conversely, given a feasible solution to D1, for all vertices x and $i = 1, \ldots, k$, set $u_i^x = \mathrm{dist}(s_i, x)$, where $\mathrm{dist}(y, x)$ denotes the length of the shortest path from y to x, under the non-negative edge lengths $d(e)$. This assignment gives D′ the same objective function value as for D1 while obeying all the constraints. ∎

A feasible solution to D' induces a mapping of the vertices into the metric space ℓ_∞^k ($\mathbb{R}^k$ with L_∞ norm). The L_∞ distances among these points have the following properties:

1. $\forall i$, $\|u^{t_i} - u^{s_i}\|_\infty \geq h_i$; and
2. $\forall e = (x,y)$, $\|u^x - u^y\|_\infty \leq d(e)$.

Next we embed this n point subspace of ℓ_∞^k into ℓ_1^d ($\mathbb{R}^d$ with L_1 norm), with u^x mapped to $\tilde{u}^x$. Let $\tilde{h}_i$ denote $\|\tilde{u}^{s_i} - \tilde{u}^{t_i}\|_1$. The embedding has the following properties:

1. d is polynomial in the size of the input (in fact, the embedding will have $d = O(\log^2 k)$);
2. $\forall i$, $\tilde{h}_i \geq h_i / O(\log k)$;
3. $\forall e = (x,y)$, $\|\tilde{u}^x - \tilde{u}^y\|_1 \leq \|u^x - u^y\|_\infty$.

Such an embedding can be obtained by a slight variation of Bourgain's theorem [3], and the algorithmic version thereof by Linial, London, and Rabinovich. A sketch of the proof is provided in the appendix (Corollary A.2; see also [21]).

For every pair of vertices x, y define the function $\delta^{x,y} : \{1, \ldots, d\} \times \mathbb{R} \to \{0, 1\}$ as

$$\delta^{x,y}(j, \xi) = \begin{cases} 1 & \text{if } \min\{\tilde{u}^x_j, \tilde{u}^y_j\} \le \xi < \max\{\tilde{u}^x_j, \tilde{u}^y_j\}, \\ 0 & \text{otherwise.} \end{cases}$$

The function $\delta^{x,y}$ is the characteristic function of the projection, on the jth axis, of the straight line connecting $\tilde{u}^x$ and $\tilde{u}^y$.

Now, define two functions

$$H : \{1, 2, \ldots, d\} \times \mathbb{R} \to \mathbb{R}^+,$$
$$C : \{1, 2, \ldots, d\} \times \mathbb{R} \to \mathbb{R}^+$$

as follows:

$$H(j, \xi) = \sum_{i=1}^{k} D_i \delta^{s_i,t_i}(j, \xi),$$
$$C(j, \xi) = \sum_{e=(x,y)\in E} c(e)\delta^{x,y}(j, \xi).$$

Notice that $H(j, \xi)$ is the sum of demands cut by a hyperplane perpendicular to the jth axis at ξ, while $C(j, \xi)$ is the sum of capacities of edges cut by the same hyperplane.

We have that

$$\sum_{j=1}^{d} \int_{-\infty}^{\infty} H(j, \xi) d\xi = \sum_{j=1}^{d} \sum_{i=1}^{k} \int_{-\infty}^{\infty} D_i \delta^{s_i,t_i}(j, \xi) d\xi = \sum_{i=1}^{k} D_i \tilde{h}_i \ge \frac{1}{O(\log k)} \,. \tag{2.1}$$

Similarly,

$$\sum_{j=1}^{d} \int_{-\infty}^{\infty} C(j, \xi) d\xi \le \sum_{e\in E} c(e)d(e). \tag{2.2}$$

Therefore, since both functions are nonnegative, there exists a point (j_0, ξ_0) such that $H(j_0, \xi_0) > 0$ and

$$\frac{C(j_0, \xi_0)}{H(j_0, \xi_0)} \le O(\log k) \sum_{e\in E} c(e)d(e).$$

To see this, consider the functions

$$H'(j, \xi) = O(\log k)H(j, \xi)$$

and

$$C'(j, \xi) = \frac{C(j, \xi)}{\sum_{e\in E} c(e)d(e)}.$$

H' is not always 0 and C' is nonnegative. If $H'(j, \xi) < C'(j, \xi)$ whenever $H'(j, \xi) > 0$, then we must have that $\sum_{j=1}^{d} \int_{-\infty}^{\infty} H'(j, \xi) < \sum_{j=1}^{d} \int_{-\infty}^{\infty} C'(j, \xi)$, in contradiction to inequalities (2.1) and (2.2).

The point (j_0, ξ_0) determines a cut $(S, \overline{S})$ by setting $S = \{x \in V \mid \tilde{u}^x_{j_0} \leq \xi_0\}$. The amount of demand between S and $\overline{S}$ is exactly $H(j_0, \xi_0)$ and the capacity of the edges connecting the two sides of the cut is $C(j_0, \xi_0)$. The point (j_0, ξ_0) can be found in polynomial time. This is because there are at most $|V|$ points of interest to check in each dimension. A sweep in each dimension can be used to obtain the best cut.

We have obtained the following theorem.

THEOREM 2.2. *For every concurrent multicommodity flow instance involving k commodities, the minimum cut ratio is within a factor of $O(\log k)$ of the maximum concurrent flow. Finding such a cut can be done in random polynomial time.*

Proof. Obtain the optimal solution to D′, e.g., using Ye's interior point polynomial time algorithm [34]. (Alternatively, find a near-optimal solution using more efficient algorithms, e.g., see Leighton et al. [19].) By Lemma 2.1 and linear programming duality, the value m of this solution is equal to the optimal value of $P1$. The above discussion shows how to find a cut with ratio within $O(\log k)$ of m. □

3. Min-multicut max-throughput. We can apply our method to derive bounds on the min-multicut to maximum-throughput ratio. However, the bounds we derive are inferior to the $O(\log k)$ bound presented in [12]. We get an $O(\log^2 k)$ bound using a randomized algorithm to find an approximate cut. The algorithm in [12] is deterministic. A sketch of the proof follows.

Using the notation of the previous section, we formulate the maximum throughput problem as the following linear program:

$$\text{(P2)} \qquad \begin{array}{lll} \text{maximize} & \sum_{i,j} f^i_j & \text{subject to} \\ & \sum_{i,j} q^i_j(e) f^i_j \leq c(e) & \forall e \in E, \\ & f^i_j \geq 0 & \forall i, j. \end{array}$$

The interpretation of this program is similar to that of (P1). The variables f^i_j denote the flow due to commodity i along the path q^i_j. The constraints guarantee that none of the edge capacities are violated.

The dual is

$$\text{(D2)} \qquad \begin{array}{lll} \text{minimize} & \sum_e c(e) d(e) & \text{subject to} \\ & \sum_e q^i_j(e) d(e) \geq 1 & \forall i, j, \\ & d(e) \geq 0 & \forall e. \end{array}$$

This program can be interpreted similarly to D1. We have a similar network of pipes. The constraints require that the distance between the pair of terminals of any commodity is at least 1. To accommodate a flow of rate $\sum_j f^i_j$ for every commodity i, the total volume of the pipes must be at least $\sum_{i,j} f^i_j$. This demonstrates weak duality.

As above, the dual (D2) can be converted into a polynomial size program where vertices are mapped to points in ℓ^k_∞. Note that in a feasible solution to D2 the distance between *each* source-destination pair is at least 1. We embed the metric space induced by the optimal solution into $\ell_1^{O(\log^2 k)}$, shrinking all distances and maintaining a distance of at least $1/O(\log k)$ among the terminal pairs. For the optimal solution, the embedded graph is contained in a cube of unit side length. Throughout the rest of this section we use the same notation as in the previous section.

Consider the following process. For each dimension j, independently choose a point $\xi_j \in [0, 1]$, uniformly at random. Place a hyperplane intersecting the jth axis at ξ_j and perpendicular to this axis. Consider a pair of vertices x, y. Let $a^{x,y}_j$ denote

the length of the projection, onto the jth axis, of the straight line connecting $\tilde{u}^x$ and $\tilde{u}^y$. Let $p^{x,y}$ be the probability that $\tilde{u}^x$ and $\tilde{u}^y$ are separated by at least one of the $d = O(\log^2 k)$ random hyperplanes. We have that

$$p^{x,y} \le \sum_{j=1}^{d} a_j^{x,y} = \|\tilde{u}^x - \tilde{u}^y\|_1 \le \|u^x - u^y\|_\infty ,$$

and

$$p^{x,y} \ge 1 - \prod_{j=1}^{d} \left(1 - a_j^{x,y}\right) \ge 1 - \left(1 - \frac{\|\tilde{u}^x - \tilde{u}^y\|_1}{d}\right)^d .$$

For s_i, t_i, we have $\|u^{s_i} - u^{t_i}\|_1 \ge 1/O(\log k)$ for all i. Thus, if we repeat the placement of d random hyperplanes $c \log^2 k = O(\log^2 k)$ times, then the probability, p_i, that $\tilde{u}^{s_i}$ and $\tilde{u}^{t_i}$ are separated by any of these hyperplanes satisfies

$$p_i \ge 1 - \left(1 - \frac{1}{d \cdot O(\log k)}\right)^{cd \cdot O(\log^2 k)} \ge 1 - k^{-c \cdot O(1)}.$$

Thus, with c sufficiently large, with probability at least $1 - k^{-1} \ge 2/3$ (assuming $k \ge 3$, for $k = 1$ or $k = 2$ the min-multicut equals the max-throughput), all source-destination pairs are separated.

For any edge $e = (x, y)$, $\|u^x - u^y\|_\infty \le d(e)$. Thus, the probability, p_e, that e is cut by any of the hyperplanes satisfies $p_e \le O(\log^2 k) d(e)$. Therefore, the expected size of the multicut is $O(\log^2 k) \sum_e c(e)d(e)$. By Markov's inequality, the probability that we get a multicut whose size is more than twice the expectation is at most $1/2$. Therefore, with probability at least $1/6$ all commodities are cut and the size of the cut is no more than twice the expectation. This guarantees that in random polynomial time we get a multicut that separates all source-destination pairs and whose size is $O(\log^2 k) \sum_e c(e)d(e)$.

Appendix A. Embeddings of finite metric spaces. An *embedding* of a finite metric space $\mathcal{M} = (X, d)$ into a (larger) metric space $\mathcal{M}' = (X', d')$ is a 1–1 mapping $\varphi : X \to X'$. An embedding φ is a *contraction* if $\forall x, y \in X$, $d'(\varphi(x), \varphi(y)) \le d(x, y)$ (see [33]). Any embedding into a normed space can be converted into a contraction without changing the ratios of distances among the points, by scaling all distances. For a contraction φ, the *distortion* is $\max_{x,y \in X} \{d(x, y)/d'(\varphi(x), \varphi(y))\}$. Obviously, the distortion is at least 1. A contraction is *isometric* if it has distortion exactly 1. For any p, a finite metric space is ℓ_p*-embeddable* if it can be isometrically embedded into the r-dimensional normed space ℓ_p^r, for some r. A finite metric space is *Euclidean* if it is ℓ_2-embeddable. We say that φ is into ℓ_p, if $\mathcal{M}'$ is ℓ_p^r, for some r. For $x \in X$, $Y \subset X$, denote by $d(x, Y)$ the distance from x to Y, defined as $\min_{y \in Y} d(x, y)$. For $x \in X$, $\rho \ge 0$, denote $B(x, \rho) = \{z \mid d(x, z) \le \rho\}$ (the closed ball around x of radius ρ).

The following lemma is due to Linial, London, and Rabinovich [21, 22] (see also [25]). It gives an algorithmic version of a theorem of Bourgain [3]. For completeness, we give a sketch of the proof.

LEMMA A.1 (see [22]). *Let $\mathcal{M} = (X, d)$ be a finite metric space with $|X| = n$. There exists a contraction, φ, of $\mathcal{M}$ into $\ell_1^{O(\log^2 n)}$ that has distortion $O(\log n)$. The contraction can be constructed in random polynomial time.*

Proof. For every $t = 1, \ldots, \log n - 1$, choose $L = O(\log n)$ subsets $Q_{t,j} \subset X$, $j = 1, \ldots, L$, such that $|Q_{t,j}| = \frac{n}{2^t}$. Each subset is chosen uniformly at random among all subsets of the specified size. The choices are mutually independent. For each $x \in X$, define a vector $\phi(x)$ with entries $\phi_{t,j}(x) = d(x, Q_{t,j})$.

Consider two points $x, y \in X$. For $t = 0, 1, \ldots$ define $\rho_t(x) = \min \rho$ such that $|B(x, \rho)| \geq 2^t$, and similarly define $\rho_t(y)$. Let $\rho_t = \max\{\rho_t(x), \rho_t(y)\}$, and let $\hat{t}$ be the largest t such that $\rho_t \leq d(x, y)/3$. Set $\rho_{\hat{t}+1} = d(x, y)/3$. (Notice that $\rho_0 = 0$.) Consider a particular $t > 0$ and one of the corresponding sets $Q_{t,j}$. W.l.o.g., $\rho_t(x) = \rho_t$ (i.e., ρ_t is obtained around x). Then, by assumption $|B(x, \rho_t)| \leq 2^t$, and by definition $|B(y, \rho_{t-1})| \geq 2^{t-1}$. Thus, a random set $Q_{t,j}$ of size $n/2^t$ has a constant probability of intersecting $B(y, \rho_{t-1})$ and not intersecting $B(x, \rho_t)$. (Notice that these balls are disjoint.) Thus, with constant probability $|\phi_{t,j}(x) - \phi_{t,j}(y)| \geq \rho_t - \rho_{t-1}$. Thus, with L sufficiently large, with high probability, $\sum_{j=1}^{L} |\phi_{t,j}(x) - \phi_{t,j}(y)| \geq cL(\rho_t - \rho_{t-1})$ for some constant c. Thus,

$$\|\phi(x) - \phi(y)\|_1 = \sum_{t,j} |\phi_{t,j}(x) - \phi_{t,j}(y)| \geq \sum_{t=1}^{\hat{t}+1} cL(\rho_t - \rho_{t-1}) = cL\rho_{\hat{t}+1} = cL\frac{d(x, y)}{3}.$$

On the other hand, by the triangle inequality, for any $x, y \in X$, and any set $Q_{t,j}$, $|d(x, Q_{t,j}) - d(y, Q_{t,j})| \leq d(x, y)$. Thus,

$$\|\phi(x) - \phi(y)\|_1 = \sum_{t,j} |\phi_{t,j}(x) - \phi_{t,j}(y)| \leq \log n \cdot L \cdot d(x, y) \ .$$

Finally, define $\varphi(x) = \frac{1}{L \log n}\phi(x)$. ∎

We get the following corollary.

COROLLARY A.2. *Let $\mathcal{M} = (X, d)$ be a finite metric space. Let $\mathcal{N} = (Y, d)$ be a subspace of $\mathcal{M}$ induced by a subset of points of cardinality k. There exists a contraction φ of $\mathcal{M}$ into $\ell_1^{O(\log^2 k)}$ such that the restriction of φ to $\mathcal{N}$ has distortion $O(\log k)$. The contraction can be constructed in random polynomial time.*

Proof. Using the construction for $\mathcal{N}$ given by the proof of Lemma A.1, we get the subsets $Q_{t,j} \subset Y$, $t = 1, \ldots, \log k - 1$, $j = 1, \ldots, L$, $L = O(\log k)$. For each $x \in X$, set $\phi_{t,j}(x) = d(x, Q_{t,j})$, and define $\varphi(x) = \frac{1}{L \log k}\phi(x)$. Now, for any $x, y \in X$, $\|\varphi(x) - \varphi(y)\|_1 \leq d(x, y)$, and for all $x, y \in Y$, $\|\varphi(x) - \varphi(y)\|_1 \geq d(x, y)/c \log k$, for some constant c. ∎

THEOREM A.3. *For any n, there exists an (explicitly constructible) metric space $\mathcal{M}_n$ over n points, such that any contraction of $\mathcal{M}_n$ into ℓ_1 has distortion $\Omega(\log n)$.*

Proof. The proof is by contradiction. Consider an n node bounded degree expander graphs G_n. (The expansion property we need is that any subset of $s \leq n/2$ vertices is connected to at least αs other vertices, for some absolute constant $\alpha > 0$. Such graphs can be constructed, e.g., via [24].) There are $\Theta(n)$ edges in G_n, and there exist $k_n = \theta(n^2)$ pairs of vertices at distance $\Theta(\log n)$ apart. For each n, consider a multicommodity flow instance where all the edges of G_n have unit capacity and there is a unit demand between each of the k_n pairs. It is not difficult to see that any cut in G_n has cut ratio at least c/n, for some constant c. Consider a feasible solution to the dual problem, where $d(e)$ is set to $d_n = \Theta(1/k_n \log n)$ for all e with an appropriate choice of constant. The value of the dual for this solution is at most $c'/n \log n$, for some constant c'. Now, consider the path metric of G_n (i.e., the n-point metric space over vertices of G_n, where the distance between two vertices is the minimum length

path connecting them). Suppose this metric space can be embedded into ℓ_1 with distortion less than $c \log n/c'$. Using the arguments from section 2, this implies that there exists a cut in G_n with cut ratio less than c/n, which is a contradiction. □

Remark. An alternative proof can be derived by noticing that for multicuts one can disconnect a constant fraction of the commodities by a multicut whose size is within an order of the distortion factor of the optimal fractional solution. The result then follows since there are instances of multicommodity flow on expander graphs, where cutting a constant fraction of the commodities requires a cut whose size is $\Omega(\log k)$ times the value of the maximum throughput (see [12]).

Bourgain [3] gives a lower bound of $\Omega(\log n/\log\log n)$ for the worst-case distortion of any contraction of n-point metric spaces into ℓ_2. From Theorem A.3 we get the following improvement over Bourgain's lower bound.

COROLLARY A.4. *Any contraction of $\mathcal{M}_n$ into ℓ_2 has distortion $\Omega(\log n)$.*

Proof. Any finite Euclidean space is ℓ_1-embeddable. (It is well known that L_2 isometrically embeds in L_1, see, e.g., [4]. For finite metric spaces, L_1-embeddability implies ℓ_1 embeddability; see [6].) □

Remark. The question of improving Bourgain's lower bound was raised by Linial, London, and Rabinovich. A similar theorem, derived independently, is shown in [21, 22].

A SUBLINEAR TIME DISTRIBUTED ALGORITHM FOR MINIMUM-WEIGHT SPANNING TREES*

JUAN A. GARAY†, SHAY KUTTEN‡, AND DAVID PELEG§

Abstract. This paper considers the question of identifying the parameters governing the behavior of fundamental *global* network problems. Many papers on distributed network algorithms consider the task of optimizing the running time successful when an $O(n)$ bound is achieved on an n-vertex network. We propose that a more sensitive parameter is the network's diameter $Diam$. This is demonstrated in the paper by providing a distributed minimum-weight spanning tree algorithm whose time complexity is sublinear in n, but linear in $Diam$ (specifically, $O(Diam + n^{\varepsilon} \cdot \log^* n)$ for $\varepsilon = \frac{\ln 3}{\ln 6} = 0.6131...$). Our result is achieved through the application of graph decomposition and edge-elimination-by-pipelining techniques that may be of independent interest.

Key words. MST, min-weight spanning trees, distributed algorithms

1. Introduction.

1.1. Motivation. In many papers on distributed network algorithms, the task of optimizing the running time is considered successful when an $O(n)$ bound is achieved on an n-vertex network. Typically, the justification is that there exist n-vertex graphs for which this bound is the best possible. The sequence of solutions to the leader election problem (LE) exemplifies the reasoning above. Following the $O(n \log n)$ running time and a first improvement by Chin and Ting [CT] and Gafni [G] (with an $O(n \log^* n)$ running time), Awerbuch gave an "optimal" $O(n)$-time solution to the problem [A1]. Again, this solution is optimal in the sense that there exist networks for which this is the best possible.

This type of optimality may be thought of as "existential" optimality; namely, there are points in the class of input instances under consideration for which the algorithm is optimal. A stronger type of optimality, which we may analogously call "universal" optimality, occurs when the proposed algorithm solves the problem optimally on *every* instance.

An interesting "side effect" of universal optimality is that a universally optimal algorithm precisely identifies the parameters of the problem that are inherently responsible for its complexity. For example, returning to the LE problem, a more careful

look reveals that the inherent parameter is the network's diameter $Diam$. Indeed, it was observed in [P] that it is possible to give a trivial $O(Diam)$-time distributed LE algorithm (although it should be noted that the solutions mentioned above were also message-optimal, whereas the algorithm of [P] is not).

The interesting question that arises is, therefore, whether it is possible to identify the inherent graph parameters associated with the distributed complexity of various fundamental network problems and to develop universally optimal algorithms for them.

A closely related question has been dealt with before in the context of studying the role of *locality* in distributed computing. Various problems were shown to be essentially local and hence amenable to a localized algorithm with very fast (e.g., polylogarithmic) running times. Notable examples include computing maximal independent sets and graph coloring [GPS, L, AGLP, PS2]. Locality-based techniques were also developed for reducing communication and time complexities for other problems whose local natures are less apparent [AP1, AP2, AKP].

In contrast, we are interested here in problems that are essentially *global*, i.e., ones that do not admit localized solutions but rather always require the algorithm to "traverse" the network. Problems of this type still raise the interesting (if more modest) question of deciding whether $\Omega(n)$ time is essential—or is the network's *diameter* the inherent parameter? In the latter case, it would be desirable to devise algorithms for these network problems that have a better complexity for the case of graphs with low diameter.

In this paper, we tackle the classical minimum-weight spanning tree (MST) problem. This problem has been studied before as a canonical example for a graph-algorithmic problem whose communication-efficient distributed solution poses some surprisingly nontrivial subtleties [GHS]. The time complexity of the algorithm of [GHS] is $O(n \log n)$, which was later improved to the (existentially) "optimal" $O(n)$ in [A1]. As with other problems, such as the above LE example, it is natural to ask whether $O(n)$ is universally optimal or if it can be improved.

Once again, the MST problem proves to be a worthy candidate for this type of study. In other tree constructions, such as the breadth-first-search (BFS) tree (which is closely related to the LE problem), it is intuitively clear that the true time bound should be related to the network's diameter $Diam$, since the depth of the constructed tree is proportional to $Diam$. In contrast, the MST of a given network may be considerably deeper than $Diam$, and in fact, may be as high as $\Omega(n)$. Hence construction methods based on communication on the tree structure itself are doomed to require $\Omega(n)$ time, and the problem of breaking the $\Omega(n)$ barrier seems intrinsically harder.

In this paper we get closer to identifying the inherent parameters governing the behavior of distributed MST construction by presenting a distributed MST algorithm whose time complexity is sublinear in n, and linear in $Diam$ (specifically, $O(Diam + n^{\varepsilon} \cdot \log^* n)$ for $\varepsilon = \frac{\ln 3}{\ln 6} = 0.6131...$), thus breaking the $O(n)$ barrier. This result is achieved through the application of graph decomposition and edge elimination techniques that may be interesting in their own right.

1.2. Model and definitions. In this paper we focus on the problem of devising a time-efficient distributed MST algorithm. The statement of the problem is as follows. The network is represented by an undirected graph $G = (V, E)$, where V is the set of nodes and E is the set of links between them. (Henceforth we use the terms "graph" and "network" interchangeably, when no ambiguity arises.) The graph

is given with a weight function $\omega : E \to R^+$ on the edges, such that each node in V is associated with its own processor, and processors are able to communicate with each other via the edges in E. The goal is to have the nodes (processors) cooperate to construct a tree covering the nodes in V whose total edge weight is no greater than any other spanning tree for G.

We assume that nodes have unique identifiers and that each edge $e \in E$ is associated with a distinct weight $\omega(e)$ known to the adjacent nodes. The usefulness of having distinct edge weights stems from the fact that this property guarantees that the MST is unique. Clearly, having distinct weights is not an essential requirement, since one can always "create" them by appending the adjacent node's numbers to them. However, it is known that if the graph has neither distinct edge weights nor distinct node identifiers, then no distributed algorithm exists for computing an MST with a bounded number of messages [GHS].

For every subgraph F of the network, let $Diam(F)$ denote the diameter of F, i.e., the maximum distance between any two vertices of F, where distance is measured in the unweighted sense, i.e., in the number of hops.

In order to be able to concentrate on the central issue of time complexity, we shall follow the common trend of stripping away nonessential complications. In particular, we ignore the communication cost of our algorithm, i.e., the number of messages it uses. (We comment that while this number is not optimized in any way in our solution as presented in the current paper, it is not very large. In particular, it is still considerably smaller than the number of messages needed for every node to learn the topology of the entire network, as is used in a number of existing routing schemes, e.g., Internet routing [MRR].)

We also assume that the computation performed by the network is *synchronous*; namely, computation proceeds in rounds, governed by a global clock, with each round taking one time unit. In each round each processor can examine the messages sent to it by its neighbors (if any), compute, and send messages to any subset of its neighbors. Such messages, if sent, are available to their recipients in the next round. The *time complexity* of a synchronous algorithm is the number of time units elapsing until the termination of the algorithm. This assumption is quite common in the literature. Note, however, that here it is not essential, since our decision to ignore communication costs allows us to freely use a synchronizer of our choice; for example, synchronizer α [A2] enables an asynchronous network to run any protocol that was designed for synchronous networks, with the same time complexity, at the cost of some increase in the message complexity.

Still, we shall not adopt the extreme model employed in previous studies of locality issues (cf. [L]), in which messages of arbitrary size are allowed to be transmitted in a single time unit, since in this model the refined distinctions we focus on here disappear. Clearly, if unbounded-size messages are allowed, then the problem can be trivially solved in time $O(Diam(G))$ by collecting the entire graph's topology into a central node, computing an MST locally, and broadcasting the result throughout the network.

Consequently, we will assume the more realistic (and rather common) model in which messages have size $O(\log n)$, and a node may send at most one message on each edge at each time unit.

We will also make the assumption that edge weights are polynomial in n, so an edge weight can be sent in a single message. (This assumption is required for the time analysis of all previous algorithms as well [GHS, A1].)

1.3. Our results. The original distributed MST algorithm of Gallager, Humblet, and Spira [GHS] has a time complexity of $O(n \log n)$. This was later improved by Awerbuch, who gave an $O(n)$-time algorithm [A1]. In this paper, we present a distributed MST algorithm with time complexity $O(Diam(G) + n^{\varepsilon} \cdot \log^* n)$ for $\varepsilon = \frac{\ln 3}{\ln 6} = 0.6131...$.

2. Overview of the MST algorithm. Our algorithm is based on a careful combination of two distinct approaches to the (distributed) construction of an MST. Thus, before explaining our algorithm, it is instrumental to review the two approaches and try to understand their shortcomings (when used individually).

2.1. Distributed growth approach. The first approach is the construction method that is at the basis of the MST algorithm of [GHS] (referred to from now on as the GHS algorithm). This algorithm does not utilize a central controller, or "center of activity," but rather allows a large number of processes to proceed simultaneously and independently in the network. These processes gradually *grow* the MST from scratch.

The GHS algorithm operates by growing so-called *fragments* in a distributed manner, with each fragment consisting of a portion of the final MST. In each iteration of the algorithm, the nodes of each fragment explore the immediate neighborhood of the fragment and collectively decide on a neighboring fragment to merge with (by adding the connecting edge to the tree), thus creating a larger fragment of the final MST. This is a distributed version of the "blue" rule for MST construction (cf. [T, p. 71]).

It is crucial to understand why algorithms based on this approach cannot guarantee a time complexity proportional to $Diam(G)$. The inherent difficulty lies in the fact that the communication necessary for making the merging decisions for each fragment is done *on the fragment itself*. This is a problem, since the MST is not guaranteed to have depth proportional to $Diam(G)$, and neither are any of its fragments. In fact, it is easy to come up with examples for n-vertex graphs with diameter 1 whose MST has depth $n - 1$. Thus, any approach based on communicating over the MST itself will have time complexity proportional to n in the worst case on some graphs.

Note, however, that in the initial stages of the GHS algorithm, the fragments are still small, and therefore communication on them is not as expensive. The idea on which our algorithm is based is thus to start by running the GHS algorithm up to an appropriately chosen point, and then switch to a different algorithm. In order for this idea to work, it is essential to have a version of the GHS algorithm that controls the rate of growth of the different fragments, preventing some fragments from growing too large while other are still very small. (The original algorithm of [GHS] allows uncontrolled growth of fragments.)

2.2. Coordinated elimination approach. The second approach to the distributed construction of an MST is based on synchronous, coordinated, centralized operation. One extreme example for an algorithm operating in this way is the centralized algorithm mentioned in the introduction, in which the entire graph's topology is collected into a central node, which then computes an MST locally and broadcasts the result throughout the network. This algorithm is slowed down considerably by the heavy communication bottlenecks that are bound to be created along the paths leading to the center node.

The crucial idea at the basis of the second approach is that some of this communication burden can be reduced by delegating the work of the center node to other

nodes along the paths leading to the center. This can be achieved if, instead of attempting to *build* the MST, we concentrate on *eliminating candidate edges*, using the so-called "red rule" for MST construction (cf. [T, p. 71]).

In order to control the complexity of the edge-elimination process, we employ a new efficient pipelining technique aimed at overcoming congestion. This new technique deserves some discussion, since it is different and considerably simplified compared to the one presented in an earlier version of this paper [GKP]. The new technique is motivated by the following complication in the solution of [GKP]. In the end of the first stage of the algorithm, nodes are informed about candidate edges in the graph (those that connect clusters). In the third stage of the [GKP] algorithm, the nodes forward the description of those edges to their parents on a spanning tree, toward the root. The problem is that there might be too many such edges, congesting the accumulation process on the tree. The algorithm of [GKP] overcomes this difficulty by introducing an intermediate stage employing a rather complex method (centered on locality-based ideas related to [ADDJ, AGPV, B, PS1]) for eliminating short cycles, and thus reducing the number of remaining edges for the third stage.

The algorithm presented here has only two stages. Both the second (cycle elimination) and the third stages of [GKP] are replaced by a single stage, similar to the third stage of [GKP], in which the nodes forward descriptions of candidate edges to their parents on a breadth-first-search spanning tree. However, we incorporate a new technique of cycle elimination into this stage. This new pipelining technique is very simple, and the main novelty lies in its analysis. As in the third stage of the algorithm in [GKP], nodes on the spanning tree forward the descriptions of their candidate edges to their parents toward the root. However, here a node avoids forwarding the description of *cycle-heavy* edges. That is, a node forwards the description of edges according to their weight and does not forward the description of an edge that closes a cycle with edges whose description has already been forwarded. Let us now give a hint regarding the difficulty in analyzing this stage of the protocol. It is not hard to prove that all non-MST edges get eliminated by this process. The difficulty lies in analyzing the time complexity. Note that the description above (i.e., that a node does not forward a description of a cycle-heavy edge) seems to suggest that at certain points in time a node might be forced to wait, due to not having an edge description that is eligible for forwarding. Thus, it may seem that the convergecast may not be fully pipelined, and hence may take a long time. We prove that this simple convergecast is fully pipelined, and thus its running time is the one required, eliminating the need for the complex cycle elimination stage of [GKP]. This pipelining proof may be of interest in itself.

2.3. Combined approach. Let us now outline the structure of our algorithm. The algorithm consists of two parts as follows.

`Algorithm Sublinear-`MST

Part I: `Controlled-GHS`;

Part II: Edge elimination.

As its name indicates, `Controlled-GHS` (part I) is a modified variant of the original algorithm of [GHS]. The purpose of the modification is to produce a balanced outcome in terms of number and diameter of the resulting fragments. This is achieved by computing, in each phase, a small dominating set on the fragment forest and merging

fragments accordingly. This, in turn, is achieved by invoking the distributed maximal independent set (MIS) algorithm of [GPS]. At the end of this phase, we are left with a "small" number of fragments, all of which have a "small" diameter.

Finally, part II performs the elimination of most of the remaining edges, leaving only a tree connecting the fragments, and thus yielding the final MST. This elimination process is carried out in a distributed manner and requires nodes to forward the description of certain edges to a central node, while eliminating the description of certain other edges. (The forwarding is done on a superimposed breadth-first tree, and the center is the root of this tree.) The central node does the final elimination, which yields the output MST tree.

The details of each part are given in the remainder of the paper, followed by the analysis of the total complexity.

3. Part I: Controlled-GHS. In this section we provide a modified, *controlled* version of the Gallager-Humblet-Spira algorithm for MST that is suitable for our purposes. We first provide a brief overview of the original algorithm of [GHS].

3.1. Brief description of the GHS algorithm. In the original distributed algorithm of [GHS], nodes form themselves into *fragments* of increasing size. Initially, all nodes are in singleton fragments. Nodes in each fragment F are connected by edges that form a *rooted* MST, $T(F)$, for the fragment. (Initially, the sole node comprising a fragment is also its root.) Each node (other than the root) in a fragment has a pointer to one of its neighbors, which is the next node on the path over the tree to the root; moreover, each node "knows" the root Id. (In the remainder of this paper we loosely use the word "fragment" to mean both the collection of nodes F and the corresponding tree $T(F)$.)

The events in the algorithm are divided into *phases*. Each phase takes as its input the fragment structure output by the previous one and outputs larger fragments. (The first phase takes as an input the singleton fragments, one per node.)

Let us now describe one phase. We present a simplified version of the GHS algorithm compared to the original algorithm of [GHS]. (The original version is more complex because of the desire to save messages and because of the asynchronous nature of the networks for which it was designed.)

Within each fragment F, nodes cooperate to find the minimum-weight *outgoing* edge in the entire fragment (an outgoing edge of a fragment F is an edge with one endpoint in F and another at a node outside it). The strategy for identifying this edge involves broadcasting over the fragment's tree $T(F)$, asking each node separately for its own minimum-weight outgoing edge. These edges are then sent upwards on the tree $T(F)$, toward the root. Each intermediate node first collects this information from all its children in the tree and then passes up only the lowest-weight edge it has seen (which is therefore the lowest-weight edge in its subtree). The minimum-weight outgoing edge is selected by the root to be included in the final MST.

Once a fragment's minimum-weight outgoing edge is found, a message is sent out over that edge to the *chosen* fragment on the other side. The two fragments then combine, possibly along with several other fragments, into a new, larger fragment. If the other fragment chose the same edge, then the two fragments agree at that point to combine, and the edge they both chose is termed the *core edge*. Otherwise, following the route from a fragment F_1, to its chosen fragment F_2, to F_2's chosen fragment F_3, and so on, [GHS] show that one must eventually reach two fragments that agree to combine over a core edge. The combined fragment includes these two, as well as all those other fragments that have such a route to them.

The combined fragment has a root; it is the node with the higher Id of the two endpoints of the core edge. (This can be simulated in the case that nodes do not have distinct Id's but edges have distinct weights.)

This concludes the description of a single phase. In the next phase, the new fragment finds its own minimum-weight outgoing edge, and the entire process is repeated until all the nodes in the graph have combined themselves into one single fragment. Each fragment (of size 2 or greater) is identified by the fragment's *core edge* and root.

We remark that in the original GHS algorithm, all nodes operate asynchronously. This creates the risk of undesirable "growth patterns" of fragments, resulting in excessive communication costs (measured in number of messages). This problem is handled by using special rules for merging fragments, designed to prevent these complications. These rules are based on a "balanced data structure" approach. A *phase number* is associated with each fragment. If $phase(F) = l$ for a given fragment F, then the number of nodes in F is greater than or equal to 2^l. Initially, all fragments (singleton nodes) are at phase 0. When two fragments at phase l are combined together, the resulting new fragment has phase $l + 1$. Thus, the total number of messages is kept to $O(n \log n)$ (although some more complex rules are needed to allow merges between fragments of unequal phases). Similarly, it is not hard to show by induction on the phase numbers that the time complexity of the algorithm is $O(n \log n)$ time units.

We refer the reader to [GHS] for further details.

3.2. Computing a small dominating set on a tree. In this subsection we present a procedure `Small-Dom-Set` for computing a small dominating set on a given tree. The procedure makes use of a subprocedure for computing a maximal independent set in the tree. (A set M of vertices in a tree T is said to *dominate* the tree if every vertex outside M has a neighbor in M.) A distributed version of procedure `Small-Dom-Set` will later be used as a component in our `Controlled-GHS` algorithm, which is a modification of GHS.

Our goal is as follows. Given a rooted tree T with a vertex set $V(T)$, find a set of vertices $M \subseteq V(T)$ such that

1. M dominates $V(T)$, and
2. $|M| \leq \frac{|V(T)|}{2}$.

Furthermore, we would like this procedure to be amenable to a fast distributed implementation.

The procedure is based on the following. For a vertex $v \in V(T)$, let $\texttt{Child}(v)$ denote the set of v's children in T. We use a *level* function $\check{L}(v)$ on the nodes, defined as follows:

$$\check{L}(v) = \begin{cases} 0 & \text{if } v \text{ is a leaf,} \\ 1 + \min_{u \in \texttt{Child}(v)}(\check{L}(u)) & \text{otherwise.} \end{cases}$$

We denote by $\check{L}_i$ the set of tree nodes at level i,

$$\check{L}_i = \{v \mid \check{L}(v) = i\}.$$

Procedure `Small-Dom-Set` for computing a dominating set M on a tree T is presented next.

`Algorithm Small-Dom-Set`

1. Mark the nodes of T with level numbers $\check{L}(v) = 0, 1, 2$;
2. Select an MIS, Q, in the set R of unmarked nodes;
3. $M \leftarrow Q \cup \check{L}_1$.

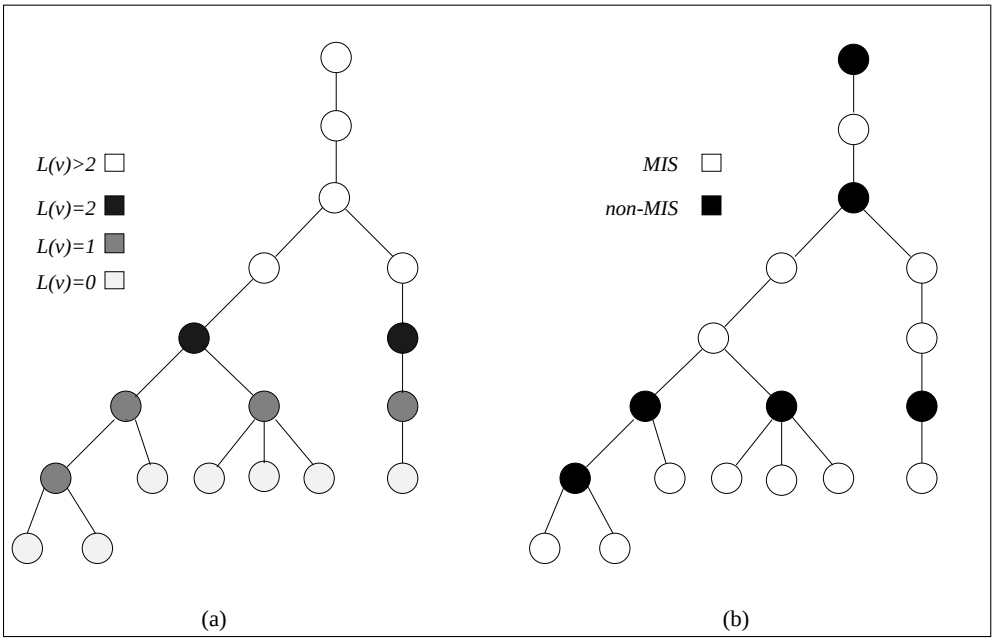

FIG. 1. (a) *The level numbers marked by the algorithm on a given tree* T. (b) *A small dominating set* M *on the tree* T.

A pictorial example is given in Figure 1.

For the distributed implementation discussed in the next subsection, it is important to note that although the level numbers $\check{L}(v)$ are defined for every vertex v in the tree, only the vertices belonging to the first three levels, $\check{L}_0$, $\check{L}_1$, and $\check{L}_2$, are actually marked.

The fact that procedure `Small-Dom-Set` produces a dominating set is established by the following lemma.

LEMMA 3.1. *Let* M *be the outcome of procedure* `Small-Dom-Set` *on the tree* T. *Then for every node* $v \notin M$ *there exists an adjacent node* $v' \in M$.

Proof. Partition $V(T)$ into $\check{L}_0 \cup \check{L}_1 \cup \check{L}_2 \cup R$. The set M output by procedure `Small-Dom-Set` is composed of $Q \cup \check{L}_1$. Now, by choice of Q, it dominates each node of $R \setminus Q$. Also, each node of $\check{L}_0 \cup \check{L}_2$ has a neighbor in $\check{L}_1$. □

The "smallness" of the resulting dominating set is guaranteed by the following lemma.

LEMMA 3.2. $|M| \leq \frac{|V(T)|}{2}$.

Proof. By construction, $M = \check{L}_1 \cup Q$. It is clear that $|\check{L}_1| \leq |\check{L}_0|$, and hence

$$|\check{L}_1| \leq \frac{|\check{L}_0 \cup \check{L}_1|}{2} \ . \tag{1}$$

We now claim that

$$|Q| \leq \frac{|R \cup \check{L}_2|}{2} \ . \tag{2}$$

This can be proved by selecting for every $v \in Q$ a *distinct* match $\omega(v) \in (R \cup \check{L}_2) - Q$, thus establishing that $|R \cup \check{L}_2| \geq 2 \cdot |Q|$. The matching is done as follows: pick $\omega(v)$ to

be an arbitrary child of v (by definition, vertices in Q always have children in $R \cup \check{L}_2$). Distinctness is guaranteed by the fact that each node in the tree has a unique parent. It now follows from (1) and (2) that

$$|M| = |Q \cup \check{L}_1| \leq \frac{|R \cup \check{L}_2|}{2} + \frac{|\check{L}_0 \cup \check{L}_1|}{2} = \frac{|V(T)|}{2}. \qquad \square$$

3.3. Controlled-GHS.

3.3.1. Description of the `Controlled-GHS` procedure. In this subsection, we provide the modified, *controlled* version of GHS (named `Controlled-GHS`) that is able to achieve the following:

1. Upon termination, the number of fragments is bounded from above by N (for N to be specified later).
2. Throughout the execution, the diameter of every fragment F satisfies $Diam(F) \leq d$ (for d to be specified later).

Intuitively, since we focus on a synchronous algorithm, and we do not care about communication complexity, our version of GHS is simpler than the original algorithm. In particular, we are oblivious to balancing fragment sizes, and we do not need to use the phase rules used in the original algorithm, since phases are imposed by phase synchronization (using the assumed global clock).

More specifically, `Controlled-GHS` starts with singleton fragments, just like GHS (see subsection 3.1), and executes a total of I phases. Each phase outputs a collection of fragments that serve as the input for the next phase. A fragment is a rooted tree, where each node (except for the root) has a pointer to the edge that leads to its parent in the tree. Each phase of `Controlled-GHS` consists of the following two stages.

Stage 1. Consider the fragments that are input to the phase. Execute a phase of GHS up to a point where each such input fragment F has chosen its minimum-weight outgoing edge, i.e., has decided with which other fragment in the current fragment collection it wants to merge.

This decision induces a "forest" structure on the fragment collection (possibly with length-2 loops at the tree roots). Henceforth we refer to this structure as the *fragment forest*, denoted FF.

Stage 2. Break the resulting trees into "small" ($O(1)$ depth) trees, and merge only these small trees.

This process is depicted in Figure 2. To accomplish Stage 2, the algorithm first computes a dominating set $M_{FF}(\tilde{T})$ on each tree $\tilde{T}$ of the fragment forest FF. Note that the nodes of this tree are input fragments of the current phase of the algorithm. Let M_{FF} be the union over the trees $\tilde{T}$ (of the FF forest) of $M_{FF}(\tilde{T})$. The algorithm then lets each fragment $F \notin M_{FF}$ pick one neighboring fragment $F' \in M_{FF}$ and merge with it. This causes the actual merges performed in a phase of `Controlled-GHS` to have the form of "stars" in the fragment forest FF, and prevents merges along long chains, hence bounding the diameter of the resulting fragments.

The dominating sets are computed using a distributed implementation of procedure `Small-Dom-Set`, denoted `Dist-SDS`, applied separately to each tree $\tilde{T}$ in the fragment forest FF. A key aspect in this computation is the use of a distributed algorithm for computing a maximal independent set. Most distributed MIS algorithms in the literature (e.g., [AGLP, PS2]) can be used for our purposes. In fact, our solution only requires to compute an MIS on a tree, so we can use a distributed version of the algorithm of [GPS], which is optimal for trees. (This algorithm makes use of $O(\log n)$-bit messages and therefore can be used within our model.)

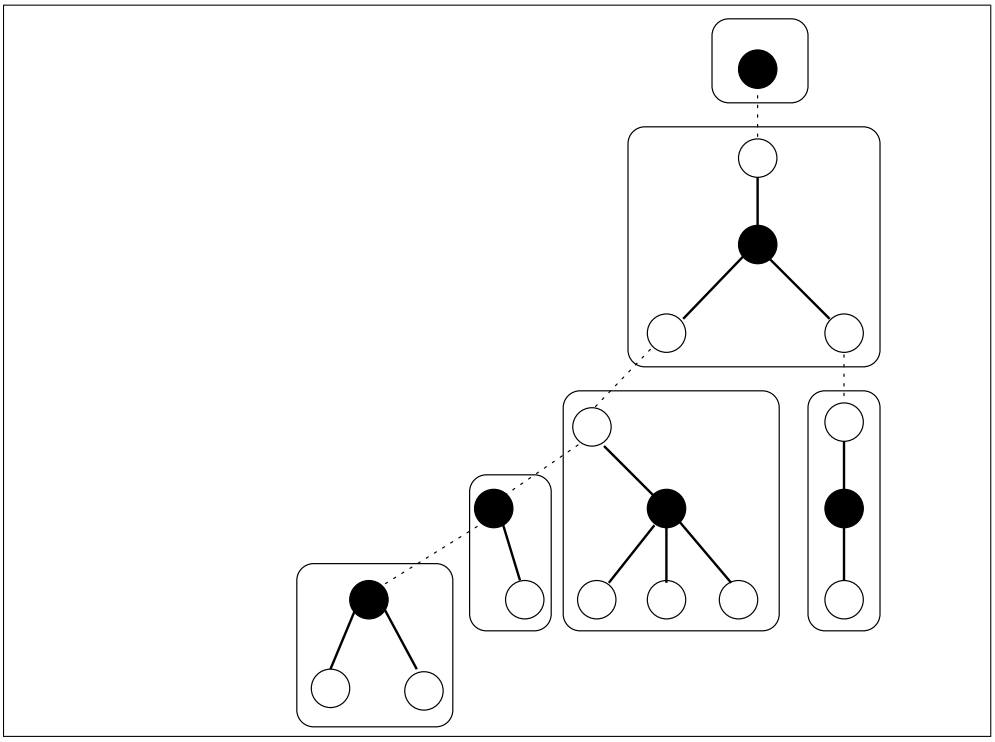

FIG. 2. *A phase of* `Controlled-GHS`*: the tree T of Figure* 1b *is broken into "small" trees (represented by the solid edges) according to the MIS.*

The algorithm of [GPS] (henceforth referred to as the `GPS` algorithm) has the following properties.

LEMMA 3.3 (see [GPS]). *Applied in a given n-vertex tree G, Algorithm* `GPS` *computes (in a synchronous manner) a maximal independent set (MIS) of G using $O(\log n)$-bit messages, and its time complexity is $O(\log^* n)$.*

Note that although procedure `Dist-SDS` is applied to the trees of the fragment forest FF, it is actually executed on the original network itself. Hence the procedure operates by simulating each fragment by a single representative, say, its root.

3.3.2. Analysis of controlled-GHS. The bounds on the number and diameter of fragments are established by the next lemma. Given a fragment forest FF, let $Diam(FF) = \max_{F \in FF}\{Diam(F)\}$. Let FF_i denote the fragment forest produced by the algorithm `Controlled-GHS` at the end of the ith phase. (FF_0 is the initial set of vertices.)

LEMMA 3.4. *In each phase i of* `Controlled-GHS`*,*

1. *the number of fragments at least halves, i.e., $|FF_i| \leq |FF_{i-1}|/2$, and*
2. *the maximum diameter of a fragment increases by a factor of at most* 3 (*possibly plus* 2)*, i.e., $Diam(FF_i) \leq 3Diam(FF_{i-1}) + 2$.*

Proof. The number of new fragments in each tree $T = T(F)$ of the fragment forest FF at the end of a phase is equal to $|M(T)|$. By Lemma 3.2, $|M(T)| \leq |V(T)|/2$. Hence the same holds for the entire fragment forest, and claim 1 of the lemma follows. Claim 2 is readily satisfied since the merges are star shaped. □

COROLLARY 3.5. *After running* `Controlled-GHS` *for I phases,*

1. *the number of fragments in* FF_I *is at most* $N(I) = \frac{n}{2^I}$, *and*
2. $Diam(FF_I) \leq d(I) = 3^I - 1$ *for every fragment* F.

Let us now turn to analyzing the time complexity of `Controlled-GHS`. We first examine the performance of procedure `Dist-SDS`.

LEMMA 3.6. *When executed on a fragment forest* FF, *procedure* `Dist-SDS` *takes time* $O(\log^* n) \cdot Diam(FF)$.

Proof. It is easy to see that if a fragment F is a leaf in the fragment forest FF, then it identifies itself as such, and subsequently marks itself $\check{L}_0$, in time $O(Diam(F))$. Similarly, fragments mark themselves $\check{L}_1$ and $\check{L}_2$ in time $O(Diam(F))$ as well. Another part that affects the time complexity is the MIS computation. By Lemma 3.3, the time complexity of the `GPS` algorithm is $O(\log^* n)$. Note that since the procedure is executed on the original network itself, it is slowed down by a factor of $O(Diam(FF))$. Hence the implementation of the `GPS` algorithm on the fragments of FF is slowed down to $O(\log^* n) \cdot Diam(FF)$ in our case. □

The properties of the `Controlled-GHS` algorithm are now summarized by the following *graph decomposition* lemma.

LEMMA 3.7. *When Algorithm* `Controlled-GHS` *is activated for* I *phases, it takes* $O(3^I \cdot \log^* n)$ *time and yields a fragment forest* FF_I *of up to* $N(I) = n/2^I$ *fragments, of diameter* $Diam(FF_I) \leq d(I) = 3^I - 1$. *Each fragment in the forest is a fragment of an MST of the graph* G.

Proof. By Lemma 3.6, each phase i, $1 \leq i \leq I$, of `Controlled-GHS` takes time at most $Diam(FF_{i-1}) \cdot O(\log^* n)$. By Corollary 3.5, this is at most $3^{i-1} \cdot O(\log^* n)$. Thus, the total time is given by

$$\sum_{i \leq I} (3^{i-1} \cdot O(\log^* n)) \leq 3^I \cdot O(\log^* n) \ .$$

The size and diameter properties of the resulting fragment forest follow directly from Corollary 3.5. □

The rather even graph decomposition obtained by Algorithm `Controlled-GHS` may conceivably be useful for other purposes as well.

4. Part II: Edge elimination. The second part of our algorithm starts at the point where we are given a fragment graph $\tilde{F}_l$, whose vertex set $V(\tilde{F}_l)$ is a fragment forest FF_I containing $N \leq N(I)$ fragments of the MST, and whose edge set $E(\tilde{F}_l)$ is a collection of interfragment edges, which are the remaining candidates for joining the MST. We now proceed to reduce the total number of remaining interfragment edges (to the necessary $N - 1$).

4.1. The pipeline algorithm. We need the following technical definition. For a set of edges Q and a cycle-free subset $U \subseteq Q$, define $Cyc(U, Q)$ as the set of all edges $e \in Q \setminus U$ such that $U \cup \{e\}$ contains a cycle.

We are now ready to describe our pipelined procedure, given in Figure 3.

4.2. Analysis. Our analysis hinges on two main properties of the procedure. First, the edges reported by each intermediate node to its parent in the tree are sent in nondecreasing weight order. Second, each intermediate node transmits edges upwards in the tree *continuously* until it exhausts all the reportable edges from its subtree; namely, once the set of candidates RC is empty, the node will learn of no more reportable edges.

Let us first make the following straightforward but crucial observation.

1. Build a *breadth-first-search* tree B on G, with a root $r(B)$.
2. Throughout the execution, each node v on the tree maintains a set Q of all the interfragment edges it knows of (either directly or by "learning" from its children in the previous rounds), ordered by nondecreasing edge weights. Initially this set contains only the interfragment edges adjacent to it. It also maintains a set U (initially empty) of all the edges it has already sent up to its parent in the tree.
3. A leaf v starts sending edges upwards at pulse 0. An intermediate node v starts sending at the first pulse after it has received messages from all its children.
4. At each pulse i, the node sends up to its parent in the tree the lightest edge e in Q that has not been sent up in the previous rounds up to round $i-1$ (i.e., $e \notin U$), and which does not close a cycle with the edges of U. If no such edge exists then terminate participation in the pipelining part of the procedure (i.e., go to step 6).
   More formally, the node computes the set of *remaining candidates (RC)*
   $$RC = Q \setminus (U \cup Cyc(U, Q)).$$
   If $RC = \emptyset$, then v sends a "terminating" message to its parent in the tree and terminates its participation in the pipelining part of the protocol; else, it sends up to its parent the lightest edge e in RC.
5. The root $r(B)$ computes locally the set S of the $N-1$ edges participating in the MST of the fragment graph $\tilde{F}$ from among the edges it hears of from its children.
6. The root $r(B)$ then broadcasts (over the tree B) the resulting set of $N-1$ interfragment edges (constituting the MST for the fragment graph $\tilde{F}$) to all nodes in G.

FIG. 3. *Procedure* `Pipeline`.

LEMMA 4.1. *The edges reported by each intermediate node to its parent in the tree form a forest.*

Proof. This follows immediately from the rule used by the procedure to select the next edge to be transmitted upwards. □

LEMMA 4.2. *Every node v starts sending messages upwards at pulse $\hat{H}(v)$, where $\hat{H}(v)$ is the* height *function defined as follows:*

$$\hat{H}(v) = \begin{cases} 0 & \text{if } v \text{ is a leaf;} \\ 1 + \max_{u \in \texttt{Child}(v)}(\hat{H}(u)) & \text{otherwise.} \end{cases}$$

Proof. The proof is straightforward by induction on the tree structure, from the leaves upward. □

Our main technical lemma concerns the properties of a node on the tree in some round of the algorithm. Consider an intermediate node v at height H that has still

not terminated its participation in the algorithm, at round t, for some $t \geq H$. Note that each of the children of v in the tree is of height $H-1$ or lower, hence, by Lemma 4.2, all of them started transmission at round $H-1$ or earlier. Call a child *active* if it has not terminated yet (i.e., it has upcast an edge to v on round $t-1$). Let

$$A_t(v) = \{v_1, \ldots, v_p\}$$

be the set of v's active children at round t.

LEMMA 4.3.

(a) *At the beginning of round t, the candidate set RC examined by v contains at least one candidate edge upcast by each of its active children from $A_t(v)$.*

(b) *If v upcasts an edge of weight ω at round t, then all of the edges which v was informed of at round $t-1$ by its active children were of weight ω or greater.*

(c) *If v upcasts an edge of weight ω at round t, then any later edge it will learn of is of weight ω or greater.*

(d) *Node v upcasts edges in nondecreasing weight order.*

Proof. We prove the lemma by induction on the height of the tree, starting from the leaves upwards.

A *leaf* v has no (active or other) children, and therefore claims (a), (b), and (c) hold vacuously. Claim (d) follows trivially from the rules of the procedure.

Let us now consider an intermediate node v, and assume that the claims hold for each of its children. We need to prove the four claims for v. We start with claim (a).

Let U be the set of m edges upcast by v during the first $m = t - H$ rounds it has participated in (namely, rounds $H, \ldots, t-1$ if $t > H$). By Lemma 4.1, U forms a forest in G. Consequently, break U into the trees $U_1, \ldots, U_\ell$ in G, with $x_i = |U_i|$, where each such tree U_i has a vertex set $V(U_i)$ of exactly $x_i + 1$ vertices, and

$$\sum_i x_i = |U| = m. \tag{3}$$

Consider an active child u of v. Denote by D the set of edges upcast by u so far (up to and including round $t-1$). Since u was still active on round $t-1$, it has transmitted continuously to v since round $\hat{H}(u)$, which, as discussed before, is at most $H-1$. Therefore, we conclude that

$$|D| \geq m + 1. \tag{4}$$

Suppose, for the sake of contradiction, that none of the edges upcast by u is a candidate in round t. In other words, for each edge $e \in D$, either e was upcast by v earlier (namely, $e \in U$), or e closes a cycle with the edges of U (namely, $e \in Cyc(U)$). Thus, every such edge e has both of its endpoints in U. Furthermore, e cannot possibly connect endpoints that belong to two different trees U_i and U_j (since in that case, e would have been in neither U nor $Cyc(U)$).

This implies that the set D can be partitioned into sets $D_1, \ldots, D_\ell$ such that all the edges of D_i are restricted to vertices $V(U_i)$ of the tree U_i, for $1 \leq i \leq \ell$. Moreover, notice that each such set D_i is a forest, since the entire set D is a forest by Lemma 4.1.

The last two facts combined imply that

$$|D_i| \leq |V(U_i)| - 1 = x_i. \tag{5}$$

Combining (3), (4), and (5) we get

$$m+1 \leq |D| = \sum_i |D_i| \leq \sum_i x_i = m,$$

which is a contradiction. Hence claim (a) must hold.

Next we prove claim (b) as follows. Consider any active child u of v. Let e be the edge upcast by u on round $t-1$. (Note that e does not necessarily have to be in RC.) Let e' be some edge that was upcast by u at some round $t' \leq t-1$ and is still in the candidate set RC on round t (such an edge must exist by claim (a)). By the inductive hypothesis of claim (d), $\omega(e) \geq \omega(e')$. By the edge selection rule of node v, $\omega(e') \geq \omega$, and claim (b) follows.

Next we note that claim (c) follows trivially from claim (b). Finally, claim (d) follows trivially from claim (c) and the edge selection rule of the procedure. □

Finally, we need to argue that nodes do not terminate the algorithm prematurely.

LEMMA 4.4. *After a node v has terminated its participation in the algorithm, it will learn of no more reportable edges.*

Proof. We need to argue that once the set RC becomes empty, no new candidate edges will become known to v. We prove this fact by induction on the structure of the tree, starting from the leaves upward. The inductive step follows directly from claim (a) of Lemma 4.3, which guarantees that if RC is empty on round t, none of v's children have upcast it an edge in round $t-1$, and hence all of them have already terminated. □

LEMMA 4.5. *The running time of procedure* `Pipeline` *is bounded by $O(N + Diam(G))$, and its output is an MST for G.*

Proof. The fact that the resulting tree is an MST follows from the fact that the trees constructed in the first stage were fragments of the MST, and from the correctness of the "red rule" employed for edge elimination in the procedure (cf. [T, p. 71]). (Essentially the red rule says that an edge that is the heaviest on any cycle is not a part of any MST.)

As for the running time, the bound is derived from the following facts. First, the root of the tree receives at most N edges from each of its children. Second, the children send these edges to the root in a fully pipelined fashion (namely, without stopping until exhausting all the edges they know of). Finally, the root starts getting such messages at time $Diam(G)$ at the latest. □

5. The complexity of the combined algorithm. Combining the two parts, we get the following distributed algorithm for MST.

1. Perform Algorithm `Controlled-GHS` for I phases.
2. Perform Algorithm `Pipeline`.

Summarizing the results of the last two sections, we get the following theorem.

THEOREM 5.1. *There exists a distributed MST algorithm with time complexity $O(Diam(G) + n^{\varepsilon} \cdot \log^* n)$ for $\varepsilon = \frac{\ln 3}{\ln 6} = 0.6131\ldots$.*

Proof. The complexities of the two parts of our algorithm are as follows, for the given parameter I specified for the first part:

Part I: $3^I \cdot O(\log^* n)$.

Part II: $Diam(G) + \frac{n}{2^I}$.

The total time complexity is thus optimized when choosing I such that $3^I = \frac{n}{2^I}$, namely, $I = \frac{\ln n}{\ln 6}$. For this choice of I, we get $3^I = \frac{n}{2^I} = n^{\varepsilon}$ for $\varepsilon = \frac{\ln 3}{\ln 6}$, which yields a total time complexity of $O(Diam(G) + n^{\varepsilon} \cdot \log^* n)$. □

Acknowledgments. It is a pleasure to thank Ambuj Singh and Jerry James for useful comments. Thanks are also due to two anonymous referees for their comments, which helped to significantly improve the readability of the paper.

ATOMIC SNAPSHOTS IN $O(n \log n)$ OPERATIONS*

HAGIT ATTIYA† AND OPHIR RACHMAN†

Abstract. The *atomic snapshot object* is an important primitive used for the design and verification of wait-free algorithms in shared-memory distributed systems. A snapshot object is a shared data structure partitioned into segments. Processors can either *update* an individual segment or instantaneously *scan* all segments of the object. This paper presents an implementation of an atomic snapshot object in which each high-level operation (scan or update) requires $O(n \log n)$ low-level operations on atomic read/write registers.

Key words. atomic read/write registers, single-reader multiwriter, snapshot objects, linearizability, asynchronous shared memory systems, wait-free computations

1. Introduction.

Wait-free algorithms for shared-memory systems have attracted considerable attention during the past few years. The difficulty of synchronization and communication in such systems caused many of the algorithms that were developed to be quite intricate. A major research effort attempts to simplify the design and verification of efficient wait-free algorithms by defining convenient synchronization primitives and efficiently implementing them. One of the most attractive primitives is the *atomic snapshot object* introduced in [1, 2, 6].

An atomic snapshot object (in short, *snapshot object*) is a data structure shared by n processors. The snapshot object is partitioned into n segments, one for each processor. Processors can either *update* their own segment or instantaneously *scan* all segments of the object. By employing a snapshot object, processors obtain an instantaneous global picture of the system. This sidesteps the need to rely on "inconsistent" views of the shared memory and reduces the possible interleavings of the low level operations in the execution. Therefore, snapshot objects greatly simplify the design and verification of many wait-free algorithms. An excellent example is provided by comparing the recent proof of a bounded concurrent timestamp algorithm using snapshot objects [15] with the original intricate proof in [10].

Unfortunately, the great conceptual gain of using snapshot objects is often diminished by the actual cost of their implementation; the best snapshot implementation to date requires $O(n^2)$ read and write operations on atomic registers [1, 4]. Compared with the cost of simply reading n memory locations, this might seem a high price to pay for modularity and transparency. Thus, significant effort has been spent on avoiding snapshots and constructing algorithms directly from read and write operations.

This paper presents a snapshot object implementation in which each update or scan operation requires $O(n \log n)$ operations on single-writer multireader atomic reg-

*Received by the editors January 3, 1995; accepted for publication (in revised form) December 18, 1995. An extended abstract of this paper appeared in *Proceedings of the 12th Annual ACM Symposium on Principles of Distributed Computing*, Association for Computing Machinery, New York, 1993, pp. 29–40. This research was supported by grant 92-0233 from the United States–Israel Binational Science Foundation (BSF), Jerusalem, Israel, by the Technion V.P.R., Argentinian Research Fund, and by the fund for the promotion of research in the Technion.

isters. Thus, we dramatically reduce the gap between the trivial lower bound of $\Omega(n)$ and the best known upper bound of $O(n^2)$ for atomic snapshots. Consequently, our snapshot object makes it feasible to design modular and easy to verify wait-free algorithms, without a great sacrifice in their efficiency.

We start with an algorithm for implementing an m-shot snapshot object, that is, a snapshot object to which up to m operations can be applied. The algorithm is simple and requires $O(n \log m)$ operations on single-writer multireader atomic registers. The algorithm is inspired by the algorithm presented in [7] for solving *lattice agreement* [4, 7, 11]. However, the algorithm of [7] uses atomic Test&Set operations, while the current algorithm uses only atomic read and write operations.

We then present ways to transform this algorithm to implement an ∞-shot snapshot object, that is, an object that supports an infinite number of operations.

One way is based on general-purpose transformations. In [7], the snapshot object was proved to be reducible to the lattice agreement problem. By employing the transformation of [7], the restriction of our algorithm to solve lattice agreement immediately implies an ∞-shot snapshot object in which each operation requires $O(n \log n)$ read and write operations on atomic registers. Unfortunately, this implementation requires an unbounded amount of memory. The bounded rounds abstraction of [13] can be used to bound the memory requirements of this implementation.

An alternative path is a direct implementation of an ∞-shot snapshot object, with $O(n \log n)$ operations for each scan or update. This implementation uses a bounded amount of memory and is based on recycling a single copy of the m-shot object. This recycling combines in a novel way synchronization techniques such as handshake bits [6], borrowing views [1] and traceable use techniques [14], and we believe it is interesting on its own.

The bounded algorithm uses atomic operations on registers that may contain up to $O(n(\log n + |V|))$ bits, where $|V|$ is the number of bits needed to represent a value of the snapshot object. (There are also operations on registers of size $O(n^4 \log n)$, but these occur infrequently.)

Besides the conceptual contribution to the design of future wait-free algorithms, our snapshot object immediately yields improvements to existing algorithms that use the snapshot object by plugging in our more efficient one. These include randomized consensus [3, 6], approximate agreement [8], bounded timestamping [15], and general constructions of wait-free concurrent objects [4, 17].

A *multiwriter* snapshot object is a generalized snapshot object in which any processor can update any segment. There is a transformation of Anderson's [2] which uses any snapshot object as a black box to construct a multiwriter snapshot object; this transformation requires a linear number of read and write operations. This transformation can be used to turn our algorithm into an algorithm for a multiwriter snapshot object with the same complexity.

Deterministic snapshot implementations have been proposed by Anderson [2] (bounded memory and exponential number of operations), by Aspnes and Herlihy [4] (unbounded memory and $O(n^2)$ operations), and by Afek et al. [1] (bounded memory and $O(n^2)$ operations). Attiya, Herlihy, and Rachman [7] give an $O(n \log^2 n)$ implementation that uses *Test&Set* registers, and an $O(n)$ implementation that uses dynamic *Test&Set* registers. Israeli, Shaham, and Shirazi [23] give a general technique to transform any snapshot implementation that requires $O(f(n))$ operations per scan or update into an (unbounded) implementation that requires $O(f(n))$ operations per scan and only a linear number of operations per update (or vice versa). Constructions of multiwriter snapshot objects appear in [1, 2].

Introduced in [7] are randomized implementations of the snapshot object ($O(n \log^2 n)$ using single-writer multireader registers, and $O(n)$ using dynamic single-writer multireader registers). Chandra and Dwork [9] also give a randomized implementation that requires $O(n \log^2 n)$ operations on atomic single-writer multireader registers. Weaker variants of the snapshot object were implemented by Kirousis, Spirakis, and Tsigas [24] (single-scanner snapshot object), and by Dwork et al. [12] (nonlinearizable snapshot object).

Independent of our work, Israeli and Shirazi [21] constructed a deterministic snapshot object that requires $O(n^{3/2} \log^2 n)$ operations and uses unbounded memory. Also, they showed a lower bound of $\Omega(\min\{w, r\})$ low-level operations for any update operation, where w is the number of updaters and r is the number of scanners [22].

As is made clear by the above review, our $O(n \log n)$ deterministic snapshot implementation significantly improves all known deterministic implementations that use only atomic registers and even improves almost all the existing randomized implementations. Note that by the general technique of [23], our snapshot implementation can be improved to require $O(n \log n)$ operations per update and only $O(n)$ operations per scan (or vice versa).

Following the original publication of our algorithm, Inoue et al. [19] presented an atomic snapshot object that requires only a linear number of read and write operations. However, this algorithm requires multiwriter registers, that is, each processor can write to each register. In contrast, our algorithms use only single-writer registers.

The rest of the paper is organized as follows. Section 2 includes definitions of the model and of the snapshot object. In section 3, we present the implementation of the m-shot snapshot object, which is then used to construct the ∞-shot snapshot object in section 4. We conclude in section 5 with a discussion of our results.

2. The snapshot object. Our model of computation is standard and follows, e.g., [8, 16].

An *atomic snapshot* object is partitioned into n segments, $S_1, \ldots, S_n$, where only processor p_i may write to the ith segment. The snapshot object supports two operations, *scan* and *update*(v). The scan operation allows a processor to obtain an instantaneous view of the segments, as if all n segments are read in a single atomic step. A scan operation returns a *view*, which is a vector $V[1, \ldots, n]$, where $V[i]$ is the value for the ith segment. The update operation with parameter v allows a processor to write the value v into its segment.

An implementation of the snapshot object should be *linearizable* [18]. That is, any execution of *scan* and *update* operations should appear as if it was executed sequentially in some order that preserves the real time order of the operations.

In more detail, each scan or update is implemented as a sequence of primitive operations. The nature of the primitive operations depends on the low-level objects used; in our case, read and write operations of atomic registers. An execution is a sequence of primitive operations, each executed by some processor as part of some scan or update operation. We assume that each processor has at most one (high-level) operation in progress at a time; that is, it does not start a new operation before the preceding one has completed.

Define a partial order $\rightarrow$ on (high-level) operations in an execution such that $op_1 \rightarrow op_2$ if (and only if) the operation op_1 has terminated before the operation op_2 has started; that is, all low-level operations that comprise op_1 appear in the execution before any low-level operation that is part of op_2. The partial order $\rightarrow$ reflects the external real time order of nonoverlapping operations in the execution.

For the snapshot implementation to be correct, we require that *scan* and *update* operations can be *linearized*. That is, there is a sequence that contains all *scan* and *update* operations in the execution that

a. extends the real time order of operations as defined by the partial order $\rightarrow$; and
b. obeys the sequential semantics of the snapshot operations; that is, if *view* is returned by some *scan* operation, then for every segment i, $view[i]$ is the value written by the last update to the ith segment which precedes the scan operation in the sequence.

In this paper, we define one operation that combines both scan and update, denoted $scate(v)$. Executing a $scate(v)$ operation by p_i both writes v into S_i and returns an instantaneous view of the n segments.[1] Intuitively, to perform $update(v)$ a processor invokes $scate(v)$ and simply ignores the view it returns; to perform a scan the processor invokes $scate(v)$, where v is the current value of its segment.

Another property that we require is *wait-freedom*; that is, every processor completes its execution of a scan or an update within a bounded number of its own (low-level) operations, regardless of the execution of other processors.

3. Implementation of an m-shot snapshot object. In this section we construct an m-shot snapshot object, which is a degenerate instance of the general snapshot object. Namely, an m-shot snapshot object is defined exactly as the general snapshot object, except that the total number of scate operations that may be performed by all processors is at most m.

3.1. Preliminaries. For the construction of the m-shot snapshot object, we modify each segment of the snapshot object to contain both the value of the segment in the field *value*, and some additional information that indicates the number of times p_i performed an operation. The additional fields *seq* and *counter* are incremented with each operation performed by p_i. Although the *seq* and *counter* fields contain exactly the same information, they have different roles in the implementation. The *seq* field determines which of two values written by p_i is more up to date. The *counter* field simply counts the number of operations performed by p_i. When we present the general implementation of the snapshot object, we shall see that the information in these two fields is maintained differently; this is why we separate them here as well.

Note that each *scate* operation returns a *view*, which is a vector with three fields in each entry. All segments are initially $(\perp, 0, 0)$. We now introduce some terminology.

The *size* of a view V, denoted by $|V|$, is $\sum_i V[i].counter$. The size of a view reflects the "amount of knowledge" that this view contains; that is, the size of a view counts the total number of operations performed on the snapshot object before this view was obtained.

A view V_1 *dominates* a view V_2, if for all i, $V_1[i].seq \geq V_2[i].seq$. Two views V_1 and V_2 are *comparable* if either V_1 dominates V_2 or V_2 dominates V_1. Two views V_1 and V_2 are *unanimous*, if for all i, $V_1[i].seq = V_2[i].seq$ implies that $V_1[i] = V_2[i]$. A set $\{V_1, \ldots, V_l\}$ of views is *unanimous* if any pair of views in the set are unanimous. The *union* of a unanimous set $\{V_1, \ldots, V_l\}$ of views, denoted by $\cup\{V_1, \ldots, V_l\}$, is the minimal view that dominates all views $V_1, \ldots, V_l$. That is, the union is a view V_u such that for every i, $V_u[i]$ equals $V_j[i]$ with maximal *seq* field. (All the sets of views that we use in the paper are trivially unanimous. Therefore we use unions of sets of views without explicitly stating that the sets are unanimous.)

[1] Combining the roles of scans and updates was implicitly done in previous works, where update operations not only write new values but also return views.

Classifier(K, I_i): returns(O_i) (Code for p_i)
0: write I_i to R_i
1: read $R_1, \ldots, R_n$
2: **if** $|\cup\{R_1, \ldots, R_n\}| > K$ **then**
3: read $R_1, \ldots, R_n$ and **return**$(O_i = \cup\{R_1, \ldots, R_n\})$
4: **else return**$(O_i = I_i)$

FIG. 1. *The classifier procedure.*

3.2. The *classifier* procedure. We start by introducing a procedure called *classifier*, with parameter K. Each processor p_i starts the procedure with an input view I_i, and upon termination, returns an output view O_i. The *classifier* procedure appears in Figure 1. The processors use a set of single-writer multireader registers $R_1, \ldots, R_n$.

In the *classifier* procedure each processor p_i starts with some local knowledge that is held in I_i. The goal of the *classifier* procedure is to update the processors' knowledge in some organized manner. Roughly speaking, the processors that use the procedure are classified into two groups such that the processors in the first group retain their original knowledge, while each processor in the second group increases its knowledge to dominate the knowledge of all the processors in the first group. Specifically, processors in the first group are called *slaves* and are defined as the processors that terminate the procedure in line 4. Processors in the second group are called *masters* and are defined as the processors that terminate the procedure in line 3. The classifying property of the procedure is the crux of the m-shot snapshot object. Notice that the *classifier* procedure provides very little guarantee on the number of masters and slaves. In particular, it is possible that all processors are classified as masters.

3.3. The implementation. To implement the scate operation for an m-shot snapshot object, we construct a full binary tree with $\log m$ levels and $m-1$ nodes.[2] The nodes of the tree are labeled by an in-order numbering on the tree, assigning labels in increasing order from the set $\{1, \ldots, m-1\}$. For each node v, we denote the label of v by $Label(v)$. The labels given by the in-order search can be presented in the following recursive manner: the root (in level 1) is labeled $\frac{m}{2}$; inductively, if a node v in level ℓ is labeled $Label(v)$, then the left child of v, denoted by $v.left$, is labeled $Label(v) - \frac{m}{2^{\ell+1}}$, and the right child of v, denoted by $v.right$, is labeled $Label(v) + \frac{m}{2^{\ell+1}}$. (See Figure 2.)

Since each processor may perform several scate operations, we do not identify an operation with the processor that executes it. In the rest of the section, we refer to operations as independent entities that "execute themselves."

Intuitively, each operation traverses the tree downwards starting from the root. Inside the tree, operations that arrive at some node execute the *classifier* procedure using the label of the node as the parameter K. The *classifier* procedure of each node separates the arriving operations so that less knowledgeable operations (slaves) proceed to the left and more knowledgeable operations (masters) proceed to the right. This process continues throughout the levels of the tree; an operation terminates when it arrives at a leaf of the tree.

The main idea in this construction is that operations are ordered in the leaves (from left to right) according to the amount of knowledge they have collected. As we prove in the following, when two operations are separated by some node, then the final

[2] We assume m is an integral power of 2. Otherwise, standard padding techniques can be applied.

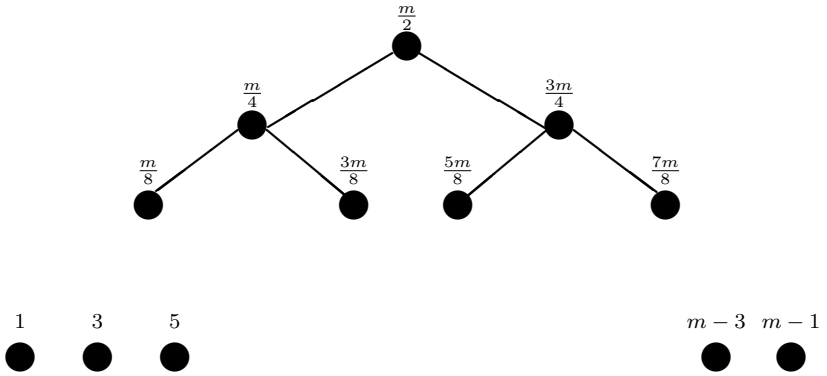

FIG. 2. *The classification tree.*

knowledge of the operation that proceeded to the right dominates the final knowledge of the operation that proceeded to the left. This guarantees that operations arriving at different leaves are comparable and are ordered from left to right. In addition, we prove that if two operations traverse exactly the same path in the tree, then they have exactly the same final knowledge. Such two operations undergo a "squeezing" process, where the difference in their knowledge is constantly reduced as they move toward the leaves of the tree. Finally, when two operations arrive at the same leaf the difference in their knowledge is squeezed to zero, and they are forced to have exactly the same knowledge.

To implement this intuitive idea, we associate with each node a separate area in the shared memory that contains a set of n single-writer multireader registers $R_1, \ldots, R_n$. These registers are initialized to empty views that contain $(\perp, 0, 0)$ in each entry and are used to execute the *classifier* procedure at that node. In addition, each processor p_i has a local variable $current_i$ that is initialized at the beginning of each operation by p_i. This local variable stores the accumulated knowledge of p_i during the execution of the operation. For ease of exposition, we add a $(\log m + 1)$th level to the tree, which now contains the leaves of the tree. These leaves have no labels and no associated registers, and they serve only as "final stations" for the operations that traverse the tree.

All *scate* operations, up to m, are executed on the tree constructed above. A *scate* operation *op* by p_i is executed as follows: first, *op* writes the value of the operation into S_i. Second, *op* reads the n segments $S_1, \ldots, S_n$, and sets $current_i$ to hold the view that contains the values read from the segments. Then *op* starts traversing the tree by entering the root. In general, when *op* enters some node v, it uses the value of $current_i$ as an input vector I_i, executes a $classifier(Label(v), current_i)$ procedure at v, and updates its $current_i$ variable to hold the value returned by the procedure. If p_i terminates the *classifier* procedure in v as a master, it enters $v.right$; otherwise it enters $v.left$. When *op* enters a leaf, it terminates and returns the value of $current_i$ as its final view. For clarity, we denote by $current_{i,\ell}$ the value of $current_i$ as *op* enters level ℓ. The precise code for a scate operation (by p_i) appears in Figure 3.

3.4. Correctness proof. We start by stating the properties of the *classifier* procedures that are executed in the various nodes of the tree. We first introduce some notation. For each node v, $Ops(v)$ denotes the set of operations that traverse through v. At each node v, each operation in $Ops(v)$ is classified either as a master or as a slave. The set of operations that are classified as masters at v is denoted by

scate(*value*) (Code for p_i)
1: $S_i := (value, incremented\ seq\ and\ counter)$
2: **for** $j := 1, \ldots, n$ $current_{i,1}[j] := S_j$
3: $v := root$
4: **for** $\ell := 1, \ldots, \log m$ **do**
5: $current_{i,\ell+1} :=$*Classifier*$(Label(v), current_{i,\ell})$
6: **if** master **then** *v:=v.right*
7: **if** slave **then** *v:=v.left*
8: **return**$(current_{i,\log m+1})$

FIG. 3. *The code for a scate operation.*

$M(v)$, and the set of operations that are classified as slaves at v is denoted by $S(v)$. In addition, we denote the input view of an operation op_i for the *classifier* procedure at level ℓ by $I_{i,\ell}$. (If p_j is the processor that executes op_i, then $I_{i,\ell}$ is the value assigned to $current_{j,\ell}$ during op_i.)

LEMMA 3.1. *Let v be some node at level ℓ. Let L and H be nonnegative integers such that $L \leq Label(v) \leq H$. If $L < |I_{i,\ell}| \leq H$ for every $op_i \in Ops(v)$, and $|\cup\{I_{i,\ell} : op_i \in Ops(v)\}| \leq H$, then*
(b1) *for every $op_i \in M(v)$, $Label(v) < |I_{i,\ell+1}| \leq H$,*
(b2) *for every $op_i \in S(v)$, $L < |I_{i,\ell+1}| \leq Label(v)$,*
(b3) $|\cup\{I_{i,\ell+1} : op_i \in M(v)\}| \leq H$,
(b4) $|\cup\{I_{i,\ell+1} : op_i \in S(v)\}| \leq Label(v)$, *and*
(b5) *for every $op_i \in M(v)$, $I_{i,\ell+1}$ dominates $\cup\{I_{j,\ell+1} : op_j \in S(v)\}$.*

Proof. Properties (b1)–(b3) are immediate from the code.

Property (b4) is proved by contradiction. Assume that $|\cup\{I_{i,\ell+1} : op_i \in S(v)\}| > Label(v)$. Since for each $op_i \in S(v)$ we have $I_{i,\ell+1} = I_{i,\ell}$, it follows that $|\cup\{I_{i,\ell} : op_i \in S(v)\}| > Label(v)$. Let op_j be the last operation in $S(v)$ that executes line 0 in the *classifier* procedure of v. When op_j executes line 1 of the procedure, all $I_{i,\ell}$ such that $op_i \in S(v)$ are already written in the registers of v. Since the value in any register of any node is overwritten only with values that dominate it, op_j collects a view with size greater than $Label(v)$. This contradicts the assumption that $op_j \in S(v)$.

To prove (b5), we show that when $op_i \in M(v)$ starts to execute line 3 in the *classifier* procedure of v, all $\{I_{j,\ell} : op_j \in S(v)\}$ are already written in the registers of v. Otherwise, if some $op_j \in S(v)$ has not yet written $I_{j,\ell}$, then when op_j executes line 1 of the procedure it reads registers' values that dominate the registers' values that op_i read in line 1. This contradicts the assumption that $op_j \in S(v)$. □

Using the properties of the *classifier* procedure as stated in the above lemma, we now prove that all the views returned in scate operations are comparable. To show that, we first prove that the views returned by operations that terminate in different leaves of the tree are comparable. The following two simple lemmas are implied by the code.

LEMMA 3.2. *Let op_i be an operation that returns V_i. Let v be a node such that $op_i \in S(v)$ and let ℓ be v's level. Then V_i is dominated by $\cup\{I_{j,\ell+1} : op_j \in S(v)\}$.*

LEMMA 3.3. *Let op_i be an operation that returns V_i. Let v be a node such that $op_i \in M(v)$ and let ℓ be v's level. Then V_i dominates $I_{j,\ell+1}$ for any $op_j \in S(v)$.*

The next lemma uses Lemmas 3.2 and 3.3 to prove that the views returned by operations that terminate in different leaves are comparable.

LEMMA 3.4. *Let op_i and op_j be two operations that terminate in leaves v_i and v_j, respectively, where $v_i \neq v_j$. Then the views returned by op_i and op_j are comparable.*

Proof. Let v be the node with maximal level (closest to the leaves) such that both op_i and op_j belong to $Ops(v)$, and let ℓ be its level. Since $v_i \neq v_j$, $\ell < \log m + 1$, that is, v is an inner node. Since v is not a leaf, one of op_i and op_j is a master in v, and the other is a slave at v. Assume, without loss of generality, that $op_i \in S(v)$ and $op_j \in M(v)$.

By Lemma 3.2, the view returned by op_i is dominated by $\cup\{I_{k,\ell+1} : op_k \in S(v)\}$. By Lemma 3.3, the view returned by op_j dominates each $I_{k,\ell+1}$, if $op_k \in S(v)$, and therefore dominates $\cup\{I_{k,\ell+1}, op_k \in S(v)\}$. Thus, the view returned by op_j dominates the view returned by op_i. □

To complete the comparability proof, we show that the output views of operations that terminate in the same leaf are comparable. The next lemma formally captures the intuitive idea of the "squeezed" difference in knowledge. The lemma bounds the size of the inputs $I_{i,\ell}$ and their union at some node v of some level ℓ as a function of $Label(v)$ and ℓ.

LEMMA 3.5. *Let v be an inner node of level ℓ. Then,*

(1) *for every $op_i \in Ops(v)$, $Label(v) - \frac{m}{2^\ell} < |I_{i,\ell}| \leq Label(v) + \frac{m}{2^\ell}$, and*
(2) $|\cup\{I_{i,\ell} : op_i \in Ops(v)\}| \leq Label(v) + \frac{m}{2^\ell}$.

Proof. The proof is by induction on ℓ. For the induction base $\ell = 1$, the lemma is straightforward since the total number of operations is at most m. For the induction step, assume the lemma holds for all nodes in level $\ell - 1$ and consider an arbitrary node v in level $\ell > 1$. Let v' be the parent of v and consider the *classifier* procedure with parameter $K = Label(v')$ that is executed by $Ops(v')$ in v'. By the induction hypothesis we have

(1) $Label(v') - \frac{m}{2^{\ell-1}} < |I_{i,\ell-1}| \leq Label(v') + \frac{m}{2^{\ell-1}}$, for any $op_i \in Ops(v')$, and
(2) $|\cup\{I_{i,\ell-1} : op_i \in Ops(v')\}| \leq Label(v') + \frac{m}{2^{\ell-1}}$.

If we denote $L = Label(v') - \frac{m}{2^{\ell-1}}$ and $H = Label(v') + \frac{m}{2^{\ell-1}}$, then these are exactly the conditions of Lemma 3.1. We have two cases.

Case 1. If $v = v'.right$, then $K = Label(v') = Label(v) - \frac{m}{2^\ell}$, and $Ops(v) = M(v')$. We have by (b1) and (b3) of Lemma 3.1 that

(1) for any $op_i \in Ops(v)$, $Label(v) - \frac{m}{2^\ell} < |I_{i,\ell}| \leq Label(v) + \frac{m}{2^\ell}$, and
(2) $|\cup\{I_{i,\ell} : op_i \in Ops(v)\}| \leq Label(v) + \frac{m}{2^\ell}$,

which are the required conditions for the operations in $Ops(v)$.

Case 2. If $v = v'.left$, then $K = Label(v') = Label(v) + \frac{m}{2^\ell}$, and $Ops(v) = S(v')$. In this case, the same equations are implied by (b2) and (b4) of Lemma 3.1. □

The next lemma proves that the views returned by two operations that terminate at the same leaf are equal, and in particular, comparable.

LEMMA 3.6. *Let op_i and op_j be two operations that terminate in the same leaf v. Then the views returned by op_i and op_j are equal.*

Proof. Let v' be the parent of v. Assume, without loss of generality, that $v = v'.right$; the proof if v is the left child of v' follows in the same manner. By Lemma 3.5, since v' is in level $\ell = \log m$,

(1) $Label(v') - 1 < |I_{k,\log m}| \leq Label(v') + 1$, for any $op_k \in Ops(v')$, and
(2) $|\cup\{I_{k,\log m} : op_k \in Ops(v')\}| \leq Label(v') + 1$.

The operations op_i and op_j execute the *classifier* procedure in v' with parameter $K = Label(v')$ and both terminate as masters and proceed to v. If we denote $L = Label(v') - 1$, and $H = Label(v') + 1$, then conditions (1) and (2) above are the required conditions for applying Lemma 3.1 to the *classifier* procedure that is executed in v'. Thus, by Lemma 3.1(b1), since op_i and op_j are in $M(v')$, we have

$|I_{i,\log m+1}| = |I_{j,\log m+1}| = \mathit{Label}(v') + 1$. In addition, by Lemma 3.1(b3), we have $|\cup \{I_{i,\log m+1}, I_{j,\log m+1}\}| = \mathit{Label}(v') + 1$. Therefore, $I_{i,\log m+1} = I_{j,\log m+1}$, which implies that the output views of op_i and op_j are equal. □

Lemmas 3.4 and 3.6 prove that the views returned by the scate operations are comparable. We now use these comparable scate operations to implement the linearizable scan and update operations of the snapshot object.

To execute an update(v) operation, a processor simply executes a scate(v) operation and ignores the view it returns. To execute a scan operation, a processor executes a scate(v) operation using the current value of its segment. Notice that although the same value is used, the *seq* and *counter* values are incremented. Thus, a scan operation by p_i changes the sequence number of S_i but does not change the value of S_i. Also notice that both scan and update operations return views. These views are later used for the linearization of the scan and update operations.

In order to define the linearization of operations on the snapshot object, we first order the scan operations and then insert the update operations. Consider any two scan operations sc_i and sc_j that return V_i and V_j, respectively. If $V_i \neq V_j$ and V_j dominates V_i, then sc_i is linearized before sc_j and vice versa if V_i dominates V_j. If $V_i = V_j$, then we order them first by the partial order $\rightarrow$, and if the operations are not ordered with respect to $\rightarrow$, then we break symmetry by the identities of the processors that execute the operations. This ordering of scans is well defined since a processor has only one operation outstanding at a time, and hence two operations by the same processor are always ordered by $\rightarrow$.

Next, we insert the update operations between the linearized scan operations. Consider an update operation that wrote a value (v, seq) to some segment S_i. The update operation is linearized after the last scan operation that returns a view that does not contain (v, seq) and before the first scan operation that contains (v, seq). Since scan operations are ordered by their views, each update operation fits exactly between two successive scan operations. We break symmetry between update operations that fit between the same two scan operations in the same manner as in the scan operations, that is, first by the partial order $\rightarrow$ and then by processors' identities. We now prove that this sequence is a linearization.

The next lemma follows immediately from the way update operations are linearized between scan operations.

LEMMA 3.7. *For any scan operation sc and for all segments S_i, the value returned by sc for S_i is the value written by the last update operation by processor p_i that is linearized before sc.*

Therefore, the linearization sequence we constructed preserves the semantics of the snapshot object. We now prove that it extends the partial order $\rightarrow$.

LEMMA 3.8. *For any two (scan/update) operations op_i and op_j, if $op_i \rightarrow op_j$ then op_i is linearized before op_j.*

Proof. There are four cases, according to operation types.

Case 1. Let sc_i and sc_j be two scan operations such that $sc_i \rightarrow sc_j$. By the code of the algorithm, the view returned by sc_i does not dominate the view returned by sc_j and hence the view returned by sc_j dominates the view returned by sc_i. Since scan operations are linearized by their views, this implies that sc_i is linearized before sc_j.

Case 2. Let sc_i be a scan operation and up_j be an update operation such that $sc_i \rightarrow up_j$. By the code of the algorithm, the view returned by sc_i does not contain the value written by up_j, and therefore, up_j is linearized after sc_i.

Case 3. Let up_i be an update operation and sc_j be a scan operation such that $up_i \rightarrow sc_j$. By the code of the algorithm, the view returned by sc_j contains the value written by up_i (or a value written by a later update operation by p_i,) and therefore, up_i is linearized before sc_j.

Case 4. Let up_i and up_j be two update operations such that $up_i \rightarrow up_j$. If up_i and up_j fit exactly between the same two scan operations, then due to the way symmetry is broken up_i is linearized before up_j, and the claim follows.

Otherwise, assume by way of contradiction that there exists a scan operation sc such that up_j is linearized before sc and sc is linearized before up_i. Thus, sc returns a view that contains the value written by up_j and does not contain the value written by up_i. Consider the scate operation that is executed to implement up_i. This scate operation returns a view that contains the value written by up_i but does not contain the value written by up_j. Therefore, this scate operation returns a view that is incomparable to the view returned by sc. This contradicts the comparability property of the views returned by the scate operations (Lemmas 3.4 and 3.6). □

Lemmas 3.7 and 3.8 prove that the scate operation of Figure 3 implements an m-shot snapshot object. The complexity analysis is obvious, and we have the following theorem.

THEOREM 3.9. *Each operation on the m-shot snapshot object implemented by the scate operation of Figure* 3 *requires $O(n \log m)$ operations on atomic single-writer multireader registers.*

Note that each processor has a view for each level of the classification tree. Denote by B the number of bits required to represent a view. Since the tree has $O(m)$ nodes, and for each node we have a view for each processor, it follows that the algorithm requires a total of $O(mnB)$ bits.

4. A general snapshot object.

4.1. An unbounded algorithm. A straightforward way to transform the m-shot snapshot object into an ∞-shot one is via the lattice agreement decision problem [4, 7, 11]. In this problem, processors start with inputs from a complete lattice and have to decide (in a nontrivial manner) on comparable outputs (in the lattice). It is fairly simple to use an n-shot snapshot object to solve lattice agreement and there is a general transformation that converts any lattice agreement algorithm into an implementation of an ∞-shot snapshot object [7]. The overhead of this transformation is $O(n)$ reads and writes per scan or update operation. Therefore, the m-shot snapshot object of the previous section can be converted into an ∞-shot snapshot object in which a scan or update operation requires $O(n \log n)$ operations.

Unfortunately, the general transformation of [7] extensively uses unbounded memory. That is, the transformation (possibly) replicates the memory area required for one lattice agreement algorithm, for each operation on the snapshot object. This is a consequence of the generality of the transformation, which does not assume anything about the lattice agreement algorithm. In tailoring the transformation to our m-shot snapshot object, the memory requirements can be reduced. That is, the number of registers can be bounded, and only their values increase by one with each new operation of the snapshot object. (The details, which are straightforward, will not be discussed here.) While these memory requirements are sufficient for any practical purpose, it is theoretically interesting to construct an ∞-shot snapshot object that requires only a bounded amount of shared memory.

A method to bound the memory requirements of the general transformation appears in [13]. Here we show a direct approach for combining the ideas of the m-shot

snapshot object with synchronization mechanisms to obtain a bounded implementation of a general snapshot object.

4.2. Bounded ∞-shot snapshot object. As mentioned before, the transformation of [7] employs an infinite number of copies of a lattice agreement algorithm so that each processor executes at most one operation on each copy. The algorithm presented here uses similar ideas but with a single copy of the m-shot snapshot object of the previous section.

Recall that in the construction of the m-shot snapshot object, each segment S_i has two additional fields, *seq* and *counter*. The *counter* field indicates how many operations were performed by p_i, while *seq* distinguishes, for any two values of p_i, which is more up to date. For the bounded implementation, we maintain this information using only bounded memory. Intuitively, the *seq* field is maintained using bounded sequential timestamps; the details are discussed in section 4.4. The more difficult task is to maintain the *counter* field, used for the classification process, using bounded memory.

In the general algorithm, we use the same tree of height $\log m+1$ which is traversed by the operations, as in the m-shot object. In order to allow one tree to support an unbounded number of operations, instead of only m, the operations are divided into *virtual* rounds, each containing exactly m operations.

By appropriate control mechanisms, we separate operations from different rounds so that they are not interleaved. In this way, the behavior of operations of the same round correspond to executing m operations on a separate m-shot snapshot object.

4.2.1. The bounded counter mechanism. In the m-shot object, the *counter* field associated with each segment specifies how many times the segment was updated; summing the *counter* fields over all segments yields the total number of operations that were performed on the snapshot object. In the general implementation, the *counter* field associated with a segment specifies the number of times the segment was updated modulo m; in this way, summing the *counter* yields the total number of operations that were performed on the object modulo m. (Although this sum is actually in the range $1, \ldots, nm$, we only refer to its value modulo m.)

We use the following terminology. The *counter* fields are called the *local counters*. The sum of the local counters modulo m is the *global counter*. The values of the local counters, as well as the global counter, are in the range $0, \ldots, m-1$.

For the sake of the proof, it is convenient to consider the unbounded values of these counters as well. That is, with each local counter we associate a virtual counter with the real (unbounded) value of that counter. Summing the virtual counters defines the real value of the global counter. The real values of the counters are not used within the code but only for the analysis.

4.2.2. The handshake mechanism. In the algorithm, we need to know the chronological order of operations by different processors. Specifically, for any two processors, p_i and p_j, we wish to know how many operations p_i started since a certain point in p_j's last operation (and vice versa). Clearly, we cannot maintain the exact number of operations since it is inherently unbounded. Therefore, we only want to know if the number of operations that p_i started is either 0, 1, 2,..., $k-1$, or strictly more than $k-1$ (for some constant k). This is done with a handshake mechanism that was introduced in [6].

For every two processors, p_i and p_j, there are two handshake variables $H_{i,j}$ and $H_{j,i}$. $H_{i,j}$ is written by p_i and read by p_j, while $H_{j,i}$ is written by p_j and read by p_i. An intuitive way to describe the functionality of the handshake variables is to consider

Handshake$_i(j)$
0: $temp = H_{j,i}$
1: **if** $Dist(H_{i,j}, temp) = 0$ **then return**$(H_{i,j} + 1)$
2: **if** $Dist(H_{i,j}, temp) \leq k$ **then return**$(temp)$
3: **if** $Dist(H_{i,j}, temp) > 2k$ **then return**$(H_{i,j} + 1)$

FIG. 4. *The handshake*$_i(j)$ *procedure.*

Takeover$_i(j)$ Invoked with every read from p_j's variable

FIG. 5. *The takeover*$_i(j)$ *procedure.*

a directed cycle with vertices numbered $0, \ldots, 3k$, where the direction is defined from t to $(t + 1)$ mod $(3k + 1)$. The variables $H_{i,j}$ and $H_{j,i}$ represent the positions of p_i and p_j on this cycle. To handshake with p_i, p_j checks the values of $H_{i,j}$ and $H_{j,i}$ and updates its own position on the cycle accordingly.

More precisely, the function *handshake*$_i(j)$ is called by p_i in order to update $H_{i,j}$ (Figure 4). Using the procedures *handshake*$_i(j)$ and *handshake*$_j(i)$ by p_i and p_j, respectively, maintains the invariant that the directed distance from $H_{i,j}$ to $H_{j,i}$ on the cycle, denoted $Dist(H_{i,j}, H_{j,i})$, is either in the range $[0, \ldots, k]$ or in the range $[2k, \ldots, 3k]$. This invariant is used to determine who is the more advanced of the two processors. If the distance from $H_{i,j}$ to $H_{j,i}$ is at most k (but not zero), then p_j is more advanced, and if the distance is between $2k$ and $3k$ then p_i is more advanced. (If the distance is zero then p_i and p_j are equally advanced.)

4.2.3. The failure detection mechanisms. In the implementation we present, a scate operation may temporarily *fail* in one of two ways. The first kind of failure occurs if some processor, say p_j, performs several operations while p_i traverses the classification tree. This kind of failure is called a *takeover* failure; when it occurs, we say that p_i was *overtaken* by p_j. The second kind of failure is a *wraparound* of the global counter, which occurs when the value of the global counter goes from m to 0 while p_i traverses the classification tree. We now describe the failures in more detail and explain the failure detection mechanisms we employ.

Takeover failures are detected by a mechanism that is constantly being operated (see Figure 5). Whenever a processor p_i reads a register of some other processor, say p_j, it checks the value of $H_{j,i}$ with respect to $H_{i,j}$. If $Dist(H_{i,j}, H_{j,i}) = k$, that is, p_j executed k or more handshakes since p_i executed its last handshake, then a takeover failure by p_j is detected. In this case, p_i jumps directly to a place in the code that handles this situation.

Wraparound failures are detected by a different mechanism. Before p_i traverses the tree, it collects the values of the local counters and computes a value for the global counter. Later, p_i checks for a wraparound by using the procedure *check-wraparound*. The procedure receives the global counter's value that p_i computed earlier and reads the local counters again to obtain a new value for the global counter. If this value is smaller than the previous one, then a wraparound has occurred, and p_i jumps directly to a place in the code that handles this situation. Note that a wraparound may occur, but the global counter's value obtained by the procedure is greater than the earlier value of the global counter and the wraparound failure is not detected. We will show

check-wraparound$_i$(*counter*)
1: *temp* := $\sum_i S_i.counter \bmod m$
2: **if** *temp* $\leq$ *counter* **then goto** Wraparound code

FIG. 6. *The check-wraparound*$_i$ *procedure.*

that when a wraparound failure occurs but is not detected, a takeover failure must be detected by the handshake mechanism.

4.2.4. Data structures. For simplicity, we assume that the shared memory consists of only n single-writer multireader registers, $R_1, \ldots, R_n$. All the information written by processor p_i is stored in its register R_i, which contains the following fields:

S_i. p_i's segment, with three fields: *value*, (unbounded) *seq*, and (modulo m) *counter*.

$Tree_i$. p_i's registers in the classification tree of the m-shot object (one register per node). Each register holds the same three fields as above.

$H_{i,1}, \ldots, H_{i,n}$. The handshake variables of p_i with respect to all of the other processors. For simplicity, we assume p_i holds handshake variables also with respect to itself.

$Last[1,2]$. $Last[1]$ holds the view returned by the last scate operation by p_i. $Last[2]$ holds the view returned by the penultimate scate operation by p_i.

In the code and throughout the correctness proof, we refer to the various fields of the registers $R_1, \ldots, R_n$ separately. Any *read* operation from some field of a register implies that the whole register is read. Any *write* operation to some field means writing some new value to that specific field and rewriting the current values to the other fields.

4.2.5. Code description. The code appears in Figure 7.

In the code, p_i starts by recording the sequence number of its last operation and then incrementing its local sequence number and counter variables. Then, p_i performs the handshake procedure for each processor and then calculates the global counter. At this point, p_i writes the value of the operation into its segment S_i. Notice that it is possible that this line is not executed at all, since p_i may detect a takeover failure while collecting the values of the local counters (in line 4). In this case, p_i jumps directly to line 17 to handle the takeover failure and writes the value of the operation into S_i there. (Failure handling is explained later.) p_i proceeds by performing a wraparound check. If a wraparound is detected, p_i jumps to line 23. If no wraparound is detected, p_i collects a local view of the segments and starts to traverse the classification tree. This part of the operation is performed almost exactly as in the m-shot snapshot object, except that the calculations regarding the sizes of views, performed in the *classifier* procedures, are done modulo m. If p_i traverses the tree without detecting any takeover failure, it obtains some temporary result. Then, p_i performs another wraparound detection procedure. If during this procedure no failure is detected, p_i returns the temporary result as the result of the operation (and updates $R_i.Last[1,2]$). Otherwise, p_i jumps to handle the detected failure.

Both kinds of failures, takeover and wraparound, are handled in a similar manner. When p_i detects that it was overtaken by p_j, it tries to copy p_j's last returned view. However, p_i is allowed to do so only if the last view returned by p_j contains p_i's current operation value. If not, p_i starts the operation all over again. When p_i detects a wraparound failure, it tries to find a sufficiently recent view that was returned by some operation and copies it. More precisely, p_i tries to find a penultimate view of

```
scate(value)      (Code for p_i)
0:  first-seq := sequence-number

    Start:
1:  sequence-number := sequence-number+1
2:  my-counter := (my-counter + 1) mod m
3:  for j = 1 to n do H_{i,j} := Handshake_i(j)
4:  g-counter := Σ_i S_i.counter mod m
5:  S_i := (value,sequence-number,my-counter)
6:  check-wraparound(g-counter)
7:  in_i := read S_1, ..., S_n
8:  v := root, current_{i,1} := in_i
9:  for ℓ = 1... log m do
10:     current_{i,ℓ+1} := Classifier(Label(v), current_{i,ℓ})
11:     if master then v := v.right
12:     if slave then v := v.left
13: temp-result := current_{i,log m+1}
14: check-wraparound(g-counter)
15: R_i.Last[1,2] := ⟨temp-result, R_i.Last[1]⟩
16: return temp-result

    Takeover by p_j code:
17: S_i := (value,sequence-number,my-counter)
18: temp-result := R_j.Last[1]
19: if temp-result[i].seq > first-seq then
20:     R_i.last[1,2] := ⟨temp-result, R_i.Last[1]⟩
21:     return temp-result
22: else goto Start

    Wraparound code:
23: if ∃R_j.Last[2][i].seq > first-seq then
24:     R_i.Last[1,2] := ⟨R_j.Last[1], R_i.Last[1]⟩
25:     return R_j.Last[1]
26: else goto Start
```

FIG. 7. *The scate operation.*

some processor that contains p_i's current operation value. If p_i finds such a processor, it copies its last view; otherwise, p_i starts the operation all over again.

As a consequence of the failure handling technique, a scate operation may consist of several *attempts*. (Each time a processor arrives at the label Start is the beginning of a new attempt.) For every scate operation, only its last attempt is successful and returns a view. The successful attempts can either return a view through the failure handling procedures or not. Therefore, we partition attempts into three types: *unsuccessful* attempts, which do not return a view; *indirect* attempts, which return a copied view in line 21 or 25; and *direct* attempts, which return a view in line 16.

Note that different attempts of the same operation have different sequence numbers. Therefore, the unsuccessful attempts may be thought of as independent operations that are "cut off" before completion. On the other hand, the same *first-seq* is used by all attempts of the same operation. The value of *first-seq* is used in order to

decide whether to copy another processor's view in the failure procedures. That is, the conditions in lines 19 and 23 are satisfied if the found view contains the sequence number of any of the attempts of the current operation.

4.3. Correctness proof. We first show that views returned by scate operations are comparable. Since only successful attempts return views, it suffices to prove comparability for them.

Define an ordering on attempts according to the order they update the segments. (This order has nothing to do with the linearization of scans and updates which will be presented later.) Specifically, for each attempt we consider the first time that it writes to S_i, either in line 5 or in line 17. This write is called the *actual update* of the attempt. Since writes are atomic, the ordering of actual updates defines an ordering among the attempts.

Based on the ordering of the attempts, we divide them into "virtual rounds" of size m. The first round contains the first m attempts, and in general, the ith round contains attempts $(i-1)m+1, \ldots, im$.

Recall that k is the constant for the handshake mechanism, and m is a constant that determines the height of the classification tree. These constants were left unspecified, and we now fix $k = 8$ and $m = (k+2)n = 10n$.

The following lemma implies that in order to prove the comparability of views returned by successful attempts, we can consider only the direct attempts.

LEMMA 4.1. *A view returned by an indirect attempt is also returned by some direct attempt.*

Proof. Toward a contradiction, let at_i be an indirect attempt that copies a view from some $R_j.Last[1]$ such that this view is not a direct view. Consider all the attempts that return the same view as at_i, and from these attempts let at_k be the attempt whose write before returning its view (in lines 20 or 24) is the first in the execution. The view returned by at_k must be direct; otherwise, there was some other attempt that returned this view and wrote it before at_k did, which is a contradiction. □

We next show that the views returned by direct attempts can be organized by the virtual rounds.

LEMMA 4.2. *Let at_i be a direct attempt in round r_i, and let at_j be a (direct or indirect) attempt in round $r_j > r_i$. Then at_i starts to execute its wraparound test in line* 14 *before at_j executes its actual update step.*

Proof. We slightly abuse notation and denote the processors that execute at_i and at_j by p_i and p_j, respectively. Note that p_i and p_j may be the same processor, while at_i and at_j are not the same attempt. This should not cause any confusion.

Consider the execution of line 4 in at_i, and let c be the value of *g-counter*. Since at_i is in round r_i, the value of the global counter is still less than $(r_i+1)m$ when p_i completes line 4. Now p_i executes its actual update step. Since at_i is direct, p_i continues without detecting any failure and arrives in line 14.

Assume, by way of contradiction, that p_j executes its actual update step in at_j before p_i starts line 14. Therefore, the value of the global counter is greater than $(r_i+1)m$ when p_i starts line 14, since at_j is in round $r_j > r_i$. Since p_i does not detect a wraparound in line 14, the value it reads is $c' \geq c$. This can happen only if the local counters were incremented at least $m = (k+2)n$ times since p_i started to execute line 4. In particular, at least one processor p_l incremented its counter at least $(k+2)$ times since p_i has started to execute line 4. Thus, p_l performs $handshake_l(i)$ at least $(k+1)$ times since p_i started to execute line 4, which implies that p_l performs

handshake$_l(i)$ at least $(k+1)$ times since p_i performed *handshake*$_i(l)$ in at_i. By the properties of the handshake mechanism, p_i will detect a takeover failure by p_l while executing line 14, which is a contradiction. □

This implies the following corollary.

COROLLARY 4.3. *Let at_i be a direct attempt in round r_i. The view returned by at_i does not contain any values written by attempts in rounds strictly greater than r_i.*

By the definition of rounds, when p_i reads $S_1, \ldots, S_n$ in line 7 it observes all the values from previous rounds. Furthermore, it is immediate from the code that any direct attempt returns a view which contains at least the values it reads in line 7. Therefore, we have the following corollary.

COROLLARY 4.4. *Let at_i be a direct attempt of round r_i. The view returned by at_i contains all the values written in rounds strictly smaller than r_i.*

The above corollaries indicate that a direct attempt in round r observes all the values of rounds smaller than r, plus some subset of the values of round r, and nothing from rounds greater than r. Thus, for any two direct attempts in different rounds, it is clear that the view returned by the later attempt dominates the view returned by the earlier one. Consequently, in order to prove comparability of all the direct views, we need only prove comparability of attempts in the same round. This is done in the next lemma.

LEMMA 4.5. *Let at_i and at_j be two direct attempts of round r. The views returned by at_i and at_j are comparable.*

Proof. By Lemma 4.2, until both at_i and at_j arrive at line 14, no value of round greater than r is written in the segments and certainly not in the registers of the tree. In addition, when either at_i or at_j reads the segments before starting to traverse the tree (at line 7), all $(r-1)m$ values of rounds $1, \ldots, r-1$ are already written in the segments. Thus, the contribution of these values to the calculations that are performed in the *classifier* procedures that are executed throughout at_i and at_j is cancelled out.

This implies that the process of traversing the tree by at_i and at_j has exactly the same properties of the m-shot object construction. The comparability of the views returned by at_i and at_j is implied by the same arguments as in the m-shot object (in the proofs of Lemmas 3.4 and 3.6). □

Combining the above lemma with Lemma 4.1 implies the following corollary.

COROLLARY 4.6. *The views returned by any two scate operations are comparable.*

Comparable scate operations are used to implement scans and updates exactly in the same way as in the m-shot object. That is, to execute an update(v) operation, a processor executes scate(v) operation and ignores the value it returns; to execute a scan operation, a processor executes a scate(v) operation with the current value of its segment.

We now linearize the scan and update operations. First we identify each (update or scan) operation with the unique pair (v, seq) that is written by the first attempt of the operation. Scans and updates are linearized as in the m-shot object. That is, the scans are linearized according to the (comparable) views they return, and the updates are linearized between the scans according to the values they write. Clearly, by the way updates are linearized between scans, we have the following lemma.

LEMMA 4.7. *For every scan sc and for every S_i, the value returned by sc for S_i is the value written by the last update by p_i that is linearized before sc.*

Therefore, the sequence preserves the semantics of the snapshot object. To show it is a linearization, it remains to prove that the above sequence is consistent with the real time order of operations, $\rightarrow$.

The proof is similar to the corresponding proof for the m-shot object, but it is more complicated since in the m-shot object all the returned views were direct, while here the proof must consider both direct and indirect views. We start by introducing some terminology.

We say that an operation *op* (scan or update) returns a direct view if the successful attempt of *op* is direct, and similarly for indirect view. In addition, we sometimes classify *op* itself as direct or indirect.

The *origin* of an operation *op* is the attempt that directly returned the view returned by *op*. Formally, the origin of an operation *op* is defined inductively as follows. If *op* is direct, then the origin of *op* is the last attempt executed in *op*. Otherwise, if *op* is indirect and copies the view returned by op', then the origin of *op* is the origin of op'. In a similar manner, we define the *depth* of an operation *op*, which specifies the distance of *op* from its origin. If *op* is direct, then its depth is zero. Otherwise, if *op* is indirect and copies the view returned by op', then the depth of *op* equals the depth of op' plus one.

An *interval* is a subsequence of consecutive primitive operations in the execution. The *interval of an operation* is the interval starting with the execution of the first statement of the operation and ending with the execution of the last statement of the operation (not including the **Return** statement). The *interval of an attempt* is defined similarly.

An interval is *unsafe* if some processor starts and terminates two consecutive unsuccessful attempts in this interval. Otherwise, the interval is *safe*.

To show that the sequence defined above is consistent with $\rightarrow$, it suffices to prove that any indirect operation starts before its origin. This implies that the view copied from the origin is sufficiently up to date, and thus, the indirect operation is linearized within its interval. The intuitive proof argues that if an operation fails (due to either takeover or wraparound), then during the time interval of the operation many other operations were performed. At least some of these operations are completely contained in the interval, and therefore, the view copied by the indirect operation must be sufficiently up to date.

Unfortunately, the above intuition is not accurate since the failure mechanisms guarantee only that during the interval of an indirect operation there are many *attempts*. However, it is possible that not many of the attempts are successful, and therefore, not many operations are completed during this interval. This means that there are no up to date views to be copied. To overcome this problem we must show that an operation does not contain many attempts. This will imply that if there are many attempts in some interval, then there are many operations as well. To prove that an operation does not contain many attempts, we have to show that after a small number of unsuccessful attempts, an operation will find its value in some already existing view (or penultimate view). In turn, this relies on the fact that when a failure is detected, there are sufficiently up to date views that were obtained by other operations. On the face of it, this argument seems circular.

Put another way, the difficulty arises because the proof of partial correctness (processors return values that are up to date) relies on the assumption that operations terminate, and vice versa. We sidestep this circularity by first proving partial correctness if the operation's interval is safe, that is, all operations inside it terminate after (at most) two attempts. Using this fact, we then prove that any interval is safe, i.e., all operations terminate after (at most) two attempts. This implies that the claim holds for any operation.

LEMMA 4.8. *If op's interval is safe, then op's origin starts after op starts.*

Proof. The proof is by induction on d, the depth of op. The base case, $d = 0$, follows since the last attempt of op is the origin of op. For the induction step, let op be an operation with depth $d > 0$, and assume the lemma holds for any operation of depth $d - 1$ whose interval is safe. Since $d > 0$, op is indirect, and it copies the view of some operation op' of processor p' with depth $d - 1$. Let at and at' denote the successful attempts of op and op', respectively. There are two cases.

Case 1. op copies the view of op' due to a takeover failure. Since takeover failures are detected by the handshake procedure, p' has executed its handshake procedure at least $k \geq 6$ times while at was executed. Therefore, p' starts and completes at least four consecutive attempts during at's interval. Since at's interval is safe, at least two of these attempts are successful. Therefore, p' completes at least two operations while at is executed. The attempt at copies the view returned by op', which is the last preceding view returned by p'. The above implies that op' starts after at starts. By the induction hypothesis, the origin of op' starts after op' starts. Since this is also the origin of op, it follows that the origin of op starts after op starts.

Case 2. op copies the view of op' due to a wraparound failure. Let op'' be the operation of p' that precedes op'. By the condition for copying the view of op', the view returned by op'' contains the value written by op. Therefore, op'' does not terminate before op starts. In particular, op' starts after op starts. By the induction hypothesis, the origin of op' starts after op' starts. Since this is also the origin of op, it follows that the origin of op starts after op starts. □

We now prove that all intervals are safe, by showing that every operation terminates after at most two attempts.

LEMMA 4.9. *Every operation contains at most two attempts.*

Proof. Assume, by way of contradiction, that there is an operation op_i by processor p_i that contains two consecutive unsuccessful attempts, at_1, at_2. Assume that the interval from the start of at_1 to the completion of at_2 is minimal, that is, all intervals contained in it are safe. (Such a minimal interval exists because the execution is a sequence.) We prove that at_2 must be successful. There are two cases.

Case 1. at_2 fails due to a takeover failure by processor p_j. In this case, p_j executes its handshake procedure at least $k \geq 6$ times during at_2's interval. This implies that in this interval p_j starts and completes at least four attempts. Since any interval strictly contained in at_2's interval is safe, at least two of these attempts are successful. Let op_j be the last operation completed by p_j in at_2's interval. It follows that op_j starts after at_2 starts, and therefore after the actual update of op_i to S_i (since at_2 is not the first attempt of op_i). Since op_j's interval is safe, Lemma 4.8 implies that op_j's origin starts after op_j starts, and therefore after the value of op_i is written in S_i. This implies that the view returned by op_j contains the value written by op_i. Therefore, when p_i discovers a takeover by p_j in at_2, it can copy the view of op_j, and hence at_2 is successful, which is a contradiction.

Case 2. at_2 fails due to a wraparound failure. Consider the interval from the start of at_1 to the completion of at_2. If at_1 is unsuccessful due to a takeover failure, then clearly there is a processor p_j that executes its handshake procedure at least $k \geq 8$ times during this interval. Otherwise, if both at_1 and at_2 fail due to a wraparound failure, then again it is guaranteed that during their interval there is a processor p_j that executes its handshake procedure at least $k \geq 8$ times. This implies that in this interval p_j starts and completes at least six attempts. Since this interval is safe, at least three of these attempts are successful. This implies that p_j starts and completes at least two operations in this interval. As before, since this interval is safe, Lemma 4.8 implies that the last two operations of p_j in this interval return views that contain

the value written by op_i. Therefore, when p_i discovers a wraparound failure in at_2, it can copy the last view returned by p_j, and hence at_2 is successful, which is a contradiction. □

Thus, all operation intervals are safe, and therefore Lemma 4.8 can be applied to any operation to obtain the following corollary.

COROLLARY 4.10. *For any operation op, the origin of op starts after op starts.*

This implies that indirect operations copy views which are up to date. Since direct operations clearly observe the value they write, and since indirect operations copy other processors' view only if it includes their value, we have the following lemma.

LEMMA 4.11. *Any scan or update operation returns a view that contains its own value.*

The following lemma proves that the linearization sequence preserves the real time order of the operations.

LEMMA 4.12. *For any two (scan/update) operations op_i and op_j, if $op_i \rightarrow op_j$ then op_i is linearized before op_j.*

Proof. There are four cases, according to operation types.

Case 1. Let sc_i and sc_j be two scan operations such that $sc_i \rightarrow sc_j$. By Lemma 4.11, sc_j returns a view that contains the value it writes. Furthermore, sc_i does not return a view that contains the value of sc_j. Since the views returned by sc_i and sc_j are comparable (Corollary 4.6), it must be that the view returned by sc_j dominates the view returned by sc_i. Therefore, sc_i is linearized before sc_j.

Case 2. Let sc_i be a scan operation and up_j be an update operation such that $sc_i \rightarrow up_j$. By the code of the algorithm, the view returned by sc_i does not contain the value written by up_j, and therefore up_j is linearized after sc_i.

Case 3. Let up_i be an update operation and sc_j be a scan operation such that $up_i \rightarrow sc_j$. By Corollary 4.10, the origin of sc_j starts after sc_j does, and therefore after up_i's actual update. Since the origin is a direct attempt, it reads up_i's value. Therefore, sc_j returns a view that contains the value written by up_i, and hence sc_j is linearized after up_i.

Case 4. Let up_i and up_j be two update operations such that $up_i \rightarrow up_j$. If up_i and up_j fit exactly between the same two scan operations, then due to the way symmetry is broken, up_i is linearized before up_j, and the lemma follows.

Otherwise, if up_j is linearized before up_i, then there exists a scan operation sc such that up_j is linearized before sc and sc is linearized before up_i. Thus, sc returns a view that contains the value written by up_j and does not contain the value written by up_i. Consider the scate operation that is executed to implement up_i. This scate operation returns a view that contains the value written by up_i (Lemma 4.11) but does not contain the value written by up_j (since $up_i \rightarrow up_j$). Therefore, this scate operation returns a view that is incomparable to the view returned by sc. This contradicts the comparability property of the views returned by scate operations (Corollary 4.6). □

Lemmas 4.7 and 4.12 imply that the sequence of scans and updates defined above is indeed a linearization. By Lemma 4.9, each scate operation contains at most two attempts. Each attempt requires $O(n \log m) = O(n \log n)$ operations on atomic single-writer multireader registers, which implies the following lemma.

LEMMA 4.13. *Any scan or update operation terminates after at most $O(n \log n)$ operations on atomic single-writer multireader registers.*

Note that, in addition to a single copy of the m-shot classification tree, each processor maintains n handshake variables (each with $O(k)$ possible values) and two views. Since k is a constant and $m = O(n)$, the algorithm requires a total of $O(n^2 B)$

bits, where as before, B is the number of bits required for representing a view. Note that B is still unbounded, since the algorithm still uses unbounded sequence numbers.

4.4. Bounding the sequence numbers. So far, we presented the ∞-shot snapshot object using unbounded sequence numbers to allow every processor to distinguish, for any set of values of another processor, which one is the most up to date. When sequence numbers are unbounded this goal is easily achieved by choosing the value with the maximal sequence number. To avoid unbounded values we use *bounded sequential timestamps*, a concept introduced in [20]. In our case, each processor generates its own set of timestamps (timestamps of different processors are not compared). Therefore, we can use ideas of [14] to implement these timestamps. Below, we briefly describe these ideas; the reader is referred to [14, 13] for further details.

The main idea is to allow a processor to know which of its sequence numbers might be in use in the system. If this can be done, then a processor can simply choose a new sequence number to be some value that is not in use; to let other processors know what is the ordering among its sequence numbers, the processor holds an ordered list of all its currently used sequence numbers. If the number of sequence numbers that might be in use is bounded, then the processor can draw its sequence numbers from a bounded set of values (thus effectively recycling them).

The difficult part of the above idea is keeping track of the sequence numbers that are in use in the system. The natural idea that comes to mind is that all of the sequence numbers of a processor that are written somewhere in the shared memory at some point are the ones that are in use. However, there might be situations where some processor, p_i, reads a certain sequence number, x, and then x is overwritten and "disappears" from the shared memory. Later on, p_i might rewrite x in the shared memory. The *traceable use* abstraction of [14] solves this problem of "hidden" values by forcing a processor that reads a sequence number from the shared memory to leave evidence that this sequence number was read. This results in a slightly more complicated mechanism for reading and writing values from the shared memory.

To allow values to be recycled the processor invokes a "garbage collection" of sequence numbers, whose execution is spread over the duration of several operations (see further details in [14, 13]).

The number of (low-level read and write) operations required for generating bounded sequence numbers is linear, and therefore the $O(n \log n)$ complexity of the snapshot algorithm is not affected.

In the implementation of the traceable use abstraction, the number of sequence numbers that each processor uses is bounded by $O(n^2)$ times the total number of sequence numbers of that processor that may be in the system concurrently (cf. [13]). In our case, each processor can have at most $O(n^2)$ of its own sequence numbers in the system concurrently. Thus, the total number of sequence numbers that are used by each processor is $O(n^4)$, and the size of the sequence numbers is therefore $O(\log n)$. In addition, each processor must hold an ordered list of all its sequence numbers that are currently in use. The list requires $O(n^4 \log n)$ bits per processor.

As was calculated before, the algorithm requires $O(n^2 B)$ bits, where B is the number of bits required to represent a view. To calculate B, recall that a view contains n entries, each with three fields: the actual value of the entry, the *counter* field ($O(\log n)$ bits), and the *seq* field (now bounded to require $O(\log n)$ bits). Therefore,

the number of bits required to represent a view is $O(n \log n)$, plus n times the number of bits required to represent an actual values of the snapshot object, which we denote by $|V|$. Thus, the total space complexity is $O(n^3(\log n + |V|) + n^5 \log n)$ bits.

5. Discussion. We introduced an implementation of a bounded atomic snapshot object in which each update or scan operation requires $O(n \log n)$ operations on atomic single-writer multireader registers. (As was previously mentioned, one of the operations can be made linear by the results of [23].) Obviously, at least $\Omega(n)$ operations are required for implementing the scan operation for an atomic snapshot object, and by [22] this is also the lower bound for implementing the update operation. Needless to say, it will be very interesting to close the $O(\log n)$ gap between our implementation and this lower bound.

CIRCUIT BOTTOM FAN-IN AND COMPUTATIONAL POWER*

LIMING CAI†, JIANER CHEN‡, AND JOHAN HÅSTAD§

Abstract. We investigate the relationship between circuit bottom fan-in and circuit size when circuit depth is fixed. We show that in order to compute certain functions, a moderate reduction in circuit bottom fan-in will cause significant increase in circuit size. In particular, we prove that there are functions that are computable by circuits of linear size and depth k with bottom fan-in 2 but require exponential size for circuits of depth k with bottom fan-in 1. A general scheme is established to study the trade-off between circuit bottom fan-in and circuit size. Based on this scheme, we are able to prove, for example, that for any integer c, there are functions that are computable by circuits of linear size and depth k with bottom fan-in $O(\log n)$ but that require exponential size for circuits of depth k with bottom fan-in c, and that for any constant $\epsilon > 0$, there are functions that are computable by circuits of linear size and depth k with bottom fan-in $\log n$ but that require superpolynomial size for circuits of depth k with bottom fan-in $O(\log^{1-\epsilon} n)$. A consequence of these results is that the three input read-modes of alternating Turing machines proposed in the literature are all distinct.

1. Introduction.

To prove lower bounds for various computational models remains as one of the most challenging tasks in complexity theory. Much progress has been made recently in deriving lower bounds for computational models with limited capabilities, with the hope that these may lead to better lower bounds for more general computational models and to better understanding of intrinsic complexity of computation.

One of the most successful trials is the derivation of lower bounds for constant depth circuits. The first strong lower bounds were given by Furst, Saxe, and Sipser [12] and, independently, by Ajtai [1] who show that the size of a constant depth circuit computing the parity function is superpolynomial. The results were subsequently sharpened by Yao [18] who derived an exponential lower bound. Håstad [14, 15] further strengthened the result and obtained near optimal lower bounds. A direct consequence of these results is that the logarithmic time hierarchy [17], i.e., the set of languages accepted by families of circuits of constant depth and polynomial size, is a proper subset of P.

The logarithmic time hierarchy was further refined by Sipser [17] who showed that for each integer $k > 1$, there are functions that are computable by a circuit of depth k and polynomial size but require superpolynomial size for circuits of depth $k - 1$. Thus, all levels of the logarithmic time hierarchy are distinct. Exponential

lower bounds for the depth k to $k-1$ conversion were first claimed by Yao [18] and then fully proved by Håstad [14, 15].

In this paper, we will further sharpen the separation results in the logarithmic time hierarchy by investigating the relationship between circuit bottom fan-in and circuit size when circuit depth is fixed. We show that in order to compute certain functions, a moderate reduction in circuit bottom fan-in will cause significant increase in circuit size. In particular, we prove that there are functions that are computable by circuits of linear size and depth k with bottom fan-in 2 but that require exponential size for circuits of depth k with bottom fan-in 1. A general scheme is established to study the trade-off between circuit bottom fan-in and circuit size. Based on this scheme, we are able to prove, for example, that for any integer c, there are functions that are computable by circuits of linear size and depth k with bottom fan-in $O(\log n)$ but that require exponential size for circuits of depth k with bottom fan-in c, and that for any constant $\epsilon > 0$, there are functions that are computable by circuits of linear size and depth k with bottom fan-in $\log n$ but that require superpolynomial size for circuits of depth k with bottom fan-in $O(\log^{1-\epsilon} n)$. Therefore, the computational power of constant depth circuits depends not only on its depth but also strictly on its bottom fan-in when the depth of the circuits is fixed.

Another motivation of our present research is the study of input read-modes of a sublinear-time alternating Turing machine, which is an important computational model in the study of complexity classes. A number of input read-modes for sublinear-time alternating Turing machines have appeared in the literature. In the standard model proposed by Chandra, Kozen, and Stockmeyer [9], a computation path of the machine can read up to $O(\log n)$ input bits in time $O(\log n)$. Ruzzo [16] proposed an input read-mode in which each computation path can read at most one input bit and the reading must be performed at the end of the path. An input read-mode studied by Sipser [17] insists that each input reading takes time $\Omega(\log n)$. These input read-modes have been carefully studied by Cai and Chen [6] who have given a precise circuit characterization for each read-mode for log-time alternating Turing machines of constant alternations. Input read-modes of log-time alternating Turing machines also find applications in the study of computational optimization problems [5, 8] and in the study of limited nondeterminism [7].

Based on the circuit characterizations of Cai and Chen and on our separation results in constant depth circuits, we are able to show that the three proposed input read-modes for alternating Turing machines are all distinct. More precisely, if we let $\Pi_k^{\mathcal{U}}$ (resp., $\Pi_k^{\mathcal{R}}$, $\Pi_k^{\mathcal{S}}$) be the class of languages accepted by log-time k-alternation alternating Turing machines using the input read-mode of Chandra, Kozen, and Stockmeyer (resp., Ruzzo, Sipser), then we can show that for all integers $k \geq 1$,

$$\Pi_k^{\mathcal{R}} \subset \Pi_k^{\mathcal{S}} \subset \Pi_k^{\mathcal{U}} \subset \Pi_{k+1}^{\mathcal{R}},$$

where $\subset$ means "proper subset." This gives a very detailed refinement of the logarithmic time hierarchy.

The paper is organized as follows. Section 2 introduces necessary definitions and related previous work. In section 3, we show that in order to compute certain functions, an $O(\log n)$ factor reduction in circuit bottom fan-in may cause exponential increase in circuit size. In section 4, we show that for circuits computing certain special functions, even reducing the circuit bottom fan-in by 1 will result in exponential

increase in circuit size. A general scheme is established in section 5 to study the trade-off between circuit bottom fan-in and circuit size. The relationship to the input read-modes of alternating Turing machines is given in section 6.

2. Preliminaries. We briefly review the fundamentals related to the present paper. For further discussion on the theory of circuit complexity and alternating Turing machines, the reader is referred to [3, 11].

An (unbounded fan-in) *Boolean circuit* α_n with input $x = x_1x_2, \ldots, x_n$ of length n is a directed acyclic graph. The *fan-in* of a node in the circuit is the in-degree of the node. The nodes of fan-in 0 are called *inputs* and are labeled from the set $\{0, 1, x_1, \overline{x}_1, \ldots, x_n, \overline{x}_n\}$. The nodes of fan-in greater than 0 are called *gates* and are labeled either AND or OR. One of the nodes is designated the *output* node. The *size* is the number of gates and the *depth* is the maximum distance from an input to the output. Without loss of generality, we assume that the circuits are of the special form where all AND and OR gates are organized into alternating levels with edges only between adjacent levels. Any circuit may be converted to one of this form without increasing the depth and by at most squaring the size [10]. In this special form, the gates that are connected to input nodes will be called *bottom level gates* or *depth* 1 *gates*. The gates that receive inputs from depth 1 gates will be called *depth* 2 *gates*, and so on. The *bottom fan-in* of a circuit is the maximum over fan-ins of all bottom level gates. The following notation introduced by Boppana and Sipser [3] will be especially convenient in our discussion.

DEFINITION 2.1. (See [3].) *A circuit α is a Π_k^s-circuit (resp., Σ_k^s-circuit) if α is a depth k circuit of size at most s with an* AND*-gate (resp., an* OR*-gate) at the output. A circuit β is a $\Pi_k^{s,c}$-circuit (resp., $\Sigma_k^{s,c}$-circuit) if β is a depth $k+1$ circuit of size at most s with bottom fan-in c and an* AND*-gate (resp., an* OR*-gate) at the output.*

A *family* of circuits is a sequence $\{\alpha_n \mid n \geq 1\}$ of circuits, where α_n is with input of length n. A family of circuits may be used to define a language. A family $\{\alpha_n \mid n \geq 1\}$ of circuits is said to be a Π_k^{poly}-family (resp., $\Pi_k^{poly,c}$-family) if there is a polynomial p such that for all $n \geq 1$, α_n is a $\Pi_k^{p(n)}$-circuit (resp., $\Pi_k^{p(n),c}$-circuit).

The *Sipser function* f_k^m, as defined in [14, 15], is given by the circuit C_k^m shown in Figure 1. The circuit C_k^m is a tree of depth k in which every gate in the bottom level has fan-in $\sqrt{km \log m/2}$, the fan-in of the output gate is $\sqrt{m/\log m}$, and the fan-in for all other gates is m. The output gate of C_k^m is always an AND-gate, while the gates in the bottom level vary depending on the parity of k. Each variable x_i, $1 \leq i \leq n$, occurs at only one leaf. Note that the number n of variables of the function f_k^m equals $m^{k-1}\sqrt{k/2}$.

The following theorem is proved by Håstad [14, 15].

THEOREM 2.2. (See [14, 15].) *There is no depth k circuit computing the function f_k^m with bottom fan-in $\frac{1}{12\sqrt{2k}}\sqrt{\frac{m}{\log m}}$ and fewer than $2^{\frac{1}{12\sqrt{2k}}\sqrt{\frac{m}{\log m}}}$ gates of depth ≥ 2, for $m > m_0$, where m_0 is an absolute constant.*

To further sharpen the separation results and study the relationship between circuit bottom fan-in and circuit size, we introduce a variation $f_k^{m,b}$ of the Sipser function by explicitly specifying the bottom fan-in for the defining circuits.

DEFINITION 2.3. *Let $C_k^{m,b}$ be the tree circuit defining the Sipser function f_k^m, as illustrated in Figure 1, except that each bottom level gate of $C_k^{m,b}$ has fan-in b instead of $\sqrt{km \log m/2}$. Define $f_k^{m,b}$ to be the function computed by the tree circuit $C_k^{m,b}$. The number n of variables of the function $f_k^{m,b}$ is $n = bm^{k-2}\sqrt{m/\log m}$.*

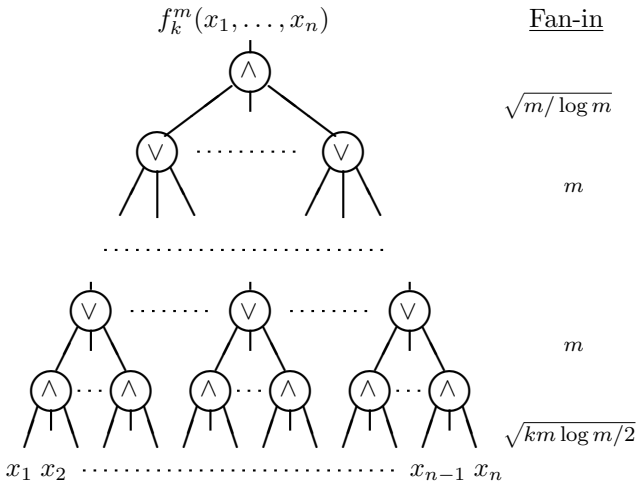

FIG. 1. *The circuit C_k^m defining the function f_k^m.*

The discussion of the present paper is centered on the complexity of the function $f_k^{m,b}$.

3. On circuits that compute $f_k^{m,\Omega(\log m)}$. In this section, we consider the complexity of the function $f_k^{m,b}$, where b is of order $\Omega(\log m)$.

Our main result in this section is that for $b > k \log m$, the function $f_k^{m,b}$ cannot be computed by any depth k circuit without exponential size and with bottom fan-in $\frac{b}{c \log m}$ for a particular constant c. This result requires two different proofs depending on whether the bottom fan-in b is larger or smaller than the bottom fan-in of the standard Sipser function circuit C_k^m given in Figure 1.

We first consider the case $b \leq \sqrt{km \log m/2}$. For this, we need to briefly review some notations and results by Håstad [14].

DEFINITION 3.1. (See [14].) *Let q be a real number and $(B_i)_{i=1}^r$ a partition of the variables. Let $R_{q,B}^+$ be the probability space of restrictions ρ that take values as follows.*

For every B_i, $1 \leq i \leq r$ independently,

1. *with probability q let $s_i = *$ and else $s_i = 0$.*
2. *for every $x_k \in B_i$ let $\rho(x_k) = s_i$ with probability q and else $\rho(x_k) = 1$.*

Similarly, an $R_{q,B}^-$ probability space of restrictions is defined by interchanging the roles played by 0 and 1.

The idea behind these restrictions is that a block B_i will correspond to the variables leading into one of the bottom level gates of the circuit $C_k^{m,b}$ that defines the function $f_k^{m,b}$. If the bottom level gates of $C_k^{m,b}$ are ANDs, we use a restriction from $R_{q,B}^+$; if the bottom level gates of $C_k^{m,b}$ are ORs, we use a restriction from $R_{q,B}^-$.

DEFINITION 3.2. (See [14].) *For a restriction $\rho \in R_{q,B}^+$, let $g(\rho)$ be the restriction defined as follows: for all B_i with $s_i = *$, $g(\rho)$ gives the value 1 to all variables which are given value $*$ by ρ except the variable with the highest index among those variables given value $*$ by ρ, to which $g(\rho)$ gives value $*$.*

If $\rho \in R_{q,B}^-$, then $g(\rho)$ is defined similarly but now takes the value 0 and $*$. Note that for a given restriction ρ, the restriction $g(\rho)$ can be obtained by a deterministic process that makes each block B_i have at most one $*$.

Let $\rho g(\rho)$ denote the composition of the two restrictions. That is, $\rho g(\rho)$ is the restriction $g(\rho)$ obtained from the restriction ρ.

LEMMA 3.3 (the switching lemma [14]). *Let σ be an* AND *of* ORs *all of size $\leq t$ and $\rho \in R^+_{q,B}$. Then the probability that under the restriction $\rho g(\rho)$ σ cannot be written as an* OR *of* ANDs *all of size $< s$ is bounded by α^s, where $\alpha < \frac{4qt}{\ln 2} < 5.78qt$.*

The switching lemma is also true if we do either or both of the following replacements: (1) replacing the probability space $R^+_{q,B}$ by the probability space $R^-_{q,B}$; and (2) replacing σ by an OR of ANDs to be converted to an AND and ORs.

Now we are ready for our first main result of this section.

THEOREM 3.4. *For $k \log m < b \leq \sqrt{km \log m/2}$, the function $f_k^{m,b}$ cannot be computed by any depth k circuit of bottom fan-in $\frac{b}{12k \log m}$ and size bounded by $2^{\frac{1}{12\sqrt{2(k-1)}}\sqrt{\frac{m}{\log m}}}$, for $m > m_0$, where m_0 is an absolute constant.*

Proof. The proof is similar to the induction step in the proof given by Håstad for Theorem 2.2 (see [14, pages 48–50]). Therefore, we only outline the proof and describe in detail those places that are different.

We set $q = \frac{k \log m}{b}$. Suppose that $\tau_1, \ldots, \tau_r$, $r = m^{k-2}\sqrt{m/\log m}$, are the bottom level gates of the tree circuit $C_k^{m,b}$ defining the function $f_k^{m,b}$. Let $(B_j)_{j=1}^r$ be the partition of the variables of $f_k^{m,b}$ such that block B_j is the set of variables leading into the bottom level gate τ_j of $C_k^{m,b}$.

Claim 1. The probability that under the restriction $\rho g(\rho)$ any bottom level gate τ_j of the tree circuit $C_k^{m,b}$ does not take value s_j is bounded by $\frac{1}{6m}$.

The proof is identical to the proof by Håstad for Fact 1 in [14, page 49]: such a gate τ_j does not take the corresponding value s_j with probability $(1-q)^{|B_j|} < \frac{1}{6}m^{-k}$. Since there are fewer than m^{k-1} bottom level gates in the tree circuit $C_k^{m,b}$, the probability in Claim 1 is bounded by $\frac{1}{6m}$.

Claim 2. The probability that under the restriction $\rho g(\rho)$ any depth 2 gate in the tree circuit $C_k^{m,b}$ gets fewer than $\sqrt{(k-1)m \log m/2}$ $*$'s from the bottom level is bounded by $\frac{1}{m}$.

Let $p_i = \binom{m}{i} q^i (1-q)^{m-i}$ be the probability that a fixed depth 2 gate μ in the tree circuit $C_k^{m,b}$ gets exactly i $*$'s from the bottom level. With the condition $b \leq \sqrt{km \log m/2}$, we can show that for $i \leq \sqrt{(k-1)m \log m}$, we have $\frac{p_i}{p_{i-1}} \geq \sqrt{2}$. Thus the probability that gate μ gets fewer than $\sqrt{(k-1)m \log m/2}$ $*$'s is bounded by m^{-k} for sufficiently large m. Since there are fewer than m^{k-1} depth 2 gates in the tree circuit $C_k^{m,b}$, the probability in Claim 2 is bounded by $\frac{1}{m}$.

Now suppose that the theorem is not true. Thus, there is a depth k circuit C_0 of size bounded by $2^{\frac{1}{12\sqrt{2(k-1)}}\sqrt{\frac{m}{\log m}}}$ and bottom fan-in $t \leq \frac{b}{12k \log m}$ that computes the function $f_k^{m,b}$. Furthermore, assume that the gates in the bottom level of the circuit C_0 are OR gates (the dual case can be proved similarly).

Claim 3. The probability that under the restriction $\rho g(\rho)$ any depth 2 gate in the circuit C_0 cannot be written as an OR of ANDs of size $\frac{1}{12\sqrt{2(k-1)}}\sqrt{\frac{m}{\log m}}$ is bounded by $\frac{1}{2}$.

Let σ be a fixed depth 2 gate in the circuit C_0. By the switching lemma, under the restriction $\rho g(\rho)$, the probability that σ cannot be written as an OR of ANDs of size $\frac{1}{12\sqrt{2(k-1)}}\sqrt{\frac{m}{\log m}}$ is bounded by $(5.78qt)^{\frac{1}{12\sqrt{2(k-1)}}\sqrt{\frac{m}{\log m}}}$. Since the circuit C_0 has at most $2^{\frac{1}{12\sqrt{2(k-1)}}\sqrt{\frac{m}{\log m}}}$ depth 2 gates, the probability in Claim 3 is bounded by

$$\begin{aligned}
&(5.78qt)^{\frac{1}{12\sqrt{2(k-1)}}\sqrt{\frac{m}{\log m}}} \cdot 2^{\frac{1}{12\sqrt{2(k-1)}}\sqrt{\frac{m}{\log m}}} \\
&< \left(\frac{5.78}{12}\right)^{\frac{1}{12\sqrt{2(k-1)}}\sqrt{\frac{m}{\log m}}} \cdot 2^{\frac{1}{12\sqrt{2(k-1)}}\sqrt{\frac{m}{\log m}}} \\
&\leq \left(\frac{5.78}{6}\right)^{\frac{1}{12\sqrt{2(k-1)}}\sqrt{\frac{m}{\log m}}},
\end{aligned}$$

which is smaller than $\frac{1}{2}$ when m is sufficiently large.

Therefore with a probability larger than $1 - (\frac{1}{6m} + \frac{1}{m} + \frac{1}{2}) > \frac{1}{3}$, the tree circuit $C_k^{m,b}$ becomes a circuit that computes a function f at least as hard as the Sipser function f_{k-1}^m, and the circuit C_0 becomes a depth $k-1$ circuit that computes the function f and has bottom fan-in $\frac{1}{12\sqrt{2(k-1)}}\sqrt{\frac{m}{\log m}}$ and fewer than $2^{\frac{1}{12\sqrt{2(k-1)}}\sqrt{\frac{m}{\log m}}}$ gates of depth ≥ 2. But this contradicts Theorem 2.2. □

Letting $b = \sqrt{km \log m/2}$ in Theorem 3.4, we obtain Theorem 2.2. Note that the size bound is slightly improved.

Note that the condition $b \leq \sqrt{km \log m/2}$ in Theorem 3.4 is essential in the proof for Claim 2. For larger bottom fan-in b, we have the following theorem.

THEOREM 3.5. *For $b \geq 2\sqrt{km \log m/2}$, the function $f_k^{m,b}$ cannot be computed by any depth k circuit of bottom fan-in $\frac{b}{25ke \log m}$ and size bounded by $2^{\frac{1}{12\sqrt{2k}}\sqrt{\frac{m}{\log m}}}$, for $m > m_0$, where m_0 is an absolute constant and e is the base of the natural logarithm.*

Proof. Let $q = \frac{1.04\sqrt{km \log m/2}}{b}$. Consider the following probability space R_q^+ of restrictions:

> For each variable x_k of the function $f_k^{m,b}$, let $\rho^+(x_k) = *$ with probability q and else $\rho^+(x_k) = 1$.

The probability space R_q^- is defined similarly except that the value 1 is replaced by value 0.

From now on, we assume that the bottom level gates of the tree circuit $C_k^{m,b}$ defining $f_k^{m,b}$ are AND gates. The case when the bottom level gates of $C_k^{m,b}$ are OR gates can be proved similarly by using the probability space R_q^- instead of the probability space R_q^+.

We first show that under a restriction $\rho^+ \in R_q^+$, with very large probability, the tree circuit $C_k^{m,b}$ computes a function at least as hard as the Sipser function f_k^m. The proof is similar to that for Claim 2 in Theorem 3.4. Thus, we only describe the differences.

Let τ be a bottom level gate in the tree circuit $C_k^{m,b}$. The gate τ is an AND gate of fan-in b. Let $p_i = \binom{b}{i} q^i (1-q)^{b-i}$ be the probability that the gate τ gets exactly i $*$'s under a restriction $\rho^+ \in R_q^+$. First we consider the ratio

$$\frac{p_i}{p_{i-1}} = \frac{b-i+1}{i} \cdot \frac{q}{1-q} > \frac{b-i}{i} \cdot \frac{q}{1-q}.$$

For $i \leq 1.02\sqrt{km \log m/2}$, we have

$$\frac{b-i}{i} \geq \frac{b - 1.02\sqrt{km \log m/2}}{1.02\sqrt{km \log m/2}}$$

and

$$\frac{q}{1-q} = \frac{(1.04\sqrt{km\log m/2})/b}{1-(1.04\sqrt{km\log m/2})/b} = \frac{1.04\sqrt{km\log m/2}}{b-1.04\sqrt{km\log m/2}}.$$

Thus, we have

$$\frac{p_i}{p_{i-1}} > \frac{b-1.02\sqrt{km\log m/2}}{1.02\sqrt{km\log m/2}} \cdot \frac{1.04\sqrt{km\log m/2}}{b-1.04\sqrt{km\log m/2}} \geq \frac{52}{51}.$$

This gives $(51/52)^{j-i}p_j > p_i$ for $i < j \leq 1.02\sqrt{km\log m/2}$.

Now under a restriction $\rho^+ \in R_q^+$, the probability that the gate τ gets fewer than $\sqrt{km\log m/2}$ $*$'s is bounded by

$$\begin{aligned}
&\sum_{i=0}^{\sqrt{km\log m/2}} p_i < \sum_{i=0}^{\sqrt{km\log m/2}} (51/52)^{\sqrt{km\log m/2}-i} p_{\sqrt{km\log m/2}} \\
\leq\ & 52 p_{\sqrt{km\log m/2}} < 52(51/52)^{0.02\sqrt{km\log m/2}} p_{1.02\sqrt{km\log m/2}} \\
\leq\ & 52(51/52)^{0.02\sqrt{km\log m/2}},
\end{aligned}$$

and $52(51/52)^{0.02\sqrt{km\log m/2}}$ is smaller than $\frac{1}{m^k}$ for sufficiently large m.

Since the circuit $C_k^{m,b}$ has fewer than m^{k-1} bottom level gates, we conclude that under a restriction $\rho^+ \in R_q^+$, the probability that any bottom level gate of the tree circuit $C_k^{m,b}$ gets fewer than $\sqrt{km\log m/2}$ $*$'s is bounded by $\frac{1}{m}$.

Now suppose that the theorem is not true. Thus, there is a depth k circuit C_0 of bottom fan-in at most $\frac{b}{25ke\log m}$ and size bounded by $2^{\frac{1}{12\sqrt{2k}}\sqrt{\frac{m}{\log m}}}$ such that the circuit C_0 computes the function $f_k^{m,b}$. We show that under a restriction $\rho^+ \in R_q^+$, with very large probability, the circuit C_0 becomes a depth k circuit of bottom fan-in at most $\frac{1}{12\sqrt{2k}}\sqrt{\frac{m}{\log m}}$.

Let μ be a bottom level gate of fan-in $c \leq \frac{b}{25ke\log m}$ in the circuit C_0, and let $r_i = \binom{c}{i}q^i(1-q)^{c-i}$ be the probability that the gate μ gets exactly i $*$'s under a restriction $\rho^+ \in R_q^+$. We have

$$\binom{c}{i}q^i(1-q)^{c-i} \leq \frac{c!}{i!(c-i)!}q^i \leq \frac{c^i q^i}{i!} \leq \left(\frac{cqe}{i}\right)^i,$$

where the last inequality is based on Stirling's approximation [13, page 452]

$$i! \geq 0.9(i/e)^i\sqrt{2\pi i} \geq (i/e)^i, \quad \text{for } i \geq 1.$$

Let $s = \frac{1}{12\sqrt{2k}}\sqrt{\frac{m}{\log m}}$. Under a restriction $\rho^+ \in R_q^+$, the probability that the gate μ gets more than s $*$'s is bounded by

$$\sum_{i=s+1}^{c} r_i \leq \sum_{i=s+1}^{c} \left(\frac{cqe}{i}\right)^i \leq \sum_{i=s+1}^{c} \left(\frac{\frac{1.04}{25\sqrt{2k}}\sqrt{\frac{m}{\log m}}}{i}\right)^i.$$

For $i > s = \frac{1}{12\sqrt{2k}}\sqrt{\frac{m}{\log m}}$, we have $\left(\frac{1.04}{25\sqrt{2k}}\sqrt{\frac{m}{\log m}}\right)\Big/ i < \frac{12.48}{25}$. Thus, under a restriction $\rho^+ \in R_q^+$ the probability that the gate μ gets more than s $*$'s is bounded by

$$\sum_{i=s+1}^{c} (12.48/25)^i < (12.48/25)^s.$$

Since the circuit C_0 has at most 2^s bottom level gates, we conclude that under a restriction $\rho^+ \in R_q^+$, the probability that any bottom level gate of the circuit C_0 gets more than s $*$'s is bounded by

$$(12.48/25)^s \cdot 2^s = (24.96/25)^s = (24.96/25)^{\frac{1}{12\sqrt{2k}}\sqrt{\frac{m}{\log m}}},$$

which is smaller than $\frac{1}{m}$ for sufficiently large m.

Thus, under a restriction $\rho^+ \in R_q^+$, with probability $\geq 1 - \frac{1}{m} - \frac{1}{m} > \frac{1}{2}$, all bottom level gates of the tree circuit $C_k^{m,b}$ get at least $\sqrt{km\log m/2}$ $*$'s (thus $C_k^{m,b}$ is converted to a circuit computing a function at least as hard as the Sipser function f_k^m), and all bottom level gates of the circuit C_0 get at most $\frac{1}{12\sqrt{2k}}\sqrt{\frac{m}{\log m}}$ $*$'s. Note that if a bottom level gate μ of the circuit C_0 gets at most $\frac{1}{12\sqrt{2k}}\sqrt{\frac{m}{\log m}}$ $*$'s, then either the gate μ is eliminated from the bottom level (e.g., μ is an AND gate and gets an input with value 0) or the gate μ becomes a gate of fan-in at most $\frac{1}{12\sqrt{2k}}\sqrt{\frac{m}{\log m}}$. In any case, we have derived that there is an assignment that converts the circuit C_0 into a depth k circuit C' of bottom fan-in bounded by $\frac{1}{12\sqrt{2k}}\sqrt{\frac{m}{\log m}}$ and size bounded by $2^{\frac{1}{12\sqrt{2k}}\sqrt{\frac{m}{\log m}}}$ such that the circuit C' computes a function at least as hard as the Sipser function f_k^m. But this contradicts Theorem 2.2.

This completes the proof. □

4. On circuits that compute $f_k^{m,2}$. In the previous section, we showed that for circuits to compute the function $f_k^{m,b}$, $b = \Omega(\log m)$, an $O(\log m)$ factor reduction in bottom fan-in may cause an exponential increase in the circuit size. In this section, we will show that in certain cases, even reducing the circuit bottom fan-in by 1 will cause an exponential increase in the circuit size. More precisely, we will show that the function $f_k^{m,2}$ can be computed by a depth k circuit of linear size and bottom fan-in 2 but requires exponential size for depth k circuits of bottom fan-in 1. Note that a depth k circuit of bottom fan-in 1 is actually a depth $k-1$ circuit.

We prove the above result with a new probability space of restrictions. We start with the following lemma.

LEMMA 4.1. *Partition the Boolean variables $\{x_1, \ldots, x_n\}$ into groups of c variables each. For each group, randomly pick r variables and assign them* 0*, and assign the rest $c-r$ variables $*$. Let σ be an* OR *of a subset S_σ of $\{x_1, \overline{x}_1, \ldots, x_n, \overline{x}_n\}$ such that S_σ contains at least h negative literals $\overline{x}_i$. Then with the above random assignment,*

$$Pr[\sigma \not\equiv 1] \leq ((c-r)/c)^h.$$

Proof. Let $s = n/c$ be the number of groups in the partition given in the statement of the lemma. We first rename the literals in the set S_σ so that $\overline{x}_1^{(d)}, \ldots, \overline{x}_{j_d}^{(d)}$, $d = 1, \ldots, s$, $j_1 + \cdots + j_s = h$, are h negative literals in S_σ, where $\overline{x}_1^{(d)}, \ldots, \overline{x}_{j_d}^{(d)}$ belong to the same group in the partition, $d = 1, \ldots, s$.

Let $A_t^{(d)}$ be the event that the variable $x_t^{(d)}$ is *not* assigned 0 by the random assignment, and let $\mathcal{E}_{\sigma\not\equiv 1}$ be the event that σ is not identical to 1. Then

$$\mathcal{E}_{\sigma\not\equiv 1} \subseteq \bigcap_{d=1}^{s} \left(A_1^{(d)} \cap \cdots \cap A_{j_d}^{(d)} \right).$$

Thus,

$$Pr[\sigma \not\equiv 1] = Pr[\mathcal{E}_{\sigma\not\equiv 1}] \leq Pr\left[\bigcap_{d=1}^{s} \left(A_1^{(d)} \cap \cdots \cap A_{j_d}^{(d)} \right) \right] = \prod_{d=1}^{s} Pr\left[A_1^{(d)} \cap \cdots \cap A_{j_d}^{(d)} \right].$$

We have the last equality because the events $A_1^{(d)} \cap \cdots \cap A_{j_d}^{(d)}$ and $A_1^{(d')} \cap \cdots \cap A_{j_{d'}}^{(d')}$ are independent for $d \neq d'$.

Now consider $Pr[A_1^{(d)} \cap \cdots \cap A_{j_d}^{(d)}]$. If $j_d > c - r$, then by the way we assign the dth group, at least one of the variables $x_1^{(d)}, \ldots, x_{j_d}^{(d)}$ is assigned 0. Therefore,

$$Pr\left[A_1^{(d)} \cap A_2^{(d)} \cap \cdots \cap A_{j_d}^{(d)} \right] = 0.$$

If $j_d \leq c - r$, then

$$Pr\left[A_1^{(d)} \cap A_2^{(d)} \cap \cdots \cap A_{j_d}^{(d)} \right]$$
$$= Pr\left[A_1^{(d)} \right] \cdot Pr\left[A_2^{(d)} | A_1^{(d)} \right] \cdot Pr\left[A_3^{(d)} | A_1^{(d)} \cap A_2^{(d)} \right] \cdots Pr\left[A_{j_d}^{(d)} | A_1^{(d)} \cap \cdots \cap A_{j_d-1}^{(d)} \right].$$

Note that

$$Pr\left[A_i^{(d)} | A_1^{(d)} \cap \cdots \cap A_{i-1}^{(d)} \right] = \frac{c - r - i + 1}{c - i + 1} \leq \frac{c - r}{c}.$$

Thus,

$$Pr\left[A_1^{(d)} \cap A_2^{(d)} \cap \cdots \cap A_{j_d}^{(d)} \right] \leq ((c - r)/c)^{j_d}.$$

This gives directly

$$Pr[\sigma \not\equiv 1] \leq \prod_{d=1}^{s} Pr\left[A_1^{(d)} \cap \cdots \cap A_{j_d}^{(d)} \right] \leq \prod_{d=1}^{s} \left(\frac{c - r}{c} \right)^{j_d} = \left(\frac{c - r}{c} \right)^{h}. \qquad \square$$

Similarly we can prove the following lemma.

LEMMA 4.2. *Partition the Boolean variables $\{x_1, \ldots, x_n\}$ into groups of c variables each. For each group, randomly pick r variables and assign them 1, and assign the rest $c-r$ variables $*$. Let σ be an* OR *of a subset S_σ of $\{x_1, \overline{x}_1, \ldots, x_n, \overline{x}_n\}$ such that S_σ contains at least h positive literals x_i. Then with the above random assignment,*

$$Pr[\sigma \not\equiv 1] \leq ((c - r)/c)^{h}.$$

Now we are ready for the main theorem of this section.

THEOREM 4.3. *The function $f_k^{m,2}$ cannot be computed by any depth $k-1$ circuit of size bounded by $2^{\frac{1}{12\sqrt{2(k-1)}}\sqrt{\frac{m}{\log m}}}$ for $m > m_0$, where m_0 is an absolute constant.*

Proof. To simplify the expressions, we let $s = \frac{1}{12\sqrt{2(k-1)}}\sqrt{\frac{m}{\log m}}$. Suppose that the theorem is not true and that there is a depth $k-1$ circuit C of size 2^s that computes the function $f_k^{m,2}$. Furthermore, we assume that the gates in the bottom level of C are OR gates (the case that the bottom level gates of C are AND gates can be proved similarly).

Randomly pick one variable from each pair x_{2i-1} and x_{2i} and assign it 0. This will reduce the tree circuit $C_k^{m,2}$ defining $f_k^{m,2}$ to the tree circuit $C_{k-1}^{m,m}$ defining $f_{k-1}^{m,m}$.

Let τ be an OR gate in the bottom level of the circuit C such that τ has more than s negative literals in its input, then by Lemma 4.1,

$$Pr[\tau \not\equiv 1] \leq (1/2)^{s+1}.$$

Let $\tau_1, \ldots, \tau_r$, $r \leq 2^s$ be all the gates in the bottom level of the circuit C such that there are more than s negative literals in their input, then

$$Pr[\tau_1 \not\equiv 1 \vee \cdots \vee \tau_r \not\equiv 1] \leq Pr[\tau_1 \not\equiv 1] + \cdots + Pr[\tau_r \not\equiv 1] \leq 2^s(1/2)^{s+1} = 1/2.$$

Thus,

$$Pr[\tau_1 \equiv 1 \wedge \cdots \wedge \tau_r \equiv 1] \geq 1/2.$$

Therefore, there is an assignment that converts the circuit $C_k^{m,2}$ to the circuit $C_{k-1}^{m,m}$ and eliminates all gates in the bottom level of the circuit C in whose input there are more than s negative literals. Let the circuit obtained from C by this assignment be C'.

Now partition the input of the function $f_{k-1}^{m,m}$ into groups of m variables each such that each group corresponds to the inputs to a bottom level gate of the tree circuit $C_{k-1}^{m,m}$. Randomly pick half of the variables in each group and assign them 1. The circuit $C_{k-1}^{m,m}$ under such an assignment is converted to the circuit $C_{k-1}^{m,m/2}$ defining the function $f_{k-1}^{m,m/2}$.

Let σ be an OR gate in the bottom level of the circuit C' with more than s positive literals in its input, then by Lemma 4.2,

$$Pr[\sigma \not\equiv 1] \leq (1/2)^{s+1}.$$

Let $\sigma_1, \ldots, \sigma_t$, $t \leq 2^s$ be all the gates in the bottom level of the circuit C' with more than s positive literals in their input, then

$$Pr[\sigma_1 \not\equiv 1 \vee \cdots \vee \sigma_t \not\equiv 1] \leq Pr[\sigma_1 \not\equiv 1] + \cdots + Pr[\sigma_t \not\equiv 1] \leq 2^s(1/2)^{s+1} = 1/2.$$

Thus,

$$Pr[\sigma_1 \equiv 1 \wedge \cdots \wedge \sigma_t \equiv 1] \geq 1/2.$$

Therefore, there is an assignment that converts the circuit $C_{k-1}^{m,m}$ to the circuit $C_{k-1}^{m,m/2}$ and eliminates all gates in the bottom level of C' that have more than s positive literals in their input. Let the circuit obtained from C' by this assignment be C''.

Since each gate in the bottom level of the circuit C'' has neither more than s negative literals nor more than s positive literals in its input, the bottom fan-in of the circuit C'' is at most $2s = \frac{1}{6\sqrt{2(k-1)}}\sqrt{\frac{m}{\log m}}$, which is smaller than $\frac{m/2}{25e(k-1)\log m}$ for

sufficiently large m. Thus, we have constructed a circuit C'' of depth $k-1$, bottom fan-in less than $\frac{m/2}{25e(k-1)\log m}$, and size bounded by $2^s = 2^{\frac{1}{12\sqrt{2(k-1)}}\sqrt{\frac{m}{\log m}}}$ such that C'' computes the function $f_{k-1}^{m,m/2}$. This contradicts Theorem 3.5. □

The following corollary will be used in section 6.

COROLLARY 4.4. *The function $f_k^{m,2}$ can be computed by a circuit of depth k, linear size, and bottom fan-in 2, but cannot be computed by any depth $k-1$ circuit of polynomial size.*

COROLLARY 4.5. *For each pair of integers $k, c > 1$, there are functions that are computable by circuits of linear size and depth k with bottom fan-in c but require exponential size for circuits of depth $k-1$.*

5. Trade-off between bottom fan-in and size. We first summarize the results in the previous two sections in the following theorem.

THEOREM 5.1. *For all integers $b \geq 2$ and sufficiently large m, the function $f_k^{m,b}$ can be computed by a depth k circuit of linear size and bottom fan-in b, but requires size larger than $2^{\frac{1}{12\sqrt{2k}}\sqrt{\frac{m}{\log m}}}$ for depth k circuits of bottom fan-in $\frac{b}{25ek\log m}$.*

Proof. For the case $2 \leq b \leq k\log m$, since $\frac{b}{25ek\log m} < 1$, the theorem is implied by Theorem 4.3. The case $k\log m < b \leq \sqrt{km\log m/2}$ is proved in Theorem 3.4. For the case $\sqrt{km\log m/2} < b < 2\sqrt{km\log m/2}$, since $\frac{b}{25ek\log m} \leq \frac{\sqrt{km\log m/2}}{12k\log m}$, the theorem is implied by Theorem 3.4. Finally, the case $b \geq 2\sqrt{km\log m/2}$ is proved by Theorem 3.5. □

A number of important consequences follow directly from Theorem 5.1.

THEOREM 5.2. *For any integers $k \geq 1$ and $h \geq 1$, and for any real number r, there are functions that are computable by circuits of linear size and depth k with bottom fan-in $O(\log^h n)$ but that require exponential size for depth k circuits of bottom fan-in $r\log^{h-1} n$.*

Proof. Let $b = 25ek(k-1)^{h-1}r\log^h m$. Note that in this case, the number of variables in the function $f_k^{m,b}$ is $n \leq m^{k-1}$ for m large enough. Thus, $\log m \leq \log n \leq (k-1)\log m$. By the definition, the function $f_k^{m,b}$ can be computed by a depth k and linear size circuit with bottom fan-in $b = O(\log^h n)$. On the other hand, according to Theorem 5.1, the function $f_k^{m,b}$ requires exponential size for depth k circuits whose bottom fan-in is $r(k-1)^{h-1}\log^{h-1} m$. Note that $r(k-1)^{h-1}\log^{h-1} m$ is at least as large as $r\log^{h-1} n$. □

By more careful selections of the bottom fan-in b in Theorem 5.1, combined with a padding technique, we are able to obtain general results for the trade-off between circuit size and circuit bottom fan-in. We illustrate this technique by the following theorem, which can be easily extended to other cases using the same technique.

THEOREM 5.3. *For any integer $k \geq 1$ and for any real number $\epsilon > 0$, there is a function F_k^ϵ that is computable by a circuit of linear size and depth k with bottom fan-in $\log n$ but that requires superpolynomial size for depth k circuits of bottom fan-in $O(\log^{1-\epsilon} n)$.*

Proof. Choose h such that $\frac{h}{h+1} > 1-\epsilon$, and then use Theorem 5.2 to choose a function $f_k^{m,b}$ of $\leq m^{k-1}$ variables which can be computed by a depth k circuit of linear size and bottom fan-in $b = 25ek\log^{h+1} m$ but that requires size

$$2^{\frac{1}{12\sqrt{2k}}\sqrt{\frac{m}{\log m}}} \tag{1}$$

when the bottom fan-in is $\leq \log^h m$.

Now make the function $f_k^{m,b}$ formally the function F_k^ϵ of $n = 2^{25ek\log^{h+1} m}$ variables by adding dummy variables that are not used. The theorem now follows for the function F_k^ϵ since the size bound (1) is superpolynomial in n and $c\log^{1-\epsilon} n < \log^h m$ for any fixed constant c when m is sufficiently large. □

In particular, if we let $\epsilon = 1$ and $h = 1$, then we obtain the following corollary that will be used in section 6.

COROLLARY 5.4. *For any integer $k \geq 1$, there is a function F_k that is computable by a circuit of linear size and depth k with bottom fan-in $\log n$ but that requires superpolynomial size for depth k circuits of bottom fan-in $O(1)$.*

6. Input read-modes of Turing machines. An important application of the above investigation is to the input read-modes of a sublinear-time alternating Turing machine, which is an important computational model in the study of complexity classes.

To make sublinear-time Turing machines meaningful, we allow a Turing machine to have a *random access input tape*, plus a read-write *input address tape*, such that the Turing machine has access to the bit of the input tape denoted by the contents of the input address tape.

An $O(\log n)$-*time alternating Turing machine* (log-*time ATM*) is defined as an extension of the $O(\log n)$-time deterministic Turing machines in the usual way [9]. Given an input, the computation of a log-time ATM M can be represented by an $\wedge$-$\vee$ tree. Each computation path in the $\wedge$-$\vee$ tree can be divided into *phases*, which are the maximal subpaths in which M does not make alternations. The first configuration in each phase is called an *alternation* (configuration). In particular, the starting configuration of M is always an alternation.

A number of input read-modes for sublinear-time alternating Turing machines have appeared in the literature. The standard input read-mode introduced by Chandra, Kozen, and Stockmeyer [9] allows a computation path of an $O(\log n)$-time alternating Turing machine to read up to $\Theta(\log n)$ input bits. Ruzzo [16] proposed an input read-mode in which each computation path can read at most one input bit and the reading must be performed at the end of the path. An input read-mode studied by Sipser [17] insists that the input address tape always be reset to blank after each input reading so that each input reading takes time $\Omega(\log n)$.

It can be shown that many complexity classes such as NC^k for $k \geq 1$ and AC^k for $k \geq 0$ remain the same for all of these input read-modes of alternating Turing machines. On the other hand, it was unknown whether these input read-modes affected the classes of lower complexity such as the levels in the logarithmic time hierarchy. Recently, Cai and Chen [6] have demonstrated how each level of the logarithmic time hierarchy based on each of the above input read-modes can be characterized by a uniform family of circuits. Combining these characterizations with the separation results given in the previous sections, we are able to show that all of these input read-modes are distinct.

Formally, the *logarithmic time hierarchy* is defined as the union of the following classes:

$$\Pi_1, \Pi_2, \ldots, \Pi_k, \ldots,$$

where Π_k is the class of languages accepted by a log-time ATM that always starts with an $\wedge$-state and makes at most k alternations.

The above definition ignores the input read-modes of the log-time ATMs and thus is not very precise. To be more precise, we will call

$$\Pi_1^U, \Pi_2^U, \ldots, \Pi_k^U, \ldots,$$

the logarithmic time hierarchy *based on the Chandra–Kozen–Stockmeyer model*,

$$\Pi_1^R, \Pi_2^R, \ldots, \Pi_k^R, \ldots,$$

the logarithmic time hierarchy *based on Ruzzo's model*, and

$$\Pi_1^S, \Pi_2^S, \ldots, \Pi_k^S, \ldots,$$

the logarithmic time hierarchy *based on Sipser's model*, where Π_k^U (resp., Π_k^R, Π_k^S) is the class of languages accepted by a log-time ATM based on the Chandra–Kozen–Stockmeyer input read-mode (resp., on Ruzzo's input read-mode, on Sipser's input read-mode) that always starts with an $\wedge$-state and makes at most k alternations.

THEOREM 6.1. (See [6].) *For all integers $k \geq 1$,*

(1) *if a language L is in the class Π_k^R, then L is accepted by a Π_k^{poly}-family of circuits;*

(2) *if a language L is in the class Π_k^S, then L is accepted by a $\Pi_k^{poly,c}$-family of circuits for some constant c;*

(3) *if a language L is in the class Π_k^U, then L is accepted by a $\Pi_k^{poly,d\log n}$-family of circuits for some constant d;*

According to the definitions, it is easy to see that $\Pi_k^R \subseteq \Pi_k^S \subseteq \Pi_k^U$. A proof for the inclusion $\Pi_k^U \subseteq \Pi_{k+1}^R$ can be found in [6]. Our main result for this section is that all of these inclusions are strict, as proved in the following theorem.

THEOREM 6.2. *For any integer $k \geq 1$, we have*

$$\Pi_k^R \subset \Pi_k^S \subset \Pi_k^U \subset \Pi_{k+1}^R,$$

where $\subset$ means "proper subset."

Proof. (1) $\Pi_k^R \subset \Pi_k^S$.

It has been proved by Cai and Chen in [6] that $\Pi_1^R \subset \Pi_1^S$. Thus, we only need to prove the strict inclusion for $k \geq 2$.

Without loss of generality, we suppose that the output gate of the tree circuit $C_{k+1}^{m,2}$ defining the function $f_{k+1}^{m,2}$ is an AND gate (otherwise, we consider the negation of the function $f_{k+1}^{m,2}$). Moreover, to make the operations such as m^k, $\log m$, and $\sqrt{m}$ feasible within $O(\log n)$ deterministic time, we consider only the case where m is a power of 2.

Let S_1 be the language whose characteristic function is given by the functions $f_{k+1}^{m,2}$, where m is a power of 2 (in particular, a string is not in the set S_1 if its length does not match the number of variables for any such function $f_{k+1}^{m,2}$). We first construct a log-time ATM M_1 that accepts the set S_1 as follows. On input x, M_1 first computes the length n of x. This can be done in deterministic $O(\log n)$ time by reading $O(\log n)$ input bits [2]. Then M_1 verifies that $n = 2m^{k-1}\sqrt{m/\log m}$ for some integer m that is a power of 2. After this, M_1 simply traces the tree circuit $C_{k+1}^{m,2}$ defining the function $f_{k+1}^{m,2}$, except that in the kth phase, M_1 reads the two consecutive input bits for the corresponding bottom level gate and directly computes the value for the gate. Since the output gate of the circuit $C_{k+1}^{m,2}$ is an AND gate, the log-time ATM M_1 starts with an $\wedge$-state and makes at most k alternations.

According to our assumption, $k \geq 2$. Thus, the log-time ATM M_1 reads at most two input bits in its last phase. By Theorem 3.1 in Cai and Chen [6], M_1 can be simulated by a log-time ATM based on Sipser's input read-mode that always starts with an $\wedge$-state and makes at most k alternations. This proves that the set S_1 is in the class Π_k^S.

Suppose that S_1 is also in the class Π_k^R. Then by Theorem 6.1(1), S_1 is accepted by a Π_k^{poly}-family of circuits. Thus, for any integer m that is a power of 2, the function $f_{k+1}^{m,2}$ is computable by a depth k circuit of polynomial size. This contradicts Corollary 4.4.

This contradiction shows $\Pi_k^R \subset \Pi_k^S$.

(2) $\Pi_k^S \subset \Pi_k^U$.

The proof is similar to that for case (1). Consider the function F_{k+1} in Corollary 5.4, which is a function of n variables obtained from the function $f_{k+1}^{m,b}$, $b = 25e(k+1)\log^2 m$ by adding dummy variables, where $n = 2^{25e(k+1)\log^2 m}$. We also make similar assumptions as we did for case (1). Thus, the output gate of the tree circuit $C_{k+1}^{m,b}$ defining the function $f_{k+1}^{m,b}$ is an AND gate, and m is a power of 2. Under these assumptions, it is easy to see that the set S_2 whose characteristic function is given by the functions F_{k+1} in Corollary 5.4 is in the class Π_k^U: a log-time ATM M_2 first verifies the length of the input and traces the tree circuit $C_{k+1}^{m,b}$ defining the corresponding function $f_{k+1}^{m,b}$ except that in the kth phase, M_2 reads directly a consecutive block of b input bits that are the inputs to the corresponding bottom level gate. Note that the b consecutive input bits can be read in deterministic $O(b + \log n)$ time [4], and that b is logarithmic in the input length n of the function F_{k+1}. This proves that the language S_2 is in the class Π_k^U.

Suppose that S_2 is also in the class Π_k^S. By Theorem 6.1(2), the language S_2 is accepted by a $\Pi_k^{poly,c}$-family of circuits for some constant c. That is, the function F_{k+1} is computable by a depth $k+1$ and bottom fan-in c circuit whose size is polynomial. But this contradicts Corollary 5.4. Thus, $\Pi_k^S \subset \Pi_k^U$.

(3) $\Pi_k^U \subset \Pi_{k+1}^R$.

The proof is similar to those of the other two cases. Let S_3 be the language whose characteristic function is given by the Sipser functions f_{k+1}^m. Then the set S_3 can be accepted by a log-time ATM M_3 that always starts with an $\wedge$-state and makes at most $k+1$ alternations. Moreover, the last phase of M_3 reads at most one input bit. By Theorem 3.1 in Cai and Chen [6], M_3 can be simulated by a log-time ATM based on Ruzzo's input read-mode that always starts with an $\wedge$-state and makes at most $k+1$ alternations. Thus, the set S_3 is in the class Π_{k+1}^R. On the other hand, by Theorem 6.1(3), $S_3 \in \Pi_k^U$ would imply that S_3 is accepted by a $\Pi_k^{poly,O(\log n)}$-family of circuits. That would in turn imply that the Sipser function f_{k+1}^m is computable by a depth $k+1$ circuit of polynomial size whose bottom fan-in is $O(\log n)$, contradicting Theorem 2.2.

This completes the proof. □

COROLLARY 6.3. *For each $k \geq 1$, the kth levels of the logarithmic time hierarchy based on the Chandra–Kozen–Stockmeyer input read-mode, Sipser's input read-mode, and Ruzzo's input read-mode are all distinct.*

Acknowledgments. The second author would like to thank Mike Sipser for an early discussion that initialized this line of research. He is also grateful to Ken Regan and Rong Chen for their comments and constructive discussions. Finally, the authors are especially thankful to two anonymous referees for comments and suggestions that have improved the presentation. In particular, one of the referees pointed out a technical bug in an earlier version of the present paper.

ON THE COMPLEXITY OF COMPUTING MIXED VOLUMES*

MARTIN DYER†, PETER GRITZMANN‡, AND ALEXANDER HUFNAGEL§

Abstract. This paper gives various (positive and negative) results on the complexity of the problem of computing and approximating mixed volumes of polytopes and more general convex bodies in arbitrary dimension.

On the negative side, we present several #$\mathbb{P}$-hardness results that focus on the difference of computing mixed volumes versus computing the volume of polytopes. We show that computing the volume of zonotopes is #$\mathbb{P}$-hard (while each corresponding mixed volume can be computed easily) but also give examples showing that computing mixed volumes is hard even when computing the volume is easy.

On the positive side, we derive a randomized algorithm for computing the mixed volumes

$$V(\overbrace{K_1,\dots,K_1}^{m_1},\overbrace{K_2,\dots,K_2}^{m_2},\dots,\overbrace{K_s,\dots,K_s}^{m_s})$$

of well-presented convex bodies $K_1,\dots,K_s$, where $m_1,\dots,m_s \in \mathbb{N}_0$ and $m_1 \geq n-\psi(n)$ with $\psi(n)=o(\frac{\log n}{\log\log n})$. The algorithm is an interpolation method based on polynomial-time randomized algorithms for computing the volume of convex bodies.

This paper concludes with applications of our results to various problems in discrete mathematics, combinatorics, computational convexity, algebraic geometry, geometry of numbers, and operations research.

Introduction. The present paper deals with algorithmic questions related to the problem of computing or approximating volumes and mixed volumes of convex bodies by means of deterministic or randomized algorithms. The emphasis will be on the case of varying dimension (but we will also mention some results for fixed dimension).

As the terms are used here, a *convex body* in $\mathbb{R}^n$ is a nonempty compact convex set and a *polytope* is a convex body that has only finitely many extreme points. A convex body or a polytope in $\mathbb{R}^n$ is called *proper* if it is n-dimensional and hence has nonempty interior. A convenient way to deal algorithmically with general convex bodies is to assume that the convex body in question is "well presented" by an algorithm (called an *oracle*) that answers certain sorts of questions about the body and also gives some a priori information; see subsection 1.2 for precise definitions.

The problem of computing the volume $\mathrm{vol}_n(K)$ of an appropriately presented convex body K of $\mathbb{R}^n$ is of fundamental importance from both a theoretical and computational point of view. If K is of the form $K=\sum_{i=1}^s \lambda_i K_i$, where $K_1,\dots,K_s$

are convex bodies and $\lambda_1, \ldots, \lambda_s$ are positive reals, then $\mathrm{vol}_n(K)$ can be expressed in terms of the *mixed volumes* $V(K_{i_1}, K_{i_2}, \ldots, K_{i_n})$ of $K_1, \ldots, K_s$; in fact,

$$V\left(\sum_{i=1}^{s} \lambda_i K_i\right) = \sum_{i_1=1}^{s} \sum_{i_2=1}^{s} \cdots \sum_{i_n=1}^{s} \lambda_{i_1} \lambda_{i_2} \cdots \lambda_{i_n} V(K_{i_1}, K_{i_2}, \ldots, K_{i_n})$$

is a multivariate homogeneous polynomial of degree n in the variables $\lambda_1, \ldots, \lambda_s$; see subsection 1.1.

The corresponding *Brunn–Minkowski* theory is the backbone of convexity theory (see [Sc93]), but it is also relevant for numerous applications in combinatorics, algebraic geometry and a number of other areas; see section 4 and [GK94].

As it is well known, $V(K, \ldots, K) = \mathrm{vol}_n(K)$, and hence, mixed volumes generalize the ordinary volume. From this observation it is already clear that, in general, any hardness result for volume computation carries over to mixed volumes. Specifically, the problem of computing the volume of polytopes (given in terms of their vertices—"$\mathcal{V}$-polytopes"—or in terms of their facet hyperplanes—"$\mathcal{H}$-polytopes"; see subsection 1.2) is known to be #$\mathbb{P}$-hard (see [DF88]), whence computing mixed volumes of polytopes is also (at least) #$\mathbb{P}$-hard.

The hardness issue of volume versus mixed volume computation is, however, more complicated than that. In the case where the number of bodies is not bounded beforehand but part of the input, the above multivariate polynomial typically has exponentially many coefficients and this implies that the task of computing *all* mixed volumes of a given set of bodies does require exponential time. But this fact also allows for the possibility that the volume of the Minkowski sum of convex bodies may be hard to compute even if each mixed volume can be computed easily. Indeed, when the bodies $K_1, \ldots, K_s$ are all line segments, each mixed volume computation is just the evaluation of a corresponding determinant; computing the volume of the zonotope $K = K_1 + \cdots + K_s$ is, in general however, hard.

THEOREM 1. *The following task is #$\mathbb{P}$-hard: given $n, s \in \mathbb{N}$ and rational vectors $z_1, \ldots, z_s$ of $\mathbb{R}^n$, compute the volume of the zonotope $\sum_{i=1}^{s} [0,1] z_i$.*

A slight strengthening of this result is contained in Theorem 5. As a corollary to Theorem 1 we show in Theorem 2 that (approximately) computing the volume of the Minkowski sum of ellipsoids is also #$\mathbb{P}$-hard, a result needed in subsection 2.4.

Conversely to Theorem 1, computing *a single* mixed volume may be hard even if the volume of the corresponding Minkowski sum is easy to compute.

THEOREM 3. *The following problem MIXED-VOLUME-OF-BOXES is #$\mathbb{P}$-hard: given a positive integer n and, for $i, j = 1, 2, \ldots, n$, positive rationals $\alpha_{i,j}$, determine the mixed volume $V(Z_1, \ldots, Z_n)$ of the axes-parallel parallelotopes $Z_i = \sum_{j=1}^{n} [0, \alpha_{i,j}] e_j$, $(i = 1, 2, , \ldots, n)$, where e_j denotes the jth unit vector.*

The #$\mathbb{P}$-hardness persists even when the boxes are restricted to having just two different (and previously prescribed) edge lengths.

Proofs of these theorems (and related results) are given in section 2. We further show that Theorem 3 can be strengthened to just two parallelotopes if one of them is permitted to deviate from being axes-parallel (Theorem 4). In view of these results it may be surprising that even though the computation of certain mixed volumes appears to be harder than volume computation, from the point of view of complexity theory it is not. Theorems 6 and 7 show that the problem of computing any specific mixed volume of polytopes (or zonotopes) is #$\mathbb{P}$-easy.

Section 2 will also discuss the problem of how efficiently mixed volumes can be approximated by means of deterministic algorithms. [GLS88], [AK90], and [BH93]

give exponential upper bounds for the error of deterministic polynomial approximations of the volume, and [BF86] gives an almost matching lower bound in the oracular model. We discuss possible extensions to mixed volumes and derive a polynomial-time algorithm for estimating any mixed volume of two convex bodies to a relative error that depends only on the dimension but is independent of the "well-boundedness" parameters of the bodies (Theorem 9). As a necessary "by-product" we further show that it can be decided in polynomial time whether the mixed volume of convex bodies vanishes (Theorem 8). This is a nontrivial result since a mixed volume may be greater than zero even if each set is contained in a lower-dimensional affine subspace.

A natural approach to mixed volumes is to try to use values (or estimates thereof) of the polynomial $\mathrm{vol}_n(\sum_{i=1}^s \lambda_i K_i)$ for computing (or estimating) (some of) its coefficients, the mixed volumes of the convex bodies K_i. This approach works under reasonable assumptions provided the above polynomial can be evaluated (approximately) in polynomial time; see [GK94]. This is particularly true for polytopes in *fixed* dimension; see [AS86], [CH79]. For variable dimension there is not much hope in ever obtaining a polynomial-time deterministic algorithm for this task, but we may utilize the polynomial-time randomized volume algorithm of [DFK91].

PROPOSITION 1. *There is a polynomial-time randomized algorithm which solves the following problem:*

Instance: *A well-presented convex body K in $\mathbb{R}^n$, positive rational numbers τ and β.*

Output: *A random variable $\hat{v} \in \mathbb{Q}$ such that*

$$prob\left\{\frac{|\hat{v} - \mathrm{vol}_n(K)|}{\mathrm{vol}_n(K)} \geq \tau\right\} \leq \beta.$$

Let us point out that after a preprocessing "rounding" step whose running time depends on the "a priori parameters" of the body, the running time of the main algorithm is bounded above by a polynomial in n, $\frac{1}{\tau}$, and $\log(\frac{1}{\beta})$.

[DFK91]'s algorithm was improved by [LS90], [AK90], [DF91], [LS93], [KLS97]; see [Kh93], [GK94], and [Lo95] for surveys. Let us point out that, when dealing with randomized algorithms of the above kind, it suffices to give the desired approximation to error probability, say $\frac{1}{4}$. Then after $O(\log(1/\beta))$ independent trials of the algorithm, the median of the results achieves the required probability β; see [JVV86], [SJ89], [KKLLL93], or [LS93].

Even for just two bodies there are two major difficulties in extending Proposition 1 to mixed volumes. First, in general there is *no* way of obtaining *relative* estimates of the coefficients from *relative* estimates of the values of a polynomial p. (This is easily seen by considering the one-parameter sequence of univariate polynomials $q_\beta(x) = 1 + \beta x + x^2$, where β may be any arbitrary small positive rational number; cf. [GK94, section 6.2]). The special structure of the "mixed volume polynomial" $p(x) = \mathrm{vol}_n(K_1 + xK_2)$ will, however, allow us to handle this problem. Second, the absolute values of the entries of the "inversion" which is used for expressing the coefficients of the polynomial in terms of its approximated values are not bounded by a polynomial, while the randomized volume approximation algorithm is polynomial only in $\frac{1}{\tau}$ but not in $size(\tau)$. This difficulty is mirrored in the restrictions on ψ in the following theorem.

THEOREM 10. *Suppose that $\psi : \mathbb{N} \to \mathbb{N}$ is nondecreasing with*

$$\psi(n) \leq n \qquad \text{and} \qquad \psi(n)\log\psi(n) = o(\log n).$$

Then there is a polynomial-time algorithm for the following problem:

Instance: *Well-presented convex bodies K_1, K_2 of $\mathbb{R}^n$, positive rational numbers ϵ and β, an integer m with $0 \le m \le \psi(n)$.*

Output: *The information that the mixed volume*

$$a_m = V(\overbrace{K_1, \dots, K_1}^{n-m}, \overbrace{K_2, \dots, K_2}^{m})$$

of K_1 and K_2 vanishes, iff $a_m = 0$, or, otherwise, a random variable $\hat{a}_m \in \mathbb{Q}$, satisfying

$$prob\left\{\frac{|\hat{a}_m - a_m|}{a_m} \ge \epsilon\right\} \le \beta.$$

The complexity of the above algorithm is only marginally worse than the complexity of the volume oracle; see section 3 for a detailed analysis. Note that the function

$$\psi(n) = \left\lceil \frac{\log n}{\log^2 \log n} \right\rceil$$

satisfies the above condition (on $\mathbb{N} \setminus \{1, 2, 3\}$).

Theorem 10 can be extended to more than two bodies.

THEOREM 11. *Suppose that $\psi : \mathbb{N} \to \mathbb{N}$ is nondecreasing with*

$$\psi(n) \le n \qquad \text{and} \qquad \psi(n) \log \psi(n) = o(\log n).$$

Then there is a polynomial-time algorithm for the following problem:

Instance: *$n, s \in \mathbb{N}$, $m_1, \dots, m_s \in \mathbb{N}_0$ with $m_1 + m_2 + \cdots + m_s = n$ and $m_1 \ge n - \psi(n)$, well-presented convex bodies $K_1, \dots, K_s$ of $\mathbb{R}^n$, positive rational numbers ϵ and β.*

Output: *The information that the mixed volume*

$$V_{m_1,\dots,m_s} = V(\overbrace{K_1, \dots, K_1}^{m_1}, \dots, \overbrace{K_s, \dots, K_s}^{m_s})$$

vanishes, iff $V_{m_1,\dots,m_s} = 0$, or, otherwise, a random variable $\hat{V}_{m_1,\dots,m_s} \in \mathbb{Q}$ such that

$$prob\left\{\frac{|\hat{V}_{m_1,\dots,m_s} - V_{m_1,\dots,m_s}|}{V_{m_1,\dots,m_s}} \ge \epsilon\right\} \le \beta.$$

Theorems 10 and 11 will be proved in section 3. But let us take a few words here to place their results into perspective. Both theorems are proved by using an interpolation (or numerical differentiation) method, which is based on Proposition 1. A special feature of such a method is that in order to compute *a specific* coefficient of the polynomial under consideration it computes essentially *all* (or at least "all previous") coefficients. Now, suppose that $\psi : \mathbb{N} \to \mathbb{N}$ is a functional with $\psi(n) \le n$ for all $n \in \mathbb{N}$; let

$$\mathcal{I}_\psi(n) = \{(m_1, \dots, m_{\psi(n)}) : m_1, \dots, m_{\psi(n)} \in \mathbb{N}_0,\ m_1 + \cdots + m_{\psi(n)} = n \\ \text{and } n - m_1 \le \psi(n)\},$$

and let $K_1, \dots, K_{\psi(n)}$ be convex bodies of $\mathbb{R}^n$. Then

$$|\mathcal{I}_\psi(n)| = \binom{2\psi(n)-1}{\psi(n)-1},$$

whence the number of different mixed volumes

$$V(\overbrace{K_1, \dots, K_1}^{m_1}, \overbrace{K_2, \dots, K_2}^{m_2}, \dots, \overbrace{K_{\psi(n)}, \dots, K_{\psi(n)}}^{m_{\psi(n)}})$$

is in general only bounded by a polynomial in n if $\psi(n) \le \kappa \log n$ for some constant κ. This means that there can possibly be a polynomial-time algorithm for computing *all such* mixed volumes only if

$$\psi(n) \le \kappa \log n.$$

As we will see in section 3, the statements of Theorems 10 and 11 are much easier to prove for ψ being constant. As the previous discussion shows, when the number of bodies is part of the input, no polynomial-time algorithm is capable of computing more than "very few" mixed volumes. This fact places severe limitations on interpolation methods that indicate that the restriction on ψ in Theorem 11 is "essentially best-possible" for any such method.

Let us remark that, for general convex bodies, it is an open problem whether there exists any method that avoids these limitations and allows one to access *single specific* mixed volumes. Hence it is open, whether the above restrictions on ψ can be lifted and whether there are polynomial-time randomized algorithms which, on arbitrarily *given* $n, s \in \mathbb{N}$, $m_1, \dots, m_s \in \mathbb{N}_0$ *with* $m_1 + m_2 + \cdots + m_s = n$, *well-presented convex bodies* $K_1, \dots, K_s$ *of* $\mathbb{R}^n$ *and positive rational numbers* ϵ *and* β, *compute a random variable* $\hat{V}_{m_1,\dots,m_s} \in \mathbb{Q}$ *such that* $\text{prob}\{|\hat{V}_{m_1,\dots,m_s} - V_{m_1,\dots,m_s}|/V_{m_1,\dots,m_s} \ge \epsilon\} \le \beta$.

Note specifically that even the case $s = n$, $m_1 = \cdots = m_s = 1$ is open.

Section 4 contains some problems related to mixed volumes and some applications of our results. In particular, we deal with the problem of counting the number of integer points in lattice polytopes and with some determinant problems involving minors of given matrices. Furthermore, we discuss possible applications of our results to problems in mixture management, combinatorics, and algebraic geometry.

1. Basic geometric and computational aspects. The following three subsections provide definitions, notation, background information, and some first results that are needed later in sections 2 and 3.

1.1. Mixed volumes. Let $\mathcal{K}^n$ denote the family of all convex bodies of $\mathbb{R}^n$.

A theorem of Minkowski [Mi11] (see also [BF34], [Sc93, section 5]) shows that for $K_1, K_2, \dots, K_s \in \mathcal{K}^n$ and nonnegative reals $\lambda_1, \lambda_2, \dots, \lambda_s$,

$$\text{vol}_n\left(\sum_{i=1}^{s} \lambda_i K_i\right)$$

is a homogeneous polynomial of degree n in $\lambda_1, \dots, \lambda_s$, and can be written in the form

$$\text{vol}_n\left(\sum_{i=1}^{s} \lambda_i K_i\right) = \sum_{i_1=1}^{s} \sum_{i_2=1}^{s} \cdots \sum_{i_n=1}^{s} \lambda_{i_1}\lambda_{i_2}\cdots\lambda_{i_n} V(K_{i_1}, K_{i_2}, \dots, K_{i_n}), \tag{1.1}$$

where the coefficients $V(K_{i_1}, K_{i_2}, \ldots, K_{i_n})$ are order-independent, i.e., invariant under permutations of their arguments. The coefficient $V(K_{i_1}, K_{i_2}, \ldots, K_{i_n})$ is called the *mixed volume* of $K_{i_1}, K_{i_2}, \ldots, K_{i_n}$. We will also use the term *mixed volume* for the functional

$$V : \overbrace{\mathcal{K}^n \times \cdots \times \mathcal{K}^n}^{n} \to \mathbb{R}, \qquad (K_1, \ldots, K_n) \mapsto V(K_1, \ldots, K_n),$$

as well as for restrictions of this functional to certain subsets of $\mathcal{K}^n \times \cdots \times \mathcal{K}^n$. Mixed volumes are nonnegative, monotone, multilinear, and continuous valuations; see [BZ88, Chapter 4], [Sa93], and [GK94] for the basic properties of mixed volumes, and see [Sc93] for an excellent detailed treatment of the Brunn-Minkowski theory.

The order-independence gives rise to the notation

$$V(\overbrace{K_1, \ldots, K_1}^{m_1}, \overbrace{K_2, \ldots, K_2}^{m_2}, \ldots, \overbrace{K_s, \ldots, K_s}^{m_s})$$

for the mixed volume $V(K_1, \ldots, K_s)$, where each K_i occurs exactly m_i times and $\sum_{i=1}^{s} m_i = n$. The following *Aleksandrov–Fenchel inequality*, [Al37], [Al38], [Fe36], plays a fundamental role in the Brunn-Minkowski theory and will be needed in the approximation algorithm of section 3.

$$V(K_1, K_2, K_3, \ldots, K_n)^2 \geq V(K_1, K_1, K_3, , \ldots, K_n)\ V(K_2, K_2, K_3, \ldots, K_n), \tag{1.2}$$

whenever $K_1, K_2, \ldots, K_n \in \mathcal{K}^n$; see [Sc93] for a proof and a discussion of this inequality.

The following "decomposition lemma" (see, e.g., [BZ88, section 19.4]) will also turn out to be useful in our analysis.

PROPOSITION 2. *Let $K_1, \ldots, K_n \in \mathcal{K}^n$ and suppose that $K_{n-m+1}, \ldots, K_n$ are contained in some m-dimensional affine subspace U of $\mathbb{R}^n$. Let V_U denote the mixed volume with respect to the m-dimensional volume measure on U, and let $V_{U^\perp}$ be defined similarly with respect to the orthogonal complement $U^\perp$ of U. Then*

$$\binom{n}{m} V(K_1, \ldots, K_{n-m}, K_{n-m+1}, \ldots, K_n) = V_{U^\perp}(K_1', \ldots, K_{n-m}')V_U(K_{n-m+1}, \ldots, K_m),$$

where $K_1', \ldots, K_{n-m}'$ denote the orthogonal projections of $K_1, \ldots, K_{n-m}$ onto $U^\perp$, respectively.

As a particular consequence, it follows that

$$V(K_1, \ldots, K_{n-m}, K_{n-m+1}, \ldots, K_n) = 0$$

if there is a proper subspace of U that contains $K_{n-m+1}, \ldots, K_n$. (Note, however, that in general the mixed volume may be greater than zero even if each set lies in *some* lower-dimensional subspace of $\mathbb{R}^n$.) In the special case $m = 1$, $K_n = [0, 1]v$, and $U = \mathrm{lin}\{v\}$, where $v \in \mathbb{R}^n \setminus \{0\}$, Proposition 2 reads

$$n \cdot V(K_1, \ldots, K_{n-1}, [0, 1]v) = \|v\| \cdot V_{U^\perp}(K_1', \ldots, K_{n-1}').$$

If all bodies $K_1, \ldots, K_s$ are line segments, say

$$K_i = S_i = p_i + [0, 1]z_i \quad (i = 1, \ldots, s),$$

with $p_i, z_i \in \mathbb{R}^n$, then $Z = \sum_{i=1}^{s} S_i$ is a *zonotope*. It follows that for any sequence $1 \le i_1, i_2, \dots, i_n \le s$ of mutually distinct indices,

$$V(S_{i_1}, S_{i_2}, \dots, S_{i_n}) = \frac{1}{n!}\big|\det(z_{i_1}, z_{i_2}, \dots, z_{i_n})\big|,$$

where $(z_{i_1}, z_{i_2}, \dots, z_{i_n})$ denotes the $n \times n$-matrix with columns $z_{i_1}, \dots, z_{i_n}$. With the aid of (1.1) this implies the well-known volume formula for zonotopes,

$$\mathrm{vol}_n\left(\sum_{i=1}^{s} S_i\right) = \sum_{1 \le i_1 < i_2 < \cdots < i_n \le s} \big|\det(z_{i_1}, z_{i_2}, \dots, z_{i_n})\big|; \tag{1.3}$$

see [Sh74], [Mo89], or [St91].

The polynomial expression in (1.1) involves all s variables $\lambda_1, \dots, \lambda_s$ but, of course, one of the variables, say λ_1, may be set to 1, whence the problem of computing all mixed volumes of s sets in $\mathbb{R}^n$ can be reduced to the task of computing the coefficients of a (generally now inhomogenous) polynomial of degree n in $s-1$ indeterminates. For $s = 2$ we obtain the univariate polynomial

$$p(x) = \mathrm{vol}_n(K_1 + xK_2) = \sum_{i=0}^{n} \binom{n}{i} a_i x^i,$$

where

$$a_i = V(\overbrace{K_1, \dots, K_1}^{n-i}, \overbrace{K_2, \dots, K_2}^{i}).$$

The *Aleksandrov–Fenchel inequality* implies that the sequence

$$q_m = \frac{a_{m-1}}{a_m} \qquad (m = 1, \dots, n)$$

is increasing, whence the sequence $a_0, \dots, a_n$ is *unimodal*.

Finally, note that when $s > 2$, $m_1, m_2, \dots, m_s \in \mathbb{N}_0$ with $\sum_{i=1}^{s} m_i = n$, and $L_x = K_0 + xK_1$ for nonnegative $x \in \mathbb{R}$,

$$q(x) = V(\overbrace{L_x, \dots, L_x}^{m_1}, \overbrace{K_2, \dots, K_2}^{m_2}, \dots, \overbrace{K_s, \dots, K_s}^{m_s})$$

is a polynomial in x of degree m_1, and we have

$$q(x) = \sum_{k=0}^{m_1} \binom{m_1}{k} V(\overbrace{K_0, \dots, K_0}^{m_1-k}, \overbrace{K_1, \dots, K_1}^{k}, \overbrace{K_2, \dots, K_2}^{m_2}, \dots, \overbrace{K_s, \dots, K_s}^{m_s}) x^k. \tag{1.4}$$

This fact will, in particular, be used in subsection 3.3.

1.2. Algorithmic preliminaries. The present subsection begins with some remarks on how to deal algorithmically with polytopes and more general convex bodies, and then collects a few results that are needed later.

The underlying model of computation is the binary Turing machine model, which—in case of convex bodies—will be augmented by certain oracles; see [GJ79], [GLS88].

From an algorithmic point of view, polytopes are dealt with much more easily than general convex bodies because polytopes can be presented in a finite manner, namely, in terms of their vertices or in terms of their facet halfspaces. Clearly, from an algorithmic point of view it is not the geometric object that is relevant but its presentation. Hence we use the following notation; see e.g., [GK94].

A string $(n, m; v_1, \ldots, v_m)$ with $n, m \in \mathbb{N}$, and $v_1, \ldots, v_m \in \mathbb{Q}^n$ is called a $\mathcal{V}$-*polytope* in $\mathbb{R}^n$; it represents the geometric object $P = \operatorname{conv}\{v_1, \ldots, v_m\}$; hence we will sometimes write $P = (n, m; v_1, \ldots, v_m)$. A string $(n, m; A, b)$, where $n, m \in \mathbb{N}$, A is a rational $m \times n$ matrix and $b \in \mathbb{Q}^m$ such that $P = \{x \in \mathbb{R}^n : Ax \leq b\}$ is a polytope is called an $\mathcal{H}$-*polytope* in $\mathbb{R}^n$, and is again identified with the geometric object P. If we want to focus more on the geometric object P we will call each corresponding $\mathcal{V}$- or $\mathcal{H}$-polytope a $\mathcal{V}$- or $\mathcal{H}$-*presentation* of P. The *binary size* (or short *size*) of a $\mathcal{V}$- or $\mathcal{H}$-polytope P is the number of binary digits needed to encode the data of the presentation.

Let us point out that each rational polytope admits a presentation as a $\mathcal{V}$- or $\mathcal{H}$-polytope, and in fixed dimension one can be computed from the other in polynomial time. This is no longer true in general when the dimension is part of the input, since the number of vertices of a polytope may be exponential in its number of facets and vice versa; see [Mc70].

Zonotopes admit specifically "compact" presentations. A string $(n, s; c; z_1, \ldots, z_s)$ with $n, s \in \mathbb{N}$ and $c, z_1, \ldots, z_s \in \mathbb{Q}^n$ is called an $\mathcal{S}$-*zonotope* in $\mathbb{R}^n$; it represents the geometric object $Z = c + \sum_{i=1}^{s} [0, 1] z_i$. Sometimes we will also work with zonotopes whose relationship to the origin (and whose scaling) is different. Specifically, zontopes of the form $\sum_{i=1}^{s} [-1, 1] z_i$ will be used. To keep the notation simple, we refrain, however, from introducing an additional name for such a presentation. Note that, in general, neither the vertices nor the facets of a zonotope are readily accessible from an $\mathcal{S}$-presentation. In fact, for zonotopes generated by s segments in general position, both the number of facets and the number of vertices grow exponentially as m increases.

A zonotope Z is called a *parallelotope* if the "generators" $z_1, \ldots, z_s$ are linearly independent; it is *rectangular* if they are pairwise othogonal, and *axes-parallel* if all generators are standard unit vectors.

A convenient way to deal algorithmically with general convex bodies K is to assume that K is given by an algorithm (called an *oracle*) that answers certain sorts of questions about the body. These oracles are designed in such a way that the standard polytope case is included, i.e., it is easy to construct the corresponding oracles for $\mathcal{V}$- or $\mathcal{H}$-polytopes. This oracular approach has been introduced and extensively studied for proper convex bodies in [GLS88]. In particular, [GLS88] shows that under suitable additional assumptions, "membership," "separation," and "optimization" are equivalent. Here we need a slight variant since we want to deal with mixed volumes of possibly improper convex bodies. Let $K \in \mathcal{K}^n$, and define for $\epsilon \geq 0$ the *outer parallel body* and the *inner parallel body* of K, respectively, by

$$K(\epsilon) = (K + \epsilon \mathbb{B}^n) \cap \operatorname{aff}(K) \quad \text{and} \quad K(-\epsilon) = K \setminus ((\operatorname{aff}(K) \setminus K) + \epsilon \mathbb{B}^n),$$

where $\mathbb{B}^n$ denotes the Euclidean unit ball in $\mathbb{R}^n$. The most natural algorithmic problem for convex bodies K is the following.

WEAK MEMBERSHIP PROBLEM FOR $K \in \mathcal{K}^n$. *Given $y \in \mathbb{Q}^n$, and a rational number $\epsilon > 0$, assert that $y \in K(\epsilon)$ or that $y \notin K(-\epsilon)$.*

If a convex body K is given by an algorithm that solves the weak membership problem, we say that K is described by a *weak membership oracle*. It is quite evi-

dent that the information given by a weak membership oracle is insufficient for most algorithmic purposes. Hence we need some additional a priori information about the body in question; see [GLS88] for a discussion of these assumptions in case of a proper convex body. A convex body K of $\mathbb{R}^n$ will be called *well presented* if it is given by a weak membership oracle and if the following additional information is provided: a nonnegative integer d and vectors $a_0, \dots, a_d \in \mathbb{Q}^n$ such that $\operatorname{aff}(K) = \operatorname{aff}\{a_0, \dots, a_d\}$; a vector $b \in Kn\mathbb{Q}^n$, and positive rational numbers ρ and R such that $(b + \rho\mathbb{B}^n) \cap \operatorname{aff}(K) \subset K \subset R\mathbb{B}^n$.

Note that d is the dimension of K and that $\operatorname{aff}(K)$ is presented in terms of an affine basis. It is, however, easy to compute from $a_0, \dots, a_d$ a presentation of $\operatorname{aff}(K)$ as the solution space of a system of (rational) linear equations and vice versa. The *size* of a well-presented convex body $K \in \mathcal{K}^n$ is then defined as n plus the sum of the binary sizes of the parameters $a_0, \dots, a_d$, b, ρ, and R, and the *input size* of the weak membership oracle for K is the sum of $size(K)$ and $size(\epsilon)$.

It is not hard to see that well presentation carries over to Minkowski sums. In fact, let $K_1, \dots, K_s \in \mathcal{K}^n$ be well presented with parameters n, d_i, $a_{i,0}, \dots, a_{i,d_i}$, b_i, ρ_i, and R_i for $i = 1, \dots, s$, and let $\lambda_1, \dots, \lambda_s$ be positive rationals whose sizes are bounded above by the sizes of $K_1, \dots, K_s$. Then it is easy to find an affine basis of the affine hull of $K = \lambda_1 K_1 + \cdots + \lambda_s K_s$, and

$$
\begin{aligned}
&d = \dim(\operatorname{lin}\{a_{i,j} - a_{i,0} : i = 1, \dots, s; j = 1, \dots, d_i\}),\\
&b = \lambda_1 b_1 + \cdots + \lambda_s b_s,\\
&R = \lambda_1 R_1 + \cdots + \lambda_s R_s
\end{aligned}
$$

are valid parameters for K. Further, one can compute in polynomial time a nontrivial lower bound ρ such that $(b+\rho\mathbb{B}^n)\cap\operatorname{aff}(K) \subset K$. It is also true that a membership oracle for K can be derived in polynomial time from membership oracles for $K_1, \dots, K_s$, but this result makes use of the nontrivial relation of the oracles studied in [GLS88].

PROPOSITION 3. *Let $K_1, \dots, K_s \in \mathcal{K}^n$ be well presented, and let $\lambda_1, \dots, \lambda_s$ be positive rationals whose sizes are bounded above by the sizes of $K_1, \dots, K_s$. Then, a well presentation for $K = \lambda_1 K_1 + \cdots + \lambda_s K_s$ can be computed in polynomial time.*

The following Löwner–John-type "rounding lemmas" in terms of $\mathbb{B}^n$ and $C_n = [-1, 1]^n$ are due to [GLS88] and [AK90], respectively; see the survey [GK94, section 6.2] for some additional results in this context.

PROPOSITION 4. *There are oracle polynomial-time algorithms which accept as input a well-presented convex body K and construct affine transformations ϕ_1 and ϕ_2 such that $0 \in \operatorname{aff}(\phi_1(K))$, $0 \in \operatorname{aff}(\phi_2(K))$ and*

$$\operatorname{aff}(\phi_1(K)) \cap \mathbb{B}^n \subset \phi_1(K) \subset n\sqrt{n+1}\mathbb{B}^n, \qquad \operatorname{aff}(\phi_2(K)) \cap C_n \subset \phi_2(K) \subset 2(n+1)C_n.$$

1.3. Some estimates for numerical differentiation. As already mentioned above, computing (some/all) mixed volumes from the ordinary volume can be regarded as computing (some/all) of the coefficients of a polynomial from its values. This can in principle be done by numerical differentiation, and we will derive a few estimates now that will be used in section 3.

Let

$$q(x) = \sum_{i=0}^{n} c_i x^i$$

be a univariate polynomial of degree n, and let $\xi_0, \dots, \xi_n$ be pairwise different interpolation points. The *Lagrange-interpolation polynomials* $l_k(x) = \sum_{i=0}^{n} b_{ki} x^i$ on the

node set $X = \{\xi_0, \ldots, \xi_n\}$ satisfy

$$l_k(\xi_j) = \sum_{i=0}^{n} b_{ki}\xi_j^i = \delta_{jk},$$

where δ_{jk} is the usual Kronecker symbol. Then

$$q(x) = \sum_{k=0}^{n} q(\xi_k)l_k(x) = \sum_{i=0}^{n} \left(\sum_{k=0}^{n} q(\xi_k)b_{ki} \right) x^i;$$

hence

$$c_i = \sum_{k=0}^{n} b_{ki}q(\xi_k) \quad \text{for } i = 0, \ldots, n.$$

In general, only estimates $\hat{q}(\xi_j)$ of the function values $q(\xi_j)$ are available. In fact, for the purpose of section 3 we can only use estimates with bounded *relative* error. Here we suppose first that the *absolute* error is bounded beforehand, i.e., there is a positive δ such that

$$|\hat{q}(\xi_j) - q(\xi_j)| \leq \delta \quad \text{for } j = 0, \ldots, n.$$

Now, let $m \in \{0, \ldots, n\}$, and let us take

$$\hat{c}_m = \sum_{k=0}^{n} b_{km}\hat{q}(\xi_k)$$

as an estimate for c_m. Then we obtain

$$|c_m - \hat{c}_m| = \left| \sum_{k=0}^{n} b_{km}(q(\xi_k) - \hat{q}(\xi_k)) \right| \leq \delta \sum_{k=0}^{n} |b_{km}|. \tag{1.5}$$

Efficient methods for performing the computations in a systematical way (e.g., by using divided differences) can be found in any textbook on numerical analysis; see for example [BZ65]. The problem of how to choose the interpolation points to minimize the error terms $\sum_{k=0}^{n} |b_{km}|$ is discussed in (among others) [Ri75]; see also [MM85], [Sa74], [Ri90]; equidistant nodes are in general not optimal. We will use equidistant interpolation points anyway since, on the one hand, the subsequent analysis becomes more tractable and, on the other hand, the additional error introduced that way is dominated by other occurring error terms and hence is essentially irrelevant.

For the estimates in this subsection, we will normalize the nodes to the set $X = \{0, 1, \ldots, n\}$; in section 3 we will use the node set hX for some suitable positive rational h.

Let M denote the (infinite) Vandermonde matrix $M = (j^i)_{i,j\in\mathbb{N}_0}$, (with the setting $0^0 = 1$); for $r \in \mathbb{N}$ let $M^{(r)} = (j^i)_{i,j=0,\ldots,r-1}$ be the restriction of M to its first r rows and columns, and let $B^{(r)} = (b_{ij}^{(r)})_{i,j=0,\ldots,r-1}$ be the inverse of $M^{(r)}$. We will now derive an upper estimate for $\sum_{i=0}^{r-1} |b_{im}^{(r)}|$.

For $i, j \in \mathbb{N}$ with $i \geq j$, let σ_{ij} denote the *Stirling numbers of the second kind*, i.e., the number of partitions of the set $\{1, \ldots, i\}$ into j pairwise disjoint nonempty subsets (see, e.g., [St86]). In addition, let $\sigma_{00} = 1$, $\sigma_{i0} = 0$ for all $i > 0$ and $\sigma_{ij} = 0$

whenever $i < j$. Note that $j!\sigma_{ij}$ is the number of surjective mappings of $\{1,\dots,i\}$ into $\{1,\dots,j\}$; hence, it follows that

$$j^i = \sum_{k=0}^{\infty} \sigma_{ik} k! \left(\begin{array}{c} j \\ k \end{array} \right) = \sum_{k=0}^{\infty} \sigma_{ik} j(j-1)\cdot\ldots\cdot(j-k+1), \tag{1.6}$$

and, in particular,

$$\sigma_{ij} \le \frac{j^i}{j!}.$$

Thus, with the notation $(x)_k = x(x-1)(x-2)\cdot\ldots\cdot(x-k+1)$, the identity

$$x^i = \sum_{k=0}^{\infty} \sigma_{ik} (x)_k$$

holds for all integers $x = 0,\dots,i$ and hence holds for all $x \in \mathbb{R}$. Let

$$L = (\sigma_{ij})_{i,j\in\mathbb{N}_0}, \quad U = \left(\begin{array}{c} j \\ i \end{array} \right)_{i,j\in\mathbb{N}_0}, \quad \text{and} \quad D = \operatorname{diag}(0!, 1!, 2!, \dots).$$

Then L and U are an (infinite) lower and upper triangular matrix, respectively, and (1.6) can be written as

$$M = LDU.$$

Left multiplication by $L^{-1} = (s_{ij})_{i,j\in\mathbb{N}_0}$ yields

$$x(x-1)\cdot\ldots\cdot(x-i+1) = \sum_{k=0}^{\infty} s_{ik} x^k.$$

Hence, s_{ij} has sign $(-1)^{i-j}$ (for $j \le i$) and, evaluating the above identity for $x = -1$ yields

$$\sum_{j=0}^{i} |s_{ij}| = i!.$$

The numbers s_{ij} are called the *Stirling numbers of the first kind.* From

$$x^j = \sum_{i=0}^{\infty} \left(\begin{array}{c} j \\ i \end{array} \right) (x-1)^i \quad \text{and} \quad (x-1)^j = \sum_{i=0}^{\infty} \left(\begin{array}{c} j \\ i \end{array} \right) (-1)^{j-i} x^i,$$

we conclude for the inverse $U^{-1} = (w_{ij})_{i,j\in\mathbb{N}_0}$ of U that

$$w_{ij} = (-1)^{j-i} \binom{j}{i}.$$

Now, note that

$$\big(L^{(r)}\big)^{-1} = \big(L^{-1}\big)^{(r)}, \quad \big(D^{(r)}\big)^{-1} = \big(D^{-1}\big)^{(r)}, \quad \big(U^{(r)}\big)^{-1} = \big(U^{-1}\big)^{(r)}$$
$$\text{and} \quad M^{(r)} = L^{(r)} D^{(r)} U^{(r)}.$$

Hence,

$$B^{(r)} = \big(U^{(r)}\big)^{-1}\big(D^{(r)}\big)^{-1}\big(L^{(r)}\big)^{-1} = \big(U^{-1}\big)^{(r)}\big(D^{-1}\big)^{(r)}\big(L^{-1}\big)^{(r)},$$

and this reads explicitly as

(1.7)
$$b_{ij}^{(r)} = \sum_{k=0}^{r-1}(-1)^{k-i}\binom{k}{i}\frac{1}{k!}s_{kj} = (-1)^{i+j}\sum_{k=0}^{r-1}\binom{k}{i}\frac{1}{k!}|s_{kj}| \qquad (i,j=0,\dots,r-1).$$

This implies that for any $m \in \{0,\dots,r-1\}$,

$$\sum_{i=0}^{r-1}|b_{im}^{(r)}| = \sum_{i=0}^{r-1}\sum_{k=0}^{r-1}\binom{k}{i}\frac{|s_{km}|}{k!} \le \sum_{k=0}^{r-1}2^k\frac{|s_{km}|}{k!} < 2^r. \tag{1.8}$$

We conclude the univariate case with an additional technical estimate that is needed in section 3. It gives an upper bound on the error induced by using only $B^{(r)}$ (for some $r \le n$) rather than the full matrix $B^{(n+1)}$ in the computation of the coefficients of a polynomial of degree n.

Let, for $i,j \in \mathbb{N}_0$ with $j < r$,

$$d_{ij} = \sum_{k=0}^{r-1} b_{kj}^{(r)}k^i.$$

Clearly $d_{ij} = \delta_{ij}$ for $i < r$. For $i \ge r$, combining (1.6) and (1.7) yields

$$\begin{aligned}\left|\sum_{k=0}^{r-1} b_{kj}^{(r)}k^i\right| &= \left|\sum_{k=0}^{r-1}\left(\sum_{p=0}^{r-1}(-1)^{p-k}\binom{p}{k}\frac{1}{p!}s_{pj}\right)\left(\sum_{q=0}^{\infty}\sigma_{iq}q!\binom{k}{q}\right)\right| \\ &= \left|\sum_{p=0}^{r-1}\sum_{q=0}^{r-1}s_{pj}\sigma_{iq}\frac{q!}{p!}(-1)^{q-p}\left(\sum_{k=0}^{r-1}(-1)^{k-q}\binom{k}{q}\binom{p}{k}\right)\right| \\ &\le \sum_{p=0}^{r-1}|s_{pj}|\sigma_{ip} \le \sum_{p=0}^{r-1}p^i \le r^i.\end{aligned} \tag{1.9}$$

Let us close this section with a few brief remarks about the general multivariate case. Let, for $n,s \in \mathbb{N}$,

$$Y_{n,s} = \big\{y = (m_1,\dots,m_s) \in (\mathbb{N}_0)^s : \sum_{i=1}^{s} m_i = n\big\}.$$

Clearly,

$$N = |Y_{n,s}| = \binom{n+s-1}{n}.$$

Suppose that the elements of $Y_{n,s}$ are ordered (for instance lexicographically) so that $Y_{n,s} = \{y_1,\dots,y_N\}$, where $y_j = (m_{j,1},\dots,m_{j,s})$. Now we want to determine the coefficients of a homogeneous multivariate polynomial

$$q(x_1,\dots,x_s) = \sum_{j=1}^{N} c_j x_1^{m_{j,1}} \cdot \ldots \cdot x_s^{m_{j,s}}$$

from its function values. So, we have to choose N interpolation points in such a way that the $N \times N$ matrix

$$\left((\xi_1^{(i)})^{m_{j,1}} \cdot (\xi_2^{(i)})^{m_{j,2}} \cdot \ldots \cdot (\xi_s^{(i)})^{m_{j,s}} \right)_{i,j=1,\ldots,N},$$

a higher-dimensional analogue of the classical Vandermonde matrix, is nonsingular. (Note that, as opposed to the univariate case, it does not suffice to choose the N points mutually different.) Sufficient conditions for nonsingularity can be found in [CY77]; see also [Ol86]. In particular, one may take an $(s-1)$-dimensional simplex $S = \operatorname{conv}\{z_1, \ldots, z_s\}$ in $\mathbb{R}^s$ and choose $\xi^{(k_1,\ldots,k_s)} = \frac{1}{n} \sum_{j=1}^{s} k_j z_j$, where $(k_1, \ldots, k_s) \in Y_{n,s}$.

This implies, in particular, that when the dimension n is *fixed*, there is a polynomial-time algorithm which, given $s \in \mathbb{N}$ and ($\mathcal{V}$- or $\mathcal{H}$-) polytopes $P_1, \ldots, P_s$, computes all mixed volumes $V(P_{i_1}, \ldots, P_{i_n})$.

2. Deterministic algorithms. The present section discusses the problem of computing or approximating (mixed) volumes by means of deterministic algorithms. In particular we give results that focus on the difference of volume versus mixed volume computation.

2.1. Computing the volume of zonotopes. In this subsection we deal with the following problem.

VOLUME-OF-ZONOTOPES.

Given an $\mathcal{S}$-zonotope $Z = (n, s; c; z_1, \ldots, z_s)$, compute its volume.

Note that the problem asks for $\operatorname{vol}_n(Z)$, where $Z = c + \sum_{i=1}^{s} [0,1] z_i$. Since the volume is translation invariant, we can always assume that $c = 0$. Now, let A denote the $n \times s$ matrix with columns $z_1, \ldots, z_s$ and let $\mathcal{J}$ denote the family of all subsets I of $\{1, \ldots, s\}$ of cardinality n. Then (1.3) can be written in the form

$$\operatorname{vol}_n(Z) = \sum_{I \in \mathcal{J}} |\det B_I|,$$

where B_I is the $n \times n$-minor of A whose columns correspond to I. It is clear that for constant n or constant $s-n$, the number $\binom{s}{n}$ of $n \times n$ subdeterminants is polynomially bounded, whence the volume of zonotopes can be computed in polynomial time. The general case is, however, #$\mathbb{P}$-hard.

THEOREM 1. *VOLUME-OF-ZONOTOPES is #$\mathbb{P}$-hard.*

Proof. The proof will use a reduction of the following #$\mathbb{P}$-complete problem.

#SUBSET-SUM (see [GJ79], [Jo90]). *Given positive integers m, $\alpha_1, \ldots, \alpha_m$, and α, determine the number of different subsets J of $\{1, \ldots, m\}$ such that $\sum_{j \in J} \alpha_j = \alpha$.*

So, suppose $(m; \alpha_1, \ldots, \alpha_m, \alpha)$ is an instance of #SUBSET-SUM, and let $n = m+2$ and $s = 2m + 3$. Further, define

$$\begin{aligned}
z_{2k-1} &= e_k + \alpha_k e_{m+2}, && k = 1, \ldots, m;\\
z_{2k} &= e_k, && k = 1, \ldots, m+1;\\
z_{2m+1} &= e_{m+1} - \alpha e_{m+2};\\
z_{2m+3}^{\delta} &= -\sum_{i=1}^{m+1} e_i + \delta e_{m+2}, && \delta \in \{-1, 0, 1\},
\end{aligned}$$

where $e_1, \ldots, e_n$ denote again the standard basis vectors of $\mathbb{R}^n$, and set

$$Z_\delta = \sum_{i=1}^{s-1} [0,1] z_i + [0,1] z_s^{\delta}.$$

Suppose now that there is a polynomial-time algorithm $\mathcal{A}$ for solving the problem VOLUME-OF-ZONOTOPES, and apply $\mathcal{A}$ to compute $\mathrm{vol}_n(Z_{-1}) - 2\mathrm{vol}_n(Z_0) + \mathrm{vol}_n(Z_1)$. In terms of the determinant formula, this means that we are only interested in those $n \times n$ submatrices B_I of the $n \times s$ matrix

$$A_\delta = \begin{pmatrix} 1 & 1 & 0 & 0 & 0 & 0 & \dots & 0 & 0 & 0 & 0 & -1 \\ 0 & 0 & 1 & 1 & 0 & 0 & \dots & 0 & 0 & 0 & 0 & -1 \\ 0 & 0 & 0 & 0 & 1 & 1 & \dots & 0 & 0 & 0 & 0 & -1 \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & & \vdots & \vdots & \vdots & \vdots & \vdots \\ 0 & 0 & 0 & 0 & 0 & 0 & \dots & 1 & 1 & 0 & 0 & -1 \\ 0 & 0 & 0 & 0 & 0 & 0 & \dots & 0 & 0 & 1 & 1 & -1 \\ \alpha_1 & 0 & \alpha_2 & 0 & \alpha_3 & 0 & \dots & \alpha_m & 0 & -\alpha & 0 & \delta \end{pmatrix}$$

which depend on δ. Then, clearly, B_I has to contain the last column z^δ_{2m+3} of A_δ, and in choosing the remaining $m+1$ columns, we have to select exactly one vector from each pair z_{2k-1}, z_{2k} $(k = 1, \dots, n-1)$. Therefore, the summands $|\det B_I|$ of the determinantal expansion of $\mathrm{vol}_n(Z_\delta)$ which are depending on δ are in one-to-one correspondence with the subsets J of $\{1, \dots, m+1\}$ via

$$j \in J \Longleftrightarrow 2j - 1 \in I.$$

From this it follows easily that there is an integer κ that depends only on $\alpha_1, \dots, \alpha_m$ and α but not on δ such that

$$\mathrm{vol}_n(Z_\delta) = \kappa + \sum_{J \subset \{1,\dots,m+1\}} |\delta + \sum_{i \in J} \alpha_j|,$$

where, for notational consistency, $\alpha_{m+1} = -\alpha$. Then,

$$\mathrm{vol}_n(Z_{-1}) - 2\mathrm{vol}_n(Z_0) + \mathrm{vol}_n(Z_1) = \sum_{J \subset \{1,\dots,m+1\}} \left(\Big|-1 + \sum_{j \in J} \alpha_j\Big| - 2\Big|\sum_{j \in J} \alpha_j\Big| + \Big|1 + \sum_{j \in J} \alpha_i\Big| \right).$$

Since for any nonzero integer γ,

$$|-1+\gamma| - 2|\gamma| + |1+\gamma| = 0,$$

it follows that

$$\frac{1}{2}\Big(\mathrm{vol}_n(Z_{-1}) - 2\mathrm{vol}_n(Z_0) + \mathrm{vol}_n(Z_1)\Big) = \Big|\big\{J \subset \{1, \dots, m+1\} : \sum_{j \in J} \alpha_i = 0\big\}\Big|.$$

But

$$\sum_{j \in J} \alpha_i = 0 \quad \text{if and only if} \quad m+1 \in J \quad \text{and} \quad \sum_{j \in J \cap \{1,\dots,m\}} \alpha_j = \alpha,$$

whence $\mathcal{A}$ gives rise to a polynomial-time algorithm for #SUBSET-SUM. □

Theorem 1 proves the #$\mathbb{P}$-hardness of evaluating $\sum_{I \in \mathcal{J}} |\det B_I|$. This result is in striking contrast to the fact that by the *Binet–Cauchy formula* (see, e.g., [BS83]),

$$\sum_{I \in \mathcal{J}} (\det B_I)^2 = \det(AA^T), \tag{2.1}$$

whence the sum of the *squares* of all $n \times n$ subdeterminants can be evaluated in polynomial time.

Note, further, that Proposition 1 can be applied to $\mathcal{S}$-zonotopes since it is standard fare to derive a well presentation for an $\mathcal{S}$-zonotope. So there is a polynomial-time randomized algorithm for VOLUME-OF-ZONOTOPES. Zonotopes come, however, with an additional structure (and in particular, with a natural dissection into parallelotopes) so it is conceivable that there are faster randomized algorithms for zonotopes than there are for general well-presented convex bodies. This question is, however, open.

For an easiness result complementing Theorem 1 see Theorem 6, and for an application of VOLUME-OF-ZONOTOPES to a problem in the oil industry see subsection 4.3.

We will now draw the first of a few consequences of Theorem 1 and prove a result that is relevant in subsection 2.4.

THEOREM 2. *The following problem VOLUME-OF-SUM-OF-ELLIPSOIDS is $\#\mathbb{P}$-hard: given $s, n \in \mathbb{N}$, nonsingular rational $(n \times n)$-matrices $A_1, \ldots, A_s$, an error bound $\epsilon \in \mathbb{Q}$, $\epsilon > 0$, compute a rational number $\hat{V}$ which satisfies*

$$\left| \hat{V} - \mathrm{vol}_n(E_1 + E_2 + \cdots + E_s) \right| < \epsilon,$$

where E_i is the ellipsoid $E_i = \{x \in \mathbb{R}^n : x^T A_i^T A_i x \leq 1\}$.

Proof. Let $(n, s; c; z_1, \ldots, z_s)$ be an instance of VOLUME-OF-ZONOTOPES and set $Z = \sum_{i=1}^{s} [-1, 1] z_i$. Note that

$$\mathrm{vol}_n(Z) = 2^n \mathrm{vol}_n \left(c + \sum_{i=1}^{s} [0, 1] z_i \right),$$

whence it suffices to show how the computation of $\mathrm{vol}_n(Z)$ can be reduced to a suitable instances of VOLUME-OF-SUM-OF-ELLIPSOIDS.

For each $i = 1, \ldots, s$ we compute first an orthogonal basis $\{v_{i,1}, \ldots, v_{i,n}\}$ of $\mathbb{R}^n$ such that $v_{i,1} = z_i$. Let B_i be the $n \times n$-matrix with rows $v_{i,1}^T, \ldots, v_{i,n}^T$, set for $\mu \in \mathbb{N}$,

$$D_i^\mu = \mathrm{diag}\left(\frac{1}{\langle z_i, z_i \rangle}, \frac{\mu}{\langle v_{i,2}, v_{i,2} \rangle}, \ldots, \frac{\mu}{\langle v_{i,n}, v_{i,n} \rangle} \right),$$

and define the ellipsoid

$$E_i^\mu = \{x \in \mathbb{R}^n : x^T (D_i^\mu B_i)^T (D_i^\mu B_i) x \leq 1\}.$$

Then we have

$$[-1, 1] z_i \subset E_i^\mu \subset [-1, 1] z_i + \frac{1}{\mu} \sum_{j=2}^{n} [-1, 1] v_{i,j}.$$

Now, let $Z' = \sum_{i=1}^{s} \sum_{j=2}^{n} [-1, 1] v_{i,j}$, and let $R \in \mathbb{N}$ such that $Z \cup Z' \subset RC_n$, where C_n denotes again the standard unit cube. Then the above inclusions yield

$$Z \subset E_1^\mu + E_2^\mu + \cdots + E_s^\mu \subset Z + \frac{1}{\mu} Z' \subset Z + \frac{R}{\mu} C_n.$$

Now note that for any $\lambda > 0$,

$$\mathrm{vol}_n(Z + \lambda C_n) - \mathrm{vol}_n(Z) = \sum_{i=1}^{n} \binom{n}{i} V(\overbrace{Z, \ldots, Z}^{n-i}, \overbrace{C_n, \ldots, C_n}^{i}) \lambda^i,$$

and this implies that

$$\mathrm{vol}_n(E_1^\mu + \cdots + E_s^\mu) - \mathrm{vol}_n(Z) \le \sum_{i=1}^{n} \binom{n}{i} V(\overbrace{Z,\ldots,Z}^{n-i}, \overbrace{C_n,\ldots,C_n}^{i}) \left(\frac{R}{\mu}\right)^i \le \frac{(4R)^n}{\mu}.$$

Hence, if for $\mu_0 = \lceil \frac{2}{\epsilon}(4R)^n \rceil$ the volume of $E_1^{\mu_0} + \cdots + E_s^{\mu_0}$ is approximated to absolute error $\frac{\epsilon}{2}$, we obtain an estimate of $\mathrm{vol}_n(Z)$ to absolute error ϵ. Further, it follows from (1.3) that $size(\mathrm{vol}_n(Z))$ is bounded by a polynomial in the input size. Therefore, it suffices to approximate $\mathrm{vol}_n(Z)$ to a sufficiently small absolute error ϵ whose size is polynomially bounded and then perform the usual rounding (with continued fractions) in order to obtain $\mathrm{vol}_n(Z)$ precisely.

Finally note that all constructions and computations can be done in polynomial time; this completes the transformation. □

2.2. Mixed volumes of paralellotopes. We give some hardness results for computing mixed volumes of parallelotopes. The first involves axes-parallel parallelotopes which (for brevity) will be called *boxes*.

Before we state the result we need two lemmas.

LEMMA 1. *Let the entries of* $A = (\alpha_{ij})_{i,j=1,2,,\ldots,n}$ *be nonnegative rationals, and for* $i = 1,\ldots,n$ *set* $Z_i = \sum_{j=1}^{n} [0, \alpha_{ij}] e_j$. *Then*

$$n! V(Z_1,\ldots,Z_n) = \mathrm{per}(A),$$

where $\mathrm{per}(A)$ *denotes the permanent of* A.

Proof. Note that the Z_i are all boxes, and so is $\sum_{i=1}^{n} \lambda_i Z_i$ for each n-tuple $(\lambda_1,\ldots,\lambda_n)$ of nonnegative reals. Hence,

$$\mathrm{vol}_n\left(\sum_{i=1}^{n} \lambda_i Z_i\right) = \mathrm{vol}_n\left(\sum_{j=1}^{n} \left[0, \sum_{i=1}^{n} \lambda_i \alpha_{ij}\right] e_j\right) = \prod_{j=1}^{n} \left(\sum_{i=1}^{n} \lambda_i \alpha_{ij}\right).$$

Comparing the coefficients of $\lambda_1 \cdot \lambda_2 \cdot \ldots \cdot \lambda_n$ we see that

$$V(Z_1,\ldots,Z_n) = \frac{1}{n!} \sum_{j_1=1}^{n} \cdots \sum_{j_n=1}^{n} \epsilon_{j_1,\ldots,j_n} \alpha_{1,j_1} \cdot \ldots \cdot \alpha_{n,j_n},$$

where

$$\epsilon_{j_1,\ldots,j_n} = \begin{cases} 1 & \text{if } j_1,\ldots,j_n \text{ is a permutation of } 1,2,\ldots,n, \\ 0 & \text{otherwise,} \end{cases}$$

and this proves the assertion. □

The problem of computing the permanent of 0-1-matrices is known to be #ℙ-complete [Va77]; see also [Va79], [Br86], [JS89], [LS90], [KKLLL93]. Hence, Lemma 1 implies that the problem of computing the mixed volume $V(Z_1,\ldots,Z_n)$ of n faces Z_i of the cube $[0,1]^n$ is also #ℙ-complete. (Note, on the positive side, that in view of Lemma 1, Theorem 11 yields a randomized polynomial-time algorithm for estimating the permanent of certain classes of matrices.) In order to extend this result to *proper* boxes, observe that if we replace the 0-entries of a given 0-1-matrix B by a parameter α to obtain an α-1-matrix B_α, then $\mathrm{per}(B_\alpha)$ is a polynomial in α; evaluation of this polynomial for $n+1$ different values of α (or for one sufficiently small value

of α) allows us to compute its constant term $\mathrm{per}(B)$. In order to prove the sharper statement of Theorem 3, we use the following strengthening of [Va77]'s hardness result to the permanent of α-β-matrices with prescribed α and β.

LEMMA 2. *The following problem is $\#\mathbb{P}$-hard for any pair α, β of (fixed) distinct rationals: given a positive integer n, and an $n \times n$ matrix A with entries α, β, compute* $\mathrm{per}(A)$.

Proof. We may assume that $\beta = \alpha + 1$ and $\alpha \neq 0$. Let $B = (b_{ik})_{i,k=1,\ldots,n}$ be an arbitrary 0-1-matrix. We will reduce the computation of $\mathrm{per}(B)$ to the computation of the permanent of several matrices with $\alpha, \alpha + 1$ entries.

Let G denote the bipartite graph on $2n$ vertices whose adjacency matrix is B, and for $k = 1, \ldots, n$ let M_k be the number of matchings of size k in G. We want to compute $M_n = \mathrm{per}(B)$. For $j = 0, \ldots, n$ let $X^{(j)} = (x_{ik}^{(j)})$, denote the $(n+j) \times (n+j)$ matrix with entries

$$x_{ik}^{(j)} = \begin{cases} \alpha + b_{ik} & \text{for } i, k = 1, \ldots, n; \\ \alpha & \text{otherwise.} \end{cases}$$

Clearly, $X^{(j)}$ has only entries $\alpha, \alpha + 1$; whence using an oracle for evaluating the permanent of matrices with $\alpha, \alpha+1$ entries $n+1$ times, we can determine the permanents of all the $X^{(j)}$. On the other hand, we have

$$\sum_{k=0}^{n} M_k (n - k + j)! \alpha^{n-k+j} = \mathrm{per}(X^{(j)}) \qquad (j = 0, \ldots, n). \tag{2.2}$$

To see this, regard α as an indeterminate, and expand $\mathrm{per}(X^{(j)})$ as a polynomial in α. Then the terms contributing to the coefficient of α^{n-k+j} arise as follows. For every k-matching in G we obtain a product $(\alpha + 1)^k$, and this can be completed in $(n - k + j)!$ ways to give a lowest term α^{n-k+j}. We do this by selecting the α term from the product of monomials (either α or $\alpha + 1$) represented by any matching on the complete bipartite graph induced by the remaining $n - k + j$ rows and columns.

Therefore, if the above system (2.2) of linear equations is nonsingular, we can solve it for M_n, and this establishes the $\#\mathbb{P}$-hardness result.

To see that (2.2) is indeed nonsingular, let us rewrite the system as follows:

$$\sum_{k=0}^{n} \binom{k+j}{j} (k! \alpha^k M_{n-k}) = \frac{j! \, \mathrm{per}(X^{(j)})}{\alpha^j} \qquad (j = 0, \ldots, n).$$

Introducing the new variables $y_k = k! \alpha^k M_{n-k}$, the question now reduces to deciding whether the $(n + 1) \times (n + 1)$ matrix C with entries $c_{kj} = \binom{k+j}{j}$ is nonsingular. But this follows easily from the Vandermonde identity

$$\sum_{r=0}^{n} \binom{k}{r} \binom{j}{r} = \binom{k+j}{j} \quad \text{for } k, j \leq n,$$

since $C = UU^T$, where U is the lower triangular matrix with entries $u_{ij} = \binom{i}{j}$ which has all its diagonal elements 1. ∎

Now we can prove Theorem 3.

THEOREM 3. *Let α, β be (fixed) distinct positive rationals. Then the following restriction of MIXED-VOLUME-OF-BOXES is $\#\mathbb{P}$-hard: given $n \in \mathbb{N}$, and for $i, j =$*

$1, 2, , \ldots, n$, *an element* $\alpha_{i,j}$ *of* $\{\alpha, \beta\}$, *compute the mixed volume* $V(Z_1, \ldots, Z_n)$ *for the proper boxes* $Z_i = \sum_{j=1}^{n} [0, \alpha_{i,j}] e_j$, $(i = 1, \ldots, n)$.

Proof. The result is a simple consequence of Lemmas 1 and 2. □

Theorem 3 implies directly the "instability" result that, while the case of $\epsilon = 0$ is trivial, it is #ℙ-hard for any $\epsilon > 0$ to compute the mixed volume of n proper boxes, all containing the unit cube C_n and all being contained in the cube $(1 + \epsilon)C_n$.

Note that MIXED-VOLUME-OF-BOXES can be solved in polynomial time if the number s of different boxes is bounded beforehand. In this case there are only $O(n^{s-1})$ different mixed volumes, and they can all be computed by the approach of subsection 1.3 (see [GK94, subsection 4.1]), since their Minkowski sum is a box whose volume can be computed easily. We will show, however, that the corresponding problem for just two proper rectangular parallelotopes is #ℙ-hard if they are not both required to be axes-parallel.

THEOREM 4. *The following problem is* #ℙ*-hard: given* $n \in \mathbb{N}$, $m \in \{0, \ldots, n\}$, $\alpha_1, \ldots, \alpha_n \in \mathbb{N}$, *and integer vectors* $y_1, \ldots, y_n$ *which form an orthogonal basis of* $\mathbb{R}^n$, *compute* $V(\overbrace{Z_1, \ldots, Z_1}^{n-m}, \overbrace{Z_2, \ldots, Z_2}^{m})$, *where* $Z_1 = \sum_{i=1}^{n} [0, 1] y_i$ *and* $Z_2 = \sum_{i=1}^{n} [0, \alpha_i] e_i$.

Proof. We use the problem VOLUME-OF-ZONOTOPES of Theorem 1 for a reduction. Let $Z = (n, s; c, z_1, \ldots, z_s)$ be an $\mathcal{S}$-zonotope. We may assume without loss of generality that $z_1, \ldots, z_s \in \mathbb{Z}^n$, that $s > n$, and that Z is proper. Now, let A denote the $n \times s$ matrix with columns $z_1, \ldots, z_s$. Since, by (1.3), elementary row operations to A do not change the volume of the zonotope generated by the columns of A, we may further assume that the rows $v_1, \ldots, v_n$ of A are orthogonal.

Let $\{v_{n+1}, \ldots, v_s\} \subset \mathbb{Q}^s$ be an orthogonal basis of the orthogonal complement of the linear hull of $\{v_1, \ldots, v_n\}$ such that the sizes of $v_{n+1}, \ldots, v_s$ are bounded by a polynomial in $size(Z)$. Note that such a basis can be computed essentially by solving a system of linear equations. Let B denote the $s \times s$ matrix that is obtained from A by augmenting the rows $v_{n+1}, \ldots, v_s$, and let $y_1, \ldots, y_s$ be the column vectors of B. Since the rows of A are orthogonal, so are the columns. Hence,

$$Z_1 = \sum_{i=1}^{s} [0, 1] y_i$$

is a proper rectangular parallelotope in $\mathbb{R}^s$. Set, further,

$$C = \sum_{i=n+1}^{s} [0, 1] e_i, \qquad \text{and for } 0 < \mu < 1, \quad Z_2^{\mu} = C + \mu \sum_{i=1}^{n} [0, 1] e_i.$$

By Proposition 2, applied with $U = \{0\}^n \times \mathbb{R}^{s-n}$ (and hence $U^{\perp} = \mathbb{R}^n \times \{0\}^{s-n}$), we obtain

$$\binom{s}{n} V(\overbrace{Z_1, \ldots, Z_1}^{n}, \overbrace{C, \ldots, C}^{s-n}) = \mathrm{vol}_n(Z),$$

and this gives already an #ℙ-hardness result for the case that one of the parallelotopes is permitted to be lower dimensional. To complete the proof of Theorem 4, observe that (by (1.4))

$$V(\overbrace{Z_1, \ldots, Z_1}^{n}, \overbrace{Z_2^{\mu}, \ldots, Z_2^{\mu}}^{s-n}) = \sum_{i=0}^{s-n} \binom{s-n}{i} V(\overbrace{Z_1, \ldots, Z_1}^{n}, \overbrace{C, \ldots, C}^{s-n-i}, \overbrace{\hat{C}, \ldots, \hat{C}}^{i}) \mu^i,$$

where $\hat{C} = [0,1]^n \times \{0\}^{s-n}$. Since there is a positive integer R of size bounded by a polynomial in $size(Z)$ such that $Z_1 \subset R[0,1]^s$, it follows that

$$V(\overbrace{Z_1,\dots,Z_1}^{n},\overbrace{C,\dots,C}^{s-n}) \le V(\overbrace{Z_1,\dots,Z_1}^{n},\overbrace{Z_2^{\mu},\dots,Z_2^{\mu}}^{s-n}) \le V(\overbrace{Z_1,\dots,Z_1}^{n},\overbrace{C,\dots,C}^{s-n}) + 2^{s-n}R^n\mu.$$

Now, let μ_0 be a positive rational of size bounded by a polynomial in the input size such that $1/\mu_0 > 2 \cdot 2^{s-n}R^n\binom{s}{n}$, and set $Z_2 = Z_2^{\mu_0}$. Then Z_2 is a proper rectangular parallelotope, and

$$\left|\mathrm{vol}_n(Z) - \binom{s}{n} V(\overbrace{Z_1,\dots,Z_1}^{n},\overbrace{Z_2,\dots,Z_2}^{s-n})\right| < \frac{1}{2}.$$

Since $\mathrm{vol}_n(Z)$ is an integer, this shows that it suffices to compute the mixed volume $V(\overbrace{Z_1,\dots,Z_1}^{n},\overbrace{Z_2,\dots,Z_2}^{n-s})$ in order to obtain $\mathrm{vol}_n(Z)$. To conclude the transformation just apply a suitable scaling to make μ_0 integer. □

As a simple consequence of Theorem 4 we can derive a sharpening of Theorem 1.

THEOREM 5. *The following problem is #ℙ-hard: given $n \in \mathbb{N}$, and two n-tuples $v_1,\dots,v_n$ and $w_1,\dots,w_n$ of integer vectors that form orthogonal bases of $\mathbb{R}^n$, compute the volume of the Minkowski sum*

$$\mathrm{vol}_n\left(\left(\sum_{i=1}^{n}[0,1]v_i\right) + \left(\sum_{j=1}^{n}[0,1]w_j\right)\right).$$

Proof. Let $Z_1 = \sum_{i=1}^{n}[0,1]v_i$ and $Z_2 = \sum_{j=1}^{n}[0,1]w_j$. For the proof of the theorem, just note that all mixed volumes of Z_1 and Z_2 can be computed by the method indicated in subsection 1.3 by evaluating $\mathrm{vol}_n(Z_1 + \xi Z_2)$ for $n+1$ mutually disjoint interpolation points $\xi_0,\dots,\xi_n$, and apply Theorem 4. □

2.3. Easiness of mixed volume computation. The results of the previous subsection show that mixed volume computation is in general at least as hard as any problem in #ℙ. The present subsection addresses the question of whether computing mixed volumes is possibly even harder.

As shown in [DF88], using any oracle which solves some #ℙ-complete problem in constant time, the volume of a $\mathcal{V}$-polytope can be computed in polynomial time; this is stated by saying that volume computation for $\mathcal{V}$-polytopes is #ℙ-*easy*.

$\mathcal{H}$-presented polytopes come with the additional difficulty that the size of their volume is not bounded by a polynomial in the input size. An example was given by [La91], showing that there is no polynomial-space algorithm for *exact* computation of the volume of $\mathcal{H}$-polytopes. However, approximation to any positive rational absolute error ϵ is again #ℙ-easy for $\mathcal{H}$-polytopes, [DF88].

It is clear from section 1.3 (see also [GK94]) that the easiness results for computing or approximating the volume can be extended to mixed volumes if the number s of sets under consideration is bounded beforehand. If, however, s is part of the input the number of volume computations needed for the numerical differentiation approach to compute a single mixed volume cannot be bounded by a polynomial in n and s. The

reason is that this method "essentially" computes all mixed volumes at once and their number is exponential.

We will show in the following, however, that even in this general case computation (for $\mathcal{V}$-polytopes or $\mathcal{S}$-zonotopes) or approximation (for $\mathcal{H}$-polytopes) of any single mixed volume is $\#\mathbb{P}$-easy. We begin with the easier case of $\mathcal{S}$-zonotopes.

THEOREM 6. *Let Π be any $\#\mathbb{P}$-complete problem. Then any oracle $\mathcal{O}_\Pi$ for solving Π can be used to produce an algorithm that runs in time that is oracle-polynomial in the input size for solving the following problem:*

Instance: *$n, s \in \mathbb{N}$, and $m_1, \ldots, m_s \in \mathbb{N}$ such that $\sum_{i=1}^s m_i = n$, $\mathcal{S}$-zonotopes $Z_i = (n, s_i; c_i; z_{i,1}, \ldots, z_{i,s_i})$, for $i = 1, \ldots, s$.*

Task: *Compute the mixed volume*

$$V(\overbrace{Z_1, \ldots, Z_1}^{m_1}, \overbrace{Z_2, \ldots, Z_2}^{m_2}, \ldots, \overbrace{Z_s, \ldots, Z_s}^{m_s}).$$

Proof. The proof reduces the problem to the task of approximating the volume of a (typically nonconvex) finite union of parallelotopes.

For $i \in S = \{1, \ldots, s\}$, let $J_i = \{(i,1), \ldots, (i, s_i)\}$, set $J = J_1 \cup \cdots \cup J_s$, and

$$\mathcal{J}_{m_1,\ldots,m_s} = \{I \subset J : |I \cap J_i| = m_i, \text{ for } i \in S\}.$$

Further, let $r = \sum_{i=1}^s s_i$, and let A denote the $n \times r$ matrix

$$A = (z_{1,1}, \ldots, z_{1,s_1}, \ldots, z_{s,1}, \ldots, z_{s,s_s}).$$

Then it is easy to see, by expanding $\mathrm{vol}_n(\sum_{i=1}^s \lambda_i Z_i)$, that

$$\binom{n}{m_1, \ldots, m_s} V(\overbrace{Z_1, \ldots, Z_1}^{m_1}, \ldots, \overbrace{Z_s, \ldots, Z_s}^{m_s}) = \sum_{I \in \mathcal{J}_{m_1,\ldots,m_s}} |\det B_I|, \tag{2.3}$$

where B_I denotes the $n \times n$ submatrix of A with column indices in I, and $\binom{n}{m_1,\ldots,m_s}$ is the usual multinomial coefficient, i.e.,

$$\binom{n}{m_1, \ldots, m_s} = \frac{n!}{m_1! \cdot \ldots \cdot m_s!}.$$

To prove the theorem, we will now interpret (2.3) geometrically. In fact, let

$$Z = \sum_{(i,j) \in J} [0,1] z_{i,j},$$

and let again $\mathcal{J}$ denote the family of all subsets I of J of cardinality n. Using a simple inductive argument (with respect to r), we see that there is a subset $\mathcal{I}$ of $\mathcal{J}$ and that there are vectors p_I $(I \in \mathcal{I})$ such that the parallelotopes

$$P_I = p_I + \sum_{i \in I} [0,1] z_i \qquad (I \in \mathcal{I})$$

form a dissection of Z into proper parallelotopes; see [Sh74]. Further, for each $x \in Z \cap \mathbb{Q}^n$, a subset $I \in \mathcal{I}$ with $x \in P_I$ can be found in time bounded by a polynomial in $size(Z)$ and $size(x)$. Note that these parallelotopes are in one-to-one correspondence with the nonsingular matrices B_I with $I \in \mathcal{J}$. Hence, with $Z_{m_1,\ldots,m_s} = \bigcup_{I \in \mathcal{J}_{m_1,\ldots,m_s}} P_I$, we have

$$\binom{n}{m_1, \ldots, m_s} V(\overbrace{Z_1, \ldots, Z_1}^{m_1}, \ldots, \overbrace{Z_s, \ldots, Z_s}^{m_s}) = \mathrm{vol}_n(Z_{m_1,\ldots,m_s}),$$

and membership in $Z_{m_1,\ldots,m_s}$ of a point $x \in \mathbb{Q}^n$ can be checked in polynomial time.

Now, let $R = \sum_{(i,j)\in J} \|z_{i,j}\|_\infty$, whence $Z \subset R[-1,1]^n$. Further, let ϵ be a positive rational, let

$$\alpha = \left\lceil \frac{2r^n n^2 (2R)^n}{\epsilon} \right\rceil, \quad \text{and} \quad \delta = \frac{R}{\alpha}.$$

For each integer vector $t = (\tau_1, \ldots, \tau_n)$, let

$$x_t = \delta \left(\tau_1 + \frac{1}{2}, \ldots, \tau_n + \frac{1}{2}\right)^T, \quad \text{and} \quad C_t = x_t + \frac{\delta}{2}[-1,1]^n.$$

For each x_t, membership in $Z_{m_1,\ldots,m_s}$ can be decided in polynomial time, so $\mathcal{O}_\Pi$ can be used to construct a counting machine that outputs the number N of integer vectors t for which $x_t \in Z_{m_1,\ldots,m_s}$. So, if ν is the number of cubes C_t that intersect the boundary of $Z_{m_1,\ldots,m_s}$, we have

$$|N\delta^n - \mathrm{vol}_n(Z_{m_1,\ldots,m_s})| \le \nu\delta^n.$$

It is readily seen that each facet of any Z_I ($I \in \mathcal{J}_{m_1,\ldots,m_s}$) is intersected by at most $2n(2\alpha)^{n-1}$ such cubes, whence (after some standard calculations)

$$|N\delta^n - \mathrm{vol}_n(Z_{(m_1,\ldots,m_s)})| \le 4r^n n^2 (2\alpha)^{n-1}\delta^n \le \epsilon \le \binom{n}{m_1,\ldots,m_s}\epsilon.$$

Therefore,

$$\left| V(\overbrace{Z_1,\ldots,Z_1}^{m_1},\ldots,\overbrace{Z_s,\ldots,Z_s}^{m_s}) - N\delta^n \binom{n}{m_1,\ldots,m_s}^{-1} \right| \le \epsilon.$$

Now, $size(\mathrm{vol}_n(Z_{m_1,\ldots,m_s}))$ is bounded above by a polynomial in the size of the input. So a suitable choice of ϵ and subsequent rounding yields $V(\overbrace{Z_1,\ldots,Z_1}^{m_1},\ldots,\overbrace{Z_s,\ldots,Z_s}^{m_s})$ exactly. □

Note that as a corollary we see that VOLUME-OF-ZONOTOPES is #ℙ-easy.

THEOREM 7. *Let Π be any #ℙ-complete problem. Then any oracle $\mathcal{O}_\Pi$ for solving Π can be used to produce an algorithm that runs in time that is oracle-polynomial in the input size (including $size(\epsilon)$ in the second case) for solving the following problems:*

Instance 1: *$n, s \in \mathbb{N}$ and $m_1, \ldots, m_s \in \mathbb{N}$ such that $\sum_{i=1}^s m_i = n$, $\mathcal{V}$-polytopes $P_i = (n, n_i; v_{i,1}, \ldots, v_{i,n_i})$, for $i = 1, \ldots, s$.*

Task 1: *Compute the mixed volume*

$$V(\overbrace{P_1,\ldots,P_1}^{m_1},\overbrace{P_2,\ldots,P_2}^{m_2},\ldots,\overbrace{P_s,\ldots,P_s}^{m_s}).$$

Instance 2: *$n, s \in \mathbb{N}$ and $m_1, \ldots, m_s \in \mathbb{N}$ such that $\sum_{i=1}^s m_i = n$, $\mathcal{H}$-polytopes $P_i = (n, n_i; A_i, b_i)$, for $i = 1, \ldots, s$, a positive rational number ϵ.*

Task 2: *Compute a rational number $\hat{V}_{m_1,m_2,\ldots,m_s}$ such that*

$$\left| \hat{V}_{m_1,m_2,\ldots,m_s} - V(\overbrace{P_1,\ldots,P_1}^{m_1},\overbrace{P_2,\ldots,P_2}^{m_2},\ldots,\overbrace{P_s,\ldots,P_s}^{m_s}) \right| \le \epsilon.$$

Proof. For $\mathcal{V}$- or $\mathcal{H}$-polytopes it is not so clear (as it was for $\mathcal{S}$-zonotopes) that mixed volumes can be reduced to a volume computation, yet it is possible. The proof makes substantial use of a formula of [Sc94] (a generalization of [Be92]), and we will begin by restating [Sc94]'s approach.

For a polytope P in some $\mathbb{R}^m$ and an integer k with $0 \le k \le m$, let, as usual, $\mathcal{F}_k(P)$ denote the set of k-faces of P, and let $\mathcal{F}(P) = \bigcup_{k=0}^{m} \mathcal{F}_k(P)$. Further, for a face F of P, let $N(P,F)$ denote the cone of outer normals of P at F.

Now, let $P_1, \dots, P_s$ be polytopes in $\mathbb{R}^n$. Set $r = s \cdot n$ and

$$\tilde{P} = P_1 \times P_2 \times \cdots \times P_s \subset \overbrace{\mathbb{R}^n \times \mathbb{R}^n \times \cdots \times \mathbb{R}^n}^{s} = \mathbb{R}^r.$$

It is easy to see that

$$\mathcal{F}(\tilde{P}) = \{F_1 \times F_2 \times \cdots \times F_s \ : F_1 \in \mathcal{F}(P_1), \dots, F_s \in \mathcal{F}(P_s)\}$$

and that

$$\mathcal{F}_k(\tilde{P}) = \bigcup_{\substack{k_1,\dots,k_s \in \mathbb{N}_0 \\ k_1+\cdots+k_s=k}} \{F_1 \times F_2 \times \cdots \times F_s : F_1 \in \mathcal{F}_{k_1}(P_1), \dots, F_s \in \mathcal{F}_{k_s}(P_s)\}.$$

Let

$$\Delta = \{(x^T, x^T, \dots, x^T)^T \in \mathbb{R}^r : x \in \mathbb{R}^n\};$$

Δ is a linear subspace of $\mathbb{R}^r$ of dimension n. For $\tilde{v} = (v_1, \dots, v_r)^T \in \Delta^\perp \setminus \{0\}$, let $\Delta_{\tilde{v}} = \mathrm{lin}(\Delta \cup \{\tilde{v}\})$, and let

$$\Delta_{\tilde{v}}^+ = \{\tilde{w} \in \Delta_{\tilde{v}} : \langle \tilde{w}, \tilde{v} \rangle > 0\},$$

the corresponding "positive" open halfspace. Further, let π_Δ and $\pi_{\Delta_{\tilde{v}}}$ denote the orthogonal projections onto Δ and $\Delta_{\tilde{v}}$, respectively, let π'_Δ be the restriction of π_Δ to the set $\Delta_{\tilde{v}}$, and set $P_{\tilde{v}} = \pi_{\Delta_{\tilde{v}}}(\tilde{P})$. Note that

$$\pi_\Delta(x_1, \dots, x_s) = \frac{1}{s}\left(\sum_{i=1}^{s} x_i^T, \dots, \sum_{i=1}^{s} x_i^T\right)^T.$$

Then $\mathrm{vol}_n(\pi_\Delta(\tilde{P}))$ is just the sum of the volumes of the projections of those facets of $P_{\tilde{v}}$ with outer normal vector $\tilde{w}$ in $\Delta_{\tilde{v}}^+$.

Suppose that none of the $\tilde{w} \in \Delta_{\tilde{v}}^+$ is orthogonal to a hyperplane in $\mathbb{R}^r$ that supports $\tilde{P}$ in a face of dimension greater than n. Then each facet of $P_{\tilde{v}}$ with outer normal $\tilde{w}$ in $\Delta_{\tilde{v}}^+$ is the projection of exactly one n-dimensional face $\tilde{F} \in \mathcal{F}_n(\tilde{P})$ such that $\tilde{w} \in N(\tilde{P}, \tilde{F})$. Let $\tilde{\mathcal{F}}_n^+$ be the set of all faces $\tilde{F} \in \mathcal{F}_n(\tilde{P})$ for which

$$N(\tilde{P}, \tilde{F}) \cap \Delta_{\tilde{v}}^+ \neq \emptyset.$$

It follows that

$$\pi_\Delta(\tilde{P}) = \bigcup_{\tilde{F} \in \tilde{\mathcal{F}}_n^+} \pi_\Delta(\tilde{F})$$

and

$$\mathrm{vol}_n(\pi_\Delta(\tilde{F}) \cap \pi_\Delta(\tilde{G})) = 0 \quad \text{for all } \tilde{F}, \tilde{G} \in \tilde{\mathcal{F}}_n^+,\ \tilde{F} \neq \tilde{G}.$$

Now, let

$$F_{m_1,\dots,m_s} = \bigcup_{\substack{\tilde{F} = F_1 \times F_2 \times \cdots \times F_s \in \tilde{\mathcal{F}}_n^+ \\ \dim(F_1)=m_1,\dots,\dim(F_s)=m_s}} \mathrm{int}(F_1 + \cdots + F_s),$$

where int is taken with respect to $\mathbb{R}^n$. (Clearly, in terms of volume computations, taking the interior does not matter, and we do it only for technical reasons that become clear when we develop a method for checking membership in $F_{m_1,\dots,m_s}$ later.) By replacing P_i by $\lambda_i P_i$ for $\lambda_i > 0$, and comparing coefficients we obtain [Sc94]'s formula

$$\binom{n}{m_1,\dots,m_s} V(\overbrace{P_1,\dots,P_1}^{m_1},\dots,\overbrace{P_s,\dots,P_s}^{m_s}) = \mathrm{vol}_n(F_{m_1,\dots,m_s}) = \sum_{\substack{\tilde{F}=F_1\times F_2\times\cdots\times F_s\in\tilde{\mathcal{F}}_n^+\\ \dim(F_1)=m_1,\dots,\dim(F_s)=m_s}} \mathrm{vol}_n(F_1+\cdots+F_s).$$

Suppose that rational vectors $v_1, v_2, \dots, v_s \in \mathbb{R}^n$ can be computed in polynomial time with $\tilde{v} = (v_1^T, v_2^T, \dots, v_s^T)^T \in \Delta^\perp$ and such that no $\tilde{w} \in \Delta_{\tilde{v}}^+$ supports $\tilde{P}$ in a face of dimension greater than n. We can then apply the same proof technique as in the proof of Theorem 6, if we can check membership of a point z in $F_{m_1,\dots,m_s}$ in polynomial time. But this can be done as follows (in both cases where $P_1, \dots, P_s$ are $\mathcal{V}$- or $\mathcal{H}$-polytopes).

Given $z \in \mathbb{R}^n$, we first check whether $z \in P_1 + P_2 + \cdots + P_s$. Clearly, this can be done by linear programming. If the answer is affirmative, we compute the vector $\tilde{z}_0$ that is given by

$$\{\tilde{z}_0\} = \{\tilde{z} + \lambda\tilde{v} : \lambda \geq 0\} \cap \mathrm{relbd}(P_{\tilde{v}}), \quad \text{where } \tilde{z} = (z^T, \dots, z^T)^T.$$

To see that this can be done in polynomial time, observe that the corresponding parameter λ_0 is the solution of the linear program

$$\max\langle \tilde{v}, \tilde{x}\rangle \quad \text{s.t.} \quad \tilde{x} \in \tilde{P} \cap (\tilde{z} + \Delta^\perp).$$

Since $\tilde{P} = \{\tilde{x} = (x_1^T, \dots, x_s^T)^T : x_1 \in P_1, \dots, x_s \in P_s\}$ and $\tilde{z} + \Delta^\perp$ can be easily expressed in the form $A\tilde{x} = b$, where A is an $n \times r$ matrix with 0-1 coefficients, $b \in \mathbb{Q}^n$, and the size is bounded by a polynomial in r and $size(z)$, the given linear program can be solved in polynomial time.

Now, if $\lambda_0 = 0$ we know that $z \in \mathrm{bd}(P_1 + P_2 + \cdots + P_s)$, and we report that $z \notin F_{m_1,\dots,m_s}$.

Otherwise we compute an outer normal $\tilde{w} \in \Delta_{\tilde{v}}^+$ of $P_{\tilde{v}}$ at $\tilde{z}_0$. This can be done in polynomial time.

Let $F_{\tilde{w}}$ denote the face of $P_{\tilde{v}}$ that corresponds to the supporting hyperplane determined by $\tilde{w}$. It may or may not be the case that $F_{\tilde{w}}$ is a facet of $P_{\tilde{v}}$ (we will find out in the final step); and we know that $z \notin F_{m_1,\dots,m_s}$ if it is not. (This situation is the reason for considering only the interiors of the sets $F_1 + \cdots + F_s$ in the definition of $F_{m_1,\dots,m_s}$.)

Next we determine the face $\tilde{F}$ of $\tilde{P}$ which is induced by the supporting hyperplane orthogonal to $\tilde{w}$. This is done by solving for $i = 1, \dots, s$ the linear program

$$\max\langle w_i, x\rangle \quad \text{s.t.} \quad x \in P_i,$$

where $w_1, \dots, w_s \in \mathbb{R}^n$ such that $\tilde{w} = (w_1^T, \dots, w_s^T)^T$. Note that is is not enough to find *a* solution; we need to find a $\mathcal{V}$- or $\mathcal{H}$-presentation of the set of *all* solutions. But this can be done in polynomial time. So, let $F_1, \dots, F_s$ be the respective solution sets. Then $\tilde{F} = F_1 \times F_2 \times \cdots \times F_s$ is the face of $\tilde{P}$ in question. Now we need to check whether $\dim F_i = m_i$ for all $i = 1, \dots, s$, a task involving just linear algebra, and, if

this is the case, finally, whether $\pi_{\Delta_{\tilde{v}}}$ does not reduce $\dim \tilde{F}$, again a simple task from linear algebra.

Hence we have derived a polynomial-time algorithm for checking membership in $F_{m_1,\dots,m_s}$ which we can now apply to the points x_t used in the proof of the easiness results for zonotopes, and we may proceed as before.

In order to finish the proof of Theorem 7, all that is left to be done is to show that an appropriate choice of the vector $\tilde{v}$ can be made in polynomial time.

The condition on $\tilde{v}$ is satisfied if

$$\bigcap_{i=1}^{s} \big(\text{relint}\,(N(P_i,F_i)) - v_i\big) = \emptyset$$

for all s-tuples $(F_1,F_2,\dots,F_s)$ of faces F_i of P_i such that

$$\dim F_1 + \dim F_2 + \cdots + \dim F_s > n.$$

We will actually produce (in polynomial time) vectors $v_1,\dots,v_s$ such that

$$\bigcap_{i=1}^{s} \big(\text{lin}\,(N(P_i,F_i)) - v_i\big) = \emptyset \tag{2.4}$$

for all s-tuples $(F_1,F_2,\dots,F_s)$ of faces F_i of P_i such that

$$\dim F_1 + \dim F_2 + \cdots + \dim F_s > n.$$

Let $(F_1,F_2,\dots,F_s)$ be such a choice of faces, i.e.,

$$k_1 + \cdots + k_s \geq n+1, \quad \text{where } k_i = \dim F_i \text{ for } i = 1,\dots,s.$$

Suppose that for $i = 1,\dots,s$ the vectors $a_{i,1},\dots,a_{i,n-k_i}$ are facet normals of P_i that span $\text{lin}(N(P_i,F_i))$. Then (2.4) is violated for some choice of $\tilde{v}$, if and only if the following inhomogenous system of linear equations (in the variables x and $\lambda_{i,j}$) is feasible.

$$x + \sum_{j=1}^{n-k_i} \lambda_{i,j} a_{i,j} = v_i \qquad (i = 1,\dots,s). \tag{2.5}$$

Note that this system is overdetermined; it consists of r equations in $n+\sum_{i=1}^{s}(n-k_i) = r + (n - \sum_{i=1}^{s} k_i) \leq r-1$ variables and is, hence, generically infeasible. In order to find a specific vector $\tilde{v}$ of size that is bounded by a polynomial in the input size, which renders *all* such systems infeasible, we have to analyze the condition a bit more carefully, since in general there are doubly exponentially many such systems. Note, however, that the coefficient matrices have the property that all entries are of size that is bounded by a polynomial in the input size. Now suppose $\tilde{v}$ is of the form

$$\tilde{v}_\xi = (v_1^T, v_2^T, \dots, v_s^T)^T = (\xi, \xi^2, \dots, \xi^r)^T \quad \text{for some } \xi > 1.$$

Note that, in general, $\tilde{v}_\xi \notin \Delta^\perp$, but since $\tilde{v}_\xi \notin \Delta$, it is of the form $(y_\xi^T,\dots,y_\xi^T)^T + \tilde{v}'_\xi$ with $\tilde{v}'_\xi \in \Delta^\perp$, whence it suffices to show that for a suitable choice of ξ the system (2.5) is infeasible for $\tilde{v}_\xi$. Now, since (2.5) is overdetermined, it is only feasible if the components of $\tilde{v}_\xi$ satisfy a linear relation with coefficients that come as subdeterminants of (2.5)'s coefficient matrices, whence are bounded in size by an integer polynomial $\pi(\Lambda)$ in the input size Λ, i.e., we have a relation

$$\xi^r + \sum_{i=1}^{r-1} \alpha_i \xi^i = 0 \quad \text{with } |\alpha_1|,\dots,|\alpha_{r-1}| \leq 2^{\pi(\Lambda)}.$$

Hence, with $\xi_0 = 2r2^{\pi(\Lambda)}$ the vector $\tilde{v}_{\xi_0}$ makes all systems (2.5) infeasible.

This completes the proof of the two asserted easiness results. □

2.4. Deterministic methods for approximating mixed volumes. The problem of how well the volume of a well-presented convex body can be approximated in polynomial time was investigated by various authors; see [GK94] for a survey.

For a positive functional ϕ on $\mathcal{K}^n$ (or on appropriate subsets of $\mathcal{K}^n$) and a functional $\lambda : \mathbb{N} \to \mathbb{R}$, a *(relative) λ-approximation* of ϕ is a functional $\hat{\phi}$ defined on the domain of ϕ such that

$$\frac{\phi(K)}{\hat{\phi}(K)} \leq \lambda \quad \text{and} \quad \frac{\hat{\phi}(K)}{\phi(K)} \leq \lambda.$$

(Note that the *relative error* $|(\hat{\phi}(K) - \phi(K))/\phi(K)|$ is only appropriate if one is confronted with small errors since taking $\hat{\phi}(K) = 0$ always gives an estimate with relative error 1.)

When looking for relative estimates for mixed volumes, the first question is if one can efficiently check whether the mixed volume under consideration is greater than zero.

THEOREM 8. *There is a polynomial time algorithm which solves the following problem: given $n, s \in \mathbb{N}$, $m_1, \ldots, m_s \in \mathbb{N}_0$ with $\sum_{i=1}^{s} m_i = n$, and well-presented convex bodies $K_1, \ldots, K_s$, decide whether*

$$V(\overbrace{K_1, \ldots, K_1}^{m_1}, \overbrace{K_2, \ldots, K_2}^{m_2}, \ldots, \overbrace{K_s, \ldots, K_s}^{m_s}) = 0.$$

Proof. For $i = 1, \ldots, s$, let $d_i = \dim(K_i)$, and let $a_{i,0}, \ldots, a_{i,d_i} \in K_i$ such that $\operatorname{aff}(K_i) = \operatorname{aff}\{a_{i,0}, \ldots, a_{i,d_i}\}$. Note that these vectors $a_{i,j}$ are part of the input of the problem. Since our task is clearly translation invariant, we may assume that $a_{1,0} = \cdots = a_{s,0} = 0$, and also that $b_1 = \cdots = b_s = 0$, where b_i is the given "center" of K_i.

Now, for $i = 1, \ldots, s$, let $Z_i = \sum_{j=1}^{d_i} [-1, 1] a_{i,j}$. Then clearly, for some $\rho, R > 0$ (which we do not have to know explicitly),

$$\rho Z_i \subset K_i \subset R Z_i.$$

Hence, by the monotonicity of mixed volumes,

$$V(\overbrace{K_1, \ldots, K_1}^{m_1}, \overbrace{K_2, \ldots, K_2}^{m_2}, \ldots, \overbrace{K_s, \ldots, K_s}^{m_s}) = 0,$$

if and only if

$$V(\overbrace{Z_1, \ldots, Z_1}^{m_1}, \overbrace{Z_2, \ldots, Z_2}^{m_2}, \ldots, \overbrace{Z_s, \ldots, Z_s}^{m_s}) = 0.$$

Using the notation introduced in the previous subsection, let $J_i = \{(i, 1), \ldots, (i, d_i)\}$ for all $i = 1, \ldots, s$, set $J = J_1 \cup \cdots \cup J_s$, set

$$\mathcal{J}_{m_1,\ldots,m_s} = \{I \subset J : |I \cap J_i| = m_i, \text{ for } i = 1, \ldots, s\}$$

and let $A_I = \{a_{i,j} : (i, j) \in I\} \quad \text{for} \quad I \subset J$.

It follows from Proposition 2 that $V(\overbrace{K_1, \ldots, K_1}^{m_1}, \overbrace{K_2, \ldots, K_2}^{m_2}, \ldots, \overbrace{K_s, \ldots, K_s}^{m_s}) \neq 0$ if and only if there is a linear independent subset A_I of A_J which, for $i = 1, \ldots, s$, contains exactly m_i elements from A_{J_i}. This is equivalent to the existence of a common basis for two matroids, the linear matroid and the partition matroid on A_J. The existence of such a common basis can be determined in polynomial time by the matroid intersection algorithm of [Ed70]; see also [GLS88, Theorem 7.5.16]. ∎

Now, assume that $K_1, \dots, K_s$ are well-presented convex bodies and we are longing for relative approximations to

$$V(\overbrace{K_1, \dots, K_1}^{m_1}, \dots, \overbrace{K_s, \dots, K_s}^{m_s}),$$

where $m_1 + \cdots + m_s = n$. Using Proposition 4, we easily obtain a $\left(\min\{\rho_n^{n/2}, \nu_n^{n/2}\}\right)$-approximation of $\mathrm{vol}_n(K)$, where

$$\rho_n = n\sqrt{n+1} \quad \text{and} \quad \nu_n = 2(n+1).$$

(In the rest of the paper we will use these abbreviations to emphasize that improvements in Proposition 4 (in general or for subclasses of $\mathcal{K}^n$) carry over to our approximation results. For such an improvement for $\mathcal{H}$-polytopes see [KT93], and see [GK94] for a survey.) Note that $\rho_n^{n/2}$ and $\nu_n^{n/2}$ depend only on the dimension n and are independent of the bounds of the in- and circumradii given in the input. On the negative side, it has been shown by [BF86] that for each polynomial-time algorithm which produces a λ-approximation of the volume of well-presented convex bodies there exists a constant c such that $\lambda(n) \geq (\frac{cn}{\log n})^{n/2}$ for all $n \in \mathbb{N}$.

It is clear that we cannot expect anything better for mixed volumes, but can we at least get polynomial-time approximations whose error depends only on the dimension n? Note that the "obvious" approach of approximating the bodies $K_1, \dots, K_s$ by parallelotopes each and then using the mixed volume of the parallelotopes as estimates fails in view of Theorem 4, and Theorem 2 indicates some limits for a similar approach using ellipsoids. The following result, however, gives a positive answer for $s = 2$; the general case is open and posed here as a problem.

THEOREM 9. *Let $m : \mathbb{N}_0 \to \mathbb{N}_0$ with $m(n) \leq n$ for all $n \in \mathbb{N}_0$, and let $\lambda : \mathbb{N} \to \mathbb{R}$ be defined by*

$$\lambda(n) = \min\left\{ \rho_n^{\frac{m(n)}{2}} \nu_n^{\frac{n-m(n)}{2}}, \rho_n^{\frac{n-m(n)}{2}} \nu_n^{\frac{m(n)}{2}} \right\}.$$

Then there is a polynomial-time algorithm which produces a λ-approximation of

$$V(\overbrace{K_1, \dots, K_1}^{n-m(n)}, \overbrace{K_2, \dots, K_2}^{m(n)})$$

for well-presented proper convex bodies K_1, K_2.

Proof. Given K_1 and K_2, let ϕ_1 and ϕ_2 be affine transformations such that

$$\mathbb{B}^n \subset \phi_1(K_1) \subset \rho_n \mathbb{B}^n \quad \text{and} \quad C_n \subset \phi_2(K_2) \subset \nu_n C_n.$$

This implies, with $Z = \phi_1(\phi_2^{-1}(C_n))$ and $m = m(n)$, that

$$\begin{aligned} V(\overbrace{\mathbb{B}^n, \dots, \mathbb{B}^n}^{n-m}, \overbrace{Z, \dots, Z}^{m}) &\leq V(\overbrace{\phi_1(K_1), \dots, \phi_1(K_1)}^{n-m}, \overbrace{\phi_1(K_2), \dots, \phi_1(K_2)}^{m}) \\ &\leq V(\overbrace{\rho_n \mathbb{B}^n, \dots, \rho_n \mathbb{B}^n}^{n-m}, \overbrace{\nu_n Z, \dots, \nu_n Z}^{m}). \end{aligned}$$

Since the common affine transformation ϕ_1 changes the mixed volume only by the absolute value of the corresponding determinant as a factor, we obtain the desired bound by taking the geometric mean of the lower and upper estimates and noticing that the roles of K_1 and K_2 can be interchanged. The polynomiality of the algorithm

follows from Proposition 4 and from the fact that the quermassintegrals of a parallelotope can be approximated to absolute positive rational error ϵ in polynomial time in n and $size(\epsilon)$; see, e.g., [GK94, Theorem 4.4.4]. □

Let us point out that Theorem 9 can be extended to improper sets K_1 and K_2 by first using Theorem 8 to check whether the mixed volume under consideration is 0, and if this is not the case, by applying Theorem 9 to the bodies $K_1 + \epsilon\mathbb{B}^n$ and $K_1 + \epsilon\mathbb{B}^n$ for suitably small positive rational ϵ.

The final result of this subsection is needed as preprocessing for the inductive step in the main algorithm of section 3. It is included here because it is approximative in the sense that it gives an algorithmic solution to the (properly phrased variant of the) question of how well a specific mixed volume $V(\overbrace{K_1,\dots,K_1}^{n-k+1},\overbrace{K_2,\dots,K_2}^{k-1})$ of two bodies approximates the "next" one, $V(\overbrace{K_1,\dots,K_1}^{n-k},\overbrace{K_2,\dots,K_2}^{k})$. First we state a theoretical bound which holds after some preliminary normalizations, then we will show how these assumptions can be satisfied in polynomial time.

LEMMA 3. *Let $K_1, K_2 \in \mathcal{K}^n$, let E be an ellipsoid centered at 0 such that $E \subset K_1 \subset \rho_n E$, and let $v_1,\dots,v_n$ be the semi-axis vectors of E, such that $\|v_1\| \le \cdots \le \|v_n\|$. Further, suppose that $\mathbb{B}^n \subset K_2 \subset \rho_n\mathbb{B}^n$ and that $\|v_m\| = 1$. Then*

$$(n+1)^{-4m+5/2} \le \frac{a_{m-1}}{a_m} \le (n+1)^{4m-3/2},$$

where, for $k = m-1, m$,

$$a_k = V(\overbrace{K_1,\dots,K_1}^{n-k},\overbrace{K_2,\dots,K_2}^{k}).$$

Proof. For $i = 1,\dots,n$, set $w_i = v_i/\|v_i\|$. Further, for $j = 1,\dots,m$, let $U_j = \mathrm{lin}\{v_1,\dots,v_j\}$, let $\pi_j : \mathbb{R}^n \to \mathbb{R}^n$ be the orthogonal projection on $U_j^\perp$, and let V_{U_j} and $V_{U_j^\perp}$ denote the (mixed) volume taken in U_j, $U_j^\perp$ (with respect to the standard j- or $(n-j)$-measure in U_j or $U_j^\perp$), respectively.

Let us begin by giving a simple lower estimate for $V(\overbrace{K_1,\dots,K_1}^{n-k},\overbrace{K_2,\dots,K_2}^{k})$, when $k = m-1, m$. Let

$$Q_k = \mathrm{conv}\{\pm w_1,\dots,\pm w_k\}.$$

Then we obtain, with the aid of Proposition 2,

$$\begin{aligned} V(\overbrace{K_1,\dots,K_1}^{n-k},\overbrace{K_2,\dots,K_2}^{k}) &\ge V(\overbrace{K_1,\dots,K_1}^{n-k},\overbrace{Q_k,\dots,Q_k}^{k}) \\ &= \binom{n}{k}^{-1} V_{U_k^\perp}(\overbrace{\pi_k(K_1),\dots,\pi_k(K_1)}^{n-k}) V_{U_k}(\overbrace{Q_k,\dots,Q_k}^{k}) \\ &= \binom{n}{k}^{-1} \mathrm{vol}_{n-k}(\pi_k(K_1))\mathrm{vol}_k(Q_k) = \frac{2^k}{(n-k+1)\cdot\ldots\cdot n}\mathrm{vol}_{n-k}(\pi_k(K_1)) \\ &\ge \left(\frac{2}{n}\right)^k \mathrm{vol}_{n-k}(\pi_k(K_1)). \end{aligned} \tag{2.6}$$

Next we derive upper bounds. Note, first, that

$$\begin{aligned}\|v_1\|K_2 &\subset \rho_n\|v_1\|\mathbb{B}^n \subset \rho_n E \subset \rho_n K_1;\\ K_1 &\subset \pi_1(K_1) + \rho_n[-1,1]v_1;\\ K_2 &\subset \pi_1(K_2) + \rho_n[-1,1]w_1.\end{aligned}$$

Now, again let $k = m-1, m$. Using the monotonicity of mixed volumes we obtain

$$\begin{aligned}&V(\overbrace{K_1,\dots,K_1}^{n-k},\overbrace{K_2,\dots,K_2}^{k})\\ &\quad\le V(\overbrace{\pi_1(K_1)+\rho_n[-1,1]v_1,\dots,\pi_1(K_1)+\rho_n[-1,1]v_1}^{n-k},\\ &\qquad\qquad \overbrace{\pi_1(K_2)+\rho_n[-1,1]w_1,\dots,\pi_1(K_2)+\rho_n[-1,1]w_1}^{k})\\ &\quad= \sum_{i=0}^{n-k}\sum_{j=0}^{k}\binom{n-k}{i}\binom{k}{j} V(\overbrace{\pi_1(K_1),\dots,\pi_1(K_1)}^{n-k-i},\overbrace{\rho_n[-1,1]v_1,\dots,\rho_n[-1,1]v_1}^{i},\\ &\qquad\qquad \overbrace{\pi_1(K_2),\dots,\pi_1(K_2)}^{k-j},\overbrace{\rho_n[-1,1]w_1,\dots,\rho_n[-1,1]w_1}^{j}).\end{aligned}$$

Proposition 2 then yields the following estimate.

$$\begin{aligned}&V(\overbrace{K_1,\dots,K_1}^{n-k},\overbrace{K_2,\dots,K_2}^{k})\\ &\quad\le (n-k)V(\overbrace{\pi_1(K_1),\dots,\pi_1(K_1)}^{n-k-1},\rho_n[-1,1]v_1,\overbrace{\pi_1(K_2),\dots,\pi_1(K_2)}^{k})\\ &\qquad\qquad + kV(\overbrace{\pi_1(K_1),\dots,\pi_1(K_1)}^{n-k},\overbrace{\pi_1(K_2),\dots,\pi_1(K_2)}^{k-1},\rho_n[-1,1]w_1)\\ &\quad= \frac{2(n-k)\rho_n\|v_1\|}{n}V_{U_1^\perp}(\overbrace{\pi_1(K_1),\dots,\pi_1(K_1)}^{n-k-1},\overbrace{\pi_1(K_2),\dots,\pi_1(K_2)}^{k})\\ &\qquad\qquad + \frac{2k\rho_n}{n}V_{U_1^\perp}(\overbrace{\pi_1(K_1),\dots,\pi_1(K_1)}^{n-k},\overbrace{\pi_1(K_2),\dots,\pi_1(K_2)}^{k-1})\\ &\quad\le \frac{2(n-k)\rho_n^2+2k\rho_n}{n}V_{U_1^\perp}(\overbrace{\pi_1(K_1),\dots,\pi_1(K_1)}^{n-k},\overbrace{\pi_1(K_2),\dots,\pi_1(K_2)}^{k-1})\\ &\quad\le 2\rho_n^2 V_{U_1^\perp}(\overbrace{\pi_1(K_1),\dots,\pi_1(K_1)}^{n-k},\overbrace{\pi_1(K_2),\dots,\pi_1(K_2)}^{k-1}).\end{aligned}$$

The same estimate can now be applied inductively; if we do this $k-1$ times for $k=m$ and k times for $k=m-1$ we obtain

(2.7)

$$\begin{aligned}&V(\overbrace{K_1,\dots,K_1}^{n-m},\overbrace{K_2,\dots,K_2}^{m}) \le (2\rho_n^2)^{m-1}V_{U_{m-1}^\perp}(\overbrace{\pi_{m-1}(K_1),\dots,\pi_{m-1}(K_1)}^{n-m},\pi_{m-1}(K_2))\\ &V(\overbrace{K_1,\dots,K_1}^{n-m+1},\overbrace{K_2,\dots,K_2}^{m-1}) \le (2\rho_n^2)^{m-1}\mathrm{vol}_{n-m+1}(\pi_{m-1}(K_1)).\end{aligned}$$

Now we combine the estimates (2.6) and (2.7) with the fact that

$$\pi_{m-1}(K_2) \subset \rho_n \mathbb{B}^{n-m+1} \subset \rho_n \pi_{m-1}(K_1),$$
$$\pi_{m-1}(K_1) \subset \pi_m(K_1) + \rho_n[-1,1]v_m,$$

and obtain

(2.8)
$$V(\overbrace{K_1,\dots,K_1}^{n-m},\overbrace{K_2,\dots,K_2}^{m}) \le (2\rho_n^2)^{m-1} V_{U_{m-1}^\perp}(\overbrace{\pi_{m-1}(K_1),\dots,\pi_{m-1}(K_1)}^{n-m},\pi_{m-1}(K_2))$$
$$\le (2\rho_n^2)^{m-1}\rho_n \mathrm{vol}_{n-m+1}(\pi_{m-1}(K_1)) \le n^{m-1}\rho_n^{2m-1} V(\overbrace{K_1,\dots,K_1}^{n-m+1},\overbrace{K_2,\dots,K_2}^{m-1})$$

and

(2.9)
$$V(\overbrace{K_1,\dots,K_1}^{n-m},\overbrace{K_2,\dots,K_2}^{m}) \ge \left(\frac{2}{n}\right)^m \mathrm{vol}_{n-m}(\pi_m(K_1))$$
$$\ge \frac{2^{m-1}}{n^m\rho_n}\mathrm{vol}_{n-m+1}(\pi_{m-1}(K_1)) \ge \frac{1}{n^m\rho_n^{2m-1}} V(\overbrace{K_1,\dots,K_1}^{n-m+1},\overbrace{K_2,\dots,K_2}^{m-1}).$$

When ρ_n is replaced by its upper bound $(n+1)^{3/2}$, the estimates (2.8) and (2.9) yield the assertion. □

LEMMA 4. *There is a polynomial-time algorithm which constructs, for given well-presented proper convex bodies K_1, K_2 of $\mathbb{R}^n$ and a given $m \in \{1,\dots,n\}$, an affine transformation ϕ and a rational number $\kappa > 0$ such that*

$$1 \le \frac{a'_{m-1}}{a'_m} \le (n+1)^{8m},$$

where, for $k = m-1, m$,

$$a'_k = V(\overbrace{K'_1,\dots,K'_1}^{n-k},\overbrace{K'_2,\dots,K'_2}^{k})$$

is the corresponding mixed volume of the transformed bodies $K'_1 = \kappa\phi(K_1)$ and $K'_2 = \phi(K_2)$.

Proof. Proposition 4 allows us to construct affine transformations ϕ and $\hat{\phi}$ such that

$$\mathbb{B}^n \subset \phi(K_2) \subset \rho_n\mathbb{B}^n \quad \text{and} \quad \mathbb{B}^n \subset \hat{\phi}(\phi(K_1)) \subset \rho_n\mathbb{B}^n.$$

So, let us assume for simplicity of notation that, already,

$$E \subset K_1 \subset \rho_n E \quad \text{and} \quad \mathbb{B}^n \subset K_2 \subset \rho_n\mathbb{B}^n,$$

where $E = A^{-1}\mathbb{B}^n$ for a nonsingular matrix A whose entries are bounded in size by a polynomial in the input size. Now, using the multilinearity of the mixed volumes, Lemma 3 implies

$$(n+1)^{-4m+5/2}\|v_m\| \le \frac{a_{m-1}}{a_m} \le (n+1)^{4m-3/2}\|v_m\|.$$

The problem of computing $\|v_m\|$ is essentially the task of computing the eigenvalues of A^TA, and this can be done in time that is polynomial in the input data and in the binary size of the required precision ϵ. (A conceptually simple way to find the largest eigenvalue of a positive definite matrix A is to perform a binary search on $A - \lambda I$ (with respect to a parameter λ) using the criterion for positive definiteness that the determinants of the $k \times k$ submatrices of the first k rows and columns are positive. The rest is then standard fare in linear algebra.) However, all these quantities are only available up to a polynomially bounded precision. So suppose that ν is a positive rational such that $|\nu - \|v_m\|| \le \epsilon$. Then we obtain

$$(n+1)^{-4m+5/2}(\nu - \epsilon) \le \frac{a_{m-1}}{a_m} \le (n+1)^{4m-3/2}(\nu + \epsilon),$$

whence, with a sufficiently small (but polynomially bounded) positive ϵ,

$$(n+1)^{-4m}\nu \le \frac{a_{m-1}}{a_m} \le (n+1)^{4m}\nu.$$

So, if we rescale K_2 by a factor $(n+1)^{4m}/\nu$, we obtain the asserted inequality. □

3. Randomized algorithms. In this section, we give a randomized algorithm for computing relative approximations of certain mixed volumes of well-presented convex bodies to relative error ϵ whose running time is polynomial in $1/\epsilon$ and the size of the input. We begin with the case of two bodies K_1 and K_2. Our algorithm uses the polynomial-time randomized volume algorithm of Proposition 1 to obtain relative estimates of the values of the polynomial

$$p(x) = \mathrm{vol}_n(K_1 + xK_2) = \sum_{j=0}^{n} c_j x^j = \sum_{j=0}^{n} \binom{n}{j} a_j x^j$$
$$= \sum_{j=0}^{n} \binom{n}{j} V(\overbrace{K_1, \ldots, K_1}^{n-j}, \overbrace{K_2, \ldots, K_2}^{j}) x^j$$

at certain interpolation points. After deriving a basic estimate in subsection 3.1 and showing that the general case of possibly improper convex bodies can be reduced to the case of all bodies in question being proper, we describe a randomized algorithm in subsection 3.2 that computes approximations $\hat{a}_m$ of the mixed volumes a_m of two proper convex bodies recursively. The scaling of Lemma 4 is used as a preprocessing step; it gives a first rough estimate for a_m. The first part of the algorithm uses a search procedure to produce an approximation of the ratio a_{m-1}/a_m to constant error; the second step gives the desired relative approximation of a_m to error ϵ. Subsection 3.2 concludes with the analysis of the complexity of the algorithm, thus establishing Theorem 10 (as stated in the introduction). Subsection 3.3 generalizes the randomized algorithm to more than two convex bodies and proves Theorem 11 (as stated in the introduction).

3.1. A basic estimate and a reduction lemma. The first part of this subsection gives an estimate that is fundamental for the algorithm presented in subsection 3.2.

Let $\xi_0, \ldots, \xi_n$ be (equidistant) interpolation nodes and for $i = 0, \ldots, n$, let $\hat{y}_i$ denote the relative estimate of $y_i = p(\xi_i)$ to error τ. Setting

$$\hat{c}_m = \sum_{k=0}^{n} b_{km} \hat{y}_k,$$

where the b_{km} are again the coefficients of the Lagrange polynomials, (1.5) yields

$$|\hat{c}_m - c_m| \le \tau \max_{i=0,\dots,n} \{q(\xi_i)\} \sum_{k=0}^{n} |b_{km}|.$$

We are, however, interested in a relative approximation, i.e., an estimate of the form

$$|\hat{c}_m - c_m| \le \tau' |c_m|.$$

Using the results of subsection 1.3, it is not hard to see that, in general,

$$\frac{1}{|c_m|} \max_{i=0,\dots,n} \{q(\xi_i)\} \sum_{k=0}^{n} |b_{km}|$$

grows exponentially in n. Unfortunately, the running time of the approximation algorithm of Proposition 1 is polynomial only in the approximation error and not in its *size*. Hence the relative approximations of y_i to error τ that are produced via Proposition 1 cannot be used in this way to give estimates for *all* coefficients in polynomial time. This is the reason for using a small (left upper corner) $r \times r$ submatrix $B^{(r)}$ of the full matrix $B^{(n+1)}$; to allow polynomiality, $(rm)^m$ must be bounded by a polynomial in n.

The following lemma gives a bound for the error $|\hat{c}_m - c_m|$, where the estimate $\hat{c}_m$ is now computed from $B^{(r)}$. The parameters used are all generated later by the algorithm.

LEMMA 5. *Let $m \in \{1, \dots, n\}$, let $r \in \mathbb{N}$ with $r \ge 4m + 7$, let α, γ, and σ be positive reals with $\alpha \ge 1$ such that*

$$\gamma^k a_k \le \begin{cases} \alpha^r \gamma^m \sigma & \text{for } k \le m-1; \\ \gamma^m \sigma & \text{for } k \ge m, \end{cases} \tag{3.1}$$

let $0 < \eta \le 1$, $h = \eta \frac{\gamma}{rn}$, and for $j = 0, \dots, r-1$ let $\xi_j = j \cdot h$. Further, let $\tau > 0$, and for $j = 0, \dots, r-1$ let $\hat{y}_j \in \mathbb{Q}$ such that $|\hat{y}_j - y_j| \le \tau y_j$. Then, taking the estimate

$$\hat{c}_m = h^{-m} \sum_{i=0}^{r-1} b_{im}^{(r)} \hat{y}_i,$$

we have

$$|\hat{c}_m - c_m| \le \frac{\sigma}{\eta^m} \binom{n}{m} \Big((2\alpha)^r e \tau (rm)^m + \frac{2\eta^r}{7!} \Big). \tag{3.2}$$

Proof. It follows from the choice of interpolation nodes and from (3.1) that

$$\begin{aligned} y_j = |p(\xi_j)| \le |p(\xi_r)| &= \sum_{i=0}^{n} c_i (rh)^i = \sum_{i=0}^{n} c_i \eta^i \gamma^i n^{-i} \\ &\le \sigma \gamma^m \alpha^r \sum_{i=0}^{n} n^{-i} \binom{n}{i} \le \sigma \gamma^m \alpha^r \sum_{i=0}^{n} \frac{1}{i!} \le \sigma \gamma^m \alpha^r e. \end{aligned} \tag{3.3}$$

Now let

$$\tilde{c}_m = h^{-m} \sum_{i=0}^{r-1} b_{im}^{(r)} y_i.$$

Since $\binom{n}{m} \geq (\frac{n}{m})^m$, it follows from (1.8) and (3.3) that

$$\begin{aligned} |\tilde{c}_m - \hat{c}_m| &\leq h^{-m}\tau \max\{y_0, \ldots, y_{r-1}\} \cdot \sum_{j=0}^{r-1} |b_{jm}^{(r)}| \ \leq h^{-m}\tau\sigma\gamma^m\alpha^r e \cdot 2^r \\ &\leq (2\alpha)^r \tau \eta^{-m} \sigma e (rm)^m \binom{n}{m}. \end{aligned} \tag{3.4}$$

Now,

$$h^m \tilde{c}_m = \sum_{j=0}^{r-1} b_{jm}^{(r)} y_j = \sum_{i=0}^{n} c_i h^i \sum_{j=0}^{r-1} b_{jm}^{(r)} j^i = c_m h^m + \sum_{i=r}^{n} c_i h^i \sum_{j=0}^{r-1} b_{jm}^{(r)} j^i.$$

Since $r \geq 4m + 7$, whence $7!\ r^{2m} \leq r!$, we obtain, with the aid of (1.9) and (3.1),

$$\begin{aligned} \left|\tilde{c}_m - c_m\right| &= h^{-m} \left| \sum_{i=r}^{n} c_i h^i \sum_{j=0}^{r-1} b_{jm}^{(r)} j^i \right| \leq h^{-m} \left| \sum_{i=r}^{n} c_i h^i r^i \right| \\ &= \eta^{-m}\gamma^{-m}(rn)^m \sum_{i=r}^{n} c_i \gamma^i \eta^i n^{-i} \leq \eta^{r-m}\sigma(rn)^m \sum_{i=r}^{n} \binom{n}{i} n^{-i} \\ &\leq \eta^{r-m}\sigma(rm)^m \binom{n}{m} \sum_{i=r}^{n} \frac{1}{i!} \leq \eta^{r-m}\sigma \binom{n}{m} \frac{2}{7!}. \end{aligned} \tag{3.5}$$

Clearly, (3.4) and (3.5) yield the asserted inequality (3.2). ∎

The next lemma will allow us to reduce the general case of mixed volume computation to the case of proper convex bodies. We use the notation of Theorem 11.

LEMMA 6. *Let $k \in \mathbb{N}$, $k \leq s$, and suppose $\mathcal{A}_k$ is a polynomial-time randomized algorithm that performs the task stated in Theorem* 11 *under the additional assumption that $K_1, \ldots, K_k$ are proper (while $K_{k+1}, \ldots, K_s$ may be improper). Then there exists a polynomial-time randomized algorithm $\mathcal{A}_{k-1}$ that performs the same task under the assumption that $K_1, \ldots, K_{k-1}$ are proper.*

Proof. Let $K_1, \ldots, K_s \in \mathcal{K}^n$ be well presented, let $K_1, \ldots, K_{k-1}$ be proper, and suppose we want to compute the mixed volume

$$v = V(\overbrace{K_1, \ldots, K_1}^{m_1}, \ldots, \overbrace{K_s, \ldots, K_s}^{m_s}).$$

Let us first use Theorem 8 to determine whether $v = 0$. If this is the case, we are done. So suppose that $v \neq 0$. Then, of course, there is a fixed integer polynomial π in the size Λ of the input such that

$$v \geq 2^{-\pi(\Lambda)}.$$

Now, consider for $0 \leq \delta \leq 1$ the mixed volume

$$\begin{aligned} p(\delta) = V(&\overbrace{K_1, \ldots, K_1}^{m_1}, \ldots, \overbrace{K_{k-1}, \ldots, K_{k-1}}^{m_{k-1}}, \overbrace{K_k + \delta\mathbb{B}^n, \ldots, K_k + \delta\mathbb{B}^n}^{m_k}, \\ &\overbrace{K_{k+1}, \ldots, K_{k+1}}^{m_{k+1}}, \ldots, \overbrace{K_s, \ldots, K_s}^{m_s}). \end{aligned}$$

Clearly,

$$p(\delta) = \sum_{i=0}^{m_k} \binom{m_k}{i} p_i \delta^i,$$

where

$$p_i = V(\overbrace{K_1, \ldots, K_1}^{m_1}, \ldots, \overbrace{K_k, \ldots, K_k}^{m_k - i}, \ldots, \overbrace{K_s, \ldots, K_s}^{m_s}, \overbrace{\mathbb{B}^n, \ldots, \mathbb{B}^n}^{i}),$$

and $p_0 = p(0) = v$. Let $R \in \mathbb{N}$ such that $K_1, \ldots, K_s \subset R[-1,1]^n$. Note that such a bound is part of the input. Then we have

$$p(\delta) - v = \delta \sum_{i=1}^{m_k} \binom{m_k}{i} p_i \delta^{i-1} \leq \delta (2R)^n \sum_{i=1}^{m_k} \binom{m_k}{i} \leq \delta (4R)^n.$$

Let $\epsilon \in \mathbb{Q}$ with $0 < \epsilon \leq 1$ be given; set

$$\delta_0 = \frac{\epsilon}{3(4R)^n 2^{\pi(\Lambda)}} \quad \text{and} \quad \tau = \frac{\epsilon}{3}.$$

From the given well-presentation of K_k we can easily derive in polynomial time a well-presentation of $K_k' = K_k + \delta \mathbb{B}^n$; hence we can apply $\mathcal{A}_k$ to the bodies

$$K_1, \ldots, K_{k-1}, K_k', K_{k+1}, \ldots, K_s.$$

We call $\mathcal{A}_k$ with error parameter τ to compute an approximation $\hat{p}$ of $p = p(\delta_0)$ to relative error τ. We take $\hat{v} = \hat{p}$ as an approximation of v, and obtain

$$\begin{aligned} \left| \frac{\hat{v} - v}{v} \right| &= \left| \frac{\hat{p} - v}{p} \right| \left| \frac{p}{v} \right| \leq \left(\frac{|\hat{p} - p|}{p} + \frac{|p - v|}{p} \right) \frac{p}{v} \leq \tau \frac{p}{v} + \frac{p - v}{v} = \tau + (\tau + 1) \frac{p - v}{v} \\ &\leq \tau + 2\delta_0 (4R)^n 2^{\pi(\Lambda)} \leq \frac{\epsilon}{3} + 2\frac{\epsilon}{3} = \epsilon. \end{aligned}$$

Hence $\hat{v}$ is the desired approximation of v to relative error ϵ. □

3.2. Mixed volumes of two proper bodies. We will now describe a randomized algorithm for computing the mixed volumes $a_0, \ldots, a_k$ of two proper convex bodies K_1 and K_2 of $\mathbb{R}^n$ recursively, where $k \leq \psi(n)$, with

$$\psi(n) \leq n \quad \text{and} \quad \psi(n) \log \psi(n) = o(\log n).$$

We use Proposition 1 to compute relative estimates of $\mathrm{vol}_n(K_1 + xK_2)$ for suitable choices of nonnegative rational x. In particular, $a_0 = \mathrm{vol}_n(K_1)$ is already (approximately) available. For the inductive step suppose that, for some $m \in \{1, \ldots, \psi(n)\}$, estimates $\hat{a}_0, \ldots, \hat{a}_{m-1}$ of the mixed volumes $a_0, \ldots, a_{m-1}$, respectively, have already been obtained to relative error, say $\frac{1}{10}$.

By Lemma 4 we may assume that

$$1 \leq q_m = \frac{a_{m-1}}{a_m} \leq (n+1)^{8m},$$

since the transformation underlying Lemma 4 changes a_m by a constant factor and does not affect relative approximation. Clearly,

$$\frac{10}{11} (n+1)^{-8m} \hat{a}_{m-1} \leq a_m \leq \frac{10}{9} \hat{a}_{m-1},$$

and this gives a first $\sqrt{(11/9)}(n+1)^{4m}$ approximation of a_m.

The main routine is divided into two parts. First, we apply a search technique to improve the above approximation of q_m to constant error. Then we run a similar procedure to obtain the required approximation of α_m to relative error ϵ.

1. Search procedure: Set $q_0 = 1$, and let

$$\gamma_0 = \begin{cases} 1 & \text{if } m = 1; \\ \max\left\{\frac{9\hat{a}_{m-2}}{11\hat{a}_{m-1}}, 1\right\} & \text{otherwise.} \end{cases}$$

Now, note that

$$\frac{11\hat{a}_{m-2}}{9\hat{a}_{m-1}} \geq q_{m-1} \geq \frac{9\hat{a}_{m-2}}{11\hat{a}_{m-1}} \quad \text{for } m \geq 2$$

and that the Aleksandrov–Fenchel inequality (1.2) implies that $q_m \geq \max\{q_{m-1}, 1\}$. This yields, for $\gamma = \gamma_0$,

$$q_m \geq \gamma \geq \left(\frac{9}{11}\right)^2 q_{m-1} \geq \frac{2}{3} q_{m-1}. \tag{3.6}$$

In the kth iteration of our search procedure we have $\gamma = \gamma_k$, also satisfying (3.6), hence,

$$\sigma_k := \frac{a_{m-1}}{\gamma_k} \geq \frac{a_{m-1}}{q_m} = a_m.$$

Now the Aleksandrov–Fenchel inequality implies that $\gamma_k \leq q_j$ for all $j \geq m$, hence, inductively,

$$\gamma_k^j a_j \leq \gamma_k^{m-1} a_{m-1} = \gamma_k^m \sigma_k \quad \text{for all } j \geq m.$$

Similarly for $j \leq m-2$, we deduce from $q_{j+1}, \ldots, q_{m-1} \leq \frac{3}{2}\gamma$ that

$$\gamma_k^j a_j \leq \left(\frac{3}{2}\right)^{m-j-1} \gamma_k^{m-1} a_{m-1} \leq \left(\frac{3}{2}\right)^r \gamma_k^m \sigma_k \quad \text{for all } j \leq m-2,$$

whenever $r \geq m$. Let us choose $r \geq 4m + 7$ such that $r = O(\psi)$. Now we apply Lemma 5 with the parameters

$$\gamma = \gamma_k, \quad \sigma = \sigma_k, \quad \alpha = \frac{3}{2}, \quad \eta = 1, \quad \text{and} \quad \tau = \frac{1}{20 \cdot 3^{r+1}(rm)^m}.$$

So, using the volume algorithm of Proposition 1 with interpolation nodes $\xi_j = j \cdot h$ for $j = 0, \ldots, r-1$, where $h = h_k = \frac{\gamma_k}{rn}$, and error bound τ we obtain relative estimates $\hat{y}_j \in \mathbb{Q}$ of $y_j = p(\xi_j)$ that can be used to produce in polynomial time an estimate $\hat{c}_m$ of c_m that satisfies (3.2), whence

$$|\hat{c}_m - c_m| \leq \sigma_k \binom{n}{m} \left(\frac{1}{20} + \frac{2}{7!}\right) \leq \sigma_k \binom{n}{m} \frac{1}{19}.$$

But then we have for

$$s_k = \hat{c}_m / \tbinom{n}{m},$$

$$|s_k - a_m| \leq \frac{1}{19}\sigma_k.$$

Now, if

$$s_k \leq \frac{4 \cdot 10}{9 \cdot 11} \frac{\hat{a}_{m-1}}{\gamma} \leq \frac{4}{9}\sigma_k,$$

then

$$a_m \le \left(\frac{4}{9} + \frac{1}{19}\right)\sigma_k < \frac{\sigma_k}{2},$$

whence $\gamma_k < \frac{q_m}{2}$. So $\gamma_{k+1} = 2\gamma_k$ still satisfies (3.6), and we can repeat the above procedure with γ_{k+1}.

Note that $\sigma_0 \le a_{m-1}$ and $\sigma_{k+1} = \frac{1}{2}\sigma_k$; this implies that after at most $8m\log(n+1)$ iterations the process stops with a $\hat{\gamma} \in \mathbb{Q}$ such that

$$s_k \ge \frac{4\hat{a}_{m-1}}{10\hat{\gamma}} \ge \frac{4}{11}\sigma_k.$$

This implies that

$$\sigma_k \ge a_m \ge \left(\frac{4}{11} - \frac{1}{19}\right)\sigma_k \ge \frac{1}{4}\sigma_k, \tag{3.7}$$

hence $q_m/4 \le \hat{\gamma} \le q_m$. Note that $10\hat{a}_{m-1}/(11\hat{\gamma})$ is already a 4-approximation of a_m.

2. Approximation: Now that we know q_m approximately, we are able to compute $\hat{a}_m$, the desired approximation of a_m to the relative error ϵ. We assume that $0 < \epsilon \le 1$ and choose a positive rational η_0 of size that is bounded by the size of the input such that

$$\eta_0 \le \epsilon^{\frac{1}{r-m}}.$$

As before, we apply Lemma 5, this time with the parameters

$$\gamma = \hat{\gamma}, \quad \sigma = \sigma_k, \quad \alpha = \frac{3}{2}, \quad \eta = \eta_0, \quad \text{and} \quad \tau = \frac{\eta_0^r}{15 \cdot 3^r (rm)^m}.$$

Then we use again the volume algorithm of Proposition 1, now with interpolation nodes $\xi_j = j \cdot h$ for $j = 0, \dots, r-1$, where $h = \frac{\hat{\gamma}}{rn}\eta_0$, and error bound τ, and we obtain relative estimates $\hat{y}_j \in \mathbb{Q}$ of $y_j = p(\xi_j)$ that lead in polynomial time to an estimate $\hat{c}_m$ of c_m that satisfies (3.2), whence

$$|\hat{c}_m - c_m| \le \sigma_k \eta_0^{r-m} \binom{n}{m}\left(\frac{e}{15} + \frac{2}{7!}\right) \le \binom{n}{m}\frac{\epsilon}{4}\sigma_k.$$

In conjunction with (3.7) this yields

$$|\hat{a}_m - a_m| \le \frac{\epsilon}{4}\sigma_k \le \epsilon a_m$$

for $\hat{a}_m = \hat{c}_m / \binom{n}{m}$ as required.

As for its running time, under the stated assumptions on ψ the algorithm uses

$$O(rm\log(n+1)) = o(\log^3 n) \quad \text{calls to the volume estimator}$$

with error, where

$$\frac{1}{\tau} = O(3^r r^{2m}) = n^{o(1)} \quad \text{in the first part,}$$
$$\frac{1}{\tau} = \left(\frac{1}{\epsilon}\right)^{1+o(1)} n^{o(1)} \quad \text{in the final step.}$$

It follows that the algorithm is polynomial. Note that the running time is only marginally worse than the running time of the volume estimator. In fact, suppose that the volume algorithm (after rounding) has complexity

$$O\left(\frac{1}{\epsilon^k} n^l \log\Big(\frac{1}{\beta}\Big)\right).$$

Then the running time of our mixed volume algorithm is bounded by

$$O\left(\frac{1}{\epsilon^{k+o(1)}} n^{l+o(1)} \log\Big(\frac{1}{\beta}\Big)\right).$$

Since by Lemma 6 the initial assumption that K_1 and K_2 are proper is irrelevant, we have completed the proof of Theorem 10.

3.3. Extension to more than two bodies. Now we extend the algorithm to the case of more than two bodies, thus proving Theorem 11. So, let us consider approximating

$$V(\overbrace{K_1,\dots,K_1}^{m_1},\overbrace{K_2,\dots,K_2}^{m_2},\dots,\overbrace{K_{s-1},\dots,K_{s-1}}^{m_{s-1}},\overbrace{K_s,\dots,K_s}^{m_s}),$$

where $\sum_{i=1}^{s} m_i = n$. We may assume again that $K_1,\dots,K_s$ are proper.

Suppose, recursively, we have an approximation procedure whenever only $s-1$ different bodies occur with $3 \le s \le n$. We want to extend it then to all s bodies by considering the polynomial

$$q(x) = \sum_{k=0}^{m} \binom{m}{k} a_k x^k,$$

for $m = m_{s-1} + m_s$, where

$$a_k = V(\overbrace{K_1,\dots,K_1}^{m_1},\dots,\overbrace{K_{s-2},\dots,K_{s-2}}^{m_2},\overbrace{K_{s-1},\dots,K_{s-1}}^{m-k},\overbrace{K_s,\dots,K_s}^{k}),$$

and using estimates of

$$q(\xi_j) = V(\overbrace{K_1,\dots,K_1}^{m_1},\dots,\overbrace{K_{s-2},\dots,K_{s-2}}^{m_2},\overbrace{K_{s-1}+\xi_j K_s,\dots,K_{s-1}+\xi_j K_s}^{m})$$

for suitably chosen interpolation points $\xi_0,\dots,\xi_m$. Note that for the coefficients a_k we still have the Aleksandrov–Fenchel inequality (1.2).

Suppose, now, that ψ satisfies the condition given in Theorem 11, and let $m_1 \ge n - \psi(n)$. Then the degrees of the corresponding mixed volume polynomials are bounded above by $\psi(n)$. This allows us to simplify the procedure by using the whole coefficient matrix. There is, however, one additional difficulty now. We do not have a polynomial-time procedure for obtaining a "good" initial scaling of the sets anymore (as Lemma 4 for $s = 2$) such that the ratio a_{m-1}/a_m of successive coefficients in the polynomial is suitably bounded. We leave it as an open question whether there is an analogue of Lemma 4 for $s \ge 3$ (with a bound that is independent of the well-presentedness parameters ρ_i, R_i). However, the input yields vectors b_i and numbers ρ, R such that for each K_i we have

$$b_i + \rho\mathbb{B}^n \subset K_i \subset b_i + R\mathbb{B}^n,$$

and we may assume without loss of generality that all b_i are 0. Using the monotonicity of mixed volumes we obtain

$$\frac{\rho}{R} \le \frac{a_{m-1}}{a_m} \le \frac{R}{\rho},$$

and this implies that the number of iterations in the binary search part of the procedure is bounded by $O\big(\log(R/\rho)\big)$. Moreover it follows that for each $\xi \ge 0$,

$$\rho(1+\xi)\mathbb{B}^n \subset K_{s-1} + \xi K_s \subset R(1+\xi)\mathbb{B}^n.$$

Hence, we have an additional factor $\log(R/\rho)$ as part of the input to the volume approximator. With these modifications, Theorem 11 is just a corollary to Theorem 10.

4. Related problems and applications. The present section contains various applications of our results to problems in discrete mathematics, combinatorics, computational convexity, algebraic geometry, geometry of numbers, and operations research.

4.1. Counting integer points in integer polytopes. A polytope is called *integer* if all vertices are integer vectors. We denote by $\mathcal{P}^n(\mathbb{Z})$ the set of all integer polyopes of $\mathbb{R}^n$. The lattice point enumerator $G : \mathcal{P}^n(\mathbb{Z}) \to \mathbb{N}$ is counting the number of lattice points of lattice polytopes P, i.e., $G(P) = |P \cap \mathbb{Z}^n|$. The following polynomial expansion of $G(kP)$ is due to [Eh67], [Eh77].

PROPOSITION 5. *There are functionals $G_i : \mathcal{P}^n(\mathbb{Z}) \to \mathbb{N}_0$ such that for every $P \in \mathcal{P}^n(\mathbb{Z})$ and $k \in \mathbb{N}$,*

$$G(kP) = \sum_{i=0}^{n} k^i G_i(P).$$

The polynomial on the right-hand side is often referred to as *Ehrhart-polynomial*; see [St86] for basic facts on this polynomial. In case of lattice zonotopes one can give an explicit formula for the Ehrhart-polynomial; this was used in [St91] to find a generating function for the number of *degree sequences* of simple m-vertex graphs. (In fact, there is a one-to-one correspondence between these degree sequences and the integer points of a suitable zonotope.) The functionals G_i have some interesting properties; see e.g., the survey [GW93]. They may be viewed as "discrete" analogues of the *quermassintegrals*

$$W_i(P) = V(\overbrace{P, \ldots, P}^{n-i}, \overbrace{\mathbb{B}^n, \ldots, \mathbb{B}^n}^{i}).$$

What is particularly important for our purpose is the fact that $G_n(P)$ is just the volume of P. Hence, it follows from Proposition 5 that determining the number of integer points of an integer polytope (that is presented in any of the standard ways) is (at least) as hard as computing its volume. In fact, it is easy to obtain from any standard presentation of an integer polytope P the same kind of presentation for kP of size that is bounded by a polynomial in $size(P)$ and $size(k)$. Hence, if we had a polynomial-time procedure for determining the number of lattice points of an integer polytope, we could run the algorithm for each polytope $0 \cdot P, 1 \cdot P, \ldots, n \cdot P$, and we would then obtain $\mathrm{vol}_n(P) = G_n(P)$ by computing the leading coefficient of the Ehrhard-polynomial, just by solving the corresponding system of linear equations. Hence, we obtain the following $\#\mathbb{P}$-hardness result as a consequence of the hardness results for volume computation of [DF88] (for $\mathcal{V}$- and $\mathcal{H}$-polytopes) and of Theorem 1 (for $\mathcal{S}$-zonotopes).

THEOREM 12. *The problem of evaluating $G(P)$ is $\#\mathbb{P}$-complete for integer $\mathcal{V}$-, integer $\mathcal{H}$-polytopes, and for integer $\mathcal{S}$-zonotopes.*

Let us remark that in fixed dimension $G(P)$ can be computed in a polynomial time, [Ba94]; see also [DK97]. Note, further, that while this task is easy for $\mathcal{V}$-polytopes, deciding whether a given $\mathcal{H}$-polytope P is an integer polytope is co$\mathbb{NP}$-complete; see [PY90]. For a survey of various other results on lattice point enumeration see [GW93].

4.2. Some determinant problems and their relatives. We will proceed by determining the complexity of the following determinant problems (using similar

methods as in the proof of Theorem 1), and then draw some consequences for a problem in computational convexity.

Let κ be an integer constant. Then κ-DETERMINANT is the following decision problem: *given positive integers n, s with $s \geq n$, and an integer $n \times s$-matrix A, is there an $n \times n$-submatrix B of A such that* $\det B = \kappa$?

#(κ-DETERMINANT) asks for the number of different such matrices.

THEOREM 13. *The problem #(κ-DETERMINANT) is #$\mathbb{P}$-complete for any $\kappa \in \mathbb{Z}$; κ-DETERMINANT is $\mathbb{NP}$-complete for $\kappa \neq 0$.*

Proof. Clearly, the first problem is in #$\mathbb{P}$ while the second is in $\mathbb{NP}$. To prove the hardness results, we use reductions from # SUBSET-SUM and SUBSET-SUM, respectively; see the proof of Theorem 1.

Let $(m; \alpha_1, \ldots, \alpha_m, \alpha)$ be an instance of SUBSET-SUM (or, equivalently, of its counting version), and define the matrix A'_δ as in the proof of Theorem 1, but with each α_j replaced by $\beta_j = (|\kappa| + 2)\alpha_j$ for $j = 1, \ldots, m$, $\alpha_{m+1} = -\alpha$ replaced by $\beta_{m+1} = -(|\kappa| + 2)\alpha + 1$, and $\delta = \kappa - 1$. It follows readily that for each maximal square submatrix B_I of A'_δ whose determinant does not depend on δ we have

$$\det B_I \in \{0, \pm\beta_1, \ldots, \pm\beta_m, \pm\beta_{m+1}\}.$$

In particular, $\det B_I \neq \kappa$, unless $\kappa = 0$.

Now, suppose $\kappa \neq 0$. Recall from the proof of Theorem 1 that in the remaining cases the index sets I of the matrices B_I in the determinantal expansion of $\mathrm{vol}_n(Z_\delta)$ are in one-to-one correspondence with the subsets J of $\{1, \ldots, m+1\}$ via

$$j \in J \Longleftrightarrow 2j - 1 \in I.$$

Further, it is easy to see that $\det B_I = \kappa$ implies $m+1 \in J$, and, hence, $\det B_I = \kappa$ if and only $J \setminus \{m+1\}$ is a solution of the given instance of SUBSET-SUM. This settles the problem for $\kappa \neq 0$.

Now, let $\kappa = 0$, and let us use the original matrix A_δ of the proof of Theorem 1. Among the $\binom{2m+3}{m+2} - 2^{m+1}$ subdeterminants for which $\det B_I$ is independent of δ, we have for each $i = 1, \ldots, m+1$ exactly $2^m + m2^{m-1}$ subsets I of $\{1, \ldots, 2m+3\}$ of cardinality $m+2$ such that $|\det B_I| = |\alpha_i|$, and all other cases give $\det B_I = 0$. Hence, with the choice of $\delta = 0$, the number of singular $(m+2) \times (m+2)$ submatrices would allow us to compute the number of subsets $J \subset \{1, \ldots, m+1\}$ for which $\sum_{i \in I} \alpha_i = 0$, and this is the number of solutions of #SUBSET-SUM. □

Let us point out that the (seemingly) similar problem of finding an $n \times n$ submatrix B of maximal determinant of a given $n \times m$ matrix A with entries in $\{0, \pm 1\}$ is also $\mathbb{NP}$-hard even for quite small classes of such matrices A; [see GKL95, Theorem 5.2]. Clearly, this problem is closely related to the problem of finding a largest (with respect to the volume) n-simplex in a $\mathcal{V}$-polytope, while the $\mathbb{NP}$-hardness result of Theorem 13 implies that, given a $\mathcal{V}$-polytope P and a positive integer κ, finding an n-simplex S with vertices at vertices of P and $\mathrm{vol}_n(S) = \kappa$ is $\mathbb{NP}$-complete.

We remark that Theorem 13 stops short of proving that SINGULAR-SUBMATRIX, the case $\kappa = 0$ of κ-DETERMINANT, is also $\mathbb{NP}$-hard. To extend Theorem 13 to SINGULAR-SUBMATRIX would be interesting since, in a geometric context, the existence of singular submatrices corresponds to configurations which are not in general position. However, general position assumptions are made frequently and it would be useful to know whether these assumptions can be checked efficiently; see [CKM82] for some related results.

4.3. Volume of zonotopes and mixture management. The following mixture management problem from the oil industry is studied in [GV89]. A seller has

a stock of m bins which contain a mixture of chemical substances. Suppose that for $i \in \{1,\dots,m\}$ and $j \in \{1,\dots,n\}$, the ith bin contains a nonnegative rational z_{ij} of volume units of chemical j. To satisfy the customer's demand of a special mixture of b_j volume units of each chemical j, the seller takes a proportion λ_i with $0 \le \lambda_i \le 1$ of volume from each container such that

$$b_j = \sum_{i=1}^{m} \lambda_i z_{ij} \quad \text{for all } j \in \{1,\dots,n\}.$$

Typically, the mixtures in each bin come with associated costs, and a linear programming approach is used to satisfy the customer's demand at minimum total cost. It is pointed out in [GV89], however, that this is not a reasonable optimality criterium if all bins have (approximately) the same costs, and this is the case for particular applications in the oil industry.

Therefore [GV89] suggest the following approach. Clearly, the zonotope

$$Z = \sum_{i=1}^{m} [0,1] z_i, \quad \text{where } z_i = (z_{i1},\dots,z_{in})^T \text{ for } i = 1,\dots,m,$$

describes all possible demands the seller can satisfy. Now, typically, there are many possibilities to satisfy a demand $b = (b_1,\dots,b_m)^T$, and the question is how to do it in such a way that "the widest possible variety of possible future demands" can still be satisfied. More precisely, [GV89] suggests choosing for each $b \in \mathbb{Q}^m$ a vector

$$l = \begin{pmatrix} \lambda_1 \\ \vdots \\ \lambda_m \end{pmatrix} \in L(b) := \left\{ \begin{pmatrix} \lambda_1 \\ \vdots \\ \lambda_m \end{pmatrix} \in [0,1]^m : b = \sum_{i=1}^{m} \lambda_i z_i \right\}$$

such that after taking λ_i volume proportions from bin i, respectively, the set

$$Z(l) := \sum_{i=1}^{m} [0,1](1-\lambda_i) z_i$$

of the remaining possible mixtures has maximal volume. The volume as objective functions is justified by the fact that if the seller has no information about the future demands, it is reasonable to assume that the future demand is uniformly distributed.

Note that the function $f(l) := \mathrm{vol}_n(Z(l))$ is a homogeneous polynomial in the $(1-\lambda_i)$'s and (due to the *Brunn–Minkowski theorem*) has nice analytic properties. But as we have seen in Theorem 1, evaluating $f(\lambda)$ is $\#\mathbb{P}$-hard. This means that, while intriguing, this approach is not practical for large numbers of bins. However, Proposition 1 suggests that a randomized variant of the algorithm presented in [GV89] may be worth considering.

4.4. Two applications of mixed volumes in combinatorics. Two interesting applications in combinatorics can be found in [St81].

For the first, suppose that $\mathcal{M}$ is a unimodular matroid of rank n with representation $v_1, v_2, \dots, v_m \in \mathbb{R}^n$ over the reals; see [We76], [Wh87]. Let $S_1,\dots,S_s$ be a partition of $\{1,2,\dots,m\}$ into proper subsets, and let $t_1,\dots,t_s$ be nonnegative integers such that $\sum_{i=1}^{s} t_i = n$. Then the number of bases of $\mathcal{M}$ with t_i elements in S_i equals

$$\binom{n}{t_1,\dots,t_s} V(\overbrace{Z_1,\dots,Z_1}^{t_1},\dots,\overbrace{Z_s,\dots,Z_s}^{t_s}),$$

where Z_i is the zonotope

$$Z_i = \sum_{j \in S_i} [0,1]v_j.$$

Note that the total number b of bases of $\mathcal{M}$ can be computed easily because the corresponding matrix A with columns $v_1, \ldots, v_m$ is unimodular and hence, by (2.1),

$$b = \sum_{I \in \mathcal{J}} |\det B_I| = \sum_{I \in \mathcal{J}} (\det B_I)^2 = \det(AA^T).$$

As we will see now, this polynomial-time computability is destroyed for mixed volumes of unimodularly generated zonotopes (unless $\#\mathbb{P} = \mathbb{P}$).

THEOREM 14. *The following problem is $\#\mathbb{P}$-hard:*

Instance: $n, s \in \mathbb{N}$ *and* $m_1, \ldots, m_s \in \mathbb{N}$ *such that* $\sum_{i=1}^{s} m_i = n$, $\mathcal{S}$*-zonotopes* $Z_i = (n, s_i; c_i; z_{i,1}, \ldots, z_{i,s_i})$, *for* $i = 1, \ldots, s$ *such that the* $(n \times r)$*-matrix* A *with columns* $z_{i,j}$ *is unimodular, where* $r = \sum_{i=1}^{s} s_i$.

Task: *Compute the mixed volume*

$$V(\overbrace{Z_1, \ldots, Z_1}^{m_1}, \overbrace{Z_2, \ldots, Z_2}^{m_2}, \ldots, \overbrace{Z_s, \ldots, Z_s}^{m_s}).$$

Proof. We reduce the problem of computing the number of perfect matchings in bipartite graphs to the given problem. For $i = 1, 2$, let $V_i = \{v_{i1}, \ldots, v_{in}\}$, let $V_1 \cap V_2 = \emptyset$, let $E \subset \big\{\{v_{1,j}, v_{2,k}\} : j, k = 1, \ldots, n\big\}$, and set $V = V_1 \cup V_2$. Let us now consider the bipartite graph $G = (V, E)$. Since it can be checked in polynomial time whether G admits a perfect matching, we may assume that the number of perfect matchings of G is not 0. We add an additional vertex $v_{2,n+1}$ to V_2 and the edges $E_{n+1} = \big\{\{v_{1,j}, v_{2,n+1}\} : j = 1, \ldots, n\big\}$ to E and obtain a new bipartite graph $G' = (V', E')$. The node-edge incidence-matrix A' of G' is totally unimodular. It has $2n + 1$ rows but is only of rank $2n$. So we delete the row that corresponds to the new vertex $v_{2,n+1}$, and we obtain a totally unimodular matrix A'' of rank $2n$ with $2n$ rows and $|E'| = |E| + n$ columns. The nonsingular $(2n) \times (2n)$-submatrices B of A'' are in one-to-one correspondence with the spanning trees of G'. (Note that in the totally unimodular case $GF(2)$-singularity is equivalent to $\mathbb{R}$-singularity; see, e.g., [Sc86, section 21.1].) Now, we partition E' into E_{n+1} and the n subsets $E_1, \ldots, E_n$ where E_j is the set of those edges of E which contain $v_{2,j}$ $(j = 1, \ldots, n)$. Further, for $j = 1, \ldots, n+1$, let Z_j be the zonotope that is generated by the column vectors of A'' that correspond to E_j. Then by (2.3), the mixed volume

$$\frac{(2n)!}{n!} V\big(Z_1, Z_2, \ldots, Z_n, \overbrace{Z_{n+1}, \ldots, Z_{n+1}}^{n},\big)$$

is just the number of those spanning trees of G' that contain all edges of E_{n+1} and for $j = 1, \ldots, n$ exactly one edge of E_j.

It is easy to see that the spanning trees with this property are in one-to-one correspondence with the perfect matchings of G. □

For the second application let $P = \{p_1, p_2, \ldots, p_s, q_1, q_2, \ldots, q_{n-s}\}$ be a poset, and suppose that $p_1 < p_2 < \cdots < p_s$. For $j = 1, 2, \ldots, s$ let $N(i_1, i_2, \ldots, i_s)$ denote the number of linear extensions σ of P such that $\sigma(p_j) = i_j$; see [St86]. Then, with $i_0 = 0$ and $i_{s+1} = n + 1$,

$$N(i_1, i_2, \ldots, i_s) = (n-s)! V(\overbrace{K_0, \ldots, K_0}^{i_1 - i_0 - 1}, \ldots, \overbrace{K_s, \ldots, K_s}^{i_{s+1} - i_s - 1}),$$

where $K_j \subset \mathbb{R}^{n-s}$ $(j = 0, 1, \ldots, s)$ are the *order polytopes*, i.e., $x \in K_j$ if and only if for all $i = 1, 2, \ldots, n-s$,

$0 \le x_i \le 1$,
$x_i \le x_k$ if $q_i < q_k$ $(k = 1, 2, \ldots, n-s)$,
$x_i = 0$ if $j > 0$ and $q_i < p_j$,
$x_i = 1$ if $j < s$ and $q_i > p_{j+1}$.

These polytopes reflect the poset "between" p_j and p_{j+1} on the subset $\{q_1, \ldots, q_{n-s}\}$. By the Aleksandrov–Fenchel inequality (applied to in the case $s = 1$) it follows that $N(i)^2 \ge N(i-1)N(i+1)$ for $i = 1, \ldots, n-1$ and, hence, the sequence $N(1), \ldots, N(n)$ is unimodal. Observe that the evaluation of $N(i_1, i_2 \ldots, i_r)$ is $\#\mathbb{P}$-complete even when $s = 0$, [BW92]; in this case, N is the number of linear extensions of the poset. It follows that computing the volume of $\mathcal{H}$-polytopes is $\#\mathbb{P}$-hard in the strong sense.

4.5. An application of mixed volumes in algebraic geometry. Let $S_1, S_2, \ldots, S_n$ be subsets of $\mathbb{Z}^n$, and consider a system $F = (f_1, \ldots, f_n)$ of Laurent polynomials in n variables such that the exponents of the monomials in f_i are in S_i for all $i = 1, \ldots, n$. Suppose, further, that F is *sparse* in that the number of monomials having nonzero coefficients is "small" as compared to the degree of the f_i. To fix the notation, let, for $i = 1, \ldots, n$,

$$f_i(x) = \sum_{q \in S_i} c_q^{(i)} x^q,$$

where $f_i \in \mathbb{C}[x_1, x_1^{-1}, \ldots, x_n, x_n^{-1}]$, and x^q is an abbreviation for $x_1^{q_1} \cdots x_n^{q_n}$; $x = (x_1, \ldots, x_n)$ are the indeterminates and $q = (q_1, \ldots, q_n)$ the exponents. Further, let $\mathbb{C}^* = \mathbb{C} \setminus \{0\}$.

Now, if the coefficients $c_q^{(i)}$ $(q \in S_i)$ are chosen "generically," the number $L(F)$ of distinct common roots of the system F in $(\mathbb{C}^*)^n$ depends only on the *Newton polytopes* $P_i = \operatorname{conv} S_i$ of the polynomials (see [GKZ90]); more precisely,

$$L(F) = n! \cdot V(P_1, P_2, \ldots, P_n). \tag{4.1}$$

Moreover, if F has less then $n!V(P_1, \ldots, P_n)$ distinct roots, there must exist a nonzero integer vector $\alpha = (\alpha_1, \ldots, \alpha_n)$ such that the "homogenized" system

$$F_\alpha = (f_1^\alpha, \ldots, f_n^\alpha),$$

where

$$f_i^\alpha(x) = \sum_{q \in S_i^\alpha} c_q^{(i)} x^q, \qquad S_i^\alpha = \big\{ q \in S_i : \alpha^T q = \min\{\alpha^T q : q \in S_i\} \big\}$$

has a root in $(\mathbb{C}^*)^n$. These results become more intuitive by noting that both sides of (4.1) are invariant under unimodular transformations of the exponent vectors and under translations by integer vectors. (Each translation of a set S_i by a vector $p^{(i)}$ corresponds to a multiplication of f_i with the monomial $x^{p^{(i)}}$.) Observe, further, that the Minkowki sum of the Newton polytopes $P_1, \ldots, P_n$ is the Newton polytope of the product of the corresponding polynomials whence both sides of the equation are also additive in each component.

The above theorem was first proved in [Be75]; see also [BZ88, Chapter 27].

A convex geometric approach (utilizing the above connections) was recently developed for computing the isolated solutions of sparse polynomial systems; see [HS95],

[VG95], and [Ro94]. The mixed volumes are determined by computing a "mixed subdivision" of the P_i using lifting methods similar to those of [Sc94] stated in subsection 2.3. See also [GKZ90] and [GS93] for further results on Newton polytopes and [VC92], [PS93], [CE93], [CR91], [VVC94], [ER94], [EC95], [LRW96], [Ro94], [Ro97], and the papers quoted therein for further results on counting the roots of polynomial systems.

Acknowledgment. We are grateful to Mark Jerrum for providing the proof of Lemma 2.

INTERPOLATING ARITHMETIC READ-ONCE FORMULAS IN PARALLEL*

NADER H. BSHOUTY† AND RICHARD CLEVE†

Abstract. A formula is read-once if each variable appears in it at most once. An arithmetic formula is one in which the operations are addition, subtraction, multiplication, and division (and constants are allowed). We present a randomized (Las Vegas) parallel algorithm for the exact interpolation of arithmetic read-once formulas over sufficiently large fields. More specifically, for n-variable read-once formulas and fields of size at least $3(n^2+3n-2)$, our algorithm runs in $O(\log^2 n)$ parallel steps using $O(n^4)$ processors (where the field operations are charged unit cost). This complements some results from [N.H. Bshouty and R. Cleve, *Proc. 33rd Annual Symposium on the Foundations of Computer Science*, IEEE Computer Science Press, Los Alamitos, CA, 1992, pp. 24–27] which imply that other classes of read-once formulas *cannot* be interpolated—or even learned with membership and equivalence queries—in polylogarithmic time with polynomially many processors (even though they can be learned sequentially in polynomial time). These classes include boolean read-once formulas and arithmetic read-once formulas over fields of size $o(n/\log n)$ (for n variable read-once formulas).

Key words. learning theory, parallel algorithm, read-once formula

1. Introduction.

The problem of *interpolating* a formula (from some class C) is the problem of exactly identifying the formula from queries to the assignment (membership) oracle. The interpolation algorithm queries the oracle with an assignment a and the oracle returns the value of the function at a.

There are a number of classes of arithmetic formulas that can be interpolated sequentially in polynomial time as well as in parallel in polylogarithmic time (with polynomially many processors). These include sparse polynomials and sparse rational functions ([BT88, BT90, GKS90b, GrKS88, RB89, GKS90b, SS93, M91]).

A formula over a variable set V is *read-once* if each variable appears at most once in it. An *arithmetic read-once* formula over a field $\mathcal{K}$ is a read-once formula over the basic operations of the field $\mathcal{K}$; addition, subtraction, multiplication, division, and constants are also permitted in the formula. The *size* of an arithmetic formula is the number of instances of variables (i.e., leaves) in it.

Bshouty, Hancock, and Hellerstein [BHH92] present a randomized sequential polynomial-time algorithm for interpolating arithmetic read-once formulas (AROFs) over sufficiently large fields. Moreover, they show that, for arbitrarily sized fields, arithmetic read-once formulas can be *learned* using equivalence queries in addition to membership queries. Other works on AROF and boolean read-once formulas can be found in [AHK89, B2H92, BHHK91, GKS90a, Han90, and HH91].

The question of whether arithmetic read-once formulas can be interpolated (or learned) quickly in parallel depends on the size of the underlying field. It is shown in [BC92] that for arithmetic read-once formulas over fields with $o(n/\log n)$ elements there is *no* polylogarithmic-time algorithm that uses polynomially many processors

*Received by the editors June 13, 1995; accepted for publication (in revised form) January 23, 1996. This research was supported in part by NSERC of Canada.

(for interpolating as well as learning with membership and equivalence queries [A87], [L88]). Also, a similar negative result holds for boolean read-once formulas.

We present a (Las Vegas) parallel algorithm for the exact interpolation of arithmetic read-once formulas over sufficiently large fields. For fields of size at least $3(n^2 + 3n - 2)$, the algorithm runs in $O(\log^2 n)$ parallel steps using $O(n^4)$ processors (where the field operations are charged unit cost). This complements some results from [BC92] which imply that other classes of read-once formulas *cannot* be interpolated—or even learned with membership and equivalence queries—in polylogarithmic time with polynomially many processors (even though they can be learned sequentially in polynomial time). These classes include boolean read-once formulas and arithmetic read-once formulas over fields of size $o(n/\log n)$ (for n variable read-once formulas).

If the "obvious" parallelizations are made to the interpolating algorithm in [BHH92] (i.e., parallelizations of independent parts of the computation) one obtains a parallel running time that is $\Theta(d)$, where d is the depth of the target formula. Since, in general, d can be as large as $\Theta(n)$, this does not result in significant speedup. Our parallel algorithm uses some techniques from the sequential algorithm of [BHH92] as well as some new techniques that enable nonlocal features of the AROF to be determined in polylogarithmic time.

The parallel algorithm can be implemented on an oracle *parallel random access machine* (PRAM). More specifically, it is an *exclusive-read exclusive-write* (EREW) PRAM—which means that processor's accesses to their communal registers are constrained so that no two processors can read from or write to the same register simultaneously. The EREW PRAM initially selects some random input values (uniformly and independently distributed) and then performs $O(n^3)$ membership queries (via its oracle).

2. Identification with queries. The learning criterion we consider is *exact identification*. There is a formula f called the *target formula*, which is a member of a class of formulas C defined over the variable set V. The goal of the learning algorithm is to halt and output a formula h from C that is equivalent to f.

In a *membership query*, the learning algorithm supplies values $(x_1^{(0)}, \ldots, x_n^{(0)})$ for the variables in V, as input to a *membership oracle*, and receives in return the value of $f(x_1^{(0)}, \ldots, x_n^{(0)})$. Let $f|(x \leftarrow x^{(0)})$ denote the projection of f obtained by hardwiring x to the value $x^{(0)}$. An assignment of values to some subset of a read-once formula's variables defines a *projection*, which is the formula obtained by hardwiring those assigned variables to their values in the formula and then rewriting the formula to eliminate constants from the leaves. Note that if f' is a projection of f, it is possible to simulate a membership oracle for f' using a membership oracle for f.

We say that the class C is learnable in polynomial time if there is an algorithm that uses the membership oracle and interpolates any $f \in C$ in polynomial time in the number of variables n and the size of f. We say that C is efficiently learnable in parallel if there is a parallel algorithm that uses the membership oracle and interpolates any $f \in C$ in polylogarithmic time with polynomial number of processors. In the parallel computation p processors can ask p membership queries in one step.

3. Preliminaries. A *formula* is a rooted tree whose leaves are labeled with variables or constants from some domain and whose internal nodes, or *gates*, are labeled with elements from a set of *basis* functions over that domain. A *read-once formula* is a formula for which no variable appears on two different leaves. An *arithmetic*

read-once formula over a field $\mathcal{K}$ is a read-once formula over the basis of addition, subtraction, multiplication, and division of field elements, whose leaves are labeled with variables or constants from $\mathcal{K}$.

In [BHH92] it is shown that a modified basis can be used to represent any arithmetic read-once formula. Let $\mathcal{K}$ be an arbitrary field. The modified basis for arithmetic read-once formulas over $\mathcal{K}$ includes only two nonunary functions, addition ($+$) and multiplication ($\times$). The unary functions in the basis are $(ax+b)/(cx+d)$ for every $a, b, c, d \in \mathcal{K}$ such that $ad - bc \neq 0$. This requirement is to prevent $ax+b$ and $cx+d$ from being identically 0 or differing by just a constant factor. We can also assume that nonconstant formulas over this modified basis do not contain constants in their leaves. We represent such a unary function as f_A, where

$$A = \begin{pmatrix} a & b \\ c & d \end{pmatrix}.$$

The restriction on a, b, c, and d is equivalent to saying the determinant of A (denoted $\det(A)$) is nonzero.

The value of a read-once formula on an assignment to its variables is determined by evaluating the formula from the bottom up. This raises the issue of division by zero. In [BHH92] this problem is handled by defining basis functions over the extended domain $\mathcal{K} \cup \{\infty, \text{ERROR}\}$, where ∞ represents $1/0$ and ERROR represents $0/0$. For the special values, we define our basis function as follows (assume $x \in \mathcal{K} - \{0\}$, $y \in \mathcal{K} \cup \{\infty, \text{ERROR}\}$, and A is as above).

$$\begin{gathered} y + \text{ERROR} = y \times \text{ERROR} = f_A(\text{ERROR}) = \text{ERROR} \\ x + \infty = x \times \infty = \infty \\ 0 + \infty = \infty \times \infty = \infty \\ 0 \times \infty = \infty + \infty = \text{ERROR} \\ f_A(\infty) = \begin{cases} \frac{a}{c} & c \neq 0 \\ \infty & c = 0 \end{cases} \quad \text{and} \quad f_A\left(\tfrac{-d}{c}\right) = \infty \quad \text{if} \quad c \neq 0. \end{gathered}$$

It is shown in [BHH92] that these definitions are designed so that the output of the read-once formula is the same as it would be if the formula were first expanded and simplified to be in the form $p(x_1, \ldots, x_n)/q(x_1, \ldots, x_n)$ for some polynomials p and q, where $\gcd(p, q) = 1$, and then evaluated.

We say that a formula f is *defined* on the variable set V if all variables appearing in f are members of V. Let $V = \{x_1, \ldots, x_n\}$. We say a formula f *depends* on variable x_i if there are values $x_1^{(0)}, x_2^{(0)}, \ldots, x_n^{(0)}$, and $x_i^{(1)}$ in $\mathcal{K}$ for which

$$f(x_1^{(0)}, x_2^{(0)}, \ldots, x_n^{(0)}) \neq f(x_1^{(0)}, \ldots, x_{i-1}^{(0)}, x_i^{(1)}, x_{i+1}^{(0)}, \ldots, x_n^{(0)})$$

and for which both those values of f are not ERROR. We call such an input vector $v = (x_1^{(0)}, \ldots, x_n^{(0)})$ a *justifying assignment* for x_i.

Between any two gates or leaves α and β in an AROF, the relationships *ancestor*, *descendant*, *parent*, and *child* refer to their relative positions in the rooted tree. Let $\alpha \leq \beta$ denote that α is a descendant of β (or, equivalently, that β is an ancestor of α). Let $\alpha < \beta$ denote that α is a *proper* descendant of β (i.e., $\alpha \leq \beta$ but $\alpha \neq \beta$). For any pair of variables x_i and x_j that appear in a read-once formula, there is a unique node farthest from the root that is an ancestor of both x_i and x_j, called their *lowest common ancestor*, which we write as $\text{lca}(x_i, x_j)$. We shall refer to the *type* of $\text{lca}(x_i, x_j)$ to mean the basis function computed at that gate. We say that a set W

of variables has a common lca if there is a single node that is the lca of every pair of variables in W.

We define the *skeleton* of a formula f to be the tree obtained by deleting any unary gates in f (i.e., the skeleton describes the parenthesization of an expression with the binary operations, but not the actual unary operations or embedded constants).

We now list a basic property of unary functions f_A that is proved in [BHH92].

PROPERTY 3.1.

1. *The function f_A is a bijection from $\mathcal{K} \cup \{\infty\}$ to $\mathcal{K} \cup \{\infty\}$ if and only if* $\det(A) \neq 0$. *Otherwise, f_A is either a constant value from $\mathcal{K} \cup \{\infty, \text{ERROR}\}$ or a constant value from $\mathcal{K} \cup \{\infty\}$, except on one input value on which it is* ERROR.
2. *The functions f_A and $f_{\lambda A}$ are equivalent for any $\lambda \neq 0$.*
3. *Given any three distinct points $p_1 = (x_1, y_1)$, $p_2 = (x_2, y_2)$, and $p_3 = (x_3, y_3)$,*
   (a) *if p_1, p_2, p_3 are on a line then there exists a unique function f_A with $f_A(x) = ax+b$ that satisfies $f_A(x_1) = y_1$, $f_A(x_2) = y_2$, and $f_A(x_3) = y_3$.*
   (b) *if p_1, p_2, p_3 are not on a line then there exists a unique function f_A with* $\det(A) \neq 0$ *that satisfies $f_A(x_1) = y_1$, $f_A(x_2) = y_2$, and $f_A(x_3) = y_3$.*
4. *If functions f_A and f_B are equivalent and* $\det(A), \det(B) \neq 0$, *then there is a constant λ for which $\lambda A = B$.*
5. *The functions $(f_A \circ f_B)$ and f_{AB} are equivalent.*
6. *If* $\det(A) \neq 0$, *functions f_A^{-1} and $f_{A^{-1}}$ are equivalent.*
7. $f_A(\lambda x) = f_{A\left(\begin{smallmatrix}\lambda & 0\\ 0 & 1\end{smallmatrix}\right)}(x)$ *and* $f_A(\lambda + x) = f_{A\left(\begin{smallmatrix}1 & \lambda\\ 0 & 1\end{smallmatrix}\right)}(x)$.
   $\lambda f_A(x) = f_{\left(\begin{smallmatrix}\lambda & 0\\ 0 & 1\end{smallmatrix}\right)A}(x)$ *and* $\lambda + f_A(x) = f_{\left(\begin{smallmatrix}1 & \lambda\\ 0 & 1\end{smallmatrix}\right)A}(x)$.

4. Collapsibility of operations. Whenever two nonunary gates of the same type in an AROF are separated by only a unary gate, it may be possible to collapse them together to a single nonunary gate of the same type with higher arity. For $\star \in \{+, \times\}$, a unary operation f_A is called *$\star$-collapsible* if

$$f_A(x \star y) \star z \equiv f_B(x) \star f_C(y) \star z$$

for some unary operations f_B and f_C. Intuitively, the above property means that if the f_A gate occurs between two nonunary $\star$ gates then the two $\star$ gates can be "collapsed" into a single $\star$ gate of higher arity, provided that new unary gates can be applied to the inputs.

In [BHH92] it is explained that a unary gate f_A is $\times$-collapsible if and only if A is of the form

$$\begin{pmatrix} a & 0 \\ 0 & b \end{pmatrix} \quad \text{or} \quad \begin{pmatrix} 0 & a \\ b & 0 \end{pmatrix},$$

and $+$-collapsible if and only if A is of the form

$$\begin{pmatrix} a & b \\ 0 & c \end{pmatrix}.$$

The following are equivalent definitions of $\star$-collapsible that will be used in this paper.

PROPERTY 4.1. *The following are equivalent.*

1. *f_A is $+$-collapsible.*
2. *$f_A(x) = \alpha x + \beta$ for some $\alpha, \beta \in \mathcal{K}$, and $\alpha \neq 0$.*
3. *$f_A(\infty) = \infty$.*

The following are equivalent.

1. f_A *is* $\times$*-collapsible.*
2. $f_A(x) = \alpha x^\beta$ *for some* $\alpha \in \mathcal{K}$, $\beta \in \{1, -1\}$ *and* $\alpha \neq 0$.
3. $\{f_A(\infty), f_A(0)\} = \{0, \infty\}$.

Proof. We prove the property by showing that $1 \Leftrightarrow 2 \Leftrightarrow 3$. If f_A is $+$-collapsible then

$$A = \begin{pmatrix} a & b \\ 0 & c \end{pmatrix},$$

and therefore $f(x) = (a/c)x + (b/c)$. Since A is nonsingular, $a \neq 0$, $c \neq 0$, and $a/c \neq 0$. $2 \Rightarrow 1$ is obvious. If $f_A(x) = \alpha x + \beta$ for some $\alpha, \beta \in \mathcal{K}$ and $\alpha \neq 0$, then $f_A(\infty) = \alpha\infty + \beta = \infty$. If $f_A(\infty) = \infty$ then, since $f_{\left(\begin{smallmatrix} a & b \\ d & c \end{smallmatrix}\right)}(\infty) = a/d = \infty$, we must have $d = 0$.

The result for $\times$-collapsible is left to the reader. □

In [BHH92], a *three-way justifying assignment* is defined as an assignment of constant values to all but three variables in an AROF such that the resulting formula depends on all of the three remaining variables. For the present results, we require assignments that meet additional requirements, which are defined below.

For any two gates α and β with $\alpha < \beta$, define the α–β *path* as the sequence of gate operations along the path in the tree from α to β (including the operations of α to β at the endpoints of the path). Define a *noncollapsing* three-way justifying assignment as a three-way justifying assignment with the following additional property. For the unassigned variables x, y, and z, if $\mathrm{lca}(x, y) < \mathrm{lca}(x, z)$ and all nonunary operations in the $\mathrm{lca}(x, y)$–$\mathrm{lca}(x, z)$ path are of the same type $\star$ (for some $\star \in \{+, \times\}$), then the function that results from the justifying assignment is of the form

$$f_E(f_C(f_A(x) \star f_B(y)) \star f_D(z)),$$

for some unary operations f_A, f_B, f_C, f_D, and f_E, where f_C is not $\star$-collapsible. Intuitively, this means that, after the justifying assignment, the two gates, $\mathrm{lca}(x, y)$ and $\mathrm{lca}(x, z)$, cannot be collapsed—and thus the relationship $\mathrm{lca}(x, y) < \mathrm{lca}(x, z)$ can still be detected in the resulting function.

Now, define a *total* noncollapsing three-way justifying assignment as a *single* assignment of constant values to all variables in an AROF such that, *for any three variables*, if all but those three are assigned to their respective constants then the resulting assignment is noncollapsing three-way justifying.

5. Parallel learning algorithm. In this section, we present a parallel algorithm for learning AROFs. The algorithm has three principal components: finding a total noncollapsing three-way justifying assignment; determining the skeleton of the AROF; and determining the unary gates of the AROF.

The basic idea is to first construct a graph (that will later be referred to as the least common ancestor hierarchy (LCAH) graph) that contains information about the relative positions of the lcas of all pairs of variables. This cannot be obtained quickly in parallel from justifying assignments because of the possibility that some of the important structure of an AROF "collapses" under any given justifying assignment. However, we shall see that any total noncollapsing justifying assignment is sufficient to determine the entire structure of the AROF at once (modulo some polylog processing).

Once the LCAH graph has been constructed, the skeleton of the AROF can be constructed by discarding some of the structure of the LCAH graph (a "garbage

collection" step). This is accomplished using some simple graph algorithms as well as a parallel prefix sum computation (which is NC^1 computable [LF80]).

Finally, once that skeleton is determined, the unary gates can be determined by a recursive tree contraction method (using results from [B74]).

5.1. Finding a total noncollapsing three-way justifying assignment. In [BHH92], it is proven that, for any triple of variables x, y, and z, by drawing random values (independently) from a sufficiently large field and assigning them to the other variables in an AROF, a three-way justifying assignment for those variables is obtained with high probability. In the parallel algorithm, a three-way justifying assignment that is *total noncollapsing* is required. We show that, if the size of the field $\mathcal{K}$ is at least $O(n^2)$ then the same randomized procedure also yields a total noncollapsing three-way justifying assignment with probability at least $\frac{1}{2}$. Therefore, in time $O(1)$ this step can be implemented.

We shall begin with some preliminary lemmas, and then the precise statement that we require will appear in Corollary 5.4.

LEMMA 5.1. *If $g(y,z) = f_B(f_A(y) \star z)$, where f_A is not $\star$-collapsing, then there exists at most one value $z^{(0)}$ for z such that $f_C(y) \equiv g(y, z^{(0)})$ is $\star$-collapsing.*

Proof. Let $\star = +$. If $f_B(f_A(y)+z_0)$ is $+$-collapsible then by Property 4.1 we have

$$f_B(f_A(y) + z_0) = \alpha y + \beta,$$

where $\alpha \in \mathcal{K}\backslash\{0\}$ and $\beta \in \mathcal{K}$. We substitute $y = \infty$ and get

$$f_B(f_A(\infty) + z_0) = \infty.$$

Since f_A is not $+$-collapsible, by Property 4.1 we have $f_A(\infty) = \gamma \neq \infty$. Solving the above system using Property 3.1 we get

$$z_0 = f_{B^{-1}}(\infty) - \gamma.$$

This shows that there is at most one value of z that makes $f_B(f_A(y)+z)$ $+$-collapsible.

Let $\star = \times$. If $f_B(f_A(y)z_0)$ is $\times$-collapsible then by Property 4.1 we have

$$f_B(f_A(y)z_0) = \alpha y^{\beta},$$

where $\alpha \in \mathcal{K}\backslash\{0\}$ and $\beta \in \{+1, -1\}$. We substitute $y = 0, \infty$ and get

$$\{f_B(f_A(0)z_0), f_B(f_A(\infty)z_0)\} = \{0, \infty\}.$$

Since f_A is not $\times$-collapsible, by Property 4.1, we have that either $f_A(0)$ or $f_A(\infty)$ is not in $\{0, \infty\}$. Suppose $f_A(0) \notin \{0, \infty\}$ and suppose $f_B(f_A(0)z_0) = 0$ (the other cases are similar). Solving this gives

$$z_0 = f_{B^{-1}}(0)/f_A(0).$$

This shows that there is at most one value of z that makes $f_B(f_A(y)z)$ $\times$-collapsible. □

LEMMA 5.2. *Let $F(x_1, \ldots, x_n)$ be an AROF with $lca(x_1, x_2) < lca(x_1, x_3)$ and suppose that all nonunary operations in the $lca(x_1, x_2) - lca(x_1, x_3)$ path are of the same type $\star \in \{+, \times\}$. Let $x_4^{(0)}, \ldots, x_n^{(0)}$ be independently, uniformly, and randomly chosen from $S \subseteq \mathcal{K}$, where $|S| = m$. Then the probability that $x_4^{(0)}, \ldots, x_n^{(0)}$ is a noncollapsing three-way justifying assignment is at least $1 - \left(\frac{3n+1}{m}\right)$.*

Proof. Note that $x_4^{(0)}, \ldots, x_n^{(0)}$ is *not* a noncollapsing three-way justifying assignment if and only if it is not a justifying assignment or there exists a path between the lcas of x_1, x_2, and x_3 such that all nonunary operations are of the same type and the path collapses under the assignment. From [BHH92], the probability of the former condition is at most $\frac{2n+4}{m}$. We need to bound the probability of the latter condition.

We have that $F(x_1, \ldots, x_n)$ is of the form

$$E(f_{H_k}(\cdots f_{H_1}(f_{H_0}(A(x_1) \star B(x_2)) \star C_1) \cdots) \star C_k) \star D(x_3)),$$

where $A(x_1), B(x_2), C_1, \ldots, C_k, D(x_3), E(y)$ may depend on variables from $x_4, \ldots, x_n$ in addition to their marked arguments. Let $\bar{A}(x_1), \bar{B}(x_1), \bar{C}_1, \ldots, \bar{C}_k, \bar{D}(x_3), \bar{E}(y)$ denote the above formulas (respectively) with $x_4^{(0)}, \ldots, x_n^{(0)}$ substituted for the variables $x_4, \ldots, x_n$. Also, let $d_1, \ldots, d_k$ denote the degrees of $C_1, \ldots, C_k$ (respectively) as functions of $x_4, \ldots, x_n$. By the assumption that F is in normal form, f_{H_0} is not $\star$-collapsing. Therefore, by Lemma 5.1, there exists at most one value of C_1 for which $f_{H_1}(f_{H_0}(y) \star C_1)$ is $\star$-collapsing. We can bound the probability of this value occurring for C_1. Since the degree of C_1 is d_1, an application of Schwartz's result in [Sch80] implies the probability that this value occurs for C_1 is at most d_1/m.

Similarly, if $f_{H_1}(f_{H_0}(y) \star C_1)$ is not $\star$-collapsing then Lemma 5.1 implies that there exists at most one value of C_2 for which $f_{H_2}(f_{H_1}(f_{H_0}(y) \star \bar{C}_1) \star C_2)$ is $\star$-collapsing, which occurs with probability at most d_2/m, and so on. It follows that the probability that

$$f_{H_k}(f_{H_{k-1}}(\cdots f_{H_1}(f_{H_0}(y) \star \bar{C}_1) \cdots) \star \bar{C}_k)$$

is $\star$-collapsing is at most $(d_1 + \cdots + d_k)\frac{1}{m} \leq \frac{n-3}{m}$.

The result now follows by summing the two bounds. □

THEOREM 5.3. *Let $F(x_1, \ldots, x_n)$ be an AROF over $\mathcal{K}$, and $x_1^{(0)}, \ldots, x_n^{(0)}$ be chosen uniformly from a set $S \subseteq \mathcal{K}$ with $|S| = m$. Then the probability that $x_1^{(0)}, \ldots, x_n^{(0)}$ is a total noncollapsing three-way justifying assignment is at least $1 - \frac{6n^2}{m}$.*

Proof. First, note that from Lemma 5.2 we can immediately infer that if $x_1^{(0)}, \ldots, x_n^{(0)}$ are drawn independently, uniformly, and randomly from $S \subseteq \mathcal{K}$, where $|S| = m$, then the probability that $x_1^{(0)}, \ldots, x_n^{(0)}$ is a noncollapsing three-way justifying assignment is at most $\binom{n}{3}(\frac{n+1}{2m}) = O(\frac{n^4}{m})$.

To obtain a better bound, consider each subformula C_i that is an input to some nonunary gate in the AROF. By results in [BHH92], there are at most two possible values of C_i that will result in some triple of variables with respect to which the assignment is not three-way justifying (the values are 0 and ∞). Thus, as in the proof of Lemma 5.2, the probability of one of these values arising for C_i is at most $\frac{2d}{m}$, where d is the degree of C_i. Also, from Lemma 5.2, there is at most one value of C_i that will result in a collapsing assignment, and the probability of this arising is at most $\frac{d}{m}$. Thus, the probability of one of the two events above arising is at most $\frac{3d}{m}$, and, since $d \leq n$, this is at most $\frac{3n}{m}$.

Since there are at most $2n$ such subformulas C_i, the probability of any one of them attaining one of the above values is at most $\frac{6n^2}{m}$. □

The constant in the proof of Theorem 5.3 can be improved to obtain probability of

$$1 - \frac{\frac{3}{2}(n^2 + 3n - 2)}{m}$$

by using the following observation. Notice that we upper bounded the degree of each subtree by n. In fact, we can upper bound the degree of the leaves (there are n leaves) by degree 1 since they are variables. Then we have $n-1$ other internal subformulas with respective degrees $2 = d_1 \le d_2 \le \cdots \le d_{n-1}$. It is easy to show that $d_i \le i+1$ (simple induction on the number of nodes). Taking all this into account we obtain the above bound.

By setting $m \ge 3(n^2+3n-2)$, we obtain the following.

COROLLARY 5.4. *Let $F(x_1,\ldots,x_n)$ be an AROF over $\mathcal{K}$, and $x_1^{(0)},\ldots,x_n^{(0)}$ be chosen uniformly from a set $S \subseteq \mathcal{K}$ with $|S| = 3(n^2+3n-2)$. Then the probability that $x_1^{(0)},\ldots,x_n^{(0)}$ is a total noncollapsing three-way justifying assignment is least $\frac{1}{2}$.*

This corollary implies that the expected time complexity of finding a total noncollapsing three-way justifying assignment is $O(1)$.

5.2. Determining the skeleton of a read-once formula in parallel. In this section, we assume that a total noncollapsing three-way justifying assignment is given and show how to construct the skeleton with $O(n^3)$ membership queries in one parallel step followed by $O(\log n)$ steps of computation.

First, suppose that, for a triple of variables x, y, and z, we wish to test whether or not $\mathrm{lca}(x,y) < \mathrm{lca}(x,z)$. If $\mathrm{op}(x,y) \ne \mathrm{op}(x,z)$ then this can be accomplished by a direct application of the techniques in [BHH92], using the fact that we have an assignment that is justifying with respect to variables x, y, and z. On the other hand, if $\mathrm{op}(x,y) = \mathrm{op}(x,z)$ then $\mathrm{lca}(x,y) < \mathrm{lca}(x,z)$ could be difficult to detect with a mere justifying assignment because the justifying assignment might collapse the relative structure between these three variables. If all the nonunary operations in the $\mathrm{lca}(x,y)$–$\mathrm{lca}(x,z)$ path are identical then, due to the fact that we have a noncollapsing justifying assignment, we are guaranteed that the substructure between the three variables does not collapse, and we can determine that $\mathrm{lca}(x,y) < \mathrm{lca}(x,z)$ in $O(1)$ time (again by directly applying techniques in [BHH92]). This leaves the case where $\mathrm{op}(x,y) = \mathrm{op}(x,z)$, but the nonunary operations in the $\mathrm{lca}(x,y)$–$\mathrm{lca}(x,z)$ path are *not* all of the same type. In this case, the techniques of [BHH92] might fail to determine that $\mathrm{lca}(x,y) < \mathrm{lca}(x,z)$ and report them as equal. We shall overcome this problem at a later stage in our learning algorithm by making inferences based on hierarchical relationships with other variables. For the time being, we can, in time $O(1)$ with one processor, compute the following.

$$\textbf{DESCENDANT}(x,y,z) = \begin{cases} \text{YES} & \text{if } \mathrm{lca}(x,y) < \mathrm{lca}(x,z) \text{ and } \mathrm{op}(x,y) \ne \mathrm{op}(x,z); \\ \text{YES} & \text{if } \mathrm{lca}(x,y) < \mathrm{lca}(x,z) \text{ and all nonunary operations} \\ & \text{in the } \mathrm{lca}(x,y)\text{–}\mathrm{lca}(x,z) \text{ path are of the same type;} \\ \text{YES or MAYBE} & \text{if } \mathrm{lca}(x,y) < \mathrm{lca}(x,z) \text{ and } \mathrm{op}(x,y) = \mathrm{op}(x,z) \text{ but } \textit{not} \\ & \text{all nonunary operations in the } \mathrm{lca}(x,y)\text{–}\mathrm{lca}(x,z) \\ & \text{path are of the same type;} \\ \text{MAYBE} & \text{otherwise.} \end{cases}$$

Note that if $\textbf{DESCENDANT}(x,y,z) = \text{YES}$ then it must be that $\mathrm{lca}(x,y) < \mathrm{lca}(x,z)$; however, if $\textbf{DESCENDANT}(x,y,z) = \text{MAYBE}$ then it is possible that $\mathrm{lca}(x,y) < \mathrm{lca}(x,z)$, but $\mathrm{op}(x,y) = \mathrm{op}(x,z)$ and the nonunary operations on the $\mathrm{lca}(x,y)$–$\mathrm{lca}(x,z)$ are not of the same type, or that $\mathrm{lca}(x,y) \not< \mathrm{lca}(x,z)$.

To construct the extended skeleton of an AROF, we first construct its LCAH graph, which is defined as follows.

DEFINITION. *The* LCAH graph *of an AROF with n variables consists of $\binom{n}{2}$ vertices, one corresponding to each (unordered) pair of variables. For the distinct*

variables x and y denote the corresponding vertex by xy or, equivalently, yx. Then, for distinct vertices xy and zw, the directed edge $xy \to zw$ is present in the LCAH graph if and only if $lca(x, y) \leq lca(z, w)$.

We shall prove that the following algorithm constructs the LCAH graph of an AROF.

Algorithm CONSTRUCT-LCAH-GRAPH.

1. **in parallel for all distinct variables** x, y, z **do**
   if DESCENDANT(x, y, z) = YES **then**
   insert edges $xy \to xz$ and $xy \to yz$ and $xz \to yz$ and $yz \to xz$
2. **in parallel for all distinct variables** x, y, z, w **do**
   if edges $xy \to xw \to xz$ are present **then**
   insert edge $xy \to xz$
3. **in parallel for all distinct variables** x, y, z **do**
   if no edges between any of xy, xz, yz are present **then**
   insert edges in each direction between every pair of xy, xz, yz
4. **in parallel for all distinct variables** x, y, z, w **do**
   if edges $xy \to xw \to zw$ present **or** edges $xy \to yw \to zw$ present **then**
   insert edge $xy \to zw$

THEOREM 5.5. *Algorithm* **CONSTRUCT-LCAH-GRAPH** *constructs the LCAH graph of an AROF.*

Proof. The proof follows from the following sequence of observations.

(i) For all distinct variables x, y, and z for which $\text{lca}(x, y) < \text{lca}(x, z) = \text{lca}(y, z)$, after executing steps 1 and 2 of the algorithm the appropriate edges pertaining to vertices xy, xz, and yz (namely, $xy \to xz$, $xy \to yz$, $xz \to yz$, and $yz \to xz$) are present.

(ii) For all distinct variables x, y, and z for which $\text{lca}(x, y) = \text{lca}(x, z) = \text{lca}(y, z)$, after executing step 3 of the algorithm the appropriate edges pertaining to vertices xy, xz, and yz (namely, edges in both directions between every pair) are present.

(iii) For all distinct variables x, y, z, and w, after executing step 4 of the algorithm the edge $xy \to zw$ is present if and only if $\text{lca}(x, y) \leq \text{lca}(z, w)$. □

It is straightforward to verify that algorithm **CONSTRUCT-LCAH-GRAPH** can be implemented to run in $O(\log n)$ time on an EREW PRAM with $O(n^4)$ processors. Moreover, the $O(n^3)$ membership queries can be made initially in one parallel step.

In an AROF, each nonunary gate corresponds to a biconnected component (which is a clique) of its LCAH graph. Thus, to transform the LCAH graph into the extended skeleton of the AROF, we simply "compress" each of its biconnected components into a single vertex and then extract the underlying tree structure of this graph (where the underlying tree structure of a graph is the tree whose transitive closure is the graph[1]). This is accomplished using standard graph algorithm techniques, including a parallel prefix sum computation [LF80]. The details follow.

We first designate a "leader" vertex for each biconnected component. We then record the individual variables that are descendants of each nonunary gate and then discard the other nodes in each biconnected component.

The algorithm below selects a leader from each connected component in an LCAH graph. We assume that there is a total ordering $\prec$ on the vertices of the LCAH graph

[1] All edges are directed toward the root.

(for example, the lexicographic ordering on the pair of indices of the two variables corresponding to each vertex).

Algorithm LEADER.

in parallel for all vertices $xy \prec zw$ **do**
if edges $xy \to zw$ **and** $zw \to xy$ are present **then**
mark xy with X.

It is easy to prove the following.

LEMMA 5.6. *After executing algorithm* **LEADER**, *there is precisely one unmarked node (namely, the largest in the* $\prec$ *ordering) in each biconnected component of the LCAH graph.*

After selecting a leader from each biconnected component of the LCAH graph, we add n new nodes to this graph that correspond to the n variables. The edge $x \to yz$ is inserted if and only if the variable x is a descendant of $\mathrm{lca}(y, z)$. This is accomplished by the following algorithm.

Algorithm LEAVES.

in parallel for all distinct variables x, y, z, w **do**
insert edge $x \to xy$
if edge $xy \to zw$ is present **then**
insert edge $x \to zw$.

LEMMA 5.7. *After executing algorithm* **LEAVES**, *the edge* $x \to yz$ *is present if and only if variable* x *is a descendant of* $lca(y, z)$.

Both Algorithms **LEADER** and **LEAVES** can be implemented in $O(\log n)$ time with $O(n^4)$ processors.

After these steps, the marked nodes are discarded from the augmented LCAH graph (that contains $\binom{n}{2} + n$ vertices), resulting in a graph with at most $2n - 1$ vertices that is isomorphic to the extended skeleton of the AROF. This discarding is accomplished by a standard technique involving the computation of prefix sums. We first adopt the convention that the order $\prec$ extends to the augmented LCAH graph as $x_1 \prec \cdots \prec x_n$ and $x \prec yz$ for any variables x, y, and z. Then, for each node v, set

$$\varphi(v) = \begin{cases} 1 & \text{if } v \text{ is unmarked} \\ 0 & \text{if } v \text{ is marked,} \end{cases}$$

and compute the prefix sums

$$\sigma(v) = \sum_{u \preceq v} \varphi(u).$$

With algorithms for parallel prefix sum computation [LF80] this can be accomplished in $O(\log(\binom{n}{2} + n)) = O(\log n)$ time with $O(\binom{n}{2} + n) = O(n^2)$ processors.

The function σ is a bijection between the unmarked nodes of the augmented LCAH graph and some $S \subseteq \{1, 2, \ldots, 2n - 1\}$, and $\sigma(x_i) = i$ when $i \in \{1, \ldots, n\}$. The following algorithm uses the values of this function to produce the extended skeleton of the AROF.

Algorithm COMPRESS-AND-PRUNE.

in parallel for all distinct vertices u, v **do**
if vertices u, v are both unmarked

and edge $u \to v$ is in augmented LCAH graph **then**
insert edge $\sigma(u) \to \sigma(v)$ in skeleton graph
in parallel for all distinct $i, j, k \in S$ **do**
if edges $i \to j \to k$ **and** $i \to k$ are in skeleton graph **then**
remove edge $i \to k$ from skeleton graph.

The following is straightforward to prove.

LEMMA 5.8. *The "skeleton" graph that* **COMPRESS-AND-PRUNE** *produces is isomorphic to the extended skeleton of the AROF, where the inputs* $x_1, \ldots, x_n$ *correspond to the vertices* $1, \ldots, n$ *(respectively) of the graph.*

5.3. Determining a read-once formula from its skeleton. Once the skeleton of an AROF is determined, what remains is to determine the constants in its unary gates (note that the nonunary operations are easy to determine using the techniques in [BHH92]). We show how to do this in $O(\log^2 n)$ steps with $O(n \log n)$ processors. The main idea is to find a node that partitions the skeleton into three parts whose sizes are all bounded by half of the size of the skeleton. Then the unary gates are determined on each of the parts (in a recursive manner), and the unary gates required to "assemble" the parts are computed.

The following lemma is an immediate consequence from a result in [B74].

LEMMA 5.9. *For any formula* $F(x_1, \ldots, x_n)$*, there exists a nonunary gate of type* $\star$ *that "evenly" partitions it in the following sense. With a possible relabelling of the indices of the variables,*

$$F(x_1, \ldots, x_n) \equiv G(f_A(f_B(H(x_1, \ldots, x_k)) \star f_C(I(x_{k+1}, \ldots, x_l))), x_{l+1}, \ldots, x_n),$$

and the number of variables in $G(y, x_{l+1}, \ldots, x_n)$*,* $H(x_1, \ldots, x_k)$*, and* $I(x_{k+1}, \ldots, x_l)$ *are all bounded above by* $\lceil \frac{n}{2} \rceil$*.*

A minor technicality in the above lemma is that, since the skeleton is not necessarily a binary tree, it may be necessary to "split" a nonbinary gate into two smaller gates.

It is straightforward to obtain the above decomposition of a skeleton in NC^1. Once this decomposition is obtained, the recursive algorithm for computing the unary gates of the AROF follows from the following lemma.

LEMMA 5.10. *Let* $x_1^{(0)}, \ldots, x_n^{(0)}$ *be a total noncollapsing justifying assignment for the AROF* $F(x_1, \ldots, x_n)$*. If*

$$F(x_1, \ldots, x_n) \equiv G(f_A(f_B(H(x_1, \ldots, x_k)) \star$$

$$f_C(I(x_{k+1}, \ldots, x_l))), x_{l+1}, \ldots, x_n)$$

then
(i) *given the skeleton of* $F(x_1, \ldots, x_n)$ *and the subformulas* $G(y, x_{l+1}, \ldots, x_n)$*,* $H(x_1, \ldots, x_k)$ *and* $I(x_{k+1}, \ldots, x_l)$*, it is possible to determine* A*,* B*, and* C*, and, thus, the entire structure of* $F(x_1, \ldots, x_n)$ *in* $O(\log n)$ *steps with* $O(n \log n)$ *processors.*
(ii) *given the skeleton of* $F(x_1, \ldots, x_n)$*, the problem of determining* $G(y, x_{l+1}, \ldots, x_n)$*,* $H(x_1, \ldots, x_k)$*, and* $I(x_{k+1}, \ldots, x_l)$ *is reducible to the problem of determining a ROF given its skeleton.*

Proof. For part (i), assume that the subformulas $G(y, x_{l+1}, \ldots, x_n)$, $H(x_1, \ldots, x_k)$, and $I(x_{k+1}, \ldots, x_l)$ are given. Since $x_1^{(0)}, \ldots, x_n^{(0)}$ is a justifying assignment, $G(y, x_{l+1}^{(0)},$

$\ldots, x_n^{(0)})$, $H(x_1, x_2^{(0)}, \ldots, x_k^{(0)})$, $I(x_{k+1}, x_{k+2}^{(0)}, \ldots, x_l^{(0)})$ are all nonconstant unary functions, so there exist nonsingular matrices A', B', C' (which are easy to determine in $O(\log n)$ parallel steps) such that

$$f_{A'}(y) \equiv G\left(y, x_{l+1}^{(0)}, \ldots, x_n^{(0)}\right)$$
$$f_{B'}(x_1) \equiv H\left(x_1, x_2^{(0)}, \ldots, x_k^{(0)}\right)$$
$$f_{C'}(x_{k+1}) \equiv I\left(x_{k+1}, x_{k+2}^{(0)}, \ldots, x_l^{(0)}\right).$$

Also,

$$F(x_1, x_2^{(0)}, \ldots, x_k^{(0)}, x_{k+1}, x_{k+2}^{(0)}, \ldots, x_n^{(0)}) \equiv f_{A'}(f_A(f_B(f_{B'}(x_1) \star f_C(f_{C'}(x_{k+1}))))),$$

so the matrices $A' \cdot A$, $B \cdot B'$, $C \cdot C'$ can be determined in $O(1)$ steps, [BHH92]. From this, the matrices A, B, C can be determined.

For part (ii), consider the problem of determining $G(y, x_{l+1}, \ldots, x_n)$. Note that

$$F(y, x_2^{(0)}, \ldots, x_l^{(0)}, x_{l+1}, \ldots, x_n) \equiv G(f_{A''}(y), x_{l+1}, \ldots, x_n),$$

for some nonsingular A''. Therefore, if we fix $x_2, \ldots, x_l$ to $x_2^{(0)}, \ldots, x_l^{(0)}$ then we have a reduction from the problem of determining $G(f_{A''}(y), x_{l+1}, \ldots, x_n)$.

Similarly, we have reductions from the problem of determining $f_{B''}(H(x_1, \ldots, x_k))$ and $f_{C''}(I(x_{k+1}, \ldots, x_l))$ for nonsingular matrices B'' and C''. Since the matrices A'', B'', C'' can be absorbed into the processing of part (i), this is sufficient. □

By recursively applying Lemmas 5.9 and 5.10, we obtain a parallel algorithm to determine an AROF given its skeleton and a total noncollapsing three-way justifying assignment in $O(\log^2 n)$ steps. The processor count for this can be bounded by $O(n \log n)$.

AN ON-LINE ALGORITHM FOR SOME UNIFORM PROCESSOR SCHEDULING*

RONGHENG LI† AND LIJIE SHI‡

Abstract. This paper considers the problem of on-line scheduling a set of independent jobs on m uniform machines $(M_1, M_2, \ldots, M_m)$ in which machine $M_i's$ processing speed is $s_i = 1(i = 1, \ldots, m-1)$ and $s_m = s > 1$. List scheduling [Y. Cho and S. Sahni, *SIAM J. Comput.*, 9 (1980), pp. 91–103] guarantees a worst-case performance of $\frac{3m-1}{m+1}(m \geq 3)$ and $\frac{1+\sqrt{5}}{2}(m = 2)$ for this problem. We prove that this worst-case bound cannot be improved for $m = 2$ and $m = 3$ and for every $m \geq 4$, an algorithm with worst-case performance at most $\frac{3m-1}{m+1} - \varepsilon$ is presented when $s_m = 2$, where ε is a fixed positive number, and then we improve the bound for general $s_m = s > 1$.

Key words. on-line scheduling, list scheduling, uniform machines

1. Introduction.

A uniform machine system consists of $m, m \geq 1$, machines $(M_1, M_2, \ldots, M_m)$. A speed $s_i, s_i \geq 1$ is associated with each machine. In one unit of time M_i can carry out s_i units of processing. A list $(t_1, t_2, \ldots, t_n)$ of n jobs is given to us on-line—that means we get the jobs one by one. Both the total number of jobs that need to be scheduled and the size of the jobs are not previously known. The processing time of job t_i becomes known only when t_{i-1} has already been scheduled. As soon as job t_i appears, it must irrevocably be scheduled. Our goal is to minimize the makespan, i.e., the maximum completion time over all jobs in a schedule. The quality of an algorithm H is measured by its worst-case ratio

$$R^H(m) = \sup_L \{C^H(L)/C^*(L) : L \textit{ is a list of jobs}\},$$

where $C^H(L)$ denotes the makespan produced by the heuristic H on the machines and the list L of jobs and $C^*(L)$ denotes the corresponding makespan in some optimal schedule. List scheduling (LS), which always assigns the current job to the machine that will complete it first, is a simple example of a nonpreemptive on-line algorithm and is always used. When $s_i = 1(i = 1, 2, \ldots, m)$, the machine system is well known as an identical machine system. For an identical machine system, Graham showed in 1969 that $R^{LS}(m) = 2 - 1/m$ [2]. For $m \geq 4$, this bound was improved by Galambos and Woeginger in 1993 [3]. They designed an algorithm called Refined List Scheduling (RLS) and showed that $R^{RLS}(m) \leq 2 - 1/m - \eta_m$, where $\eta_m > 0$ for $m \geq 4$. Bartal et al. [4] made some progress for large numbers of machines by devising an algorithm whose worst-case guarantee is $2 - \frac{1}{7}$ for all m. When $s_i = 1(i = 1, \ldots, m-1)$ and $s_m = s \geq 1$, Cho and Sahni showed in 1980 that $R^{LS}(m, s) \leq 1 + \frac{m-1}{m+s-1} \min\{2, s\} \leq 3 - \frac{4}{m+1}$, and the bound $3 - \frac{4}{m+1}$ is achieved when s=2.

In this paper, for $m \geq 4$ machines we present a heuristic that has a significantly better worst-case performance guarantee than LS when $s_i = 1(i = 1, \ldots, m-1)$ and

$s_m = 2$ and then show that the bound $3 - \frac{4}{m+1}$ can be improved when $s_i = 1 (i = 1, \ldots, m-1)$ and $s_m = s > 1$. For $m = 2$ and 3, we will show that the worst-case performance guarantee of LS cannot be improved by any heuristic.

2. Lower bounds for on-line scheduling. For a heuristic H, let

$$R^H(m,s) = \sup_L \{C^H(L)/C^*(L) \mid L \text{ is a list of jobs and } s_i = 1 (i = 1, 2, \ldots, m-1), \quad s_m = s \geq 1 \text{ is fixed}\}, \tag{2.1}$$

$$R^H(m) = \sup_{s \geq 1} R^H(m,s). \tag{2.2}$$

In the remainder of this paper we always assume that the speed $s_i = 1 (i = 1, \ldots, m-1)$ and $s_m = s \geq 1$ if there is no special notation.

THEOREM 2.1. *The following inequalities hold.*

(i) $R^{LS}\left(2, \frac{1+\sqrt{5}}{2}\right) = R^{LS}(2) = \frac{1+\sqrt{5}}{2}$,

(ii) $R^{LS}(m,s) \leq 1 + \frac{m-1}{m+s-1} \min\{2, s\}$,

(iii) $R^{LS}(m) = R^{LS}(m,2) = 3 - \frac{4}{m+1}, \qquad (m \geq 3)$.

Proof. For the proof see [1]. ∎

THEOREM 2.2. *For any heuristic H, the following inequalities hold.*

(i) $R^H(2) \geq \frac{1+\sqrt{5}}{2}$,

(ii) $R^H(m) \geq 2, \qquad (m \geq 3)$.

Proof. Claim (i) is easily proved by using list $L_1 = \left\{1, \frac{1+\sqrt{5}}{2}\right\}$ when $s_1 = 1$ and $s_2 = \frac{1+\sqrt{5}}{2}$. Suppose that there exists an on-line algorithm H with $R^H(m) < 2$ for $m \geq 3$. Consider list $l_k = \{1, 2, \ldots, 2^k\}$ $(k = 0, 1, 2, \ldots)$. Obviously

$$R^H(m) \geq \frac{C^H(l_k)}{C^*(l_k)}$$

for any $k \geq 0$. One can easily verify that $C^*(l_k) = 2^{k-1}$. Because $R^H(m) < 2$, the jobs in list l_k must all be assigned to machine M_m; then $C^H(l_k) = 2^k - \frac{1}{2}$ and

$$R^H(m) \geq \frac{C^H(l_k)}{C^*(l_k)} = 2 - \frac{1}{2^k}.$$

We conclude that $R^H(m) \geq 2$ for the arbitrariness of k. ∎

From Theorems 2.1 and 2.2, we know that $R^{LS}(2)$ and $R^{LS}(3)$ cannot be improved anymore.

3. The algorithm. In this section we will give a heuristic. As the algorithm gets the jobs one by one, the values of C^* and C^H vary during the algorithm. To simplify notation, we will identify each job with its length. The load L_i of a machine M_i is the sum of processing times over all jobs assigned to it. In the remainder of this paper, we always assume that the speed $s_i = 1 (i = 1, 2, \ldots, m-1)$ and $s_m = s \geq 1$ if there is no special notation.

We are ready to present our heuristic A. In the algorithm, two real numbers α_m and β_m are used that satisfy $0 < \alpha_m < 1$ and $\beta_m > 1$. In order to keep the presentation simple, we drop the indices and write α and β instead. The exact values of α and β will be specified later.

ALGORITHM A.

Step 1. Reorder the machines such that $L_1 \le L_2 \le \cdots \le L_{m-1}$ holds. Let x be a new job given to the algorithm.

Step 2. Let $L = \sum_{i=1}^{m-1} L_i + sL_m$ be the total length of jobs given before x. If

$$L_m \ge \frac{(3m-5)\alpha}{s(m+1)(m-2)}L \quad \text{and} \quad x \le \frac{\beta}{m-2}L,$$

then put x on L_1.

Step 3. Assign x by LS, that is to say, assign x to the machine that will complete it first.

Throughout the following analysis, we always denote by x the current job. In order to keep the analysis simple, we present the following simple inequalities.

$$(m+s-1)C^* \ge L + x \tag{3.1}$$

and

$$t_i \le sC^* \tag{3.2}$$

for any given job t_i.

LEMMA 3.1. *If x is put on L_1 in Step* 2, *then*

$$(L_1 + x)/C^* \le \frac{m+s-1}{m-1}\left[1 + \frac{(m-2)\beta}{m+\beta-2} - \frac{(3m-5)\alpha}{(m+1)(m+\beta-2)}\right].$$

Proof. Because $x \le \frac{\beta}{m-2}L$, we have

$$x \le \frac{\beta}{m+\beta-2}(L+x). \tag{3.3}$$

Since

$$L + x = \sum_{1}^{m-1} L_i + sL_m + x$$

$$\ge (m-1)(L_1+x) + \frac{(3m-5)\alpha}{(m+1)(m-2)}(L+x) - \left[m + \frac{(3m-5)\alpha}{(m+1)(m-2)} - 2\right]x.$$

From the above and (3.3) we get

$$\left[1 + \frac{(m-2)\beta}{m+\beta-2} - \frac{(3m-5)\alpha}{(m+1)(m+\beta-2)}\right](L+x) \ge (m-1)(L_1+x). \tag{3.4}$$

By (3.1) and (3.4), Lemma 3.1 is proved. □

LEMMA 3.2. *If $x \le \frac{\beta}{m-2}L$ and x is assigned to M_i in Step* 3, *then*

$$L_i^x/C^* \le \frac{m + m\beta - 2}{m+\beta-2},$$

where L_i^x represents the load of the machine M_i after x has been assigned to M_i.

Proof. We know that in Step 3 x is assigned to either M_1 or M_m. If x is put on L_1, then $L_1 + x \le L_m + \frac{x}{s}$ and

$$\begin{aligned} L + x &= \sum_{i=1}^{m-1} L_i + sL_m + x \\ &\ge (m-1)(L_1 + x) + s\left(L_m + \frac{x}{s}\right) - (m-1)x \\ &\ge (m+s-1)(L_1 + x) - \frac{(m-1)\beta}{m+\beta-2}(L+x). \end{aligned}$$

From the above and (3.1), we get

$$(L_1 + x)/C^* \le \frac{m + m\beta - 2}{m + \beta - 2}.$$

Similarly we can prove

$$\left(L_m + \frac{x}{s}\right)/C^* \le \frac{m + m\beta - 2}{m + \beta - 2}$$

if x is put on L_m. □

In the remainder of this paper, the real number $\bar{\alpha}$ satisfies that $\bar{\alpha} > \alpha$.

LEMMA 3.3. *If*

$$\frac{\beta}{m-2}L < x \le \frac{\bar{\beta}}{m-1}L \quad \textit{and} \quad L_m < \frac{(3m-5)\bar{\alpha}}{s(m+1)(m-2)}L$$

then

$$L_i^x/C^* \le \frac{(m+s-1)(m-1)}{(m+\bar{\beta}-1)s}\left[\frac{(3m-5)\bar{\alpha}}{(m+1)(m-2)} + \frac{\bar{\beta}}{(m-1)}\right].$$

Proof. From (3.1) we have

$$\begin{aligned} \left(L_m + \frac{x}{s}\right)\Big/ C^* &\le \left(L_m + \frac{x}{s}\right)\Big/ \frac{L+x}{m+s-1} \\ &\le (m+s-1)\left(L_m + \frac{\bar{\beta}L}{s(m-1)}\right)\Big/\left(L + \frac{\bar{\beta}}{m-1}L\right) \\ &\le \frac{(m+s-1)(m-1)}{(m+\bar{\beta}-1)s}\left[\frac{(3m-5)\bar{\alpha}}{(m+1)(m-2)} + \frac{\bar{\beta}}{(m-1)}\right]. \end{aligned}$$

Because x is assigned in Step 3, $L_i^x \le L_m + \frac{x}{s}$. Lemma 3.3 is proved. □

LEMMA 3.4. *If x is assigned to machine M_i and*

$$L_m \ge \frac{(3m-5)\bar{\alpha}}{s(m+1)(m-2)}L, \qquad \frac{\beta}{m-2}L \le x < \frac{\bar{\beta}}{m-1}L$$

and

$$\frac{(3m-5)\alpha}{(m+1)(m+\beta-2)} + \frac{\beta}{m+\beta-2} \le \frac{(3m-5)\bar{\alpha}}{(m+1)(m-2)}, \tag{3.5}$$

then

$$L_i^x/C^* \le \max\left\{\frac{s(m-2)(m\bar{\beta}+m-1)(m\beta+m-2)(m+1)}{(m-1)(m+s-1)^2(3m-5)\bar{\alpha}\beta},\right.$$
$$\left.1+\frac{m-1}{m+s-1}\max\{1,s-1\}\right\}.$$

Proof. Let t be the last task assigned to machine M_m before x.

Case 1. $t \le C^*$. Let $\bar{L}_i (i=1,2,\ldots,m)$ be the machine $M_i's$ load before t is assigned and let $\bar{L}$ be the total length of tasks before t is given. If

$$t \le \frac{\beta}{m-2}\bar{L}, \quad \text{then } \bar{L}_m < \frac{(3m-5)\alpha}{s(m+1)(m-2)}\bar{L}.$$

So

$$\begin{aligned} L_m &= \bar{L}_m + \frac{t}{s} < \frac{(3m-5)\alpha}{s(m+1)(m-2)}\bar{L} + \frac{t}{s} \\ &= \frac{(3m-5)\alpha}{s(m+1)(m-2)}(\bar{L}+t) + \frac{1}{s}\left[1-\frac{(3m-5)\alpha}{(m+1)(m-2)}\right]t \\ &\le \frac{(3m-5)\alpha}{s(m+1)(m-2)}(\bar{L}+t) + \frac{1}{s}\left(1-\frac{(3m-5)\alpha}{(m+1)(m-2)}\right)\frac{\beta}{m+\beta-2}(\bar{L}+t) \\ &\le \frac{1}{s}\left[\frac{(3m-5)\alpha}{(m+1)(m+\beta-2)}+\frac{\beta}{m+\beta-2}\right]L. \end{aligned}$$

This is a contradiction because

$$L_m \ge \frac{(3m-5)\bar{\alpha}}{s(m+1)(m-2)}L \ge \frac{1}{s}\left[\frac{(3m-5)\alpha}{(m+1)(m+\beta-2)}+\frac{\beta}{m+\beta-2}\right]L.$$

So we get

$$t > \frac{\beta}{m-2}\bar{L} \tag{3.6}$$

and t is assigned as in Step 3. Since

$$\begin{aligned} \bar{L}+t &\ge (m-1)\bar{L}_1 + s\bar{L}_m + t \\ &= (m-1)(\bar{L}_1+t) + s\left(\bar{L}_m+\frac{t}{s}\right) - (m-1)t \\ &\ge (m+s-1)\left(\bar{L}_m+\frac{t}{s}\right) - (m-1)t \\ &= (m+s-1)L_m - (m-1)t, \end{aligned}$$

and by

$$L_m \ge \frac{(3m-5)\bar{\alpha}}{s(m+1)(m-2)}L$$

and (3.6), we conclude that

$$t \geq \frac{\beta\bar{\alpha}(3m-5)(m+s-1)}{s(\beta m+m-2)(m+1)(m-2)}L. \tag{3.7}$$

If x is assigned to M_m, then

$$\begin{aligned} L+x &= \sum_{i=1}^{m-1} L_i + sL_m + x \\ &\geq (m-1)(L_1+x) + s\left(L_m+\frac{x}{s}\right) - (m-1)x \\ &\geq (m+s-1)\left(L_m+\frac{x}{s}\right) - \frac{(m-1)\bar{\beta}}{m+\bar{\beta}-1}(L+x). \end{aligned}$$

From the above we get

$$L+x \geq \frac{(m+s-1)(m+\bar{\beta}-1)}{m\bar{\beta}+m-1}\left(L_m+\frac{x}{s}\right).$$

So

$$\begin{aligned} \left(L_m+\frac{x}{s}\right)/C^* &\leq \left(L_m+\frac{x}{s}\right)\Big/ t \\ &\leq \frac{m\bar{\beta}+m-1}{(m+s-1)(m+\bar{\beta}-1)}\frac{L+x}{t} \\ &\leq \frac{m\bar{\beta}+m-1}{(m+s-1)(m+\bar{\beta}-1)}\cdot\left(L+\frac{\bar{\beta}}{m-1}L\right) \\ &\quad\cdot\frac{s(m\beta+m-2)(m+1)(m-2)}{\beta\bar{\alpha}(3m-5)(m+s-1)L} \\ &= \frac{s(m\bar{\beta}+m-1)(m\beta+m-2)(m+1)(m-2)}{\beta\bar{\alpha}(m+s-1)^2(m-1)(3m-5)}. \end{aligned}$$

Case 2. $t > C^*$. In this case, we conclude that

$$x \leq C^*\max\{1, s-1\}.$$

So

$$\begin{aligned} (m+s-1)C^* \geq L+x &\geq (m-1)L_1 + s\left(L_m+\frac{x}{s}\right) \\ &\geq (m+s-1)\left(L_m+\frac{x}{s}\right) - (m-1)x \\ &\geq (m+s-1)\left(L_m+\frac{x}{s}\right) - (m-1)C^*\max\{1, s-1\}. \end{aligned}$$

From the above we get

$$\left(L_m+\frac{x}{s}\right)\Big/ C^* \leq 1 + \frac{m-1}{m+s-1}\max\{1, s-1\}.$$

Similarly, we can prove it if x is assigned to M_1. □

LEMMA 3.5. *If* $x > \frac{\bar{\beta}}{m-1}L$ *and* x *is assigned to* M_i *in Step* 3, *then*

$$L_i^x/C^* \le \frac{sm}{m+s+1} + \frac{s(m-1)}{\bar{\beta}(m+s-1)},$$

where L_i^x *represents the load of machine* M_i *after* x *is assigned to* M_i.

Proof. If x is assigned to M_1, then

$$\begin{aligned} L + x &= \sum_{i=1}^{m-1} L_i + sL_m + x \\ &\ge (m+s-1)(L_1 + x) - (m-1)x. \end{aligned}$$

From the above, $x \le sC^*$, and $x > \frac{\bar{\beta}}{m-1}L$ we have

$$\begin{aligned} \frac{L_1 + x}{C^*} &\le (L_1 + x) \Big/ \frac{x}{s} \le \frac{s(L+mx)}{(m+s-1)x} \\ &\le \frac{ms}{m+s-1} + \frac{sL}{m+s-1} \cdot \frac{m-1}{\bar{\beta}L} \\ &= \frac{ms}{m+s-1} + \frac{(m-1)s}{(m+s-1)\bar{\beta}}. \end{aligned}$$

If x is assigned to M_m, the proof is similar. □

LEMMA 3.6. *Let* $R_m = \min R$, *subject to*

$$\begin{cases} (m+1)R^2 - 2(m-1)R - 2m > 0 \\ 2 < R < \dfrac{3m-1}{m+1} \\ \dfrac{(m+1)R^2 - 2(m-1)R - m - 1}{(m+1)^2 R - 2m(m+1)} \\ \qquad \ge \dfrac{1}{2}\left[\dfrac{(m+1)R^2 - 2(m-1)R - m - 1}{(m+1)R^2 - 2(m-1)R - 2m} - \dfrac{(m-1)R}{m+1}\right]. \end{cases} \tag{3.8}$$

We have that R_m *is the only real root of*

$$\begin{aligned} (m+1)^3 R^4 - (m+1)(5m^2 + 4m - 5)R^3 + (6m^3 - 18m + 4)R^2 \\ + (m^3 + 11m^2 - m - 3)R - 2m(m^2 - 1) = 0 \end{aligned} \tag{3.9}$$

in interval $(2, 3 - \frac{4}{m+1})$, *and* R_m *is an increasing function of* m. $\lim_{m\to\infty} R_m$ *is the only real root of equation* $R^3 - 3R^2 + 1 = 0$ *between* 2 *and* 3.

Proof. Equation (3.8) is equivalent to

$$\begin{aligned} \frac{1}{2}R + \frac{2}{(m+1)^2} - \frac{(m-1)^2}{(m+1)^2[(m+1)R - 2m]} \\ \ge \frac{m-1}{2[(m+1)R^2 - 2(m-1)R - 2m]} + \frac{1}{2}. \end{aligned} \tag{3.10}$$

If m is fixed, the left-hand side of (3.10) is an increasing function of R and the right-hand side of (3.10) is a decreasing function of R in interval

$$\left(2, \frac{m-1+\sqrt{3m^2+1}}{m+1}\right)$$

and

$$\left(\frac{m-1+\sqrt{3m^2+1}}{m+1}, \frac{3m-1}{m+1}\right],$$

respectively. If $R = 2$ or $\frac{3m-1}{m+1}$, the inequality (3.10) is strict and

$$\frac{m-1+\sqrt{3m^2+1}}{m+1}$$

is an odd point of the right-hand side. So R_m exists and is the only real root of equation

$$\frac{1}{2}R + \frac{2}{(m+1)^2} - \frac{(m-1)^2}{(m+1)^2((m+1)R-2m)} = \frac{m-1}{2[(m+1)R^2-2(m-1)R-2m]} + \frac{1}{2}. \tag{3.11}$$

If R is fixed, it is easy to verify that the right-hand side of (3.10) is an increasing function of m but the left-hand side is a decreasing function of m. So we can conclude that R_m is an increasing function of m. From (3.11) we get (3.9), and letting m tend to infinity in (3.11), we get $R^3 - 3R^2 + 1 = 0$. □

THEOREM 3.7. *For Algorithm A there exists $\varepsilon_m > 0$ such that*

$$R^A(m,2) \le \frac{3m-1}{m+1} - \varepsilon_m$$

and there exists a positive ε such that $\varepsilon_m \ge \varepsilon$ for every $m \ge 4$.

Proof. Lemmas 3.1–3.5 give upper bounds on the worst-case ratios in the five scenarios. If $\alpha < 1$ and $\beta > 1$, we can easily verify that

$$\frac{m+1}{m-1}\left[1 + \frac{(m-2)\beta}{m+\beta-2} - \frac{(3m-5)\alpha}{(m+1)(m+\beta-2)}\right] > \frac{m+m\beta-2}{m+\beta-2}. \tag{3.12}$$

Let R be the real root of equation (3.9), and

$$\alpha_1 = \frac{2(m+1)^2R^4 - 8(m^2-1)R^3 + 2(3m^2-10m+3)R^2 + (3m^2-2m-5)R + 2m(m+1)}{[(m+1)R-2m][(m+1)R^2-2(m-1)R-2m-1]},$$

$$\alpha = \frac{m-2}{3m-5}\alpha_1,$$

$$\beta = \frac{m-2}{(m+1)R^2-2(m-1)R-2m-1},$$

$$\bar{\alpha} = \frac{2(m-2)[(m+1)R^2-2(m-1)R-m-1]}{(3m-5)[(m+1)R-2m]},$$

$$\bar{\beta} = \frac{2(m-1)}{(m+1)R-2m};$$

TABLE 3.1

m	α_m	β_m	$R^{LS}(m,2)$	$R^{A}(m,2)$
4	0.9482	1.1512	2.2	2.1835
5	0.8951	1.2557	2.3333	2.3025
9	0.7634	1.4854	2.6	2.5353
∞	0.5357	1.8779	3	2.8795

then inequality (3.5) becomes equality and the upper bounds given in Lemma 3.1, 3.3, 3.4, and 3.5 are all equal to R. From Lemma 3.6, let $\varepsilon_m = \frac{3m-1}{m+1} - R$; then we get

$$R^A(m,2) \le R = \frac{3m-1}{m+1} - \varepsilon_m.$$

Because ε_m tends to a positive number when m tends to infinity, there exists a positive number ε such that $\varepsilon_m \ge \varepsilon$ for every $m \ge 4$. □

The comparison for some m between the two algorithms is shown in Table 3.1.

In the following we devise an algorithm $\bar{A}$ for general $s_m = s > 1$.

ALGORITHM $\bar{A}$. Let ε_1 and ε_2 be two positive numbers. If $2 - \varepsilon_1 \le s \le 2 + \varepsilon_2$, then we use algorithm A to schedule; otherwise we use algorithm LS.

THEOREM 3.8. *There exist suitable* $\varepsilon_1 > 0$, $\varepsilon_2 > 0$, *and* $\varepsilon_m > 0$ *such that*

$$R^{\bar{A}}(m) \le \frac{3m-1}{m+1} - \varepsilon_m$$

for every $m \ge 4$.

Proof. Because the upper bounds given in Lemmas 3.1, 3.2, 3.4, and 3.5 are continuous functions of s, from Theorems 2.1 and 3.7, Theorem 3.8 is proved. □

4. Conclusion. In this paper we derived two on-line algorithms that beat list scheduling in the measure of worst-case performance (for $m \ge 4$) on two conditions, respectively. However, the following question may be very interesting. First, asymptotically our analysis did not improve the heuristic LS in Theorem 3.8, since ε_m may tend to zero as m tends to infinity. Second, in Theorem 3.8 $R^{\bar{A}}(m,s) = R^{LS}(m,s)$ for most $s > 1$. Are there on-line scheduling algorithms with worst case better than $R^{LS}(m,s)$ for any fixed $s \ge 1$? Third, for $m \ge 4$ machines, we gave a lower bound of 2. How can we get a greater lower bound?

Acknowledgment. We are grateful to our supervisor, Professor Minyi Yue, for his encouragement on this problem.

THE LOAD, CAPACITY, AND AVAILABILITY OF QUORUM SYSTEMS*

MONI NAOR† AND AVISHAI WOOL‡

Abstract. A *quorum system* is a collection of sets (quorums) every two of which intersect. Quorum systems have been used for many applications in the area of distributed systems, including mutual exclusion, data replication, and dissemination of information.

Given a strategy to pick quorums, the load $\mathcal{L}(\mathcal{S})$ is the minimal access probability of the busiest element, minimizing over the strategies. The capacity *Cap*(S) is the highest quorum accesses rate that $\mathcal{S}$ can handle, so $Cap(\mathcal{S}) = 1/\mathcal{L}(\mathcal{S})$.

The availability of a quorum system $\mathcal{S}$ is the probability that at least one quorum survives, assuming that each element fails independently with probability p. A tradeoff between $\mathcal{L}(\mathcal{S})$ and the availability of $\mathcal{S}$ is shown.

We present four novel constructions of quorum systems, all featuring optimal or near optimal load, and high availability. The best construction, based on paths in a grid, has a load of $O(1/\sqrt{n})$, and a failure probability of $\exp(-\Omega(\sqrt{n}))$ when the elements fail with probability $p < \frac{1}{2}$. Moreover, even in the presence of faults, with exponentially high probability the load of this system is still $O(1/\sqrt{n})$. The analysis of this scheme is based on percolation theory.

Key words. quorum systems, load, fault tolerance, distributed computing, percolation theory, linear programming

1. Introduction.

1.1. Motivation. *Quorum systems* serve as basic tools providing a uniform and reliable way to achieve coordination between processors in a distributed system. Quorum systems are defined as follows. A *set system* is a collection of sets $\mathcal{S} = \{S_1, \ldots, S_m\}$ over an underlying universe $U = \{u_1, \ldots, u_n\}$. A set system is said to satisfy the *intersection property* if every two sets $S, R \in \mathcal{S}$ have a nonempty intersection. Set systems with the intersection property are known as *quorum systems*, and the sets in such a system are called quorums.

Quorum systems have been used in the study of problems such as *mutual exclusion* (cf. [39]), *data replication protocols* (cf. [7, 18]), *name servers* (cf. [32]), *selective dissemination of information* (cf. [46]), and *distributed access control and signatures* (cf. [34]).

A protocol template based on quorum systems works as follows. In order to perform some action (e.g., update the database, enter a critical section), the user selects a quorum and *accesses all its elements.* The intersection property then guarantees that the user will have a consistent view of the current state of the system. For example,

if all the members of a certain quorum give the user permission to enter the critical section, then any other user trying to enter the critical section before the first user has exited (and released the permission-granting quorum from its lock) will be refused permission by at least one member of any quorum it chooses to access.

In this work we consider three criteria of measuring how good a quorum system is:

1. `Load`. A strategy is a rule giving each quorum an access frequency (so that the frequencies sum up to 1). A strategy induces a load on each element, which is the sum of the frequencies of all quorums it belongs to. This represents the fraction of the time an element is used. For a given quorum system $\mathcal{S}$, the load $\mathcal{L}(\mathcal{S})$ is the minimal load on the busiest element, minimizing over the strategies. The load measures the quality of a quorum system in the following sense. If the load is low, then each element is accessed rarely; thus it is free to perform other unrelated tasks.

2. `Capacity`. We would like the system to handle as many requests as possible. For this purpose we define $a(\mathcal{S}, k)$ as the number of quorum accesses that $\mathcal{S}$ can handle during a period of k time units. This is the maximal t for which there exists a way to schedule t quorum accesses, to quorums $S^1, \ldots, S^t$ (allowing repetitions), such that no element is accessed more than k times. The capacity $Cap(\mathcal{S})$ is then the limit as $k \to \infty$ of $a(\mathcal{S}, k)$ normalized by k.

3. `Availability`. Assuming that each element fails with probability p, what is the probability, F_p, that the surviving elements do not contain any quorum? This failure probability measures how resilient the system is, and we would like F_p to be as small as possible.

Our goal is to investigate these criteria and find quorum systems that perform well according to all three.

1.2. Related work. The first distributed control protocols using quorum systems [42, 14] use *voting* to define the quorums. Each processor has a number of votes, and a quorum is any set of processors with a combined number of votes exceeding half of the system's total number of votes. The simple majority system is the most obvious voting system.

The availability of voting systems is studied in [4]. It is shown that in terms of availability, the majority is the best quorum system when $p < \frac{1}{2}$. In [35] the failure probability function F_p is characterized, and among other things it is shown that the singleton has the best availability when $p > \frac{1}{2}$. The case when the elements fail with different probabilities p_i, all less than $\frac{1}{2}$, is addressed in [41].

The first paper to explicitly consider mutual exclusion protocols in the context of intersecting set systems was [13]. In this work the term *coterie* and the concept of *domination* are introduced. Several basic properties of dominated and nondominated coteries are proved.

Alternative protocols based on quorum systems (rather than on voting) appear in [28] (using finite projective planes), [1] (the Tree system), [5, 25] (using a grid), and [23, 24, 38] (hierarchical systems). The triangular system is due to [26, 9]. The Wheel system appears in [29]. The CWlog system appears in [37, 36]. The motivation for several of these alternative systems was to find constructions with high availability and low load (which is referred to in most of these papers as quorum systems with small quorums).

In [19], the question of how evenly balanced the work load can be is studied. Tradeoffs between the potential load balancing of a system and its average load are obtained, and it is shown that in some quorum systems it is impossible to have a perfect load balance in which all the elements have an equal load.

A concept of capacity in voting systems is defined in [21] and some voting systems are compared. The analysis does not distinguish between properties of the quorum system and properties of the strategy that chooses which quorum to access.

A good reference to percolation theory is [15]. Two successful applications of percolation to questions of computer science are shown in [30] and [8].

While the majority quorum system is the best in terms of availability, and the finite projective planes construction have excellent load, they fail miserably according to the other criteria: the load of majority is $\frac{1}{2}$ and the failure probability of the projective planes (FPP) goes to 1 (quickly) as the number of elements grows. In fact, all of the existing constructions are less successful than ours in the simultaneous achievement of high availability and low load.

1.3. New results. We start by defining the concepts of load and capacity and showing that they can be formulated as linear or integer linear programs. Then using results of hypergraph theory we show that $Cap(\mathcal{S}) = 1/\mathcal{L}(\mathcal{S})$. Therefore, all the information regarding the capacity is captured by $\mathcal{L}(\mathcal{S})$.

We obtain several lower bounds on the load $\mathcal{L}(\mathcal{S})$. We show that if the minimal quorum size is $c(\mathcal{S})$, then $\mathcal{L}(\mathcal{S}) \geq \max\{1/c(\mathcal{S}), c(\mathcal{S})/n\}$; hence $\mathcal{L}(\mathcal{S}) \geq 1/\sqrt{n}$. We also obtain a tradeoff between the load and failure probability, i.e., $F_p \geq p^{n\mathcal{L}(\mathcal{S})}$. In some cases the linear program formulation of load also allows us to efficiently compute the load of a given quorum system, even if the quorums are not represented explicitly, using the ellipsoid algorithm adaptation of [16]. The behavior of the load when the elements may fail is also studied. We assume the common model that the elements fail independently with probability p. The load then becomes a random variable $\mathcal{L}_p(\mathcal{S})$.

Next we show some conditions that prove that a given strategy w induces the optimal load. This enables us to find optimal strategies and to calculate $\mathcal{L}(\mathcal{S})$ of some quorum systems without actually solving the linear program.

The major contributions of this work are four novel quorum system constructions, all of which have optimal or near optimal load *and* high availability, i.e., a failure probability that tends to 0 exponentially fast when $p < \frac{1}{2}$, or at least when $p < \beta < \frac{1}{2}$. Our best construction is the Paths system, which is based on a percolation grid. It has a load of $O(1/\sqrt{n})$, and a failure probability of $\exp(-\Omega(\sqrt{n}))$ when the elements fail with probability $p < \frac{1}{2}$. Moreover, even in the presence of faults, with exponentially high probability the load of this system is still $O(1/\sqrt{n})$. Two other constructions resemble the Grid construction but are enhanced so their failure probability tends to 0. The B-Grid system has $\mathcal{L}(\text{B-Grid}) = O(1/\sqrt{n})$ and if $p < \frac{1}{3}$, then $F_p(\text{B-Grid}) = O(\exp(-n^{1/4}/2))$. The SC-Grid system has $\mathcal{L}(\text{SC-Grid}) = O(\sqrt{(\ln n)/n})$, and if $p < \frac{1}{2} - \delta$ for some $\delta > 0$, then $F_p(\text{SC-Grid}) \leq \exp(-\Omega(\sqrt{n \ln n}))$. The AndOr system uses the AND/OR trees of [43]. It has $\mathcal{L}(\text{AndOr}) = O(1/\sqrt{n})$, $F_p(\text{AndOr}) \leq \exp(-\Omega(\sqrt{n}))$ when $p < \frac{1}{4}$, and $F_p \leq \exp(-\Omega(n^{0.19}))$ if $p \leq 0.38 - \Omega(n^{-0.19})$. The three latter constructions also enjoy the property that their quorums are all of size $O(\sqrt{n})$.

Finally, we analyze the load of some known quorum system constructions. We show that all voting systems have a load of at least $\frac{1}{2}$, which is very high. We also show that nondominated coteries have lower load than dominated ones.

The paper is organized in as follows. In section 2 we present some basic definitions. In section 3 we define the load and the capacity, their linear programs, and the relationship between them. In section 4 we prove the basic properties of the load. In section 5 we present the new constructions. In section 6 we analyze the load of some quorum systems.

2. Preliminaries.

2.1. Definitions and notation.

DEFINITION 2.1. *A* set system $\mathcal{S} = \{S_1, \ldots, S_m\}$ *is a collection of subsets* $S_i \subseteq U$ *of a finite universe* U. *A* quorum system *is a set system* $\mathcal{S}$ *that has the* intersection property: $S \cap R \neq \varnothing$ *for all* $S, R \in \mathcal{S}$.

Alternatively, quorum systems are known as *intersecting set systems* or *intersecting hypergraphs*. The sets of the system are called *quorums*. The number of elements in the underlying universe is denoted by $n = |U|$. The number of quorums in the system is denoted by m. The cardinality of the smallest quorum in $\mathcal{S}$ is denoted by $c(\mathcal{S}) = \min\{|S| : S \in \mathcal{S}\}$.

The *degree* of an element $i \in U$ in a quorum system $\mathcal{S}$ is the number of quorums that contain i: $\deg(i) = |\{S \in \mathcal{S} : i \in S\}|$.

DEFINITION 2.2. *Let* $\mathcal{S}$ *be a quorum system.* $\mathcal{S}$ *is* s-uniform *if* $|S| = s$ *for all* $S \in \mathcal{S}$.

DEFINITION 2.3. *A quorum system* $\mathcal{S}$ *is* (s,d)-fair *if it is* s*-uniform and* $\deg(i) = d$ *for all* $i \in U$. $\mathcal{S}$ *is called* s*-fair if it is* (s,d)*-fair for some* d.

DEFINITION 2.4. *A* coterie *is a quorum system* $\mathcal{S}$ *that has the* minimality property: *there are no* $S, R \in \mathcal{S}$, $S \subset R$.

DEFINITION 2.5. *Let* $\mathcal{R}, \mathcal{S}$ *be coteries* (*over the same universe* U). *Then* $\mathcal{R}$ dominates $\mathcal{S}$, *denoted* $\mathcal{R} \succ \mathcal{S}$, *if* $\mathcal{R} \neq \mathcal{S}$ *and for each* $S \in \mathcal{S}$ *there is* $R \in \mathcal{R}$ *such that* $R \subseteq S$. *A coterie* $\mathcal{S}$ *is called* dominated *if there exists a coterie* $\mathcal{R}$ *such that* $\mathcal{R} \succ \mathcal{S}$. *If no such coterie exists, then* $\mathcal{S}$ *is* nondominated (ND). *Let* NDC *denote the class of all* ND *coteries.*

2.2. The probabilistic failure model. We use a simple probabilistic model of the failures in the system. We assume that the elements (processors) fail independently with probabilities p_i. We assume that the failures are *transient*. We assume also that the failures are *crash* failures and that they are *detectable*.

DEFINITION 2.6. *A* configuration *is a vector* $\mathbf{x} \in \{0,1\}^n$ *in which* $x_i = 1$ *iff the element* $i \in U$ *has* failed.

Notation. For a configuration $\mathbf{x}$ let $dead(\mathbf{x}) = \{i \in U : x_i = 1\}$ denote the set of failed elements, and let $live(\mathbf{x}) = \{i \in U : x_i = 0\}$ denote the set of functioning elements.

Notation. We use $q_i = 1 - p_i$ to denote the probability of survival of element i.

DEFINITION 2.7. *For every quorum* $S \in \mathcal{S}$ *let* $\mathcal{E}_S$ *be the event that* S *is* hit, *i.e., at least one element* $i \in S$ *has failed* (*or,* $x_i = 1$ *for some* $i \in S$). *Let* $fail(\mathcal{S})$ *be the event that all the quorums* $S \in \mathcal{S}$ *are hit, i.e.,* $fail(\mathcal{S}) = \bigcap_{S \in \mathcal{S}} \mathcal{E}_S$.

When the failure probabilities are equal, i.e., $\mathbf{p} = (p, \ldots, p)$, we use the definition of [35] of the global system failure probability of a quorum system $\mathcal{S}$, as follows.

DEFINITION 2.8. $F_p(\mathcal{S}) = \mathbb{P}_p(fail(\mathcal{S})) = \mathbb{P}_p(\bigcap_{S \in \mathcal{S}} \mathcal{E}_S)$.

When we consider the asymptotic behavior of $F_p(\mathcal{S}_n)$ for a sequence $\mathcal{S}_n$ of quorum system over a universe with an increasing size n, we find that for many constructions it is similar to the behavior described by the Condorcet Jury Theorem [6]. Hence, we have the following definition of [35].

DEFINITION 2.9. *A parameterized family of functions* $g_p(n) : \mathbb{N} \to [0,1]$, *for* $p \in [0,1]$, *is said to be* Condorcet *iff*

$$\lim_{n \to \infty} g_p(n) = \begin{cases} 0, & p < \frac{1}{2}, \\ 1, & p > \frac{1}{2}, \end{cases}$$

and $g_{1/2}(n) = \frac{1}{2}$ *for all* n. *If* $g_p(n)$ *has this behavior for* $p \neq \frac{1}{2}$ *but* $g_{1/2}(n) \neq \frac{1}{2}$, *then it is said to be* almost Condorcet.

3. Load and capacity.

3.1. Strategies and load. A protocol using a quorum system (for mutual exclusion, say) occasionally needs to access quorums during its run. A strategy is a probabilistic rule that governs which quorum is chosen each time. In other words, a strategy gives the frequency of picking each quorum S_j.

DEFINITION 3.1. *Let a quorum system* $\mathcal{S} = (S_1, \ldots, S_m)$ *be given over a universe* U. *Then* $w \in [0,1]^m$ *is a* strategy *for* $\mathcal{S}$ *if it is a probability distribution over the quorums* $S_j \in \mathcal{S}$, *i.e.,* $\sum_{j=1}^m w_j = 1$.

For every element $i \in U$, a strategy w of picking quorums induces the frequency of accessing element i, which we call the *load* on i. The *system load*, $\mathcal{L}(\mathcal{S})$, is the load on the *busiest* element induced by the *best* possible strategy. Formally, we have the following definition.

DEFINITION 3.2. *Let a strategy* w *be given for a quorum system* $\mathcal{S} = (S_1, \ldots, S_m)$ *over a universe* U. *For an element* $i \in U$, *the* load *induced by* w *on* i *is* $\ell_w(i) = \sum_{S_j \ni i} w_j$. *The* load *induced by a strategy* w *on a quorum system* $\mathcal{S}$ *is*

$$\mathcal{L}_w(\mathcal{S}) = \max_{i \in U} \ell_w(i).$$

The system load *on a quorum system* $\mathcal{S}$ *is*

$$\mathcal{L}(\mathcal{S}) = \min_w \{\mathcal{L}_w(\mathcal{S})\},$$

where the minimum is taken over all strategies w.

Remarks.

(i) The load $\mathcal{L}(\mathcal{S})$ should be viewed as a "best case" definition. A load of $\mathcal{L}(\mathcal{S})$ is achieved only if the quorums are chosen according to an optimal strategy. However, a protocol using the quorum system may use some other strategy (for instance, if computing an optimal strategy is too costly) hence, the actual load might be higher than $\mathcal{L}(\mathcal{S})$. This also means that $\mathcal{L}(\mathcal{S})$ is a property inherent in the combinatorial structure of the *quorum system* and not in the protocol using the system.

(ii) In the definition of $\mathcal{L}(\mathcal{S})$ we are assuming that all the elements of the universe are functioning, so all the quorums of the system are usable. In the following the definition is extended to the case where the elements may fail.

3.2. A linear programming formulation of the load. An alternative way to define the load is via a linear programming formulation. This formulation shows that the load $\mathcal{L}(\mathcal{S})$ can be computed in polynomial time using linear programming algorithms (cf. [40]) if $\mathcal{S}$ is given explicitly.

DEFINITION 3.3. *Let a quorum system* $\mathcal{S} = (S_1, \ldots, S_m)$ *be given over a universe* U *of size* n. *Define a variable* w_j *for each quorum* $S_j \in \mathcal{S}$ *and an additional variable* L. *Then the* system load $\mathcal{L}(\mathcal{S})$ *is defined by the following linear program.*

$$LP : \mathcal{L}(\mathcal{S}) = \min L, \quad s.t. \begin{cases} \sum_{j=1}^m w_j = 1, & \text{(i)} \\ \sum_{S_j \ni i} w_j \leq L, \quad \textit{for all } i \in U, & \text{(ii)} \\ w_j \geq 0,\ L \geq 0. & \text{(iii)} \end{cases}$$

Notation. We use $(w; L)$ to denote a tuple of a strategy and a possible load that together constitute a point in the problem domain $[0,1]^{m+1}$.

Remark. The program LP is always feasible, since for any quorum system $\mathcal{S}$ and strategy w, the point $(w; 1)$ is trivially feasible. Clearly, LP is also a bounded linear program, so $\mathcal{L}(\mathcal{S})$ is always finite.

The next definition and lemma show that the load $\mathcal{L}(\mathcal{S})$ is closely related to the well-known *fractional matching number* of a hypergraph (cf. [12, p. 149]).

DEFINITION 3.4. *The fractional matching number of a quorum system, denoted by ν^*, is*

$$FM : \nu^*(\mathcal{S}) = \max \sum_{j=1}^{m} f_j, \quad s.t. \begin{cases} \sum_{S_j \ni i} f_j \leq 1, & \text{for all } i \in U, \\ f_j \geq 0. \end{cases}$$

LEMMA 3.5. *$\mathcal{L}(\mathcal{S}) = 1/\nu^*(\mathcal{S})$ for any quorum system $\mathcal{S}$.*

Proof. Let w be an optimal strategy for program LP, attaining $\mathcal{L}(\mathcal{S})$. Then f defined by $f_j = w_j/\mathcal{L}(\mathcal{S})$ is feasible in program FM. Since FM is maximizing, it follows that $\nu^*(\mathcal{S}) \geq \sum_j f_j = 1/\mathcal{L}(\mathcal{S})$.

On the other hand, consider f which optimizes program FM, with $\sum_j f_j = \nu^*(\mathcal{S})$. Then w defined by $w_j = f_j/\nu^*$ is a strategy (since $\sum_j w_j = 1$), and $(w; 1/\nu^*)$ is feasible for program LP. Since $\mathcal{L}(\mathcal{S})$ is minimal it follows that $\mathcal{L}(\mathcal{S}) \leq 1/\nu^*(\mathcal{S})$. □

Notation. For a vector $\mathbf{y} \in [0, 1]^n$ and a set $S \subseteq U$, let $\mathbf{y}(S) = \sum_{i \in S} y_i$.

FACT 3.6. *Let $\mathcal{S}$ be a quorum system as in Definition 3.3. Define a variable y_i for each element $i \in U$, and an additional variable T. The dual of program LP is*

$$DLP : t(\mathcal{S}) = \max T, \quad s.t. \begin{cases} \sum_{i=1}^{n} y_i \leq 1, & \text{(iv)} \\ \mathbf{y}(S_j) \geq T, \quad \text{for all } S_j \in \mathcal{S}, & \text{(v)} \\ y_i \geq 0, & \text{(vi)} \\ T \lneqq 0. & \text{(vii)} \end{cases}$$

Remarks.

(i) Formally the variable T is unconstrained (vii). However, at the optimum, $t(\mathcal{S}) = T$ is positive, since $T = 0$ is feasible for any vector $\mathbf{y} \in [0, 1]^n$ and DLP is a maximization problem.

(ii) The value of $t(\mathcal{S})$ does not change if we require equality in (iv), since we can increase the y_i values without violating any inequality in (v) and without changing T.

Using the dual program DLP allows us in some cases to compute $\mathcal{L}(\mathcal{S})$, even when $\mathcal{S}$ is given implicitly, using the ellipsoid algorithm of [16, 27] (see section 4.3).

3.3. The capacity of a quorum system. Each time that a distributed protocol generates an access to a quorum $S \in \mathcal{S}$, it causes work to be done by the elements of S. During the time that the elements of S are busy with one quorum access, they cannot handle another. However, other elements may be used in the next quorum access, making use of the parallelism in the system. We want to find what is the maximal rate of quorum access that the system allows.

Assume that it takes one unit of time for an element to complete the work required for a single quorum access. Now consider a period of k time units, and some schedule of quorum accesses that need to take place during this period. Let the integers r_j count the number of times that each quorum $S_j \in \mathcal{S}$ is accessed, with the total number of accesses being $a = \sum_{S_j \in \mathcal{S}} r_j$. Ignoring the order in which the quorum accesses are scheduled, a necessary condition for the system to handle all a accesses within this period of k time units is that every element $i \in U$ be accessed at most k times. The following definition formalizes this condition using an integer linear program.

DEFINITION 3.7. *The maximum number of quorum accesses which a quorum system $\mathcal{S}$ can handle within k units of time is*

$$IP: a(\mathcal{S},k) = \max \sum_{j=1}^{m} r_j, \qquad s.t. \begin{cases} \sum_{S_j \ni i} r_j \le k, & \text{for all } i \in U, \\ r_j \ge 0, \\ r_j \in \mathbb{N}. \end{cases}$$

The capacity of the system $\mathcal{S}$ is defined as the maximal rate at which the system handles quorum accesses. In other words, the capacity is the number of accesses $a(\mathcal{S},k)$ that the system can handle, normalized by k. Since we are interested in the behavior over long time periods, we let the period k tend to infinity.

DEFINITION 3.8. *The* capacity *of a quorum system $\mathcal{S}$ is*

$$Cap(\mathcal{S}) = \lim_{k\to\infty} \frac{a(\mathcal{S},k)}{k}.$$

In hypergraph theory the quantity $a(\mathcal{S},k)$ is known as the *k-matching number* of $\mathcal{S}$ and is usually denoted by ν_k (cf. [12, p. 154]). Furthermore, Proposition 5.12 of [12] shows that $\lim_{k\to\infty} \nu_k/k = \nu^*$; hence by the definition of the capacity and Lemma 3.5 we obtain the following corollary.

COROLLARY 3.9. *Cap(S)= 1/$\mathcal{L}(\mathcal{S})$.*

Therefore, all the information regarding the capacity is captured by $\mathcal{L}(\mathcal{S})$. In [33] we gave a direct proof of Corollary 3.9 (without using the hypergraph machinery) which indicates how to schedule the quorum accesses so the capacity tends to $1/\mathcal{L}(\mathcal{S})$: select the quorums independently at random using a strategy w which optimizes the load.

3.4. The load with failures. In this section we extend our definition of the load to the case where the elements may fail. We use the simple probabilistic failure model of section 2.2, namely that the elements fail independently with probabilities $\mathbf{p} = (p_1, \ldots, p_n)$.

DEFINITION 3.10. *Let $\mathbf{x} \in \{0,1\}^n$ be the current configuration. Then $\mathcal{S}_\mathbf{x}$ is the subcollection of functioning quorums, $\mathcal{S}_\mathbf{x} = \{S \in \mathcal{S} : S \subseteq live(\mathbf{x})\}$.*

DEFINITION 3.11. *The load of a quorum system $\mathcal{S}$ over a configuration $\mathbf{x} \in \{0,1\}^n$ is defined as follows. If $\mathcal{S}_\mathbf{x} = \varnothing$ then $\mathcal{L}(\mathcal{S}_\mathbf{x}) = 1$. If there are functioning quorums, i.e., $\mathcal{S}_\mathbf{x} \neq \varnothing$, then*

$$\mathcal{L}(\mathcal{S}_\mathbf{x}) = \min L, \qquad s.t. \begin{cases} \sum_{S_j \in \mathcal{S}_\mathbf{x}} w_j = 1, \\ \sum_{\mathcal{S}_\mathbf{x} \ni S_j \ni i} w_j \le L, & \text{for all } i \in live(\mathbf{x}), \\ w_j \ge 0,\ L \ge 0. \end{cases}$$

Remark. When there are no functioning quorums in the current configuration, there is no natural concept of load. We choose to define $\mathcal{L}(\mathcal{S}_\mathbf{x}) = 1$ for such a configuration to capture the intuition of a monotonic load; as more elements fail, the load increases. The intuition behind this definition is justified in Proposition 3.16.

DEFINITION 3.12. *Let the elements fail with probabilities $\mathbf{p} = (p_1, \ldots, p_n)$. Then the load is a random variable $\mathcal{L}_\mathbf{p}(\mathcal{S})$ defined by*

$$\mathbb{P}\Big(\mathcal{L}_\mathbf{p}(\mathcal{S}) = L\Big) = \sum_{\substack{\mathbf{x} \\ \mathcal{L}(\mathcal{S}_\mathbf{x})=L}} \prod_{i \in dead(\mathbf{x})} p_i \prod_{i \in live(\mathbf{x})} q_i.$$

If the probabilities $\mathbf{p} = (p, \ldots, p)$ *are all equal, we denote the random load by* $\mathcal{L}_p(\mathcal{S})$. *Let* $E\mathcal{L}_p(\mathcal{S})$ *denote the expectation of* $\mathcal{L}_p(\mathcal{S})$.

FACT 3.13. *For any quorum system* $\mathcal{S}$, *if the elements never fail, then* $E\mathcal{L}_0(\mathcal{S}) = \mathcal{L}(\mathcal{S})$ *and if the elements fail with probability* 1, *then* $E\mathcal{L}_1(\mathcal{S}) = 1$.

LEMMA 3.14. *Let* $\mathcal{S}$ *be a quorum system. Then* $E\mathcal{L}_p(\mathcal{S}) \geq F_p(\mathcal{S})$ *for any* $p \in [0, 1]$.

Proof. By Definition 3.11, in a configuration $\mathbf{x}$ that causes a system failure (i.e., all the quorums are hit) the load is 1. Since $F_p(\mathcal{S})$ is the probability of a system failure, we get

$$E\mathcal{L}_p(\mathcal{S}) = [1 - F_p(\mathcal{S})] \cdot g(\mathcal{S}, p) + F_p(\mathcal{S}) \cdot 1$$

for some $g(\mathcal{S}, p) \geq 0$, and we are done. □

The following examples show that although the FPP quorum system and the Grid system have optimal or near optimal load of $O(1/\sqrt{n})$ when all the elements are functioning (see Example 4.11), this load is not *stable*.

Example 3.15. In [35] it is shown that $F_p(\text{FPP}) \underset{n\to\infty}{\longrightarrow} 1$ and $F_p(\text{Grid}) \underset{n\to\infty}{\longrightarrow} 1$ for any $p > 0$. Therefore Lemma 3.14 gives that $E\mathcal{L}_p(\mathcal{S}) \underset{n\to\infty}{\longrightarrow} 1$ for both systems. □

The next proposition shows the correctness of the intuition that if the elements are more fail prone, then the load is higher. For the proof we need some notation and two lemmas.

PROPOSITION 3.16. $E\mathcal{L}_p(\mathcal{S})$ *is a monotone nondecreasing function of* $p \in [0, 1]$ *for any* $\mathcal{S}$.

Notation. For configurations $\mathbf{x}$ and $\mathbf{z}$, denote $\mathbf{x} \geq \mathbf{z}$ if $x_i \geq z_i$ for all $i \in U$.

Notation. For a vector $\mathbf{z} = (z_1, \ldots, z_n)$, let $(1_i; \mathbf{z})$ denote the vector $\mathbf{z}$ with a 1 plugged into the ith coordinate: $(1_i; \mathbf{z}) = (z_1, \ldots, z_{i-1}, 1, z_{i+1}, \ldots, z_n)$, and similarly for $(0_i; \mathbf{z})$.

LEMMA 3.17. *Consider the function* $L(\mathbf{x}) : \{0, 1\}^n \mapsto [0, 1]$ *defined by* $L(\mathbf{x}) = \mathcal{L}(\mathcal{S}_\mathbf{x})$ *for some quorum system* $\mathcal{S}$. *If* $\mathbf{x} \geq \mathbf{z}$ *then* $L(\mathbf{x}) \geq L(\mathbf{z})$.

Proof. If $\mathbf{x} \geq \mathbf{z}$ then every element that is functioning in configuration $\mathbf{x}$ (with $x_i = 0$) is also functioning in $\mathbf{z}$. Therefore $\mathcal{S}_\mathbf{x} \subseteq \mathcal{S}_\mathbf{z}$. If $\mathcal{S}_\mathbf{x} = \varnothing$, then by Definition 3.11 $L(\mathbf{x}) = 1$ and we are done. Otherwise, any strategy w that uses only quorums of $\mathcal{S}_\mathbf{x}$ is a valid strategy for $\mathcal{S}_\mathbf{z}$ as well, and by the minimality of $\mathcal{L}(\mathcal{S}_\mathbf{z})$ the claim follows. □

LEMMA 3.18. *Let* $\mathcal{S}$ *be a quorum system, let the elements fail with probabilities* $\mathbf{p} = (p_1, \ldots, p_n)$, *and let* $L(\mathbf{x}) = \mathcal{L}(\mathcal{S}_\mathbf{x})$ *be the load over configuration* $\mathbf{x}$. *Consider the multilinear function* $h(\mathbf{p}) : [0, 1]^n \mapsto [0, 1]$ *defined by*

$$h(\mathbf{p}) = \sum_{\mathbf{x}\in\{0,1\}^n} L(\mathbf{x}) \prod_{x_k=1} p_k \prod_{x_k=0} q_k = \mathbb{E}[L(\mathbf{x})].$$

Then $\frac{\partial h}{\partial p_i} = h(1_i; \mathbf{p}) - h(0_i; \mathbf{p}) = \mathbb{E}[L(1_i; \mathbf{x}) - L(0_i; \mathbf{x})]$.

Proof. Sum $h(\mathbf{p})$ separately for configurations in which element i is failed ($x_i = 1$) or is functioning ($x_i = 0$).

$$\begin{aligned} h(\mathbf{p}) &= p_i \sum_{\mathbf{x}:x_i=1} L(\mathbf{x}) \prod_{\substack{x_k=1\\k\neq i}} p_k \prod_{x_k=0} q_k + q_i \sum_{\mathbf{x}:x_i=0} L(\mathbf{x}) \prod_{x_k=1} p_k \prod_{\substack{x_k=0\\k\neq i}} q_k \\ &= p_i h(p_1, \ldots, p_{i-1}, 1, p_{i+1}, \ldots, p_n) + q_i h(p_1, \ldots, p_{i-1}, 0, p_{i+1}, \ldots, p_n) \\ &= p_i h(1_i; \mathbf{p}) + q_i h(0_i; \mathbf{p}). \end{aligned}$$

Taking partial derivatives we get $\frac{\partial h}{\partial p_i} = h(1_i; \mathbf{p}) - h(0_i; \mathbf{p})$. Having element i fail with probability 1 is the same as having a constant 1 in the random configuration $\mathbf{x}$, so $h(1_i; \mathbf{p}) = \mathbb{E}[L(1_i; \mathbf{x})]$. Linearity of the expectation completes the lemma. □

Proof of Proposition 3.16. Consider the case where the elements fail with probabilities $\mathbf{p} = (p_1, \ldots, p_n)$, and let $L(\mathbf{x})$ and $h(\mathbf{p})$ be as before. By Lemma 3.17 $L(\mathbf{x})$ is nondecreasing, so $L(1_i; \mathbf{x}) \geq L(0_i; \mathbf{x})$ for every i. Therefore by Lemma 3.18, $\frac{\partial h}{\partial p_i} \geq 0$ as an expectation of nonnegative terms, so $h(\mathbf{p})$ is nondecreasing in every coordinate. Plugging $\mathbf{p} = (p, \ldots, p)$ shows that $E\mathcal{L}_p(\mathcal{S}) = h(p, \ldots, p)$ is a nondecreasing function. □

3.5. Other measures of load. In order to measure an intuitive notion of "load" of a quorum system, our definition of $\mathcal{L}(\mathcal{S})$ (Definitions 3.2 and 3.3) is not the only one that comes to mind. Here we discuss the shortcomings of some alternatives.

Several authors (e.g., [28, 1] have emphasized the criterion of having small quorums. This is an important parameter since it captures the message complexity of a protocol using the quorum system. However, it does not tell us *how to use* the quorums so each element is used as infrequently as possible. Moreover, our lower bounds (Propositions 4.1 and 4.2) show that if the quorum size is small (i.e., $c(\mathcal{S}) < \sqrt{n}$) then decreasing it any further actually increases the load. We therefore argue that when analyzing a quorum system, one should consider *both* its quorum size and load (and of course its availability) since each measures a different aspect of the system's quality. Having a small quorum size does not give us the whole picture.

Looking for systems with small average quorum size can also be misleading. For instance, the average quorum size in the Wheel system [29] is very small (≈ 3) but the load is high: $\mathcal{L}(\text{Wheel}) \approx 1/2$.

Another tempting definition is that of an average load, rather than the maximum, i.e., $AvL(\mathcal{S}) = \min_w \frac{1}{n} \sum_{i \in U} \sum_{S_j \ni i} w_j$, minimizing over strategies w. An equivalent notion is that of the total load, which is the same as the average except for the scaling factor of $1/n$. However, by changing the summation order it follows that $AvL(\mathcal{S}) = \min_w \frac{1}{n} \sum_{1 \leq j \leq m} w_j |S_j|$. A strategy that minimizes this expression is the trivial strategy that always uses the smallest quorum $S_{\min}$ (with probability 1), so AvL is an uninteresting measure.

4. Properties of the load.

4.1. Lower bounds and a tradeoff of the load. In this section we present three lower bounds on the load $\mathcal{L}(\mathcal{S})$, in terms of the smallest quorum cardinality $c(\mathcal{S})$ and the universe size n. Two of these can be found in the hypergraph literature as upper bounds for the fractional matching number ν^*, and we present them here using our terminology. We also show a tradeoff between the availability of a quorum system, quantified by the failure probability F_p, and the load.

PROPOSITION 4.1. (See [12, p. 150].) $\mathcal{L}(\mathcal{S}) \geq \frac{c(\mathcal{S})}{n}$ *for any quorum system* $\mathcal{S}$.

PROPOSITION 4.2. $\mathcal{L}(\mathcal{S}) \geq \frac{1}{c(\mathcal{S})}$ *for any quorum system* $\mathcal{S}$.

Proof. Let $S_{\min} \in \mathcal{S}$ be a quorum such that $|S_{\min}| = c(\mathcal{S})$ and let $\mathbf{y}$ be defined by $y_i = \frac{1}{c(\mathcal{S})}$ for $i \in S_{\min}$ and $y_i = 0$ otherwise. Then $(\mathbf{y}; 1/c(\mathcal{S}))$ is feasible for program DLP so the claim follows by the weak duality of linear programming. □

PROPOSITION 4.3. (See [2]; cf. [12, p. 170].) *Let* $m(\mathcal{S})$ *be the number of quorums in* $\mathcal{S}$. *Then*

$$\mathcal{L}(\mathcal{S}) \geq \frac{1}{\sqrt{n}} \sqrt{1 + \frac{c(\mathcal{S}) - 1}{m(\mathcal{S})}} \geq \frac{1}{\sqrt{n}}.$$

Example 4.4. The following examples show that both Propositions 4.1 and 4.2 give meaningful lower bounds on the load of some quorum systems.

(i) Over an odd-sized universe, all the quorums of the simple majority system Maj are of size $(n+1)/2$; therefore, by Proposition 4.1 $\mathcal{L}(\text{Maj}) \geq (n+1)/2n > \frac{1}{2}$.

(ii) In the Tree system [1], the smallest quorums have cardinality $\log(n+1)$. Therefore, by Proposition 4.2 $\mathcal{L}(\text{Tree}) \geq 1/\log(n+1)$. □

The following proposition shows a tradeoff between the failure probability and the load.

PROPOSITION 4.5. *$F_p(\mathcal{S}) \geq p^{n\mathcal{L}(\mathcal{S})}$ for any quorum system $\mathcal{S}$ and any $p \in [0,1]$.*

Proof. Consider a quorum $S_{\min}$ with $|S_{\min}| = c(\mathcal{S})$. If all the elements of $S_{\min}$ fail then by the intersection property the system fails; therefore $F_p(\mathcal{S}) \geq p^{c(\mathcal{S})}$. The claim follows since $c(\mathcal{S}) \leq n\mathcal{L}(\mathcal{S})$ by Proposition 4.1. □

DEFINITION 4.6. *An infinite family of quorum systems $\mathcal{S}_n$ over universes of increasing size n is said to have a* tight tradeoff *if*

$$\mathcal{L}(\mathcal{S}) \leq C \cdot \frac{-\log F_p(\mathcal{S}_n)}{n}$$

for some constant $C = C(p) > 0$ that depends only on $0 < p < \frac{1}{2}$.

Remark. It is pointless to consider values of $p \geq \frac{1}{2}$ since in [35] it is proved that $F_p(\mathcal{S}) \geq \frac{1}{2}$ for such p and any quorum system $\mathcal{S}$, so Proposition 4.5 is meaningless asymptotically in this case.

4.2. Conditions for optimality of the load. In this section we present several conditions that guarantee the optimality of a strategy w. The first condition, which can be applied to any system $\mathcal{S}$, is an immediate consequence of linear programming duality.

PROPOSITION 4.7. *Let a quorum system $\mathcal{S}$ be given, and let w be a strategy for $\mathcal{S}$ with an induced load of $\mathcal{L}_w(\mathcal{S}) = L$. Then L is the optimal load iff there exists $\mathbf{y} \in [0,1]^n$ such that $\mathbf{y}(U) = 1$ and $\mathbf{y}(S) \geq L$ for all $S \in \mathcal{S}$.*

Proof. By the premise, $(w; L)$ is a feasible point of LP, with an objective function value of L. Therefore, by duality L is the optimum iff there exists a feasible point of the dual problem DLP with an objective function value of L as well. By the definition of DLP, this implies that L is optimal iff there exists $\mathbf{y}$ such that $(\mathbf{y}; L)$ is dual-feasible, which is guaranteed by the conditions on $\mathbf{y}$. □

One way to search for a good strategy w is to try to find a *balancing strategy.* We can try to do this by constructing a feasible point $(w; L)$ for the following *balanced* load linear program, in which the inequalities (ii) of LP are replaced by equalities (ix).

$$BLP: \begin{cases} \sum_{j=1}^{m} w_j = 1, & \text{(viii)} \\ \sum_{S_j \ni i} w_j = L, \quad \text{for all } i \in U, & \text{(ix)} \\ w_j \geq 0,\ L \geq 0. & \text{(x)} \end{cases}$$

The program BLP is not always feasible, since finding a solution would imply that $\mathcal{S}$ can be *perfectly balanced*, which cannot be done for all quorum systems [19]. Nevertheless, one could hope that such a balancing strategy (if found) would induce the optimal load. The next proposition shows that this is true for a certain subclass of quorum systems.

PROPOSITION 4.8. *Let $\mathcal{S}$ be an s-uniform quorum system. Let w be a strategy and let $L \geq 0$ be such that $(w; L)$ is a feasible point for program BLP. Then the optimal load is $\mathcal{L}(\mathcal{S}) = L = s/n$.*

Proof. First let us show that $L = s/n$. Using the equalities (ix) we get

$$\sum_{i \in U} \sum_{S_j \ni i} w_j = nL. \tag{1}$$

By switching the summation order and using the s-uniformity of $\mathcal{S}$ and equality (viii) we get

$$\sum_{i \in U} \sum_{S_j \ni i} w_j = \sum_{j=1}^{m} w_j \sum_{i \in S_j} 1 = s \sum_{j=1}^{m} w_j = s. \tag{2}$$

By equating (1) and (2) we conclude that $L = s/n$.

Now let $\mathbf{y} = (1/n, \ldots, 1/n)$ be a weight vector for the elements. Clearly $\mathbf{y}(U) = 1$, and $\mathbf{y}(S) = |S|/n = s/n = L$ for any quorum $S \in \mathcal{S}$, since $\mathcal{S}$ is s-uniform. Therefore $(\mathbf{y}; L)$ is dual-feasible, so by Proposition 4.7, $\mathcal{L}(\mathcal{S}) = L$. □

Remark. The proof does not use the fact that $\mathcal{S}$ is a *quorum system* in any way, and it holds for nonintersecting set systems as well.

The condition that Proposition 4.8 places on a strategy w is a very weak one. It suffices to show that w is a feasible balancing strategy for it to induce the unique optimal load, if $\mathcal{S}$ is uniform. The following example shows that the uniformity is crucial; nonuniform quorum systems can have several balancing strategies, with different induced loads.

Example 4.9. Consider the quorum system

$$\mathcal{S} = \{\ \{1,4,6\}, \{2,4,7\}, \{3,5,6,7\}, \{1,2,3,5\},$$
$$\{1,2,3,4\}, \{2,3,4,5\}, \{3,4,5,6\}, \{4,5,6,7\}, \{5,6,7,1\}, \{6,7,1,2\}, \{7,1,2,3\}\ \}.$$

The strategy $w = (0, 0, 0, 0, \frac{1}{7}, \frac{1}{7}, \frac{1}{7}, \frac{1}{7}, \frac{1}{7}, \frac{1}{7}, \frac{1}{7})$ is balancing with a load of $\mathcal{L}_w(\mathcal{S}) = \frac{4}{7}$. However, the strategy $w' = (\frac{1}{4}, \frac{1}{4}, \frac{1}{4}, \frac{1}{4}, 0, 0, 0, 0, 0, 0, 0)$ is also balancing, with a load of $\mathcal{L}_{w'}(\mathcal{S}) = \frac{1}{2}$. □

If $\mathcal{S}$ is a fair system, then the next proposition shows that we can compute the load and optimal strategy immediately. This is a restatement of Proposition 5.1 of [12] using the fact that $\mathcal{L}(\mathcal{S}) = 1/\nu^*$.

PROPOSITION 4.10. *Let $\mathcal{S}$ be an (s, d)-fair quorum system. Then $\mathcal{L}(\mathcal{S}) = s/n = d/m$.*

Example 4.11. The following examples demonstrate the use of Proposition 4.10. The first shows that the lower bound of Example 4.4 is tight, and the other two show that the optimal load of Proposition 4.3, $1/\sqrt{n}$, can be attained.

(i) Over an odd-sized universe, Maj is an $\frac{n+1}{2}$-fair quorum system, so $\mathcal{L}(\text{Maj}) = \frac{n+1}{2n} \approx \frac{1}{2}$.

(ii) The FPP system [28] is a $(t+1)$-fair quorum system over $n = t^2 + t + 1$ elements, so $\mathcal{L}(\text{FPP}) = \frac{t+1}{t^2+t+1} \approx \frac{1}{\sqrt{n}}$. In fact, equality holds in the tighter lower bound of Proposition 4.3 for this system.

(iii) The Grid system [5] is a $(2h-1)$-fair system over $n = h^2$ elements, so $\mathcal{L}(\text{Grid}) = \frac{2h-1}{h^2} \approx \frac{2}{\sqrt{n}}$.

4.3. Effective calculation of the load. If a quorum system $\mathcal{S}$ is given explicitly, as a list of all m quorums, then program LP of Definition 3.3 can be solved in $poly(n, m)$ time using linear programming (cf. [40]). However, often $\mathcal{S}$ is given implicitly, say, via some data structure containing the elements coupled with a polynomial-time procedure to produce a quorum on demand. In such a case just writing program

```
Input a point (y; T).
The rows are U_1, ..., U_d.
Q ← ∅; s ← 0
for i = d to 1                          // bottom to top
    r ← Σ_{j∈U_i} y_j
    if r + s < T then
        return U_i ∪ Q                  // y(U_i ∪ Q) < T
    else
        j ← argmin_{k∈U_i}{y_k}         // min weight in row i
        s ← s + y_j
        Q ← Q ∪ {j}
end-for
return TRUE                             // (y; T) is dual-feasible
```

FIG. 1. *An oracle for a crumbling wall quorum system.*

LP could be an exponential task since typically $m = 2^{\Omega(n)}$. Calculating the load quickly is especially important when failures may occur, since the computation needs to be done repeatedly after each configuration change.

Instead we make use of the adaptation of the ellipsoid algorithm of [16]. Let d denote the dimension of the problem at hand. The ellipsoid algorithm uses an oracle, which receives a point $x \in \mathbb{R}^d$ and performs the following action.

(i) If x is a feasible point, then return TRUE.

(ii) Otherwise, return a hyperplane separating x from the feasible region (i.e., return a violated constraint).

Given such an oracle that works in time τ, the algorithm solves the linear program in time $poly(\tau, d)$.

We achieve nothing by applying this algorithm to problem LP since its dimension is $m + 1$. However, we can apply this algorithm to the dual problem DLP, whose dimension is $n+1$. Translated to our terminology, we need to provide an oracle whose input is a point $(\mathbf{y}; T)$. If $(\mathbf{y}; T)$ is feasible in DLP then the oracle returns TRUE, otherwise it returns a quorum $S \in \mathcal{S}$ such that $\mathbf{y}(S) < T$. If this oracle works in $poly(n)$ time, then the algorithm calculates the load in $poly(n)$ time.

Remark. Solving problem DLP gives us the optimal value of the load, but does *not* find a strategy that induces this load. Just writing down a strategy would cause a time complexity of $\Omega(m)$.

Example 4.12. In the systems of the crumbling wall class [37] the elements are arranged in rows of different widths, and a quorum is the union of a full row and a representative from each row below the full row. The procedure in Figure 1 is an oracle of the required kind, with a time complexity of $O(n)$. Therefore, we can compute the load of any crumbling wall using the ellipsoid algorithm outlined above. □

5. Optimal load, high availability quorum systems.

5.1. The paths system. In this system, the elements constitute a type of square grid, and a quorum is the union of two paths, one connecting the left and right sides and one connecting the top and bottom sides. Our analysis shows that $\mathcal{L}(\text{Paths}) = O(\frac{1}{\sqrt{n}})$ and that $F_p(\text{Paths}) \leq e^{-\Omega(\sqrt{n})}$ for $p < \frac{1}{2}$, so the tradeoff between the load

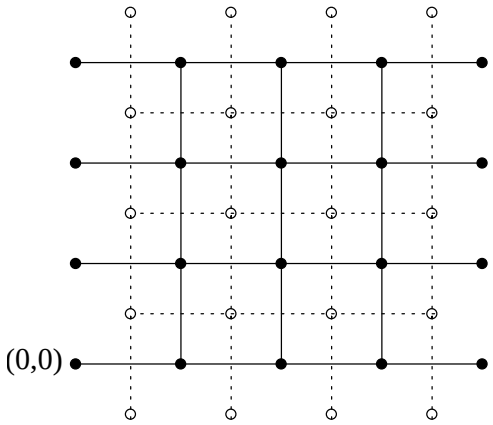

FIG. 2. *The grids* $G(3)$ (*full lines*) *and* $G^*(3)$ (*dotted lines*).

and failure probability is tight. Moreover, we show that even in the presence of faults, with exponentially high probability the load is still $\mathcal{L}_p(\text{Paths}) = O(\frac{1}{\sqrt{n}})$ for all $p < \frac{1}{2}$, which is the best we can hope for. We also give a simple and efficient algorithm for computing a strategy which induces an almost optimal load when some elements are faulty. The proofs are based on theorems of percolation theory (see the appendix).

DEFINITION 5.1. *Let* $G(d)$ *be the subgrid of* $\mathbb{Z}^2$ *with vertex set* $\{v \in \mathbb{Z}^2 : 0 \le v_1 \le d+1, 0 \le v_2 \le d\}$ *and edge set consisting of all edges joining neighboring vertices* except *those joining vertices* u, v *with either* $u_1 = v_1 = 0$ *or* $u_1 = v_1 = d+1$.

DEFINITION 5.2. *Let* $G^*(d)$, *the dual of* $G(d)$, *be the subgrid with vertex set* $\{v + (\frac{1}{2}, \frac{1}{2}) : 0 \le v_1 \le d, -1 \le v_2 \le d\}$ *and edge set consisting of all edges joining neighboring vertices* except *those joining vertices* u, v *with either* $u_2 = v_2 = -\frac{1}{2}$ *or* $u_2 = v_2 = d + \frac{1}{2}$.

See Figure 2 for a drawing of $G(d)$ and $G^*(d)$. Note that every edge $e \in G(d)$ has a dual edge $e^* \in G^*(d)$ which *crosses* it. We call such e and e^* a *dual pair of edges*. Note also that $G(d)$ and $G^*(d)$ are isomorphic; $G^*(d)$ may be obtained by rotating $G(d)$ at a right angle around the origin and relocating the vertex labeled $(0,0)$ to the point $(d + \frac{1}{2}, -\frac{1}{2})$. Both $G(d)$ and $G^*(d)$ contain $d^2 + (d+1)^2 = 2d^2 + 2d + 1$ edges.

DEFINITION 5.3. *The* Paths *quorum system of order* d *has* $n = 2d^2 + 2d + 1$ *elements, and we identify an element in* U *with a dual pair of edges* $e \in G(d)$ *and* $e^* \in G^*(d)$. *A quorum in the system is the union of (elements identified with) the edges of a left-right path in* $G(d)$ *and the edges of a top-bottom path in* $G^*(d)$.

PROPOSITION 5.4. $\frac{\sqrt{2}}{\sqrt{n}} \lessapprox \mathcal{L}(\text{Paths}) \lessapprox \frac{2\sqrt{2}}{\sqrt{n}}$.

Proof. For the lower bound, note that the smallest quorum has size $c(\text{Paths}) = 2d+1$, and we can apply Proposition 4.1 to get $\mathcal{L}(\text{Paths}) \ge \frac{2d+1}{2d^2+2d+1}$. For the upper bound, consider the quorums of the type $S_j = \{\text{edges joining } u, v \in G(d) : u_2 = v_2 = j\} \cup \{\text{edges joining } u, v \in G^*(d) : u_1 = v_1 = j + \frac{1}{2}\}$, for $j = 0, \ldots, d$. Each element corresponding to a horizontal edge in $G(d)$ appears in two such quorums, except elements on the diagonal that appear only once. A strategy choosing only these quorums with probability $\frac{1}{d+1}$ induces a load of $\frac{2}{d+1}$. □

We now wish to calculate the failure probability of the Paths system. We assume that the elements fail with probability p. A failed element corresponds to *two* closed

percolation edges: an edge $e \in G(d)$ and its dual edge $e^* \in G^*(d)$. We say that a *path in $G(d)$ is closed* if *all* its edges are closed. Define the following events:

(i) $LR =$ "there exists an open left-right path in $G(d)$,"
(ii) $LRC =$ "there exists a closed left-right path in $G(d)$,"
(iii) $TB =$ "there exists a open top-bottom path in $G^*(d)$,"
(iv) $TBC =$ "there exists a closed top-bottom path in $G^*(d)$."

LEMMA 5.5. *If $p > \frac{1}{2}$, then there exists a positive function φ such that $\mathbb{P}_p(LR) \le e^{-\varphi(p)d}$.*

Proof. Consider the grid $G(d)$, and let $\lambda = \{v \in \mathbb{Z}^2 : v_1 = d+1\}$ be the set of $\mathbb{Z}^2$ vertices on the infinite vertical line on the right side of $G(d)$. Let R denote the vertices on the right side of $G(d)$. Then summing along the possible starting points on the left side,

$$\mathbb{P}_p(LR) \le \sum_{k=0}^{d} \mathbb{P}_p((0,k) \leftrightarrow R) \le \sum_{k=0}^{d} \mathbb{P}_p((0,k) \leftrightarrow \lambda) = (d+1)\mathbb{P}_p(0 \leftrightarrow \lambda).$$

A path from the origin to λ must exit the ball $B(d)$, so we can apply Theorem A.1 to get

$$\le (d+1)\mathbb{P}_p(0 \leftrightarrow \partial B(d)) \le (d+1)e^{-\psi(p)d} \le e^{-\varphi(p)d}. \qquad \square$$

COROLLARY 5.6. *If $q > \frac{1}{2}$ ($p < \frac{1}{2}$), then there exists a positive function φ such that $\mathbb{P}_p(LRC) \le e^{-\varphi(q)d}$.*

Proof. Exchanging the roles of p and q we get that $\mathbb{P}_p(LRC) = \mathbb{P}_q(LR)$, so we can apply Lemma 5.5. $\square$

PROPOSITION 5.7. *There exists a positive function φ such that $F_p(\text{Paths})$ obeys*

$$\begin{cases} F_p(\text{Paths}) \le 2e^{-\varphi(q)d}, & p < \frac{1}{2}, \\ F_p(\text{Paths}) \ge 1 - e^{-\varphi(p)d}, & p > \frac{1}{2}, \\ \frac{1}{2} < F_p(\text{Paths}) \le \frac{3}{4}, & p = \frac{1}{2}, \end{cases}$$

so $F_p(\text{Paths})$ is almost Condorcet.

Proof. By definition, the event "there is a live quorum" is $LR \cap TB$. A moment's reflection shows that an open left-right path exists in $G(d)$ iff no closed top-bottom path exists in $G^*(d)$, since a dual pair of edges e and e^* have the same state (see discussion in [15, pp. 198–199]). Therefore, the events LR and TBC are complementary. Since $G(d)$ and $G^*(d)$ are isomorphic, then TB and LRC are also complementary events. Therefore, the system failure event is

$$\mathit{fail} = \overline{LR \cap TB} = TBC \cup LRC.$$

Additionally, the isomorphism between $G(d)$ and $G^*(d)$ implies that $\mathbb{P}_p(LR) = \mathbb{P}_p(TB)$ and $\mathbb{P}_p(LRC) = \mathbb{P}_p(TBC)$. Now we consider the three cases as follows.

(i) Let $p < \frac{1}{2}$. Then $F_p = \mathbb{P}_p(\mathit{fail}) = \mathbb{P}_p(LRC \cup TBC) \le 2\mathbb{P}_p(LRC)$ and so $F_p(\text{Paths}) \le 2e^{-\varphi(q)d}$ by Corollary 5.6.

(ii) Let $p > \frac{1}{2}$. Then $1 - F_p = \mathbb{P}_p(LR \cap TB) \le \mathbb{P}_p(LR) \le e^{-\varphi(p)d}$ by Lemma 5.5.

(iii) Let $p = \frac{1}{2}$. From the above discussion and the proof of Corollary 5.6 it follows that $\mathbb{P}_{1/2}(LR) = \mathbb{P}_{1/2}(TB) = \frac{1}{2}$. For the upper bound, note that both LR and TB are increasing events, so we can use the FKG inequality [10]. Therefore,

$$F_{1/2} = 1 - \mathbb{P}_{1/2}(LR \cap TB) \le 1 - \mathbb{P}_{1/2}(LR)\mathbb{P}_{1/2}(TB) = \frac{3}{4}.$$

For the lower bound, note that Paths is a *dominated* quorum system. Therefore, $F_{1/2}(\text{Paths}) > \frac{1}{2}$ by a result of [35]. □

Finally, we show that, with high probability, the load of the Paths system is $O(\frac{1}{\sqrt{n}})$ in the presence of failures, for any failure probability $p < \frac{1}{2}$. In other words, the load has essentially the same asymptotic behavior as long as there is a good probability that at least one functioning quorum exists.

PROPOSITION 5.8. *For any* $0 \le p < \frac{1}{2}$ *there exists* $\gamma > 0$ *such that* $\mathcal{L}_p(\text{Paths}) = O(\frac{1}{\sqrt{n}})$ *with probability* $\ge 1 - e^{-\gamma d}$.

Proof. Let LR_r be the event "there exist at least $r+1$ edge disjoint left-right paths in $G(d)$." Fix some $\frac{1}{2} > p' > p$. Then by Theorem A.3,

$$1 - \mathbb{P}_p(LR_r) \le \left(\frac{q}{q-q'}\right)^r [1 - \mathbb{P}_{p'}(LR)].$$

Now for $p' < \frac{1}{2}$,

$$\mathbb{P}_{p'}(LR) = 1 - \mathbb{P}_{p'}(TBC) = 1 - \mathbb{P}_{p'}(LRC) \ge 1 - e^{-\varphi(q')d}$$

by Corollary 5.6, so

$$\mathbb{P}_p(LR_r) \ge 1 - \left(\frac{q}{q-q'}\right)^r e^{-\varphi(q')d}.$$

Fix $0 < \gamma < \varphi$, let $0 < \beta = \frac{\varphi-\gamma}{\ln[q/(q-q')]}$, and let $r = \beta d$. Then $\mathbb{P}_p(LR_r) \ge 1 - e^{-\gamma d}$. In other words, with high probability, there exist $\beta d + 1$ edge disjoint left-right paths in $G(d)$. The same also happens for top-bottom paths in $G^*(d)$. Therefore, we can find $\beta d + 1$ quorums such that any element appears in at most two of them (once as an edge $e \in G(d)$ and once as the dual edge). We conclude that when such quorums are found, $\mathcal{L}_p(\text{Paths}) \le \frac{2}{\beta d+1} = O(\frac{1}{\sqrt{n}})$. □

Remark. This is the strongest possible result regarding load with failures, since if $p \ge \frac{1}{2}$ then by Lemma 3.14 and a result of [35], $E\mathcal{L}_p(\mathcal{S}) \ge F_p(\mathcal{S}) \ge \frac{1}{2}$ for any quorum system $\mathcal{S}$.

Proposition 5.8 guarantees that, with high probability, a good strategy (that induces a load of $O(1/\sqrt{n})$) exists. We now describe an efficient algorithm that finds a nearly optimal strategy w for any given configuration $\mathbf{x}$; the load induced by w is at most twice the optimal load under configuration $\mathbf{x}$, $\mathcal{L}(\text{Paths}_\mathbf{x})$.

The algorithm mimics the structure of the existence proof. As a preprocessing step that needs to be performed after each configuration change, the algorithm finds a maximum collection of disjoint left-right paths, say k_{LR} such paths, and similarly finds k_{TB} disjoint top-bottom paths. This can be done by connecting a source vertex s to all the vertices on the left side and a sink t to the vertices on the right, assigning a capacity of 1 to all the edges, and finding the maximum (s,t) flow (and repeating for TB paths). Since the network is planar we can find the flow in time $O(n \log n)$ using the algorithm of [20], or in time $O(n\sqrt{\log n})$ by [17] using the methods of [11].

Given these path collections, the strategy w is the following: if either $k_{LR} = 0$ or $k_{TB} = 0$, then no live quorums exist in configuration $\mathbf{x}$. Otherwise, whenever a quorum is needed, pick an LR path with uniform probability $1/k_{LR}$ and a TB path with uniform probability $1/k_{TB}$, and use their union. Since the paths are disjoint, each element can appear at most once in an LR path and once in a TB path, so

$$\mathcal{L}_w(\text{Paths}_\mathbf{x}) \le 1/k_{LR} + 1/k_{TB}.$$

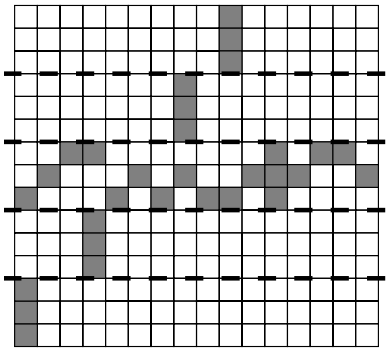

FIG. 3. *The* B-Grid *system over* $n = 240$ *elements with width* $d = 16$, $h = 5$ *bands, and* $r = 3$ *rows per band. One quorum is shaded.*

However, if the maximum flow is k_{LR}, then the max-flow min-cut theorem implies the existence of a k_{LR}-size cut. Therefore, any LR path that is open in configuration $\mathbf{x}$ must cross this cut via an edge, so some edge in this cut must have a load of at least $1/k_{LR}$ under any strategy. This implies a lower bound on the load

$$\mathcal{L}(\text{Paths}_{\mathbf{x}}) \geq \max\{1/k_{LR}, 1/k_{TB}\};$$

hence $\mathcal{L}_w(\text{Paths}_{\mathbf{x}})$ is at most twice the best possible.

Remark. A related construction, using paths on a triangular lattice with elements corresponding to the nodes, was suggested in [45] (see [44]). They show that their construction has asymptotically high availability ($F_p \to 0$ when $p < \frac{1}{2}$ in our notation). The rate of convergence is not analyzed and neither is the load (with or without failures). Nevertheless, it seems that an analysis similar to ours would show that the characteristics of their system are comparable to those of our Paths system, with a load of $O(1/\sqrt{n})$ and $F_p \leq e^{-\Omega(\sqrt{n})}$ when $p < \frac{1}{2}$.

5.2. The B-Grid system. Arrange the elements in a rectangular grid of width d. Split the grid logically into h *bands* of r rows each (so there are $n = dhr$ elements). Call r elements in a column that are all contained in a single band a *minicolumn*. Then a quorum consists of one minicolumn in every band, and a representative element in each minicolumn of one band (see Figure 3).

LEMMA 5.9. $\mathcal{L}(\text{B-Grid}) = \frac{d+hr-1}{dhr}$.

Proof. Clearly B-Grid is a fair quorum system, with a quorum size of $d + hr - 1$, and the lemma follows from Proposition 4.10. □

LEMMA 5.10. $F_p(\text{B-Grid}) \leq \left(dp^r\right)^h + h\left(1 - q^r\right)^d$.

Proof. Define $\mathcal{E}_1$ to be the event "in every band there exists a minicolumn whose elements all failed," and $\mathcal{E}_2$ to be the event "there exists a band in which every minicolumn contains a failed element." Clearly the system failure event is $fail = \mathcal{E}_1 \cup \mathcal{E}_2$, so $F_p(\text{B-Grid}) \leq \mathbb{P}(\mathcal{E}_1) + \mathbb{P}(\mathcal{E}_2)$. We get the result since $\mathbb{P}(\mathcal{E}_1) \leq \left(dp^r\right)^h$ and $\mathbb{P}(\mathcal{E}_2) \leq h\left(1 - q^r\right)^d$. □

In the next lemma we give a condition on r under which F_p decays exponentially fast in a large range of p values.

LEMMA 5.11. *If* $0 \leq p \leq \frac{1}{3}$ *and* $r = \lfloor \ln d \rfloor$, *then* $F_p(\text{B-Grid}) \leq e^{-h} + e^{-\frac{1}{2}\sqrt{d}}$ *for large values of* d *such that* $\ln h < \frac{1}{2}\sqrt{d}$.

AbC	bCD	CDE	DEA	EAb

Klm	lmN	mNo	NoK	oKl

FIG. 4. *The* SC-Grid *system over* $n = 15$ *elements with width* $d = 5$, $h = 3$ *rows, and* $r = 3$ *elements per cell. The elements of one quorum are marked by capitalized letters, and the cells where a majority is achieved are shaded.*

Proof. To get $\mathbb{P}(\mathcal{E}_1) \le \left(dp^r\right)^h \le e^{-h}$ we require the condition

$$r > \frac{\ln d + 1}{\ln 1/p} \ . \tag{3}$$

To get $\mathbb{P}(\mathcal{E}_2) \le h\left(1-q^r\right)^d \le e^{-\frac{1}{2}\sqrt{d}}$ we require the condition

$$r < \frac{\ln d - \ln(\ln h + \frac{1}{2}\sqrt{d})}{\ln 1/q} \ . \tag{4}$$

If we consider only $p \le \frac{1}{3}$, then $\frac{1}{\ln 1/p} \le 0.91$ and $\frac{1}{\ln 1/q} \ge 2.466$, and a simple check shows that $r = \lfloor \ln d \rfloor$ fills both conditions (3) and (4) for sufficiently large d if $\ln h < \frac{1}{2}\sqrt{d}$. □

The next propositions are proved by plugging the parameters into Lemmas 5.11 and 5.9. In Proposition 5.12 the failure probability is minimal for the B-Grid system (up to a logarithmic factor in the exponent). In Proposition 5.13 the load is minimal.

PROPOSITION 5.12. *If* $d = n^{2/3}$, $r = \lfloor \ln d \rfloor$, *and* $h = n/(rd)$, *then* $\mathcal{L}(\text{B-Grid}) = O(n^{-1/3})$ *and* $F_p(\text{B-Grid}) = O(\exp(-\frac{n^{1/3}}{\ln n}))$ *in the range* $0 \le p \le \frac{1}{3}$.

PROPOSITION 5.13. *If* $d = \sqrt{n}$, $r = \lfloor \ln d \rfloor$, *and* $h = n/(rd)$, *then* $\mathcal{L}(\text{B-Grid}) = O(1/\sqrt{n})$ *and* $F_p(\text{B-Grid}) = O(\exp(-\frac{n^{1/4}}{2}))$ *in the range* $0 \le p \le \frac{1}{3}$.

Remark. Taking either $d > n^{2/3}$ or $d < \sqrt{n}$ makes both the load and the availability worse. Note that, in any case, the tradeoff between the load and failure probability is *not* tight. By Proposition 4.5 we could hope for a failure probability of $O(\exp(-n^{2/3}))$ when the load is $\approx n^{-1/3}$.

5.3. The SC-Grid system. Consider a grid made of h rows of cells with width d. In a universe of size $n = dh$, allocate d different elements to each row. Assume that row j is allocated elements $\{1, \ldots, d\}$. Then for a parameter $r < d$, place the elements into cells in shifted cyclic order: $\{1, \ldots, r\}$ in cell $(1, j)$, $\{2, \ldots, r+1\}$ in cell $(2, j)$ and so forth. Every element appears in r cells in the same row. A quorum in the system is a set of elements that are a majority in one cell of every row and a majority in every cell of one row (see Figure 4). This system is somewhat similar to that of [38] in which each grid cell contains a *distinct* set of elements. For simplicity assume that both d and r are odd.

LEMMA 5.14. *Let* r *be odd and let* $d > r$. *Consider a cycle of* d *elements, and the* d *subsets* $C_1, \ldots, C_d$ *of* r *consecutive elements along the cycle. Color* G *of the*

elements in green, and let g_j count the number of green elements in C_j. If $g_j \geq \frac{r+1}{2}$ for all j, then $G \geq \lceil d \cdot \frac{r+1}{2r} \rceil$. If $d \mid r$ then the bound can be achieved.

Proof. Sum the number of green elements in each C_j. Then $\sum_{j=1}^{d} g_j = rG$ since every green element is counted precisely r times. Since $g_j \geq \frac{r+1}{2}$ then $rG \geq d \cdot \frac{r+1}{2}$ and we are done.

If $d = rx$ for some integer x, then consider the x disjoint sets $C_\ell = \{(\ell-1)r + 1, \ldots, \ell r\}$ for $1 \leq \ell \leq x$. In each set color the first $\frac{r+1}{2}$ elements in green. Then *every* set C_j contains $\frac{r+1}{2}$ green elements and $G = x \cdot \frac{r+1}{2}$, so the lower bound is achieved. ∎

LEMMA 5.15. $\frac{rh+d}{2n} \lessapprox \mathcal{L}(\text{SC-Grid}) \lessapprox \frac{r}{d}$.

Proof. By Lemma 5.14 the smallest quorum size is $c(\text{SC-Grid}) \geq \frac{r+1}{2}(h-1) + \frac{d+1}{2}$, so the lower bound follows from Proposition 4.1. For the upper bound, consider the quorums $S_1, \ldots, S_{k+1}$, where S_j contains all the d elements of row j, and $\frac{r+1}{2}$ elements of every row $i \neq j$. Consider a specific row j. As long as $k\frac{r+1}{2} \leq d$ we can use a different set of $\frac{r+1}{2}$ elements from row j in quorum S_i for $i \neq j$, so every element appears in at most two quorums. Therefore we can take $k = \lfloor \frac{2d}{r+1} \rfloor$. A strategy that chooses one of these quorums with equal probability induces a load of $\frac{2}{k+1} \approx \frac{r}{d}$. ∎

Notation. Let f_x be the probability that at least $\frac{x+1}{2}$ elements fail out of x when each element fails independently with probability p.

LEMMA 5.16. $F_p(\text{SC-Grid}) \leq (df_r)^h + hf_d$.

Proof. Call a cell *failed* if a majority of its elements fail. Let $\mathcal{E}_1$ be the event "all the rows contain at least one failed cell," and let $\mathcal{E}_2$ be the event "there exists a row in which all the cells failed." Then $F_p(\text{SC-Grid}) \leq \mathbb{P}(\mathcal{E}_1) + \mathbb{P}(\mathcal{E}_2)$. Clearly $\mathbb{P}(\mathcal{E}_1) \leq (df_r)^h$. By Lemma 5.14, if all the cells in row j have failed, then at least $\frac{d+1}{2}$ of the elements in row j have failed, so $\mathbb{P}(\mathcal{E}_2) \leq hf_d$. ∎

LEMMA 5.17. *For every $\delta < \frac{1}{2}$ there exists $\varepsilon > 0$ such that, when $0 \leq p \leq \frac{1}{2} - \delta$ and $r \geq \frac{2}{\varepsilon} \ln d$, then*

$$F_p(\text{SC-Grid}) \leq d^{-h} + he^{-\varepsilon d}.$$

Proof. By a Chernoff inequality, there exists $\varepsilon > 0$ such that $f_x \leq e^{-\varepsilon x}$ for all x when $0 \leq p \leq \frac{1}{2} - \delta$. For this ε, if $r \geq \frac{2}{\varepsilon} \ln d$ then $f_r \leq 1/d^2$. Plugging this into Lemma 5.16 finishes the lemma. ∎

By plugging the parameter values into Lemmas 5.15 and 5.17 we obtain the following result.

PROPOSITION 5.18. *For every $\delta < \frac{1}{2}$ there exists $\varepsilon > 0$ such that if $0 \leq p \leq \frac{1}{2} - \delta$, then taking $r = \lceil \frac{2}{\varepsilon} \ln d \rceil$, $d = \sqrt{n \ln n}$, and $h = n/d$ gives $F_p(\text{SC-Grid}) = \exp(-\Omega(\sqrt{n \ln n}))$ and $\mathcal{L}(\text{SC-Grid}) = O(\sqrt{(\ln n)}/n)$.*

Remark. The parameters were chosen to minimize the failure probability. The tradeoff between the load and failure probability is tight for this construction.

5.4. The AndOr system. Consider a complete rooted binary tree of height h, rooted at *root*, and identify the $n = 2^h$ leaves of the tree with the system elements. We define two recursive procedures that operate on a subtree rooted at v and return a set of elements.

(i) For a leaf v, $ANDset(v) = ORset(v) = \{v\}$.
(ii) $ANDset(v) = ORset(v.left) \cup ORset(v.right)$.
(iii) $ORset(v)$ has a choice; it can be either $ANDset(v.left)$ or $ANDset(v.right)$.

A quorum in the AndOr system is any set $Q = S \cup R$ where S is an $ANDset(root)$ and R is an $ORset(root)$.

It is easy to think of the AndOr system as the conjunction of two boolean functions corresponding to the top level activations of *ANDset* and *ORset*. Each function is defined by a complete tree of alternating AND and OR gates, over the same inputs, but one function has an AND gate at the root while the other has an OR gate at the root.

LEMMA 5.19. *If* $S = ANDset(root)$ *and* $R = ORset(root)$, *then* $|S \cap R| = 1$ *for any choices made by the activations of the ORset procedure. Hence* AndOr *is a quorum system.*

Proof. The proof is by induction on the tree height h. The case $h = 0$ is obvious. For $h \geq 1$, assume w.l.o.g. that the *ORset* procedure uses the left subtree. Then any element in the right subtree is not in the intersection, and by the induction hypothesis the intersection in the left subtree has size 1. □

LEMMA 5.20. *The* AndOr *system is a fair system, with*

$$c(\text{AndOr}) = \begin{cases} 2\sqrt{n} - 1, & h \text{ even,} \\ 3\sqrt{n/2} - 1, & h \text{ odd.} \end{cases}$$

Proof. The fairness is obvious from symmetry. Let $ANDsize(h) = |ANDset(root)|$ denote the size of the output of the *ANDset* procedure on a tree with height h, and similarly let $ORsize(h) = |ORset(root)|$. Then by definition, $ANDsize(0) = ORsize(0) = 1$, and

$$\begin{aligned} ANDsize(h) &= 2ORsize(h-1), \\ ORsize(h) &= ANDsize(h-1). \end{aligned}$$

It is easy to show by induction on h that $ORsize(h) = 2^{\lfloor \frac{h}{2} \rfloor}$ and $ANDsize(h) = 2^{\lfloor \frac{h+1}{2} \rfloor}$. Combining with Lemma 5.19 finishes the proof. □

PROPOSITION 5.21. $\mathcal{L}(\text{AndOr}) = O(1/\sqrt{n})$.

Proof. To obtain the proof, apply Proposition 4.10 using Lemma 5.20. □

The following proposition shows the high availability of the AndOr system. The proof is an adaptation of the proof in [43]. We include it here for completeness, omitting some of the technical details.

PROPOSITION 5.22. *Let* $\alpha = \frac{3-\sqrt{5}}{2} \approx 0.38$. $F_p(\text{AndOr}) \leq \exp(-\Omega(\sqrt{n}))$ *when* $p < \frac{1}{4}$ *and* $F_p \leq \exp(-\Omega(n^{0.19}))$ *when* $p \leq \alpha - \Omega(n^{-0.19})$.

Proof. Let $f_A(h)$ denote the probability that all of the possible outputs sets of the *ANDset* procedure are hit, and similarly let f_O denote the probability for the *ORset* procedure, on a tree with height h. Clearly $F_p(\text{AndOr}) \leq f_A(h) + f_O(h)$. By the definitions,

$$\begin{aligned} f_A(h) &= 2f_A^2(h-2) - f_A^4(h-2), \\ f_O(h) &= 4f_O^2(h-2) - 4f_O^3(h-2) + f_O^4(h-2), \end{aligned}$$

and $f_A(0) = f_O(0) = p$. Obviously $f_A(h) < 2f_A^2(h-2)$, and also $f_O(h) = f_O^2(h-2)$ $(2 - f_O(h-2))^2 < 4f_O^2(h-2)$. Therefore, by induction, when h is even,

$$f_A(h) < 2^{2^{\frac{h}{2}}-1} p^{2^{\frac{h}{2}}} < (2p)^{\sqrt{n}}$$

and similarly $f_O(h) < (4p)^{\sqrt{n}}$. So it follows that $F_p(\text{AndOr}) \leq \exp(-\Omega(\sqrt{n}))$ when $p < \frac{1}{4}$. When h is odd the bound is similar.

Now f_O has a stable point at $p = \alpha$ and f_A has a stable point at $p = 1 - \alpha$. As shown by [43], if there are $n = O(d^{5.3})$ leaves in the tree and $p < \alpha - \Omega(d^{-1}) < 1 - \alpha - \Omega(d^{-1})$, then $f_A(h) < 2^{-d-1}$, and the same is true for f_O. Setting $d = O(n^{1/5.3}) = O(n^{0.19})$ finishes the claim. □

We now describe how to use the AndOr system when some elements have failed. We show an algorithm that finds a nearly optimal strategy w for any given configuration $\mathbf{x}$; the load induced by w is at most twice the optimal load under configuration $\mathbf{x}$, $\mathcal{L}(\text{AndOr}_{\mathbf{x}})$. The description is of an activation at the top level of *ANDset*(*root*), say. The description of the *ORset* activation is identical.

The algorithm is a preprocessing step which needs to be done after each configuration change. It begins by recursively marking the internal nodes in the tree as "alive" or "dead" in the obvious way; an AND node is alive if both of its children are alive, and an OR node is alive if at least one of its children is alive.

Consider a live node v. If it is either an AND node, or an OR node with a single live child, then any strategy that chooses to use (elements in the tree rooted at) v is forced to use all of v's live children. Therefore, to complete the description of our strategy w we need to show what happens at OR nodes with two live children. For this, during the preprocessing each such node v is given a probability $\beta(v)$. If the strategy w decides to use v's tree, then it uses its left subtree with probability $\beta(v)$ and its right subtree with probability $1 - \beta(v)$.

To compute the $\beta(v)$ values for live OR nodes v with two live children, the algorithm recursively computes the optimal loads ℓ_L and ℓ_R in the left and right subtrees, respectively. To achieve an optimal load for v's tree, $\beta(v)$ must satisfy $\beta\ell_L = (1-\beta)\ell_R$. Therefore, $\beta(v) = \ell_R/(\ell_L + \ell_R)$, and the load induced on v's tree is $\ell_L\ell_R/(\ell_L + \ell_R)$.

The above computation is performed twice, once starting with *ANDset*(*root*) and once starting with *ORset*(*root*). Note that a node may be marked "alive" w.r.t. the *ANDset*(*root*) activation and "dead" w.r.t. the *ORset*, or vice versa. However, every v is assigned a single $\beta(v)$ value since it is an OR node only w.r.t. one top level activation.

This w would clearly induce an optimal load for any configuration $\mathbf{x}$ if we were interested in a single top-level activation. However, since we must activate both *ANDset* and *ORset* at the top level, a moment's reflection shows that $\mathcal{L}_w(\text{AndOr}_{\mathbf{x}}) \leq 2\mathcal{L}(\text{AndOr}_{\mathbf{x}})$.

Remarks.

(i) A quorum system can be constructed from any monotone read-once boolean function in a similar way. This is achieved by taking some AND/OR formula F implementing the function and making a dual copy of it F^d (in which every AND gate is replaced by an OR gate and vice versa). A quorum is defined to be a union of two sets of elements, one satisfying F and the other satisfying F^d. The proof of Lemma 5.19 would still hold for such a system. However, the load and failure probability would depend on the specific structure of the function used.

(ii) The AndOr system is isomorphic to the hierarchical grid construction of [24], when the grids at all the levels are 2×2 grids. The read-quorum and write-quorum procedures of [24] correspond to our top-level activations of the *ANDset* and *ORset* procedures, respectively. However, ours is a much stronger analysis; we calculate the load and analyze the rate of decay of F_p and the critical probability α.

6. Load analyses of some quorum systems.

6.1. Nondominated coteries have lower loads. The following proposition shows that nondominated coteries (see Definition 2.5) have the lowest loads. This

gives further support to the intuitive view that NDC's are preferable to dominated coteries for practical applications.

PROPOSITION 6.1. *Let $\mathcal{S}$, $\mathcal{R}$ be quorum systems over the same universe U such that $\mathcal{R} \succ \mathcal{S}$. Then $\mathcal{L}(\mathcal{R}) \leq \mathcal{L}(\mathcal{S})$.*

Proof. Assume that $\mathcal{S} = \{S_1, \ldots, S_m\}$ and $\mathcal{R} = \{R_1, \ldots, R_{m'}\}$. Define a mapping $\varphi : \mathcal{S} \mapsto \mathcal{R}$ as follows. For every set $S_k \in \mathcal{S}$ consider the minimal j such that $R_j \subseteq S_k$, and let $\varphi(S_k) = R_j$. By Definition 2.5 there exists such an R_j for every S_k, so φ is well defined. Let w be an optimal strategy for $\mathcal{S}$. Define w' for $\mathcal{R}$ by

$$w'_j = \begin{cases} \sum_{\varphi(S_k)=R_j} w_k, & \text{if } \exists k : \varphi(S_k) = R_j, \\ 0, & \text{otherwise.} \end{cases}$$

Clearly w' is a strategy for $\mathcal{R}$. The load induced by strategy w' on an element i is

$$\ell_{w'}(i) = \sum_{R_j \ni i} w'_j = \sum_{R_j \ni i} \left(\sum_{\varphi(S_k)=R_j} w_k \right) \leq \sum_{S_k \ni i} w_k = \ell_w(i).$$

Applied to the load on the busiest element i this implies that

$$\mathcal{L}_{w'}(\mathcal{R}) \leq \mathcal{L}_w(\mathcal{S}) = \mathcal{L}(\mathcal{S}),$$

and by the minimality of $\mathcal{L}(\mathcal{R})$ the result follows. □

Remark. Proposition 6.1 does not imply that *dominated* quorum systems necessarily have a *high* load. In fact, all our constructions in section 5 are dominated and have optimal or near-optimal load. By Proposition 6.1 there exist NDC's with loads which are as good or better—but these are more cumbersome to describe explicitly.

6.2. Voting systems have high loads. A popular and simple way to construct a quorum system is by *weighted voting* [14, 13, 41, 29]. In this section we show that $\mathcal{L}(\mathcal{S}) > \frac{1}{2}$ for any voting system $\mathcal{S}$, i.e., any voting system is at least as bad as the Maj system in terms of load.

DEFINITION 6.2. *For each $i \in U$ let the integer $v_i \geq 0$ denote the* weight *of i. Let $V = \sum_i v_i$ be the* total weight*. The* voting system *defined by the weights v_i is*

$$\text{Vote} = \left\{ S \subseteq U : \sum_{i \in S} v_i > \frac{V}{2} \right\}.$$

PROPOSITION 6.3. $\mathcal{L}(\text{Vote}) > \frac{1}{2}$.

Proof. Consider the vector $\mathbf{y}$ defined by $y_i = v_i/V$ for all $i \in U$. Clearly $\mathbf{y}(U) = 1$. By Definition 6.2,

$$\mathbf{y}(S) = \frac{1}{V} \sum_{i \in S} v_i > \frac{1}{2},$$

for any quorum $S \in \text{Vote}$. Therefore $(\mathbf{y}; \frac{1}{2})$ is a feasible point to program DLP, so $\mathcal{L}(\text{Vote}) > \frac{1}{2}$ by the weak duality of linear programming. □

6.3. The tree system. We have shown in Example 4.4 that the load of the Tree quorum system [1] is $\mathcal{L}(\text{Tree}) \geq \frac{1}{\log(n+1)}$. In this section we show that the bound is almost tight; the precise load is $\mathcal{L}(\text{Tree}) = \frac{2}{\log(n+1)+1}$. We first show an upper bound

by balancing the load on the elements, and then show a matching lower bound. We use h to denote the height of the tree ($n = 2^{h+1} - 1$).

CLAIM 6.4. $\mathcal{L}(\text{Tree}) \leq \frac{2}{h+2}$.

Proof. Denote a tree rooted at node i by $T(i)$, and denote its left and right subtrees by $T_L(i)$ and $T_R(i)$. We build a probabilistic recursive strategy *Pick* to pick a quorum, using values β_h, to be defined later, as follows.

$$Pick(T(i)) = \begin{cases} \{i\} \cup Pick(T_L(i)), & \text{with probability } \beta_h, \\ \{i\} \cup Pick(T_R(i)), & \text{with probability } \beta_h, \\ Pick(T_L(i)) \cup Pick(T_R(i)), & \text{with probability } 1 - 2\beta_h. \end{cases}$$

Let $L(h)$ denote the load induced by strategy *Pick* in a tree of height h. The load is determined either by the load on the root i, or by the most heavily loaded element in one of the subtrees. Therefore $L(h) = \max\{2\beta_h, (1 - \beta_h)L(h-1)\}$. Choosing $\beta_h = \frac{L(h-1)}{L(h-1)+2}$ balances the load, so with this choice the load obeys the recurrence

$$L(h) = \frac{2L(h-1)}{L(h-1)+2},$$

and $L(0) = 1$. A simple check shows that $L(h) = \frac{2}{h+2}$ solves this recurrence, and then $\beta_h = \frac{1}{h+2}$ for $h \geq 1$. □

CLAIM 6.5. $\mathcal{L}(\text{Tree}) \geq \frac{2}{h+2}$.

Proof. Let $0 \leq t_i \leq h$ denote the distance from node i to the root. To show a matching lower bound we build a dual-feasible vector of weights $\mathbf{y}$, defined by

$$y_i = \begin{cases} \frac{1}{h+2}\left(\frac{1}{2}\right)^{t_i}, & 0 \leq t_i < h, \\ \frac{1}{h+2}\left(\frac{1}{2}\right)^{h-1}, & t_i = h. \end{cases}$$

It is easy to see that $\mathbf{y}$ is a valid weight vector. We need to show that $\mathbf{y}(S) \geq \frac{2}{h+2}$ for every quorum $S \in \text{Tree}$.

By induction from the leaves toward the root, one can show that

$$\mathbf{y}(S \cap T(i)) = \begin{cases} \frac{2}{h+2}\left(\frac{1}{2}\right)^{t_i}, & S \cap T(i) \neq \varnothing, \\ 0, & \text{otherwise}, \end{cases} \tag{5}$$

for every $i \in U$ and $S \in \text{Tree}$. Plugging the root of the tree we obtain $\mathbf{y}(S) = \frac{2}{h+2}\left(\frac{1}{2}\right)^0 = \frac{2}{h+2}$. Therefore, $(\mathbf{y}; \frac{2}{h+2})$ is feasible for program DLP so the claim follows from the weak duality of linear programming. □

6.4. The hierarchical quorum system. In this section we analyze the load and availability of the hierarchical system of [23]. In this system the elements are the leaves of a complete ternary tree. The internal nodes are 2-of-3 majority gates. We show that $F_p(\text{HQS}) \leq \exp(-\Omega(n^{0.63}))$ when $p < \frac{1}{3}$ and $F_p(\text{HQS}) \leq n^{-\alpha(p)}$ when $p < \frac{1}{2}$, and that $\mathcal{L}(\text{HQS}) = n^{-0.37}$.

The analysis is similar in nature to that of the AndOr system. However, HQS is a nondominated system, so the analysis is good up to $\frac{1}{2}$ rather than up to the 0.38 of the AndOr system. On the other hand, the load of HQS is worse than the $O(1/\sqrt{n})$ of the AndOr system.

We use h to denote the height of the tree ($n = 3^h$).

PROPOSITION 6.6. $\mathcal{L}(\text{HQS}) = n^{-0.37}$.

Proof. By symmetry it follows that HQS is a fair system, with $c(\text{HQS}) = n^{\log_3 2} = n^{0.63}$. Therefore by Proposition 4.10, $\mathcal{L}(\text{HQS}) = n^{0.63}/n = n^{-0.37}$. □

PROPOSITION 6.7. *$F_p(\text{HQS}) \leq \exp(-\Omega(n^{0.63}))$ when $p < \frac{1}{3}$ and $F_p(\text{HQS}) \leq n^{-\alpha(p)}$ when $p < \frac{1}{2}$.*

Proof. Let $f(h)$ denote $F_p(\text{HQS})$ on a tree with height h. Then $f(h)$ obeys the recurrence

$$f(h) = 3f^2(h-1) - 2f^3(h-1),$$

and $f(0) = p$. We observe that $p = \frac{1}{2}$ is a stable point, so by a result of [35] it follows that HQS is nondominated. Now certainly $f(h) < 3f^2(h-1)$, so by induction on h we show that $f(h) < 3^{2^h-1}p^{2^h} < (3p)^{n^{\log_3 2}}$, which proves the case when $p < \frac{1}{3}$.

For larger values of p, we prove by induction on h that $f(h)$ is decreasing when $p < \frac{1}{2}$, and then, that

$$f(h) \leq p \cdot (3p - 2p^2)^h.$$

If $p = \frac{1}{2} - \varepsilon$ then $3p - 2p^2 < 1 - \varepsilon$ so $f(h) < \frac{1}{2}(1-\varepsilon)^{\log_3 n} < n^{-\alpha}$ for some $\alpha(p)$. □

Remark. The HQS system has a tight tradeoff between its availability and load when $p < \frac{1}{3}$.

Appendix. Results of percolation theory. In this section we list the definitions and results that are used in our analysis of the Paths system, following [15].

The percolation model we are interested in is as follows. Let $\mathbb{Z}^2$ be the graph of the square lattice in the plane. Assume that an edge between neighboring vertices in $\mathbb{Z}^2$ is *closed* with probability p and *open* with probability $q = 1 - p$, independently of other edges. This model is known as bond percolation on the square lattice. Another natural model, which plays a minor role in our work, is the site percolation model. In it the *vertices* are closed with probability p. Unless otherwise stated, we always use the bond percolation model.

Notation. For an event $\mathcal{E}$ defined in the percolation model (either on $\mathbb{Z}^2$ or on some finite subgraph of $\mathbb{Z}^2$), we denote the probability of $\mathcal{E}$ by $\mathbb{P}_p(\mathcal{E})$.

A key idea in percolation theory is that there exists a *critical probability*, p_c, such that graphs with $p < p_c$ exhibit qualitatively different properties than graphs with $p > p_c$. For example, $\mathbb{Z}^2$ with $p < p_c$ has a single connected (open) component of infinite size. When $p > p_c$ there is no such component (see [15, p. 110]). For bond percolation in the plane $p_c = \frac{1}{2}$ [22].

Notation. Let $B(d)$ be the ball of radius d with center at the origin; $B(d) = \{v \in \mathbb{Z}^2 : |v_1| + |v_2| \leq d\}$. Let $\partial B(d)$ be the surface of $B(d)$, $\partial B(d) = \{v \in \mathbb{Z}^2 : |v_1| + |v_2| = d\}$. For a vertex v and a set of vertices A, let $v \leftrightarrow A$ denote the event that there exists an open path between v and some vertex in A.

The following theorem shows that when the probability p for a closed edge is above the critical probability, the probability of having long open paths decays exponentially fast.

THEOREM A.1. (See [31].) *If $p > \frac{1}{2}$, then there exists $\psi(p) > 0$ such that*

$$\mathbb{P}_p(0 \leftrightarrow \partial B(d)) < e^{-\psi(p)d} \quad \textit{for all } d.$$

DEFINITION A.2. *Let $\mathcal{E}$ be an event defined in the percolation model. Then the* interior *of $\mathcal{E}$ with depth r, denoted $I_r(\mathcal{E})$, is the set of all configurations in $\mathcal{E}$ which are still in $\mathcal{E}$ even if we perturb the states of up to r edges.*

We may think of $I_r(\mathcal{E})$ as the event that $\mathcal{E}$ occurs and is "stable" with respect to changes in the states of r or fewer edges. The definition is useful to us in the following situation. If LR is the event "there exists an open left-right path in a rectangle D," then by flow considerations it follows that $I_r(LR)$ is the event "there are at least $r+1$ edge disjoint open left-right paths in D."

THEOREM A.3. (See [3].) *Let $\mathcal{E}$ be an increasing event and let r be a positive integer. Then*

$$1 - \mathbb{P}_p(I_r(\mathcal{E})) \leq \left(\frac{q}{q-q'}\right)^r [1 - \mathbb{P}_{p'}(\mathcal{E})]$$

whenever $0 \leq p < p' \leq 1$.

The theorem amounts to the assertion that if $\mathcal{E}$ is likely to occur when the edge failure probability is p', then $I_r(\mathcal{E})$ is likely to occur when the failure probability is smaller than p'.

Acknowledgments. We are grateful to David Peleg for his encouragement and to Danny Raz for his careful reading of our manuscript. We thank the anonymous referees for remarks which helped us improve our presentation, and for bringing [12] and [45] to our attention.

SPACE-EFFICIENT DETERMINISTIC SIMULATION OF PROBABILISTIC AUTOMATA*

IOAN I. MACARIE†

Abstract. Given a description of a probabilistic automaton (one-head probabilistic finite-state automaton or probabilistic Turing machine) and an input string x of length n, we ask how much space does a deterministic Turing machine need in order to decide the acceptance of the input string by that automaton?

The question is interesting even in the case of one-head one-way probabilistic finite-state automata (1pfa's). We call (*rational*) *stochastic languages* ($S^{>}_{rat}$) the class of languages recognized by 1pfa's whose transition probabilities and cutpoints (i.e., recognition thresholds) are rational numbers. The class $S^{>}_{rat}$ contains context-sensitive languages that are not context-free, but on the other hand there are context-free languages not included in $S^{>}_{rat}$.

Our main results are as follows:

- The (proper) inclusion of $S^{>}_{rat}$ in Dspace($\log n$), which is optimal (i.e., $S^{>}_{rat} \not\subset$ Dspace($o(\log n)$)). The previous upper bounds were Dspace(n) (obtained by P. D. Dieu in 1972) and Dspace($\log n \log\log n$) (obtained by H. Jung in 1984).
- Probabilistic Turing machines with space bound $f(n) \in O(\log n)$ can be deterministically simulated in space $O(\min(c^{f(n)} \log n, \log n(f(n)+\log\log n)))$, where c is a constant depending on the simulated probabilistic Turing machine. The best previously known simulation uses $O(\log n(f(n) + \log\log n))$ space (obtained by H. Jung in 1984).

To obtain these results we develop and use two space-efficient (but also parallel-time-efficient) techniques, which are of independent interest:

- a technique to compare deterministically, using only $O(\log n)$ space, large numbers given in terms of their values modulo a sequence of primes, $p_1 < p_2 < \cdots < p_n \in O(n^a)$ (where a is some arbitrary constant);
- a technique to compare deterministically a threshold with entries of the inverse of a given banded matrix.

1. Introduction.

The *(one-head one-way) probabilistic finite(-state) automaton* (1pfa) was introduced by Rabin in 1963 as a generalization of the deterministic finite automaton. He proved that, in general, probabilistic automata are stronger than their deterministic counterparts. The concepts of *cutpoint* and *isolated cutpoint* are due to the same author. He also showed that probabilistic automata with isolated cutpoint[1] recognize only regular languages, and he stated a relation between the complexities (i.e., the minimal numbers of states) of probabilistic automata and the complexities of deterministic automata that recognize the same languages. The languages recognized by one-head one-way probabilistic finite automata are called

[1]Probabilistic automata with isolated cutpoint are also known as probabilistic automata that recognize with bounded-error.

stochastic languages ($S^{>}$). Turakainen [Tu68] defined the concepts of *generalized probabilistic finite automaton* and *generalized stochastic language* and proved the equality between the class of stochastic languages and the class of generalized stochastic languages. Dieu [Di72] showed that *rational stochastic languages* ($S^{>}_{rat}$), i.e., languages recognized by probabilistic finite automata with rational transition probabilities and rational cutpoint, can be recognized by $O(n)$-space-bounded deterministic Turing machines.

In 1973, Kuklin [Ku73] introduced the *(one-head) two-way probabilistic finite automaton* (2pfa) as a generalization of 1pfa. Some time later, Freivalds [Fr81] proved that the language $\{a^n b^n \mid n \in \mathbf{N}\}$ can be recognized, although slowly, by a *two-way probabilistic finite automaton with isolated cutpoint* (2bpfa). Jung [Ju84] found an $O(\log n \log\log n)$-space deterministic simulation for 2pfa's, and later Wang [Wa92] provided a much weaker $O(n)$-space deterministic simulation for 2bpfa's using an interesting technique based on the Markov chain tree theorem of Leighton and Rivest [LR86]. In spite of the fact that the classes of languages recognized by 1pfa's and 2pfa's are the same (if their transition probabilities are either all rationals or all reals) [Ka89], the class of languages recognized by 2bpfa's is larger than the class of languages recognized by 1pfa's with isolated cutpoint. Jung [Ju84] obtained an optimal $O(\log n)$ deterministic space simulation for 2bpfa's.

The significance of finite-state automata is limited by their weakness. Therefore, in the 1970's the general interest moved to more powerful devices. Gill [Gi77] introduced the concept of *probabilistic Turing machines* (PTM). Later Simon [Si77, Si81], Borodin, Cook, and Pippenger [BCP83], and Jung [Ju81, Ju84] obtained several results on space-bounded (unbounded-error) probabilistic computation. Probably the most important result is that the languages recognized by PTM's in space $f(n) \in \Omega(\log n)$ can be recognized by deterministic Turing machines in space $O(f^2(n))$. This result, together with the fact that $f(n)$-space PTM's are at least as strong as $f(n)$-space nondeterministic Turing machines, generalizes Savitch's theorem [Sa70]. In the case of small space-bounded probabilistic complexity classes, Jung proved the inclusion of languages recognized by $f(n) \in O(\log n)$ space-bounded PTM's in $\mathrm{Dspace}(\log n(f(n) + \log\log n))$ [Ju84].

In this article we present space-efficient simulations of small space-bounded (unbounded-error) PTM's by derandomized (i.e., deterministic) Turing machines: we show a more efficient simulation of $f(n) \in o(\log n)$ space-bounded PTM's and an optimal $O(\log n)$-space simulation of one-head probabilistic finite automata with rational transition probabilities. Our simulations are presented for the more general setting of Markov chains, so they may have other applications as well. To obtain these results we develop and use two techniques that are of independent interest:

- a technique to compare deterministically, using only $O(\log n)$ space, numbers given in terms of their values modulo a sequence of primes, $p_1 < p_2 < \cdots < p_n \in O(n^a)$ (where a is some arbitrary constant);
- a technique to compare deterministically a threshold with entries of the inverse of a given banded matrix.

In section 2 we define the notions used in this article and we recall some basic results on stochastic languages.

Section 3 presents optimal deterministic logspace simulations for one-head probabilistic finite automata (Theorems 3–4), and a space-efficient technique to work with residue representations (Lemmas 1–3).

In section 4 we show that probabilistic Turing machines with space-bound $f(n) \in O(\log n)$ can be simulated by deterministic Turing machines that use only

$O(\min(c^{f(n)} \log n, \log n(\log f(n) + \log\log n)))$ space, where c is a constant depending on the simulated machine (Theorem 5).

Finally, in section 5 we discuss the significance of our results and we state some open problems.

2. Background. This section presents the definitions and the notations used in this article, and gives reminders of some properties of stochastic languages.

DEFINITION 1. (See [Ra63].) *A* (one-head one-way) probabilistic finite automaton (1pfa) *A is a* 5*-tuple*

$$A = (Q, \Sigma, \pi, \{(x, M(x)) | x \in \Sigma\}, F),$$

where

Q is the (finite) set of states, whose cardinal is denoted by n (i.e., $n = |Q|$);

Σ is the input alphabet;

π is the initial state-distribution vector, satisfying $\sum_{i=1}^{n} \pi(i) = 1$, where $\pi(i) \in [0, 1]$;

F is the set of accepting states, $F \subset Q$ (implicitly, $Q - F$ is the set of rejecting states);

$M(x)$ is an n-by-$n stochastic matrix*, whose entry $m_{ij}(x)$ is the probability of transition from state s_i to state s_j under the input symbol x, and where $\sum_{j=1}^{n} m_{ij}(x) = 1$, for each $i \in \{1, \ldots, n\}$.*

DEFINITION 2. (See [Tu68].) *A* generalized (one-head one-way) probabilistic finite automaton (1Gpfa) *is a* 5*-tuple as above with the following relaxed constraints: π is an n-dimensional real vector (and not a state-distribution vector), and the transition matrices $M(x)$ are arbitrary real matrices not constrained to be stochastic. Such a machine is also known as a* weighted finite automaton [CK94].

Observation 1. Equivalently, a 1pfa (1Gpfa) is a finite-state automaton that has one head restricted to move from left to right on an input string $y = x_1, \ldots, x_k$. (We consider that the length of y is k, and that $x_i, i \in \{1, \ldots, k\}$ are symbols from the input alphabet. Also, we may consider that the input string is delimited by a left and a right endmarker.) From a current state i, after reading the symbol x_l scanned by its head the automaton switches to state j with probability (weight) $m_{ij}(x_l)$ and moves its head to the next input symbol.

In what follows, we describe the acceptance procedure of the string y by such an automaton. Let Σ^* be the set of words over the input alphabet Σ, and let ϵ be the empty word. A word matrix $M(y), y \in \Sigma^*$ is the matrix product $M(y) = M(x_1), \ldots, M(x_k)$, where $y = x_1, \ldots, x_k$, $x_i \in \Sigma$, and $M(\epsilon) = I_n$, where I_n is the identity matrix of order n. The state-distribution vector of a probabilistic automaton A after scanning the word $y \in \Sigma^*$ is $r_A(y) = \pi M(y)$. The *acceptance probability* of y by A (i.e., the probability that A reaches an accepting state when processing y) is $p_A(y) = \pi M(y) \eta^F$ where η^F is the column vector whose ith component is equal to 1 or 0 depending on whether or not the ith state is an accepting state.

For a 1Gpfa A, we define the *acceptance function* p_A in a similar way, but in this case p_A is real-valued, and it is not necessarily a probability function anymore.

DEFINITION 3. (See [Ra63].) *The class of* stochastic languages ($S^>$) *is the class containing the languages of the form*

$$T(A, \lambda) = \{y \in \Sigma^* | p_A(y) > \lambda\},$$

where A is a 1pfa *and λ is a real number in* [0,1], *called* cutpoint *(or recognition*

threshold). If $\exists \epsilon > 0$ *such that* $\forall y \in \Sigma^* \Rightarrow |p_A(y) - \lambda| > \epsilon$, *then* λ *is called* isolated cutpoint. *(The recognition with isolated cutpoint is identical to bounded-error recognition.)*

DEFINITION 4. (See [St66].) $\mathrm{S}^{=}$ *is the class of languages of the form* $T^{=}(A, \lambda) = \{y \in \Sigma^* | P_A(y) = \lambda\}$ *where* A *is a* 1pfa *and* λ *is a cutpoint in* [0,1].

DEFINITION 5. $\mathrm{S}^{\neq}$ *is the class of languages of the form* $T^{\neq}(A, \lambda) = \{y \in \Sigma^* | P_A(y) \neq \lambda\}$, *where* A *is a* 1pfa *and* λ *is a cutpoint in* $[0, 1]$.

DEFINITION 6. (See [Tu69b].) *For each class* S^{a} *(* $a \in \{>, =, \neq\}$*) we define the rational subclasses* $\mathrm{S}^{\mathrm{a}}_{\mathrm{rat}}$ *containing the languages of the form* $T^a(A, \lambda)$, *where* A *is a* 1pfa *with the elements of its stochastic matrices and of its initial state-distribution vector all rationals, and* λ *is a rational cutpoint. We have defined in this way* $\mathrm{S}^{>}_{\mathrm{rat}}$, $\mathrm{S}^{=}_{\mathrm{rat}}$, $\mathrm{S}^{\neq}_{\mathrm{rat}}$.

In what follows, we call $\mathrm{S}^{>}_{\mathrm{rat}}$,$\mathrm{S}^{=}_{\mathrm{rat}}$, and $\mathrm{S}^{\neq}_{\mathrm{rat}}$ (rational) stochastic classes. All the probabilistic automata used in this article have rational transition probabilities; for simplicity, sometimes we drop the word "rational" without creating misunderstanding.

It is easy to prove that if in all the previous definitions we fix the value of the threshold λ to be $1/2$, the classes of languages defined so far do not change. Consequently, we will use only probabilistic automata whose cutpoint is $1/2$.

A *one-head two-way probabilistic finite automaton* (2pfa) is similar to a 1pfa, but its head can move in both directions on the input string, which is delimited by a left and right endmarker. Such an automaton has final (accepting and rejecting) states, and it halts when reaching these states. A 2pfa accepts an input string x if its acceptance probability when processing x (i.e., the probability to reach an accepting state) is larger than $1/2$. A one-head two-way probabilistic finite automaton with *isolated cutpoint* (2bpfa) is a 2pfa with the following restriction: there is an open interval I containing the cutpoint such that for any input string x its acceptance probability by the automaton does not fall inside I. A formal definition of these devices can be found in [Ka89]. We use the notations $\mathrm{2PFA}_{rat}$ ($\mathrm{2BPFA}_{rat}$) for the classes of languages recognized by one-head two-way probabilistic finite automata with rational transition probabilities (and isolated cutpoint).

The definition for probabilistic Turing machine (PTM) is standard [Gi77]. To simplify our presentation, in this article we simulate probabilistic Turing machines that have a single head on the input tape and a single head on the worktape. The computation of a space-bounded PTM (or of a probabilistic finite automaton) on an input string is viewed as a Markov process [Gi77, Si77] that is characterized by its state transition matrix. This approach is used in section 4.

Other notations we use in this article are as follows:

- $\subsetneq$ means proper inclusion,
- $\subset$ means inclusion (not necessarily proper),
- $|x|$ is the length of x if x is a string or the absolute value of x if x is a number or the number of elements of x if x is a set,
- $\|X\|$ is the norm of the matrix X defined by $\|X\| = \max_i(\sum_j |x_{ij}|)$,
- $\mathrm{Dspace}(S(n))$, $\mathrm{Nspace}(S(n))$, and $\mathrm{PrSpace}(S(n))$ are the classes of languages recognized by deterministic, nondeterministic, and probabilistic, respectively, $S(n)$-space-bounded Turing machines,
- $\mathbf{N}$ is the set of natural numbers.

Next we recall some closure properties of these classes and we present relations between them and the Chomsky's hierarchy.

PROPOSITION 1. (See [Di71].) *The classes* $S^{=}_{rat}$ *and* $S^{\neq}_{rat}$ *are closed under intersection and union but are not closed under complementation. The complement of any language from one class is in the other class.*

THEOREM 1. (See [Tu69a].) $S^{\neq}_{rat}$ *and* $S^{=}_{rat}$ *are properly included in* $S^{>}_{rat}$.

PROPOSITION 2. (See [Bu67].) *The class of regular languages is properly included in* $S^{=}_{rat} \bigcap S^{\neq}_{rat}$.

The rational stochastic classes are properly included in the class of context-sensitive languages (denoted CSL) (since $S^{>}_{rat} \subsetneq \text{Dspace}(n)$ [Di72] and $\text{Dspace}(n) \subset \text{Nspace}(n) = \text{CSL}$) but are not included in the class of context-free languages (denoted CFL); using the closure properties of $S^{=}_{rat}$, we can prove that the non-context-free language $\{a^n b^n c^n \mid n \in \mathbf{N}\}$ is included in $S^{=}_{rat}$ [Ma93].

On the other hand, there are context-free languages which are not contained in any of the rational stochastic classes: $\{x1y \mid x, y \in (0+1)^*,\ |x| = |y|\} \in \text{CFL} - S^{>}_{rat}$. (In fact this language is not even in $S^{>}$ [DS90, Ra92].)

It follows that rational stochastic classes do not fit neatly into the Chomsky's hierarchy. The next step is to compare them with space-bounded deterministic complexity classes. This problem is addressed in section 3.

Finally, we recall a useful result relating complexity classes defined by one-head one-way and one-head two-way probabilistic finite automata.

THEOREM 2. (See [Ka89].) $S^{>}_{rat} = 2\text{PFA}_{rat}$.

In other words, any 2pfa with rational transition probabilities can be simulated by a corresponding 1pfa with rational transition probabilities.

3. Space-efficient deterministic recognition of stochastic languages. In this section we compare the stochastic complexity classes we have defined so far ($S^{=}_{rat}$, $S^{\neq}_{rat}$, and $S^{>}_{rat}$) with classes of languages defined by space-bounded deterministic Turing machines. The main result is the (proper and optimal) inclusion of the class $S^{>}_{rat}$ in $\text{Dspace}(\log n)$. Lemma 3, used to compare integers given in terms of their residue representations, is of independent interest.

First, we present the background which is common to all the proofs in this section. For a 1pfa processing an input string w of length n, we have to compute its accepting probability and compare it with $1/2$. After some transformations, this task is equivalent to comparing two integers. Since the two integers are too large to fit in our working space, we work modulo relatively small primes, and we compare the residue representations of the two integers. In what follows, the representation of an integer modulo a set of primes (that is determined by the context) is called a *residue representation*. We denote by $X = (x_1, x_2, \ldots, x_n)$ (where $x_i = X \bmod p_i$, for all $i \in \{1, \ldots, n\}$) the residue representation of an integer X modulo the set of primes $\{p_1, p_2, \ldots, p_n\}$.

Now we present these steps in more detail. Let A be a 1pfa. Its transition probabilities are rational numbers. It follows that $M(w)$ has only rational elements for all $w \in \Sigma^*$. In constant space we can find the least common multiple (let us call it b) of the denominators of the transition probabilities and of the components of the initial-distribution vector. Without loss of generality, we suppose $\pi = (1, 0, \ldots, 0)$. We compute the accepting probability for the input string $w = w_1, \ldots, w_n$ of length n

$$p(w) = \pi M(w_1), \ldots, M(w_n)\eta_F^T$$

$$= (1/b^n)\pi M'(w_1), \ldots, M'(w_n)\eta_F^T,$$

where each $M'(w_i) = bM(w_i)$ has only integer elements from the interval [0,b]. Every element of $M'(w_i)$ can be computed in constant space. We have $p(w) = (1/b^n)p'(w)$ where $p'(w)$ is the word function generated by a 1Gpfa having $M'(w_i)$ as transition matrices $(p'(w) = \pi M'(w_1), \ldots, M'(w_n)\eta^T)$.

Comparing $p(w)$ with $1/2$ is equivalent to comparing $2p'(w)$ with b^n.

The values of $p'(w)$ and b^n are integers from the interval $[0, b^n]$, so $O(n)$ space is needed for storing them (too much); the standard solution is to compute the two numbers modulo relatively small primes and then to compare them using the Chinese Remainder Theorem. In this paper we work with the primes greater than 3. The reason why we avoid the prime 2 will be obvious from the proof of Lemma 1. (In fact this restriction is not essential because we can avoid using Lemma 1, but we have to modify Lemmas 2 and 3 accordingly [DMS94].)

Let us chose a constant c such that

$$\prod_{i=1}^{cn} p_i > 2^{cn} > 4b^n$$

and p_i is the ith prime starting with $p_1 = 3$. Then both $2p'(w)$ and b^n are natural numbers smaller than $\prod_{i=1}^{cn} p_i - 1$. We compute these numbers modulo $p_1, \ldots, p_{cn}$.

The advantage of using residue representations is that, at any given time, we do not have to store on the worktape all the residues, but only a finite number of them. Of course, when we need it, we have to be able to compute each such residue in a small amount of space. (In this way we use only $O(\log p_{cn}) = O(\log n)$ deterministic space.) Note that the ith prime can be found in $O(\log i)$ deterministic space. Also for each $k \in \{1, \ldots, cn\}$, the computation of $2p'(w) \bmod p_k$ requires $O(\log p_k) \in O(\log n)$ space since it is enough to keep on the work tape all the elements of the partial product matrix

$$M(w_1, \ldots, w_j) = \prod_{i=1}^{j} M(w_i) \bmod p_k, \text{ for } j \in \{1, \ldots, n\}.$$

For each $k \in \{1, \ldots, cn\}$ the computation of $b^n \bmod p_k$ uses only $O(\log n)$ space. It follows that the residue representations of $2p'(w)$ and b^n can be computed in $O(\log n)$ space, for one prime at a time.

Now we turn to the presentation of the main results of this section.

THEOREM 3. $\mathrm{S}^{=}_{\mathrm{rat}} \subsetneq \mathrm{Dspace}(\log \mathrm{n})$; $\mathrm{S}^{\neq}_{\mathrm{rat}} \subsetneq \mathrm{Dspace}(\log \mathrm{n})$ *and both inclusions are optimal.*

Proof. We prove the first relation. Since $\mathrm{Dspace}(\log n)$ is closed under complementation [Si80] and the complement of each language from $\mathrm{S}^{\neq}_{\mathrm{rat}}$ is in $\mathrm{S}^{=}_{\mathrm{rat}}$, it follows the second relation.

Let L be a language from $\mathrm{S}^{=}_{\mathrm{rat}}$, and let A be a 1pfa that recognizes L. Let w be an input word of length n and let $p(w)$ be the acceptance probability of w by A. It follows that

$$w \in L \Longleftrightarrow 1/2 = p(w) \Longleftrightarrow 2p'(w) = b^n.$$

We check the last equality (whose members are integers) modulo the first cn primes. If $2p'(w) \bmod p_i = b^n \bmod p_i$ for all $i \in \{1, \ldots, cn\}$ then $w \in L$; else $w \notin L$. It follows that the acceptance or rejection of w can be decided deterministically in $O(\log n)$ space, i.e., $L \in \mathrm{Dspace}(\log n)$. The time required by this simulation is $O(n^2)$. (We have assumed that each arithmetic operation between two $O(\log n)$-bit integers is done in constant time.)

Both inclusions are proper because the classes $\mathrm{S}^{=}_{\mathrm{rat}}$ and $\mathrm{S}^{\neq}_{\mathrm{rat}}$ are not closed under complementation. From the relations $\{a^n b^n \mid n \in \mathbf{N}\} \in \mathrm{Dspace}(\Omega(\log n))$ [LSH65] and $\{a^n b^n \mid n \in \mathbf{N}\} \in \mathrm{S}^{=}_{\mathrm{rat}}$ [Ma93], we obtain that both inclusions are optimal (i.e., it is not possible to include $\mathrm{S}^{=}_{\mathrm{rat}}$ and $\mathrm{S}^{\neq}_{\mathrm{rat}}$ in $\mathrm{Dspace}(o(\log n))$). □

In the rest of this section we show the stronger inclusion $\mathrm{S}^{>}_{\mathrm{rat}} \subsetneq \mathrm{Dspace}(\log \mathrm{n})$. To prove it we design a simulation of one-head probabilistic finite automata with rational transition probabilities by logspace deterministic Turing machines. The difference from the proof of Theorem 3 is that, at a given moment, we have to compare the numbers $2p'(w)$ and b^n using their residue representations. The standard procedure is to recompute the numbers from their residue representations (using the Chinese Remainder Theorem) and to compare them bit by bit. This approach was used by Jung [Ju84] who made crucial use of two results from circuit theory obtained by Reif [Re86] and Borodin [Bo77]. However, with this technique we can prove only $\mathrm{S}^{>}_{\mathrm{rat}} \subsetneq \mathrm{Dspace}(\log n \log\log n)$.

One observation about the method mentioned above is that we do not need to recompute the numbers (whose residue representations we already have) in order to decide which is larger. The comparison of these numbers can be done working directly on their residue representations. In what follows we focus on this idea and we prove $\mathrm{S}^{>}_{\mathrm{rat}} \subsetneq \mathrm{Dspace}(\log \mathrm{n})$ (Theorem 4). First we describe a technique to compare numbers, whose residue representations can be deterministically obtained in $O(\log n)$ space, using only $O(\log n)$ space. This result is contained in Lemmas 1–3.

LEMMA 1. *If N is an odd integer and $X, Y \in [0, N-1]$ are also integers, then $X \geq Y$ iff $(X-Y)$ has the same parity as $(X-Y) \bmod N$.*

Proof. It follows from the fact that N is odd and

$$(X-Y) \bmod N = \begin{cases} (X-Y) & if \quad X \geq Y \\ N+(X-Y) & if \quad X < Y. \end{cases}$$ □

LEMMA 2. *For every finite ascending sequence of primes $p_1, \ldots, p_n$, for every integer $X \in [0, \prod_{i=1}^{n} p_i)$, if the residue representation of X modulo these primes can be computed in $O(\log p_n)$ deterministic space, then $X \bmod N$ can be computed in $O(\log p_n + \log N)$ deterministic space, for every positive integer N.*

Proof. Let $X = (x_1, \ldots, x_n)$ be the residue representation of $X \in [0, \prod_{i=1}^{n} p_i)$ modulo the primes $p_1, \ldots, p_n$ (i.e., $x_i = X \bmod p_i$, for $i \in \{1, \ldots, n\}$), and let $M_n = \prod_{i=1}^{n} p_i$. Using the Chinese Remainder Theorem we obtain

$$X = \sum_{i=1}^{n} (x_i c_i)_{p_i} \frac{M_n}{p_i} - r \cdot M_n,$$

where r is a natural number, $c_i \in [0, P_i)$ is defined by $c_i \frac{M_n}{p_i} = 1 \pmod{p_i}$, and $(x_i c_i)_{p_i}$ denotes $x_i c_i \bmod p_i$, for $i = 1, n$. It follows that

$$r = \sum_{i=1}^{n} \frac{(x_i c_i)_{p_i}}{p_i} - \frac{X}{M_n},$$

where $0 \leq \frac{X}{M_n} < 1$ and $r = \lfloor \sum_{i=1}^{n} \frac{(x_i c_i)_{p_i}}{p_i} \rfloor \in [0, n)$.

The next step is to find deterministically r using small space. After computing r, using the Chinese Remainder Theorem we can easily compute $X \bmod N$ using only multiplications and additions modulo N.

In the rest of the proof we show how to space-efficiently find r. We compute each $t_i = \frac{(x_i c_i)_{p_i}}{p_i}$ with $(k+1)\lceil \log n \rceil$ exact digits and then we sum them up. We obtain the

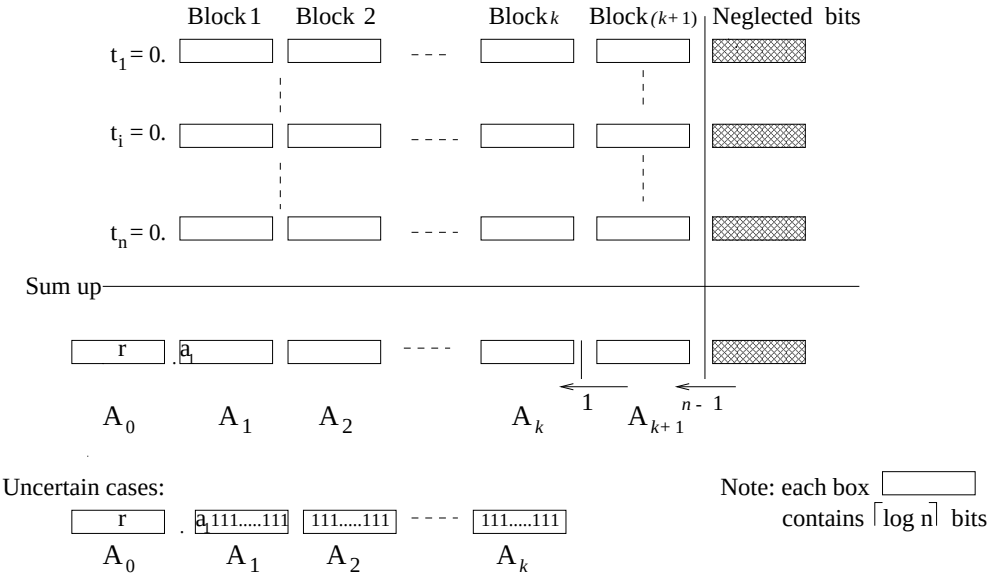

FIG. 1. *The "approximate" computation of r.*

number $A_0.A_1, \ldots, A_kA_{k+1}$, where A_i, $i \in \{0, \ldots, k+1\}$ are blocks of $\lceil \log n \rceil$ digits, and $A_0 \in [0, n)$ is the integer part of the sum. See Fig. 1. The value of k is obtained from the condition

$$\frac{M_n}{n^k} < \frac{M_{n-1}}{4} \Longleftrightarrow n^k > 4 \cdot p_n, \text{ for all } n \in \mathbf{N} \text{ greater than a threshold.}$$

(For example, if the sequence $p_1, p_2, \ldots, p_n$ contains the first n odd primes, then we can take $k = 2$.) In an exact computation of $\sum_{i=1}^{n} t_i$, it is possible to have a $(n-1)$-unit carry from the right of block A_{k+1}. Furthermore, block A_k may get at most one additional unit carry from block A_{k+1}. As a result, the bits in the blocks A_i, $i \in \{0, \ldots, k\}$, are exact or are affected by a one-unit carry to block A_k. If for all $i \in \{1, \ldots, k\}$ the blocks A_i have all their bits equal to 1, then a carry from block A_{k+1} does increment A_0, and this is the only situation when A_0 is affected by our computation error. We call such a situation an *uncertain* case. Therefore, we test whether all blocks A_i, $i \in \{1, \ldots, k\}$ have all their bits equal to 1; if not, we stop returning $r = A_0$, or else we continue with our investigation to decide whether $r = A_0$ or $r = A_0 + 1$. In this case we have

$$X \in \left[M_n - \frac{M_n}{n^k}, M_n\right] \text{ or } X \in \left[0, \frac{M_n}{n^k}\right]$$

(because our computation error is smaller than $1/n^k$). In order to treat both variants in a uniform way, we consider *negative* the numbers from the interval $(M_n/2, M_n)$ and *positive* the numbers from the interval $[0, M(n)/2)$. For every prime $p > 2$, let *smod* p be the function defined on integers and with values in the interval $(-p/2, p/2]$ such that

$$(X \; smod \, a) \bmod a = X \bmod a$$

for every integer X. Note that the function *smod* p is similar to the standard function *mod* p but it has values in the interval $(-p/2, p/2]$. It follows that the inclusion of X

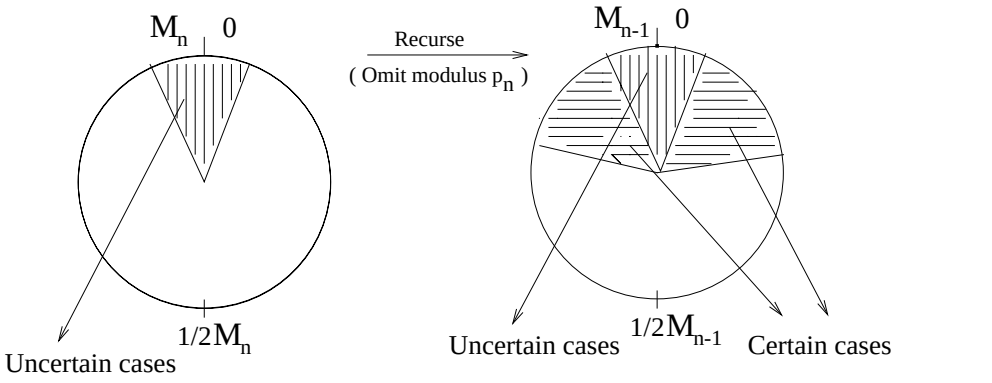

FIG. 2. *The reduction of uncertain cases.*

mentioned above is equivalent to

$$X \; smod \, M_n \in \left(-\frac{M_n}{n^k}, \frac{M_n}{n^k} \right).$$

We obtain that, in an uncertain case, our problem is reduced to finding the sign of $X \; smod \, M_n$.

This problem will be solved recursively. If $Y \; smod \, M_{n-1}$ is the number with the residue representation $(x_1, \ldots, x_{n-1})$, then the next recurrence holds:

$$X \; smod \, M_n = Y \; smod \, M_{n-1} + \alpha M_{n-1},$$

where α is an integer in the interval $(-p_n/2, p_n/2]$. From the fact that $X \; smod \, M_n \in (-\frac{M_n}{n^k}, \frac{M_n}{n^k}) \subset (-\frac{M_{n-1}}{4}, \frac{M_{n-1}}{4})$ (the value k has been computed to make this last inclusion true), and $Y \; smod \, M_{n-1} \in (-\frac{M_{n-1}}{2}, \frac{M_{n-1}}{2})$, it follows that $\alpha = 0$ in the previous recurrence. (This observation belongs to Dietz [Di93].) As a result,

$$X \; smod \, M_n = Y \; smod \, M_{n-1} \in \left(-\frac{M_{n-1}}{4}, \frac{M_{n-1}}{4} \right),$$

and we reduce the problem of computing the sign of $X \; smod \, M_n$ to computing the sign of $Y \; smod \, M_{n-1}$. If $Y \; smod \, M_{n-1} \in [0, \frac{M_{n-1}}{4})$, then $r = A_0 + 1$; else $r = A_0$. Note that this recursive step converts a large fraction of uncertain cases into certain cases. See Fig. 2.

If we still have an uncertain case, we continue the recursion as above. □

LEMMA 3. *Consider $p_1, p_2, \ldots, p_n$ strictly increasing odd primes and $M_n = \prod_{i=1}^{n} p_i$. If for two integers $X, Y \in [0, M_n - 1]$ their residue representations can be computed deterministically in $O(\log p_n)$ space, then the relations $X > Y, X = Y$, and $X < Y$ can be decided in $O(\log p_n)$ deterministic space.*

Proof. Let $X = (x_1, \ldots, x_n)$, $Y = (y_1, \ldots, y_n)$ be the residue representation of X and Y and let

$$Z = ((x_1 - y_1) \bmod p_1, \ldots, (x_n - y_n) \bmod p_n)$$

$$= (X - Y) \bmod M_n.$$

We compute the parity of X, Y, and Z using Lemma 2 with $N = 2$, we check whether $Z = 0$, and we apply Lemma 1 to compare X and Y. Every operation is done in $O(\log p_n)$ deterministic space. □

Observation 2. This lemma has a crucial role in proving the most important results of this paper. It gives us a space-efficient tool to compare large numbers given in terms of their residue representations. Another presentation and other applications of this technique can be found in [DMS94]. Davida and Litow, independently, propose another method to efficiently compare numbers given their residue representations [DL91]. The two methods turn out to have similar strength. Although one was expressed in the setting of deterministic space and the other in the setting of parallel time, they can easily be adapted to the other context. A more detailed comparison between them can be found in [DMS94].

THEOREM 4. $S^{>}_{\text{rat}} \subsetneqq \text{Dspace}(\log n)$ *and the inclusion is optimal.*

Proof. We work with odd primes and we follow the method presented at the beginning of this section until we have to compare two integers given (on demand) their residue representations. Then, we apply Lemma 3. The time required by this simulation is $O(n^3)$, under the assumption that arithmetic operations between $O(\log n)$-bit integers are done in constant time.

The inclusion is proper since $\{x1y \mid x, y \in (0+1)^*,\ |x| = |y|\} \in \text{Dspace}(\log n) - S^{>}_{\text{rat}}$. Also, it is optimal since $S^{=}_{\text{rat}}$ is optimally included in $\text{Dspace}(\log n)$ and $S^{=}_{\text{rat}} \subsetneqq S^{>}_{\text{rat}}$. □

This theorem improves the result of Dieu [Di72], $S^{>}_{\text{rat}} \subsetneqq \text{Dspace}(n)$.

COROLLARY 1. $2\text{PFA}_{rat} \subsetneqq \text{Dspace}(\log n)$ *and the inclusion is optimal.*

Proof. Use the equality $S^{>}_{\text{rat}} = 2\text{PFA}_{rat}$. □

This corollary improves the results of Wang [Wa92] ($2\text{BPFA}_{rat} \subsetneqq \text{Dspace}(n)$) and Jung [Ju84] ($\text{PrSpace}(\text{O}(1)) \subsetneqq \text{Dspace}(\log n \log\log n)$).

4. Space-efficient deterministic simulations of $o(\log\ n)$-space-bounded probabilistic Turing machines. The main result of this section is a space-efficient deterministic simulation of small-space-bounded probabilistic Turing machines. The simulation is presented for the more general setting of Markov chains. Our technique to compare a threshold with entries of the inverse of a given banded matrix is of independent interest.

We recall first some basic knowledge about space-bounded probabilistic computations. Let us consider the computation of a space-bounded PTM A on an input string x of length n. A configuration of A contains the state of its finite control, the description of the worktape content, and the position of heads on the worktape and on the input tape. Without loss of generality, we suppose that A has only one accepting configuration, one rejecting configuration, and that the computation halts when it enters these configurations. For an input x, the accepting probability of x is the probability that A enters the accepting configuration. The machine A accepts x if its accepting probability of x is larger than $1/2$.

In what follows, with the computation of A on an input string x, we associate a Markov process whose states are the possible configurations of A, and whose transition probabilities are given by the probabilities of A's moves. The Markov process has one starting state, one rejecting state, and one accepting state, according to the configurations of A. The accepting probability of x equals the long-run transition probability of the Markov process to move from the starting state into the accepting state. The Markov process is characterized by a state transition matrix. Each entry of this matrix represents the probability to move from one state to another state

in one step and corresponds to the transition probability of A to move from one configuration to another in one step. We call this matrix the *configuration transition matrix*. In order to compute easily the long-run transition from the initial state to the accepting state, we use a "simplified" configuration transition matrix in which we omit the rejecting state and some of the states that are not connected (directly or indirectly) to the accepting state. Obviously, the configuration transition matrix and the simplified configuration transition matrix have the same long-run transition probability from the initial state to the accepting state.

The acceptance decision of A on x is equivalent to comparing $1/2$ with a long-run transition probability in the associated Markov process. Using only logarithmic space, Simon [Si77, Si81] presents a way to reduce nondeterministically this problem to the problem of comparing $1/2$ with an element of a matrix inverse. This decision is obtained by a parallel-time-efficient (and also space-efficient, as follows from a result of Borodin [Bo77]) algorithm for matrix inversion due to Csanky [Cs76]. Jung [Ju84] finds a logspace deterministic reduction to reduce the acceptance decision of A on x to the problem of comparing $1/2$ with an entry of a matrix inverse, and he designs a space-efficient (and also parallel-time efficient) algorithm to solve the last problem in the particular case of matrices with small bandwidth.

In what follows we extend these previous techniques, and we present a more space-efficient deterministic simulation of small-space PTM's that makes crucial use of Lemmas 1–3.

THEOREM 5. *The languages recognized by $f(n) \in O(\log n)$ space-bounded probabilistic Turing machines can be recognized by deterministic Turing machines in space*

$$O(\min(c^{f(n)} \log n, \log n(f(n) + \log\log n))),$$

where c is a constant depending on the probabilistic Turing machine.[2]

Proof. Let A be an $f(n) \in O(\log n)$ space-bounded PTM processing an input string x of length n. By $p_A(x)$ we denote the acceptance probability of x by A. The number of possible configurations of A is

$$m = q(n+2)f(n)a_0^{f(n)} \in O(n^a),$$

where q is the number of states, a_0 is the size of the worktape alphabet of A, and a is a constant. (We remind the reader that A has one head on the input tape and one head on the worktape. Its input string is delimited by left and right end-markers.) We enumerate these configurations in increasing order of the input head's position. The computation of A on x is seen as a Markov process.

Let N be the m-by-m (simplified) configuration transition matrix associated with this Markov process in which the first row corresponds to the starting configuration of A (i.e., to c_1), the mth row, which corresponds to the accepting configuration (i.e., to c_m) is filled with 0, and the row (and the column) corresponding to the rejecting state is omitted. The bandwidth of N is $B \in O(f(n)a_0^{f(n)}) \subset O(c^{f(n)})$ (we can take $c = a_0 + \epsilon$ for arbitrarily small $\epsilon > 0$). Without loss of generality, we suppose that the elements of N are rational numbers all having the same denominator b. In the case of standard definition of PTM's b is 2, but we present the case with b natural, since the applicability of this result can be extended to other probabilistic devices whose computation can be represented by a Markov chain.

[2]More precisely, c depends on the size of the worktape alphabet of the probabilistic Turing machine.

The entry $(1, m)$ of the matrix sum $I + N + \cdots + N^k$ goes to $p_A(x)$ when k goes to infinity. Our problem is to space-efficiently approximate this entry. Also note that $\|N\| \leq 1$ and that the above matrix sum is not necessarily convergent. In what follows, we slightly modify N, using transformations computable deterministically in logarithmic space, to obtain the sequence of matrices Q, M, and finally $M - \Delta M$, so that $\|Q\| < 1$, $\|M\| < 1$, $\|M - \Delta M\| < 1$. Moreover, the sum $I + (M - \Delta M) + \cdots + (M - \Delta M)^k$ is convergent to F^{-1}, where $F = I - (M - \Delta M)$ is also easy to invert. The entry in the last column of the first row of F^{-1} will closely approximate the long-run transition probability from configuration c_1 into configuration c_m of the initial Markov process (i.e., $p_A(x)$). As a result, we can determine whether A accepts x by comparing that entry with $1/2$. This is equivalent to comparing two determinants whose elements are integers. We compute each of these determinants modulo relatively small primes and we use Lemma 3, where X and Y are the values of the two determinants.

In what follows we present the sequence of modifications of configuration transition matrices in steps. Recall that $\|X\|$ denotes the norm of the m-by-m matrix X, defined by $\|X\| = \max_i \sum_{j=1,m} |x_{ij}|$.

Step 1 (*obtaining* Q). Gill [Gi77] and Simon [Si81] proved that there is an integer d_1 independent of n, such that for every input x of length n the acceptance probability of x does not fall in the interval $[1/2, 1/2 + 1/b^{n^{d_1}}]$. (Such an integer can be found deterministically in $O(1)$ space. Using the technique from [RST82] (they used it to build "a probabilistic clock"), we find an integer $d_2 > d_1$ such that for every input x of length n, from each configuration c_i, A rejects with probability $1/b^{n^{d_2}}$ and enters in the next configuration c_j with probability $(1 - 1/b^{n^{d_2}}) \cdot n_{ij}$. Then the acceptance probability for x will decrease by a quantity less than $1/b^{n^{d_1}}$ and the set of recognized words is not changed. This modification of the computation of A corresponds to a modification of the associated Markov process and to a modification of the (simplified) configuration transition matrix N. (In fact, our goal is to modify the original Markov process corresponding to the computation of A on the input x. Some of these modifications could not correspond to any simple modification of the machine A.)

We obtain a configuration transition matrix Q of size m-by-m with its elements defined by $q_{ij} = (1 - 1/b^{n^{d_2}}) \cdot n_{ij}$. From $\|N\| \leq 1$ it follows $\|Q\| \leq 1 - 1/b^{n^{d_2}}$. In the associated Markov process the modified acceptance probability of x does not fall in the interval $[1/2, 1/2 + 1/b^{n^{d_3}}]$ for some integer $d_3 > d_1$ independent of n but dependent on d_1 and d_2.

So far we have obtained that $I - Q$ is nonsingular. In addition we would like to have the following property: the modified acceptance probability of x does not fall in an open interval containing $1/2$. In order to obtain this additional property in the next step we modify Q and obtain M.

Step 2 (*obtaining* M). We modify the Markov process by introducing a new state c_0 such that from c_0 the new Markov process goes into c_1 with probability $1 - 1/b^{n^{d_4}}$, where $d_4 > d_3$, and we consider c_0 its starting state. The long-run transition probability to move from state c_0 to state c_m is equal to $(1 - 1/b^{n^{d_4}})$ multiplied by the long-run transition probability to move from state c_1 to state c_m in the previous Markov process. Its values fall outside the interval $[1/2 - 1/b^{n^{d_5}}, 1/2 + 1/b^{n^{d_5}}]$, for some integer $d_5 > d_4$ independent of n, and are on the same side of $1/2$ as the original acceptance probability of x by A. We denote by M the new $(m + 1)$-by-$(m + 1)$

configuration transition matrix associated with this new Markov process. We recall that the last row of M (corresponding to the accepting configuration) contain only zeros. The matrix M has a bandwidth equal to B or $B+1$ and $\|M\| < 1-1/b^{n^{d_5}} < 1$. The matrix $I-M$ is nonsingular since it is *diagonally dominant*, i.e., for each row the absolute value of the diagonal element is larger than the sum of the absolute values of the other elements.

As a result, $I + M + \cdots + M^k + \cdots = (I-M)^{-1}$. Let $E = (I-M)^{-1}$. The element $e_{1,m+1}$ approximates the accepting probability of x by A in the following sense: if x is accepted by A, then $e_{1,m+1} > 1/2 + 1/b^{n^{d_5}}$, and if x is rejected by A, then $e_{1,m+1} < 1/2 - 1/b^{n^{d_5}}$. The integer d_5 is independent of n.

In the next step we apply one more transformation on M and obtain $M - \Delta M$, such that $I-(M-\Delta M)$ can be inverted space-efficiently using a Gaussian elimination. We achieve this by forcing $M-\Delta M$ to have nonnull elements on the diagonal situated immediately above the band of M.

Step 3 (*obtaining* $M-\Delta M$). We slightly modify M (and the Markov process) in a way that does not change the acceptance decision for x. We call ΔM the matrix having all its elements zeros with the exception of the elements on the diagonal immediately above the band of M, which are all equal to $1/b^{n^{d_6}}$, for an integer $d_6 > d_5$. Clearly, $\|\Delta M\| = 1/b^{n^{d_6}}$ and $\|M-\Delta M\| \le 1-1/b^{n^{d_5}} + 1/b^{n^{d_6}} < 1-1/2\cdot 1/b^{n^{d_5}}$. We compute the difference between $[I-(M-\Delta M)]^{-1}$ and $(I-M)^{-1}$ using a lemma of Banach [Go83]:

$$\|[I-(M-\Delta M)]^{-1} - (I-M)^{-1}\| \le \|\Delta M\| \cdot \|[I-(M-\Delta M)]^{-1}\| \cdot \|(I-M)^{-1}\|.$$

From $\|(I-M)^{-1}\| \le \|I\| + \|M\| + \cdots + \|M^k\| + \cdots \le \frac{1}{1-\|M\|}$ when $\|M\| < 1$, it follows that

$$\|(I-M)^{-1}\| \le \frac{1}{1-(1-1/b^{n^{d_5}})} = b^{n^{d_5}},$$
$$\|[I-(M-\Delta M)]^{-1}\| \le \frac{1}{1-(1-1/b^{n^{d_5}}+1/b^{n^{d_6}})} \le 2\cdot b^{n^{d_5}}.$$

Using Banach's lemma we obtain

$$\|[I-(M-\Delta M)]^{-1} - (I-M)^{-1}\| \le \frac{2\cdot b^{2n^{d_5}}}{b^{n^{d_6}}} < \frac{1}{b^{n^{d_5}}}$$

if $d_6 > d_5$ and if n is large enough. Let us denote $F = I-(M-\Delta M)$.

Based on the fact that $e_{1,m+1}$ closely approximates the acceptance probability of x in the sense described at the end of Step 2, and that the norm of $(E-F^{-1})$ is small enough, it follows that the element of F^{-1} from the entry $(1, m+1)$ lies on the same side of $1/2$ as $p_A(x)$. Computing this element is equivalent to computing the element y_1 from the system

$$F \cdot \begin{bmatrix} y_1 \\ \vdots \\ y_m \\ y_{m+1} \end{bmatrix} = \begin{bmatrix} 0 \\ \vdots \\ 0 \\ 1 \end{bmatrix}.$$

Step 4 (*clear denominators*). Now, we transform the matrix F into an integer matrix. On the left, we multiply both sides of the previous system by the diagonal

matrix

$$F_1 = \begin{bmatrix} b^{n^{d_6}} & & & & & & \\ & \ddots & & & & & \\ & & \ddots & & & & \\ & & & b^{n^{d_6}} & & & \\ & & & & b^{n^{d_6}} & & \\ & & & & & 1 & \end{bmatrix}.$$

This yields the equivalent system

$$G \cdot \begin{bmatrix} y_1 \\ \vdots \\ y_m \\ y_{m+1} \end{bmatrix} = \begin{bmatrix} 0 \\ \vdots \\ 0 \\ 1 \end{bmatrix}.$$

G has only integer elements, since d_6 exceeds the earlier constants, and it is nonsingular since F and F_1 are nonsingular. Its bandwidth is at most one larger than the bandwidth of N, and its elements on its highest nonnull diagonal are all 1. We have to find y_1 and how it compares with $1/2$. The element y_1 is the entry $(1, m+1)$ of G^{-1}, so its value is $y_1 = \frac{u}{v}$, where $u = (-1)^{(m+1)+1}\Delta_{(m+1,1)}$, $v = \det G$, u and v are both integers, and $u/v > 1/2$ iff $2u > v$. $\Delta_{(m+1,1)}$ is the minor $(m+1, 1)$ of G, and is the determinant of a matrix having the same structure as G; so our problem is reduced to comparing the determinants of two matrices that have the same type as G.

Step 5 (*Gaussian elimination*). We show how to compute the determinant of G. The determinants giving u and v can be computed in a similar way. First, we do a partial Gaussian elimination of the elements under the highest nonnull diagonal (now filled with 1's). Next we have to compute the determinant of a $O(B)$-by-$O(B)$ integer matrix G_2 (see Fig. 3) that can be done in $O(\log B(\log B + \log\log P))$ deterministic space, where P is the largest number used in that computation.

We comment now on different ways to do the Gaussian elimination and to compute the elements of the matrices G_1 and G_2. The first remark is that we can compute the elements of G_1 and G_2 column by column. For a given column, each element can be computed by a linear recurrence involving a constant number of elements belonging to the same column and situated in the next upper $(B+1)$ positions above it. We have to compute the first $m+1$ elements generated by this recurrence. (Note that the operations involved in the recurrence are additions, subtractions, and multiplications.) We indicate two ways to solve this recurrence, whose space-efficiencies depend on the magnitude of B.

- One way is to always keep the last $(B+1)$ elements on the worktape, and, when computing a new element, to replace the oldest element. The space used in this approach is $O(B \cdot \log P)$.
- The other way is to solve the recurrence in parallel using a circuit model. We recall the result of Stone [St73], which states that obtaining the first m numbers satisfying a linear recurrence of order B is equivalent to multiplying m B-by-B matrices, and this is equivalent to performing $\log m$ iterations, where each iteration involves parallel multiplications of B-by-B matrices. Matrix multiplication can be done by logspace-uniform (polynomial-size) boolean circuits of depth $O(\log B + \log\log P)$, where P is the largest number involved in the computation. As a result, we can solve the linear recurrence using

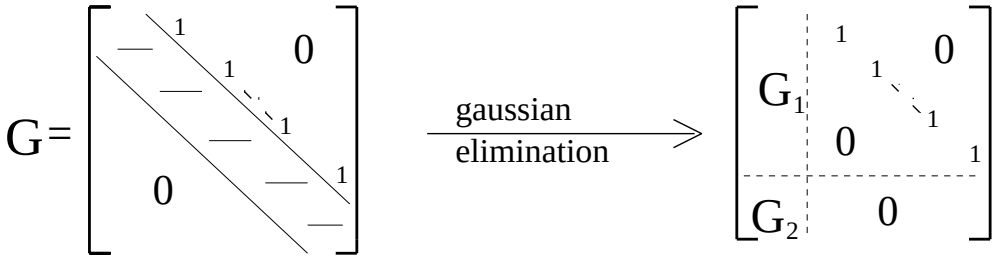

FIG. 3. *Gaussian elimination.*

logspace-uniform boolean circuits of depth $O(\log m(\log B + \log\log P))$, which can be simulated in $O(\log m(\log B + \log\log P))$ deterministic space using a result of Borodin [Bo77]. Essentially, Jung found another variant of this second method [Ju84].

In summary, the acceptance or rejection of x is equivalent to deciding whether y_1 is larger or smaller than $1/2$, which is equivalent to deciding which of the integers $2u$ and v is larger. The magnitude of these two numbers is $O(m(b^{n^{d_6}})^m) = O(b^{n^{d_6+a+1}})$ (recall that $m \in O(n^a)$). Let $h \in \Theta(n^{d_6+a+1})$. We have $\max(2u, v) < \prod_{i=1}^{h} p_i$, where p_i, $i \in \{1, \ldots, h\}$ are the first h primes starting with $p_1 = 3$. We can compute $2u$ and v modulo these h primes and then compare them using Lemma 3. Their computation modulo a prime p_i can be done deterministically, using the previous remarks, in $O(\log m + \min(B \log p_i, \log m(\log B + \log\log p_i)))$ space. Also note that $\log p_h \in O(\log n)$ (because $p_h \in O(h \log h)$), $\log m \in O(\log n)$, and $B = O(c^{f(n)})$. □

THEOREM 6. *The languages recognized by $f(n) \in o(\log\log\log n)$ space-bounded probabilistic Turing machines can be recognized by deterministic Turing machines in space $O(c^{f(n)}(\log n))$, where c is a constant depending on the probabilistic Turing machine.*

This theorem improves the following result of Jung [Ju84]:

$$\mathrm{PrSpace}(f(n)) \subset \mathrm{Dspace}(\log n(f(n) + \log\log n))$$

for $f(n) \in o(\log\log\log n)$.

5. Discussion and open problems. This article presents space-efficient derandomized (i.e., deterministic) simulations of probabilistic automata. Depending on the amount of space used by the simulated probabilistic automaton, we obtain results at three different levels:

- Probabilistic (one-head one-way and one-head two-way) finite automata (with rational transition probabilities) can be simulated deterministically in $O(\log n)$ space. This simulation is optimal and represents a significant improvement over the previously reported simulations [Di72, Ju84, Wa92]. It follows as a corollary that the languages recognized by these automata have simple characterizations in extended first-order logics. (See [Im87] for some connections among space-bounded complexity classes and first-order logic with ordering and closure operators.)
- Probabilistic Turing machines with space bound $f(n) \in o(\log\log\log n)$ are simulated deterministically in $O(c^{f(n)} \log n)$ space, where c is a constant depending on the size of the worktape alphabet of the simulated machine. This

improves a simulation of Jung, which uses $O(\log n \log\log n)$ space independently of the size of $f(n)$ [Ju84]. The existence of languages with probabilistic space complexities at this level was pointed out by Freivalds [Fr81].[3] In the nondeterministic case, on the other hand, there are no such languages since there is a space complexity gap below $\log\log n$ [SHL65].

- Probabilistic Turing machines with space bound $f(n)$ between $\Theta(\log\log\log n)$ and $\Theta(\log n)$ can be simulated deterministically in $O(\log n(f(n) + \log\log n))$ space. Our new simulation uses the same space as Jung's [Ju84]. When $f(n)$ is between $\Theta(\log\log n)$ and $\Theta(\log n)$ these simulations generalize Monien and Sudborough's deterministic simulation of space-bounded nondeterministic Turing machines [MS82].

Our simulations are presented in the more general setting of Markov chains, so they may have other applications as well. We also design a space-efficient method to compare a threshold with entries of the inverse of banded matrices. One tool for proving these results is a space-efficient (and also parallel-time-efficient) technique to deterministically compare numbers given in terms of their residue representations.

We turn now to some open problems.

The main limitation in the proof of Theorem 5 is that we are able to use only the bandwidth of the matrix, but not its sparse structure, within the band. We are looking for more sophisticated algorithms for inverting matrices, able to take advantage of bandwidth combined with sparseness. Interestingly, for the problem of iterated matrix product, to which matrix inversion is efficiently reducible [Co85], there is known an approximation technique that takes advantage of the matrix sparseness within each row [SZ95]. This technique uses pseudorandom generators for space-bounded bounded-error probabilistic computation [Ni90, Ni92]. However, it does not provide tight approximations and, consequently, it can be used for simulating only *bounded*-error probabilistic computation. It may be possible to combine the advantages of both techniques.

Another question is how to take further advantage of the fact that we can do small modifications on the configuration transition matrices when inverting them.

Acknowledgments. I am very grateful to Joel Seiferas and Paul Dietz for many valuable discussions on this subject. I also thank them for carefully reading an earlier version of this paper and suggesting significant improvements. I also thank Helmut Jürgensen for his comments on a preliminary version of this paper and Marius Zimand and Bruce Litow for bringing to my attention the paper by Davida and Litow [DL91].

EFFICIENT MATRIX CHAIN ORDERING IN POLYLOG TIME*

PHILLIP G. BRADFORD†, GREGORY J. E. RAWLINS‡, AND GREGORY E. SHANNON§

Abstract. The matrix chain ordering problem is to find the cheapest way to multiply a chain of n matrices, where the matrices are pairwise compatible but of varying dimensions. Here we give several new parallel algorithms including $O(\lg^3 n)$-time and $n/\lg n$-processor algorithms for solving the matrix chain ordering problem and for solving an optimal triangulation problem of convex polygons on the common CRCW PRAM model. Next, by using efficient algorithms for computing row minima of totally monotone matrices, this complexity is improved to $O(\lg^2 n)$ time with n processors on the EREW PRAM and to $O(\lg^2 n \lg\lg n)$ time with $n/\lg\lg n$ processors on a common CRCW PRAM. A new algorithm for computing the row minima of totally monotone matrices improves our parallel MCOP algorithm to $O(n \lg^{1.5} n)$ work and polylog time on a CREW PRAM. Optimal log-time algorithms for computing row minima of totally monotone matrices will improve our algorithm and enable it to have the same work as the sequential algorithm of Hu and Shing [*SIAM J. Comput.*, 11 (1982), pp. 362–373; *SIAM J. Comput.*, 13 (1984), pp. 228–251].

1. Introduction.

The design of efficient parallel algorithms for problems with elementary serial dynamic programming solutions has been the focus of much recent research. These problems include string editing [2, 5, 30], context-free grammar recognition [35, 37], and optimal tree building [7, 32]. Polylog time parallel algorithms for solving these problems use new approaches, since straightforward parallelization of sequential dynamic programming algorithms produce very slow (linear-time) parallel algorithms. Many efficient parallel algorithms designed to date rely on *monotonicity conditions* to give divide-and-conquer schemes. By "efficient" we mean that the processor-time product is within a polylog factor of the best sequential time.

The *matrix chain ordering problem* (MCOP) is to find the cheapest way to multiply a chain of n matrices, where the matrices are pairwise compatible but of varying dimensions. This problem can be found in many classic textbooks on parallel and sequential algorithms, such as [3, 18]. The MCOP is often the focus of dynamic programming research and pedagogy because of its amenability to an elementary dynamic programming solution. There has been significant sequential and parallel work on the MCOP [11, 17, 19, 20, 21, 25, 26, 27, 28, 29, 38, 40, 41, 39, 42, 43, 44] and a related convex polygon triangulating problem. However, until recently none of this work has given an efficient (linear-processor) polylogarithmic-time algorithm for the

MCOP. (See Bradford [11].) Recently in [40] and [41] Ramanan independently gave an $O(\lg^4 n)$-time and n-processor algorithm for solving the MCOP on the CREW PRAM. Moreover, in [15] we gave a $O(\lg^4 n)$-time and $n/\lg n$ processor algorithm for solving the MCOP on the common-CRCW PRAM.

Algorithm-design paradigms often aid the design of efficient sequential algorithms. However, some algorithm-design paradigms may not lead to efficient parallel algorithms. In particular, some variations of the greedy paradigm appear to be inherently sequential [4]. This highlights the significance of research in parallel dynamic programming.

1.1. Main results of this paper. Our approach follows [11], recasting the MCOP as a shortest path problem in a graph modeling a dynamic programming table. (In fact, this paper is an update of a part of [10] and a revision of [15]; see also the first author's dissertation [12].) This graph has $O(n^2)$ nodes and with an all-pairs shortest paths algorithm finding a shortest path in this graph results in a $n^6/\lg n$ processor MCOP algorithm. Reducing the number of nodes to $O(n)$ using a tree decomposition and applying an all-pairs shortest path algorithm gives an $n^3/\lg n$ processor and polylog-time algorithm.

In this paper, we convert the successive applications of the brute force all-pairs shortest paths algorithm to successive applications of parallel partial prefix and binary search algorithms. As in the $n^3/\lg n$-processor algorithm, the applications of the prefix and binary search algorithms are controlled by a rake-compress paradigm operating on a tree-based decomposition of the original graph. All of this results in a polylog-time ($O(\lg^3 n)$) and linear-processor ($n/\lg n$) parallel algorithm for the MCOP on the common-CRCW PRAM. This improves our result of $O(\lg^4 n)$ time and $n/\lg n$ processors of [15]. In addition, using efficient algorithms for computing row minima on totally monotone matrices, our algorithm can run in $O(\lg^2 n \lg\lg n)$ time using $n/\lg\lg n$ processors on a common-CRCW PRAM or in $O(\lg^2 n)$ time using n processors on an EREW PRAM. Using the most efficient polylog-time parallel algorithms for computing row minima on totally monotone matrices, our algorithm can run in $O(\lg^{1.5} n \lg\lg n)$ time using $O(n\sqrt{\lg n})$ work on a common-CRCW PRAM or in $O(\lg^{2.5} n\sqrt{\lg\lg n})$ time using $O(n\sqrt{\lg n \lg\lg n})$ processors on an EREW PRAM. See Bradford, Fleischer, and Smid [14] for the most efficient polylog-time parallel algorithms to date for computing row minima in totally monotone matrices.

1.2. Previous results. Elementary dynamic programming algorithms sequentially solve the matrix chain ordering problem in $O(n^3)$ time; see [3, 18]. Several recent textbooks on the design and analysis of parallel algorithms discuss the MCOP; see [36, 23]. However, the best sequential solution of the MCOP is Hu and Shing's $O(n \lg n)$ algorithm [28, 29]. (Much work has been done on lower bounds on the MCOP and related problems; see [38, 39, 13].) Using straight-line arithmetic programs, Valiant et al. [43] showed that many classical optimization problems with efficient sequential dynamic programming solutions are in $\mathcal{NC}$. Their algorithms require $\Theta(\lg^2 n)$ time and n^9 processors. Using pebbling games, Rytter [42] gave more efficient parallel algorithms for a similar class of optimization problems costing $O(\lg^2 n)$ time with $n^6/\lg n$ processors. In [11], an algorithm was given that takes $O(\lg^3 n)$ time and $n^3/\lg n$ processors, and [20] gave an algorithm that takes $O(\lg^3 n)$ time and $n^2/\lg^3 n$ processors. In [40], Ramanan gives an extended abstract of an n-processor and $O(\lg^4 n)$-time CREW PRAM algorithm for solving the MCOP which came after our buggy version in [10]; his full version appears in [41]. A full version of our $n/\lg n$-processor and $O(\lg^4 n)$-time algorithm described and improved upon in this paper

appears in [15]. In addition, there are serial and parallel approximation algorithms for the MCOP [11, 17, 19, 27].

1.3. Structure of the paper. In section 2 we briefly review the interpretation of the MCOP as a shortest path graph problem from [11] and then summarize the $n^3/\lg n$-processor algorithm. In section 3 we isolate this algorithm's $n^3/\lg n$-processor bottlenecks. The $n^3/\lg n$-processor cost of these bottlenecks is from an all-pairs shortest paths algorithm. In section 4 we show how to replace the all-pairs shortest path algorithm with parallel prefix and an all-pairs *comparison* algorithm. In section 5 we replace the all-pairs comparison algorithm with applications of parallel prefix and binary search. Finally, it is shown that the key problems solved in section 4, and more efficiently in section 5, can be solved by finding the row minima of a totally monotone matrix.

2. An $O(\lg^3 n)$ time and $n^3/\lg n$ processor MCOP algorithm. This section contains a brief review of the polylog-time and $n^3/\lg n$-processor MCOP algorithm from [11].

Let T be an $n \times n$ dynamic programming table for the matrix chain ordering problem. It has entries $T[i,k]$ representing the cheapest cost of the matrix product $M_i \bullet \cdots \bullet M_k$. For any such T there is a graph D_n where the cost of a shortest path to node (i,k), denoted $sp(i,k)$, is the same as the final value of $T[i,k]$. Given a chain of n matrices, finding a shortest path from $(0,0)$ to $(1,n)$ in D_n solves the MCOP [11].

The weighted digraph D_n has vertices in the set, $\{(i,j) : 1 \le i \le j \le n\} \cup \{(0,0)\}$ and edges

$$\{(i,j) \to (i,j+1) : 1 \le i \le j < n\} \cup \{(i,j) \uparrow (i-1,j) : 1 < i \le j \le n\}$$
$$\cup \{(0,0) \nearrow (i,i) : 1 \le i \le n\},$$

known as *unit* edges, together with the edges

$$\{(i,j) \Longrightarrow (i,t) : 1 < i < j < t \le n\} \cup \{(s,t) \Uparrow (i,t) : 1 \le i < s < t \le n\},$$

known as *jumpers*; see the jumper from $(1,2)$ to $(1,4)$ in Figure 1. The unit edge $(i,j) \to (i,j+1)$ represents the product $(M_i \bullet \cdots \bullet M_j) \bullet M_{j+1}$ and weighs $f(i,j,j+1) = w_i w_{j+1} w_{j+2}$, which is taken as the cost of multiplying a $w_i \times w_{j+1}$ matrix and a $w_{j+1} \times w_{j+2}$ matrix. Similarly, the unit edge $(i,j) \uparrow (i-1,j)$ represents the product $M_{i-1} \bullet (M_i \bullet \cdots \bullet M_j)$ and costs $f(i-1,i-1,j) = w_{i-1} w_i w_{j+1}$. A shortest path to (i,k) through the jumpers $(i,j) \Longrightarrow (i,k)$ and $(j+1,k) \Uparrow (i,k)$ represents the product $(M_i \bullet \cdots \bullet M_j) \bullet (M_{j+1} \bullet \cdots \bullet M_k)$, and these jumpers weigh $sp(j+1,k) + f(i,j,k)$ and $sp(i,j) + f(i,j,k)$, respectively, where $sp(j+1,k)$ is the cost of a shortest path to node $(j+1,k)$ and $f(i,j,k) = w_i w_{j+1} w_{k+1}$. The jumper $(i,j) \Longrightarrow (i,t)$ is of length $t-j$. See Figure 1.

Using this model the MCOP can be solved in polylog time with $n^6/\lg n$ processors by using an all-pairs shortest path algorithm and exploiting the following theorem.

THEOREM 1 (Duality Theorem [11]). *If a shortest path from* $(0,0)$ *to* (i,k) *contains the jumper* $(i,j) \Longrightarrow (i,k)$*, then there is a* dual *shortest path containing the jumper* $(j+1,k) \Uparrow (i,k)$.

Furthermore, using a tree decomposition of D_n and an all-pairs shortest path algorithm, the MCOP was solved in polylog time using $n^3/\lg n$ processors [11].

2.1. Matrix dimensions as nesting levels of matching parentheses. The next four subsections show that using the list of matrix dimensions as nesting levels of

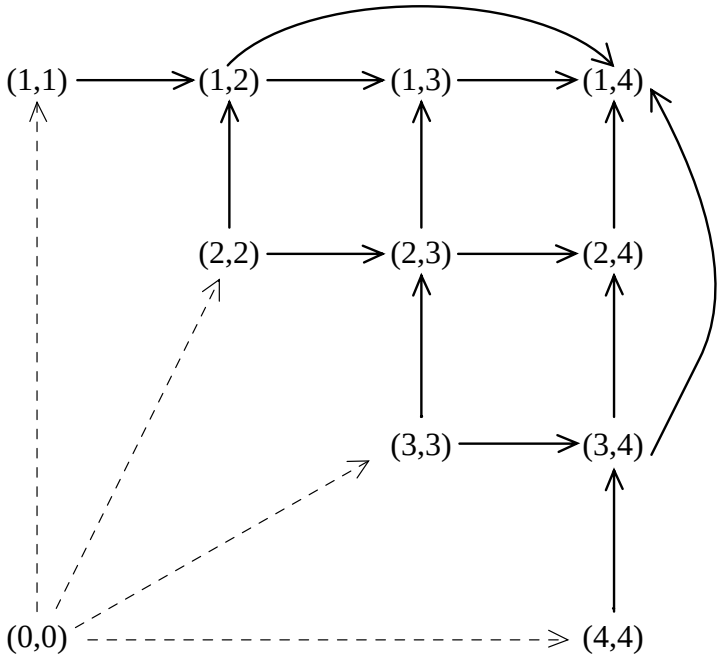

FIG. 1. *The weighted graph D_4.*

matching parentheses gives a tree decomposition of D_n that leads to efficient solutions of the MCOP.

Given an associative product with the level of each parenthesis known, for each parenthesis find its matching parenthesis by solving the all nearest smaller value (ANSV) problem [8, 9]: given weights $w_1, w_2, \ldots, w_n$, for each w find the indices, if they exist, of the nearest proceeding and succeeding weights both less than w. Let's call this pair of indices, if they exist, an ANSV *match*. That is, for each w the problem is to find the largest j where $1 \leq j < i$, and find the smallest k where $i < k \leq n$, so that $w_j < w_i$ and $w_k < w_i$, if such values exist. In D_n, (i, k) is a *critical node* if $[w_i, w_{k+1}]$ is an ANSV match.

By solving the ANSV problem we can compute all critical nodes of D_n. The bottom of Figure 2 depicts a list of matrix dimensions (called weights) and dashed lines representing four key ANSV matches. The four corresponding critical nodes are circled in D_n.

In our nomenclature, [8] shows that the following theorem holds.

THEOREM 2. *Computing all critical nodes costs $O(\lg n)$ time with $n/\lg n$ processors or in $O(\lg \lg n)$ time using $n/\lg \lg n$ processors on the common-CRCW PRAM.*

In addition, [16, 34] give the following theorem.

THEOREM 3. *Computing all critical nodes costs $O(\lg n)$ time with $n/\lg n$ processors on the EREW PRAM.*

Two critical nodes on the same diagonal are *compatible* if no vertices other than $(0, 0)$ can reach both of them by a unit path. Since a path of critical nodes represents a parenthesization, all critical nodes are compatible. Also, D_n has at most $n - 1$ critical nodes and there is at least one path from $(0, 0)$ to $(1, n)$ that includes all critical nodes [11].

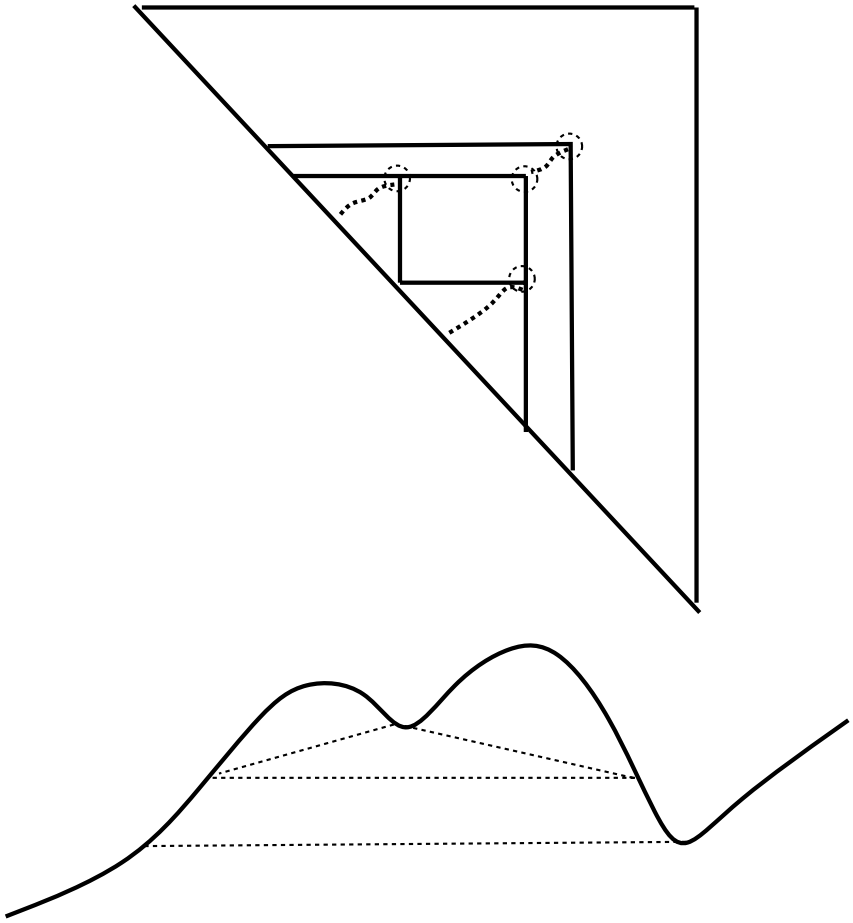

FIG. 2. *Two leaf subgraphs inside a band subgraph with critical nodes shown.*

2.2. Canonical subgraphs of D_n. In this subsection we investigate the interaction between subgraphs containing critical nodes.

All vertices and edges that can reach (i,t) by a unit path form the subgraph $D(i,t)$. Given $D(i,j)$ if the weight list $w_i,\ldots,w_{j+1}$ is monotonic, then $D(i,j)$ is monotonic. A *band canonical subgraph* $D^{(i,t)}_{(j,k)}$ is the subgraph containing the maximal unit edge-connected path of critical nodes beginning at critical node (j,k) and terminating at critical node (i,t) with the vertex set $\{(0,0)\}\cup(V[D(i,t)]-V[D(j+1,k-1)])$ and associated edges. A canonical subgraph of the form $D^{(i,t)}_{(j,j+1)}$ is a *leaf* canonical subgraph and is written $D^{(i,t)}$; it has the same nodes and edges as $D(i,t)$. The top of Figure 2 shows two leaf subgraphs nested inside of a band subgraph. Leaf and band subgraphs are the only two types of canonical subgraphs. Canonical subgraphs are easily distinguishable by the properties of their critical nodes shown in Theorem 2. From here on p denotes the path of critical nodes in band or leaf canonical subgraphs.

Given $D(i,u)$ with a monotone list of weights $w_i \le w_{i+1} \le \cdots \le w_{u+1}$, a shortest path from $(0,0)$ to (i,u) is the straight unit path $(0,0) \nearrow (i,i) \to (i,i+1) \to \cdots \to (i,u)$ that costs $w_i \sum_{j=i+1}^{u} w_j w_{j+1}$. On the other hand, if $D(i,t)$ has no

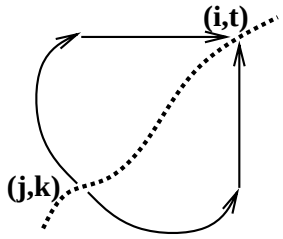

FIG. 3. *Two angular paths.*

critical nodes, then its associated weight list is monotonic. As in [28, 29, 11] let $\|w_i : w_k\| = \sum_{j=i}^{k-1} w_j w_{j+1}$, which is easily computable using differences of components of the parallel partial prefixes $\|w_1 : w_i\|$ for $2 \le i \le n+1$. This is useful since the unit path $(i,j) \to \cdots \to (i,k)$ costs $w_i\|w_{j+1} : w_{k+1}\| = w_i(\|w_1 : w_{k+1}\| - \|w_1 : w_{j+1}\|)$.

Suppose (j,k) and (i,t) are two critical nodes in a canonical graph such that from (j,k) we can reach (i,t) by a unit path, that is if $i \le j \le k \le t$, then the *angular* paths of (j,k) and (i,t) are, (see Figure 3)

$$(j,k) \Uparrow (i,k) \to \cdots \to (i,t) \text{ and } (j,k) \Longrightarrow (j,t) \uparrow \cdots \uparrow (i,t).$$

THEOREM 4 (see [11]). *In a canonical subgraph the shortest path between any two critical nodes that contains no other critical nodes is an angular path or edge.*

In addition, any shortest path not including critical nodes is a straight path of unit edges. Thus, any shortest path to a critical node that contains no other critical nodes is a straight path of unit edges [11].

Now a polylog-time algorithm for finding shortest paths to all critical nodes in $D^{(1,m)}$ graphs is given. This algorithm takes $O(\lg^2 m)$ time and uses $m^3/\lg m$ processors.

First compute the parallel partial prefixes $\|w_1 : w_i\|$ for $2 \le i \le m+1$. Find all critical nodes. Now, in constant time using m processors compute the costs of all of the unit paths to nodes in p. Next compute the cost of the $O(m^2)$ angular paths in constant time with m^2 processors. Finally, compute the shortest path to each node in p by treating every angular path as an edge and applying a parallel all-pairs shortest path algorithm.

2.3. Combining the canonical graphs for an efficient parallel algorithm. In this subsection we discuss a tree contraction algorithm that contracts the tree structure joining the canonical subgraphs to form a shortest path in D_n; see also [28, 29, 11].

In D_n a *canonical tree* joins all of the canonical subgraphs. A node in a canonical tree is critical node, say (i,j), and is written $\overline{(i,j)}$. Initially, for every leaf $D^{(i,j)}$ the critical node (i,j) is the tree leaf $\overline{(i,j)}$. Internal tree nodes are either isolated critical nodes or $\overline{(i,t)}$ and $\overline{(j,k)}$ in the band $D^{(i,t)}_{(j,k)}$. Tree edges are straight unit paths connecting tree nodes, and jumpers may reduce the cost of tree edges.

Given an instance of the MCOP with the weight list $l_1 = w_1, w_2, \ldots, w_{n+1}$, cyclically rotating it, getting l_2, and finding an optimal parenthesization for l_2 gives an optimal solution to the original instance of the MCOP with l_1, [28, 21]. So in the rest of this paper let w_1 denote the smallest weight in any weight list.

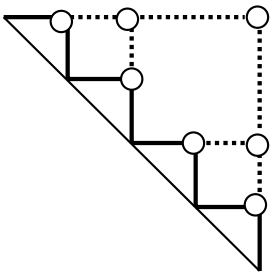

FIG. 4. *A tree of canonical graphs (the circles denote tree nodes).*

A result of Hu and Shing [28] leads directly to the next corollary.

COROLLARY 1 (Atomicity Corollary [11]). *Suppose a weight list* $w_1, \ldots, w_{n+1}$, *with the three smallest weights* w_1, w_{j+1}, *and* w_{k+1}, *is given such that* $1 < j < k-1$. *Then the critical nodes* $(1, j)$ *and* $(1, k)$ *are in a shortest path from* $(0, 0)$ *to* $(1, n)$ *in* D_n.

For this corollary to work it is central that if w_1, w_{j+1}, and w_{k+1} are the three smallest weights; then $j+1 > 2$ and $k > j+1$. This generally means that Corollary 1 cannot be applied in a canonical subgraph. For instance, take the leaf $D^{(1,m)}$ where we can assume $w_1 < w_{m+1} < w_i$ for $1 < i < m+1$. However, Corollary 1 can be used to break D_n into a tree of canonical graphs; see Figure 4.

If D_n has fewer than $n-1$ critical nodes, then D_n may have disconnected canonical trees and monotone subgraphs. But there is at least one path joining these subtrees, and at the same time we can discount the monotone subgraphs. There are several relationships canonical graphs may have; these follow directly from the relationships of critical nodes that are tree nodes.

The tree edge $\overline{(i,j)} \to \cdots \to \overline{(i,v)}$ along row i initially costs $w_i \| w_{j+1} : w_{v+1} \|$ where $w_i < w_{v+1} < w_{j+1}$ are the three smallest weights in $D(i, v)$. Let $\overline{p}$ denote a shortest path of critical nodes in $D(j+1, v)$ from $(j+1, v)$ back to $(0, 0)$. *Edge minimizing* the unit path along the ith row to the critical node $\overline{(i,v)}$ is done as follows. First let $L = w_i \| w_{i+1} : w_{v+1} \|$ and $W((i,k) \Longrightarrow (i,u)) = sp(k+1, u) + f(i, k, u)$, then compute

$$A[i,v] = \min_{\forall (k+1,u) \in V[\overline{p}]} \{L,\ w_i \| w_{i+1} : w_{v+1} \| - w_i \| w_{k+1} : w_{u+1} \| + W((i,k) \Longrightarrow (i,u))\}.$$

Since the three smallest weights in $D(i, v)$ are $w_i < w_{v+1} < w_{j+1}$, by Corollary 1 the cheapest cost to critical node (i, v) is now in $A[i, v]$.

THEOREM 5 (see [11]). *When edge minimizing a tree edge* $\overline{(i,j)} \to \cdots \to \overline{(i,v)}$ *in a canonical subgraph we only have to consider jumpers* $(i,k) \Longrightarrow (i,t)$ *such that* $(k+1, t) \in V[\overline{p}]$.

The critical node (i, u) in the band $D^{(i,u)}_{(j,k)}$ is the *front* critical node. In general, Theorem 5 holds when $\overline{p}$ is a shortest path through a band from the front critical node back to $(0, 0)$. Also, Theorem 5 holds for leaves in the canonical tree that, after raking, have become conglomerates of other leaves, bands, and isolated critical nodes. Here, jumpers derived from critical nodes in different subtrees are independent so we can minimize tree edges with them simultaneously.

2.4. Contracting a canonical tree. In this subsection we show how to contract a canonical tree efficiently in parallel.

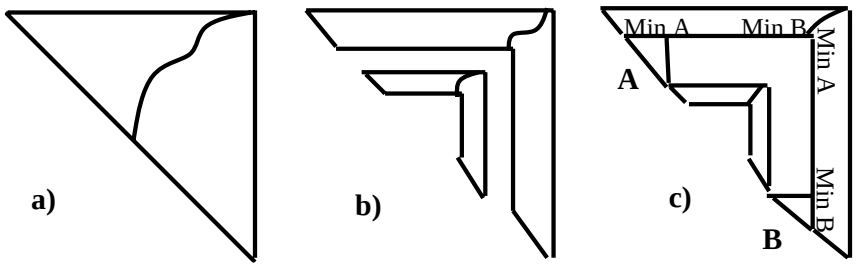

FIG. 5. *Bottlenecks* 1, 2, *and* 3 *for the* $n^3/\lg n$*-processor algorithm.*

Assume that all critical nodes (i, j) in tree leaves have the minimum cost back to $(0, 0)$ stored in $sp(i, j)$. Compute these values using an all-pairs shortest path parallel algorithm. There is an ordering of the leaves that prevents the simultaneous raking of two adjacent leaves. Given two neighboring leaves $D^{(i,j)}$ and $D^{(j+1,k)}$ with the three tree leaves $\overline{(i,j)}, \overline{(j+1,k)}$, and $\overline{(i,k)}$, assume $w_i < w_{k+1} < w_{j+1}$. Then leaf $\overline{(j+1,k)}$ must be raked, since $\overline{(i,j)}$ is in a shortest path from $(0, 0)$ to $\overline{(i,k)}$. Use the Euler tour technique [33] when the raking order is arbitrary.

Given two nested bands, assume $D^{(i,v)}_{(j,u)}$ is nested around $D^{(k,t)}_{(r,s)}$, that is, $j \leq k < t \leq u$. Without loss of generality, suppose any trees between $D^{(i,v)}_{(j,u)}$ and $D^{(k,t)}_{(r,s)}$ have been contracted. Then joining these bands costs $O(\lg^2 n)$ time with $n^3/\lg n$ processors. To achieve this, first, edge minimize all straight unit paths in $D^{(i,v)}_{(j,u)}$ with the shortest paths from critical nodes that are between $D^{(i,v)}_{(j,u)}$ and $D^{(k,t)}_{(r,s)}$ back to $(0, 0)$. Next, take all angular paths connecting these two bands and apply a parallel all-pairs shortest path algorithm merging the bands. Merging the bands $D^{(i,v)}_{(j,u)}$ and $D^{(j,u)}_{(r,s)}$ gives a shortest path from the front critical node (i, v) back to $(0, 0)$ through $D^{(i,v)}_{(r,s)}$. Incorporating this band merging with the tree contraction completes the polylog-time and $n^3/\lg n$-processor MCOP algorithm.

3. The structure of shortest paths in canonical subgraphs. In this section we give the $n^3/\lg n$-processor bottlenecks of the algorithm in section 2. In addition, we give a metric for measuring the relative contributions of angular paths to shortest paths and some theorems about shortest paths forward from critical nodes in canonical graphs. From this section on, we only address rows in the canonical graphs; the arguments for columns follow immediately.

3.1. The $n^3/\lg n$ processor bottlenecks. In this subsection we give the $n^3/\lg n$-processor bottlenecks of the algorithm sketched in section 2.

Three parts of the algorithm in section 2 use $n^3/\lg n$ processors. All other parts of this algorithm use a total of $n/\lg n$ processors and take $O(\lg n)$ time. The three bottlenecks are: finding shortest paths from all critical nodes in leaf graphs back to $(0, 0)$ (see Figure 5a); merging two bands (see Figure 5b); and merging two bands that have contracted canonical trees between them (see Figure 5c).

In Figure 5c, contracted trees **A** and **B** are used to edge minimize the unit paths marked by "**Min-A**" and "**Min-B**." Edge minimizing the unit paths in the outer band with the contracted trees gives an instance of the second bottleneck; see Figure 5b. Edge minimizing the unit paths in the outer band with the contracted trees costs $O(\lg n)$ time with $n^2/\lg n$ processors. In section 5 we will see how to perform such edge minimization in $O(\lg^2 n)$ time with $n/\lg n$ processors.

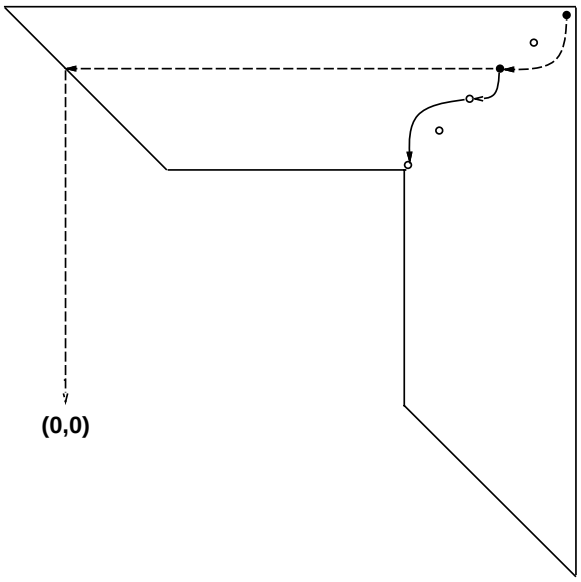

FIG. 6. *The dashed path is $\overline{p}$ and the two black nodes are supercritical nodes.*

Finding shortest paths back to $(0,0)$ from all critical nodes in a leaf graph, as in Figure 5a, will be done by breaking a leaf graph into nested bands. Therefore, finding efficient parallel methods of band merging and edge minimization will give an efficient parallel algorithm for the MCOP. So, the focus of the rest of the paper is finding efficient ways to get shortest paths from all critical nodes back to $(0,0)$ by edge minimization in leaf subgraphs partitioned as bands.

Given the band $D^{(i,v)}_{(j,t)}$, let $\overline{p}^{(i,v)}_{(j,t)}$ denote a shortest path from (i,v) back to $(0,0)$ totally contained in $D^{(i,v)}_{(j,t)}$; see Figure 6. When there is no ambiguity, $\overline{p}^{(i,v)}_{(j,t)}$ will be written as $\overline{p}$. Given a band $D^{(i,v)}_{(j,t)}$, whenever $\overline{p} = \overline{p}^{(i,v)}_{(j,t)}$ starts from the front critical node of the band it is in, the nodes $V[\overline{p}]$ are *super*critical nodes. Considering the minimal path back from the front critical node in Figure 6, we can see that only the two black critical nodes are supercritical nodes. Supercritical nodes of any band are all critical nodes in some minimal path back form the front critical node in the band back to $(0,0)$. Any two supercritical nodes in $\overline{p}$ are connected by supercritical nodes interspersed with the angular paths shown by Theorem 4.

When a canonical tree of D_n is totally contracted, then the final path $\overline{p}$ from $(1,n)$ back to $(0,0)$ gives the optimal order to multiply the set of n matrices. In addition, the cost of $\overline{p}$ is the minimal cost of multiplying the given chain of n matrices.

3.2. A metric for finding minimal cost angular paths. In this subsection we give a metric for finding minimal cost angular paths by using the equivalence of angular paths and jumpers along unit paths. This equivalence comes directly from Theorem 1.

When merging two bands, a unit path has at most one jumper minimizing it, since all the relevant jumpers are nested. These jumpers get their *sp* values from supercritical nodes of the inner band.

The influence of an angular edge can be taken as a jumper in a straight unit path by Theorem 1. In the case of Figure 5c, notice that any unit edge minimization using

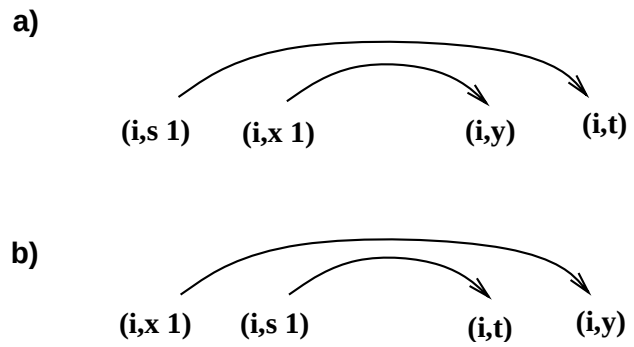

FIG. 7. *Two different nestings of two jumpers.*

sp values from **A** or **B** is independent of unit edge minimization using *sp* values from the inner band. Therefore, measuring the potential contribution of angular edges to shortest paths is done by measuring the potential contribution of jumpers to shortest paths along straight unit paths.

Take a node $(s,t) \in V[\overline{p}]$, where $sp(s,t)$ is the cost of a shortest path back to $(0,0)$ with respect to a band; then in row i we want to compare the cost of the jumper $(i,s-1) \Longrightarrow (i,t)$ with the cost of the associated unit path $(i,s-1) \rightarrow \cdots \rightarrow (i,t)$.

Given $(s,t) \in V[\overline{p}]$, take row i above p with the jumper $(i,s-1) \Longrightarrow (i,t)$; define

$$\Delta_i(s,t) = w_i \| w_s : w_{t+1} \| - [\ sp(s,t) + f(i,s-1,t)\ ].$$

If $\Delta_i(s,t) > 0$, then the jumper $(i,s-1) \Longrightarrow (i,t)$ provides a *cheaper* path along row i than the unit path $(i,s-1) \rightarrow \cdots \rightarrow (i,t)$. In particular, take both $(s,t) \in V[\overline{p}]$ and $(x,y) \in V[\overline{p}]$, and the two possible jumper nestings of Figure 7.

Considering the nesting of the jumpers in Figure 7a, if $\Delta_i(s,t) > \Delta_i(x,y) > 0$, then the jumper $(i,s-1) \Longrightarrow (i,t)$ "saves more" than the jumper $(i,x-1) \Longrightarrow (i,y)$ along row i because $(i,s-1) \Longrightarrow (i,t)$ doesn't have to deal with the paths $(i,s-1) \rightarrow \cdots \rightarrow (i,x-1)$ and $(i,y) \rightarrow \cdots \rightarrow (i,t)$ and $\Delta_i(s,t) > \Delta_i(x,y) > 0$. Similarly, for the nesting of the jumpers in Figure 7b, if $\Delta_i(x,y) > \Delta_i(s,t) > 0$, then the jumper $(i,x-1) \Longrightarrow (i,y)$ "saves more" than the jumper $(i,s-1) \Longrightarrow (i,t)$ along row i. Notice that considering the jumpers in Figure 7**b**, if $\Delta_i(s,t) > \Delta_i(x,y) > 0$, then the jumper $(i,s-1) \Longrightarrow (i,t)$ may or may not make row i cheaper than the jumper $(i,x-1) \Longrightarrow (i,y)$. On the other hand, in Figure 7b, if $(i,s-1) \Longrightarrow (i,t)$ makes row i cheaper than the jumper $(i,x-1) \Longrightarrow (i,y)$ does, then $\Delta_i(s,t) > \Delta_i(x,y) > 0$.

In $D^{(1,m)}$, if $(s,t) \in V[p]$, then above the path of critical nodes p the function $\Delta_i(s,t)$ is defined for all rows i such that $s > i \geq 1$.

Notice that edge minimizing a unit path is only half the game, for we also must consider the shortest paths forward.

Figure 8 is for the next theorem; also see [28].

THEOREM 6. *Let $D^{(i,v)}_{(r,s)}$ be a leaf graph and let (j,u) and (k,t) be any two critical nodes in $D^{(i,v)}_{(r,s)}$ such that there is a unit path from (k,t) to (j,u). Then a shortest path from (j,u) to (i,v) costs less than a shortest path from (k,t) to (i,v).*

A proof follows inductively by shadowing trivial angular paths without any jumpers, then showing that any shortest path from (k,t) forward to (i,v) can be

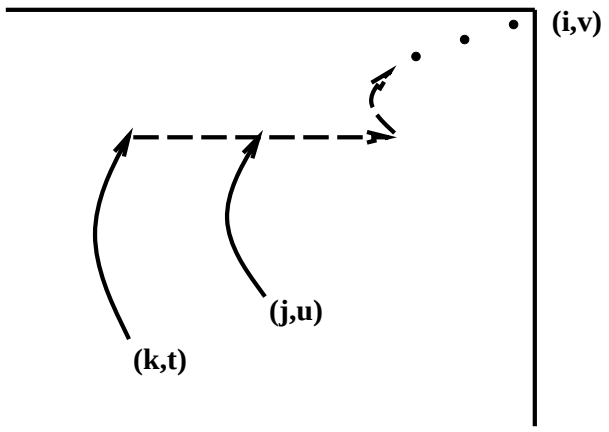

FIG. 8. *(j,u) shadowing (k,t)'s shortest path forward.*

"shadowed" by a shorter path from (j,u) forward to (i,v). While in the process we have taken into account the f values. Naturally, Theorem 6 also holds for shortest paths forward in leaf graphs.

The next theorem will also be useful.

THEOREM 7. *Let $(i,s-1) \Longrightarrow (i,t)$ be a shortest path forward. Suppose that the next band merging the value of $sp(s,t)$ decreases due to an edge minimization of row s or a lower row. Then $(i,s-1) \Longrightarrow (i,t)$ is still in a shortest path forward.*

A proof of this theorem follows directly from the basic notions of shortest paths. In particular, if the shortest path forward from the critical node (s,t) goes through $(s,t) \Uparrow (i,t)$, then making the path to (s,t) shorter will not affect the jumper $(s,t) \Uparrow (i,t)$ or the path from (i,t) to the front node of the present band.

4. A polylog-time and $n^2/\lg n$-processor MCOP algorithm. In this section we give an $O(\lg^2 n)$-time and $n^2/\lg n$-processor algorithm for the MCOP. This algorithm works by using a key induction invariant that allows recursive doubling techniques to break through the bottlenecks given in the last section.

The basic idea of the algorithm is as follows. All critical nodes know their shortest paths to the front of the present bands they are in. Only supercritical nodes have their shortest paths back to $(0,0)$ through their present bands. When merging two bands, by Theorem 5, we only have to consider shortest paths from supercritical nodes in the inner band to any critical node in the outer band. Therefore, all critical nodes must maintain a shortest path to the front of the band they are in. At the same time, all supercritical nodes must maintain a shortest path backwards to $(0,0)$ through the band they are in. Much of this section supplies the details and correctness of this algorithm.

Each critical node in D_n has two pointers called *front-ptr* and *back-ptr* that represent angular edges. *Back-ptr*s are only used by supercritical nodes. With each *front-ptr* there are two values, *cost-of-front-ptr* and *cost-to-front*; and with each *back-ptr* there is one value, *cost-to-back*. *Cost-of-front-ptr* is the cost of the angular edge going forward to the front critical node in the present band, where the value of *cost-to-front* is the entire cost to the front critical node of the present band containing *front-ptr*. Similarly, the value of *cost-to-back* is the cost from the supercritical node at hand back to $(0,0)$ through the present band. Initially, these pointers connect critical nodes and tree edges in the canonical tree.

1. All critical nodes in both bands have their *front-ptr*s in trees of shortest paths that eventually go to supercritical nodes. The supercritical nodes have their *front-ptr*s form a linked list that goes to the front (super)critical nodes of their respective bands.

2. In the two bands both shortest paths back to $(0,0)$ of supercritical nodes are known. These shortest paths of supercritical nodes are made of linked lists of *back-ptrs* from the front (super)critical nodes of each band back through their respective bands to $(0,0)$.

FIG. 9. *Inductive invariant for band merging.*

Let $D^{(i,v)}_{(j,t)}$ and $D^{(j,t)}_{(k,s)}$ be nested bands with paths of critical nodes labeled $p^{(i,v)}_{(j,t)}$ and $p^{(j,t)}_{(k,s)}$, respectively. Note (i,v) and (j,t) are the front critical nodes of these bands. As before, $\overline{p}^{(i,v)}_{(j,t)}$ and $\overline{p}^{(j,t)}_{(k,s)}$ are shortest paths from the front critical nodes back to $(0,0)$ through the bands $D^{(i,v)}_{(j,t)}$ and $D^{(j,t)}_{(k,s)}$, respectively. Let $\overline{p}^{(i,v)}_{(j,t)}$ and $\overline{p}^{(j,t)}_{(k,s)}$ be made by two linked lists of *back-ptrs* along supercritical nodes back to $(0,0)$ in their bands. It turns out that the shortest paths forward form all critical nodes in each of these bands and are made up of linked lists of trees of *front-ptr*s. We will see that this linked list of trees of *front-ptr*s is interconnected through the supercritical nodes as in Figure 10.

Figure 9 gives the induction invariant for merging two bands.

Figure 10 gives an example of the data structures for maintaining the inductive invariant. In this figure only critical nodes are shown and the supercritical nodes are black. The solid arrows are *front-ptr*s and the dashed arrows are *back-ptr*s.

Now, say (s,t) is a critical node but not a supercritical node, that is $(s,t) \in V[p]$ and $(s,t) \notin V[\overline{p}]$. There is a unique angular edge $(x,y) \Uparrow (r,y) \rightarrow \cdots \rightarrow (r,u)$ in $\overline{p}$ that "goes around" (s,t); see Figure 11. If we consider all rows above p in a given canonical graph, then $w_i < w_r$ implies that row i is "above" row r as in Figure 11. From here on we focus on finding shortest paths above the path p of critical nodes. The symmetric case of shortest paths below the path p of critical nodes follows.

Once we edge minimize all unit paths in $D^{(i,v)}_{(j,k)}$ with jumpers that get their *sp* values from supercritical nodes in $D^{(j,k)}_{(s,t)}$, then we can find the shortest path from (i,v) back to $(0,0)$ through $D^{(i,v)}_{(s,t)}$. First, take one processor at each critical node in $D^{(i,v)}_{(j,k)}$ that sums the cost of the path back to $(0,0)$, possibly through an edge-minimized unit path with the cost of its shortest path forward. Next, find the minimum of all of these sums, giving the shortest path from (i,v) back to $(0,0)$ through $D^{(j,k)}_{(s,t)}$.

The basic intuition for the next lemma is that, if the shorter of two nested jumpers edge minimizes a unit path r, then any unit path above r with both of these jumpers is not minimized by the longer jumper; see Figure 12. For the next lemma, assume there is a unit path of critical nodes from (x,y) to (s,t) to (r,u) as in Figure 11.

LEMMA 1. *Let (s,t) be a critical node between the* super*critical node (x,y) and the critical node (r,u) and suppose that $i < r < s < x$ and row i is above row r. That is, $w_i < w_r$, where rows i and r are above p. Then*

$$\textbf{if } \Delta_r(x,y) \geq \Delta_r(s,t), \textbf{ then } \Delta_i(x,y) \geq \Delta_i(s,t).$$

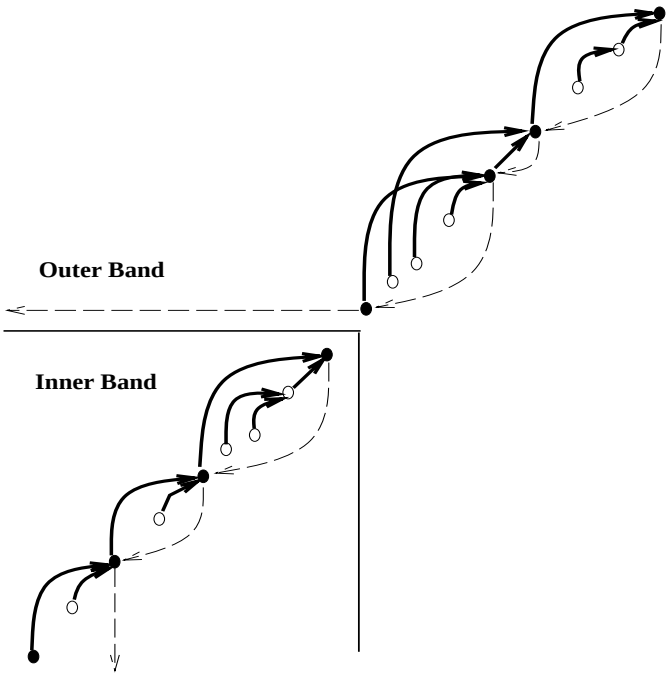

FIG. 10. *Solid arrows: forward linked lists of trees; dashed arrows: backward linked lists* $\overline{p}$.

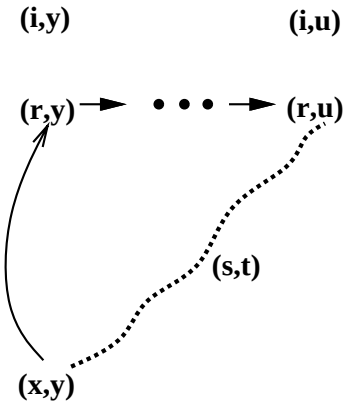

FIG. 11. $(s,t) \notin V[\overline{p}]$ *and the angular edge* $(x,y) \Uparrow (r,y) \rightarrow \cdots \rightarrow (r,u)$.

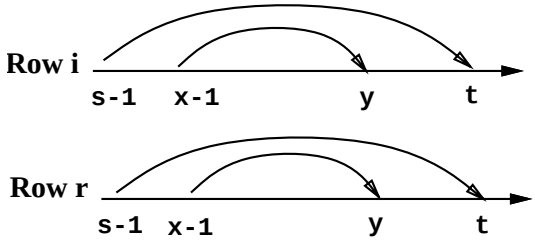

FIG. 12. *Two jumpers in different rows.*

Proof. Suppose $\Delta_r(x,y) \geq \Delta_r(s,t)$. This means

$$w_r\|w_x : w_{y+1}\| - [sp(x,y) + f(r,x-1,y)] \geq w_r\|w_s : w_{t+1}\| - [sp(s,t) + f(r,s-1,t)].$$

Using some algebra we obtain the following (where $\|w_i : w_i\| = 0$):

$$w_r[\ \|w_s : w_x\| + \|w_{y+1} : w_{t+1}\|\ ] < sp(s,t) - sp(x,y) + w_r(w_s w_{t+1} - w_x w_{y+1}).$$

Moreover, $sp(s,t) - sp(x,y)$ is always positive because $(r,x-1) \Longrightarrow (r,y)$ is nested inside of $(r,s-1) \Longrightarrow (r,t)$ and $f(r,s-1,t) < f(r,x-1,y)$. Therefore, if $sp(x,y) > sp(s,t)$, then a shortest path $\overline{p}$ would go through (s,t) to (r,u) and *not* over (s,t). In particular, if $sp(x,y) > sp(s,t)$, then since $f(r,x-1,t) > f(r,s-1,t)$, it must be the case that $sp(x,y) + f(r,x-1,t) > sp(s,t) + f(r,s-1,t)$. Therefore, row r would have been edge minimized by jumper $(r,s-1) \Longrightarrow (r,t)$ and *not* by $(r,x-1) \Longrightarrow (r,y)$; see Figure 12.

In addition, $w_s w_{t+1} - w_x w_{y+1} < 0$, since both (x,y) and (s,t) are critical nodes where $s \leq x < y \leq t$. So it must be that $w_x w_{y+1} - w_s w_{t+1} > 0$. Therefore, since

$$w_r[\ \|w_s : w_x\| + \|w_{y+1} : w_{t+1}\| + w_x w_{y+1} - w_s w_{t+1}\ ] < sp(s,t) - sp(x,y)$$

holds, and because $w_i < w_r$ and the term $sp(s,t) - sp(x,y)$ is independent of i and r, then $\Delta_i(x,y) \geq \Delta_i(s,t)$ follows. □

The next theorem follows from Lemma 1.

THEOREM 8. *Let (s,t) be a critical node between the* super*critical node (x,y) and the critical node (r,u). Suppose $i < r < s < x$ and row i is above row r, that is, $w_i < w_r$, where rows i and r are above p. Then*

if $(r,x-1) \Longrightarrow (r,y)$ makes row r cheaper than $(r,s-1) \Longrightarrow (r,t)$ does,
then $(i,x-1) \Longrightarrow (i,y)$ makes row i cheaper than $(i,s-1) \Longrightarrow (i,t)$ does.

A proof follows from Lemma 1 and by the fact that the rows

$$(i,s-1) \rightarrow \cdots \rightarrow (i,x-1) \text{ and } (i,y) \rightarrow \cdots \rightarrow (i,t)$$

are cheaper than the rows

$$(r,s-1) \rightarrow \cdots \rightarrow (r,x-1) \text{ and } (r,y) \rightarrow \cdots \rightarrow (r,t),$$

and the change in f values between $(r,x-1) \Longrightarrow (r,y)$ and $(i,x-1) \Longrightarrow (i,y)$ is greater than the change of f values between $(r,s-1) \Longrightarrow (r,t)$ and $(i,s-1) \Longrightarrow (i,t)$. That is,

$$f(r,x-1,y) - f(i,x-1,y) > f(r,s-1,t) - f(i,s-1,t),$$

since w_x and w_{y+1} are both bigger than w_s and w_{t+1}. In addition, $w_r > w_i$; therefore

$$(w_r - w_i)[w_x w_{y+1} - w_s w_{t+1}] > 0.$$

Consider two nested bands with paths of critical nodes p_i for the inner band and p_o for the outer band, where $\overline{p_i}$ and $\overline{p_o}$ are shortest paths from the front critical nodes back to $(0,0)$ in each of these bands. Now, suppose (s,t) is between (x,y) and (r,u) and $(s,t) \in V[\overline{p_i}]$. If $(x,y) \in V[\overline{p_i}]$ and $(r,u) \in V[p_o]$, then Lemma 1 and Theorem 8

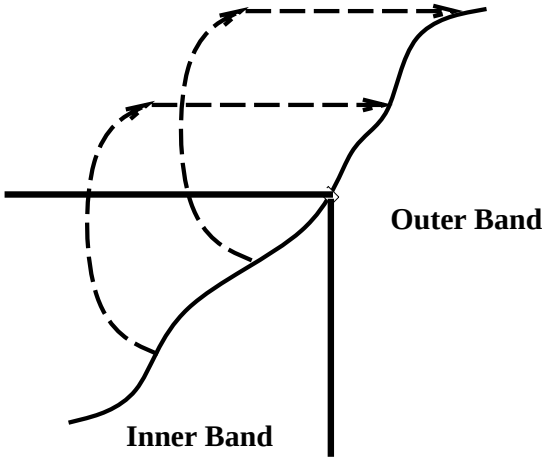

FIG. 13. *Conflicting angular paths* between *two bands being merged.*

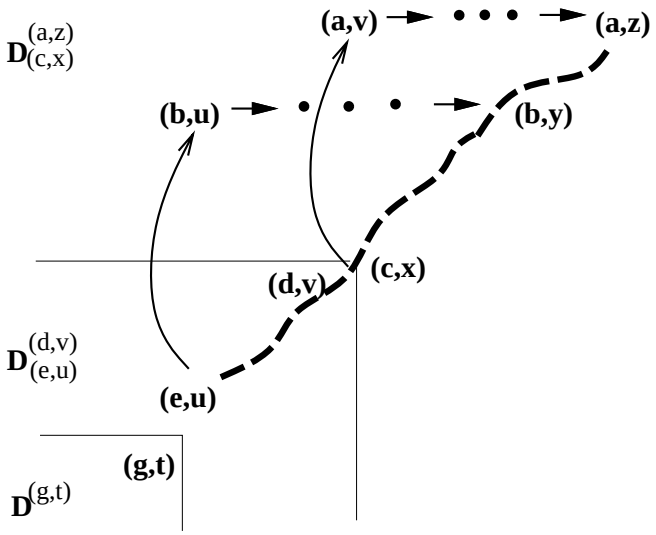

FIG. 14. *The bands* $D^{(a,z)}_{(c,x)}$, $D^{(d,v)}_{(e,u)}$ *and the leaf* $D^{(g,t)}$.

also hold. This is because $sp(s,t) - sp(x,y)$ is positive by an argument similar to that in the proof of Lemma 1.

Two angular edges above p, say $(x,y) \Uparrow (r,y) \to \cdots \to (r,u)$ and $(i,j) \Uparrow (s,j) \to \cdots \to (s,t)$, are *compatible* if they don't cross each other. Compatibility also holds for angular paths below p. Theorem 9 shows that *when merging* two bands and computing shortest paths forward, only compatible angular edges need to be considered. Figure 13 shows two conflicting angular paths.

Take the canonical graphs $D^{(a,z)}_{(c,x)}$, $D^{(d,v)}_{(e,u)}$ and $D^{(g,t)}$, where $D^{(g,t)}$ is nested inside of $D^{(d,v)}_{(e,u)}$ which is, in turn, inside of $D^{(a,z)}_{(c,x)}$; see Figure 14. Furthermore, assume that $D^{(a,z)}_{(c,x)}$ and $D^{(d,v)}_{(e,u)}$ are to be merged together. Then, in the next recursive doubling step, the new band $D^{(a,z)}_{(e,u)}$ will be merged with the leaf $D^{(g,t)}$. We can assume $D^{(g,t)}$ is a leaf or a band.

The next theorem assumes we have found a shortest path from supercritical nodes in $D^{(d,v)}_{(e,u)}$, through critical nodes in the outer band $D^{(a,z)}_{(c,x)}$; see Figure 14. We know $(d,v) \in V[\overline{p}^{(d,v)}_{(e,u)}]$ and, without loss of generality, we can assume $(e,u) \Uparrow (d,u) \rightarrow \cdots \rightarrow (d,v)$ is $\overline{p}^{(d,v)}_{(e,u)}$. Now, suppose the angular edge $(e,u) \Uparrow (b,u) \rightarrow \cdots \rightarrow (b,y)$ is in $\overline{p}^{(a,z)}_{(e,u)}$, where $\overline{p}^{(a,z)}_{(e,u)}$ is the minimal path from (a,z) back to $(0,0)$ through $D^{(a,z)}_{(e,u)}$.

THEOREM 9 (Main Theorem). *In merging two nested bands computing shortest paths forward from supercritical nodes of the inner band, we only need to consider compatibly nested angular edges.*

Proof. The proof is by contradiction. Suppose $(e,u) \Uparrow (b,u) \rightarrow \cdots \rightarrow (b,y)$ is in $\overline{p}^{(a,z)}_{(e,u)}$, that is, the angular edge $(e,u) \Uparrow (b,u) \rightarrow \cdots \rightarrow (b,y)$ is in a shortest path from (a,z) back to $(0,0)$ through $D^{(a,z)}_{(e,u)}$; see Figure 14. Suppose (d,v) is in the band $D^{(d,v)}_{(e,u)}$. Therefore (d,v) is between (e,u) and (a,z) in $D^{(a,z)}_{(e,u)}$. Now, when merging $D^{(g,t)}$ with $D^{(a,z)}_{(e,u)}$ we will show that a shortest path forward to (a,z) that goes through (d,v) must go through a critical node in row b or a critical node in a row below b.

Now, for the sake of a contradiction, assume otherwise. Suppose after merging $D^{(a,z)}_{(c,x)}$ with $D^{(d,v)}_{(e,u)}$ there is some shortest path from $(0,0)$ through (d,v) to (a,z). This shortest path travels through an angular path connecting the bands $D^{(a,z)}_{(c,x)}$ and $D^{(d,v)}_{(e,u)}$ and this angular path is conflicting with the angular path $(e,u) \Uparrow (b,u) \rightarrow \cdots \rightarrow (b,y)$. Say, without loss of generality, this conflicting angular path is $(d,v) \Uparrow (a,v) \rightarrow \cdots \rightarrow (a,z)$; see Figure 14. That is, we have conflicting angular paths since the shortest path from (d,v) forward goes through an angular path that terminates above row b, and the shortest path forward from (e,u) goes through an angular path that terminates in row b. But notice *in* $D^{(a,z)}_{(e,u)}$ that the shortest path from (a,z) back to $(0,0)$ still goes through the angular edge $(e,u) \Uparrow (b,u) \rightarrow \cdots \rightarrow (b,y)$.

In $D^{(a,z)}_{(e,u)}$ the angular edge $(d,v) \Uparrow (a,v) \rightarrow \cdots \rightarrow (a,z)$ can't be the shortest path forward from (d,v).

By Theorem 1, the shortest path to (b,y) through the angular edge

$$(e,u) \Uparrow (b,u) \rightarrow \cdots \rightarrow (b,y)$$

is equivalent to the path

$$(b,b) \rightarrow \cdots \rightarrow (b,e-1) \Longrightarrow (b,u) \rightarrow \cdots \rightarrow (b,y).$$

Moreover, since $\overline{p}^{(a,z)}_{(e,u)}$ goes through $(e,u) \Uparrow (b,u) \rightarrow \cdots \rightarrow (b,y)$, the jumper $(b,e-1) \Longrightarrow (b,u)$ edge minimizes row b. Thus, the jumper $(b,d-1) \Longrightarrow (b,v)$ saves at most as much as $(b,e-1) \Longrightarrow (b,u)$, and $(b,d-1) \Longrightarrow (b,v)$ is nested around $(b,e-1) \Longrightarrow (b,u)$. Thus,

$$\Delta_b(e,u) \geq \Delta_b(d,v).$$

Also, by Theorem 1, the shortest path from (d,v) to (a,z) that goes through the angular edge

$$(d,v) \Uparrow (a,v) \rightarrow \cdots \rightarrow (a,z)$$

is equivalent to the path

$$(a,a) \rightarrow \cdots \rightarrow (a,d-1) \Longrightarrow (a,v) \rightarrow \cdots \rightarrow (a,z).$$

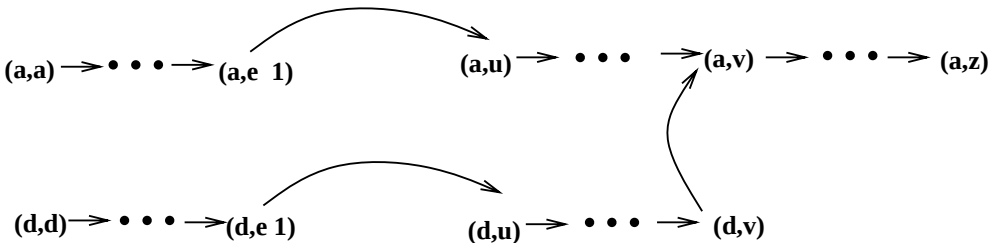

FIG. 15. *The two paths $\mathcal{A}$ and $\mathcal{D}$.*

But, consider the path

$$(a,a) \to \cdots \to (a,e-1) \Longrightarrow (a,u) \to \cdots \to (a,z),$$

and we know that the jumper $(a,e-1) \Longrightarrow (a,u)$ is nested inside of $(a,d-1) \Longrightarrow (a,v)$. In this case, it is possible that $d = e$ or $u = v$, but not both, since (d,v) is between (e,u) and (b,y) and $a < b$ and $w_a < w_b$, where row a is above row b and they are both above p. Furthermore, since the appropriate Δ values are defined, the following holds by Lemma 1:

$$\textbf{if } \Delta_b(e,u) \geq \Delta_b(d,v), \textbf{ then } \Delta_a(e,u) \geq \Delta_a(d,v).$$

Therefore,

$$\Delta_a(e,u) \geq \Delta_a(d,v),$$

which means the jumper $(a,e-1) \Longrightarrow (a,u)$ saves at least as much as the jumper $(a,d-1) \Longrightarrow (a,v)$ in a path to (a,z).

By Theorem 8, since $(b,e-1) \Longrightarrow (b,u)$ edge minimizes row b, and $\Delta_a(e,u) \geq \Delta_a(d,v)$, the jumper $(a,e-1) \Longrightarrow (a,u)$ saves more in row a than $(a,d-1) \Longrightarrow (a,v)$.

Now, take the two paths

$$\mathcal{A} = (a,a) \to \cdots \to (a,e-1) \Longrightarrow (a,u) \to \cdots \to (a,v),$$
$$\mathcal{D} = (d,d) \to \cdots \to (d,e-1) \Longrightarrow (d,u) \to \cdots \to (d,v) \Uparrow (a,v)$$

as in Figure 15.

$\mathcal{A}$ is cheaper than $\mathcal{D}$ going from (a,z) back to $(0,0)$ in $D^{(a,z)}_{(e,u)}$ by Theorem 8. Now, if $(d,v) \Uparrow (a,v)$ is in a shortest path forward from (d,v), then the shortest path forward from (e,u) must be through the angular path $(e,u) \Uparrow (a,u) \to \cdots \to (a,z)$ and not the angular path $(e,u) \Uparrow (b,u) \to \cdots \to (b,y)$, which is a contradiction. This follows by applying Theorem 8 to the jumpers $(b,d-1) \Longrightarrow (b,v)$ and $(b,e-1) \Longrightarrow (b,u)$ in row b and then up to row a, since (b,y) is between (d,v) and (a,z).

Now, suppose $D^{(g,t)}$ is merged with the outer band $D^{(a,z)}_{(e,u)}$. Then, none of the angular paths connecting supercritical nodes in $D^{(g,t)}$ with paths forward $D^{(a,z)}_{(e,u)}$ change. This case is a straightforward application of the proof above and Theorem 7. ∎

It is important to note that Theorem 9 shows that only angular paths starting from supercritical nodes in the same path back to $(0,0)$ are compatible. Theorem 9 doesn't say that all angular paths are always compatible.

Suppose that there is some angular path from a supercritical node in the inner band, say (s,t), to the outer band that is in a shortest path from the front node

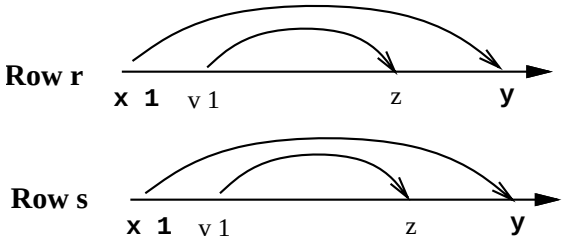

FIG. 16. *Two jumpers in different rows.*

of the outer band back to $(0,0)$. Then all supercritical nodes from (s,t) back to $(0,0)$ have their shortest paths forward through the angular path starting at (s,t). On the other hand, by Theorem 9 all supercritical nodes after (s,t) up to the front supercritical node of the inner band have their shortest paths through nested angular paths connecting the inner and outer bands. In fact, we can inductively apply this argument together with Theorem 6 giving the following corollary.

COROLLARY 2. *Consider the nested angular paths connecting two bands that are shortest paths forward from the different supercritical nodes of the inner band. Then, listing the path containing the outermost such angular path to the path containing the innermost such angular path gives more and more costly paths forward.*

The next lemma assumes we are merging two nested bands to find a shortest path from the front critical node of the outer band back to $(0,0)$.

LEMMA 2. *Let (s,t) be a critical node and let the ith and rth rows above p be such that $i < r < s$ and $w_i < w_r$. Then $\Delta_i(s,t) < \Delta_r(s,t)$.*

Proof. The function $\Delta_i(s,t)$ measures the potential minimizing effect of $(i, s-1) \Longrightarrow (i,t)$ on the path $(i,i) \rightarrow \cdots \rightarrow (i,u)$, where $(i,u) \in V[p]$ and $i < s < t \leq u$. The cost of the jumper $(i, s-1) \Longrightarrow (i,t)$ is $sp(s,t) + f(i, s-1, t)$. Therefore, the difference $\Delta_{i+1}(s,t) - \Delta_i(s,t)$ is

$$(w_{i+1} - w_i)[\ \|w_s : w_{t+1}\| - w_s w_{t+1}\ ],$$

where $w_{i+1} > w_i$. Since the expression $\|w_s : w_{t+1}\| - w_s w_{t+1}$ is independent of the difference of weights w_i and w_{i+1} and $\|w_s : w_{t+1}\| - w_s w_{t+1} > 0$, because $(s,t) \in V[p]$. Also, when $s = t-1$ we have

$$\|w_s : w_{t+1}\| = w_s w_{s+1} + w_{s+1} w_{t+1}.$$

In addition, since $(s,t) \in V[p]$, it must be that $\max\{w_s, w_{t+1}\} < w_u$, for $s < u \leq t$. Thus $\max\{w_s, w_{t+1}\} < w_{s+1}$. Therefore,

$$w_s w_{s+1} + w_{s+1} w_{t+1} > w_s w_{t+1}$$

and the proof follows inductively. □

The proof of the next lemma is similar to that of Lemma 1. The basic intuition here is that, if the longer of two nested jumpers edge minimizes a unit path r, then any unit path below r, with both of these jumpers, is not minimized by the shorter jumper; see Figure 16.

This next lemma only considers supercritical nodes since we are interested in merging two nested bands. For the next lemma assume there is a unit path of critical nodes from (v,z) to (x,y).

LEMMA 3. *Let* (v,z) *and* (x,y) *be two* super*critical nodes, where* $r<s<x<v$, *and assume* $w_r<w_s$ *such that rows* s *and* r *are above* p. *Then*

$$\textbf{if } \Delta_r(x,y)\geq\Delta_r(v,z), \textbf{ then } \Delta_s(x,y)\geq\Delta_s(v,z).$$

Proof. Assume $\Delta_r(x,y)\geq\Delta_r(v,z)$. Then

$$\begin{aligned} &w_r\|w_x:w_{y+1}\|-[\ sp(x,y)+f(r,x-1,y)\ ]\\ &\quad\geq w_r\|w_v:w_{z+1}\|-[\ sp(v,z)+f(r,v-1,z)\ ]. \end{aligned}$$

By Lemma 2 and, since each of these jumpers is of length at least 2, we know that $w_rw_vw_{z+1}<w_r\|w_v:w_{z+1}\|$ and $w_rw_xw_{y+1}<w_r\|w_x:w_{y+1}\|$. In addition, since $w_r<w_s$, we know that $f(r,x-1,y)<f(r,v-1,z)$ and $w_r\|w_x:w_{y+1}\|>w_r\|w_v:w_{z+1}\|$. Furthermore, the same holds in row s. Therefore, it must be that $\Delta_s(x,y)\geq\Delta_s(v,z)$. □

THEOREM 10. *Suppose we are given two* super*critical nodes* (v,z) *and* (x,y), *where* $r<s<x<v$, *and* $w_r<w_s$ *such that rows* s *and* r *are above* p. *Then*

if $(r,x-1)\Longrightarrow(r,y)$ *makes row* r *cheaper than* $(r,v-1)\Longrightarrow(r,z)$ *does,*

then $(s,x-1)\Longrightarrow(s,y)$ *makes row* s *cheaper than* $(s,v-1)\Longrightarrow(s,z)$ *does.*

A proof of this theorem follows from Lemma 3 and the fact that the change of the f values between $(r,v-1)\Longrightarrow(r,z)$ and $(s,v-1)\Longrightarrow(s,z)$ increases faster than the change in the f values between $(r,x-1)\Longrightarrow(r,y)$ and $(s,x-1)\Longrightarrow(s,y)$.

While merging $D^{(i,v)}_{(j,t)}$ and $D^{(j,t)}_{(k,s)}$ to form $\overline{p}^{(i,v)}_{(k,s)}$, the next lemma shows that we only need shortest path values backwards to $(0,0)$ from supercritical nodes and we don't need shortest path values backwards to $(0,0)$ from any other critical nodes. Hence, the *back-ptr*s will form a linked list between supercritical nodes backwards eventually to $(0,0)$, and we can compute the *cost-to-back* weights using a parallel pointer jumping partial prefix computation.

LEMMA 4. *Suppose we are given* $\overline{p}^{(i,v)}_{(j,t)}$ *and* $\overline{p}^{(j,t)}_{(k,s)}$ *in* $D^{(i,v)}_{(j,t)}$ *and* $D^{(j,t)}_{(k,s)}$, *respectively. Consider critical nodes in the outer band, say* $(u,z)\in V[p^{(i,v)}_{(j,t)}]$ *and* $(u,z)\notin V[\overline{p}^{(i,v)}_{(k,s)}]$; *then we don't need shortest paths* back *to* $(0,0)$.

Proof. Consider the angular path $(x,y)\Uparrow(q,y)\rightarrow\cdots\rightarrow(u,z)$ between $D^{(j,t)}_{(k,s)}$ and $D^{(i,v)}_{(j,t)}$. That is, $(x,y)\in V[\overline{p}^{(j,t)}_{(k,s)}]$ and $(u,z)\in V[p^{(i,v)}_{(j,t)}]$. But, suppose $(u,z)\notin V[\overline{p}^{(i,v)}_{(k,s)}]$ is the case. Notice that (u,z) may be a supercritical node in $\overline{p}^{(i,v)}_{(j,t)}$.

Consider the following cases.

Case i: Suppose $D^{(i,v)}_{(k,s)}$ is merged with another band nested around it.

Then, since (u,z) is not in $V[\overline{p}^{(i,v)}_{(k,s)}]$, by Theorem 5 we do not have to consider any angular paths starting from (u,z) going forward to critical nodes in the band nested around $D^{(i,v)}_{(k,s)}$.

Case ii: Suppose $D^{(i,v)}_{(k,s)}$ is merged with a smaller band inside $D(k,s)$.

Node (u,z) could be the terminal node of an incoming angular path contributing to a shortest path forward for *some* supercritical node in $D(k,s)$. In this case (u,z) needs to have a shortest path from (u,z) forward. Of course, in this case (u,z) could become a supercritical node and would have a minimal path back to $(0,0)$. On the other hand, since the critical node (u,z) is not a *super*critical node it has no need of a shortest path back to $(0,0)$. □

We want to find a shortest path forward for every critical node, since some angular path from some future inner band may terminate at any critical node. Therefore, after finding each supercritical node's minimal cost to the front critical node of the outer band, then compute a tree partial prefix sum from the critical nodes to the supercritical nodes. This lets all critical nodes know their shortest paths to the front of the outer band.

Suppose, through recursive doubling, we generate the band $D_{(j,t)}^{(i,v)}$ and the shortest path $\overline{p}_{(j,t)}^{(i,v)}$ from (i, v) back to $(0, 0)$ in this band. The next theorem shows that we can build the appropriate data structures to maintain the inductive invariant through recursive doubling.

THEOREM 11. *Suppose we have just merged any two nested bands into a new band. Then the front pointers of the new band form a tree and the back pointers of the new band form a linked list.*

There is a proof by induction based on Theorem 9.

Theorem 11 shows that the inductive invariant holds given the appropriate data structures and computations.

4.1. Merging bands using $n^2/\lg n$ processors. In this subsection we show how to merge two bands using $n^2/\lg n$ processors in $O(\lg n)$ time. This algorithm also merges two optimally triangulated convex polygons when all of the weights of one polygon are heavier than all of the weights of the other. Given a triangle with vertices w_i, w_j, and w_k its cost is $w_i w_j w_k$; also see [18, 28].

Recursively doubling the band merging algorithm while using the proper data structures and appropriate tree contracting gives the $n^2/\lg n$-processor and $O(\lg^3 n)$-time MCOP algorithm.

The algorithm in Figure 17 merges two bands in $O(\lg n)$ time using $n^2/\lg n$ processors. Adding the cost of recursive doubling and tree contraction gives a factor of $O(\lg^2 n)$ time to the entire algorithm, making the total cost for solving the MCOP $O(\lg^3 n)$ time using $n^2/\lg n$ processors.

The two **for** loops in step 1 of the algorithm in Figure 17 perform the edge minimizing. This is the only part of this algorithm that uses $n^2/\lg n$ processors. In $O(\lg n)$ time using $n^2/\lg n$ processors we can edge minimize unit paths with contracted trees such as those depicted in the bottleneck of Figure 5c.

The **for** loops in step 2 compute the supercritical nodes of the band that are being created by merging. Step 3 computes the shortest paths forward for all critical nodes in the inner band.

The base case for the recursive doubling can be established by breaking the canonical subgraphs into bands of constant width. Then for each band sequentially, let the $n/\lg n$ processors set up the inductive invariant in $O(\lg n)$ time. Number the nested bands consecutively according to their nestings by the Euler tour technique so the algorithm can track adjacent bands for merging.

The correctness of the algorithm in Figure 18 comes from Theorems 7, 9, and 11.

The time complexity of solving the MCOP can be reduced to $O(\lg^2 n)$ time with $n^2/\lg n$ processors by performing band merging and then tree contraction.

THEOREM 12. *Recursive doubling with band merging can be done simultaneously with tree contraction, thereby solving the MCOP in $O(\lg^2 n)$ time with $n^2/\lg n$ processors.*

Proof. Take any canonical tree T with nontrivial bands and leaves. Then T has at most $n-1$ critical nodes. In general, for any arithmetic expression tree with $n-1$ nodes, it takes $O(\lg n)$ time to contract it. In a canonical tree we have just seen

Take two adjacent nested bands, say $D^{(i,v)}_{(j,t)}$ nested around $D^{(j,t)}_{(k,s)}$, such that for each band individually the inductive invariant holds.

1. **for all** supercritical nodes $(x, y) \in V[\overline{p}^{(j,t)}_{(k,s)}]$ **in parallel do**
   for all angular edges from (x, y) to all $(u, z) \in V[p^{(i,v)}_{(j,t)}]$ **in parallel do**
   find the angular edge between the bands that gives a shortest path from (x, y) all the way to (i, v), compute the *cost-of-front-ptr*s for these new edges
   let each supercritical node (x, y) have a pointer to a shortest path through $p^{(i,v)}_{(j,t)}$ to (i, v)
   for the supercritical nodes in $\overline{p}^{(j,t)}_{(k,s)}$ put the angular edge that gives them a shortest path forward to (i, v) in M
2. **for all** angular edges in M **in parallel do**
   find the shortest path N from (i, v) back to $(0, 0)$ through $D^{(i,v)}_{(k,s)}$
   for all critical nodes in the path N **in parallel do**
   using pointer jumping build the *back-ptr*s giving any new supercritical nodes and compute the values of *cost-to-back* for each new supercritical node
3. **for all** *non*-supercritical nodes in $p^{(j,t)}_{(k,s)}$ **in parallel do**
   using pointer jumping expand the tree of *front-ptr*s through the new angular edges in M and their minimal values to (i, v). This gives trees joined by a linked list through the supercritical nodes.
   With this find the shortest path to (i, v) for all non-supercritical nodes in $p^{(j,t)}_{(k,s)}$ by computing a partial prefix in a rooted tree.
   Also compute all of the new *cost-to-front* values using a parallel partial prefix.

FIG. 17. *An $O(\lg n)$-time and $n^2/\lg n$-processor algorithm for merging two bands.*

that each contraction operation (raking) can be done in $O(\lg n)$ time using $n^2/\lg n$ processors. This is because in the worst case a leaf raking operation in a canonical tree is the merging of two bands. Now, each band can be seen as no more than a linked list in the canonical tree that must be contracted where there is one leaf per list node. Now, we can simply take every band that has k critical nodes and is in any canonical tree, and we can assume that it has 2^c "linked list nodes" such that $2^{c-1} < k \leq 2^c$. With this, each raking operation will cost at most $O(\lg n)$ time using $n^2/\lg n$ processors. In addition, by assuming k is the nearest power of two greater than or equal to k, we are at most doubling the number of critical nodes in T. Hence the asymptotic bound we claim must hold. □

5. An efficient polylog-time MCOP algorithm. In this section we reduce the processor complexity of the band merging algorithm of section 4. The results of this section are based on a parallel divide-and-conquer form of binary search which is tied into some classical problems of finding row minima in totally monotone matrices.

Theorems 8 and 10 supply the basis for a parallel divide-and-conquer binary search algorithm that finds the jumpers that minimize each unit path in a canonical graph.

1. Find the middle supercritical node in the inner band, say $(x-1, y)$.
2. Using $m/\lg m$ processors and in $O(\lg m)$ time find a shortest path forward from $(x-1, y)$ to the front of the outer band. Suppose that this shortest path forward from the supercritical node $(x-1, y)$ has an angular edge between the two bands that terminates in row r.
3. Split the jumpers into two sets:
   (a) Those smaller than or equal to $(r, x) \Longrightarrow (r, y)$; call them S. They are nested *inside* $(r, x) \Longrightarrow (r, y)$.
   (b) Those larger than or equal to $(r, x) \Longrightarrow (r, y)$; call them L. They are nested *around* $(r, x) \Longrightarrow (r, y)$.
4. Do the following two steps in parallel:
   (a) Assign $|S|$ processors to rows r up through 1 and recursively repeat this algorithm with the jumpers in S.
   (b) Assign $|L|$ processors to rows r down through m and recursively repeat this procedure with the jumpers in L.

FIG. 18. *An $O(\lg^2 n)$-time and $n/\lg n$-processor band merging algorithm.*

THEOREM 13. *Suppose that r is the row in the outer band such that the dual of $(r, x) \Longrightarrow (r, y)$ gives a shortest path forward from the supercritical node $(x-1, y)$ of the inner band to the front node of the outer band. Then to find shortest paths forward from other supercritical nodes,*

- *it is sufficient to consider only larger nested jumpers in any row s below row r, that is, $w_s > w_r$, and*
- *it is sufficient to consider only smaller nested jumpers in any row i above row r, that is, $w_i < w_r$.*

A proof of this theorem comes directly from Theorems 8 and 10.

The next algorithm replaces the two nested **for** loops in step 1 in the algorithm of Figure 17. This next algorithm gives shortest paths forward for all supercritical nodes originally in the inner band and a shortest path back to $(0, 0)$ through the two merged bands.

Assuming that each band has m critical nodes, the next procedure finds shortest paths from all supercritical nodes of the inner band to the front of the outer band. In addition, assume the shortest path information before the merging and all shortest paths to the front of the outer band. Then the shortest path back from the front node of the outer band is easily computed. As before, begin assuming the inductive invariant. Also, all jumpers in the next algorithm are jumpers that get their *sp* values from the inner band where the jumpers themselves are in unit rows or columns of the outer band.

The following algorithm is strikingly similar to those discussed in [1] and [2]. This key observation leads to some complexity improvements.

Now assign one processor to each unit path in the outer band. For each unit path, summing the cost to the critical node and the cost from the critical node to the front supercritical node of the outer band gives a shortest path backwards from the front node of the outer band to $(0, 0)$. These minimal paths can be computed in $O(\lg n)$ time using $n/\lg n$ processors. If a unit path has no edge minimizing jumpers, then this algorithm just finds the shortest path forward for all supercritical nodes in the

inner band, since, in this case, the shortest path back to $(0, 0)$ from the front critical node of the outer band does not go through the inner band.

The algorithm in Figure 18 also breaks through the bottleneck of Figure 5c. It takes $O(\lg^2 n)$ time and uses $n/\lg n$ processors in the worst case. Considering the cost of the recursive doubling and the tree contraction gives the $O(\lg^3 n)$-time and $n/\lg n$-processor matrix chain ordering algorithm.

The next corollary shows that the algorithm given here can be improved by using efficient algorithms for finding row minima in totally monotone matrices. A $m \times n$ matrix M is *totally monotone* if every 2×2 submatrix is monotone. That is, for all $1 \leq i < k \leq m$ and $1 \leq j < l \leq n$, if $M[i, j] > M[i, l]$, then $M[k, j] > M[k, l]$.

This row minima problem is classical and has been shown to be at the root of many important problems; see for example [1, 2].

COROLLARY 3. *Solving the row minima problem on totally monotone matrices allows us to merge two bands.*

Proof. Given two nested bands to merge, for ease of exposition take only the horizontal straight unit paths of the outer band. Let each of these straight unit paths denote the row of a matrix M. Each column of M represents the jumpers that get their *sp* values from the supercritical nodes of the inner band. The first column represents the effect of the innermost jumper, the second column represents the effect of the immediate jumper containing it, etc. Similarly, several sets of independent jumpers give several totally monotone matrices.

By Theorem 13, M is a monotone matrix. But, any submatrix of M represents neighboring straight unit paths in the rows and neighboring jumpers along the columns. Similarly, every 2×2 submatrix is monotone. Since Theorems 8 and 10 still hold, we know that such a submatrix is also monotone since we can again apply Theorem 13. □

Therefore, our algorithm is one of the many known to depend on the row minima problem on a totally monotone matrix. Hence, by the results of Aggarwal and Park [2] and Atallah and Kosaraju [6], our algorithm runs in $O(\lg^2 n \lg\lg n)$ time using $n/\lg\lg n$ processors on a common CRCW PRAM, or in $O(\lg^2 n)$ time using n processors on an EREW PRAM. For the EREW PRAM algorithm note that from pointer jumping to tree contraction the time complexity stays the same asymptotically.

An asymptotically optimal polylog-time row minima algorithm for totally monotone matrices would make the work of our MCOP algorithm the same as the work of Hu and Shing's $O(n \lg n)$ sequential algorithm. Very recently Bradford, Fleischer, and Smid [14] give an algorithm for computing the row minima of totally monotone matrices with $O(n\sqrt{\lg n})$ work and $O(\lg n \lg\lg n)$ time on a CREW PRAM (and several variations on other PRAM models). The results of [14] lead to an $O(n \lg^{1.5} n)$ work and polylog time CREW PRAM algorithm for the MCOP.

Hu and Shing's algorithm has the best known work for solving the MCOP to date [28, 29]. In this regard, in [38, 39] Ramanan shows that problems closely related to the MCOP have a $\Omega(n \lg n)$ lower bound. Furthermore, in [13] Bradford, Choppella, and Rawlins give several lower bounds for the MCOP on different models of computation, including a simple $\Omega(n \lg n)$ lower bound on the comparison based model for a constrained version of the MCOP.

6. Conclusions. The study of efficient parallel algorithms for problems with elementary dynamic programming solutions is rich with interesting results. This paper gives an algorithm that solves the matrix chain ordering problem to within less than

a log factor of the best serial solution. Furthermore, the best serial solution is in some sense optimal. This algorithm also solves a problem of finding an optimal triangulation of a convex polygon.

Acknowledgments. We acknowledge conversations with Alok Aggarwal, Venkatesh Choppella, Artur Czumaj, Ming Kao, Larry Larmore, and Kunsoo Park that were very helpful. In addition, conversations with Danny Chen were highlighted when, at Midwest Theory Day, he pointed out reference [16] which helps make our algorithm more efficient on the EREW PRAM.

COMPUTING MANY FACES IN ARRANGEMENTS OF LINES AND SEGMENTS*

PANKAJ K. AGARWAL†, JIŘÍ MATOUŠEK‡, AND OTFRIED SCHWARZKOPF§

Abstract. We present randomized algorithms for computing many faces in an arrangement of lines or of segments in the plane, which are considerably simpler and slightly faster than the previously known ones. The main new idea is a simple randomized $O(n \log n)$ expected time algorithm for computing $\sqrt{n}$ cells in an arrangement of n lines.

1. Introduction. Given a finite set S of lines in the plane, the *arrangement* of S, denoted by $\mathcal{A}(S)$, is the cell complex induced by S. The 0-faces (or *vertices*) of $\mathcal{A}(S)$ are the intersection points of S, the 1-faces (or *edges*) are maximal portions of lines of S that do not contain any vertex, and the 2-faces (called *cells*) are the connected components of $\mathbb{R}^2 - \bigcup S$. For a finite set S of segments we define the arrangement, $\mathcal{A}(S)$, in an analogous manner. Notice that while the cells are convex in an arrangement of lines, they need not even be simply connected in an arrangement of segments.

Line and segment arrangements have been extensively studied in computational geometry (as well as in some other areas), as a wide range of computational geometry problems can be formulated in terms of computing such arrangements or their parts [11, 14].

Given a set S of n lines and a set P of m points in the plane, we define $\mathcal{A}(S, P)$ to be the collection of all cells of $\mathcal{A}(S)$ that contain at least one point of P. The *combinatorial complexity* of a cell C in $\mathcal{A}(S)$, denoted by $|C|$, is the number of edges of C. Let $\kappa(S, P) = \sum_{C \in \mathcal{A}(S,P)} |C|$ denote the total combinatorial complexity of all cells in $\mathcal{A}(S, P)$, and let

$$\kappa(n, m) = \max \kappa(S, P)\,,$$

where the maximum is taken over all sets of n lines and over all sets of m points in

the plane. It is known that

$$\kappa(n,m) = \Theta(n^{2/3}m^{2/3} + n + m)\,.$$

The upper bound was proven by Clarkson et al. [9] and the lower bound follows from a result of Szemerédi and Trotter [21]; previous results and related work can be found in Canham [4] and Edelsbrunner and Welzl [13].

In this paper we study the problem of computing $\mathcal{A}(S,P)$, that is, for each cell $C \in \mathcal{A}(S,P)$, we want to return the vertices of C in, say, clockwise order. We will refer to the cells of $\mathcal{A}(S,P)$ as the *marked* cells of $\mathcal{A}(S)$. Edelsbrunner, Guibas, and Sharir [12] presented a randomized algorithm, based on the random-sampling technique [16], for computing $\mathcal{A}(S,P)$, whose expected running time was

$$O(m^{2/3-\varepsilon}n^{2/3+2\varepsilon}\log n + n\log n\log m),$$

for any fixed $\varepsilon > 0$. A deterministic algorithm with running time

$$O(m^{2/3}n^{2/3}\log^{O(1)} n + n\log^3 n + m\log n)$$

was given by Agarwal [1]. These algorithms thus are nearly worst-case optimal, but both of them are rather involved.

Recently, randomized incremental algorithms have been developed for a variety of geometric problems, which add the input objects one by one in random order and maintain the desired structure; see e.g., [6, 10, 18, 19]. In our case, we can add the lines of S one by one in random order and maintain the marked cells in the arrangement of lines added so far. However, the expected running time of this approach is $\Omega(n\sqrt{m} + m\log n)$ in the worst case. We, therefore, do not quite follow the randomized incremental paradigm.

We begin by presenting an expected $O((m^2+n)\log n)$-time randomized algorithm for computing $\mathcal{A}(S,P)$. Notice that for $m \le \sqrt{n}$, the expected running time of the algorithm is $O(n\log n)$, which matches the known lower bound for computing a single cell in line arrangements. We then apply the randomized geometric divide-and-conquer technique in a standard way, obtaining an algorithm with expected time

$$O\left(m^{2/3}n^{2/3}\log\frac{n}{\sqrt{m}} + (m+n)\log n\right).$$

We also study a similar but more difficult problem of computing the marked cells in an arrangement of n line segments. Let S be a set of n segments in the plane. We use an analogous notation $\mathcal{A}(S,P)$ to denote the set of cells in $\mathcal{A}(S)$ containing at least one point of P, and $\eta(n,m)$ to denote the maximum combinatorial complexity of $\mathcal{A}(S,P)$ over all sets S of n segments and over all sets P of m points in the plane. Aronov et al. [2] proved that

$$\eta(n,m) = O\left(m^{2/3}n^{2/3} + n\log m + n\,\alpha(n)\right).$$

A randomized algorithm with expected running time

$$O(m^{2/3-\varepsilon}n^{2/3+2\varepsilon}\log n + n\alpha(n)\log^2 n\log m)$$

is described by Edelsbrunner, Guibas, and Sharir [12], and a slightly faster deterministic algorithm is presented by Agarwal [1]. See [20] for results on computing a single cell in arrangements of segments.

Following the same strategy as for the case of lines, we first develop a randomized algorithm with $O((m^2 \log m + n \log m + n\,\alpha(n)) \log n)$ expected running time. Note that the above upper bound for $\eta(n, m)$ is not known to be tight, and a bound such as $\eta(n, \sqrt{n}) = O(n\,\alpha(n))$ (which is conjectured to be the complexity of $\sqrt{n}$ cells) will immediately improve the expected running time of our algorithm to $O(n \log n\,\alpha(n))$. Plugging this algorithm into the standard random-sampling technique, as in the case of lines, we obtain a randomized algorithm for computing $\mathcal{A}(S, P)$ whose expected running time is

$$O\left(m^{2/3}n^{2/3} \log^2 \frac{n}{\sqrt{m}} + (m + n \log m + n\,\alpha(n)) \log n\right).$$

If the segments of S have only $k = o(n^2)$ intersection points, the expected running time of the algorithm is

$$O\left(m^{2/3}k^{1/3} \log^2 \frac{k}{m} + (m + n \log m + n\,\alpha(n)) \log n\right).$$

For the analysis of the expected running time of our algorithms we will use a generalization of a lemma due to Chazelle and Friedman [7]. (An alternative analysis could probably be obtained using a method similar to that of Chazelle et al. [6], but we hope that our approach is somewhat more intuitive).

2. A generalization of the Chazelle–Friedman lemma. Let S be a set of lines or segments and P a set of points in the plane. For a cell C in the collection $\mathcal{A}(S, P)$, let $C^{\|}$ denote the collection of trapezoids in the vertical decomposition[1] of C, and let $\mathcal{A}^{\|}(S, P) = \bigcup_{C \in \mathcal{A}(S,P)} C^{\|}$ denote the set of trapezoids in the vertical decomposition of $\mathcal{A}(S, P)$. Abusing the notation slightly, we will use $\mathcal{A}^{\|}(S, P)$ to denote the corresponding planar subdivision as well. For any subset $X \subseteq S$ and any trapezoid $\Delta \in \mathcal{A}^{\|}(X, P)$, let $w(\Delta)$ denote the number of elements of S intersecting the interior of Δ.

Let $n = |S|$, and let R be a random subset of S of size r. For the analysis of our algorithms, we are interested in estimating the expectation, over all random choices of R,

$$\mathrm{E}\left[\sum_{\Delta \in \mathcal{A}^{\|}(R,P)} w(\Delta)^c\right], \tag{2.1}$$

where c is a small constant; for instance, $c = 2$. Well-known results concerning the so-called ε-nets (Haussler and Welzl [16]) imply that, for every $\Delta \in \mathcal{A}^{\|}(R)$, $w(\Delta) \leq a(n/r) \log r$ with high probability, where a is a suitable constant. This inequality can be used to derive a weaker bound for (2.1). We are, however, interested in the following, slightly stronger bound (better by a factor of $\log^c r$).

PROPOSITION 2.1. (i) *Let S be a set of n lines and P a set of m points in the plane. If $R \subseteq S$ is a random subset of size r, where each subset of size r is chosen with equal probability, then for any constant $c \geq 1$,*

$$\mathrm{E}\left[\sum_{\Delta \in \mathcal{A}^{\|}(R,P)} w(\Delta)^c\right] = \kappa(r, m) \cdot O((n/r)^c).$$

[1]The vertical decomposition $C^{\|}$ of a cell C in an arrangement of segments (or of lines) is obtained by drawing a vertical line segment from each vertex of C in both directions (within C) until it hits another edge of C. If the segment does not intersect any edge of C, then it is extended to infinity.

(ii) *Let S be a set of n segments and P a set of m points in the plane. If $R \subseteq S$ is a random subset of size r, where each subset of size r is chosen with equal probability, then for any constant $c \geq 1$,*

$$\mathrm{E}\left[\sum_{\Delta \in \mathcal{A}^{\parallel}(R,P)} w(\Delta)^c\right] = \eta(r,m) \cdot O((n/r)^c)\,.$$

These bounds essentially say that the cth moment of the quantities $w(\Delta)$ behaves as if $w(\Delta)$ were $O(n/r)$. If we sum $w(\Delta)$ over all cells in $\mathcal{A}(R)$—the case where every cell of $\mathcal{A}(R)$ contains a point of P—then Proposition 2.1 follows from a result of Clarkson and Shor [10]. In our situation, where the sum is taken over only some of the cells, the Clarkson–Shor framework does not apply directly anymore (the main distinction between these two situations will be outlined below). We give a proof based on a generalization of the approach by Chazelle and Friedman [7], which is somewhat different from the Clarkson–Shor method. Recently, de Berg, Dobrindt, and Schwarzkopf [3] gave an alternative proof of Proposition 2.1.

We derive a key lemma in a somewhat abstract framework; see also [6, 7, 10] for various approaches to axiomatize similar situations.

Let S be a set of objects. For a subset $R \subseteq S$, we define a collection of "regions" called $\mathrm{CT}(R)$; in Proposition 2.1 the objects are lines or segments, the regions are trapezoids, and $\mathrm{CT}(R) = \mathcal{A}^{\parallel}(R,P)$. Let $T = T(S) = \bigcup_{R \subseteq S} CT(R)$ denote the set of regions defined by all possible subsets of S. We associate two subsets $D(\Delta), K(\Delta) \subseteq S$ with each region $\Delta \in T$.

$D(\Delta)$, called the *defining set*, is a subset of S defining the region Δ in a suitable geometric sense.[2] We assume that for every $\Delta \in T$, $|D(\Delta)| \leq d$ for a (small) constant d. In Proposition 2.1, each trapezoid Δ is defined by at most four segments (or lines) of S, which constitute the set $D(\Delta)$; details can be found in Chazelle et al. [6].

$K(\Delta)$, called the *killing set*, is a set of objects of S such that including any object of $K(\Delta)$ into R prevents Δ from appearing in $\mathrm{CT}(R)$. In many applications, $K(\Delta)$ is the set of objects intersecting the cell Δ; this is also the case in Proposition 2.1. Set $w(\Delta) = |K(\Delta)|$.

Let $S, \mathrm{CT}(R), D(\Delta)$, and $K(\Delta)$ be such that for any subset $R \subseteq S$, $\mathrm{CT}(R)$ satisfies the following axioms:

(i) For any $\Delta \in \mathrm{CT}(R)$, $D(\Delta) \subseteq R$ and $R \cap K(\Delta) = \emptyset$, and
(ii) If $\Delta \in \mathrm{CT}(R)$ and R' is a subset of R with $D(\Delta) \subseteq R'$, then $\Delta \in \mathrm{CT}(R')$.

It is easily checked that these axioms hold in the situations of Proposition 2.1.

For any natural number t, let

$$\mathrm{CT}_t(R) = \{\Delta \in \mathrm{CT}(R) \mid w(\Delta) \geq tn/r\}\,.$$

We establish the following.

LEMMA 2.2. *Given a set S of n objects, let R be a random sample of size $r \leq n$ drawn from S, and let t be a parameter, $1 \leq t \leq r/d$, where $d = \max|D(\Delta)|$. Assuming that $\mathrm{CT}(R)$, $D(\Delta)$, and $K(\Delta)$ satisfy axioms* (i) *and* (ii) *above, we have*

$$\mathrm{E}\left[|\mathrm{CT}_t(R)|\right] = O(2^{-t}) \cdot \mathrm{E}\left[|\mathrm{CT}(R')|\right], \tag{2.2}$$

where $R' \subseteq S$ denotes a random sample of size $r' = \lfloor r/t \rfloor$.

[2] We need not make this precise here, as this is only an intuitive meaning of $D(\Delta)$. The analysis depends only on the axioms involving $D(\Delta)$ given below, and these will be satisfied in our specific applications.

Roughly speaking, Lemma 2.2 says that the expected number of "large" trapezoids in $\mathrm{CT}(R)$, that is, trapezoids for which the value of $w(\Delta)$ exceeds the "right" value n/r more than t times, decreases exponentially with t.

Chazelle and Friedman [7] proved a result analogous to Lemma 2.2 under the following stronger axiom replacing (ii):

(ii′) If $D(\Delta) \subseteq R$ and $K(\Delta) \cap R = \emptyset$, then $\Delta \in \mathrm{CT}(R)$.

This assumption implies that the presence of Δ in $\mathrm{CT}(R)$ depends only on $D(\Delta)$ and $K(\Delta)$; thus it is determined purely "locally." Notice that (ii′) may fail in the situation of Proposition 2.1. However, (ii′) holds in the special case, when $\mathrm{CT}(R)$ is the vertical decomposition of *all* cells in $\mathcal{A}(R)$.

Proof of Lemma 2.2. Let $T_t = \bigcup_{R \subseteq S} \mathrm{CT}_t(R)$. We have

$$\mathrm{E}\left[|\mathrm{CT}_t(R)|\right] = \sum_{\Delta \in T_t} \Pr[\Delta \in \mathrm{CT}(R)]\,, \tag{2.3}$$

$$\begin{aligned}\mathrm{E}\left[|\mathrm{CT}(R')|\right] &= \sum_{\Delta \in T} \Pr[\Delta \in \mathrm{CT}(R')] \\ &\geq \sum_{\Delta \in T_t} \Pr[\Delta \in \mathrm{CT}(R')]\,. \end{aligned} \tag{2.4}$$

We will prove that, for each $\Delta \in T_t$,

$$\Pr[\Delta \in \mathrm{CT}(R)] = O(2^{-t}) \cdot \Pr[\Delta \in \mathrm{CT}(R')]\,, \tag{2.5}$$

which in conjunction with (2.3) and (2.4) implies (2.2).

Let A_Δ denote the event $D(\Delta) \subseteq R$ and $K(\Delta) \cap R = \emptyset$, and let A'_Δ denote the event $D(\Delta) \subseteq R'$ and $K(\Delta) \cap R' = \emptyset$.

We rewrite $\Pr[\Delta \in \mathrm{CT}(R)]$ using the following definition of conditional probability:

$$\Pr[\Delta \in \mathrm{CT}(R)] = \Pr[A_\Delta] \cdot \Pr[\Delta \in \mathrm{CT}(R) \mid A_\Delta]$$

and analogously,

$$\Pr[\Delta \in \mathrm{CT}(R')] = \Pr[A'_\Delta] \cdot \Pr[\Delta \in \mathrm{CT}(R') \mid A'_\Delta]\,.$$

We observe that, by axiom (ii), we have

$$\Pr[\Delta \in \mathrm{CT}(R) \mid A_\Delta] \leq \Pr[\Delta \in \mathrm{CT}(R') \mid A'_\Delta]\,. \tag{2.6}$$

To see this, consider the following random experiment. Select a set R' by including all the elements of $D(\Delta)$ into it, and adding $r' - |D(\Delta)|$ elements chosen randomly among the elements of $S \setminus (D(\Delta) \cup K(\Delta))$. By definition of the conditional probability, the probability that Δ appears in $\mathrm{CT}(R')$ is precisely $\Pr[\Delta \in \mathrm{CT}(R') \mid A'_\Delta]$. Now take this R' and add $r - r'$ randomly chosen elements of $S \setminus (R' \cup K(\Delta))$ to it, obtaining a set R. The distribution of this R is clearly the same as if we took the elements of $D(\Delta)$ and added $r - |D(\Delta)|$ random elements of $S \setminus (D(\Delta) \cup K(\Delta))$, and hence the probability of $\Delta \in \mathrm{CT}(R)$ is $\Pr[\Delta \in \mathrm{CT}(R) \mid A_\Delta]$. On the other hand, since R was created by adding extra elements to R', whenever Δ is present in $\mathrm{CT}(R)$ it must be in $\mathrm{CT}(R')$ as well, and thus (2.6) holds.

Therefore,

$$\frac{\Pr[\Delta \in \mathrm{CT}(R)]}{\Pr[\Delta \in \mathrm{CT}(R')]} \le \frac{\Pr[A_\Delta]}{\Pr[A'_\Delta]}.$$

(Note that $r' = \lfloor r/t \rfloor \ge d$, and hence both denominators are nonzero.)

It remains to estimate the latter ratio, which can be done in the same way as by Chazelle and Friedman. Let $\delta = |D(\Delta)| \le d$, $w = w(\Delta)$, and for two nonnegative integers $a \le x$, let $x^{\underline{a}} = x(x-1)\cdots(x-a+1)$. Then

$$\begin{aligned}\frac{\Pr[A_\Delta]}{\Pr[A'_\Delta]} &= \frac{\binom{n-w-\delta}{r-\delta}}{\binom{n}{r}} \cdot \frac{\binom{n}{r'}}{\binom{n-w-\delta}{r'-\delta}} \\ &\le \frac{r^{\underline{d}}}{r'^{\underline{d}}} \cdot \frac{(n-w-r')^{\underline{r-r'}}}{(n-r')^{\underline{r-r'}}}.\end{aligned}$$

By our assumption, $r' \ge d$, so we obtain

$$\frac{r-i}{r'-i} \le dt \quad \text{for } i = 0, 1, \ldots, d-1.$$

Thus, the first factor in the above expression is $O(t^d)$. To bound the second factor, we observe that, for $i = r', r'+1, \ldots, r-1$,

$$\frac{n-w-i}{n-i} = 1 - \frac{w}{n-i} \le 1 - \frac{w}{n} \le \exp(-w/n).$$

Since $w \ge tn/r$, we have $w/n \ge t/r$, and therefore,

$$\begin{aligned}\frac{\Pr[A_\Delta]}{\Pr[A'_\Delta]} &\le O(t^d)\exp\left(\frac{-t(r-r')}{r}\right) \\ &= O(t^d)\exp(-(t-1)) = O(2^{-t}),\end{aligned}$$

as desired. □

We now prove Proposition 2.1.

Proof of Proposition 2.1. We will only prove the first part; the second part is identical. For any subset $R \subseteq S$ of size r, let $CT(R)$ denote the set of trapezoids in the vertical decomposition of the marked cells of $\mathcal{A}(R)$, i.e., $CT(R) = \mathcal{A}^{\shortparallel}(R, P)$. Obviously, $|CT(R)| \le \kappa(r, m)$. Now

$$\begin{aligned}&\mathrm{E}\left[\sum_{\Delta \in \mathcal{A}^{\shortparallel}(R,P)} w(\Delta)^c\right] \\ &= \mathrm{E}\left[\sum_{t \ge 1} \left(t\frac{n}{r}\right)^c \left(|CT_t(R)| - |CT_{t-1}(R)|\right)\right] \\ &\le \left(\frac{n}{r}\right)^c \sum_{t \ge 0} (t+1)^c \cdot \mathrm{E}\left[|CT_t(R)|\right] \\ &= \left(\frac{n}{r}\right)^c \sum_{t \ge 0} t^c O(2^{-t}) \cdot \kappa\left(\frac{r}{t}, m\right) \\ &\le \kappa(r,m)\left(\frac{n}{r}\right)^c \sum_{t \ge 0} O(t^c \cdot 2^{-t}) \\ &= \kappa(r,m) \cdot O\left((n/r)^c\right). \qquad \square\end{aligned}$$

3. Computing cells in line arrangements. Let S be a set of n lines and P a set of m points in the plane. We assume that the points of P are sorted in nondecreasing order of their x-coordinates, and that the lines of S are sorted by their slopes. In this section we describe a randomized algorithm for computing $\mathcal{A}(S,P)$. In fact, it computes the vertical decomposition $\mathcal{A}^{\|}(S,P)$ of $\mathcal{A}(S,P)$. Each face of $\mathcal{A}^{\|}(S,P)$ is a trapezoid, bounded by at most two vertical segments and portions of at most two edges of a cell of $\mathcal{A}^{\|}(S,P)$. We begin by presenting a very simple randomized algorithm for computing $\mathcal{A}^{\|}(S,P)$ with $O((m^2+n)\log n)$ expected time, which we will use as a subroutine in the main algorithm. This algorithm is optimal for $m \le \sqrt{n}$. If $n \le n_0$, where n_0 is an appropriate constant, the algorithm computes the vertical decomposition of the entire arrangement using any standard algorithm. Otherwise, it proceeds as follows.

1. Let t be a sufficiently large constant. Choose a random subset $R \subseteq S$ of $r = \lfloor n/t \rfloor$ lines.
2. Partition P into $q = \lceil \sqrt{t}\, \rceil$ subsets $P_1, \ldots, P_q$, each of size at most $k = \lfloor m/\sqrt{t} \rfloor$, where
$$P_i = \{p_{(i-1)k+1}, \ldots, p_{ik}\} \quad \text{for } i < q,$$
$$P_q = \{p_{(q-1)k+1}, \ldots, p_m\}.$$
3. For each $i \le q$, compute $\mathcal{A}^{\|}(R, P_i)$ recursively. If a cell C of $\mathcal{A}(R)$ is computed more than once, retain only one copy of C. (Note that multiple copies of a cell C are computed if C contains the points of more than one P_i.) Since P is sorted in the x-direction, it is easy to detect multiple copies of a cell. In this way, we obtain $\mathcal{A}^{\|}(R,P)$.
4. For each line $\ell \in S \setminus R$, compute the cells of $\mathcal{A}(R,P)$ that ℓ intersects.
5. For each trapezoid Δ of $\mathcal{A}^{\|}(R,P)$, compute the set $S_\Delta \subseteq S \setminus R$ of lines that intersect the interior of Δ.
6. For each trapezoid $\Delta \in \mathcal{A}^{\|}(R,P)$, compute the arrangement of lines of S_Δ, clip it within Δ, and compute the vertical decomposition of the clipped arrangement. For each cell $C \in \mathcal{A}(R,P)$, perform a graph search on trapezoids of these vertical decompositions to merge appropriate trapezoids and to discard superfluous ones, thus forming the portion of $\mathcal{A}^{\|}(S,P)$ within the cell C.

Steps 1–3 are trivial, so we only describe steps 4–6 in more detail.

Step 4. We want to compute the cells of $\mathcal{A}(R,P)$ intersected by each line in $S \setminus R$. The situation can be viewed as follows: we have a collection $\mathcal{C}$ of disjoint convex polygons (the cells of $\mathcal{A}(R,P)$), and a set $S \setminus R$ of lines. The collection $\mathcal{C}$ has at most m polygons with a total of $O(n+m^2)$ edges.[3] For each polygon $C \in \mathcal{C}$, consider C^*, the set of points that are dual to the lines intersecting C. C^* is a polygonal region, bounded by an infinite convex chain from above and by an infinite concave chain from below. Each vertex of C^* is dual to the line supporting an edge of C. For a pair of polygons $C_1, C_2 \in \mathcal{C}$, an intersection point of the edges of C_1^*, C_2^* is dual to a common tangent of C_1 and C_2. Since C_1, C_2 are disjoint, the boundaries of C_1^*, C_2^* intersect in at most four points.

Consider the arrangement $\mathcal{A}(\mathcal{C}^*)$ of the polygonal chains bounding the regions C^*, for all $C \in \mathcal{C}$. It has $O(n+m^2)$ complexity and can be computed in expected time

[3]The latter estimate follows from the bound for $\kappa(n,m)$ mentioned in Section 1, in fact it is the weaker bound proved by Canham [4].

$O((m^2+n)\log n)$, using a randomized incremental algorithm [6, 18]. This algorithm actually computes the vertical decomposition $\mathcal{A}^{\|}(\mathcal{C}^*)$ of the arrangement, together with a point-location data structure with $O(\log n)$ expected query time. We use this data structure to locate the points ℓ^* dual to all lines $\ell \in S \setminus R$. From this we can determine, for every ℓ, the regions of $\mathcal{C}^*$ containing ℓ^*, or in other words, the polygons of $\mathcal{C}$ intersecting ℓ. Indeed, after having located all points of the form ℓ^*, we traverse the adjacency graph of the trapezoids in $\mathcal{A}^{\|}(\mathcal{C}^*)$. At each trapezoid $\tau \in \mathcal{A}^{\|}(\mathcal{C}^*)$ we compute $\mathcal{C}^*(\tau)$, the set of regions that contain the trapezoid $\tau \in \mathcal{A}^{\|}(\mathcal{C}^*)$, and output the pairs (ℓ, C) for $\ell^* \in \tau$ and $C^* \in \mathcal{C}^*(\tau)$. Suppose we arrive at τ from τ'; then $\mathcal{C}^*(\tau)$ and $\mathcal{C}^*(\tau')$ differ by at most one region (the region whose boundary separates τ from τ'), and thus $\mathcal{C}^*(\tau)$ can be obtained from $\mathcal{C}^*(\tau')$ in $O(1)$ time.

The total time spent in this step is $O((m^2+n)\log n)$ plus the number of polygon/line incidences. The expected number of these incidences is bounded by $O(\kappa(r,m)\cdot(n/r)) = O(m^2+n)$, using Proposition 2.1 with $r = n/t$ and $c = 1$.

Step 5. Let C be a cell in $\mathcal{A}(R,P)$, and let $S_C \subseteq S \setminus R$ be the set of lines intersecting the interior of C. For each line $\ell \in S_C$, we compute the trapezoids of $C^{\|}$ intersected by ℓ, as follows. We compute, in $O(\log n)$ time, the intersection points of ∂C and ℓ and also the trapezoids of $C^{\|}$ containing these intersection points. Next, by tracing ℓ through $C^{\|}$, we compute all b trapezoids of $C^{\|}$ that ℓ intersects. The time spent in finding the intersection points and tracing ℓ is $O(\log n + b)$. By repeating this procedure for all cells C and all lines $\ell \in L \setminus R$, we obtain S_Δ, for every $\Delta \in \mathcal{A}^{\|}(R,P)$. The running time of this step is $O(\sum_{\Delta\in\mathcal{A}^{\|}(R,P)} w(\Delta)\log n)$. The expected value of $O(\sum_{\Delta\in\mathcal{A}^{\|}(R,P)} w(\Delta))$, by Proposition 2.1 as before, is $O(m^2+n)$. Hence, the expected time spent in step 5 is $O((m^2+n)\log n)$.

Step 6. Let Δ be a trapezoid of $\mathcal{A}^{\|}(R,P)$. After having computed S_Δ, we compute the arrangement $\mathcal{A}(S_\Delta)$ using, say, a randomized incremental algorithm. We clip $\mathcal{A}(S_\Delta)$ within Δ and compute the vertical decomposition of the clipped arrangement. For each point $p \in P \cap \Delta$, we also compute the trapezoid of this vertical decomposition containing p. The time spent in this step is easily seen to be $O(w(\Delta)^2 + |P\cap\Delta|\log w(\Delta))$ per trapezoid $\Delta \in \mathcal{A}^{\|}(R,P)$.

For a cell $C \in \mathcal{A}(R,P)$, let $\mathbf{\Delta}_C$ be the set of resulting trapezoids that lie in C. We now define a graph $\mathcal{G}_C$ on the trapezoids of $\mathbf{\Delta}_C$. The vertices of $\mathcal{G}_C$ are the trapezoids of $\mathbf{\Delta}_C$, and two trapezoids are connected by an edge if they share a vertical edge. By performing a depth-first search on $\mathcal{G}_C$, we can extract all connected components of $\mathcal{G}_C$ whose trapezoids contain any point of P. That is, we pick a point $p \in P \cap C$. Let $\tau_p \in \mathbf{\Delta}_C$ be the trapezoid containing p. We perform a depth first search in $\mathcal{G}_C$ starting from τ_p until we find the entire connected component of $\mathcal{G}_C$ containing τ_p. Let $\mathbf{\Delta}_C(p)$ be the set of trapezoids in this component; then the union of these trapezoids is exactly the cell of $\mathcal{A}(S,\{p\})$. The vertices of the cell, sorted in clockwise order, can be obtained by merging the trapezoids of $\mathbf{\Delta}_C(p)$ in an obvious manner.

If there is a point $q \in P \cap C$ that does not lie in $\mathbf{\Delta}_C(p)$, we repeat the same procedure with q. We continue this process until we have extracted all components of $\mathcal{G}_C$ that contain any point of $P \cap C$. This gives $\mathcal{A}(S, P\cap C)$.

Repeating this step for all cells of $\mathcal{A}(R,P)$, we obtain all cells of $\mathcal{A}(S,P)$. Finally, we compute the vertical decomposition of all the cells. The total running time for Step 6 is

$$O(m\log n) + \sum_{\Delta\in\mathcal{A}(R,P)} O(w(\Delta)^2)\,,$$

and its expected value is

$$O(m \log n + \kappa(r, m)(n/r)^2) = O(m^2 + n)\,.$$

Putting all the pieces together, the total expected running time of Steps 4–6 is $O((m^2 + n) \log n)$. Let $T(n, m)$ denote the maximum expected time of the entire algorithm; then we obtain the following recurrence.

$$T(n, m) \leq \begin{cases} c_1 & \text{if } n \leq n_0, \\ \displaystyle\sum_{i=1}^{q} T\left(\lfloor n/t \rfloor, m_i\right) + c_2(m^2 + n) \log n & \text{if } n > n_0, \end{cases}$$

where $m_i \leq m/\sqrt{t}$ for $i \leq q = \lceil \sqrt{t}\, \rceil$, $\sum_{i=1}^{q} m_i = m$, and c_1, c_2 are appropriate constants. The solution of this recurrence is

$$T(n, m) = O((m^2 + n) \log n)\,.$$

If $m > \sqrt{n}$, we can divide the points of P into groups of size $\sqrt{n}$ and solve the subproblems separately. This standard batching technique yields a more convenient bound for the expected running time, namely $O((m\sqrt{n} + n) \log n)$. Hence, we can conclude the following lemma.

LEMMA 3.1. *Given a set S of n lines and a set P of $m \leq n^2$ points in the plane, the cells of $\mathcal{A}(S)$ containing the points of P can be computed by a randomized algorithm in expected time $O((m\sqrt{n} + n) \log n)$.*

We now present another randomized algorithm whose running time is significantly better for larger values of m. Although the basic idea is the same as in [1], the algorithm presented here is simpler because we allow randomization.

We choose a random subset $R \subseteq S$ of size r, where $r = \lceil m^{2/3}/n^{1/3} \rceil$. Using a randomized incremental algorithm, we construct $\mathcal{A}^{\shortparallel}(R)$ plus a point-location data structure for $\mathcal{A}^{\shortparallel}(R)$ in expected time $O(r^2)$ [6]. For each trapezoid $\Delta \in \mathcal{A}^{\shortparallel}(R)$, let $S_\Delta \subseteq S \setminus R$ be the set of lines that intersect the interior of Δ and $P_\Delta \subseteq P$ the set of points that are contained in Δ. S_Δ can be computed in time $O(nr)$ by tracing each line through $\mathcal{A}^{\shortparallel}(R)$ and P_Δ can be computed in expected time $O(m \log n)$ by locating each point of P in $\mathcal{A}^{\shortparallel}(R)$. Set $n_\Delta = |S_\Delta|$ and $m_\Delta = |P_\Delta|$. For the sake of convenience, we assume that $\mathcal{A}(S_\Delta), \mathcal{A}(S_\Delta, P_\Delta)$ are clipped within Δ, and $\mathcal{A}^{\shortparallel}(S_\Delta), \mathcal{A}^{\shortparallel}(S_\Delta, P_\Delta)$ are their vertical decompositions. Let Z_Δ denote the set of cells in $\mathcal{A}(S_\Delta)$ that intersect the vertical edges of Δ. It is well known that the number of edges in the faces in Z_Δ is $O(n_\Delta)$ [9].

Let p be a point of P_Δ. If the cell $\mathcal{A}(S_\Delta)$ containing p lies entirely in the interior of Δ, then $\mathcal{A}(S, \{p\}) = \mathcal{A}(S_\Delta, \{p\})$. Otherwise, $A(S, \{p\})$ may have edges that lie outside Δ, but each such edge lies on the boundary of faces in $Z_{\Delta'}$, $\Delta' \in A^{\shortparallel}(R)$. Hence, for each trapezoid Δ, it is sufficient to compute $\mathcal{A}(S_\Delta, P_\Delta)$ and Z_Δ. We compute $\mathcal{A}(S_\Delta, P_\Delta)$ in expected time $O((m_\Delta\sqrt{n_\Delta} + n_\Delta) \log n_\Delta)$ using Lemma 3.1. If we clip the lines of S_Δ within Δ, then Z_Δ is the unbounded face in the arrangement of the clipped segments, and we can compute it in expected time $O(n_\Delta \log n_\Delta)$ using a (simplified version of) the algorithm by Chazelle et al. [6]. Hence, the expected running time of the algorithm is

$$\mathrm{E}\left[\sum_{\Delta \in \mathcal{A}^{\shortparallel}(R)} O\left((m_\Delta\sqrt{n_\Delta} + n_\Delta) \log n_\Delta\right)\right] + O(nr) + O(m \log n)\,.$$

By a result of Clarkson and Shor [10, Theorem 3.6], we have

$$\mathrm{E}\left[\sum_{\Delta\in\mathcal{A}^{\shortparallel}(R)} n_\Delta \log n_\Delta\right] = O\left(nr\log\frac{n}{r}\right) \quad \text{and}$$

$$\mathrm{E}\left[\sum_{\Delta\in\mathcal{A}^{\shortparallel}(R)} m_\Delta\sqrt{n_\Delta}\log n_\Delta\right] = O\left(m\sqrt{\frac{n}{r}}\log\frac{n}{r}\right).$$

Thus, the expected running time of the algorithm is bounded by

$$O\left(\left(m\sqrt{\frac{n}{r}}+nr\right)\log\frac{n}{r}+m\log n\right).$$

Substituting the value r in the above expression, we obtain the following theorem.

THEOREM 3.2. *Given a set S of n lines and a set P of m points in the plane, the faces of $\mathcal{A}(S)$ containing the points of P can be computed by a randomized algorithm in expected time*

$$O\left(m^{2/3}n^{2/3}\log\frac{n}{\sqrt{m}}+(m+n)\log n\right).$$

4. Computing cells in segment arrangements. Next, we present an algorithm for computing marked cells in arrangements of segments. Let S be a set of n segments and P a set of m points in the plane. The goal is to compute $\mathcal{A}(S,P)$ and its vertical decomposition $\mathcal{A}^{\shortparallel}(S,P)$. Again, we begin with a simpler algorithm, which is effective for computing few cells, and then plug in the random-sampling technique to handle larger values of m.

The outline of the first algorithm is the same as in the previous section except that we must now interpret the operations in terms of segments. Since the cells of $\mathcal{A}^{\shortparallel}(R,P)$ are not necessarily simply connected, the boundary of m cells may consist of $m+n$ polygonal chains. Consequently, the computation of the sets of cells intersected by each segment of $S\setminus R$ in Step 4 and the computation of S_Δ for each trapezoid $\Delta\in\mathcal{A}^{\shortparallel}(R,P)$ in Step 5 now become considerably more complicated. Another difficulty in computing S_Δ is that we now have to detect intersections between simple polygons and segments rather than between convex polygons and lines. In the remainder of this section we will describe the details of Steps 4 and 5.

The boundary ∂C of each cell $C\in\mathcal{A}(R,P)$ is composed of (at most) one *outer* component and a family of *inner* components; C lies in the interior of the outer component and in the exterior of each inner component. Each component of ∂C can be regarded as a simple polygonal chain. Let $\mathcal{O}$ be the set of outer boundary components of the cells in $\mathcal{A}(R,P)$, and let $\mathcal{I}$ be the set of the inner boundary components of these cells. We have $|\mathcal{O}|\le m$ and $|\mathcal{I}|\le m+n$. Let μ be the total number of edges of all polygons in $\mathcal{O}\cup\mathcal{I}$; obviously,

$$\mu\le\eta(n/t,m)=O(m^2\log m+n\log m+n\alpha(n)); \tag{4.1}$$

the last inequality follows from a weaker result of Aronov et al. [2].

We first decompose each segment $g\in S\setminus R$ into maximal subsegments so that each subsegment lies in the interior of some outer component O. We cut each segment at the intersection points of $\mathcal{O}$ and S and discard the subsegments that lie in the exterior

of $\mathcal{O}$. Let Σ be the set of resulting subsegments. Next, for each subsegment $\sigma \in \Sigma$, we compute the trapezoids of $\mathcal{A}^{\parallel}(R, P)$ intersected by σ.

Suppose that we have already computed Σ in Step 4. Then in Step 5 we compute S_Δ, for all $\Delta \in \mathcal{A}^{\parallel}(R, P)$, as follows. We preprocess each polygonal chain $I \in \mathcal{I}$, in linear time, for ray-shooting queries, so that the first intersection point of a query ray and I can be computed in logarithmic time; see [5, 15]. The total time spent in preprocessing $\mathcal{I}$ is $O(\mu) = O(\eta(n, m))$.

Let σ be a subsegment of Σ that lies in the interior of the outer component of the boundary of a cell C. We trace σ through $C^{\parallel}$ to compute the trapezoids of $C^{\parallel}$ intersected by σ. In more detail, let a, b be the endpoints of σ, and let $\Delta(a)$ be the trapezoid of $C^{\parallel}$ containing a. If a is not an endpoint of a segment of $S \setminus R$, then a lies on the boundary of $\Delta(a)$. We check whether $b \in \Delta(a)$. If the answer is "yes," then $\Delta(a)$ is the only trapezoid of $C^{\parallel}$ intersected by σ, and we stop. If $b \notin \Delta(a)$, we compute the other intersection point, a_1, of σ and $\Delta(a)$. If a_1 lies on a vertical edge of $\Delta(a)$, we also compute, in constant time, the next trapezoid $\Delta(a_1)$ of $C^{\parallel}$ intersected by σ and repeat the same step with a_1 and $\Delta(a_1)$. If a_1, on the other hand, lies on an edge of the cell C, then a_1 lies on the boundary of some inner component $I \in \mathcal{I}$ of C, and the portion of the segment σ immediately following a_1 lies outside C. Using the ray-shooting data structure, we compute the next intersection point a_2 of the polygonal chain I and the segment $\overrightarrow{a_1 b}$. Once we know a_2, we can also compute the trapezoid of $C^{\parallel}$ containing a_2, and we continue tracing σ through $C^{\parallel}$.

For each trapezoid intersected by σ, we spend $O(\log n)$ time, so the total time spent in computing the k_σ trapezoids intersected by σ is $O(k_\sigma \log n)$. Summing over all segments of Σ, the total time spent is

$$\sum_{\sigma \in \Sigma} O(k_\sigma \log n) = O\left(\sum_{\Delta \in \mathcal{A}^{\parallel}(R,P)} n_\Delta \log n \right),$$

where $n_\Delta = |S_\Delta|$.

Next, we describe how to compute the set Σ. Notice that it is sufficient to compute all intersection points between the segments of $S \setminus R$ and the outer polygonal chains in $\mathcal{O}$.

Let $\mathcal{J}$ be the set of intervals corresponding to the x-projections of the polygonal chains in $\mathcal{O}$. We construct in time $O(m \log m)$ an interval tree T on $\mathcal{J}$; see [17] for details on interval trees. T is a minimum-height binary tree with at most $2m$ leaves, each of whose nodes v is associated with a vertical strip W_v and a point x_v; x_v is the median of the endpoints of $\mathcal{J}_v$ that lie in the interior of W_v. For the root u, W_u is the entire plane. If v, z are the children of u, then W_v and W_z are obtained by splitting W_u into two vertical strips by the vertical line passing through x_u. An interval $J \in \mathcal{J}$ is stored at the highest node v of T for which $x_v \in J$.

Let $\mathcal{O}_v \subseteq \mathcal{O}$ be the subset of polygonal chains whose projections are stored at v. Each chain belongs to exactly one $\mathcal{O}_v$. Let $Z_v = \bigcup_w \mathcal{O}_w$, where the union is taken over all descendants of v, including v; set $z_v = |Z_v|$. Finally, let ζ_v denote the total number of edges in Z_v. Since each polygonal chain of $\mathcal{O}$ appears in at most $O(\log m)$ Z_v's, we have $\sum_{v \in T} \zeta_v = O(\mu \log m)$, where μ is, as above, the total number of edges in $\mathcal{O}$. Moreover, by the construction of T, if v_1, v_2 are the children of v, then $z_{v_1}, z_{v_2} \leq z_v/2$, and therefore $\sum_{v \in T} z_v^2 = O(m^2)$.

The polygonal chains in $\mathcal{O}_v$ are pairwise disjoint and all of them intersect the vertical line passing through x_v, so we can regard $\mathcal{O}_v$ along with appropriate portions

of the vertical line as a simple polygon and preprocess it in linear time for answering ray-shooting queries. The time spent in this step is $O(\mu)$, as each polygonal chain belongs to exactly one O_v. Using this data structure, all a intersection points of a segment g and $\mathcal{O}_v$ can be reported in time $O((a+1)\log n)$.

Next, we take the convex hull of each polygonal chain in Z_v and preprocess the resulting convex polygons into a data structure, as described in the previous section, so that all convex polygons intersected by a query line can be reported quickly. Since any two polygonal chains of $\mathcal{O}$ are disjoint, the boundaries of their convex hulls intersect in at most two points and they have at most four common tangents. Consequently, the line intersection-searching structure has size $O(z_v^2+\zeta_v)$, and it can be computed in time $O(z_v^2 + z_v \log \zeta_v + \zeta_v)$, using the algorithm described in [19]. We also preprocess each $O \in \mathcal{O}$ in linear time for ray-shooting queries as in [15]. The total time spent in preprocessing $\mathcal{O}$ is therefore

$$\begin{aligned} &O\left(m\log m + \mu + \sum_v \left(z_v^2 + z_v \log \zeta_v + \zeta_v\right)\right) \\ &\qquad = O(m^2 + m\log m \log n + \mu \log m) \\ &\qquad = O((m^2 \log m + n \log m + n\alpha(n)) \log m), \end{aligned} \tag{4.2}$$

where the last inequality follows from (4.1).

Let $g \in S \setminus R$ be a segment. All intersection points of g and $\mathcal{O}$ can be computed as follows. We search the tree T with g starting from the root. Let v be a node visited by the query procedure. We need to compute the intersection points of g and the polygonal chains in Z_v. If the endpoints of g do not lie in the vertical strip W_v, that is, g completely crosses W_v, then g intersects a polygonal chain $O \in Z_v$ if and only if the line supporting g intersects the convex hull of O. Thus, we first compute all polygonal chains of Z_v intersected by the line supporting g, using the line intersection-searching structure, and then, for each $O \in Z_v$ intersected by g, we compute the intersection points of g and O using the ray-shooting data structure. If a is the number of intersection points between g and the polygonal chains of Z_v, then the total time in reporting these intersections is $O((a+1)\log n)$. If, on the other hand, one of the endpoints of g lies in W_v, we can compute all b intersection points between $\mathcal{O}_v$ and g in time $O((b+1)\log n)$ using the ray-shooting data structure for $\mathcal{O}_v$. Let v_1, v_2 be the children of the node v. If g intersects W_{v_1} (resp., W_{v_2}), we recursively visit v_1 (resp., v_2).

It is easily seen that the query procedure visits $O(\log m)$ nodes and that the query time is $O((\log m + k_g)\log n)$, where k_g is the total number of intersection points reported. We repeat this procedure for all segments $g \in S \setminus R$. Since

$$\sum_{g \in S\setminus R} k_g \;\le\; \sum_{\Delta \in \mathcal{A}^{\shortparallel}(R,P)} n_\Delta\,,$$

the total cost of computing the intersection points between $S \setminus R$ and $\mathcal{O}$ is

$$\sum_{g\in S\setminus R} O((\log m + k_g)\log n) = O\left(n \log m \log n + \sum_{\Delta \in \mathcal{A}^{\shortparallel}(R,P)} n_\Delta \log n\right).$$

The expected value of $\sum_\Delta n_\Delta$ is $\eta(r,m)O(n/r) = O(\eta(r,m))$; therefore we obtain

$$\sum_{g\in S\setminus R} O((\log m + k_g)\log n) = O(n\log m \log n + \eta(r,m)\log n). \tag{4.3}$$

As in the previous section, the time spent in step 6 (refining the cells of $\mathcal{A}^{\shortparallel}(R,P)$) is $O(\sum_\Delta n_\Delta^2)$. Using Proposition 2.1 (ii), we obtain that

$$\mathrm{E}\left[\sum_\Delta n_\Delta^2\right] = \eta(r,m)O((n/r)^2) = O(\eta(r,m)). \tag{4.4}$$

Summing (4.2), (4.3), and (4.4), and using the fact that $m \le n^2$, the total expected time spent in the merge step is $O((m^2\log m + n\log m + n\,\alpha(n))\log n)$.

This gives the following recurrence for $T(n,m)$ (the maximum expected running time):

$$T(n,m) \le \begin{cases} c_1 \quad \text{if } n \le n_0, \\ \displaystyle\sum_{i=1}^{\sqrt{t}} T\left(\frac{n}{t}, m_i\right) + O((m^2\log m + n\log m + n\,\alpha(n))\log n) \quad \text{if } n > n_0, \end{cases}$$

where $m_i \le m/\sqrt{t}$ for all $i \le \sqrt{t}$. The solution of this recurrence is

$$T(n,m) = O((m^2\log m + n\log m + n\alpha(n))\log n).$$

Hence, we can conclude that the expected running time of the overall algorithm for computing $\mathcal{A}(S,P)$ is

$$O\left((m^2\log m + n\log m + n\,\alpha(n))\log n\right).$$

We can again use the same batching technique if m is large. That is, partition P into groups of size $\sqrt{n}$ and solve the subproblems separately. Omitting the details, we obtain the following lemma.

LEMMA 4.1. *Given a set S of n segments and a set P of m points in the plane, the faces of $\mathcal{A}(S)$ that contain at least one point of P can be computed by a randomized algorithm in expected time $O\left((m\sqrt{n}\log n + n\log m + n\alpha(n))\log n\right)$.*

For larger values of m, we again use the random-sampling technique as in the previous section. That is, we choose a random subset $R \subseteq S$ of size $r = \lceil m^{2/3}/n^{1/3}\rceil$ and compute $\mathcal{A}^{\shortparallel}(R)$. For each $\Delta \in \mathcal{A}^{\shortparallel}(R)$, we compute $P_\Delta = P \cap \Delta$ and S_Δ, the set of segments that intersect Δ. We clip the segments within Δ. The total expected time spent in this step is $O(r^2 + (m+nr)\log r)$. Let z be a point lying in the unbounded face of $\mathcal{A}(S)$. For each $\Delta \in \mathcal{A}^{\shortparallel}(R)$, we compute $\mathcal{A}^{\shortparallel}(S_\Delta, P_\Delta \cup \{z\})$, in expected time

$$O((m_\Delta\sqrt{n_\Delta}\log m_\Delta + n_\Delta\log m_\Delta + n_\Delta\alpha(n_\Delta))\log n_\Delta),$$

using Lemma 4.1, and then glue these faces together. The overall expected running time of the algorithm is

$$\mathrm{E}\left[\sum_{\Delta\in\mathcal{A}^{\shortparallel}(R)} O((m_\Delta\sqrt{n_\Delta}\log n_\Delta + n_\Delta\alpha(n_\Delta) + n_\Delta\log m_\Delta)\log n_\Delta)\right] + O((m+nr)\log r)\,. \tag{4.5}$$

Again, using the results by Clarkson–Shor [10], we have

$$\mathrm{E}\left[\sum_{\Delta\in\mathcal{A}^{\shortparallel}(R)} m_\Delta\sqrt{n_\Delta}\log n_\Delta\right] = O\left(m\sqrt{\frac{n}{r}}\log\frac{n}{r}\right) \tag{4.6}$$

$$\sum_{\Delta\in\mathcal{A}^{\shortparallel}(R)} n_\Delta = \mathrm{E}\left[|\mathcal{A}^{\shortparallel}(R)|\right]O\left(\frac{n}{r}\right) = O(nr). \tag{4.7}$$

Substituting (4.5), (4.6), and the value of r in (4.7), we obtain the following theorem.

THEOREM 4.2. *Given a set S of n segments and a set P of m points in the plane, the faces of $\mathcal{A}(S)$ that contain a point of P can be computed by a randomized algorithm in expected time*

$$O\left(m^{2/3}n^{2/3}\log^2\frac{n}{\sqrt{m}} + (m + n\log m + n\,\alpha(n))\log n\right).$$

Finally, we remark that if $\mathcal{A}(S)$ has only $k = o(n^2)$ vertices, then using the fact that the expected number of trapezoids in $\mathcal{A}^{\|}(R)$ is $O(kr^2/n^2 + r)$ we can obtain a better bound on the expected running time of the algorithm. In particular, choosing $r = \lceil n(m/k)^{2/3}\rceil$ and using (4.4), (4.5), it can be shown that the expected running time of the algorithm is

$$O\left(m^{2/3}k^{1/3}\log^2\frac{k}{m} + (m + n\log m + n\,\alpha(n))\log n\right).$$

Acknowledgments. The authors thank Mark de Berg, Mark Overmars, and Micha Sharir for several useful discussions. The comments by an anonymous referee helped improve the presentation of the paper.

FAULT-TOLERANT COMPUTATION IN THE FULL INFORMATION MODEL*

ODED GOLDREICH†, SHAFI GOLDWASSER‡, AND NATHAN LINIAL§

Abstract. We initiate an investigation of general fault-tolerant distributed computation in the *full-information* model. In the full information model no restrictions are made on the computational power of the faulty parties or the information available to them. (Namely, the faulty players may be infinitely powerful and there are no private channels connecting pairs of honest players).

Previous work in this model has concentrated on the particular problem of simulating a single bounded-bias global coin flip (e.g., Ben-Or and Linial [*Randomness and Computation*, S. Micali, ed., JAI Press, Greenwich, CT, 1989, pp. 91–115] and Alon and Naor [*SIAM J. Comput.*, 22 (1993), pp. 403–417]). We widen the scope of investigation to the general question of how well arbitrary fault-tolerant computations can be performed in this model. The results we obtain should be considered as first steps in this direction.

We present efficient two-party protocols for fault-tolerant computation of any bivariate function. We prove that the advantage of a dishonest player in these protocols is the minimum one possible (up to polylogarithmic factors).

We also present efficient m-party fault-tolerant protocols for sampling a general distribution ($m \geq 2$). Such an algorithm seems an important building block towards the design of efficient multiparty protocols for fault-tolerant computation of multivariate functions.

Key words. fault-tolerant multiparty protocols, influences in general two-party computations, sampling with weak sources of randomness

1. Introduction.

The problem of how to perform general distributed computation in an unreliable environment has been extensively addressed. Two types of models have been considered. The first model assumes that one-way functions exist and considers adversaries (faults) which are computationally restricted to probabilistic polynomial time [24, 13, 25, 14, 11, 2]. The second model postulates that private channels exist between every pair of players [3, 7, 8, 17, 15]. Hence, in both models fault-tolerance is achieved at the cost of restricting the type of faults.

We want to avoid any such assumption and examine the problem of fault-tolerant distributed computation where the faults are computationally unrestricted, and no private channels are available. Clearly, the assumption that one-way functions exist is of no use here. The situation here corresponds to games of complete information.

The general problem can be described informally as follows: m players are interested in globally computing $v = f(x_1, \ldots, x_m)$, where f is a predetermined m-variate function and x_i is an input given to party i (and initially known only to it). The input x_i is assumed to have been drawn from probability distribution D_i (which without loss of generality can be assumed to be uniform). A coalition F of faulty players may

favor a particular value v for f and play any strategy to maximize the probability of such an outcome. We want to bound, for each value v in the range of f, the probability (under the best strategy for the faults) that the outcome of the protocol used to distributively compute f is v. How good can this bound be?

Regardless of the protocol under consideration, there is always one avenue that is open for the faulty players, namely, alter their input values to ones under which the value v is most likely. This is always possible, since players' inputs are not visible to others. That is,

$$q_v := \max_{x_i, i \in F} \{\text{Prob}(f(\vec{x}) = v \text{ where } x_j \in_R D_j, j \notin F)\}$$

is a lower bound on the influence of coalition F towards value v, no matter what protocol is used.

Consider the simple procedure in which each player announces its x_i, and the global output is taken to be $f(x_1, \ldots, x_m)$. If all players (including the faulty ones) act simultaneously, then for every v, the probability of v being the outcome is indeed at most q_v. Unfortunately, in a distributed network simultaneity cannot be guaranteed, and a delayed action by the faults can result in much better performance for them (e.g., for $f = \sum_{i=1}^{m} x_i \bmod N$ with $x_i \in \{0, 1, \ldots, N-1\}$, $q_0 = \frac{1}{N}$, but a single faulty player acting last has complete control of the outcome).

In both of the previously studied models (private channels or computationally bounded faults) protocols were developed where for all values v and all *minority* coalitions F, the probability of outcome v is as close to q_v as desired. The key to these protocols is the notion of *simultaneous commitment*. At the outset of these protocols, each player P_i commits to its input x_i. It should be stressed that a faulty party may alter its input in this "committing phase" but not later and that a party's commitment is "independent" of the inputs of the other honest parties.

Obviously, in the full-information model such a qualitative notion of commitment cannot be implemented (even if the faulty parties are in minority). Instead, we need to look for *quantitative* results. Faulty players can and will be able to "alter their inputs" throughout the execution of the protocol in order to influence the outcome. Yet, we can bound the advantage gained by their improper behavior.

1.1. Results concerning the two-party case. The main focus of this paper is on the two-player case of this problem. Even this restricted case provides interesting problems and challenges. We resolve the main problems in this case, showing:

1. A lower bound: for every bivariate function f, for any protocol to compute f, and every value v in the range of f, there is a strategy for one of the players, so that if the other player plays honestly, then the probability for the outcome $f = v$ is at least $\max(q_v, \sqrt{p_v})$, where $p_v = \text{Prob}(f(\vec{x}) = v | x_i \in_R D_i))$.
2. More interestingly, we show a matching (up to polylogarithmic factor) constructive upper bound. We describe a probabilistic polynomial-time protocol that computes f, given a single oracle access to f, such that for all v,

$$Pr(f \text{ evaluates to } v) = O(\text{poly}\log(1/p_v) \cdot \max(q_v, \sqrt{p_v})).$$

   In the special case where $q_v = p_v$, this protocol is shown to match the lower bound up to a constant factor. Namely,

$$Pr(f \text{ evaluates to } v) = O(\sqrt{p_v}).$$

The spirit of our protocol is best illustrated by the following example.

Example. Define $id(x,y)=1$ if $x=y$ and 0 otherwise. Suppose that the local inputs x,y are chosen uniformly in $\{0,1\}^n$. Clearly, $p_1=\frac{1}{N}$, and $p_0=1-\frac{1}{N}$, where $N=2^n$. A protocol in which the first player declares x and then the second player declares y allows the second player complete control on the value of id. A protocol in which the two players alternately exchange bits in the description of their inputs is no better if these bits are exchanged in the same order (i.e., both parties send their respective ith bit in round i). A much better idea is for the two players to alternate in describing the bits of their inputs but do so from opposite directions (i.e., in round i the first party sends its ith bit, whereas the second party sends its $(n-i+1)$st bit). Clearly, whichever player is faulty, the probability that the outcome of this protocol is "1" is bounded by $\frac{1}{\sqrt{N}}$. In light of the lower bound, this is the best result possible. This idea of gradually revealing appropriately chosen "bits of information" is the key to the general problem of two-party computation.

1.2. Results concerning the multiparty case. The problem of m-party computations, where a subset of $t<m$ faults may exist, is more involved than the two-party case (even for $m=3$); see discussion in section 5. Here, we only consider the problem of collectively sampling a given distribution. Without loss of generality, it suffices to consider the uniform distribution (say, on strings in $\{0,1\}^l$). We provide a probabilistic polynomial-time sampling protocol such that for every $S\subset\{0,1\}^l$, for every t faults,

$$\Pr(\text{sample } \in S) < \left(\frac{|S|}{2^l}\right)^{1-c\cdot\frac{t}{m}}$$

for some constant $c>0$. This result is the best possible (up to the constant c), and is superior to the bound obtained by the trivial protocol which consists of l repeated applications of "collective coin flipping"; consider, for example, the set S consisting of all strings having at least $(\frac{1}{2}+\frac{t}{m})\cdot l$ ones; under the trivial protocol, t faulty parties can influence the output to almost always hit S, whereas our result guarantees that this set S which forms a negligible fraction of $\{0,1\}^l$ is hit with negligible probability (for, say, $t<m/2c$).[1]

The above sampling protocol can be used to present a (generic probabilistic polynomial-time) protocol that works well for computing *almost all* functions (see our technical report [12]).

1.3. Previous work in the full-information model. Previous work in this model [4, 5, 16, 1] has focused on the task known as *collective coin flipping*, which in our terminology amounts to fault-tolerant multiparty sampling in $\{0,1\}$. Matching lower and (constructive) upper bounds of $\frac{1}{2}+\theta(\frac{t}{m})$ have been shown (by Ben-Or and Linial [4] and Alon and Naor [1],[2] respectively). Our work can be viewed as an extension of these investigations which were concerned with the influences of players on *Boolean* functions (i.e., $Range(f)=\{0,1\}$). The general case considered in this paper gives rise to additional difficulties. Let us stress that even the problem of sampling in arbitrary sets is more difficult than collective coin flipping. As mentioned above, the obvious approach to the sampling problem fails; namely, a sampling protocol that

[1] Using the above choice of parameters, we have a set S of density $\rho\approx\exp\{-(t/m)^2\cdot l\}$ which our protocol hits with probability at most $\sqrt{\rho}$, as long as at most t players are faulty. On the other hand, when repeated collective coin flippings are used, t faulty players can influence the outcome to be in S with probability at least $1-\rho$, by biasing each coin flip toward 1.

[2] Furthermore, the upper bound can be met by protocols of logarithmic round-complexity [9, 19].

consists of repeatedly applying a given coin-tossing protocol can be easily influenced to almost always output strings in a subset of negligible size.[3]

However, fault-tolerant computation (of arbitrary functions) is more complex than sampling, which can be viewed as fault-tolerant computation of a function specially designed for this purpose.

1.4. Relation to work on slightly random sources. In this paper we present a multiparty protocol for sampling a set of strings $\{0,1\}^l$. In "sampling" we mean producing a single string in $\{0,1\}^l$ so that, for every subset $S \subset \{0,1\}^l$, the probability that the sample hits S is related to the density of S. Our protocol uses the collective coin flipping of [1] as a subroutine. In fact, our sampling protocol can be viewed as a deterministic reduction to the problem of collective coin tossing. The collective coin can be viewed as a slightly random source in the sense of Santha and Vazirani [22], i.e., an *SV-source*.[4] Hence, our result can be interpreted as presenting a sampling algorithm which uses an SV-source (with a parameter $\gamma < \frac{1}{\sqrt{2}}$). Our sampling algorithm performs much better than the obvious algorithm which uses as a sample a sequence of coins produced by the source. (The situation is analogous to the discussion of the multiparty sampling protocols above.)

Our sampling algorithm provides an alternative way of recognizing languages in BPP by polynomial-time algorithms which use an SV-source with a parameter $\gamma < \frac{1}{\sqrt{2}}$. First, reduce the error probability in the BPP-algorithm so that it is bounded by a sufficiently small constant. Next, use our sampling algorithm to produce a sequence of coin tosses for a *single run* of the new BPP-algorithm. Since the "bad runs" form a negligible fraction of all possible runs of the BPP-algorithm, it follows that the probability we will sample a bad run (when using an SV-source with parameter $\gamma < \frac{1}{\sqrt{2}}$) is bounded by $\frac{1}{3}$. This simulation method is different from the original method of Vazirani and Vazirani [23] (adopted also in [6]) where the BPP-algorithm is invoked *many* times, each time with a different sequence of coin tosses.

1.5. Other related work. We also present efficient sampling protocols for the two-party case. The basic sampling protocol guarantees, for every set $S \subseteq \{0,1\}^l$, that as long as one party is honest the output hits S with probability at most $O(\sqrt[4]{|S|/2^l})$. (The basic sampling protocol is essential for efficiently implementing our generic two-party function-computation protocol. Interestingly, the basic sampling protocol is also used as a building block for a better sampling protocol, which is optimal up to a constant factor.)

Our basic two-party sampling protocol is very similar to a protocol, called interactive hashing, which was discovered independently by Ostrovsky, Venkatesan, and Yung [20] (see Naor et al. [18]). Interactive hashing has found many applications in cryptography (cf. [20, 18, 21, 10]). For details see Remark 4.26.

1.6. Organization. We start with some preliminaries (section 2) and lower bounds (section 3). The main part of this paper is section 4, which presents efficient fault-tolerant two-party protocols. The construction of fault-tolerant multiparty protocols is discussed in section 5.

[3] An alternative method which also fails is to try to generalize the work of Alon and Naor [1] as follows: The method of [1] consists of randomly selecting one of the players who is appointed to flip a fair coin. Letting this player select a random string is a natural idea, but it is obvious that this approach performs very poorly for a sample space of nonconstant size. Specifically, each set $S \subset \{0,1\}^l$ can be hit with probability at least $\frac{t}{m}$, independently of S and l.

[4] An SV-source with parameter γ is a sequence of binary random variables $X_1, X_2, \ldots$, so that for every n, $\alpha \in \{0,1\}^n$ and $\sigma \in \{0,1\}$, $\text{Prob}(X_{n+1}=\sigma | X_1, \ldots, X_n = \alpha) \leq \gamma$.

2. Preliminaries. In this section, we present our conventions regarding functions and protocols. We also explain what we mean when we talk of influence and sampling.

2.1. Bivariate functions. Throughout the paper we represent the bivariate function $f:\{0,1\}^n\times\{0,1\}^n\mapsto\{0,1\}^*$ as an N-by-N matrix, where $N\stackrel{\text{def}}{=}2^n$. An entry, (x,y), in the matrix which has value v (i.e., $f(x,y)=v$) is called a *v-entry*. The following quantities, related to the function f and a value v in its range, are central to our analysis.

Notation. The *density of* v, denoted p_v, is the fraction of v-entries in the matrix of f (i.e., $p_v=|\{(x,y):f(x,y)=v\}|/2^{2n}$). The *maximum row density of* v, denoted r_v, is the maximum, taken over all rows, of the fraction of v-entries in a row of f (i.e., $r_v=\max_{x\in\{0,1\}^n}\{|\{y:f(x,y)=v\}|/2^n\}$). The *maximum column density of* v is denoted $c_v=\max_{y\in\{0,1\}^n}\{|\{x:f(x,y)=v\}|/2^n\}$, and q_v is defined as $\max\{r_v,c_v\}$.

Throughout the paper, we consider the case of uniform input distribution. Namely, we assume that each input is selected uniformly from $\{0,1\}^n$ and independently of the other input(s). The more general case, where each input is selected from an arbitrary distribution (yet independently of the other inputs) can be reduced to the uniform case as follows. Suppose that the probability for each input can be expressed as $\frac{q}{2^{\text{poly}(n)}}$, where q is an integer (for some polynomial poly). Then we can replace this input, say z, by q inputs, denoted $(z,1),(z,2),\ldots,(z,q)$, and consider the function $F((x,i),(y,j))\stackrel{\text{def}}{=}f(x,y)$ $(1\le i\le\phi(x)2^{\text{poly}(n)}$ and $1\le j\le\psi(y)2^{\text{poly}(n)}$, where $\phi(x)$ is the probability of the row-input x and $\psi(y)$ is the probability of the column-input y). Protocols for computing F (under the uniform distribution) translate easily to protocols for computing f (under the distribution (ϕ,ψ)) and vice versa. To efficiently transform protocols for computing F into protocols for computing f, an efficient algorithm is needed for computing the original density functions (i.e., ϕ and ψ).

2.2. Protocols. The communication model consists of a single broadcast channel. Each party can, at any time, place a message on this channel which arrives immediately (bearing the identity of its originator) to all other parties. It is not possible to impose "simultaneity" on the channel; namely, the protocols may not contain a mechanism ensuring simultaneous transmission of messages by different parties. Thus, it is best to think of the model as being asynchronous and of the protocols as being message-driven. However, asynchronicity is not a major issue here as all parties share the unique communication medium and thus have the same view.

The output of an execution of a protocol is defined as the last message sent during the execution. We consider the output of the protocol when the inputs are selected uniformly.

We call a player *honest* if it follows the protocol. *Dishonest* players may deviate arbitrarily from the protocol. In discussing our protocols we assume, without loss of generality, that dishonest players do not deviate from the protocol in a manner which may be detected. This assumption can be easily removed by augmenting our protocols with simple detection and recovery procedures (which determine the output of the protocol in case deviation from the protocol is detected). For example, the protocol may be restarted with the input of the cheating party fixed to some predetermined value and all its actions being simulated by the other parties.

All our protocols are *generic*: Players are instructed to take steps that depend only on their inputs, but not on the function f. When the inputs are finally revealed, f is evaluated once, and the protocol terminates.

2.3. Influences. Unlike previous work, we use the term "influence" in a colloquial manner. Typically, by talking "the influence of a party towards a value" we mean the probability that this party can make this value appear as output of the protocol. When discussing the computation of functions, we treat only the influence towards a single value; the influence towards a set of values can be treated by defining a corresponding indicator function.

2.4. Sampling. We also consider the problem of designing two-party and multiparty protocols for sampling in a universe $\{0,1\}^l$. The objective here is to provide upper bounds for the probability that the output falls in some subset $S \subset \{0,1\}^l$. We note that the problem of designing a two-party protocol for sampling $\{0,1\}^l$ can be reduced to the problem of designing a protocol for computing any function $f : \{0,1\}^n \times \{0,1\}^n \mapsto \{0,1\}^l$ for which all values have the same density and this density equals the maximum row/column densities (i.e., $q_v = p_v = 2^{-l}$ for every $v \in \{0,1\}^l$). An analogous reduction holds also in the multiparty case.

3. Lower bounds. In this section we present lower bounds which will guide our search for the best possible fault-tolerant protocols.

THEOREM 3.1. *Let $f : D_1 \times D_2 \times \cdots \times D_m \mapsto R$ be a function of m variables, Π an m-party protocol for computing f, and $v \in R$ a value in the range of f. Consider performing Π where players in the set S are dishonest, while all other players are honest. Let ϕ_S be the maximum, over all strategies of coalition S of the probability of the outcome being v. Then, for any $1 \le t \le m$ there is a coalition Q of t players with $\phi_Q \ge p_v^{1-\frac{t}{m}}$.*

In particular, we have the following result.

COROLLARY 3.2. *Let f be any bivariate function, Π any two-party protocol for computing f, and v a value in the range of f. Then at least one of the players can, by playing (possibly) dishonestly, force the outcome to be v with probability at least $\max\{q_v, \sqrt{p_v}\}$ (the other party plays honestly).*

Proof of Theorem 3.1. The proof is very similar to that of Theorem 5 in [4], although some changes are required. One observes first that if the time complexity of the protocol is no issue, and the only consideration is to keep influences down, then nothing is lost if all actions are taken sequentially and not in parallel. Therefore, Π can be encoded by a tree T as follows: leaves of T are marked with values in the range of f, and each internal node of T is marked with a name of a player. The run of Π starts at the root of T. Whenever an internal node is reached, player P_i, whose name marks that node, is to take the next step. For each input value in D_i, the protocol Π specifies a probability distribution according to which the next node, a child of the present one, is selected (assuming P_i is honest). The key observation, beyond the technique of [4], is that these distributions (together with the input distribution over D_i) induce a single distribution for the next move of (honest) player i, conditioned on the execution having reached the present node. The outcome of this process is determined by the leaf it reaches (i.e., $f = u$, where u is the mark of the leaf that is reached).

For the analysis, let z be an internal node of T, and consider the same process as above, performed on the subtree of T rooted at z. Suppose that coalition S plays its best strategy to make the outcome $f = v$ most likely, and let $\phi_S^{<z>}$ be that maximum probability (clearly, when z is taken to be the root of T, then $\phi_S^{<z>} = \phi_S$). The key step in the proof is to establish the following inequality for every internal z:

$$\prod_{|R|=t} \phi_R^{<z>} \ge p_{v,z}^{\binom{m-1}{t}}, \tag{1}$$

where $p_{v,z}$ is the probability of reaching a v-marked leaf on that subtree, when all players are honest. Extracting the $\binom{m}{t}$th root of the above inequality, we get $\max_{|R|=t} \phi_R^{<z>} \geq p_{v,z}^{(m-t)/m}$. Taking z to be the root of T the theorem follows.

Inequality (1) is proven by induction on the distance from the leaves in T. In the induction step, we assume that the inequality holds for the children of an internal node z and derive the inequality for node z. Let I denote the set of edges emanating from z and let $\{z_i : i \in I\}$ denote the corresponding children. Suppose, without loss of generality, that node z is marked by player 1. The protocol Π and the probability distributions on the sets D_i determine the probabilities, $\{\lambda_i > 0 : i \in I\}$, governing the player's next move provided that the player is honest and conditioned on the execution having reached node z. (This distribution may not be easy to determine, but we only need to know that it exists.) Now, clearly $p_{v,z} = \sum_{i \in I} \lambda_i p_{v,z_i}$ and $\phi_R^{<z>} = \sum_{i \in I} \lambda_i \phi_R^{<z_i>}$, for every coalition R that does not contain player 1. On the other hand, for every coalition R which does contain player 1, we have $\phi_R^{<z>} = \max_{i \in I} \phi_R^{<z_i>}$. Now, denoting $\phi_R^{<z_i>}$ by $a_{i,R}$ (where $R \subseteq [m]$, $|R| = t$) and p_{v,z_i} by b_i, the inductive step reduces to proving the following numerical lemma, which in turn is a generalization of Lemma 5.3 in [4].

LEMMA 3.3. *Let I be a finite set, let $\{a_{i,R} : i \in I, R \subseteq [m], |R| = t\}$, $\{b_i : i \in I\}$ be nonnegative reals, let $\{\lambda_i : i \in I\}$ be positive with $\sum_{i \in I} \lambda_i = 1$, and assume that for every $i \in I$,*

$$\prod_{R \subseteq [m], |R|=t} a_{i,R} \geq b_i^{\binom{m-1}{t}}.$$

Furthermore, let α_R equal $\max_{i \in I} a_{i,R}$ if $1 \in R$ and $\sum_{i \in I} \lambda_i a_{i,R}$ otherwise. Also, let $\beta = \sum_I \lambda_i b_i$. Then,

$$\prod_{R \subseteq [m], |R|=t} \alpha_R \geq \beta^{\binom{m-1}{t}}.$$

Lemma 5.3 in [4] is a special case of Lemma 3.3 (in which $|I| = 2$ and $\lambda_1 = \lambda_2 = \frac{1}{2}$). However, the ideas presented in the proof of Lemma 5.3 in [4] suffice for proving the general case. In fact, we further generalize Lemma 3.3.

LEMMA 3.4. *Let J, K, and I be disjoint finite sets, let $\{a_{i,j} | i \in I, j \in J \cup K\}$, $\{b_i | i \in I\}$ be nonnegative reals, let $\{\lambda_i | i \in I\}$ be positive, with $\sum_{i \in I} \lambda_i = 1$, and assume that for every $i \in I$,*

$$\prod_{j \in J \cup K} a_{i,j} \geq b_i^{|K|}.$$

For every $j \in J$, let α_j equal $\max_{i \in I} a_{i,j}$ and for every $k \in K$, let $\alpha_k = \sum_{i \in I} \lambda_i a_{i,k}$. Also $\beta = \sum_I \lambda_i b_i$. Then,

$$\prod_{j \in J \cup K} \alpha_j \geq \beta^{|K|}.$$

Lemma 3.3 follows from Lemma 3.4 by letting J be the set of all t-subsets of $[m]$ which contain the element 1 and K be the set of all t-subsets which do not contain 1.

Proof of Lemma 3.4. There is, of course, no loss in assuming

$$b_i = \left(\prod_{j \in J \cup K} a_{i,j} \right)^{1/|K|}$$

for every $i \in I$. Fix all $a_{i,j}$ (over all $i \in I, j \in J$) as well as all $a_{i,k}$ (all $i \in I, k \in K \setminus \{k_1, k_2\}$). Now consider the minimum of $(\sum_{i\in I} \lambda_i a_{i,k_1})(\sum_{i\in I} \lambda_i a_{i,k_2})$ subject to the condition that $a_{i,k_1} \cdot a_{i,k_2}$ are fixed, for all i. A simple calculation with Lagrange multipliers shows that the vectors $(a_{i,k_1}|i \in I)$ and $(a_{i,k_2}|i \in I)$ are proportionate. In other words, there is a nonnegative vector $(u_i|i \in I)$ and nonnegative constants $\rho_k (k \in K)$ such that $a_{i,k} = \rho_k \cdot u_i$ for every $i \in I, k \in K$. Multiply by λ_i and sum over $i \in I$ to conclude that for any $k \in K$, $\alpha_k = \rho_k \sum_I \lambda_i u_i$. We can write now, for every $i \in I$:

$$\left(\prod_{j\in J} \alpha_j\right)^{1/|K|} = \left(\prod_{j\in J} (\max_{i\in I} a_{i,j})\right)^{1/|K|} \geq \left(\prod_{j\in J} a_{i,j}\right)^{1/|K|}$$

and,

$$\left(\prod_{k\in K} \rho_k\right)^{1/|K|} u_i = \left(\prod_{k\in K} a_{i,k}\right)^{1/|K|}.$$

So, for every $i \in I$,

$$\left(\prod_{j\in J} \alpha_j\right)^{1/|K|} \left(\prod_{k\in K} \rho_k\right)^{1/|K|} u_i \geq \left(\prod_{j\in J\cup K} a_{i,j}\right)^{1/|K|} = b_i. \tag{2}$$

Multiply equation (2) by $\rho_t \lambda_i$, sum over $i \in I$, and use $\alpha_t = \rho_t \sum_{i\in I} \lambda_i u_i$ and $\beta = \sum_{i\in I} \lambda_i b_i$, to conclude that for every $t \in K$,

$$\left(\prod_{j\in J} \alpha_j\right)^{1/|K|} \left(\prod_{k\in K} \rho_k\right)^{1/|K|} \alpha_t \geq \rho_t \cdot \beta.$$

Now multiply over all $t \in K$ to get the desired conclusion. □

4. Two-party protocols. In this section we present protocols which meet the lower bounds presented in section 3, up to a polylogarithmic factor. We first present a general framework for the construction of such protocols (subsection 4.1), argue that this framework does indeed yield protocols meeting the lower bound (subsection 4.2), and finally use the framework to present *efficient* protocols meeting the lower bound (subsection 4.3).

Without loss of generality, we assume throughout that every value v in the range of f appears in each row and column in the matrix of f at least $\frac{p_v}{4} \cdot 2^n$ times. If some row or column has too few occurrences of v, we'd like to augment them, without a significant increase in q_v. This can be done as follows: Let $(A_1, \ldots, A_k)$ be a partition of $\{1, \ldots, 2^n\}$, where each A_i has cardinality between $\frac{p_v}{4} \cdot 2^n$ and $\frac{p_v}{2} \cdot 2^n$. It is easy to see that by changing some elements within the $A_i \times A_i$ minors of the matrix to v, it is possible to guarantee that v-values have density $\geq \frac{p_v}{4}$ in every row and column without increasing the largest density in any row or column beyond $q_v + \frac{p_v}{4} = O(q_v)$.

Also, without loss of generality, we assume $p_v \leq 1/2$ (otherwise, the claims hold vacuously).

4.1. Framework for protocols meeting the lower bounds. The goal of the protocol is to enable the parties to gradually reveal their inputs to each other, without granting any party a substantial influence on the value of f.

The protocol proceeds in rounds, each consisting of two steps. In each step one party sends one bit of information about its input to the other party. In the next step the other party sends such a bit. The bits sent by each party specify in which side, of a bipartition of the residual input space, its actual input lies. These partitions must satisfy some "value-balance" properties to be discussed below. Following is the code of the *generic protocol*.

> *Inputs:* $x \in X_0 \stackrel{\text{def}}{=} \{0,1\}^n$ for the row player, $y \in Y_0 \stackrel{\text{def}}{=} \{0,1\}^n$ for the column player.
>
> *Round i:* Let (X^0_{i-1}, X^1_{i-1}) be a partition of X_{i-1}, and (Y^0_{i-1}, Y^1_{i-1}) a partition of Y_{i-1}.
>
> The row player sends $\sigma \in \{0,1\}$ such that $x \in X^\sigma_{i-1}$. Let $X_i \stackrel{\text{def}}{=} X^\sigma_{i-1}$.
>
> The column player sends $\sigma \in \{0,1\}$ such that $y \in Y^\sigma_{i-1}$. Let $Y_i \stackrel{\text{def}}{=} Y^\sigma_{i-1}$.
>
> *Output:* When both residual sets become singletons (i.e., $|X_t| = |Y_t| = 1$ after round t) the protocol terminates and the output is defined as $f(x,y)$, where $X_t = \{x\}$ and $Y_t = \{y\}$).

The reader may think of the partitions as splitting the current set evenly and, in fact, this is almost the case as asserted in Property (P0). In such a case, the protocol terminates after n rounds. For the protocol to achieve its goal (of minimizing the advantage of each party), it employs bipartitions satisfying various (additional) *value-balance* properties. There will be several different types of value-balance properties all sharing the following features, and being applied to both row partitions and column partition. A typical row-partition property (resp., column-partition property) requires that a subset of the rows (resp., columns), specified by some pattern of v-entries, is split almost evenly between the two sides of the partition. For example, Property (P1) below (regarding column-partitions) requires that, for each row, the set of columns containing a v-entry in this row is split almost evenly.

We will introduce the various properties in an ad-hoc manner, each property being introduced just where it becomes essential for analyzing the generic protocol. Thus, at the end of this subsection, we will have a set of properties and a proof that if the protocol utilizes only partitions having these properties, then the advantage of both parties is bounded as claimed in the introduction. The question of whether such partitions exist will be ignored altogether in the current subsection but will be the focus of the next subsection, whereas the third subsection shows how to efficiently generate "pseudorandom" partitions which satisfy these properties.

4.1.1. Motivation to the analysis of the protocol. In analyzing the influence of a dishonest party we consider, without loss of generality, the probability that the row player (following an arbitrary adversarial strategy) succeeds in having the protocol yield a particular value v (in the range of f). For simplicity, we consider first the special case where $q_v = p_v$. In this case there are exactly $K \stackrel{\text{def}}{=} p_v \cdot N$ entries of value v in each row of the matrix. The analysis proceeds in three stages:

> *Stage* 1. Consider the first $\log_2 K$ rounds. If every column (resp., row) partition employed halves the number of v-entries in each row (resp., column), then at the end of this stage the residual $1/p_v$-by-$1/p_v$ matrix contains a single v-entry in each row (resp., column), thus preserving the density of v-entries in each row and column. Using a v-balance property of the partitions called (P1), we show that this is roughly the situation (see Corollary 4.6).

Stage 2. Consider the next $\frac{1}{2} \cdot \log_2(1/p_v)$ rounds. If each row (resp., column) partition employed halves the number of v-entries in the residual matrix, then at the end of this stage the residual $\frac{1}{\sqrt{p_v}}$-by-$\frac{1}{\sqrt{p_v}}$ matrix contains a single v-entry, thus preserving the density of v-entries. Using a v-balance property of the partitions called (P2), we show that this is roughly the situation (see Lemma 4.7).

Stage 3. At the last $\frac{1}{2} \cdot \log_2(1/p_v)$ rounds the row player can force the outcome to be v only if the input of the column player is a column containing a v-entry. The probability that the input column of the column player contains a v-entry does not exceed $\Delta \cdot \sqrt{p_v}$, where Δ is the number of v-entries at the outset of this stage.

4.1.2. Preliminaries. All value-balance properties are geared to guarantee an "almost even split" of certain sets. This is quantified in the following definition with bounds that depend on the size of the set to be split. The size ranges are parameterized by b. For sets smaller than b we require nothing. For sets larger than b^4 we require sublinear discrepancy/bias, and in the midrange we require a small-but-linear discrepancy.

DEFINITION 4.1 (almost unbiased partitions). *Let $S \subseteq U$ be finite sets and $b > 1$. A partition (U^0, U^1) of U is at most b-biased with respect to S if*

(1) *If $|S| \geq b^4$ then $\left||U^0 \cap S| - \frac{|S|}{2}\right| < |S|^{3/4}$.*

(2) *If $b < |S| < b^4$ then $\left||U^0 \cap S| - \frac{|S|}{2}\right| < \frac{|S|}{20}$.*

In our analysis of the protocol, we assume that it utilizes partitions which are at most $\delta \cdot \log_2(1/p_v))$-biased with respect to specific sets, where δ is a constant to be determined as a function of other constants which appear in the analysis (see subsections 4.2 and 4.3). We stress that p_v denotes the density of v-entries in the original matrix corresponding to the function f (and not the density in any residual submatrices defined by the protocol). We denote $\Delta_v \stackrel{\text{def}}{=} \delta \log_2(1/p_v)$. Whenever obvious from the context, we abbreviate Δ_v by Δ.

In addition to value-balance properties, we use the following more elementary property asserting that the partitions are into almost equal sizes. The parameter of approximation is determined by the frequency of the value being discussed in the context.

DEFINITION 4.2 (balance property P0). *A partition (U^0, U^1) of U is said to have Property* (P0) (with respect to a parameter Δ) *if the partition is at most Δ-biased with respect to U. When $|U| \geq 2$ it is also required that the partition be nontrivial; namely $|U^0|, |U^1| \geq 1$.*

The additional condition guarantees that if the generic protocol uses only partitions with Property (P0) then it terminates. The main condition in Property (P0) implies termination in at most $n+\Delta$ rounds (see Claim 4.4 and the proof of Lemma 4.5).

We consider executions of the generic protocol under various strategies of the row player, typically assuming that the column player plays honestly. The *residual submatrix* after i rounds is the submatrix corresponding to $X_i \times Y_i$. We denote by $\#_v(X, Y)$ the number of v-entries in the submatrix induced by $X \times Y$. When X is a singleton, $X = \{x\}$, we abbreviate and write $\#_v(x, Y)$ instead of $\#_v(X, Y)$. For example, for $x \in X_i$, the number of v-entries in the residual x-row after i rounds (resulting in the residual submatrix $X_i \times Y_i$) is denoted $\#_v(x, Y_i)$.

4.1.3. Analysis of the protocol: The special case of $q_v = p_v$. For the analysis of this special case, we need two types of "value-balance" properties. The

definition is phrased for column partition. An analogous definition holds for row partitions.

DEFINITION 4.3 (value-balance properties P1 and P2). *Let X_i and Y_i be residual sets of rows and columns and let (Y_i^0, Y_i^1) be a* (column) *partition of Y_i, and v be a value in the range of f. We consider the following two properties:*

Property (P1). *The partition is* v-balanced with respect to individual rows *if the following holds. For every* (remaining) *row $x \in X_i$, the partition is at most Δ_v-biased with respect to set of columns having v-entries in row x* (i.e., w.r.t. the sets $\{y \in Y_i : f(x,y) = v\}$, for each $x \in X_i$).

Property (P2). *Either $|Y_i| \geq 2/p_v$ or the partition is* v-balanced with respect to the standard coloring *in the following sense. Consider a standard* minimum *coloring, ξ, of the v-entries in $X_i \times Y_i$, where no two v-entries in the same column or row are assigned the same color. For every color α, the partition is at most Δ_v-biased with respect to the set of columns containing a v-entry of color α* (i.e., w.r.t. the sets $\{y \in Y_i : \exists x \in X_i \text{ s.t. } f(x,y) = v \text{ and } \xi(x,y) = \alpha\}$, over $\alpha \in \text{Range}(\xi)$).

The following is an elementary technical claim, which we use extensively in the analysis.

CLAIM 4.4. *Let $\alpha < 1$. Suppose that $z_{i+1} < \frac{z_i}{2} + (z_i)^\alpha$, for every $i = 0, \ldots, T$. Then, there exists a constant c_α, so that $z_t < \frac{z_0}{2^{t-1}}$, for every $t < \min\{T, (\log_2 z_0) - c_\alpha\}$. Likewise, if $z_{i+1} > \frac{z_i}{2} - (z_i)^\alpha$, for every $0 \leq i \leq T$, then $z_t > \frac{z_0}{2^{t+1}}$, for every $t < \min\{T, (\log_2 z_0) - c_\alpha\}$.*

Proof. By successively applying the inequality t times, we get $z_t < \frac{z_0}{2^t} + \sum_{i=1}^{t} \frac{z_{t-i}^\alpha}{2^{i-1}}$. Using induction on t, we get

$$\begin{aligned} z_t &< \frac{z_0}{2^t} + \sum_{i=1}^{t} \frac{(z_0/2^{t-i-1})^\alpha}{2^{i-1}} \\ &= \frac{z_0}{2^t} + 2 \cdot \left(\frac{2z_0}{2^t}\right)^\alpha \cdot \sum_{i=1}^{t} \left(\frac{1}{2^{1-\alpha}}\right)^i \\ &< \frac{z_0}{2^t} + 2^{1+\alpha} \cdot \left(\frac{z_0}{2^t}\right)^\alpha \cdot \frac{1}{2^{1-\alpha} - 1}, \end{aligned}$$

which is bounded by $\frac{z_0}{2^{t-1}}$, provided that $\frac{z_0}{2^t} > 2^{c_\alpha}$ where $c_\alpha \stackrel{\text{def}}{=} \frac{1}{1-\alpha} \cdot \log_2(2^{1+\alpha}/(2^{1-\alpha} - 1))$. □

We start by showing that the density of v-entries in individual rows and columns hardly changes as long as each such row/column contains enough v-entries and the partitions split them almost evenly. This assertion corresponds to stage (1) in the motivating discussion.

LEMMA 4.5 (stage 1). *Let v be a value in the range of f, and suppose that the protocol uses* column *partitions satisfying Property* (P1) w.r.t. the value v. *Let K_x denote the number of v entries in the original row x. Then, regardless of the players' steps, if row x is in the residual matrix after the first $i \stackrel{\text{def}}{=} \log_2 K_x$ rounds, then there are at most Δ_v residual v-entries in row x.* (i.e., $\#_v(x, Y_i) \leq \Delta_v$). *Furthermore, after $t < K_x$ rounds $\#_v(x, Y_t) \leq \Delta_v \cdot 2^{K_x - t}$.*

Proof. The analysis uses the fact that the column partitions are v-balanced with respect to each row. Using condition (1) of the almost unbiased property (Def. 4.1) and Claim 4.4, we see that after the first $s \stackrel{\text{def}}{=} \log_2 K_x - 4 \log_2 \Delta$ rounds the residual row x has at most $\frac{K_x}{2^{s-1}} = 2\Delta^4$ entries of value v. For the remaining $r \stackrel{\text{def}}{=} 4 \log_2 \Delta$ rounds we use condition (2) of the almost unbiased property, to show that the number

of v-entries in the row is at most Δ. This follows by considering r iterations of condition (2), namely,

$$\begin{aligned} 2\Delta^4 \cdot \left(\frac{1}{2}+\frac{1}{20}\right)^{4\log_2\Delta} &= 2\cdot\left(1+\frac{1}{10}\right)^{4\log_2\Delta} \\ &= 2\cdot\Delta^{4\log_2(1+\frac{1}{10})} \\ &< 2\cdot\Delta^{2/3} \\ &\le \Delta, \end{aligned}$$

where in the last inequality we use $\delta \ge 8$ (and $p_v \le 1/2$). The lemma follows. □

As an immediate corollary, we get the following.

COROLLARY 4.6 (stage 1 for $q_v = p_v$). *Let $v \in Range(f)$, and suppose that $q_v = p_v$. Suppose that the protocol uses* column (resp., row) *partitions satisfying Property* (P1) w.r.t. the value v. *Then after the first $n - \log_2(1/p_v)$ rounds, the number of v-entries in each residual row* (resp., column) *is at most Δ_v $(= \delta \cdot \log 1/p_v)$. This statement holds regardless of the steps taken by the players.*

Proof. Observe that $q_v = p_v$ implies that each (original) row has $p_v \cdot 2^n$ entries of value v, and apply Lemma 4.5. □

When the number of v-entries in individual rows and columns is small, but not too small, we'd like to assert something in the spirit of stage (2) of the motivating discussion. Namely, that the density of v-entries in the *entire* matrix is preserved as long as their total number is not too small and the partitions behave nicely w.r.t the existing v-entries.

LEMMA 4.7 (stage 2). *Let $M < 2/p_v$. Consider an M-by-M matrix where no row or column contains more than B v-entries. Suppose that the protocol is applied to this matrix, using* column and row *partitions that satisfy Property* (P2) w.r.t. the value v. *Then, after the first $\frac{1}{2}\log_2 M$ rounds, the number of v-entries in the residual submatrix is at most $(2B+1)\cdot\Delta_v$. This statement holds regardless of the steps taken by the players.*

Proof. The analysis uses only the fact that the row and column partitions are v-balanced with respect to the standard coloring. (The upper bound on M implies that this is the only way to satisfy Property (P2).) Note that the standard coloring, being a minimum coloring, uses at most $2B+1$ colors since the underlying graph has maximum degree $\le 2B$. Let α be a color. In each row and column there is at most one v-entry of color α, hence each row/column partition approximately halves the number of remaining v-entries of color α. Hence, using the same arguments as in Lemma 4.5, we see that after $\frac{1}{2}\log_2 M$ rounds the residual matrix contains at most Δ_v v-entries of color α. The lemma follows. □

Finally, when the total number of v-entries in the residual matrix is small we observe that v may be the output only if the input of the column player corresponds to a residual column containing a v-entry. This corresponds to stage (3) in the motivating discussion. Thus, using Corollary 4.6 and Lemma 4.7, we get the following.

COROLLARY 4.8 (advantage in case $q_v = p_v$). *Let $q_v = p_v$ for $v \in Range(f)$. Suppose that the protocol uses only partitions that satisfy Properties* (P0), (P1) *and* (P2) *w.r.t. v. Then the protocol outputs v with probability at most $O(\Delta_v^2\sqrt{p_v})$ $(= O((\delta \log 1/p_v)^2\sqrt{p_v}))$, regardless of the row player's steps.*

Proof. Corollary 4.6 and Lemma 4.7 imply that after the first $\log_2(p_v N) + \frac{1}{2}\log_2(1/p_v)$ rounds, the number of v-entries in the residual matrix is at most $O(\Delta^2)$. If in all partitions the two parts have equal size, then the residual matrix has dimen-

sion $\sqrt{1/p_v}$-by-$\sqrt{1/p_v}$. Property (P0) is applied to show that the residual submatrix has size at least $\frac{1}{2}\sqrt{1/p_v}$-by-$\frac{1}{2}\sqrt{1/p_v}$. To this end we use Claim 4.4 and the observation that $\sqrt{1/p_v} > \Delta_v^4 = (\delta \log_2(1/p_v))^4$, provided that p_v is bounded above by some constant. Such a bound on p_v may be assumed, possibly increasing some constants in the O-terms. Finally, we observe that the output of the protocol is v only if the input of the column player specifies a column containing a v-entry in the residual submatrix. The corollary follows. □

Using "sufficiently random" partitions, the above bound can be improved to $O(\sqrt{p_v})$. For details see Theorem 4.27.

4.1.4. Analysis of the protocol: The general case — row classes. The analysis of the general case (where q_v may exceed p_v) is more cumbersome. To facilitate the understanding we precede each technical step by a motivating discussion. As before, we analyze the advantage of the row player towards some value v. Throughout the analysis we introduce additional value-balance properties that the partitions used in the protocol should satisfy for the analysis to proceed. Later in the paper we discuss how to find such partitions and show that "slightly random" partitions do have these properties.

We classify the rows by density and apply the analysis separately to each class. Let $\rho_v(x)$ denote the density of v-entries in row x of the original matrix; that is,

$$\rho_v(x) \stackrel{\text{def}}{=} \frac{|\{y \in Y_0 : f(x,y) = v\}|}{|Y_0|} = \frac{\#_v(x, Y_0)}{|Y_0|}. \tag{3}$$

By our assumption, $\frac{p_v}{4} < \rho_v(x) \leq q_v$, for every $x \in X_0$, and the average of ρ_v, over all $x \in X_0$, equals p_v. For $0 \leq j \leq \log_2(1/p_v) + 1$, define R^j as the class of all rows with v-entry density between 2^{-j} and 2^{-j-1}; that is,

$$R^j \stackrel{\text{def}}{=} \{x \in X_0 : \lfloor \log_2(1/\rho_v(x)) \rfloor = j\}. \tag{4}$$

Note that the last class, $R^{\log_2(1/p_v)+1}$, contains all rows with v-entry density smaller than $p_v/2$.

Clearly, the influence of the row player towards value v is bounded by the sum of its influences (towards v) when restricting itself to inputs/rows of a certain class. Recall that the row player behavior is always restricted (by our hypothesis that it is not detected cheating) to sending a single bit in each round. The assumption that the row player restricts itself to inputs/rows in a particular set means that its answers must be consistent with some input in the set (i.e., in round i he may send σ only if X_i^σ intersects the restricted set). The above is summarized and generalized in the following claim.

CLAIM 4.9. *For $Z \subseteq X$ a set of rows, we let θ_Z be the probability for an outcome of v, assuming that the actions of the row player are consistent with some row in Z, but is otherwise free to choose any adversarial strategy. If $(Z_1, \ldots, Z_r)$ is a partition of the set of rows, then the probability for the protocol to have outcome v does not exceed $\sum_i \theta_{Z_i}$.*

Proof. The claim follows applying a union bound. □

We now partition the row classes into two categories: *heavy* rows with density above $\sqrt{p_v}$ and rows below this density. First, we bound the advantage of the row player when it restricts itself to heavy inputs/rows. A simple counting argument implies that there are at most $\sqrt{p_v}N$ heavy rows. We will consider the situation after $\log_2(\sqrt{p_v}N)$ rounds of the protocol. Using an additional v-balance property, denoted

P3, which asserts that the row partitions split almost evenly the set of heavy rows, we will show that after $\log_2(\sqrt{p_v}N)$ rounds at most Δ of the heavy rows remain in the residual matrix and furthermore that each such row maintains its original v-density up to a multiplicative factor of Δ. Loosely speaking, the row player can now choose only between Δ possible inputs/rows with probabilities of success that equal the density of the residual row. Thus, the advantage of the row player (towards v) when restricting itself to heavy rows is bounded by $\Delta^2 \cdot q_v = O((\log_2(1/p_v))^2 q_v)$.

DEFINITION 4.10 (value-balance property P3). *Let X_i and Y_i be residual sets of rows and columns and and let $v \in Range(f)$. A row partition has Property* (P3) (is said to be v-balanced with respect to heavy rows) *if it is at most Δ_v-biased with respect to the set of the* (remaining) *heavy rows* (i.e., w.r.t. the set $\{x \in X_i : \rho_v(x) \geq \sqrt{p_v}\}$).

LEMMA 4.11 (advantage via heavy-row strategies). *Suppose that the protocol is performed using* column and row *partitions satisfying Properties* (P0), (P1), and (P3) w.r.t. the value v. *Then, as long as the row player restricts itself to heavy rows and the column player plays honestly, the output equals v with probability at most $2\Delta_v^2 \cdot q_v$.*

Proof. Consider the situation after $\log_2(\sqrt{p_v}N)$ rounds of the protocol. Heavy rows have at least $\sqrt{p_v}N$ entries of value v and so we will be able to apply Lemma 4.5 to these rows. Using Property (P1) and applying Lemma 4.5 to each heavy row, we conclude that every remaining heavy row x contains at most $\Delta \cdot 2^i$ v-entries, where

$$\begin{aligned} i &\stackrel{\text{def}}{=} \log_2(\rho_v(x)N) - \log_2(\sqrt{p_v}N) \\ &\leq \log_2(q_v N) - \log_2(\sqrt{p_v}N) \\ &= \log_2(q_v/\sqrt{p_v}). \end{aligned}$$

(We are assuming that heavy rows exist, i.e., $q_v \geq \sqrt{p_v}$, whence $i \geq 0$.) Thus, each such heavy row contains at most $\Delta \cdot q_v/\sqrt{p_v}$ v-entries. Also, using Property (P3) and an argument as in the proof of Lemma 4.5, it follows that the residual matrix has at most Δ heavy rows. Thus, the entire residual matrix contains at most $\Delta^2 \cdot q_v/\sqrt{p_v}$ *v-entries in heavy rows*. Using Property (P0) we know that the residual matrix at this stage contains at least $\frac{1}{2}\sqrt{1/p_v}$ columns. Thus, by an argument as in the proof of Corollary 4.8, the probability that the protocol terminates with a pair (x, y) so that x is heavy and $f(x, y) = v$ does not exceed

$$\frac{\#_v(H \cap X_i, Y_i)}{|Y_i|} \leq \frac{\Delta^2 \cdot q_v/\sqrt{p_v}}{1/(2\sqrt{p_v})} = 2\Delta^2 q_v,$$

where H is the set of heavy rows and $X_i \times Y_i$ is the residual matrix. The lemma follows. □

Having analyzed strategies where the row player confines itself to heavy rows, we turn to strategies where it refrains from heavy rows. The analysis is split according to the remaining row classes; that is, for every $1 \leq j \leq \frac{1}{2}\log_2(1/p_v)$, we bound the advantage of the row player assuming that it restricts itself to the class (of rows) $R \stackrel{\text{def}}{=} R^{j+\frac{1}{2}\log_2(1/p_v)}$ that have density $\approx \sqrt{p_v}2^{-j}$. By a counting argument,

$$|R| \leq \sqrt{p_v}2^j N. \tag{5}$$

Consider the situation after $\log_2(\sqrt{p_v}2^{-j}N)$ rounds. Note that this corresponds to stage (1) in the motivating discussion and thus we can apply Lemma 4.5 and assert that after these $\log_2(\sqrt{p_v}2^{-j}N)$ rounds no residual row of R has more than Δ v-entries. Using an additional v-balance property, denoted **P4**, which asserts that the

row partitions split R almost evenly, we will show that after these $\log_2(\sqrt{p_v}2^{-j}N)$ rounds the residual matrix contains at most $\max\{\Delta, 2^{2j+1}\}$ rows of R.

DEFINITION 4.12 (value-balance property P4). *Let X_i and Y_i be residual sets of rows and columns and $v \in Range(f)$. A row partition has Property* (P4) (is said to be v-balanced with respect to row-density classes) *if, for every j ($\frac{1}{2}\log_2(1/p_v) \leq j \leq 1 + \log_2(1/p_v)$), it is at most Δ_v-biased with respect to the set of the* (remaining) *rows in R^j* (i.e., w.r.t. the sets $\{x \in X_i : \lfloor \log_2 \rho_v(x) \rfloor = j\}$, for $\frac{1}{2}\log_2(1/p_v) \leq j \leq 1 + \log_2(1/p_v)$).

LEMMA 4.13 (strategies restricted to $R = R^{j+\frac{1}{2}\log_2(1/p_v)}$ — the first rounds). *Let $v \in Range(f)$, and suppose that the protocol uses* row and column *partitions satisfying Properties* (P0), (P1), *and* (P4) *w.r.t. the value v. Then after the first $i \stackrel{\text{def}}{=} n - j - \frac{1}{2}\log_2(1/p_v)$ rounds, the resulting $X_i \times Y_i$ submatrix satisfies the following conditions, regardless of the players' steps:*

1. *each remaining row of R contains at most Δ_v entries of value v (i.e., $\#_v(x, Y_i) \leq \Delta_v$, for every $x \in R \cap X_i$);*
2. *at most $\Delta_v \cdot 2^{2j+1}$ rows of R remain (i.e., $|R \cap X_i| \leq \Delta_v \cdot 2^{2j+1}$);*
3. *the number of columns is at least $\frac{1}{2} \cdot \frac{2^j}{\sqrt{p_v}}$ (i.e., $|Y_i| \geq \frac{1}{2} \cdot \frac{2^j}{\sqrt{p_v}}$).*

Proof. Item (1) follows from Lemma 4.5 (using Property (P1)). Using Property (P4), we derive item (2) as in the second part of the proof of Lemma 4.11. Finally, item (3) follows using Property (P0). □

For "small" j's (say, $j \leq \log_2 \Delta$) we get into a situation as in the analysis of heavy rows. Actually, the following applies to any j, but is useful only for $j = O(\log \Delta_v)$.

COROLLARY 4.14 (advantage via $R = R^{j+\frac{1}{2}\log_2(1/p_v)}$ strategies — simple analysis). *Consider a protocol in which all* column and row *partitions satisfy Properties* (P0), (P1), and (P4) w.r.t. the value v. *Then, as long as the row player restricts itself to rows in R and the column player plays honestly, the output equals v with probability at most $2^{j+2}\Delta_v^2 \cdot \sqrt{p_v}$.*

Proof. Using Lemma 4.13 we infer that the residual matrix after i rounds has at most $\Delta^2 \cdot 2^{2j+1}$ v-entries in rows of R and at least $\frac{1}{2} \cdot \frac{2^j}{\sqrt{p_v}}$ columns. Thus, the probability that the column chosen by the column player has a v-entry in a residual row of R does not exceed

$$\frac{\#_v(R \cap X_i, Y_i)}{|Y_i|} \leq \frac{\Delta^2 \cdot 2^{2j+1}}{\frac{1}{2} \cdot \frac{2^j}{\sqrt{p_v}}} = 2^{j+2}\Delta^2\sqrt{p_v}.$$

The corollary follows. □

So far we dealt with heavy rows and the row classes $R^{j+\frac{1}{2}\log_2(1/p_v)}$ for "small" j's, $j \leq \log_2 \Delta_v$. The rest of the analysis concentrates on row classes $R^{j+\frac{1}{2}\log_2(1/p_v)}$ for $j > \log_2 \Delta_v$.

4.1.5. Analysis of the protocol: The general case — column subclasses. Lemmas 4.11 and 4.13 summarize what we can infer by considering only row classes defined by the density of v-entries. We learned that after $i = n - j - \frac{1}{2}\log_2(1/p_v)$ rounds the resulting matrix has approximately 2^{2j} rows of the class $R = R^{j+\frac{1}{2}\log_2(1/p_v)}$ with no more than Δ v-entries in each such row. Thus, in total the resulting submatrix has approximately 2^{2j} v-entries in rows of R. Had these v-values been distributed evenly among the columns, then we could apply an argument analogous to Lemma 4.7 (corresponding to stage (2) in the motivating discussion). At the other extreme, if these v-values are all in one column, then we should have further applied Lemma 4.5

to this column. In general, however, the distribution of these v-entries may be more complex and in order to proceed we classify columns according to the approximate density of v-entries within each particular row class. Once this is done, the matrix is split to submatrices such that the density of v-entries in each induced subcolumn is about the same. Each such submatrix is easy to analyze and we can combine these analyses to derive the final result.

Let $\ell \stackrel{\text{def}}{=} \frac{1}{2}\log_2(1/p_v)$. Recall that we are currently dealing with an arbitrary $R = R^{j+\ell}$, where $1 < j \leq \ell + 1$. For $0 \leq k \leq 2j$, let

$$C_j^k \stackrel{\text{def}}{=} \{y \in Y_0 : \lfloor \log_2(1/\mu_v(y, R^{j+\ell})) \rfloor = k\}, \tag{6}$$

where $\mu_v(y, R)$ is the density of v-entries in the *portion* of column y restricted to rows R, that is

$$\mu_v(y, R) = \frac{|\{x \in R : f(x, y) = v\}|}{|R|}. \tag{7}$$

Columns having lower v-density within R (i.e., $\mu_v < 2^{-2j-1}$) are defined to be in $C_j = C_j^{2j+1}$ and will be treated separately. The advantage of the row player towards v when restricting its input to R is the sum, over all k, of the probabilities of the following $2j + 2$ events. For $k = 0, \ldots, 2j + 1$, the kth *event* occurs if the input of the column player happens to be in C_j^k *and* the output of the protocol is v (when the row player restricts its input to be in R). Thus, it suffices to bound the probability of each of these $2j + 2$ events. We first observe that, for $j = 0, \ldots, l + 1$ and $0 \leq k \leq 2j$,

$$|C_j^k| \leq \frac{\#_v(R^{j+\ell}, Y_0)}{\min_{y \in C_j^k}\{\#_v(R^{j+\ell}, y)\}} \leq \frac{|R^{j+\ell}| \cdot (\sqrt{p_v} 2^{-j} \cdot N)}{2^{-k-1} \cdot |R^{j+\ell}|} = 2^{k+1-j}\sqrt{p_v} \cdot N. \tag{8}$$

Thus, the probability that the input of the column player is in C_j^k is bounded by $2^{k+1-j}\sqrt{p_v}$. This by itself provides a sufficiently good bound for the case $k \leq j$ and so it is left to consider the case where $j < k \leq 2j$ and to deal with the columns in C_j. We start with the latter. (Warning: the next two paragraphs consist of an imprecise motivating discussion; a rigorous treatment follows.)

Considering the submatrix $R \times C_j$ and using item (2) of Lemma 4.13 we know that, after $i = n - j - \ell$ rounds, each residual row in this submatrix contains at most Δ v-entries. Assuming that the row partitions split the v-entries in the subcolumn of this submatrix almost evenly (as postulated in an additional value-balance property, denoted **P6**), we conclude that residual subcolumns of the submatrix contain at most Δ v-entries (note that there are at most 2^{2j+1} rows of R and that the v-density of columns in $R \times C_j$ is at most 2^{-2j-1}). Thus, we can apply an analysis analogous to stage (2) in the motivating discussion. It follows that after an additional j rounds, the resulting submatrix contains at most Δ^2 v-entries. At this stage, there are still $\ell = \frac{1}{2}\log_2(1/p_v)$ rounds to go so we conclude that the probability that the column player's input is in C_j and the output is v (when the row player restricts its input to be in R) is at most $\Delta^2\sqrt{p_v}$. This argument will be made precise as a special case of the argument for C_j^k, $k > j$.

We now consider the submatrix $R \times C$, where $C \stackrel{\text{def}}{=} C_j^k$ for $k > j$. Again, by Property (P6) we expect each residual subcolumn to contain $2^{-k} \cdot 2^{2j}$ entries of value v. Assuming that the column partitions split C almost evenly, as postulated in yet another value-balance property (**P5** below), and using equation (8), we expect the residual submatrix to contain at most 2^{k+1} columns of C_j^k (and, recall, 2^{2j} rows of R).

Thus, the next $2j-k<k$ rounds are expected to preserve the density of C columns in the residual matrix as well as the density of v-entries in residual subcolumns of the submatrix $R\times C$, provided that Properties (P5) and (P6) hold. Thus, at this point (after a total of $(n-j-\ell)+(2j-k)$ rounds) each remaining row of R is left with at most Δ entries of value v and each remaining column of C has at most Δ entries of value v in the portion of the rows of R. Furthermore, we expect the residual $R\times C$ to have $2^{2j-(2j-k)}=2^k$ rows and $2^{k-(2j-k)}=2^{2k-2j}$ columns. We can now apply an argument analogous to Lemma 4.7 (corresponding to stage (2) in the motivating discussion). To this end we introduce the last value-balance property, denoted **P7**, which analogously to (P2) asserts that, with respect to each color in a standard minimum coloring of the v-entries in $R\times C$, the row (resp., column) partitions split almost evenly the set of rows (resp., columns) having v-entries colored by this color. Finally, consider the situation after another additional $k-j$ rounds. Using (P7) in an argument analogous to Lemma 4.7, we show that after these $k-j$ rounds, the residual $R\times C$ submatrix has at most Δ^2 v-entries. Furthermore, this residual submatrix is expected to have $2^{k-(k-j)}=2^j$ rows and $2^{(2k-2j)-(k-j)}=2^{k-j}$ columns. Thus, assuming that the column player's input, denoted y, is in C the probability that it falls in one of the residual columns which has a v-entry in the R-portion is at most $\Delta^2/2^{k-j}$. It follows that the probability for the input column to be in C_j^k *and* the output be v (when the row player restricts its input to R) is at most

$$\frac{\Delta^2}{2^{k-j}}\cdot 2^{k-j}\sqrt{p_v}=\Delta^2\cdot\sqrt{p_v}.$$

Thus, the claimed bound follows also in this case.

We now turn to a rigorous analysis of the advantage of the row player in executions where it restricts itself to inputs in $R=R^{j+\ell}$ and the input column happens to fall in $C\stackrel{\text{def}}{=}C_j^k$, for some $k>j>0$. (Recall that for $k\le j$, equation (8) by itself asserts that input column falls in C_j^k with probability at most $\sqrt{p_v}$.)

DEFINITION 4.15 (value-balance properties P5, P6, and P7). *Let X_i and Y_i be residual sets of rows and columns. Let (X_i^0,X_i^1) be a* row *partition, (Y_i^0,Y_i^1) be a* column *partition, and $v\in Range(f)$. We consider the following three properties.*

Property (P5). *The column partition (Y_i^0,Y_i^1) is* v-balanced with respect to column subclasses *if, for every j,k satisfying $0<j<k\le 2j\le 2\ell+2$, the partition is at most Δ_v-biased with respect to the set of columns in C_j^k* (i.e., w.r.t. the sets $Y_i\cap C_j^k$, for each j,k s.t. $0<j<k\le 2j\le 2\ell+2$).

Property (P6). *For every j and every $y\in Y_i$, either $\frac{\#_v(X_i\cap R^{j+\ell},y)}{|Y_i|}\le\frac{p_v}{4\Delta_v}$ or the row partition (X_i^0,X_i^1) is* v-balanced with respect to the jth subcolumn y *in the sense that the partition is at most Δ_v-biased with respect to the set of rows in $R^{j+\ell}$ having v-entries in y* (i.e., w.r.t. $\{x\in X_i\cap R^{j+\ell}: f(x,y)=v\}$, for each $y\in Y_i$ and j s.t. $0<j\le\ell+1$).

Property (P7). *Either $|Y_i|\ge 4/p_v$ or the partition (Y_i^0,Y_i^1) is* v-balanced with respect to the standard coloring of subclasses *in the following sense. For every j,k as in* (P5)*, consider a standard* minimum *coloring ξ, of the v-entries in $(X_i\cap R^{j+\ell})\times(Y_i\cap C_j^k)$ so that every two v-entries in the same column or row are colored differently. For every color α, the partition is at most Δ_v-biased with respect to the set of columns containing a v-entry of color α* (i.e., w.r.t. the sets $\{y\in Y_i\cap C_j^k:\exists x\in X_i\cap R^{j+\ell}\text{ s.t. }f(x,y)=v\text{ and }\xi(x,y)=\alpha\}$, for each j,k, and α.)

DEFINITION 4.16 (the (j,k)-event). *Let $0 < j \leq \ell + 1$ and $0 \leq k \leq 2j+1$. Fix an arbitrary strategy in which the row player restricts its input to rows in $R^{j+\ell}$. The (j,k)-event* (or kth event) *is said to occur if both the input column is in C_j^k and the output is v.*

LEMMA 4.17 (bounding individual events). *Let $0 < j \leq \ell+1$ and $0 \leq k \leq 2j+1$. Suppose that the protocol uses partitions which satisfy Properties* (P0), (P1), (P4), (P5), (P6), and (P7). *Then, for any strategy in which the row player restricts its input to rows in $R^{j+\ell}$, the probability of the (j,k)-event is at most $5\Delta_v^4 \cdot \sqrt{p_v}$.*

We remark that a lower power of Δ_v can be obtained by a more careful analysis.

Proof. As observed above, the bound holds in case $k \leq j$, since in this case equation (8) implies that the column player's input is in C_j^k with probability at most $\sqrt{p_v}$. We thus turn to the case $j < k \leq 2j+1$.

First, we consider the situation after $i \stackrel{\text{def}}{=} (n-j-\ell) + (2j-k) = n+j-k-\ell$ rounds. Note that $j < k \leq 2j+1$ implies $i \geq (n-j-\ell) - 1 \geq n - \log_2(2/p_v)$ and $i < n - \ell$. We first bound the number of v-entries in the residual subrows and subcolumns of $R \times C$.

Claim 4.17.1. Each remaining row of $R \stackrel{\text{def}}{=} R^{j+\ell}$ contains at most Δ v-entries; namely, $\#_v(x, Y_i) \leq \Delta$, for every $x \in R \cap X_i$.

Proof. Since $i \geq (n-j-\ell)-1$, we can apply Lemma 4.13, and the claim follows by item (1). □

Claim 4.17.2. Each remaining column of $C \stackrel{\text{def}}{=} C_j^k$ contains at most Δ entries of value v within its R-portion; namely, $\#_v(R \cap X_i, y) \leq \Delta$, for every $y \in C \cap Y_i$.

Proof. We first bound the number of v-entries in the R-portion of each column $y \in C$. By combining the definition of C and equation (5), we get

$$\begin{aligned} \#_v(R, y) &\leq 2^{-k} \cdot |R| \\ &\leq \sqrt{p_v} \cdot 2^{j+n-k} \\ &= 2^{j+n-k-\ell} \\ &= 2^i. \end{aligned}$$

We now wish to apply Property (P6) and argue that $\#_v(R \cap X_i, y) \leq \Delta \cdot \#_v(R, y) \cdot 2^{-i}$, but we need to be careful since Property (P6) is useful only when $\#_v(R \cap X_t, y) \geq \frac{p_v}{4\Delta} \cdot |Y_t|$. Thus, before applying Property (P6), we consider the simple case in which there are many v-entries in the R-portion of y; namely, $\#_v(R, y) \geq p_v \cdot |Y_0|$. Using Properties (P6) and (P0), we infer inductively that the ratio $\#_v(R \cap X_i, y)/|Y_i|$ is maintained after $r < i$ rounds. In the induction step we assume that the ratio after r rounds is at least $p_v/2$ and applying Proposition (P6) infer the same for $r+1$ rounds, provided $\#_v(R \cap X_r, y) \geq \Delta^4$. In the last ($\approx 4\log_2 \Delta$) rounds we maintain as invariant the assumption that the ratio is at least p_v/Δ_v. We conclude (analogously to Lemma 4.5) that $\#_v(R \cap X_i, y) \leq \Delta \cdot 2^{i-i} = \Delta$ as claimed. Yet, all the above is valid only in case the initial number of v-entries in the subcolumn is large enough (i.e., $\#_v(R, y) \geq p_v \cdot |Y_0|$), which need not be the case in general. Intuitively, this cannot be a problem since fewer v-entries in the subcolumn can only help. Formally, we proceed as follows. Let $y_0 \stackrel{\text{def}}{=} |Y_0|$ and $z_0 \stackrel{\text{def}}{=} \#_v(R, y)$. Consider i iterations of the following rule:

- If $y_t > \Delta^4$ then set y_{t+1} to be in the interval $[(y_t/2) \pm y_t^{3/4}]$. If $y_t > \Delta$ then set y_{t+1} to be in the interval $[(y_t/2) \pm (y_t/20)]$. Otherwise, set y_{t+1} to be in the interval $[0, y_t]$.

- If $z_t > (p_v/\Delta)\cdot y_t$ then set z_{t+1} analogously to the way y_{t+1} is set. Otherwise, (i.e., $z_t \leq (p_v/\Delta)\cdot y_t$), set z_{t+1} to be in the interval $[0, z_t]$.

The above process corresponds to the decline (with $t = 0, \ldots, i$) of $|Y_t|$ (represented by y_t) and $\#_v(R \cap X_t, y)$ (represented by z_t), as governed by Properties (P0) and (P6). In case the initial ratio z_0/y_0 is sufficiently large, say at least p_v/Δ, Claim 4.4 implies that $z_i \leq \Delta$. As far as the y_t's are concerned, Claim 4.4 can be applied to yield $y_i \leq \Delta \cdot 2^{\ell+k-j}$, which by $k \leq 2j+1$ and $j \leq \ell+1$ yields $y_i \leq 2\Delta \cdot (1/p_v)$. Thus, it is clear that z_i is bounded by the maximum of the bound obtained in the simple case (i.e., Δ) and $(p_v/\Delta)\cdot y_i \leq 2$. The claim follows. □

We are now in a situation analogous to the end of stage (1) in the motivating discussion, except that the bounds on v-entries hold with respect to the residual $R \times C$ submatrix (rather than to the entire residual matrix). Our goal is to now apply a process analogous to stage (2) in the motivating discussion. To this end we first consider a minimum coloring of the v-entries in this residual submatrix (i.e., a coloring in which no v-entries in the same row/column are assigned the same color). Using Claims 4.17.1 and 4.17.2, we first observe that this coloring requires at most $2\Delta + 1$ colors (since the degrees in the induced graph do not exceed 2Δ). Next we derive an upper bound on the size of independent sets in the graph, (i.e., on individual color classes in this coloring). An independent set in this graph meets every row and column at most once, so its cardinality cannot exceed $\min\{|R \cap X_i|, |C \cap Y_i|\}$.

Claim 4.17.3. $\min\{|R \cap X_i|, |C \cap Y_i|\} \leq 2\Delta \cdot 2^{2(k-j)}$.

Proof. Using Property (P4) and equation (5), we get $|R \cap X_i| \leq \Delta \cdot 2^{(n+j-\ell)-i} = \Delta \cdot 2^k$, so the claim holds when $k \geq 2j-1$ and in particular for the class $C_j = C_j^{2j+1}$. Likewise, using Property (P5) and equation (8) and assuming $k \leq 2j$, we get $|C_j^k \cap Y_i| \leq \Delta \cdot 2^{(n+k+1-j-\ell)-i} = \Delta \cdot 2^{2(k-j)+1}$. This proves the claim for the range $k \leq 2j$. □

We now consider an execution of the next $(k-j)$ rounds. Using Property (P7), we proceed analogously to Lemma 4.7. First, we upper bound the size of each residual color class by $\Delta \cdot \frac{2\Delta 2^{2(k-j)}}{2^{2(k-j)}} = 2\Delta^2$ (essentially, its size after i rounds divided by a factor of 2 for each of the $2(k-j)$ steps in the next $k-j$ rounds). Adding up the bounds for all color classes, we obtain a bound on the total number of v-entries in the resulting $R \times C$ submatrix; namely,

$$\#_v(X_{i+k-j} \cap R, Y_{i+k-j} \cap C) \leq (2\Delta+1)\cdot 2\Delta^2 < 5\Delta^3. \tag{9}$$

We are now in a situation analogous to the end of stage (2) in the motivating discussion. We note that till now $i + (k-j) = n - \ell$ rounds were performed. We distinguish two cases.

Case 1. If $|C| < \Delta^3\sqrt{p_v}\cdot N$ then the bound on the (j,k)-event is obvious by equation (8) (as in case $k \leq j$).

Case 2 (the interesting case). Suppose $|C| \geq \Delta^3\sqrt{p_v}\cdot N$. In this case we use Property (P5) to infer that $|C \cap Y_{n-\ell}| \geq \frac{1}{\Delta}\cdot\frac{|C|}{\sqrt{p_v}N}$. Thus, using equation (9), the probability for the (j,k)-event is at most

$$\begin{aligned}\frac{|C|}{N}\cdot\frac{\#_v(X_{i+k-j}\cap R, Y_{i+k-j}\cap C))}{|C\cap Y_{n-\ell}|} &\leq \frac{|C|}{N}\cdot\frac{5\Delta^3}{|C|/(\Delta\sqrt{p_v}N)}\\ &= 5\Delta^4\cdot\sqrt{p_v}.\end{aligned}$$

The lemma follows. □

Combining Lemmas 4.11 and 4.17, we get the following.

THEOREM 4.18 (advantages in the general case). *Let f be an arbitrary bivariate function and suppose the generic protocol is performed with row and column partitions satisfying Properties* (P0) *through* (P7). *Then, for every value v in the range of f, if one party plays honestly then, no matter how the other player plays, the outcome of the protocol is v with probability at most $O(\log^6(1/p_v) \cdot \max\{q_v, \sqrt{p_v}\})$.*

Proof. Just sum up the bounds for the probabilities of the ℓ^2 events corresponding to the advantage from "nonheavy" strategies (provided by Lemma 4.17) and add the bound on the advantage from heavy strategies provided by Lemma 4.11. (The summation over the strategies is an upper bound, whereas summation over the events corresponding to different column subclasses is exact.) □

We stress that some logarithmic factors (but not all) can be eliminated by a more careful analysis.

4.1.6. Digest of the value-balanced properties. The value-balance properties, referred to in Theorem 4.18, are tabulated in Table 1. Property (P2) is a specialization of Property (P7) for the case $q_v = p_v$ and is not used in the proof of Theorem 4.18 (but rather in the proof of Corollary 4.8). Properties (P2) and (P7) differ from all other value-balance properties in that their definition depends on a standard coloring of a graph induced by the current residual matrix $X_i \times Y_i$. In particular, the sets relevant to these properties in different rounds vary in size. In contrast, we stress that sets relevant to the other properties reduce to about a half with every round. This "irregularity" of Properties (P2) and (P7) introduces difficulties in the subsequent subsections. To compensate for these difficulties, these properties were defined to hold vacuously as long as the residual matrix is "large" (i.e., $\Omega(1/p_v)$). As we pointed out, this convention does not affect the analysis, since Properties (P2) and (P7) are applied only to "small" residual matrices. For similar reasons, Property (P6) which refers to many (i.e., $|Y_i|$) sets which may be very small is also defined to hold vacuously in case the number of sets is much larger than the size of these sets. Note that all other properties either apply to fewer (i.e., $\text{poly}(\ell)$) sets or refer to relatively big sets. Specifically, Properties (P3), (P4), and (P5) apply to $\text{poly}(\ell)$ sets. On the other hand, whenever Properties (P0) and (P1) are applied to many, say M, sets each of these sets has cardinality at least $M/2$ and $(p_v/4) \cdot M$, respectively.

4.2. On the existence of value-balanced partitions. In this subsection we prove the existence of partitions that have all the value-balanced properties used in the previous subsection. We first bound the probability that a random partition is not balanced with respect to a specific set. In the analysis we use an unspecified constant, denoted c_1. The constant δ (in the definition of Δ_v) is determined in terms of c_1 (in fact $\delta = O(c_1)$ will do, $c_1 \geq 2$ suffices for the results of the current subsection and $c_1 \geq 10$ suffices for all the results of the entire section).

LEMMA 4.19. *Let $S \subseteq U$ be finite sets, with $|S| = k$. Then, for every $c_1 > 0$ there exists δ, so that a uniformly selected bipartition of U is Δ_v-biased with respect to S with probability $\geq 1 - (p_v/k)^{c_1}$.*

Proof. We consider two cases corresponding to the two conditions of Definition 4.1. By Chernoff's Bound, the probability that a uniformly selected partition fails condition (1) in Definition 4.1 (with respect to a set S with $k \geq \Delta_v^4$) does not exceed

$$2\exp\{-2(k^{-1/4})^2 \cdot k\} = 2\exp\{-2k^{1/2}\}. \tag{10}$$

TABLE 1
Value-balanced properties (recall $\ell \stackrel{\text{def}}{=} (1/2)\log_2(1/p_v)$*).*

	stated for	Description of the property: the partition approximately halves the number of	Number of sets for $M \times M$ matrix	Applicable for
P0	col	columns	1	all M
P1	col	columns with v-entries in row x, per row	M	all M
P2	col	columns with v-entries in color ϕ, per color	$\leq 2M+1$	$M \leq 2/p_v$
P3	row	heavy rows	1	all M
P4	row	rows of approximate weight 2^{-j}, per $j = 0, \ldots, \ell$	$\leq \ell$	all M
P5	col	columns of a weight class inside a row class, per row class and column subclass	$< 2\ell^2$	all M
P6	row	rows with v-entries in subcolumn, per column and row class (provided residual subcolumn is sufficiently dense)	$M \cdot \ell$	all M
P7	col	columns with v-entries in color ϕ, per color in rectangle	$\leq (2M+1) \cdot \ell^2$	$M \leq 4/p_v$

Using $k \geq (\delta \log_2(1/p_v))^4$, we upper bound equation (10) by

$$\exp\{-k^{1/2}\} \cdot \exp\{(\delta \cdot \log_2(1/p_v))^2\},$$

which for sufficiently large δ (or $1/p_v$) yields the desired bound (of $(p_v/k)^{c_1}$). Similarly, the probability that condition (2) is not satisfied by a random partition is bounded by

$$2\exp\{-2(1/20)^2 \cdot k\} = 2\exp\{-k/200\}. \tag{11}$$

Using $k > \delta \log_2(1/p_v)$ and $\delta \geq 400c_1$, we upper bound equation (11) by

$$\exp\{-k/400\} \cdot \exp\{c_1 \log_2(1/p_v)\},$$

which for sufficiently large δ (or $1/p_v$) yields again the desired bound. □

PROPOSITION 4.20 (existence of value-balance partitions). *Let the generic protocol run for i rounds, using only partitions which satisfy all value-balance properties* w.r.t. all values in *Range*(f). *Let $X_i \times Y_i$ be the residual matrix after these i rounds. Then there exist a row partition* (of X_i) *and a column partition* (of Y_i) *that satisfy all value-balance properties* w.r.t. all values. *Furthermore, for every $v \in$ Range(f), all but a $p_v^{c_1-1}$ fraction of the possible partitions satisfy all v-balance properties.*

Proof. We consider only row partitions, the proof for column partitions being identical. Let $v \in \text{Range}(f)$. For $|X_i| < \Delta_v$ every nontrivial partition will do, so henceforth we assume $|X_i| \geq \Delta_v$. Lemma 4.19 yields an upper bound on the probability that a uniformly chosen partition of X_i violates one of the v-balance properties. For each property, we multiply the number of sets considered by the probability that a uniformly selected bipartition of X_i is not Δ_v-biased with respect to an individual set. An obvious (lower) bound on the size of an individual set considered is Δ_v, but in some cases better lower bounds hold. For each of the eight properties, we prove an upper bound of $p_v^{c_1-1}/8$ on the probability that a uniformly chosen partition violates the property.

- Property (P0) is violated with probability at most $|X_i| \cdot (p_v/|X_i|)^{c_1}$ which can be bounded by $p_v^{c_1-1}/8$.
- Property (P1) is violated with probability at most $|Y_i| \cdot \max_{y \in Y_i}\{(p_v/\#_v(X_i, y))^{c_1}\}$. In case $|Y_i| < \Delta/p_v$, this probability is easily bounded by $(p_v/\Delta_v)^{c_1-1} <$

$p_v^{c_1-1}/8$. Otherwise, we argue as follows. Since Property (P1) was satisfied in previous rounds, it follows (as in Lemma 4.5) that

$$\begin{aligned}\#_v(X_i, y) &\geq 2^{-i-1} \cdot \#_v(X_0, y) \\ &\geq \frac{p_v}{8} \cdot |X_i|\end{aligned}$$

and so Property (P1) is violated with probability at most $|Y_i| \cdot (8/|X_i|)^{c_1}$. Using Property (P0) for the previous rounds we get $|X_i| \geq |Y_i|/4$ and again obtain a bound of $O((p_v/\Delta_v)^{c_1-1}) < p_v^{c_1-1}/8$.

- For Property (P2), we need only consider the case $|X_i| < (2/p_v)$. In this case, Property (P2) is violated with probability at most $(|X_i| + |Y_i| + 1) \cdot (p_v/\Delta_v)^{c_1}$ which is bounded by $O(p_v^{c_1-1}/\Delta_v^{c_1}) < p_v^{c_1-1}/8$. Property (P7) is dealt similarly, but the bound here is $O(p_v^{c_1-1}/\Delta^{c_1-2}) < p_v^{c_1-1}/8$.
- For Property (P6) we need to consider only $j \leq \ell + 1$ and $y \in Y_i$ such that $\#_v(R^{j+\ell} \cap X_i, y) \geq \max\{\Delta_v, (p_v/4\Delta_v) \cdot |Y_i|\}$. Let us denote the set of these pairs by P_i. Then, Property (P6) is violated with probability at most

$$\begin{aligned}\sum_{(j,y)\in P_i} \left(\frac{p_v}{\#_v(R^{j+\ell} \cap X_i, y)}\right)^{c_1} &\leq \left(\frac{p_v}{\Delta}\right)^{c_1-1} \cdot \left(|P_i| \cdot \frac{p_v}{(p_v/4\Delta_v) \cdot |Y_i|}\right) \\ &\leq \left(\frac{p_v}{\Delta}\right)^{c_1-1} \cdot \frac{(\ell+1) \cdot |Y_i|}{|Y_i|/4\Delta} \\ &< \frac{p_v^{c_1-1}}{8}.\end{aligned}$$

- For the remaining properties (i.e., (P3), (P4), and (P5)) we have a total of $O(\log^2(1/p_v))$ sets and so the bound holds easily.

Thus, the probability that a random partition of X_i violates some property with respect to the value v is at most $p_v^{c_1-1}$. The main claim of the proposition follows by summing the bounds obtained for all possible v's and using $c_1 \geq 2$. □

Combining Theorem 4.18 and Proposition 4.20, we get the following.

COROLLARY 4.21 (existence of a protocol meeting the lower bound). *Let f be as in Theorem 4.18. Then, there exists a (deterministic) two-party protocol for computing the function f, so that for every $v \in Range(f)$, if one party plays honestly, then the outcome of the protocol is v with probability at most $O(\log^6(1/p_v) \cdot \max\{q_v, \sqrt{p_v}\})$.*

4.3. Efficient protocols meeting the lower bounds. The protocols guaranteed by Corollary 4.21 are not efficient. In particular, merely specifying the partitions used by the protocol takes space that is exponential in length of the inputs, not to mention that the proof is nonconstructive and that a naive construction would require double exponential time. An efficient implementation of the protocols is achieved by using partitions which can be specified by polynomially many bits. These partitions will not be hardwired into the protocol but rather selected online by the two parties. Namely, at the outset of each step, the parties perform a sampling protocol to select a partition for that step. The partition is specified by an mth degree ($m = \text{poly}(n)$) polynomial over the field $F \stackrel{\text{def}}{=} GF(2^n)$ and a fixed partition of the elements of F into two equal parts F^0 and F^1. For example, suppose polynomial P (over F) is chosen to specify a partition of Y_i, then Y_i^σ is defined as the set of all points $y \in Y_i$ satisfying $P(y) \in F^\sigma$. This plan is materialized via a two-party protocol for sampling these partitions and a proof that, with probability at least $1 - P_v$, every partition

selected (for the generic protocol) by the sampling protocol satisfies all v-balance properties. To this end we first bound the probability that, for an appropriately chosen $m = \text{poly}(n)$, a random mth degree polynomial induces a partition that fails to satisfy some v-balance properties. Next, we present a two-party protocol for sampling l-bit strings and bound the advantage of each party towards any set as a function of the density of that set.

Terminology. Partitions induced by $(\delta n)^4$-degree polynomials are hereafter called *polynomial partitions*. We modify these partitions so that they are never trivial (e.g., by replacing each trivial partition by a fixed nontrivial partition). Recall that Property (P0) forbids trivial partitions, except if the universe is a singleton. The modification is introduced to guarantee this.

4.3.1. Bounding the probability of nonbalanced polynomial partitions. We start by bounding the probability for a random polynomial partition to fail some v-balance property.

LEMMA 4.22. *For every $c_1 > 0$ there exists δ, so that for every set S of cardinality k, a uniformly selected polynomial partition is not Δ_v-biased with respect to S with probability at most $(p_v/k)^{c_1}$.*

Proof. The modification described in the terminology (above) can only decrease the probability that a partition is not Δ-biased (w.r.t. any set S). Thus, it suffices to analyze the distribution of unmodified polynomial partitions.

A $2t$th moment argument easily shows that if $x_1, x_2, \ldots, x_k$ are m-wise independent random variables uniformly distributed in $\{0,1\}$ then $\text{Prob}(|\sum_{i=1}^{k} x_i - \frac{k}{2}| > B) < (\frac{\sqrt{k}t}{B})^{2t}$, for every $t \leq m/2$. Therefore, the probability for a uniformly chosen polynomial partition to fail condition (1) in Definition 4.1 does not exceed

$$\left(\frac{\sqrt{k}\cdot t}{k^{3/4}}\right)^{2t} = \left(\frac{t}{k^{1/4}}\right)^{2t} \tag{12}$$

for any $t \leq (\delta n)^4/2$. We now use equation (12) with two different settings for t. First we set $t = \Delta_v/2$ (since $p_v \geq 2^{-n}$, it follows that $\Delta_v \leq \delta \cdot 2n$ and this t is indeed smaller than $(\delta n)^4/2$) and using $k \geq \Delta^4$, we bound equation (12) by

$$\left(\frac{\Delta_v/2}{\Delta_v}\right)^{\Delta_v} = p_v^{\delta} < p_v^{2c_1},$$

where the last inequality comes from $\delta \geq 2c_1$. Secondly, we set $t = 8c_1$, and bound equation (12) by

$$\left(\frac{8c_1}{k^{1/4}}\right)^{16c_1} = \left(\frac{(8c_1)^8}{k^2}\right)^{2c_1} < \frac{1}{4}\cdot k^{-2c_1},$$

where we have used $k \geq \Delta^4 \geq 4 \cdot (8c_1)^8$. Multiplying these two bounds, we bound equation (12) by

$$\sqrt{p_v^{2c_1} \cdot \frac{k^{-2c_1}}{4}} = \frac{1}{2}\cdot (p_v/k)^{c_1}$$

as desired. To bound the probability for failure in condition (2), note that for $k \leq \Delta^4$ we have, $k \leq (\delta n)^4$ (as previously observed $\Delta_v \leq \delta n$). Thus, a uniformly selected

polynomial partition splits k elements exactly as a totally random partition and so the bound obtained for this case (i.e., for $k \leq \Delta^4$) in Lemma 4.19 holds also here. □

PROPOSITION 4.23 (polynomial-partition satisfy value-balance properties). *Fix $v \in Range(f)$, and consider an execution of the generic protocol with uniformly selected polynomial partitions. Let π_i be the probability that the first failure of some v-balance property occurs on the ith round. Then,*

$$\sum_{i\geq 1} \sqrt[4]{\pi_i} \leq O(\Delta_v \cdot p_v).$$

The mysterious choice of the 4th roots will be clarified when we apply the proposition (in the proof of Theorem 4.27).

Proof. It suffices, of course, to consider only row partitions. Let $\pi_{i,t}$ be the probability that our first failed row partition occurred in round i and that Property (P_t) was violated (for some $0 \leq t \leq 7$ and $i \geq 1$). Clearly,

$$\begin{aligned}\sum_{i\geq 1} \sqrt[4]{\pi_i} &\leq \sum_{i\geq 1} \sqrt[4]{\sum_{t=0}^{7} \pi_{i,t}} \\ &\leq \sum_{t=0}^{7} \sum_{i\geq 1} \sqrt[4]{\pi_{i,t}}.\end{aligned}$$

So it remains to bound, $\sum_{i\geq 1} \sqrt[4]{\pi_{i,t}}$, for each $t = 0, \ldots, 7$. Analogously to the proof of Proposition 4.20, we use Lemma 4.22 to upper bound the probability that a uniformly chosen polynomial partition violates one of the v-balance properties. (Again, for each property, we multiply the number of sets considered by the probability that a uniformly selected polynomial partition is not Δ_v-biased with respect to an individual set. An obvious (lower) bound on the size of an individual set considered is Δ_v, but in some cases better lower bounds hold). We now assume $c_1 \geq 10$.

- We upper bound the probability that Property (P0) is violated for the first time in the ith round by $|X_{i-1}| \cdot (p_v/|X_{i-1}|)^{c_1}$. Letting $x_j := |X_j|$, we have

$$\pi_{i,0} \leq x_{i-1} \cdot (p_v/x_{i-1})^{c_1}, \tag{13}$$

$$\text{where } x_j \geq \max\{\Delta, |X_0|/2^{j-1}\}, \tag{14}$$

  where the lower bound on x_j follows, since Property (P0) held in the previous rounds. Furthermore, if Property (P0) held in all first n rounds, then $|X_n| \leq \Delta$ and henceforth every nontrivial partition satisfies all properties vacuously. Therefore,

$$\begin{aligned}\sum_{i\geq 1} \sqrt[4]{\pi_{i,0}} &= \sum_{i=1}^{n} \sqrt[4]{\pi_{i,0}} \\ &\leq \sum_{i=1}^{n} \sqrt[4]{x_{i-1} \cdot \left(\frac{p_v}{x_{i-1}}\right)^{c_1}} \\ &< \sum_{i=1}^{n} \frac{p_v}{x_{i-1}} \\ &< p_v \cdot \sum_{i=1}^{n} \frac{2^{i+2}}{2^n},\end{aligned}$$

where the last inequality uses the lower bounds for the x_j's. It follows that $\sum_{i\geq 1}\sqrt[4]{\pi_{i,0}} = O(p_v)$.

- Adopting the analysis in the proof of Proposition 4.20, we know that the probability that the first failure is with Property (P1) in round i is at most $4|X_{i-1}|\cdot(p_v/|X_{i-1}|)^{c_1}$. Using the same analysis as above, we conclude $\sum_{i\geq 1}\sqrt[4]{\pi_{i,1}} = O(p_v)$.
- For Properties (P2) and (P7), we need only consider rounds i so that $|X_i| < (2/p_v)$. Using the analysis in the proof of Proposition 4.20, we bound the probability that the partition in such a round violates Property (P2) (resp., (P7)) by $O(p_v^{c_1-1}/\Delta_v^{c_1})$ (resp., $O(p_v^{c_1-1}/\Delta^{c_1-2})$). The bound on $\sum_{i\geq 1}\sqrt[4]{\pi_{i,t}}$, for $t = 2, 7$, follows, since there are at most Δ such rounds.
- Following the analysis in the proof of Proposition 4.20, we consider for Property (P6) only $j \leq \ell+1$ and $y \in Y_i$ such that $\#_v(R^{j+\ell}\cap X_i, y) \geq \max\{\Delta_v, (p_v/4\Delta_v)\cdot|Y_i|\}$. Let us denote the set of these pairs by P_i. The probability that our first violation is on round i and Property (P6) is being violated, is at most

$$\begin{aligned}\sum_{(j,y)\in P_i}\left(\frac{p_v}{\#_v(R^{j+\ell}\cap X_i, y)}\right)^{c_1} &\leq |P_i|\cdot\left(\frac{p_v}{\Delta}\right)^{(c_1+1)/2}\cdot\left(\frac{p_v}{(p_v/4\Delta_v)\cdot|Y_i|}\right)^{(c_1+1)/2}\\ &\leq ((\ell+1)\cdot|Y_i|)\cdot\left(\frac{p_v}{\Delta}\right)^4\cdot\left(\frac{4\Delta}{|Y_i|}\right)^5\\ &< \left(\frac{\Delta_v\cdot p_v}{|Y_i|}\right)^4.\end{aligned}$$

  Using the same analysis as for Property (P0), we obtain $\sum_{i\geq 1}\sqrt[4]{\pi_{i,6}} < \Delta_v\cdot p_v$.
- For the remaining properties (i.e., (P3), (P4), and (P5)) we have a total of $O(\log^2(1/p_v))$ sets and so we can handle each of these sets separately. Consider, for example, the set $R^{j+\ell}$ from the definition of Property (P4). The row partition of round $i+1$ violates the balance property on this set with probability at most $(\frac{p_v}{|R^{j+\ell}\cap X_i|})^{c_1}$. Setting $x_i \stackrel{\text{def}}{=} |R^{j+\ell}\cap X_i|$, we can apply the same analysis as applied to equation (13), except that here we use Property (P4) for the previous rounds. The desired bound for $\sum_{i\geq 1}\sqrt[4]{\pi_{i,t}}$ follows, for $t = 3, 4, 5$.

Having shown that $\sum_{i\geq 1}\sqrt[4]{\pi_i} < \Delta_v\cdot p_v$, for each $t = 0,\ldots,7$, the proposition follows. □

4.3.2. A protocol for string sampling. We now present a two-party protocol for sampling l-bit strings and bound the advantage of each party towards any set as a function of the set's density. The protocol is a simplification of the protocol for computing a function. The parties proceed in l rounds. In each round one party should select a pseudorandom partition of the residual sample space and the other party should flip a coin to select a side of this partition. In the next round the parties switch roles. All partitions selected by each party must divide the residual space into two sets of equal cardinality. Specifically, the partition is defined by a linear combination of the bits in the representation of the sample point. Following is the code of the protocol (the parties are called P_0 and P_1).

Round i:

- $P_{i \bmod 2}$ uniformly selects an l-dimensional binary vector v_i, which is linearly independent of the vectors used in previous rounds, and sends v_i to the other party.
- $P_{(i+1) \bmod 2}$ uniformly selects $\sigma_i \in \{0,1\}$ and sends it to the other party.

Intuition: The residual sample space after round i consists of all l-dimensional binary vectors x so that $< x, v_j > = \sigma_j$ for every $j \le i$ ($< \cdot, \cdot >$ is mod-2 inner product, and this residual set is an affine subspace).

PROPOSITION 4.24 (analysis of the two-party sampling protocol). *Let $S \subseteq \{0,1\}^l$ be arbitrary and let $p \stackrel{\text{def}}{=} |S|/2^l$. If one of the parties that participate in the above protocol plays honestly, then the probability for the protocol's outcome to be in S is at most $O(p^{\frac{1}{4}})$.*

Proof. Let U_i denote the residual sample space after round i; namely,

$$U_i \stackrel{\text{def}}{=} \{x :< x, v_j > = \sigma_j \ \ \forall j \le i\}.$$

Let $S_i \stackrel{\text{def}}{=} S \cap U_i$ denote the residual target set ($U_0 = \{0,1\}^l$ and $S_0 = S$). We want to consider the cardinality of S_i as i grows (i.e., the execution proceeds) and treat differently "small" and "large" S_i. For "small" S_i we bound the probability of hitting S_i as $|S_i|$ times the probability of hitting any specific element. If S_i is "large," then with sufficiently high probability $|S_{i+1}| \approx |S_i|/2$ and hence the density, $|S_i|/|U_i|$, is approximately preserved. Details follow.

The following three claims do not depend on the residual sample space U_i. Thus, S_i (the residual target set after i rounds) can be considered fixed, too.

Claim 4.24.1. If the $(i+1)$st partition is chosen by an honest player, then, with probability at least $1 - |S_i|^{-\frac{4}{5}}$:

$$\frac{|S_i|}{2} - |S_i|^{\frac{9}{10}} < |S_{i+1}| < \frac{|S_i|}{2} + |S_i|^{\frac{9}{10}},$$

regardless of the choice of σ_{i+1}.

Proof. By hypothesis, v_{i+1} is uniformly selected among the vectors which are linearly independent of $v_1, \ldots, v_i$. Instead, let us select v_{i+1} uniformly at random from the entire space Z_2^l. The additional partitions come from v_{i+1} in the linear span of $(v_1, \ldots, v_i)$, and thus induce a trivial partition on U_i, so the modified partitioning procedure is only less likely to yield good partitions.

We show that with very high probability, even the partition induced by a uniformly chosen vector is quite balanced. For any $\sigma \in \{0,1\}$, we consider random variables ζ_s, $(s \in S_i)$ where $\zeta_s = 1$ if $< s, v_{i+1} >= \sigma$ and 0 otherwise. Since v_{i+1} is selected uniformly, each ζ_s is uniformly distributed in $\{0,1\}$. Furthermore, these random variables are pairwise independent, as long as $|U_i| \ge 2$ (i.e., the protocol did not terminate). Thus, we have

$$\text{Prob}\left(\left|\sum_{s \in S_i} \zeta_s - \frac{|S_i|}{2}\right| \ge |S_i|^{\frac{9}{10}}\right) < \frac{|S_i|}{|S_i|^{2 \cdot \frac{9}{10}}}$$

and the claim follows. □

On the other hand, the following claim is obvious.

Claim 4.24.2. If σ_{i+1} is selected by an honest player, then the expected cardinality of S_{i+1} is $|S_i|/2$.

The probability of hitting S_i is bounded by $|S_i|$ times the probability of hitting any specific element of S_i, so we have the following.

Claim 4.24.3. With the above notation, the probability that the output of the protocol is in S (or, equivalently, in S_i) does not exceed $|S_i| \cdot 2^{-(l-i-1)/2}$.

Proof. Clearly $|U_i| = 2^{l-i}$ and there remain $r \stackrel{\text{def}}{=} l - i$ rounds to termination, of which σ will be chosen by an honest player at least $\lfloor r/2 \rfloor$ times. Any $s \in S_i$

survives each such round with probability $\frac{1}{2}$, and is the output with probability at most $\cdot 2^{-\lfloor r/2 \rfloor}$, as claimed. □

In case $|S| < p^{-\frac{1}{2}}$ the proposition follows by using Claim 4.24.3; namely, the probability for output in S is bounded by

$$\begin{aligned} |S_0| \cdot 2^{-l/2} &= \sqrt{|S| \cdot \frac{|S|}{2^l}} \\ &= \sqrt{|S| \cdot p} \\ &< p^{\frac{1}{4}}. \end{aligned}$$

So in what remains we consider the case $|S| \geq p^{-\frac{1}{2}}$. Let the protocol be executed for $t \stackrel{\text{def}}{=} \log_2 |S| - \frac{1}{2}\log_2(1/p) \geq 0$ rounds. In the rest of the proof we essentially show that, at this stage, $|S_t| \approx p^{-\frac{1}{2}}$. Using Claim 4.24.3 at this point, we obtain (again) the upper bound of $|S_t| \cdot 2^{-(l-t)/2} = p^{\frac{1}{4}}$ (using $l - t = l - \log_2 |S| + \frac{1}{2}\log_2(1/p) = (1+\frac{1}{2}) \cdot \log_2(1/p)$).

We assume, without loss of generality, that the honest party picks the partitions at the even rounds. Also, there is no loss in assuming that his opponent plays a pure (i.e., deterministic) strategy: since the honest party's strategy is fixed, the adversary's optimal move maximizes his expected payoff. On even-numbered rounds he selects one side of a partition presented by the honest player, while on round $2i+1$ he selects a partition that is determined by a function Π_i. Formally, each of his moves is a function of the history of the execution, but this whole history is encoded by the current residual sample space. Thus, we may view each Π_i as a mapping $\Pi_i : 2^U \mapsto 2^U$, where U_{2i-2}, the residual sample space after $2i-2$ rounds is partitioned into $(\Pi_i(U_{2i-2}), U_{2i-2} - \Pi_i(U_{2i-2}))$. Having fixed the adversary's strategy, the residual sample space after j rounds, U_j is a well-defined random variable. The following two sequences of random variables, depend now only on the coin tosses of the honest party:

1. π_i is the cardinality of $S \cap \Pi_i(U_{2i-2})$, for $i \geq 1$;
2. ζ_j is the cardinality of $S \cap U_j$, for $j \geq 0$ (where, $\zeta_0 = |S|$ is constant).

The following facts are immediate by the definitions and Claims 4.24.1 and 4.24.3.

Claim 4.24.4. For every $i \geq 1$,

1. (*effect of round* $2i-1$: adversary presents partition)
   $\text{Prob}(\zeta_{2i-1} = \pi_i) = \text{Prob}(\zeta_{2i-1} = \zeta_{2i-2} - \pi_i) = \frac{1}{2}$.
2. (*effect of round* $2i$: adversary selects side)
   $|\zeta_{2i} - \frac{\zeta_{2i-1}}{2}| < \zeta_{2i-1}^{\frac{9}{10}}$ with probability at least $1 - \zeta_{2i-1}^{-\frac{4}{5}}$. Always $0 \leq \zeta_{2i} \leq \zeta_{2i-1}$.
3. (*termination*: as a function of the situation after $t \stackrel{\text{def}}{=} \log_2 |S| - \frac{1}{2}\log_2(1/p)$ rounds)
   The protocol terminates with output in S with probability at most
   $$\text{Exp}(\zeta_t) \cdot 2^{-(l-t)/2} = \text{Exp}(\zeta_t) \cdot p^{3/4}$$
   the expectation being over the coin tosses of the honest player in the first t rounds.

In proving item (3), use $\text{Exp}(\zeta_t \cdot 2^{-(l-t)/2}) = \text{Exp}(\zeta_t) \cdot 2^{-(l-t)/2}$ and $l - t = l - \log_2 |S| + \frac{1}{2}\log_2(1/p) = (1 + \frac{1}{2}) \cdot \log_2(1/p)$. It remains to use items (1) and (2) in order to prove the following.

Claim 4.24.5. Let $t \stackrel{\text{def}}{=} \log_2 |S| - \frac{1}{2}\log_2(1/p)$ and suppose $t \geq 0$. Then

$$\text{Exp}(\zeta_t) = O(p^{-1/2})$$

the expectation being over the coins tossed by the honest player in the first t rounds.

Proof. Using item (2) of Claim 4.24.4, we obtain

$$\begin{aligned}\mathrm{Exp}(\zeta_{2i+2}) &\leq \mathrm{Exp}\left(\frac{\zeta_{2i+1}}{2} + \zeta_{2i+1}^{\frac{9}{10}} + \zeta_{2i+1}^{-\frac{4}{5}} \cdot \zeta_{2i+1}\right) \\ &\leq \mathrm{Exp}\left(\frac{\zeta_{2i+1}}{2} + 2 \cdot \zeta_{2i+1}^{\frac{9}{10}}\right).\end{aligned}$$

On the other hand, using item (1) of Claim 4.24.4, we obtain both

$$\mathrm{Exp}(\zeta_{2i+1}) = \frac{1}{2} \cdot \mathrm{Exp}(\zeta_{2i})$$

and

$$\mathrm{Exp}(\zeta_{2i+1}^{\frac{9}{10}}) = \frac{1}{2} \cdot \mathrm{Exp}(\pi_i^{\frac{9}{10}}) + \frac{1}{2} \cdot \mathrm{Exp}((\zeta_{2i} - \pi_i)^{\frac{9}{10}}).$$

Combining the three (in)equalities, we get

$$\begin{aligned}\mathrm{Exp}(\zeta_{2i+2}) &\leq \frac{1}{4} \cdot \mathrm{Exp}(\zeta_{2i}) + \mathrm{Exp}(\pi_i^{\frac{9}{10}}) + \mathrm{Exp}((\zeta_{2i} - \pi_i)^{\frac{9}{10}}) \\ &< \frac{1}{4} \cdot \mathrm{Exp}(\zeta_{2i}) + 2 \cdot \mathrm{Exp}(\zeta_{2i}^{\frac{9}{10}}).\end{aligned}$$

For $0 < \alpha < 1$, the function x^α over $x \geq 0$ is concave, so we may apply Jensen's inequality, and conclude

$$\mathrm{Exp}(\zeta_{2i+2}) < \frac{1}{4} \cdot \mathrm{Exp}(\zeta_{2i}) + 2 \cdot \mathrm{Exp}(\zeta_{2i})^{\frac{9}{10}}.$$

Setting $z_i \stackrel{\text{def}}{=} \mathrm{Exp}(\zeta_{2i})$, a minor adaptation of Claim 4.4 yields $\mathrm{Exp}(\zeta_t) = O(\frac{\zeta_0}{2^t})$. Recall now that $t = \log_2 |S| - \frac{1}{2}\log_2(1/p))$ and $\zeta_0 = |S|$, to conclude the claim. □

The proposition follows. □

Remark 4.25. The bound provided in Proposition 4.24 is not tight. Yet, it suffices for the purpose of sampling partitions in the generic protocol (see the proof of Theorem 4.27). Much better protocols can be obtained—see Theorem 4.28. These (more complex) sampling protocols use the above protocol and the bound from Proposition 4.24 as a bootstrapping step. In our best sampling protocol, if one party plays honestly, the probability for the protocol to land in an element of any set of density p does not exceed $O(\sqrt{p})$.

Remark 4.26. Our two-party sampling protocol is very similar to *interactive hashing*, a protocol that was discovered independently by Ostrovsky, Venkatesan, and Yung [20] (see Naor et. al. [18]). However, in interactive hashing one party always picks the partition and the other always chooses the side. Also, interactive hashing terminates after $l - 1$ (rather than l) rounds. Interactive hashing was invented for completely different purposes and consequently its analysis, as in [18] (and subsequent studies), is very different from what appears above. Interactive hashing was used for implementing various types of commitment protocols (cf. [20, 18, 21, 10]).

4.3.3. The main result. Combining Propositions 4.23 and 4.24 with Theorem 4.18, we get the following.

THEOREM 4.27 (efficient protocol meeting the lower bound). *There exists a (generic) two-party protocol, for evaluating an arbitrary bivariate function f. This protocol is performed by a pair of uniform probabilistic polynomial-time programs with a single oracle call to the function f and satisfies the following properties:*

- *If both parties play honestly and their inputs are x and y respectively, then the output is $f(x,y)$.*
- *For every value v in the range of f, if one party plays honestly then the outcome of the protocol is v with probability at most*

$$O(\log^6(1/p_v)\cdot\max\{q_v,\sqrt{p_v}\}).$$

Furthermore, in case $q_v = p_v$, this bound can be improved to $O(\sqrt{p_v})$.

Proof. The protocol is an implementation of the generic protocol where the partitions are determined by poly(n)-degree polynomials that are selected using the sampling protocol described above. This proves the first item. For the second item we consider the event in which during the execution of the protocol (with at least one party being honest) a partition was selected which does not satisfy all v-balanced properties. Using Propositions 4.23 and 4.24, the probability of this event is $O(\Delta_v \cdot p_v)$. (Here we use the fact that Proposition 4.23 bounds the sum of the fourth root of the density of "bad" partitions.) In the complementary case, when every partition that is used satisfies all v-balance properties, Theorem 4.18 applies, and the main part of the second item follows.

A bound of $O(\sqrt{p_v}\log^2(1/p_v))$ for the special case of $q_v = p_v$ can be obtained by using Corollary 4.8 instead of Theorem 4.18. The better bound of $O(\sqrt{p_v})$ requires a slightly more careful analysis that we turn to perform.

We slightly change the classification of rounds as appearing in the motivating discussion (subsection 4.1). We first consider the situation after $i \stackrel{\text{def}}{=} n - \log_2(1/p_v) - 4\log_2\Delta_v$ rounds. Following the ideas in the proof of Lemma 4.5 (and using Proposition 4.23 and 4.24), we first observe that, with probability $\geq 1 - p_v$, the number of v-entries in each row (column) of the residual matrix is at most $2\cdot\Delta_v^4$ (i.e., $\#_v(x,Y_i) \leq 2\Delta_v^4$, $\forall x \in X_i$). (Here and below the probability space is comprised of runs of the generic protocol in which polynomial partitions are selected using the sampling protocol of Proposition 4.24.) Next, we consider the situation after an additional $\ell \stackrel{\text{def}}{=} \frac{1}{2}\log_2(1/p_v)$ rounds. Using similar ideas (this time following Lemma 4.7), we conclude that, with probability $\geq 1 - p_v$, the total number of v-entries in the entire residual matrix, is at most $(4\Delta_v^4+1)\cdot 2\Delta_v^4 < 9\Delta_v^8$ (i.e., $\#_v(X_{i+\ell},Y_{i+\ell}) < 9\Delta_v^8$). Furthermore, with probability at least $1-p_v$, the residual matrix at this point is of size approximately $\frac{\Delta_v^4}{\sqrt{p_v}}$ by $\frac{\Delta_v^4}{\sqrt{p_v}}$. In the original analysis, we did not try to argue that the number of v-entries in each row/column decreases during these additional ℓ rounds. But this is most likely to be the case as shown below.

Claim 4.27.1. There exists a constant c so that with probability at least $1-p_v$, after $i+\ell = n - \frac{1}{2}\log_2(1/p_v) - 4\log_2\Delta_v$ rounds, there are at most c v-entries in each residual row (resp., column) (i.e., $\#_v(x,Y_{i+\ell}) \leq c$, $\forall x \in X_{i+\ell}$).

Proof. We consider again these additional ℓ rounds, assuming that previously (i.e., after i rounds) each residual row/column contains at most $2\Delta_v^4$ v-entries. We want to bound, for each individual row $x \in X_i$, the probability that $\#_v(x,Y_{i+\ell}) > c$. Say that a column partition is *good* if either there are fewer than c v-entries in the x-row, or each side of the partition contains at least one-third of these entries. (In a *good* round, a good column partition is performed). A *uniformly* selected polynomial partition fails to be good with probability that is exponentially small in the number of v-entries, since at this point, the degree of the polynomials that determine the partition exceeds the number of v-entries in row x. However, the polynomial partitions are selected using the sampling protocol of Proposition 4.24. As Proposition 4.24 states, the same remains valid also when using the sampling algorithm to select the partitions (at the

cost of a different constant in the exponent). Therefore, there exists a constant c so that, as long as row x has more than c v-entries, the next round is good with probability at least 16/17 (a great underestimate for all but the very last rounds). On the other hand, if we go through at least $t \stackrel{\text{def}}{=} \log_{3/2}(2\Delta_v^4)$ *good* rounds, then row x has at most c v-entries. Thus $\#_v(x, Y_{i+\ell}) > c$ only if fewer than $t \ll \ell = \frac{1}{2}\log_2(1/P_v)$ out of the last ℓ rounds are good, and the probability of this event is bounded above by

$$\binom{\ell}{t} \cdot (1/17)^{\ell-t} < (1/16)^{(1+\epsilon)\cdot\ell} = p_v^{(1+\epsilon)\cdot 2},$$

where $\epsilon > 0$ is some small constant, the inequality follows by $t = o(\ell)$ and the equality uses the definition of ℓ. Summing over all possible $x \in X_i$, the claim follows. □

Combining Claim 4.27.1 with the discussion which precedes it, we conclude that after $i+\ell = n - \frac{1}{2}\log_2(1/p_v) - 4\log_2 \Delta_v$ rounds, with very high probability, the residual matrix contains at most $9\Delta_v^8$ entries of value v with at most c such entries in any row or column. Since we are seeking an $O(\sqrt{p_v})$ bound, we can and will ignore those rare runs (of probability $O(p_v)$), for which this is not the case. Proceeding analogously to subsection 4.1, we could consider the situation after another $r = 4\log_2 \Delta_v$ rounds and bound by p_v the probability that after a total of $i + \ell + r = n - \frac{1}{2}\log_2(1/p_v)$ rounds the residual submatrix contains more than Δ_v entries of value v. This would yield a bound of $O(\Delta_v \cdot \sqrt{p_v})$ on the influence towards v. To obtain the better bound claimed above, we observe that it suffices to bound the *expected number* of v-entries in the residual matrix (rather than bounding the probability that too many v-entries remain). Specifically, we consider a standard coloring of the v-entries after $i+\ell$ rounds. This coloring uses at most $2 \cdot c + 1$ colors. Fixing one of these colors, we consider the next $r \stackrel{\text{def}}{=} 4\log_2 \Delta_v$ rounds, and bound the expected number of the remaining v-entries. A *diagonal* is a set of entries in a matrix that has no more than a single element in common with any row/column.

Claim 4.27.2. Consider a diagonal D of at most $9\Delta_v^8$ entries in the residual matrix $(X_{i+\ell} \times Y_{i+\ell})$. Then the expected number of entries from D in the residual matrix $X_{i+\ell+r} \times Y_{i+\ell+r}$ is $O(1)$.

Proof. It suffices to analyze a process in which $2r = 8\log_2 \Delta_v$ polynomial partitions, selected by the sampling protocol of Proposition 4.24, are applied to a space containing $9 \cdot \Delta_v^8$ elements so that after selecting each partition we proceed with the side containing more elements. Our claim is that the expected number of elements after applying these $2r$ partitions is $O(1)$. To prove this claim, let us consider first what happens after applying a single partition. Namely, let S be a subset (of some universe) and ζ be a random variable representing the number of S-elements in the S-heavier side (i.e., the side containing more S-elements) of a partition, selected by the sampling protocol. Clearly,

$$\text{Exp}(\zeta) < \left[\frac{|S|}{2} + |S|^{3/4}\right] + \text{Prob}\left(\zeta > \frac{|S|}{2} + |S|^{3/4}\right) \cdot |S|.$$

For a uniformly selected polynomial partition the probability that the S-heavy side contains more than $|S|/2 + |S|^{3/4}$ elements of S is exponentially small in $\sqrt{|S|}$ and by Proposition 4.24 the same holds (with a smaller constant in the exponent) when the polynomial partition is selected by the sampling protocol. Thus, $\text{Exp}(\zeta) < \frac{|S|}{2} + |S|^{3/4} + O(1)$. Hence, we have a sequence of random variables, $\zeta_0, \zeta_1, \ldots, \zeta_{2r}$, so that $\zeta_0 < 9\Delta_v^8$ and $\text{Exp}(\zeta_i | \zeta_{i-1} = s) < \frac{s}{2} + s^{3/4} + O(1)$, for $i = 1, \ldots, 2r$. Manipulating the

expectation operators (as in the proof of Claim 4.24.5), we conclude that $\mathrm{Exp}(\zeta_{2r}) = O(1)$ and the current claim follows. □

Combining Claims 4.27.1 and 4.27.2, we conclude that with probability $1 - p_v$ we reach round $i + \ell + r = n - \frac{1}{2}\log_2(1/p_v)$ with an expected number of $O(1)$ entries of value v. Using the analysis of Corollary 4.8 (corresponding to stage 3 in the motivating discussion) we establish the claimed $O(\sqrt{p_v})$ bound and the theorem follows. □

As stated in Remark 4.25, we have sampling protocols that improve on Proposition 4.24. This can be done either directly (with the techniques used in proving Theorem 4.27) or by applying Theorem 4.27 to any function f with $q_v = 2^{-l}$ $(\forall v \in \{0,1\}^l)$. In either case, the resulting sampling protocols use the simple sampling protocol (and the bound presented in Proposition 4.24 as a bootstrapping step).

THEOREM 4.28 (a better two-party sampling protocol). *There exists a protocol for sampling $\{0,1\}^l$ that is performed by a pair of uniform probabilistic polynomial-time programs, so that: For every $S \subseteq \{0,1\}^l$ of density p, if one party plays honestly, the outcome of the protocol is in S with probability at most $O(\sqrt{p})$.*

Proof (using the second alternative). Let $f : \{0,1\}^n \times \{0,1\}^n \mapsto \{0,1\}^l$ satisfy $q_v = 2^{-l}$ for every $v \in \{0,1\}^l$. For example, $f(x,y) = x + y \bmod 2^l$, where x and y are viewed as residues mod 2^n (and $n \geq l$, say $n = l$). An honest party is supposed to select its input uniformly in $\{0,1\}^n$ and to invoke the protocol of Theorem 4.27. The current theorem follows from the (furthermore part of) Theorem 4.27, by considering the indicator function $\chi_S(v) = 1$ if $v \in S$ (and $\chi_S(v) = 0$ otherwise). Namely, we consider the function $g(x,y) \stackrel{\mathrm{def}}{=} \chi_S(f(x,y))$ and take advantage of the fact that the protocol in Theorem 4.27 is generic (i.e., determines a pair of inputs (x,y) for the function independently of the function). □

5. Towards the multiparty case. We believe that the ideas developed in the two-party case will prove useful also for the multiparty case. However, even the problem of computing a 3-argument function by a 3-party protocol in the presence of one dishonest party is much more involved than the problem of computing a bivariate function by a 2-party protocol, as in the previous section. A natural extension of our two-party protocol is to let each round consist of three steps (rather than two) and refer to three partitions of the three residual input spaces. In each step, a predetermined party announce in which side of the partition its input lies, and by doing so makes its residual input space smaller. We believe that this (generic) protocol when used with random partitions, nearly minimizes the advantage of any dishonest party, regardless of the function that is being computed. We also believe that this protocol nearly minimizes the advantage of any coalition of two dishonest players. However, this seems to require a much more complex analysis, and additional parameters of the function need to be taken into account. In particular, the advantage of a single adversary towards a value v depends not only on the density of v-entries in the entire function (denoted p_v above) and on the density of v-entries in the function restricted by the best input (denoted q_v). For example, a single party can influence any protocol for computing the function $f(x,y,z) = x + y + z \bmod N$ to produce output 0 (or any other residue mod N) with probability $N^{-2/3}$ (and the generic protocol can be shown to bound the advantage of a dishonest party to about this value). On the other hand, a single party can influence any protocol for computing the function $g(x,y,z) = x + y \bmod N$ to produce output 0 with probability $N^{-1/2}$ (and again the generic protocol meets this bound). However, both functions have the same $p_v = q_v = 1/N$.

Another difficulty which arises in the context of multiparty protocols is that, when the number of parties is large, we cannot afford to let the parties reveal information

in a predetermined order (as in the two-party case and the three-part case above). This difficulty is best demonstrated in the special case where each input is one bit (i.e., $Domain(f) = \{0,1\} \times \{0,1\} \cdots \times \{0,1\}$). Here, the influence of parties which are last to reveal their input is more substantial than the influence of parties which reveal their input first. This calls for choosing a random permutation to determine the order of playing. Thus, the role of a sampling protocol in the multiparty case is more fundamental than in the two-party situation. (Recall that in the two-party protocols, sampling was introduced only for increased efficiency.)

5.1. A multiparty sampling protocol. In this paper we confine ourselves to the presentation of an efficient fault-tolerant multiparty sampling protocol.

THEOREM 5.1 (multiparty sampling protocol). *There exists an m-party sampling protocol that is performed by m (identical) uniform probabilistic polynomial-time programs, so that: For every set $S \subseteq \{0,1\}^l$, if $m-t$ parties play honestly, then the outcome of the protocol is in S with probability at most $O(\log(1/p) \cdot p^{1-O(\frac{t}{m})})$, where $p \stackrel{\text{def}}{=} |S|/2^l$.*

Our proof of Theorem 5.1 adapts the ideas used in Theorem 4.28 to the multiparty context. Namely, our protocol uses partitions which are in turn selected by a lower quality sampling protocol. Specifically, the protocol proceeds in l rounds. In each round, the m parties first select at random (using a simpler sampling protocol) a $\text{poly}(n \cdot m)$-degree polynomial specifying a partition of the residual sample space, and next use the collective coin tossing protocol of Alon and Naor [1] to choose one side of this partition. The sampling protocol used to choose $\text{poly}(nm)$-degree polynomials is similar except that the partitions are specified by linear transformations (as in the protocol of Proposition 4.24). These linear transformations are selected using a trivial sampling protocol which consists of selecting each bit individually by the collective coin tossing protocol of Alon and Naor [1].

We prefer an alternative presentation of our proof, in which the construction of multiparty sampling protocols is reduced to the construction of sampling algorithms that use an SV-source as their source of randomness. Recall that an *SV-source with parameter $\gamma \geq \frac{1}{2}$* (cf. [22]) is a sequence of Boolean random variables, $X_1, X_2, \ldots$, so that for each i and every $\alpha \in \{0,1\}^i$ and every $\sigma \in \{0,1\}$:

$$\text{Prob}(X_{i+1} = \sigma | X_1 \cdots X_i = \alpha) \leq \gamma.$$

Theorem 5.1 follows from the next proposition.

PROPOSITION 5.2 (sampling with an SV-source). *For every constant γ, $\frac{1}{2} \leq \gamma < \frac{1}{\sqrt{2}}$, there exist a probabilistic polynomial-time algorithm, A_1, which on input 1^n uses any SV-source with parameter γ for its internal coin tosses and satisfies, for every sufficiently large n and every set $S \subseteq \{0,1\}^n$,*

$$\text{Prob}(A_1(1^n) \in S) = O(\log(1/p) \cdot p^{\log_2(1/\gamma)}),$$

where $p \stackrel{\text{def}}{=} \frac{|S|}{2^n}$, and the probability is taken over an arbitrary SV-source with parameter γ.

In particular, for $\gamma = \frac{1}{2}(1+\epsilon)$, we have $\log_2(1/\gamma) = 1 - \log_2(1+\epsilon) \geq 1 - \frac{1}{\ln 2} \cdot \epsilon$. Thus, observing that the Alon–Naor protocol implements an SV-source with parameter $\gamma = \frac{1}{2}(1 + O(\frac{t}{n}))$, we derive Theorem 5.1 as a corollary of Proposition 5.2. Furthermore, Proposition 5.2 yields an alternative way of recognizing BPP languages in polynomial time using an arbitrary SV-source with parameter $\gamma < \frac{1}{\sqrt{2}} \approx 0.7$. Consider, without loss of generality, an algorithm A that using n (perfect) random coins

errs with probability at most ϵ, where $\epsilon > 0$ is a small constant (depending on γ). In order to utilize A when only an SV-source is available, we first use algorithm A_1 (with the SV-source) to generate a "somewhat random" n-bit string, r, and then invoke algorithm A with the string r as a substitute for the n coins required by A. We stress that algorithm A is only invoked once. To analyze the performance of the new algorithm, let S be the set of coin sequences on which A errs. By our hypothesis $|S| \leq \epsilon \cdot 2^n$ and thus using Proposition 5.2 a string $r \in S$ is generated with probability at most $\log(1/\epsilon) \cdot \epsilon^{\log(1/\gamma)} < 1/3$ for sufficiently small $\epsilon > 0$. Thus, using an SV-source (with parameter $\gamma < \frac{1}{\sqrt{2}}$), our algorithm errs with probability at most 1/3.

The logarithmic factors in Theorem 5.1 and Proposition 5.2 can be eliminated; see subsection 5.3.

5.2. Proof of Proposition 5.2. Following is a description of the *algorithm* A_1. The constant δ used in the description will be determined later (as a function of γ). On input 1^n, the algorithm proceeds in rounds, each round consisting of two steps. In the first step, algorithm A_1, uses a second sampling algorithm, denoted A_2, to select a succinct description of a "pseudorandom" partition of the residual sample space. In the second step, algorithm A_1 uses the next bit of the SV-source to determine a side of this partition and so further restricts the residual sample space. We use two types of partitions. In the first $n - 4\log_2 \delta n$ rounds, algorithm A_1 uses partitions defined, as in subsection 4.3, by a polynomial of degree $(\delta n)^4$ over $GF(2^n)$. In the remaining rounds, where the residual sample space is most likely to be smaller than $2(\delta n)^4$, algorithm A_1 uses partitions uniformly chosen from the set of all *perfectly balanced* partitions (i.e., bipartitions in which the cardinalities of the two sides are either equal or differ by one). The two-step process is repeated until the residual sample space contains a unique element. We will see that algorithm $A_1(1^n)$ almost certainly halts after no more than $n + 2$ rounds. (Longer executions can be truncated after $n + 2$ rounds with an arbitrary output.)

We now turn to the description of *algorithm* A_2, which is invoked by $A_1(1^n)$ on input 1^m, where $m = (\delta n)^4 \cdot n$ for the first $n - 4\log_2 \delta n$ rounds of $A_1(1^n)$ and where m is the size of the residual sample space of A_1 later on. On input 1^m, algorithm A_2 proceeds in m rounds. In the ith round, the algorithm uses a third sampling algorithm, denoted A_3, to selects a random m-dimensional binary vector v_i that is linearly independent of previously used vectors. Clearly, the candidate vectors constitute an $(m - (i - 1))$-dimensional vector space over GF_2. The chosen vector partitions the residual sample space into two subsets of equal cardinality (as in Proposition 4.24). Algorithm A_2 uses the next bit of the SV-source to select a side of this partition.

Algorithm A_3, invoked by $A_2(1^m)$, on input 1^k (for $k = m, m-1, \ldots, 1$), is the trivial sampling algorithm which generates a sample point in $\{0,1\}^k$ by merely using the next k bits of the SV-source.

We now turn to the analysis of the sampling algorithm A_1. We first consider what happens if one replaces algorithm A_2 by an algorithm that uniformly selects the appropriate partitions (i.e., $(\delta n)^4$-degree polynomial for the first $n - 4\log_2 \delta n$ rounds and perfectly balanced partitions for later rounds). The analysis is done following the paradigm of the previous section. Namely, we first analyze the performance of the algorithm assuming it employs partitions which satisfy some combinatorial properties (cf., Claim 5.2.1), and next consider the probability that uniformly selected partitions satisfy these properties (cf., Claim 5.2.2).

Claim 5.2.1 (A_1 with balanced partitions). Let U_i be the residual sample space after round i, and $S_i \stackrel{\text{def}}{=} S \cap U_i$ ($U_0 \stackrel{\text{def}}{=} \{0,1\}^n$). Suppose that, for every i, algorithm

A_1 partitions U_{i-1} in a way that is Δ-balanced with respect to S_{i-1} as well as to U_{i-1}. Furthermore, suppose that for every $i > n - 4\log_2 \Delta$, the ith partition chosen for algorithm A_1 is perfectly balanced (i.e., $-1 \leq 2|U_i| - |U_{i-1}| \leq 1$.) Then

$$\text{Prob}(A_1(1^n) \in S) \leq 2\Delta \cdot p^{\log_2(1/\gamma)}.$$

In addition, $|U_{n-4\log_2 \delta n}| < 2(\delta n)^4$, provided that $\Delta \leq \delta n$.

Proof. The proof is analogous to the proof of Corollary 4.8. Using an argument analogous to one used in the proof of Lemma 4.5, we conclude that after $t \stackrel{\text{def}}{=} n - \log_2(1/p)$ rounds the residual sample space contains at most Δ elements of S (i.e., $|S_t| \leq \Delta$). Actually, the argument only uses the hypothesis that the ith partition is Δ-balanced with respect to S_{i-1}, for every $i \leq t$, and is indifferent to the way in which the sides of the partitions are selected in these t rounds. Using the hypothesis that the ith partition is Δ-balanced with respect to U_{i-1}, for every $i \leq t$, we conclude that after these t rounds, the residual sample space contains at least $\frac{1}{2p}$ elements (i.e., $|U_t| \geq 1/2p$). Furthermore, using the hypothesis that also the following $s \stackrel{\text{def}}{=} \log_2(1/p) - 4\log_2 \Delta$ rounds use partitions which are Δ-balanced with respect to the residual sample space, we conclude that after $t + s = n - 4\log_2 \Delta$ rounds the residual sample space has cardinality at least $\frac{1}{2}\Delta^4$ (use Claim 4.4). Now, since all the remaining partitions are assumed to be perfectly balanced, there must be at least $l \stackrel{\text{def}}{=} (4\log_2 \Delta) - 1$ rounds until termination. We now return to the situation after t rounds, and consider the remaining rounds, which by the above are at least $r \stackrel{\text{def}}{=} s + l = \log_2(1/p) - 1$ in number. Since the side of the partition is selected by an SV-source with parameter γ, the probability that any specific element in U_t survives the remaining (i.e., at least r) rounds is at most γ^r. Thus, the probability that some element of S_t survives these rounds does not exceed

$$\begin{aligned} |S_t| \cdot \gamma^r &\leq \Delta \cdot \gamma^{\log_2(1/p)-1} \\ &\leq \Delta \cdot p^{\log_2(1/\gamma)} \cdot 2^{\log_2(1/\gamma)}. \end{aligned}$$

But $\gamma \geq 1/2$, whence $\log_2(1/\gamma) \leq 1$ and the main part of the claim follows.

The additional part (i.e., $|U_{n-4\log_2 \delta n}| < 2(\delta n)^4$) follows easily by using Claim 4.4. □

Claim 5.2.2 (A_1 — probability of balanced partitions). For every $\epsilon > 0$ there exists a $\delta > 0$ so that the following holds. Let π_i denote the probability that a *uniformly chosen* partition for round i is not $\delta \cdot \log_2(1/p)$-balanced with respect to either S_{i-1} or U_{i-1}. Then,

$$\sum_{i \geq 1} \pi_i^{\epsilon} < p.$$

As in Proposition 4.23, it is very useful for the sequel (though, admittedly, not very natural) to raise the probabilities to the ϵth power.

Proof. For $i \leq n - 4\log_2 \delta n$, the proof is identical to the simpler cases (e.g., Properties (P0) and (P1)) considered in the proof of Proposition 4.23. For $i > n - 4\log_2 \delta n$, we observe that the probability of any event, assuming a uniformly selected *perfectly-balanced* partition is at most $\sqrt{|U_{i-1}|}$ times larger than its probability assuming a uniformly selected partition. Since the argument of Proposition 4.23 can tolerate such factors, the claim follows also for $i > n - 4\log_2 \delta n$. □

Combining Claims 5.2.1 and 5.2.2, we conclude that it suffices to show that for some constant $\epsilon > 0$ and for any set of "bad" partitions, $B \subseteq \{0,1\}^m$, the probability that $A_2(1^m)$ produces an output in B is at most $(|B|/2^m)^\epsilon$. Once this is done, the proposition follows by considering $B^{(i)}$, the set of partitions which are not $\delta \cdot \log_2(1/p)$-balanced with respect to either S_{i-1} or U_{i-1}, and noting that $\delta \cdot \log_2(1/p) \leq \delta n$ (which guarantees that in the last $4\log_2(\delta \log_2(1/p))$ rounds perfectly-balanced partitions are used). Namely,

$$\begin{aligned}\text{Prob}(A(1^n) \in S) &< \text{Prob}(A(1^n) \in S | \forall i\ A(1^m) \notin B^{(i)}) \\ &\quad + \text{Prob}(\exists i \text{ s.t. } A(1^m) \in B^{(i)}) \\ &< 2\delta \log(1/p) \cdot p^{\log_2(1/\gamma)} + \sum_{i \geq 1} \left(\frac{|B^{(i)}|}{2^m} \right)^\epsilon \\ &< 3\delta \log(1/p) \cdot p^{\log_2(1/\gamma)},\end{aligned}$$

where the second inequality is based on Claim 5.2.1 and our hypothesis concerning A_2 and the last inequality follows from Claim 5.2.2. Also note that Claim 5.2.1 guarantees that the residual sample space after $n - 4\log_2(\delta n)$ rounds has size at most $\text{poly}(n)$, whence it is possible to represent and generate random partitions of it. Thus, we turn to the analysis of algorithm A_2. Recall that our goal is to show that for some ϵ, (that depends on γ), and for every $B \subseteq \{0,1\}^m$ of cardinality $q \cdot 2^m$,

$$\text{Prob}(A_2(1^m) \in B) = O(q^\epsilon). \tag{15}$$

Let $\epsilon \stackrel{\text{def}}{=} \log_2(1/\gamma) - \frac{1}{2} > 0$ and $\beta \stackrel{\text{def}}{=} \frac{1}{1+\epsilon} < 1$ (recall that $\gamma < \frac{1}{\sqrt{2}}$ is assumed). Also, $\epsilon \leq \frac{1}{2}$ and $\beta \geq \frac{2}{3}$, since $\gamma \geq \frac{1}{2}$. Henceforth, we fix an arbitrary set $B \subseteq \{0,1\}^m$ and let $q \stackrel{\text{def}}{=} \frac{|B|}{2^m}$ (as above). We separately analyze the performance of A_2 throughout the first t rounds (hereafter referred to as *phase* 1), and in the remaining $m - t$ rounds (*phase* 2), where

$$t \stackrel{\text{def}}{=} \max\{0, m - \frac{2\beta}{2\beta - 1} \log_2(1/q)\}. \tag{16}$$

Let B_i denote the residual set (of bad polynomials) after i rounds of algorithm A_2 (e.g., $B_0 = B$).

Claim 5.2.3 (A_2 — *phase* 1).

$$\text{Prob}(|B_t| > 2q \cdot 2^{m-t}) \leq O(q^{2\epsilon}).$$

That is, the probability that B_t is greater than twice its "expected size" is small. Note that by definition of t, we have $m - t = \frac{2\beta}{2\beta-1} \cdot \log_2(1/q)$ and $q \cdot 2^{m-t} = 2^{(m-t)/2\beta}$.

Proof. For every i, let $b_i \stackrel{\text{def}}{=} \frac{|B|}{2^i}$. Our plan is to prove that with very high probability, $|B_i| \approx b_i$ for every $i \leq t$, which would establish our claim. We consider the first time when $|B_i| \not\approx b_i$. Thus, the probability that $|B_t| > 2q \cdot 2^{m-t}$ is bounded above by

$$\text{Prob}\left[\exists i < t : \left(\left| |B_{i+1}| - \frac{|B_i|}{2} \right| > |B_i|^{\frac{1+\beta}{2}} \right) \wedge \left(\forall j < i : \left| |B_{j+1}| - \frac{|B_j|}{2} \right| \leq |B_j|^{\frac{1+\beta}{2}} \right) \right].$$

Now, using Chebyshev's Inequality (as in the proof of Proposition 4.24), we can show that *for a uniformly chosen random linear partition*,

$$\text{Prob}\left(\left||B_{i+1}| - \frac{|B_i|}{2}\right| > |B_i|^{\frac{1+\beta}{2}}\right) < \frac{1}{|B_i|^{\beta}}.$$

Call a linear partition for round $i+1$ *bad*, if $\left||B_{i+1}| - \frac{|B_i|}{2}\right| > |B_i|^{\frac{1+\beta}{2}}$. We now know that the number of bad partitions is bounded by $\frac{1}{|B_i|^{\beta}} \cdot 2^{m-i}$. We need to bound the probability that $A_3(1^{m-i})$ selects a bad partition in round $i+1$. Using the union bound, the definition of A_3 and Claim 4.4 (for $|B_i|$), we have

$$\begin{aligned}\text{Prob}(A_3(1^{m-i}) \text{ is bad}) &\leq \frac{2^{m-i}}{|B_i|^{\beta}} \cdot \gamma^{m-i} \\ &< 2 \cdot \gamma^{m-i} \cdot \frac{2^{m-i}}{b_i^{\beta}},\end{aligned}$$

where the last inequality uses our assumption that all previous partitions are good (whence for each $j < i$, $|B_{j+1}| > \frac{|B_j|}{2} - |B_j|^{\frac{1+\beta}{2}}$ and, consequently, $|B_i| > \frac{b_i}{2}$). Since $b_i = 2^{t-i} \cdot b_t$ and $b_t^{\beta} = (q2^{m-t})^{\beta} = 2^{(m-t)/2}$ (see remark above), we get

$$\begin{aligned}\text{Prob}(A_3(1^{m-i}) \text{ is bad}) &< 2 \cdot \gamma^{m-i} \cdot \frac{2^{m-i}}{2^{(t-i)\beta} \cdot 2^{(m-t)/2}} \\ &= 2 \cdot \gamma^{m-i} \cdot 2^{(m-i)-\frac{m-t}{2}-\beta(t-i)} \\ &= 2 \cdot \left(\gamma\sqrt{2}\right)^{m-i} \cdot 2^{-(\beta-\frac{1}{2})\cdot(t-i)}.\end{aligned}$$

Letting $\rho \stackrel{\text{def}}{=} \gamma \cdot \sqrt{2} < 1$ (as $\gamma < \frac{1}{\sqrt{2}}$) and using $m - i \geq m - t > 2\log_2(1/q)$ (as $m - t = \frac{2\beta}{2\beta-1}\log_2(1/q)$ and $\beta < 1$), we get

$$\begin{aligned}\text{Prob}(A_3(1^{m-i}) \text{ is bad}) &< 2 \cdot \rho^{2\log_2(1/q)} \cdot 2^{-(\beta-\frac{1}{2})\cdot(t-i)} \\ &= 2 \cdot q^{2\log_2(1/\rho)} \cdot 2^{-(\beta-\frac{1}{2})\cdot(t-i)} \\ &= a \cdot b^{t-i},\end{aligned}$$

where $a \stackrel{\text{def}}{=} 2q^{2\log_2(1/\rho)}$ and $b \stackrel{\text{def}}{=} 2^{-(\beta-\frac{1}{2})} < 1$ (as $\beta > \frac{1}{2}$). Hence, the probability that A_3 chooses a bad partition for some round i, throughout phase 1, is bounded by $\sum_{i=1}^{t} a \cdot b^{t-i} < \frac{a}{1-b}$. Using $\epsilon = \log_2(1/\gamma) - \frac{1}{2} = \log_2(1/\rho) \leq \frac{1}{2}$ and $\beta = \frac{1}{1+\epsilon}$, we get

$$\begin{aligned}\frac{a}{1-b} &= \frac{2q^{2\epsilon}}{1 - 2^{-\frac{1-\epsilon}{2(1+\epsilon)}}} \\ &\leq \frac{2q^{2\epsilon}}{1 - 2^{-1/6}} \\ &< 20 \cdot q^{2\epsilon},\end{aligned}$$

and the claim follows. □

Claim 5.2.4 (A_2 — *phase* 2). Let B_t be the residual target set after t rounds and consider an execution of the $m - t$ remaining rounds. Suppose that $|B_t| \leq 2b_t$, where

$b_t \stackrel{\text{def}}{=} \frac{|B|}{2^t}$ (as in Claim 5.2.3). Then the probability that $A_2(1^m)$ terminates with output in B_t is at most $2q^\epsilon$.

Proof. We consider the executions of rounds $t+1$ through m. Regardless of which linear partitions are used in the remaining $m-t$ rounds, the probability that a particular element of B_t is output by $A_2(1^m)$ is bounded by γ^{m-t}. Hence,

$$\begin{aligned}\text{Prob}(A_2(1^m) \text{ hits } B_t) &\le |B_t| \cdot \gamma^{m-t} \\ &\le 2b_t \cdot \gamma^{m-t} \\ &= 2 \cdot 2^{\frac{m-t}{2\beta}} \cdot \gamma^{m-t} \\ &= 2 \cdot \left(\gamma \cdot 2^{\frac{1}{2\beta}}\right)^{m-t}.\end{aligned}$$

Setting (as before) $\rho = \gamma\sqrt{2}$, and using $\epsilon = \log_2(1/\rho)$ and $\beta = \frac{1}{1+\epsilon}$, we get $2^{\frac{1}{2\beta}} = \sqrt{2/\rho}$. Hence, using again $\rho < 1$ and $m - t > 2\log_2(1/q)$, we get

$$\begin{aligned}\text{Prob}(A_2(1^m) \text{ hits } B_t) &\le 2 \cdot \left(\gamma \cdot \sqrt{\frac{2}{\rho}}\right)^{m-t} \\ &< 2 \cdot \sqrt{\rho}^{\,2\log_2(1/q)} \\ &= 2q^{\log_2(1/\rho)} \\ &= 2q^\epsilon,\end{aligned}$$

and the claim follows. □

Combining Claims 5.2.3 and 5.2.4, we have established equation (15) and the proposition follows. □

5.3. Further improvements. Actually, the result of Proposition 5.2 can be improved using a slightly more careful analysis of the algorithm A_1 provided in the above proof. The improved analysis is analogous to the proof of the tighter bound for the case $q_v = p_v$ of Theorem 4.27. Namely, we replace Claims 5.2.1 and 5.2.2 by the following three claims. In the first two claims we assume that algorithm A_2 satisfies equation (15).

Claim 1. With probability at least $1-p$, after $i \stackrel{\text{def}}{=} n - \log_2(1/p) - 4\log_2(\delta\log_2(1/p))$ rounds the residual sample space contains at most $2(\delta\log_2(1/p))^4$ elements of S; namely,

$$\text{Prob}(|S_i| > 2(\delta\log_2(1/p))^4) < p.$$

Claim 2. Consider an arbitrary subset S' of U_t so that $|S'| \le 2(\delta\log_2(1/p))^4$. Then the expected number of elements of S' which survive an additional number of $4\log_2(\delta\log_2(1/p))$ rounds is bounded above by $O(1)$.

Claim 3. Let $t \stackrel{\text{def}}{=} n - \log_2(1/p)$. Then,

$$\text{Prob}(A(1^n) \in S) \le \text{Exp}(|S_t|) \cdot \gamma^{\log_2(1/p)-1}.$$

(Here, we do use a part of the proof of Claim 5.2.1 to assert that with probability $1-p$ the protocol does not terminate before $n-1$ rounds.)

Consequently, we get

- Improvement to Proposition 5.2: *For every constant* γ, $\frac{1}{2} \leq \gamma < \frac{1}{\sqrt{2}}$, *the algorithm* A_1 *appearing in the proof of Proposition* 5.2 *satisfies, for every set* $S \subseteq \{0,1\}^n$,

$$\mathrm{Prob}(A_1(1^n) \in S) = O(p^{\log_2(1/\gamma)}),$$

  where $p \stackrel{\mathrm{def}}{=} |S|/2^n$, *and the probability is taken over an arbitrary SV-source with parameter* γ.
- Theorem 5.1 can be improved analogously. Namely, *for every set* $S \subseteq \{0,1\}^l$, *if* $m - t$ *parties plays honestly then the outcome of the protocol is in* S *with probability bounded above by* $O(p^{1-O(\frac{t}{m})})$, *where* $p \stackrel{\mathrm{def}}{=} |S|/2^l$.

A SPECTRAL APPROACH TO LOWER BOUNDS WITH APPLICATIONS TO GEOMETRIC SEARCHING*

BERNARD CHAZELLE†

Abstract. We establish a nonlinear lower bound for halfplane range searching over a group. Specifically, we show that summing up the weights of n (weighted) points within n halfplanes requires $\Omega(n \log n)$ additions and subtractions. This is the first nontrivial lower bound for range searching over a group. By contrast, range searching over a semigroup (which forbids subtractions) is almost completely understood.

Our proof has two parts. First, we develop a general, entropy-based method for relating the linear circuit complexity of a linear map A to the spectrum of $A^\top A$. In the second part of the proof, we design a "high-spectrum" geometric set system for halfplane range searching and, using techniques from discrepancy theory, we estimate the median eigenvalue of its associated map. Interestingly, the method also shows that using up to a linear number of help gates cannot help; these are gates that can compute *any* bivariate function.

Key words. lower bounds, eigenvalues, range searching, circuit complexity

1. Introduction.

Given n weighted points in the plane and n halfplanes, we consider the classical *halfplane range searching* problem, which is to compute the sum of the weights of the points within each of the given regions. If subtractions are not allowed (the semigroup model) the problem is almost completely solved [7, 11, 15]; see also [9, 16, 17, 19] for surveys of the vast literature on the subject. In the (commutative) group model, where subtractions are allowed, there is little evidence that any power should be gained beyond polylog speedups, but proving it has been elusive. In fact, in that model no superlinear lower bound has ever been established for any range searching problem of any kind. The problem is equivalent to asking for the nonmonotone circuit complexity of some fairly unwieldy linear transformation over the reals, so the lack of progress should not come as a big surprise.

This paper takes a first, modest step toward resolving this question. We establish a lower bound of $\Omega(n \log n)$ on the complexity of range searching with respect to n points and n halfplanes (given in advance). The model of computation is a straight-line program: each step performs a group operation of the form

$$z \leftarrow x \pm y,$$

where x and y are previously computed variables or input weights. The underlying group is assumed to be commutative. Note that it is easy to prove an $\Omega(n \log n)$ lower bound by reduction from sorting, but this says nothing about the number of times weights have to be added or subtracted. In the group model, memory accesses are not

charged; only group operations are. Note that this makes lower bounds even stronger. The program must work for all groups and all weight assignments.

This formulation of the group model is probably the most natural. But one might ask what happens if we extend the model by allowing extra computations free of charge. For example, can adding the same variable a large number of times, e.g., $z \leftarrow Mx$ (M integral), possibly help? How about encoding special functions in lookup tables? In general, we call a *free computation* any assignment of the form

$$z \leftarrow f(x, y),$$

where f is an arbitrary function. We show that allowing close to $n/4$ free computations cannot help. To put this result in perspective, one should note that over the reals $2n$ free computations suffice to make the problem trivial.

THEOREM 1.1. *Range searching with respect to n points and n halfplanes requires $\Omega(n \log n)$ group operations. This remains true even with the help of up to $n/4 - \varepsilon n$ free computations, for any fixed $\varepsilon > 0$. On the other hand, over the reals, the problem can be solved in linear time with only $2n - 1$ free computations.*

It is likely that the lower bound is far from optimal. The best known upper bound is slightly above $O(n^{4/3})$ [15], and in the semigroup model the best lower bound (for the on-line version) is also $\Omega(n^{4/3})$ [7]. On the brighter side, Theorem 1.1 provides the only lower bound known for the group model, so at least it is a step in the right direction.

Proof. The proof consists of two distinct parts. First, we establish a general *spectral lemma*, which asserts a lower bound of $\Omega((k-2m)\log \lambda_k)$ on the linear circuit complexity of any linear transformation A (with integer coefficients) from $\mathbf{R}^n$ to $\mathbf{R}^n$, where λ_k is the kth largest eigenvalue of $A^\top A$, and m is the number of help gates. These are the circuit equivalent of free computations. (This shows that allowing up to roughly $k/2$ help gates does no good.) The lower bound holds for any value of k between $2m$ and n. This freedom is useful because often only a small range of the whole spectrum can be accurately estimated without too much effort.

In the second part of the proof, we design a *hard* instance of range searching by nonconstructive means. Then we use spectral methods from discrepancy theory to estimate the median eigenvalue of the quadratic form associated with the corresponding set system.

Remark 1. Our technique trivially implies an $\Omega(n \log n)$ lower bound for range searching over a finite projective plane. In general, the technique will yield a lower bound on any instance of range searching whose corresponding spectrum can be mapped out reasonably well. Powerful techniques in discrepancy theory [4], such as those used in section 3 of this paper, raise hope that more lower bounds can be derived by this approach.

Remark 2. A simple application of the spectral lemma is that computing Hx, where H is the $n \times n$ Sylvester Boolean matrix, takes $\Omega(n \log n)$ time even in the presence of about $n/2$ help gates. (All the eigenvalues λ_k of $H^\top H$ are equal to n.) Note that the choice of ground field is crucial, since Hx can be computed in linear time over GF(2) [2]. If we forbid help gates, the same bound can be obtained more simply by using Morgenstern's volume argument [18]. The spectral lemma works in a model that is ideally suited for range searching. If, instead of a group, the linear transformation operates over a ring or a field (like the discrete Fourier transform), then for the lemma to hold, the (nonhelp) gates must evaluate linear forms with bounded coefficients. This is the same limitation found in Morgenstern's result. Help gates can be thought of as a way of partly overcoming this limitation.

Remark 3. The proof of the spectral lemma is based on entropy considerations. By avoiding standard volume arguments, we are able to accommodate help gates. Indeed, a weakness of the volume argument of [18] is that it collapses even in the presence of a single help gate. Intuitively, the idea of that argument is to relate the work of the circuit to the volume of the ellipsoid into which the circuit "transforms" the unit sphere. Any such argument is vulnerable to even a single help gate, because any one of them has the ability to blow up the entire sphere. On the contrary, our entropy-based approach ensures that the "contribution" of a single help gate to the work of the circuit is always bounded, regardless of the gate's power.

There has been a substantial amount of work in arithmetic circuit complexity—see surveys in [13, 20]—but, to our knowledge, nothing that allows us to tackle a geometric problem such as range searching. Most of the recent research in circuit complexity [5], including work involving help bits or oracle queries (variants of our help gates) [3, 6], has been mostly concerned with problems over finite fields and seems of little relevance to our problem.

2. Eigenvalues, entropy, and linear circuits. Let A be an $n \times n$ matrix with integer elements. A linear circuit for computing $y = Ax$, where $x \in \mathbf{R}^n$, is a directed acyclic graph with n input nodes $x = (x_1, \ldots, x_n)$ and n output nodes $y = (y_1, \ldots, y_n)$. The size of the circuit is its number of edges. A node is a gate that computes a real-valued function

$$f(z_1, z_2) = \alpha_1 z_1 + \alpha_2 z_2,$$

where $z_i \in \mathbf{R}$ and $\alpha_i \in \{-1, 0, 1\}$. In addition, we allow the presence of m help gates: these gates can evaluate *any* function $f(z_1, z_2)$ from $\mathbf{R}^2$ to $\mathbf{R}$. Recall that the matrix $M \stackrel{\text{def}}{=} A^\top A$ is diagonalizable and its eigenvalues are real:

$$\lambda_1 \geq \cdots \geq \lambda_n \geq 0.$$

All logarithms are to the base 2.

SPECTRAL LEMMA. *Given any $1 \leq k \leq n$, any circuit for computing Ax has size at least $c(k - 2m) \log \lambda_k$, for some constant $c > 0$, where $m \leq k/2$ is the number of help gates and λ_k is the kth largest eigenvalue of $A^\top A$.*

Proof. Let K be the invariant subspace spanned by the eigenvectors for M associated with $\lambda_1, \ldots, \lambda_k$. We ensure that K is of dimension exactly k by dropping some of the eigenvectors for λ_k, in case of multiplicity. Let $B_n(p, r)$ denote the Euclidean n-ball of radius r centered at p and let $V_n(r)$ be its volume. Consider the cubes of the form $\mathbf{Z}^n + [0, 1]^n$ that intersect $K \cap B_n(O, R)$, for some (large enough) parameter R. Let L be the set of centers of these cubes. Finally, let $H(x)$ denote the entropy of a random variable x with values distributed uniformly in L. We estimate the entropy of x (Lemma 2.1) and then we prove the key lemma, which says that if the spectrum of M is not too low we can suitably hash the image of x under A without losing much entropy (Lemma 2.2).

LEMMA 2.1.

$$H(x) \geq \log V_k(R) - \log V_k(\sqrt{n}\,).$$

Proof. Let $M_R^-(n, k)$ denote the minimum number, over all k-flats F containing the origin, of the n-cubes of the form $\mathbf{Z}^n + [0, 1]^n$ that intersect $F \cap B_n(O, R)$. Observe that the cubes to be counted cover the ball $B_k(O, R)$ embedded in F. Furthermore,

the intersection of F with each of these cubes fits into a k-ball of radius $\sqrt{n}/2$, so

$$M_R^-(n,k) \geq V_k(R)/V_k(\sqrt{n}\,).$$

The lemma follows from the fact that $|L| \geq M_R^-(n,k)$ and $H(x) = \log|L|$. □

Another useful quantity, denoted by $M_r^+(n,m)$, is the maximum number over all m-flats F of the n-cubes of the form $\mathbf{Z}^n + [0,1]^n$ that intersect $F \cap B_n(O,r)$. In the case $n-m=0$, the cubes counted by $M_r^+(n,m)$ all lie within $B_n(O, r+\sqrt{n}\,)$; therefore

$$M_r^+(n,n) \leq V_n(r+\sqrt{n}\,). \tag{1}$$

Assume now that $n-m>0$. In the appendix we show that, for n and r large enough,

$$M_r^+(n,m) \leq 3^n V_m(r). \tag{2}$$

LEMMA 2.2. *If A is a matrix with real elements, such that $1 \leq \lambda_k \leq 2$, then*[1]

$$H(\lfloor Ax \rfloor) \geq H(x) - \log V_n(5\sqrt{n}\,).$$

Proof. Let $x, x' \in L$ be such that $\lfloor Ax \rfloor = \lfloor Ax' \rfloor$. It follows that $\|A(x-x')\|_2 \leq \sqrt{n}$. Write x as the direct sum $x_0 + u$, where $x_0 \in K$, $u \in K^\perp$, and do the same with x'. Observe that

$$\|u-u'\|_2 \leq \|u\|_2 + \|u'\|_2 \leq \sqrt{n}.$$

By the variational characterization of eigenvalues, $\|A(x_0-x_0')\|_2 \geq \sqrt{\lambda_k}\,\|x_0-x_0'\|_2$ and, because $K^\perp$ contains $u-u'$ and is spanned by eigenvectors corresponding to $\lambda_j \leq \lambda_k$, we have $\|A(u-u')\|_2 \leq \sqrt{\lambda_k}\,\|u-u'\|_2$. It follows that (for $1 \leq \lambda_k \leq 2$)

$$\begin{aligned}
\|x-x'\|_2 &\leq \|x_0-x_0'\|_2 + \|u-u'\|_2 \\
&\leq \|A(x_0-x_0')\|_2 + \|u-u'\|_2 \\
&\leq \|A(x-x')\|_2 + \|A(u-u')\|_2 + \|u-u'\|_2 \\
&\leq \sqrt{n} + 3\|u-u'\|_2 \leq 4\sqrt{n}.
\end{aligned}$$

Thus, the preimage of a fixed $z \in \mathbf{R}^n$ under $x \in L \mapsto \lfloor Ax \rfloor$ lies entirely in a ball $B_n(x, 4\sqrt{n}\,)$, where $x \in L$, and therefore, the uniform distribution within that preimage has entropy at most $\log M^+_{4\sqrt{n}}(n,n)$. By (1) this does not exceed $\log V_n(5\sqrt{n}\,)$. Standard identities on the entropy of joint distributions, namely,

$$H(x) = H(x, \lfloor Ax \rfloor) = H(\lfloor Ax \rfloor) + H(\,x \mid \lfloor Ax \rfloor\,),$$

complete the proof. □

Let $z = (z_1, \ldots, z_s)$ be the vector of $\mathbf{R}^n$ whose coordinates are the intermediate variables computed by the gates. For convenience, we append the input variables at the beginning of the list ($z_j = x_j$, for $1 \leq j \leq n$) and the output variables at the end ($z_{s-n+j} = y_j$, for $1 \leq j \leq n$). We also assume that the list corresponds to a topological ordering of the DAG (directed acyclic graph), meaning that for any $j > n$,

$$z_j = \alpha_j z_{f(j)} + \beta_j z_{g(j)},$$

[1] Given $z = (z_1, \ldots, z_n) \in \mathbf{R}^n$, we use the shorthand $\lfloor z \rfloor$ for $(\lfloor z_1 \rfloor, \ldots, \lfloor z_n \rfloor)$.

where $f(j) \le g(j) < j$ and $|\alpha_j|, |\beta_j| \le 1$. In the case of a help gate, z_j is an arbitrary real function of $z_{f(j)}$ and $z_{g(j)}$. Let

$$\mu_k = \lfloor \sqrt{\lambda_k} \rfloor.$$

The input x to the circuit is chosen so that $\tilde{x} = \mu_k x$ is a random variable uniformly distributed in L. We shall now assume that λ_k is large enough, which the spectral lemma obviously allows us to do. We now argue that $\lfloor z \rfloor$ has high entropy. Lemmas 2.4–2.6 will then show that only a large circuit can produce a "hashed" vector $\lfloor z \rfloor$ with that much entropy.

LEMMA 2.3.

$$H(\lfloor z \rfloor) \ge \log V_k(R) - \log V_k(\sqrt{n}\,) - \log V_n(5\sqrt{n}\,).$$

Proof. Because A is a linear map, the circuit outputs $B\tilde{x}$, where $B \stackrel{\text{def}}{=} A/\mu_k$, obviously satisfies the conditions of Lemma 2.2. Thus,

$$H(\lfloor z \rfloor) \ge H(\lfloor B\tilde{x} \rfloor) \ge H(\tilde{x}) - \log V_n(5\sqrt{n}\,).$$

The proof now follows from Lemma 2.1. □

To be able to isolate the action of help gates, we devise the following artifice. Regard the outputs of the help gates, $z_{h(1)}, \ldots, z_{h(m)}$, as new (help) variables, and express each z_j $(1 \le j \le s)$ as a linear form over the set of variables $Z = \{\, x_1, \ldots, x_n, z_{h(1)}, \ldots, z_{h(m)} \,\}$. How this is done is best seen by induction. The input gates are linear forms over single variables. For any other gate z_j, if it is of the helping type, then the form is z_j itself. Otherwise, $z_j = \alpha_j z_{f(j)} + \beta_j z_{g(j)}$ and, by induction, z_j is a linear combination of two linear forms over Z and hence a linear form itself. (Note that even though the outputs of the help gates might be algebraically related, the $z_{h(j)}$ are added by adjunction and so are considered independent.) In the expression for z_j, let z_j^x (resp., z_j^y) denote the linear form obtained by taking only the nonhelp (resp., help) variables. A key step now is to look at z_j^x and z_j^y no longer as linear forms but as real functions $z_j^x(x_1, \ldots, x_n)$ and $z_j^y(x_1, \ldots, x_n)$. While the circuit computes $z_j = z_j^x + z_j^y$, we wish to monitor the information contents of the complex number,[2]

$$z_j^c \stackrel{\text{def}}{=} \lfloor z_j^x \rfloor + i z_j^y.$$

We denote by z^c the vector $(z_1^c, \ldots, z_s^c)$. Our strategy is this: first, we establish that a small circuit can produce only a small entropy $H(z^c)$. We do this in three steps: Lemma 2.4 looks at the effect of the hashing on the entropy of the input variables. Lemmas 2.5 and 2.6 bound how much entropy the nonhelp and help gates, respectively, can inject into the vector of hashed variables. Finally, we show that $H(z^c)$ cannot be much smaller than $H(\lfloor z \rfloor)$, which by Lemma 2.3 is already known to be big.

LEMMA 2.4.

$$H(\, z_1^c, \ldots, z_n^c \,) \le 2n + \log V_k(R/\mu_k).$$

Proof. Let $\mathcal{C}$ be the set of cubes of the form $(\mu_k \mathbf{Z})^n + [0, \mu_k]^n$. Any cube of $\mathcal{C}$ that contains a point of L contains the entire unit cube centered at that point, and so

[2] We use complex numbers simply as a device for representing ordered pairs.

it intersects $K \cap B_n(O,R)$. Thus, the number of such cubes is at most $M^+_{R/\mu_k}(n,k)$, which, by (2), does not exceed $3^n V_k(R/\mu_k)$ so that (recall that $z^c_i = \lfloor x_i \rfloor$, for $i = 1,\ldots,n$)

$$\begin{aligned} H(\, z^c_1,\ldots,z^c_n\,) &= H(\, \lfloor \tilde{x}_1/\mu_k \rfloor,\ldots,\lfloor \tilde{x}_n/\mu_k \rfloor\,) \\ &\le 2n + \log V_k(R/\mu_k). \qquad \square \end{aligned}$$

LEMMA 2.5. *For any nonhelp variable z_j, $n < j \le s$, we have*

$$H(\, z^c_j \,|\, z^c_{f(j)}, z^c_{g(j)}\,) \le 3.$$

Proof. Recall that $z^c_j = \lfloor z^x_j \rfloor + i z^y_j$. Obviously, since the imaginary part is completely determined by those of $z^c_{f(j)}$ and $z^c_{g(j)}$, we have

$$H(\, z^y_j \,|\, z^y_{f(j)}, z^y_{g(j)}\,) = 0.$$

To deal with the real part, we use the inequality $H(\,A\,|\,B\,) \le H(\,A\,|\,C\,) + H(\,C\,|\,B\,)$ to derive

$$\begin{aligned} &H(\, \lfloor z^x_j \rfloor \,|\, \lfloor z^x_{f(j)} \rfloor, \lfloor z^x_{g(j)} \rfloor\,) \\ &\qquad \le H(\, \lfloor z^x_j \rfloor \,|\, \lfloor \alpha_j z^x_{f(j)} \rfloor, \lfloor \beta_j z^x_{g(j)} \rfloor\,) \\ &\qquad\quad + H(\, \lfloor \alpha_j z^x_{f(j)} \rfloor \,|\, \lfloor z^x_{f(j)} \rfloor\,) \\ &\qquad\quad + H(\, \lfloor \beta_j z^x_{g(j)} \rfloor \,|\, \lfloor z^x_{g(j)} \rfloor\,). \end{aligned}$$

Given two random variables ξ, ξ' arbitrarily distributed in $\mathbf{R}$,

$$H(\, \lfloor \xi + \xi' \rfloor \,|\, \lfloor \xi \rfloor, \lfloor \xi' \rfloor\,) \le 1.$$

Intuitively, the only information missing is a one-bit carry. Similarly, given a fixed $\alpha \in \mathbf{Z}$, $|\alpha| \le 1$, and a real random variable ξ, we have $H(\, \lfloor \alpha\xi \rfloor \,|\, \lfloor \xi \rfloor\,) \le 1$. The lemma follows from the fact that $z_j = \alpha_j z_{f(j)} + \beta_j z_{g(j)}$. $\square$

LEMMA 2.6. *For any help variable z_j, $n < j \le s$, we have $H(\, z^c_j \,|\, z^c_{f(j)}, z^c_{g(j)}\,) \le 2(\log \mu_k + 1)$.*

Proof. We have $z^c_j = i z^y_j$, where z^y_j is an arbitrary function of $z_{f(j)}$ and $z_{g(j)}$. Regarding $z_{f(j)} = z^x_{f(j)} + z^y_{f(j)}$, the only information we have at our disposal is $z^c_{f(j)} = \lfloor z^x_{f(j)} \rfloor + i z^y_{f(j)}$. There is no loss of information in the imaginary part. The same is not true of the real part, however. The key observation is that $z^x_{f(j)}$ is a linear form over $x_1,\ldots,x_n$ with integer coefficients. Thus, since $2\mu_k x_i$ is itself integral, so is $2\mu_k z^x_{f(j)}$. It follows that the fractional part of $z^x_{f(j)}$ can be one of only $2\mu_k$ possible values, and hence, $H(\, z^x_{f(j)} \,|\, \lfloor z^x_{f(j)} \rfloor) \le \log \mu_k + 1$, from which the lemma follows. $\square$

We can use the last three lemmas to upper bound $H(\lfloor z \rfloor)$:

$$\begin{aligned} H(z^c) &= H(\, z^c_1,\ldots,z^c_n\,) + \sum_{n+1 \le j \le s} H(\, z^c_j \,|\, z^c_1,\ldots,z^c_{j-1}\,) \\ &\le H(\, z^c_1,\ldots,z^c_n\,) + \sum_{n+1 \le j \le s} H(\, z^c_j \,|\, z^c_{f(j)}, z^c_{g(j)}\,). \end{aligned}$$

By Lemmas 2.4, 2.5, and 2.6,

$$\begin{aligned} H(z^c) &\le 2n + \log V_k(R/\mu_k) + 3(s-n-m) + 2m(\log \mu_k + 1) \\ &\le 3s - n + \log V_k(R/\mu_k) + 2m \log \mu_k, \end{aligned}$$

and therefore,

$$\begin{aligned} H(\lfloor z \rfloor) &\le H(z^c, \lfloor z \rfloor) = H(z^c) + H(\lfloor z \rfloor \mid z^c) \\ &\le H(z^c) + \sum_{j=n+1}^{s} H(\lfloor z_j^x + z_j^y \rfloor \mid \lfloor z_j^x \rfloor + i z_j^y) \\ &\le 4s + 2m \log \mu_k + \log V_k(R/\mu_k). \end{aligned}$$

Bringing the lower bound of Lemma 2.3 to bear, we derive

$$\begin{aligned} 4s \ge &-2m \log \mu_k - \log V_k(R/\mu_k) + \log V_k(R) \\ &- \log V_k(\sqrt{n}) - \log V_n(5\sqrt{n}). \end{aligned}$$

Using the approximation [12],

$$V_d(r) = \frac{\pi^{d/2} r^d}{\Gamma(d/2+1)} \approx \frac{1}{\sqrt{\pi d}} \Big(\frac{2e\pi}{d}\Big)^{d/2} r^d,$$

and the fact that $\log V_d(rs) = \log V_d(r) + d \log s$, we find that

$$4s \ge -2m \log \mu_k + k \log \mu_k - \log V_k(\sqrt{n}) - \log V_n(5\sqrt{n}).$$

The last two terms add up to $O(n)$; therefore,

$$s \ge \frac{1}{8}(k - 2m) \log \lambda_k - O(n),$$

which establishes the spectral lemma. □

3. Range searching over a group. Let P be the point set consisting of the vertices of a $(\sqrt{n}-1) \times (\sqrt{n}-1)$ square grid. Each point x_i of P is weighted by some real number, which by abuse of notation we also call x_i. Our goal is to exhibit n halfplanes $h_1, \ldots, h_n$, and prove that computing the sum of the weights within each h_k, i.e., $\sum_{x_i \in h_k} x_i$, requires $\Omega(n \log n)$ time.

The model of computation is a straight-line program: each step performs a group operation of the form $z \leftarrow \alpha_1 x + \alpha_2 y$, where x and y are input weights or previously computed variables and $\alpha_i \in \{-1, 0, 1\}$. As a bonus, we also allow the use of close to $n/4$ instructions of the form $z \leftarrow f(x, y)$, where f is an arbitrary real function. The only requirement is that the same program should work for any assignment of real weights to the points. The analogy with the previous section is obvious. Let A be the $n \times n$ matrix whose kth row is the characteristic vector of $P \cap h_k$. By the spectral lemma, the lower bound of Theorem 1.1 follows directly from this lemma.

LEMMA 3.1. *There is a choice of n halfplanes, for which the matrix A of the corresponding set system is such that the kth largest eigenvalue of $A^\top A$ is $n^{\Omega(1)}$, for some $k \ge n/2 - \varepsilon n$, for any fixed $\varepsilon > 0$.*

Proof. We use a nonconstructive configuration of halfplanes. Scale down the square grid so that it fits within $[1/\sqrt{n}, 1 - 1/\sqrt{n}\,]^2$. Let ω be the motion-invariant measure for lines: we normalize ω to provide a probability measure for the lines crossing $[0,1]^2$. Given a halfplane h^+ bounded below by a nonvertical line h, consider the discrepancy function $f(h) \stackrel{\text{def}}{=} \sum_{x_i \in h^+} x_i$. A beautiful result of Alexander [1] (see [8, 10] for a simpler proof and various extensions) says that if $x_1 + \cdots + x_n = 0$, then[3]

$$\int f^2(h)\, d\omega(h) \gg \frac{1}{\sqrt{n}} \|x\|_2^2.$$

[3]We use the notation $\ll$ and $\gg$ to denote inequality up to a constant factor.

Subdivide the space of lines crossing $[0,1]^2$ into $N + O(n^2)$ regions within which the form $f(h)$ remains invariant. By choosing N large enough, say, $N = 2^n$, we can also ensure that the ω-area of N of these regions is exactly the same; call it σ, which is about $1/N$. The other $O(n^2)$ regions may have smaller areas. (Consider the arrangement in dual space to obtain this result.) Thus, the difference between integrating f^2 over the whole probability space and over the equal-area regions only is at most $O(n^2/N)\sup f^2$. Because $|f|$ cannot exceed

$$|x_1| + \cdots + |x_n| \le \sqrt{n}\ \|x\|_2,$$

the error is bounded by $O(n^3\|x\|_2^2/N)$. This provides us with a good discrete approximation of the L^2-norm of f. Indeed, let B be the $N \times n$ matrix whose rows are indexed by the N equal-area regions $\hat{\sigma}$ and are the characteristic vectors of the set of x_i's appearing in (the unique form) $f(h)$, for $h \in \hat{\sigma}$. We have

$$\Big|\ \|Bx\|_2^2 - \frac{1}{\sigma}\int f^2(h)\,d\omega(h)\ \Big| = O(n^3)\frac{\|x\|_2^2}{N\sigma}.$$

But $\sigma = 1/N \pm O(n^2/N^2)$, so

$$\Big|\ \|Bx\|_2^2 - N\int f^2(h)\,d\omega(h)\ \Big| = O(n^3\|x\|_2^2).$$

LEMMA 3.2.

$$\det B^\top B = \Omega\Big(N\Big/\sqrt{n}\Big)^{n-1}.$$

Proof. Let $\mu_1 \ge \cdots \ge \mu_n \ge 0$ be the eigenvalues of $B^\top B$ and let $\{v_i\}$ be an orthonormal eigenbasis, where v_i is associated with μ_i. We express $x = (\xi_1, \ldots, \xi_n)$ in the basis $\{v_i\}$. The solution space of the system of equations, $x_1 + \cdots + x_n = 0$ and $\xi_j = 0$ $(j < n-1)$, is of dimension at least 1. Since it lives in the (ξ_{n-1}, ξ_n) plane, it intersects the cylinder $\xi_{n-1}^2 + \xi_n^2 = 1$. For any point x of the intersection,

$$\|Bx\|_2^2 = \sum_{i=1}^{n}\mu_i\xi_i^2 = \mu_{n-1}\xi_{n-1}^2 + \mu_n\xi_n^2 \le \mu_{n-1}.$$

This implies that for this unit vector x,

$$\mu_{n-1} \ge N\int f^2(h)\,d\omega(h) - O(n^3\|x\|_2^2) \gg \frac{N}{\sqrt{n}} - O(n^3),$$

and hence,

$$\mu_{n-1} \gg \frac{N}{\sqrt{n}}. \tag{3}$$

We need a lower bound on the smallest eigenvalue, but almost any one will do. With N being large enough, we can always assume that for each point x_i there exist two lines, each represented by a distinct row of B, that pass right above and below x_i. The contribution of these two rows to $\|Bx\|_2^2$ is of the form $\Phi^2 + (\Phi + x_i)^2$, which is always at least $x_i^2/2$. It follows that $\|Bx\|_2^2 \ge \frac{1}{2}\|x\|_2^2$, and hence, $\mu_n \ge 1/2$. The lemma follows from (3) and the fact that $\det B^\top B$ is the product of the eigenvalues. □

Of course, the set system B is much too big. Indeed, the map $x \mapsto Bx$ is actually trivial to compute. We use a nonconstructive argument to prove the existence of a hard $n \times n$ set system A. By the Binet-Cauchy formula,[4]

$$\det B^\top B = \sum_{1 \le j_1 < \cdots < j_n \le N} \left| \det B \begin{pmatrix} j_1 & j_2 & \cdots & j_n \\ 1 & 2 & \ldots & n \end{pmatrix} \right|^2.$$

Therefore, there exists an $n \times n$ submatrix A of B such that

$$\begin{aligned} \det A^\top A &= \left| \det B \begin{pmatrix} j_1 & j_2 & \cdots & j_n \\ 1 & 2 & \ldots & n \end{pmatrix} \right|^2 \\ &\ge \binom{N}{n}^{-1} \det B^\top B = \Omega(1)^n \Big(\frac{n}{eN}\Big)^n \Big(\frac{N}{\sqrt{n}}\Big)^{n-1} \\ &\ge n^{n/2 - o(n)}, \end{aligned}$$

from which we find that

$$\log \det A^\top A \ge \Big(\frac{n}{2} - o(n)\Big) \log n. \tag{4}$$

By Morgenstern's result [18], it follows easily that in the absence of any help gates, halfplane range searching requires $\Omega(n \log n)$ operations. To be able to deal with help gates we must collect more information about the spectrum of $A^\top A$. Let $\lambda_1 \ge \cdots \ge \lambda_n \ge 0$ be the eigenvalues of $A^\top A$.

LEMMA 3.3. *For some constant $c > 0$,*

$$\lambda_k \le \frac{cn^2 \log(k+1)}{k}.$$

Proof. Let L be a set of representative lines whose corresponding upper halfplanes define the sets encoded in the rows of A. Subdivide the unit square into a regular $r \times r$ grid of lines (r to be chosen later), and throw in a random sample of r lines chosen among L. Form the arrangement of these $3r$ lines and triangulate it. With high probability, no triangle is cut by more than $cn(\log r)/r$ lines of L, and none contains more than cn/r^2 points, for some constant c (assumed large enough for future purposes). For each triangle write the linear constraint expressing that the sum of the x_i's within the triangle is null. This gives us a set of $k_0 \le cr^2$ linear constraints, called *canonical*. Assume that all are satisfied. Then, A can be rewritten in simpler form by means of a sparse matrix C. Specifically, by the zone theorem for line arrangements, we know that no line can cut more than cr triangles. Therefore, within the restriction to the constraint space, each row of A corresponds to a linear form with at most $c^2 n/r$ nonzero coefficients. Let C be the new matrix formed by those relevant entries. Note that no column (resp., row) of C contains more than $cn(\log r)/r$ (resp., $c^2 n/r$) ones.

It is a standard result [14] that the spectral norm of a matrix Q satisfies

$$\|Q\|_s^2 \le \Big(\max_i \sum_j |q_{ij}|\Big)\Big(\max_j \sum_i |q_{ij}|\Big),$$

[4]The notation refers to the matrix obtained by picking the rows indexed $j_1, \ldots, j_n$ in B.

and therefore the Rayleigh quotient $x^\top C^\top Cx/x^\top x$ ($x \neq 0$) is at most $c^3n^2(\log r)/r^2$. As a result, for any x satisfying the canonical constraints and $\|x\|_2 = 1$, we have

$$\|Ax\|_2^2 \leq \frac{c^3n^2 \log r}{r^2}. \tag{5}$$

Let $\{u_i\}$ be an orthonormal eigenbasis for $A^\top A$, where u_i is associated with λ_i. We express $x = (\xi_1, \ldots, \xi_n)$ in the basis $\{u_i\}$. The solution space of the system of equations consisting of $\xi_j = 0$ ($j \geq k_0 + 2$) and the canonical constraints is of dimension at least 1. It is embedded in the (k_0+1)-flat spanned by $(\xi_1, \ldots, \xi_{k_0+1})$, so it intersects the cylinder $\xi_1^2 + \cdots + \xi_{k_0+1}^2 = 1$. For any point x in the intersection, $\|x\|_2 = 1$ and

$$\|Ax\|_2^2 = \sum_{i=1}^{n} \lambda_i \xi_i^2 = \sum_{i=1}^{k_0+1} \lambda_i \xi_i^2 \geq \lambda_{k_0+1},$$

so by (5), $\lambda_{k_0+1} \leq c^3n^2(\log r)/r^2$. In the worst case, k_0 is proportional to r^2, so the lemma is true for any k large enough. For small k, we can use the straightforward bound $\lambda_k \leq n^2$. □

From the lemma we find that

$$\begin{aligned}
\log \det A^\top A &= \sum_{i=1}^{n} \log \lambda_i \\
&\leq (n-k) \log \lambda_k + \sum_{j=1}^{k} \log \frac{cn^2 \log(j+1)}{j} \\
&\leq (n-k) \log \lambda_k + k(2 \log n \\
&\qquad - \log k + \log \log k + c').
\end{aligned}$$

In view of (4) we find that we can set $k = n/2 - \varepsilon n$, for any fixed $\varepsilon > 0$, and still derive the lower bound $\log \lambda_k = \Omega(\log n)$, which proves Lemma 3.1. □

We conclude that halfplane range searching requires $\Omega(n \log n)$ time, even in the presence of close to $n/4$ free computations. Notice that over the reals the problem can be solved in linear time with only $2n-1$ free computations: the circuit is a tree of help gates whose leaves are the x_i's and whose root "collects" the vector $(x_1, \ldots, x_n)$ and encodes it as a real. Then, with another n help gates, we can distribute the correct n outputs: the total number of help gates is $2n-1$. This completes the proof of Theorem 1.1. □

Appendix. We prove (2): $M_r^+(n,m) \leq 3^n V_m(r)$, for $n > m$. Let $\mathcal{C}$ be the set of cubes counted by $M_r^+(n,m)$. Any cube $c \in \mathcal{C}$ has at least one $(n-m)$-face intersecting $F \cap B_n(O,r)$ in exactly one point (call it q_c). This face is supported by an $(n-m)$-flat which is specified by fixing exactly m integer coordinates. In other words, it is specified by an integral point p_c in the m-flat spanned by a set of m axes. Since by convexity such a point p_c corresponds to at most $2^{n-m}(n-m)$-faces and at most 2^m cubes can share the same $(n-m)$-face, counting the number of points p_c gives an upper bound on $M_r^+(n,m)$, up to a factor of 2^n. Of course, we can restrict the counting to the number of integral points that lie within any of the projections of $F \cap B_n(O,r)$ onto m-flats spanned by $x_{i_1}, \ldots, x_{i_m}$. Furthermore, we can discount projections that map F to a flat of dimension less than m (because q_c is uniquely defined). Let $E_{i_1,\ldots,i_m}$ be the ellipsoid obtained by projecting $F \cap B_n(O,r)$ onto

the flat $(x_{i_1}, \ldots, x_{i_m})$. We say that a point p_c is *peripheral* if it is the upper corner (upper with regard to all m dimensions) of a cube not fully contained in the projected ellipsoid, and we let N denote the total number of peripheral points. We have

$$M_r^+(n,m) \le 2^n N + 2^n \sum_{1 \le i_1 < \cdots < i_m \le n} \operatorname{vol} E_{i_1,\ldots,i_m}. \tag{6}$$

Let $v_1, \ldots, v_m$ be an orthonormal basis for F and let U be the $n \times m$ matrix whose columns are the v_i's. (Note that $U^\top U$ is the identity matrix.) The determinant of the $m \times m$ submatrix of U specified by the rows $(i_1, \ldots, i_m)$ is equal, in absolute value, to the volume of $E_{i_1,\ldots,i_m}$ divided by $V_m(r)$. (We need only sketch the proof of this simple fact: lift to F the principal vectors of the ellipsoid and scale them to unit length; this provides an orthonormal basis for F that satisfies the claim. Because the basis $\{v_i\}$ can be derived from it by a unitary transformation within F, the claim follows.) By the Binet-Cauchy formula, the determinant of $U^\top U$ can be expressed as

$$\sum_{1 \le i_1 < \cdots < i_m \le n} \left| \det U \begin{pmatrix} i_1 & i_2 & \ldots & i_m \\ 1 & 2 & \ldots & m \end{pmatrix} \right|^2,$$

and by Cauchy-Schwarz,

$$\sum_{i_1,\ldots,i_m} \operatorname{vol} E_{i_1,\ldots,i_m} \le V_m(r) \binom{n}{m}^{1/2} \sqrt{\det U^\top U} = V_m(r) \binom{n}{m}^{1/2}.$$

On the other hand, in the flat $(x_{i_1}, \ldots, x_{i_m})$, every cube of the unit lattice that has a vertex in $E_{i_1,\ldots,i_m}$ and that intersects $\partial E_{i_1,\ldots,i_m}$ does so along at least one edge: at most four such edges can be collinear, and no more than 2^{m-1} cubes can charge the same edge. Projecting $E_{i_1,\ldots,i_m}$ by dropping one coordinate gives an $(m-1)$-ellipsoid whose integral points are contained in an $(m-1)$-ball of radius r. Within a factor of 2^{m+1}, the total number of such points is an upper bound on N. Each such point is the upper corner of a distinct unit cube in a ball of radius $r + \sqrt{m-1}$; therefore, $N \le m 2^{m+1} \binom{n}{m} V_{m-1}(r + \sqrt{m-1})$, and by (6),

$$M_r^+(n,m) \le m\, 4^n \binom{n}{m} V_{m-1}(r + \sqrt{m-1}) + 2^n \binom{n}{m}^{1/2} V_m(r).$$

As r goes to infinity the second term becomes dominant, and for n large enough, (2) follows.

Acknowledgments. I wish to thank Dick Lipton, Ran Raz, Avi Wigderson, and Andy Yao for helpful discussions. I also thank the referees for many useful comments and suggestions.

INCREMENTAL STRING COMPARISON*

GAD M. LANDAU†, EUGENE W. MYERS‡, AND JEANETTE P. SCHMIDT§

Abstract. The problem of comparing two sequences A and B to determine their longest common subsequence (LCS) or the edit distance between them has been much studied. In this paper we consider the following incremental version of these problems: given an appropriate encoding of a comparison between A and B, can one incrementally compute the answer for A and bB, and the answer for A and Bb with equal efficiency, where b is an additional symbol? Our main result is a theorem exposing a surprising relationship between the dynamic programming solutions for two such "adjacent" problems. Given a threshold k on the number of differences to be permitted in an alignment, the theorem leads directly to an $O(k)$ algorithm for incrementally computing a new solution from an old one, as contrasts the $O(k^2)$ time required to compute a solution from scratch. We further show, with a series of applications, that this algorithm is indeed more powerful than its nonincremental counterpart. We show this by solving the applications with greater asymptotic efficiency than heretofore possible. For example, we obtain $O(nk)$ algorithms for the longest prefix approximate match problem, the approximate overlap problem, and cyclic string comparison.

1. Introduction.

Sequence comparison is an extensively studied topic. Applications are numerous and include file comparison [HS-77], spelling correction [HD-80], information retrieval [WM-92], and searching for similarities among biosequences [NW-70, Se-80, SW-81]. Given string $A = a_1a_2a_3 \ldots a_m$ and $B = b_1b_2b_3 \ldots b_n$, one seeks an *alignment* between the two strings that exposes their similarity. An alignment is any pairing of symbols subject to the restriction that if lines were drawn between paired symbols as in Figure 1 below, the lines would not cross. Scores are assigned to alignments according to the concept of similarity or difference required by the context of the application, and one seeks alignments of optimal score [WF-74].

While for applications such as comparing protein sequences the methods of scoring can involve arbitrary scores for symbol pairs and for gaps of unaligned symbols, in many other contexts simple unit cost schemes suffice. Two of these, the *longest common subsequence (LCS)* and the *edit-distance* measures, have been studied extensively within computer science, and the unit cost nature of the scoring provides combinatorial leverage not found in the more general framework [Hi-77, HS-77, NKY-82, Uk-85a, Uk-85b, My-86a, LV-89, GP-90]. In the edit distance problem, each mismatched aligned pair and unaligned symbol is called a *difference* and scores 1. All

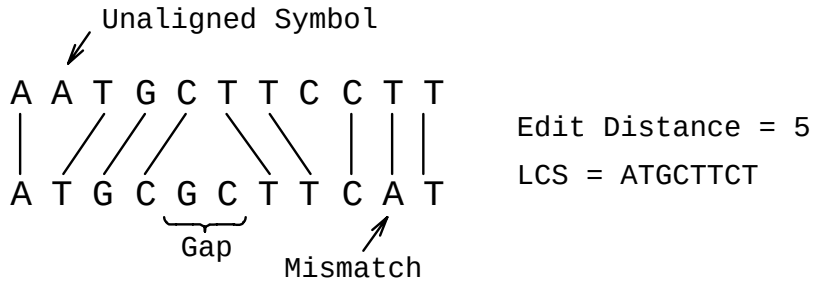

FIG. 1. *An alignment between two strings.*

pairs of equal aligned characters score 0. One seeks an alignment that minimizes the score or number of differences and this minimal score, $ED(A, B)$, is called the *edit distance* between A and B. Conversely, in the LCS problem matched pairs score 1, mismatches and unaligned symbols score 0, and the goal is to find an alignment of maximum score $LCS(A, B)$. In this case, the sequence of matched characters is a subsequence common to both sequences and is of maximum length, hence the name longest common subsequence. Figure 1 illustrates these measures.

Although certainly complementary, the LCS and edit distance problems are not formal duals. The LCS problem is equivalent to finding the minimum edit distance, *where mismatches are not allowed*, or equivalently, where a mismatch scores 2, so that it is no better than leaving the two characters unaligned. The reader may wish to also verify that the edit distance problem is equivalent to the following "LCS-like" problem: find an alignment of maximum score where matches score 1, unaligned characters score 0, and *mismatches score* $\frac{1}{2}$.

In this paper we consider the following incremental version of the sequence comparison problem: given a solution for the comparison of A and B, can one incrementally compute a solution for A versus bB, where b is an additional symbol prepended to B? By *solution* we mean some encoding of a relevant portion of the traditional dynamic programming matrix D computed in comparing A and B. D is an $(m + 1) \times (n + 1)$ matrix, where entry $D[i, j]$ is the best score for the problem of comparing A^i with B^j, and A^i is the prefix, $a_1 a_2 \ldots a_i$, of A's first i symbols. As will be seen in detail later, the data-dependencies of the fundamental recurrence, used to compute an entry $D[i, j]$, is such that it is easy to extend D to a matrix D' for A versus Bb by computing an additional column. However, efficiently computing a solution for A versus bB given D is much more difficult, in essence requiring one to work against the "grain" of these data-dependencies. The further observation that the matrix for A versus B, and that the matrix for A versus bB can differ in $O(mn)$ entries, suggests that the relationship between such adjacent problems is nontrivial.

One might immediately suggest that by comparing the reverse of A and B, prepending symbols becomes equivalent to appending symbols, and so the problem, as stated, is trivial. But in this case, we would ask for the delivery of a solution for A versus Bb. The point is that our method allows one to append *and* prepend symbols to A and/or B in any order, efficiently solving one problem from the previous one. More formally, given an initial solution $S^{(0)}$ for $A^{(0)} = A$ versus $B^{(0)} = B$, and a sequence of operations $op^{(t)}$ that either prepend or append a single symbol to $A^{(t-1)}$ or $B^{(t-1)}$ to produce $A^{(t)}$ and $B^{(t)}$, we can deliver the corresponding sequence of solutions $S^{(t)}$ with linear efficiency. Moreover, we can do so online, i.e., the sequence of

operations need not be known in advance. To keep matters simple, however, we will focus on the core problem of computing a solution for A versus bB, given a "forward" solution for A versus B. A "forward" solution of the problem contains an encoding of a comparison of all (relevant) prefixes of A with all (relevant) prefixes of B. It turns out that the ability to efficiently prepend a symbol to B when given all the information contained in a "forward" solution allows one to solve the applications given in section 4 with greater asymptotic efficiency than heretofore possible.

As an example of such application, consider the problem of approximate string matching within k differences: find *all* substrings of a text B of length n whose edit distance from a query A is not greater than threshold k. With our $O(k)$ incremental version of the well-known $O(n + k^2)$ greedy algorithm for edit distance, the problem can be solved in $O(nk)$ time by starting with an empty text and building it up from the right, one character at a time. Proceeding formally, let B_l denote the *suffix* of B starting at its $l + 1$st symbol, $b_{l+1}b_{l+2} \ldots b_n$. Begin the search by building the trivial k-thresholded solution for A versus B_n $(= \varepsilon)$. Then incrementally compute the solutions to A versus B_l for $l = n - 1, n - 2, n - 3 \ldots 0$ in $O(k)$ time per step. While the overall time, $O(nk)$, is no better than previous results, [LV-89, GP-90], the algorithm is superior in that for each left index l it reports *all* right indexes r, (and for each right index r it hence reports *all left* indexes l), delimiting a substring $B_l^r = b_{l+1}b_{l+2} \ldots b_r$ that matches A within k differences. For each such match-pair (l, r), the algorithm delivers the number of differences, $ED(A, B_l^r)$, in the match. Previous algorithms either report for each right index r, the matches with the smallest number of differences ending at r (the "forward" solution), or report the matches with the smallest number of differences starting at l (the "backward" solution). In our solution at each potential left-index l, the entire k-thresholded solution for A versus B_l is available and can be examined in $O(k)$ time to find any corresponding right-indices and their match score. In addition, if A does not match any prefix of B_l with at most k differences, we can report the longest prefix of A that matches a prefix of B_l with k differences. If desired, one can also build an $O(nk)$ table $T[0 \ldots n][-k \ldots k]$ during the search where $T[l][r - (l + m)]$ equals $ED(A, B_l^r)$, if (l, r) delimits a k-match (i.e., a match with at most k differences) and $k + 1$ otherwise. The table T is a record of all k-matches found, as r must be in the interval $[l + m - k, l + m + k]$ if (l, r) delimits a k-match. It is impossible for previous string-matching algorithms to be augmented (1) to report, at each position of B, the longest prefix of A matching with k differences, (2) to build T, or, equivalently, (3) to report *all* k-matching substrings and their match distances in $O(nk)$ time. Such a capability is essential, for example, if one is searching for the best match under a scoring criterion that is a complex function of the length and number of differences in the match.

The algorithmic results of this paper hinge on what we find to be the rather surprising fact that there are exploitable relationships between the dynamic programming solutions of adjacent problems computed by several well-known comparison algorithms for LCS and edit distance. Throughout the paper we will focus on formulating incremental versions of the well-known $O(n + k^2)$ greedy algorithms for finding the edit distance and the LCS between two sequences [My-86a, LV-88]. A similar and somewhat simpler incremental version [My-86b] also holds for the $O(r \log n)$ Hunt–Szymanski algorithm [HS-77]. After a presentation of preliminary concepts and a review of the $O(n + k^2)$ greedy algorithm in section 2, we present the main theorem exposing the relationship between adjacent solutions and sketch an incremental algorithm based on it in section 3. Section 4 then presents four applications of incremental algorithms in order to demonstrate the power of such algorithms.

FIG. 2. *A sample dynamic programming matrix.*

2. Preliminaries.

2.1. The dynamic programming algorithm. Consider the problem of computing the edit distance between strings $A = a_1a_2 \ldots a_m$ and $B = b_1b_2 \ldots b_n$ where without loss of generality we assume that $m \leq n$ hereafter. The well-known dynamic programming algorithm [NW-70, WF-74] computes an $(m+1) \times (n+1)$ *edit-distance matrix* $D[0 \ldots m][0 \ldots n]$, where entry $D[i,j]$ is the edit distance $ED(A^i, B^j)$ between the prefixes A^i and B^j of A and B, and where $A^i = A^i_0 = a_1 \ldots a_i$ and $B^j = B^j_0 = b_1 \ldots b_j$ as defined in the introduction. Figure 2 gives an example of the matrix $D[0 \ldots 8, 0 \ldots 9]$ for $A = ATGGTATA$ versus $B = AGGATATTA$. The edit distance between A and B is given in entry $D[8,9]$ which is 3. Conceptually we think of D as an $(m+1) \times (n+1)$ grid of *points* (i,j) to which we assign value $D[i,j]$.

A best alignment between $A^i = a_1 \ldots a_i$ and $B^j = b_1 \ldots b_j$ must either (1) leave a_i unaligned and optimally align A^{i-1} and B^j, (2) leave b_j unaligned and optimally align A^i and B^{j-1}, or (3) align a_i and b_j and optimally align A^{i-1} and B^{j-1}. This observation leads immediately to the following fundamental dynamic programming recurrence.

LEMMA 2.1. *For all* $i + j > 0$,

$$D[i,j] = \min \left\{ \begin{array}{ll} D[i-1,j]+1 & \text{if } i > 0 \\ D[i,j-1]+1 & \text{if } j > 0 \\ D[i-1,j-1]+\delta_{a_i,b_j} & \text{if } i,j > 0 \end{array} \right\}$$

where $\delta_{a,b}$ *is* 1 *or* 0 *depending on whether or not* $a = b$*, respectively.*

Coupled with the obvious boundary condition that $D[0,0] = 0$, this recurrence can be used to efficiently compute the $O(mn)$ entries of the matrix D in an order of i and j that observes the data-dependencies of the recurrence, i.e., an order that computes $D[i-1,j]$, $D[i,j-1]$, and $D[i-1,j-1]$ before $D[i,j]$. Traditionally, the lexicographical order of (i,j) (which clearly observes data-dependencies) is used to determine the value of the equation in Lemma 2.1 in $O(1)$ time. An algorithm based on this recurrence thus takes $O(mn)$ time to compute the value of every point of D. The edit distance $ED(A,B)$ is delivered in $D[m,n]$.

The matrix D has a number of useful monotonicity properties with respect to diagonals that are essential to our result.

DEFINITION 2.2. *Diagonal* d *is the list of all points* (i,j) *for which* $j = i + d$.

Note that with this definition the lowest, leftmost diagonal is numbered $-m$ and the highest, rightmost diagonal is numbered n. The first essential property is that values are nondecreasing along diagonals and never increase by more than one.

LEMMA 2.3 (see [Uk-85a]). *For all points* (i, j)*:* $D[i, j] - D[i-1, j-1] \in \{0, 1\}$.

The second essential property is that adjacent values in adjacent diagonals never differ by more than one.

LEMMA 2.4 (see [Uk-85b]). *For all points* (i, j)*:* $D[i, j]-D[i-1, j], D[i, j]-D[i, j-1] \in \{-1, 0, 1\}$.

2.2. The greedy algorithm. In the mid-80s [NKY-82, Uk-85a] came upon the idea of computing the points of the matrix D in an order dictated by a greedy approach, (i.e., to compute the values in nondecreasing order), instead of the lexicographic order of (i, j). In this way entries whose values are 0 are computed first, then those whose values are 1, and then 2, and so on until either (i) some threshold k is reached, or (ii) the value $D[m, n]$ is determined.

By Lemma 2.1, $D[0, j] = j$ for $j = 0, \ldots, n$, and $D[i, 0] = i$ for $i = 0, \ldots, m$. By Lemma 2.3, the values along a diagonal are nondecreasing, so that $D[0, d]$ (resp., $D[d, 0]$) are the smallest values on diagonal d, (resp., $-d$). We conclude that all values not greater than k are on diagonals $-k, -k+1, \ldots, k$ in D, and there are therefore at most $(2k + 1)m$ entries with such values. This idea gives rise to an $O(km)$ algorithm to determine the k-thresholded edit distance of A and B.

The algorithm can be realized by a modified version of Dijkstra's shortest path algorithm on a directed, weighted *edit graph* $G = (V, E)$. V consists of the set of all points (i, j) of D. For each point (i, j) there is an edge into it from $(i-1, j)$ weighted 1, another from $(i, j-1)$ also weighted 1, and a third edge from $(i-1, j-1)$ weighted δ_{a_i, b_j}. For points along the left and upper boundaries of D, there is an edge from a predecessor of (i, j) only if the predecessor exists. Observe that the edge weights are chosen in exact correspondence with Lemma 2.1, and that $D[i, j]$ is the length of the shortest path from $(0, 0)$ to (i, j) in this edit graph. The algorithm stops when either (i) the distance to (m, n) is determined, or (ii) the first node with distance greater than k from $(0, 0)$ is reached. Since the lengths of all paths are integers in $[0 \ldots k]$, and the outdegree of each node in the graph is at most 3, a standard modification of Dijkstra's algorithm will run in $O(km)$ time and space.

Ukkonen [Uk-85a] noticed that it suffices to determine, for all h, the last h on each diagonal d of the matrix D, as this determines all other values in D by Lemma 2.3. More precisely, let $L^h(d)$ denote the largest row index of a point on diagonal d that has value h.

DEFINITION 2.5. $L^h(d) = \max\{\, i \,:\, D[i, i+d] = h \,\}$.

Figure 3 illustrates this definition by labeling just these *furthest h-points* with their values. Note that the row number, $i = L^h(d)$, of the furthest h-point on diagonal d identifies the point itself as $(i, i + d)$. So henceforward, we will liberally use $L^h(d)$ to denote either the point $(i, i + d)$ or the row i. The interpretation of $L^h(d)$ will be obvious from context.

As observed earlier, there are no h-points outside diagonals $[-h \ldots h]$. Thus it suffices to compute for each value h, the *h-wave*.

DEFINITION 2.6. $L^h = \langle L^h(-h), L^h(-h+1), \ldots, L^h(0), \ldots, L^h(h-1), L^h(h)\rangle$.

That is, L^h is the orderered list consisting of the $2h + 1$ furthest h-points in diagonals $-h$ up to h.

The algorithm then computes wave L^h, for $h = 0, 1, 2, \ldots$, until either (i) a wave e is computed for which $L^e(n-m) = m$, or (ii) wave L^k is computed in the case that the algorithm is thresholded by k. In the event that termination is by condition (i) it follows that $ED(A, B) = D[m, n] = e$.

Note that the highest values on some of the diagonals may be less than h. In Figure 3 for example, the highest value in diagonal -2 is 2 (in $D[8, 6]$), and $L^3(-2)$

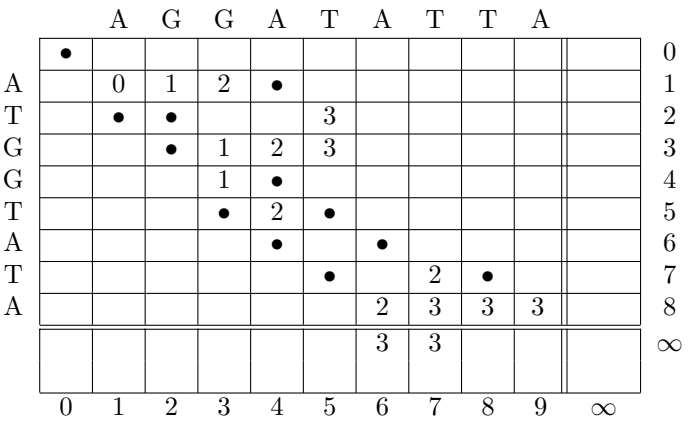

FIG. 3. *The h-waves of the matrix of Figure* 2.

therefore does not exist, as there is no 3-point in diagonal -2. We handle this overflow by adding a "dummy" point $L^h(d)$ with value ∞ to wave h, whenever no real point $L^h(d)$ exists, so that L^h always has $2h+1$ points. In addition, when the extreme point on diagonal d has value h, it is also convenient to set $L^h(d)$ to ∞ whenever (1) this extreme point is $(m, m+d)$, $D[m, m+d] = h$, and $D[m, m+d+1] = h-1$, or when (2) this extreme point is $(n-d, n)$, $D[n-d, n] = h$, and $D[n-d+1, n] = h-1$. Intuitively, this is justified because if we were to extend the matrix D with one more row and column, then $D[m+1, m+d+1]$ (resp., $D[n-d+1, n+1]$) would still always have value h, regardless of how we interpret the "dummy" character associated with that row (resp., column). This is shown in Figure 3, where $L^3(-3)$ is shown outside the boundary of the matrix and hence assigned ∞, although the preceding point on that diagonal, $D[8, 5]$, also has value 3.

Given wave L^{h-1}, wave L^h is computed from it by induction. Consider $i = L^{h-1}(d)$, the furthest $(h-1)$-point in diagonal d, and a corresponding optimal alignment between A^i and B^j, where $j = i+d$. The alignment involves $h-1$ differences and $a_{i+1} \neq b_{j+1}$, as otherwise $(i+1, j+1)$ would also be an $(h-1)$-point (a contradiction). Observe that in this case this alignment can be maximally extended, with one additional difference, in the following three ways: (1) leave a_{i+1} unaligned and then align a_{i+1+q} with b_{j+q} for $q > 0$ as long as the symbols are equal, (2) leave b_{j+1} unaligned and then align a_{i+q} with b_{j+1+q} for $q > 0$ as long as the symbols are equal, and (3) mismatch a_{i+1} with b_{j+1} and then align a_{i+1+q} with b_{j+1+q} for $q > 0$ as long as the symbols are equal. In each case, we visualize the alignment of equal symbols as "sliding down" the relevant diagonal: $d-1$ in case (1), $d+1$ in case (2), and d in case (3).

We capture such a substring of equal characters, resulting in a slide down a diagonal, with the following definition.

DEFINITION 2.7. $Slide_d(i) = \max\{\ q\ :\ A_i^q = B_{i+d}^{q+d}\ \}$.

That is, $Slide_d(i)$ corresponds to a slide in diagonal d starting on row i. In order to correctly handle the cases where $L^h(d)$ is or becomes ∞, we define $Slide_d(i) = \infty$, when $i > m$ or $i + d > n$. Note that by definition $Slide_d(i) = i$ when $i = m$ or $i + d = n$.

The gist of earlier papers was a proof that the furthest point reached in diagonal d over the relevant extensions from the points $L^{h-1}(d-1)$, $L^{h-1}(d)$, and

$L^{h-1}(d+1)$ on wave $h-1$ is the point $L^h(d)$.[1] Combining this with the identity, $\max\{Slide_d(a), Slide_d(b)\} = Slide_d(\max\{a,b\})$, leads to the following recurrence for a furthest h-point in terms of furthest $(h-1)$-points.

LEMMA 2.8.

$$\textit{For all } h > 0, L^h(d) = Slide_d\left(\max\left\{\begin{array}{ll} L^{h-1}(d+1)+1 & \textit{if } d < h-1 \\ L^{h-1}(d)+1 & \textit{if } -h < d < h \\ L^{h-1}(d-1) & \textit{if } d > -h+1 \end{array}\right\}\right).$$

Using Lemma 2.8 one can immediately compute the $2h+1$ points of wave L^h, given the $2h-1$ points of wave L^{h-1}. The induction of the algorithm is started by observing that wave L^0 is the single point $L^0(0) = Slide_0(0)$.

In Figure 3 the furthest points of waves 0 through 3 are indicated by the placement of their value at their location, and the solid circles annotate points that the function *Slide* extends through to reach a furthest point. Note that many of the points in the matrix D of Figure 2, that have value 3 or less, are not marked in Figure 3.

The time complexity of the greedy algorithm depends on the efficiency with which the function *Slide* is realized. When *Slide* is computed by a brute-force comparison of the relevant characters, computing $s = Slide_d(i)$ takes $O(s-i)$ time, resulting in $O(km)$ total time. However, Myers [My-86a] has shown that when one of the strings, say A, is a random string[2] then the algorithm takes $O(m+k^2)$ *expected time*. This result is true even if B is chosen so as to maximize the time spent by the *Slide* function.

2.3. An $O(n+k^2)$ algorithm. The worst-case time of the previous algorithm is improved to $O(n+k^2)$ by computing *Slide* in constant time [My-86a, LV-88].

In a preprocessing step one computes a suffix tree [Wn-73, Mc-76] of the string $AxBy = a_1a_2\ldots a_m x b_1 b_2 \ldots b_n y$ where $x \neq y$ are two symbols not in the alphabets of A and B. One further preprocesses this suffix tree using any of the algorithms [HT-84, SV-88, BV-93], to allow any LCA (least common ancestor) query over the tree to be answered in $O(1)$ time. This preprocessing takes $O(n)$ time.[3]

For given indices i, j the *Slide* function must return the largest q for which $a_i \ldots a_{i+q} = b_j \ldots b_{j+q}$. The key observation is that this q can be retrieved from the suffix tree described above with an LCA query in $O(1)$ time. Specifically, it has been shown that $Slide_d(i) = depth(LCA(leaf(i), leaf(m+1+i+d)))$ where $leaf(t)$ is the leaf in the suffix tree for suffix $(AxBy)_t$, $LCA(u,v)$ is the LCA of vertices u and v, and $depth(v)$ is the length of the string that labels the path from the root of the suffix tree to vertex v.

As noted earlier, wave L^h has $2h+1$ points, each of which can now be computed in $O(1)$ time. Thus it takes $O(k^2)$ worst-case time to compute the $(k+1)^2$ points in waves L^0 through L^k after the initial $O(n)$ preprocessing. This results in an $O(n+k^2)$ worst-case time algorithm.

3. The central theorem and basic algorithm. Given two strings $A = a_1a_2\ldots a_m$ and $B = b_1b_2\ldots b_n$, we now show how to compute the $k+1$ waves $L^0_{new}, \ldots, L^k_{new}$ of the edit-distance matrix $D_{new}[i,j]$ of A and bB, when given the $k+1$ waves $L^0_{old}, \ldots, L^k_{old}$ of the edit-distance matrix $D_{old}[i,j]$ of A versus B.

---

[1] This is not immediately obvious as indicated by the fact that this property is *not* true for more general, weighted-cost comparison models.

[2] Specifically, the result of Bernoulli trials over a finite distribution.

[3] $O(n \log \Sigma)$ time if the alphabet size, Σ, is not considered fixed.

D_{new}, when viewed as a leftward extension of D_{old}, is an $(m+1)\times(n+2)$ matrix $D_{new}[0\ldots m][-1\ldots n]$, with main diagonal labeled -1. Labeling the columns in D_{new} from -1 to n (as opposed to $0\ldots n+1$) has the advantage that entry $D_{new}[i,j]$ corresponds to the edit distance, $ED(A^i, bB^j)$ between the prefixes A^i and bB^j of A and bB, establishing the correspondence of the points $D_{new}[i,j]$ and $D_{old}[i,j]$. Furthermore, for any index pair (i,j) that is valid in both D_{old} and D_{new}, $Slide_{j-i}(i)$ is the same in both matrices.

Since the waves for D_{new} are computed after those for D_{old} have been computed, we shall refer to L^h_{old} and D_{old} as the old h-wave and old matrix and to L^h_{new} and D_{new} as the new h-wave and matrix. We show that L^h_{new} is composed of a concatenation of a prefix of L^{h+1}_{old}, a sublist of L^h_{old}, a suffix of L^{h-1}_{old}, and at most two points p_1 and p_2, separating the sublists of L_{old}, not included in any of the old waves L^{h-1}_{old}, L^h_{old}, L^{h+1}_{old}. Furthermore, the two points p_1 and p_2 can be computed in $O(1)$ time and the entire list L^h_{new} can be pasted together from the lists L^{h+1}_{old}, L^h_{old}, L^{h-1}_{old} in $O(1)$ time.

The following five observations define the concepts and terminology needed to formulate and prove our central theorem.

The first observation relates the values in the matrices D_{old} and D_{new}. We note that any alignment between A^i and B^j with k differences can easily be used to obtain an alignment between A^i and bB^j with at most $k+1$ differences, and any alignment between A^i and bB^j with k differences can easily be used to obtain an alignment between A^i and B^j with at most $k+1$ differences. This implies the following.

Observation 1.

$$\forall (i,j) \in [0\ldots m, 0\ldots n],\ \ D_{old}[i,j]-1 \le D_{new}[i,j] \le D_{old}[i,j]+1$$
$$\forall i \in [0\ldots m],\ \ D_{new}[i,-1] = i.$$

D_{old} is not defined on $(i,-1)$. The point following $(i,-1)$ on diagonal $-i-1$ is $(i+1,0)$ and $D_{old}[i+1,0] = i+1$.

The second observation is an immediate consequence of the recurrence for computing $L^h(d)$ from $L^{h-1}(d-1)$, $L^{h-1}(d)$, and $L^{h-1}(d+1)$ given in Lemma 2.8. Recall that we identify the points on a given diagonal by their row number. Hence, an inequality $p > q$ (even if p and q are not on the same diagonal) is always interpreted as "the row number of p is higher than the row number of q."

Observation 2. If the three points of wave L^{g-1}_{old} on diagonals $d-1$, d, and $d+1$ are all less than or equal to (resp., greater than or equal to) the three points on those diagonals for L^{h-1}_{new}, then $L^g_{old}(d) \le L^h_{new}(d)$ (resp., $L^g_{old}(d) \ge L^h_{new}(d)$). If the three points on the two waves are all equal, then clearly $L^g_{old}(d) = L^h_{new}(d)$. Furthermore, if $\max\{L^{g-1}_{old}(d+1)+1, L^{g-1}_{old}(d)+1, L^{g-1}_{old}(d-1)\}$ is less than or equal to $\max\{L^{h-1}_{new}(d+1)+1, L^{h-1}_{new}(d)+1, L^{h-1}_{new}(d-1)\}$, then $L^g_{old}(d) \le L^h_{new}(d)$.

In the following it will be important to distinguish how a given point $L^h(d)$ got its value in the equation of Lemma 2.8. We will say that

$L^h(d)$ was *obtained from above* iff $L^h(d) = Slide_d(L^{h-1}(d+1)+1)$.

$L^h(d)$ was *obtained diagonally* iff $L^h(d) = Slide_d(L^{h-1}(d)+1)$.

$L^h(d)$ was *obtained from the left* iff $L^h(d) = Slide_d(L^{h-1}(d-1))$.

Note that a point can be obtained in more than one way.

Our third observation compares the scope of the new h wave with the scope of the old $h-1$, h, and $h+1$ wave.

Observation 3. Wave $L^h_{new} = \langle L^h_{new}(-h-1), \ldots, L^h_{new}(h-1)\rangle$, and so it has a point on each of diagonals $-h-1$ through $h-1$ and only these diagonals. Similarly, observe that L^g_{old} has a point on each (and only) the diagonals $-g$ through g. Thus

the leftmost diagonal of L^h_{new}, $-h-1$, is also the leftmost diagonal of L^{h+1}_{old} and both L^h_{old} and L^{h-1}_{old} do not have a point on this diagonal or to the left of this diagonal. On the other hand, the rightmost diagonal of L^h_{new}, $h-1$ is also the rightmost diagonal of L^{h-1}_{old}, and both L^h_{old} and L^{h+1}_{old} do have a point on this diagonal as well as to the right of this diagonal.

Crucial to our central result is the idea of the *key value* of a point, $p = L^h_{new}(d)$, on a new wave, which describes p's position relative to points in the old waves. Informally, if a point $p = L^h_{new}(d)$ of a new wave coincides with a point $L^g_{old}(d)$ of an old wave, then the key value of p is the wave number, g, of the old wave. The other possibility is that p is an *in-between point* that does not coincide with any old point and, in this case, its key value is $g-\frac{1}{2}$, where g is the smallest wave number for which $p < L^g_{old}(d)$. Note that if wave L^{g-1}_{old} has a point on diagonal d, then clearly p lies on diagonal d between the points of the old $g-1$ and g waves; hence the term *in-between* point.

DEFINITION 3.1. *Formally, for a point p on diagonal d,*

$$key(p) = \min\ \{\ g\ :\ g \in \left\{0, \frac{1}{2}, 1, 1\frac{1}{2}, \ldots,\right\}\ \ and\ \ \left(p = L^{\lfloor g \rfloor}_{old}(d)\ \ or\ \ p < L^{\lfloor g+\frac{1}{2} \rfloor}_{old}(d)\right)\}.$$

In terms of key values, Observation 1 yields the following fact.

Observation 4. $\forall\ h, d, \quad h-1 \le key(L^h_{new}(d)) \le h+1$.

Also in terms of key values, Observations 2 and 3 yield the following.

Observation 5. If $key(L^h_{new}(d-1))$, $key(L^h_{new}(d))$, and $key(L^h_{new}(d+1))$ are all $\le$, $=$, or $\ge g$, (for $g \in \{h-1, h, h+1\}$), then $key(L^{h+1}_{new}(d))$ is $\le$, $=$, or $\ge g+1$, respectively. However, $L^{h+1}_{new}(d)$ may exist, although some of the above h-wave points do not exist, i.e., when d is in $\{-h-2, -h-1, h-1, h\}$. If those that do exist all have key values $\le g$, then it still follows that $key(L^{h+1}_{new}(d)) \le g+1$. Greater care has to be taken for the $=$ and $\ge$ case. If for all diagonals $\delta \in \{d-1, d, d+1\}$, for which $L^h_{new}(\delta)$ does not exist, $L^g_{old}(\delta)$ does not exist either, and all other relevant h-wave points have key values $=$ or $\ge g$, then $key(L^{h+1}_{new}(d))$ will still be $=$, or $\ge g+1$, respectively.

We now have the concepts and terminology needed to proceed with our central theorem.

THEOREM 3.2. *L^h_{new} is the concatenation of (up to) five pieces:* (i) *a prefix of L^{h+1}_{old},* (ii) *an in-between point p_1, with $key(p_1) = h+\frac{1}{2}$,* (iii) *a sublist of L^h_{old},* (iv) *an in-between point p_2, with $key(p_2) = h-\frac{1}{2}$, and* (v) *a suffix of L^{h-1}_{old}. Each individual piece may be empty.*

Proof. The proof of Theorem 3.2 is essentially by induction on h, but we will first show that certain monotonicity properties imply Theorem 3.2 and then prove these properties inductively.

We will prove that the following monotonicity property on key values holds for all h waves. The key values of the points along L^h_{new} are nonincreasing and strictly decreasing around in-between points as one proceeds from left to right (i.e., from diagonal $-h-1$ to $h-1$). Formally, we have the following key property.

First key property. For $d \in [-h, h-1]$, $\lfloor key(L^h_{new}(d-1)) \rfloor \ge key(L^h_{new}(d))$.

Observation 4 says that all key values on L^h_{new} are between $h-1$ and $h+1$. The *first key property* says that key values are strictly decreasing along in-between points and are otherwise nonincreasing. This implies that there is at most one point with key value $h+\frac{1}{2}$, (and it is to the right of any points with key value $h+1$, and to the left of any points with key value h), and at most one point with key value $h-\frac{1}{2}$, (to the right of any points with key value h, and to the left of any points with key value $h-1$). It follows that the *first key property* implies that L^h_{new} is the concatenation of the (up to) five pieces given in Theorem 3.2.

We shall prove by induction on h that the *first key property* holds for all h waves.

Before proceeding with a formal proof, we provide some intuition on why the Theorem holds and, at the same time, point to some of the difficulties in proving it. Suppose that L^h_{new} is indeed a concatenation of a prefix $\langle L^{h+1}_{old}(-h-1), \ldots, L^{h+1}_{old}(r)\rangle$ of L^{h+1}_{old}, a point p_1 on diagonal $r+1$, a sublist $\langle L^h_{old}(r+2), \ldots, L^h_{old}(s)\rangle$ of L^h_{old}, a point p_2 on diagonal $s+1$, and a suffix $\langle L^{h-1}_{old}(s+2), \ldots, L^h_{old}(h-1)\rangle$ of L^{h-1}_{old}. By Observation 2, clearly L^{h+1}_{new} will be equal to L^{h+2}_{old} on diagonals $-h-2 \ldots r-1$, will be equal to L^{h+1}_{old} on diagonals $r+3 \ldots s-1$, and will be equal to L^h_{old} on diagonals $s+3 \ldots h-1$. It is hence easy to see that the Theorem can be proven by induction for "most points." One of the difficulties lies in proving that at most one of the diagonals in $\{r, r+1, r+2\}$ and at most one in $\{s, s+1, s+2\}$ can contain an in-between point. A further (more serious) difficulty comes from the fact that any individual piece (of the five pieces composing L^h_{new}) can be empty, resulting in the necessity to examine an enormous number of cases. In addition, points on extreme diagonals behave differently than points on the inner diagonals. In particular, since the various scopes of the waves L^h_{new}, L^{h-1}_{new}, L^{h-1}_{old}, L^h_{old}, and L^{h+1}_{old} are different, special care has to be taken to cover all cases, where a diagonal is in the scope of one wave but outside the scope of another (see Observations 3 and 5).

Therefore, instead of proving Theorem 3.2 directly, we choose to prove that the *first key property* holds for all waves. This will allow us to reduce the number of cases we need to examine significantly, although a large number still remain.

In order to prove the *first key property*, it is very helpful to have established the following second key property for wave h, which is implied by the first key property on wave $h-1$, as shown below in Lemma 3.3.

Second key property. If $key(L^h_{new}(d)) = g + \frac{1}{2}$, then $L^{g+1}_{old}(d)$ was obtained from above.

In other words, the second key property asserts that if there is a new point p in diagonal d between the g- and $g+1$-points of the old waves, then the $g+1$-point must have been obtained from the g-point on diagonal $d+1$.

See Figure 4(a) for an illustration of the situation.

The *second key property* is quite intuitive, but its proof is not immediate. Key values (on wave $h-1$) are nonincreasing, hence if the old $g+1$ value was not reached on diagonal d in the new h wave, it would seem likely that this happened because the key value on diagonal $d+1$ of L^{h-1}_{new} "dropped below" g, and the old $g+1$ point was obtained from this "missing" old g point, $L^g_{old}(d+1)$.

The remainder of the proof of Theorem 3.2 is complex enough that we capture it in three lemmas below. First we prove in Lemma 3.3 that if the first key property holds on new wave $h-1$, then the second holds on new wave h. Then a useful corollary (Lemma 3.4) of Lemma 3.3 is given. Finally, with the aid of the second key property and its corollary, we complete the proof of Theorem 3.2 by inductively showing the first key property to hold for all waves in Lemma 3.5.

LEMMA 3.3. *If the first key property holds up to wave $h-1$ of D_{new}, then the second key property holds up to wave h of D_{new}.*

Proof. The lemma is proven by induction on h.

BASIS: Wave L^0_{new} has only one point, which is on diagonal -1. By Observation 4 $key(L^0_{new}(-1)) \leq 1$, and since L^0_{old} does not have a point on diagonal -1, we also know that $key(L^0_{new}(-1)) > 0$. Hence $key(L^0_{new}(-1))$ is either 1 or $\frac{1}{2}$. $L^1_{old}(-1)$, (whether it collides with the new zero point or not) was obtained from the (only) old zero point $L^0_{old}(0)$, i.e., from above. It follows that the *second key property* holds for wave 0 of D_{new}.

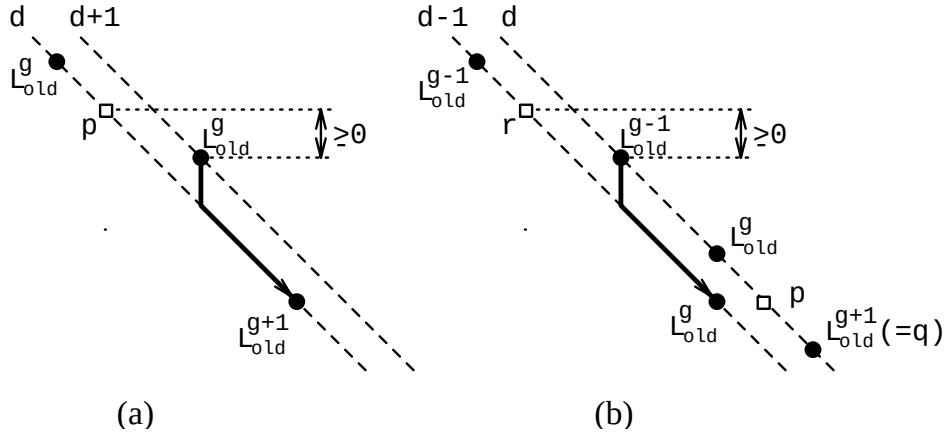

FIG. 4. *The second key property. Old points are shown as solid circles and new points as open squares.* (a) *If the new point p has key value* $g + \frac{1}{2}$, *then* $L_{old}^{g+1}(d)$ *was obtained from above, i.e., from* $L_{old}^{g}(d+1)$. (b) *Shown are new points p and r on diagonals d and* $d-1$ *with key values* $g - \frac{1}{2}$ *and* $g + \frac{1}{2}$, *respectively. The second key property implies that p could not have been obtained from r.*

INDUCTION: Assume that our claim holds for all new waves up to wave $h-1$, i.e., given an *in-between point* $L_{new}^{h-1}(d)$ with $key(L_{new}^{h-1}(d)) = g - \frac{1}{2}$, $L_{old}^{g}(d)$ was obtained from $L_{old}^{g-1}(d+1)$. As easily seen in Figure 4(a), with $p = L_{new}^{h-1}(d)$ and g replaced by $g-1$, the inductive assumption implies that

(1) if $key(L_{new}^{h-1}(d)) = g - \frac{1}{2}$, then $L_{old}^{g-1}(d+1) \geq L_{new}^{h-1}(d)$.

Henceforward, consider an in-between point $p = L_{new}^{h}(d)$, for which $key(L_{new}^{h}(d)) = g + \frac{1}{2}$. That is, $L_{old}^{g}(d)$ (if it exists) $< p < L_{old}^{g+1}(d)$, and Observation 4 further implies that $g \in \{h-1, h\}$.

To prove the *second key property* it suffices to show that $q = L_{old}^{g+1}(d)$ could not have been obtained diagonally or from the left. If $L_{old}^{g}(d)$ exists, then $Slide_d(L_{old}^{g}(d)+1)$ is at most p as $L_{old}^{g}(d) < p$ and p is a furthest point. Thus since $p < q$, q could not have been obtained diagonally.

It remains to show that q could not have been obtained from the left. Again we only need to examine the case when $L_{old}^{g}(d-1)$ exists. (If it did not exist, then clearly q could not have been obtained from the left.) This implies by Observation 3 that $d - 1 \geq -g$, and since $g \leq h$, $d-1$ is at least $-h$ and $L_{new}^{h-1}(d-1)$ exists also.

The assumption that $key(p) = g + \frac{1}{2}$, $(p = L_{new}^{h}(d))$ implies by Observation 5 that one of the three points $L_{new}^{h-1}(d-1)$, $L_{new}^{h-1}(d)$, $L_{new}^{h-1}(d+1)$ must have a key value greater than $g-1$, and since $key(L_{new}^{h-1}(d-1)) \geq key(L_{new}^{h-1}(d))$ (if it exists) $\geq key(L_{new}^{h-1}(d+1))$ (if it exists), it must always be that the key value of $r = L_{new}^{h-1}(d-1)$ is greater than $g-1$. Hence $key(r) = g - \frac{1}{2}$ or $key(r) \geq g$.

$key(r) \geq g$ means that $r = L_{new}^{h-1}(d-1) \geq L_{old}^{g}(d-1)$; hence if $q = L_{old}^{g+1}(d)$ were obtained from $L_{old}^{g}(d-1)$ (i.e., the left), then $L_{new}^{h-1}(d-1)$ would produce a point greater than or equal to q, but $L_{new}^{h}(d)$, the point reached on diagonal d, is strictly less than q, which is a contradiction.

We now show that assuming that $key(r) = g - \frac{1}{2}$ leads to a contradiction because none of the three points $L_{new}^{h-1}(d-1)$, $L_{new}^{h-1}(d)$, or $L_{new}^{h-1}(d+1)$ could have produced $L_{new}^{h}(d)$. Figure 4(b) will help in understanding the argument that follows. Since $r = L_{new}^{h-1}(d-1)$ is an in-between point in this case, it follows from (1) that $L_{old}^{g-1}(d) \geq r$; hence r cannot produce $p = L_{new}^{h}(d)$, a point with key value (much) higher than

$g-1$. On the other hand, $key(L_{new}^{h-1}(d-1)) = g - \frac{1}{2}$ implies that the key values of both $L_{new}^{h-1}(d)$ and $L_{new}^{h-1}(d+1)$ are at most $g-1$ (if they exist); hence neither could have produced $L_{new}^{h}(d)$ with key value $g + \frac{1}{2}$.

We have shown that for all legal key values of $L_{new}^{h-1}(d-1)$, q could not have been obtained from the left, and we have shown earlier that q could not have been obtained diagonally. It must be that q was obtained from the right. □

The following lemma is an immediate corollary of Lemma 3.3.

LEMMA 3.4. *If the first key property holds up to wave $h-1$, then the following holds. If $key(L_{new}^{h-1}(d)) = g - \frac{1}{2}$, then $key(L_{new}^{h}(d+1)) \leq g$. Moreover, if $L_{new}^{h}(d+1)$ was obtained from $L_{new}^{h-1}(d)$, then $key(L_{new}^{h}(d+1)) \leq g-1$.*

Proof. Since $L_{new}^{h-1}(d)$ is an in-between point, $L_{old}^{g}(d)$ was obtained from $L_{old}^{g-1}(d+1)$. As observed earlier and seen in Figure 4(a), it must be the case that $L_{old}^{g-1}(d+1) \geq L_{new}^{h-1}(d)$. Hence $Slide_{d+1}(L_{new}^{h-1}(d))$ cannot be greater than $L_{old}^{g-1}(d+1)$ (a furthest point), which proves the second part of the lemma. Moreover, if the *first key property* holds for wave $h-1$, the key values of both $L_{new}^{h-1}(d+1)$ and $L_{new}^{h-1}(d+2)$ are at most $g-1$, and hence $key(L_{new}^{h}(d+1)) \leq g$ by Observation 2. □

We conclude the proof of Theorem 3.2 by proving by induction that the *first key property* holds for all waves in D_{new}.

LEMMA 3.5. *The first key property holds for all waves in D_{new}.*

Proof. The proof is by induction on h.

BASIS: Wave 0 in D_{new} has only one point $L_{new}^{0}(-1)$. The first key property therefore trivially holds for L_{new}^{0}.

INDUCTION: Assume now that the *first key property* holds up to wave $h-1$ and the *second key property* holds up to wave h. We shall prove that the *first key property* also holds for wave h. To achieve this it suffices to examine all adjacent pairs of diagonals in wave h and to prove the required inequality on their key values. Henceforward consider the pair of points $L_{new}^{h}(d)$ and $L_{new}^{h}(d+1)$. The proof is divided into two cases depending on whether $L_{new}^{h}(d)$ is the leftmost point of the wave.

Case 1. Diagonal d is not the leftmost (lowest) diagonal on L_{new}^{h}, i.e., $d \geq -h$.

By Observation 3, L_{new}^{h-1} also has a point on diagonal d. On the other hand, we do not assume that $d < h-1$, and hence the point $L_{new}^{h-1}(d+1)$ may not exist. Let $g = \lfloor key(L_{new}^{h-1}(d)) \rfloor$ and note that by Observation 4, $g \in \{h-2, h-1, h\}$, and by definition, $key(L_{new}^{h-1}(d)) \in \{g, g+\frac{1}{2}\}$. We now further divide the proof of this case into four subcases depending on the key values of $L_{new}^{h-1}(d)$ and $L_{new}^{h-1}(d+1)$ in relation to g. Table 1 illustrates the four cases factored into two conditions on the key value of $L_{new}^{h-1}(d)$ and two conditions on the key value of $L_{new}^{h-1}(d+1)$, and for each case gives the implication on the key values of $L_{new}^{h}(d)$ and $L_{new}^{h}(d+1)$ that will be proven below. Note in each of the four cases we prove that $\lfloor key(L_{new}^{h}(d)) \rfloor \geq key(L_{new}^{h}(d+1))$.

Subcase 1(a). $key(L_{new}^{h-1}(d)) = g$ and $key(L_{new}^{h-1}(d+1)) = g$.

It suffices to show that $key(L_{new}^{h}(d)) \geq g+1 \geq key(L_{new}^{h}(d+1))$. Either $key(L_{new}^{h-1}(d+2))$ does not exist, (i.e., $d+1$ is the rightmost diagonal of L_{new}^{h-1}), or by the *first key property* on wave $h-1$ $key(L_{new}^{h-1}(d+2)) \leq g$. In either case, Observation 5 implies $key(L_{new}^{h}(d+1)) \leq g+1$. We now show that $key(L_{new}^{h}(d)) \geq g+1$. Either $key(L_{new}^{h-1}(d-1)) \geq g$, (by the *first key property* on wave $h-1$), or $key(L_{new}^{h-1}(d-1))$ does not exist because $d = -h$ is the leftmost diagonal of wave L_{new}^{h-1}, in which case, by Observation 3, neither $L_{old}^{h-2}, L_{old}^{h-1}$, nor L_{old}^{h} have points on diagonal $d-1$, and d is also the leftmost diagonal on L_{old}^{g}. In either case, Observation 5 implies $key(L_{new}^{h}(d)) \geq g+1$.

Subcase 1(b). $key(L_{new}^{h-1}(d)) = g$ and $key(L_{new}^{h-1}(d+1)) \leq g - \frac{1}{2}$ (or doesn't exist).

If $key(L_{new}^{h}(d+1)) \leq g$ we are immediately done, as $L_{new}^{h}(d)$ is always greater than $L_{new}^{h-1}(d)$, and since $key(L_{new}^{h-1}(d)) = g$, we have $key(L_{new}^{h}(d)) > g$. So

TABLE 1

The key values of the pair $L^h_{new}(d), L^h_{new}(d+1)$, as implied by the key values of the pair $L^{h-1}_{new}(d), L^{h-1}_{new}(d+1)$.

	$key(L^{h-1}_{new}(d+1)) = g$	$key(L^{h-1}_{new}(d+1)) \leq g - \frac{1}{2}$ (or doesn't exist)
$key(L^{h-1}_{new}(d)) = g$	$key(L^h_{new}(d)) \geq g+1 \geq key(L^h_{new}(d+1))$	$key(L^h_{new}(d)) > g \geq key(L^h_{new}(d+1))$ or $key(L^h_{new}(d)) \geq g+1 \geq key(L^h_{new}(d+1)) > g$
$key(L^{h-1}_{new}(d)) = g + \frac{1}{2}$	$key(L^h_{new}(d)) \geq g+1 \geq key(L^h_{new}(d+1))$	$key(L^h_{new}(d)) \geq g + \frac{1}{2} > key(L^h_{new}(d+1))$

we assume $key(L^h_{new}(d+1)) \geq g + \frac{1}{2}$ and show that $key(L^h_{new}(d)) \geq g + 1 \geq key(L^h_{new}(d+1))$. $L^h_{new}(d+1)$ got its value from one of the points in $\{L^{h-1}_{new}(d), L^{h-1}_{new}(d+1), L^{h-1}_{new}(d+2)\}$. Since all three points have key values of g or less, clearly $key(L^h_{new}(d+1)) \leq g+1$. In addition, since $key(L^{h-1}_{new}(d+1))$ is either $g - \frac{1}{2}$ or $\leq g-1$, $key(L^{h-1}_{new}(d+2))$ (if it exists) $\leq g-1$ by the first key property, and cannot produce $L^h_{new}(d+1)$, a point with key value greater than g. $L^{h-1}_{new}(d+1)$ (if it exists) $< L^g_{old}(d+1)$, (by definition of Subcase 1(b)) and hence $L^{h-1}_{new}(d+1)$ cannot produce a point beyond $L^g_{old}(d+1)$ either. It follows that $L^h_{new}(d+1)$ got its value from the left, (i.e., from $L^{h-1}_{new}(d) = L^g_{old}(d)$). Since $key(L^h_{new}(d+1))$ is also $\geq g + \frac{1}{2}$, it must be the case that

$$L^{h-1}_{new}(d) > L^g_{old}(d+1); \text{ and by Subcase 1(b) } L^g_{old}(d+1) > L^{h-1}_{new}(d+1).$$

It follows that $L^h_{new}(d)$ was not obtained from above. If $L^{h-1}_{new}(d-1)$ exists, then $key(L^{h-1}_{new}(d-1)) \geq g$, (by the first key property), otherwise $d = -h$ and $L^g_{old}(d-1)$ does not exist either (since by Observation 3 none of the three relevant old waves have a point on diagonal $-h$). Thus $L^h_{new}(d)$ was obtained from the left or diagonally, and both of these source points in the L^{h-1}_{new} wave have key values of g or greater (or do not exist on both L^{h-1}_{new} and L^g_{old}). Thus by Observation 5 $key(L^h_{new}(d)) \geq g+1$.

Subcase 1(c). $key(L^{h-1}_{new}(d)) = g + \frac{1}{2}$ and $key(L^{h-1}_{new}(d+1)) = g$.
Immediately note that because $key(L^{h-1}_{new}(d)) = g + \frac{1}{2} \in [h-2, h]$ by Observation 4, it follows that $g < h$. It suffices to show that $key(L^h_{new}(d)) \geq g+1 \geq key(L^h_{new}(d+1))$. Lemma 3.4 immediately implies that $key(L^h_{new}(d+1)) \leq g+1$. $L^{h-1}_{new}(d)$ and $L^{h-1}_{new}(d+1)$ have key values g or more and the key value of $L^{h-1}_{new}(d-1)$ (if it exists) is also $> g$ (by the first key property). If $L^{h-1}_{new}(d-1)$ does not exist, then $L^g_{old}(d)$ does not exist either, (Observation 3), and it follows from Observation 5 that $key(L^h_{new}(d)) \geq g+1$.

Subcase 1(d). $key(L^{h-1}_{new}(d)) = g + \frac{1}{2}$ and $key(L^{h-1}_{new}(d+1)) \leq g - \frac{1}{2}$ (or doesn't exist).
It suffices to show that $key(L^h_{new}(d)) \geq g + \frac{1}{2} > key(L^h_{new}(d+1))$. Clearly $L^h_{new}(d) > L^{h-1}_{new}(d)$ and hence $key(L^h_{new}(d)) \geq g + \frac{1}{2}$. The first key property on wave $h-1$ implies that $key(L^{h-1}_{new}(d+2)) \leq g-1$ (if it exists); hence $key(L^h_{new}(d+1)) \leq g$ if it was obtained from above. Similarly, $key(L^h_{new}(d+1)) \leq g$ if it was obtained diagonally, as $key(L^{h-1}_{new}(d+1)) \leq g - \frac{1}{2}$. Lastly, the second part of Lemma 3.4 also implies $key(L^h_{new}(d+1)) \leq g$ if it was obtained from $L^{h-1}_{new}(d)$, whose key value is $g + \frac{1}{2}$. Thus, regardless of how it was obtained, $key(L^h_{new}(d+1)) \leq g$.

Case 2. Diagonal d is the leftmost (lowest) diagonal on L^h_{new}, i.e., $d = -h-1$. This case is not covered by Table 1, since $L^{h-1}_{new}(d)$ does not exist. We need

to prove that $\lfloor key(L^h_{new}(-h-1))\rfloor \geq key(L^h_{new}(-h))$. The key value of the point $L^{h-1}_{new}(-h)$, (the leftmost point on L^{h-1}_{new}), is strictly greater than $h-1$, since L^{h-2}_{old} and L^{h-1}_{old} do not have a point on diagonal $-h$, (Observation 3), and obviously $\leq h$ by Observation 4; hence $key(L^{h-1}_{new}(-h)) \in \{h, h-\frac{1}{2}\}$.

Subcase 2(a). $key(L^{h-1}_{new}(-h)) = h$.

L^{h-1}_{new} does not have a point on either diagonal $-h-1$ or $-h-2$; hence $L^h_{new}(-h-1)$ was obtained from $L^{h-1}_{new}(-h)$ which is the same point as $L^h_{old}(-h)$ since $key(L^{h-1}_{new}(-h)) = h$. L^h_{old} does not have points on these two diagonals either; hence $L^{h+1}_{old}(-h-1)$ was obtained from $L^h_{old}(-h)$. It follows that $L^h_{new}(-h-1) = L^{h+1}_{old}(-h-1)$, or equivalently $key(L^h_{new}(-h-1)) = h+1$. Since all key values on the new h wave are less or equal to $h+1$, (Observation 4), $key(L^h_{new}(-h)) \leq h+1$, which proves the required inequality.

Subcase 2(b). $key(L^{h-1}_{new}(-h)) = h-\frac{1}{2}$.

In this case $key(L^{h-1}_{new}(-h+1))$(if it exists) $\leq h-1$, (by the first key property), (while $L^{h-1}_{new}(-h-1)$ does not exist), and hence if $L^h_{new}(-h)$ was obtained from above, then $key(L^h_{new}(-h)) \leq h$. On the other hand, if $L^h_{new}(-h)$ was obtained diagonally, we also have $key(L^h_{new}(-h)) \leq h$, since $L^{h-1}_{new}(-h) < L^h_{old}(-h)$, and $L^h_{old}(-h)$ is a furthest point. On the other hand, (as noted earlier), the key value of the lowest diagonal on the new h wave ($L^h_{new}(-h-1)$) is always strictly greater than h, which proves that $key(L^h_{new}(-h-1)) > h \geq key(L^h_{new}(-h))$. This terminates the proof of this last subcase and hence the proof of Lemma 3.5. □

In summary, Observation 4 says that all key values on L^h_{new} are between $h-1$ and $h+1$, and Lemma 3.5 shows that for all diagonals $-h-1 \leq d < h-1$, $\lfloor key(L^h_{new}(d))\rfloor \geq key(L^h_{new}(d+1))$. The key values are hence nondecreasing and L^h_{new} has at most two in-between points. It follows that Theorem 3.2 holds: L^h_{new} can be pasted together from a prefix of L^{h+1}_{old}, a sublist of L^h_{old}, and a suffix of L^{h-1}_{old} and at most two additional points, which may occur between sublists. Any individual piece may be empty. □

3.1. Formal presentation of algorithm. We now show how Theorem 3.2 and the lemmas and observations of the previous subsection directly lead to an efficient algorithm for computing $L^0_{new} \ldots L^k_{new}$ from $L^0_{old} \ldots L^k_{old}$.

Suppose the wave L^h_{new} has been constructed, and let $L^h_{new}[a \ldots b]$ denote the sublist $\langle L^h_{new}(a), L^h_{new}(a+1), \ldots, L^h_{new}(b)\rangle$ of L^h_{new}, (when $b < a$ $L^h_{new}[a \ldots b]$ denotes the empty list). Let $\delta_1 \in \{0,1\}$ be the number of points on L^h_{new} with key value $h+\frac{1}{2}$, and let $\delta_2 \in \{0,1\}$ be the number of points with key value $h-\frac{1}{2}$. Define p^h_1 to be the largest (rightmost) diagonal for which $key(L^h_{new}(p^h_1)) = h+1$, or let p^h_1 be $-h-2$ if no such diagonal exists. Similarly, let $p^h_2 = \max\{d : (\, key(L^h_{new}(d)) = h\,)$ or $(\, d = p^h_1 + \delta_1\,)\}$. Theorem 3.2 says that $L^h_{new}[-h-1 \ldots p^h_1] = L^{h+1}_{old}[-h-1 \ldots p^h_1]$, $L^h_{new}[p^h_1 + 1 + \delta_1 \ldots p^h_2] = L^h_{old}[p^h_1 + 1 + \delta_1 \ldots p^h_2]$, and that $L^h_{new}[p^h_2 + 1 + \delta_2 \ldots h-1] = L^{h-1}_{old}[p^h_2 + 1 + \delta_2 \ldots h-1]$. Notice that the above equalities hold even if individual pieces are empty. By Observation 2 it follows that if $L^h_{new}[a \ldots b] = L^g_{old}[a \ldots b]$, then $L^{h+1}_{new}[a+1 \ldots b-1] = L^{g+1}_{old}[a+1 \ldots b-1]$. In addition, if $g = h+1$, we also have $L^{h+1}_{new}[a] = L^{g+1}_{old}[a]$, and if $g = h-1$ we also have $L^{h+1}_{new}[b] = L^{g+1}_{old}[b]$. Thus, all of L^{h+1}_{new} is determined by these equalities except for the two or three points on the diagonals in the interval $[p^h_1, p^h_1 + 1 + \delta_1]$ and the two or three points on the diagonals in the interval $[p^h_2, p^h_2 + 1 + \delta_2]$. In addition, Lemma 3.4 implies that if $key(L^h_{new}(p^h_2 + 1)) = h - \frac{1}{2}$, (i.e., $\delta_2 = 1$), then $key(L^{h+1}_{new}(p^h_2 + 2)) \leq h$, and hence $key(L^{h+1}_{new}(p^h_2 + 2)) = h$ (since all key values on L^{h+1}_{new} are at least h). Simi-

larly, if $key(L^h_{new}(p^h_1+1)) = h+\frac{1}{2}$, (i.e., $\delta_1 = 1$), then $key(L^{h+1}_{new}(p^h_1+2)) \leq h+1$, and if in addition $p^h_2 > p^h_1+2$, then $key(L^{h+1}_{new}(p^h_1+2)) = h+1$. Thus, the only points on L^{h+1}_{new} that cannot be determined by merely examining the key value of the points on L^h_{new} are the four points on diagonals p^h_1, p^h_1+1, p^h_2, and p^h_2+1.

If L^g_{old} is a doubly linked list so that, given a pointer to $L^g_{old}(d)$, one can move to $L^g_{old}(d-1)$ or $L^g_{old}(d+1)$ in constant time, and each diagonal across the waves is a doubly linked list, so that given a pointer to $L^g_{old}(d)$, one can move to $L^{g+1}_{old}(d)$ or $L^{g-1}_{old}(d)$ in constant time, we can construct L^{h+1}_{new} from L^h_{new} and the old L waves by performing at most $O(1)$ computations and pointer changes. To do so requires knowing the *break diagonals* p^h_1 and p^h_2 of L^h_{new} and determining the new *break diagonals* p^{h+1}_1 and p^{h+1}_2 during the computation of L^{h+1}_{new}. Notice that all but $O(1)$ of the diagonal links from L^h_{new} to L^{h+1}_{new} will be imported directly from the corresponding diagonal links of L^{h-1}_{old}, L^h_{old}, and L^{h+1}_{old} so that only those for the points on diagonals p^h_1, p^h_1+1, p^h_2, p^h_2+1 need to be recomputed. A formal algorithmic description is given in Figures 5, 6, and 7, which shows that such a cross-linked structure can be maintained to realize an incremental update in $O(k)$ time of $L^0_{new}, \ldots, L^{k-1}_{new}$.

For reasons of simplicity, the explicit algorithm in Figures 5, 6, and 7 is given as if the waves were stored in an array and $O(1)$ access to $L^h_{new}(d)$, for any d, were possible. The cross-linked structure is clearly necessary to realize an incremental update in $O(k)$ time, but the description of the algorithm is much simpler in the latter form. The reader can verify that, given the cross-linked structure and pointers to $L^h_{new}(p^h_1)$ and $L^h_{new}(p^h_2)$, as well as to $L^{h+1}_{old}(p^h_1+1)$ and $L^h_{old}(p^h_2+1)$, every pertinent wave element in *Construct_new_wave* in Figure 6 is $O(1)$ links away from either of these four "break pointers," or the first element of a completed new wave or an as yet unused old wave. In more detail (which is not necessary to understand the explicit algorithms in Figures 5, 6, and 7), the following elements can be accessed in $O(1)$ time.

1. The first $O(1)$ elements of L^h_{new} and L^{h+2}_{old}: $L^h_{new}(-h-1+O(1))$ and $L^{h+2}_{old}(-h-2+O(1))$.
2. All points on L^h_{new} within $O(1)$ diagonals of p^h_1 and p^h_2: $L^h_{new}(p^h_1 \pm O(1))$ and $L^h_{new}(p^h_2 \pm O(1))$.
3. Points on old waves that are identical to the above points: $L^{h+1}_{old}[-h-1 \ldots p^h_1] = L^h_{new}[-h-1 \ldots p^h_1]$.
4. The first $O(1)$ points on the suffixes of the relevant old L lists: $L^{h+1}_{old}(p^h_1+1+O(1))$ and $L^h_{old}(p^h_2+1+O(1))$.
5. Points accessible from any of the above points through old diagonal links: $L^{h+2}_{old}(p^h_1)$, which is diagonally linked to $L^{h+1}_{old}(p^h_1) = L^h_{new}(p^h_1)$, as well as $L^{h+2}_{old}(p^h_1 \pm O(1))$. If $L^h_{new}(p^h_2) = L^h_{old}(p^h_2)$ (which is always true when $p^h_2 > p^h_1+1$), then $L^{h+1}_{old}(p^h_2)$ is accessible through the diagonal link from $L^h_{old}(p^h_2)$, and hence $L^{h+1}_{old}(p^h_2 \pm O(1))$ is also accessible in $O(1)$ time. If $L^h_{new}(p^h_2) < L^h_{old}(p^h_2)$, (and hence $p^h_2 \in \{p^h_1, p^h_1+1\}$), then $L^{h+1}_{old}(p^h_2 \pm O(1))$ is still accessible in $O(1)$ steps, as $p^h_2 = p^h_1 + O(1)$.

The computation of the last wave L^k_{new} and its diagonal links from and to L^{k-1}_{new} may take an additional $O(k)$ time since the required L^{k+1}_{old} piece and its diagonal links from L^k_{old} have not been computed previously and need to be computed now (see lines 6 and 7 in Figure 7). In total, the computation of the k waves requires computing $O(k)$ new points and updating $O(k)$ links. The computation of each new point is done by calling the *Slide* function (line 2 in Figure 6), which takes $O(1)$ time. In total the computation of the k waves for D_{new} takes $O(k)$ time, when given the k waves for D, cross-linked across waves and diagonals as described above.

Procedure Construct_new_wave$(h, p_1^h, p_2^h, p_1^{h+1}, p_2^{h+1})$
1. $L_{new}^{h+1}[-h-2 \ldots p_1^h-1] \leftarrow L_{old}^{h+2}[-h-2 \ldots p_1^h-1]$
2. Compute($L_{new}^{h+1}(p_1^h)$)
3. Compute($L_{new}^{h+1}(p_1^h+1)$)
4. $p_1^{h+1} \leftarrow \begin{cases} p_1^h - 1 & \text{if } L_{new}^{h+1}(p_1^h) < L_{old}^{h+2}(p_1^h) \\ p_1^h & \text{if } L_{new}^{h+1}(p_1^h) = L_{old}^{h+2}(p_1^h) \text{ and } L_{new}^{h+1}(p_1^h+1) < L_{old}^{h+2}(p_1^h+1) \\ p_1^h + 1 & \text{otherwise} \end{cases}$
5. **if** $p_2^h > p_1^h + 2$ **then**
6. { $L_{new}^{h+1}[p_1^h+2 \ldots p_2^h-1] \leftarrow L_{old}^{h+1}[p_1^h+2 \ldots p_2^h-1]$
7. Double_Link($L_{new}^{h+1}(p_1^h+2)$, $L_{new}^{h+1}(p_1^h+1)$)
8. }

3.2. An analogous theorem for longest common subsequences. As pointed out in the introduction, the model in which one allows insertions and deletions, called indels, but not mismatches is an important variation because it is dual

to finding the longest common subsequence. A theorem similar to Theorem 3.2, but simpler, holds in this situation. We simply sketch the result here, since the proof method and outline remain the same.

When mismatches are not allowed, several of the preliminary lemmas of section 2 change in small ways. In Lemma 2.1, the term δ_{a_i,b_j} should be multiplied by two, as a substitution can now only be achieved by an insertion and deletion. In Lemma 2.3, values increase along a diagonal by zero or two, i.e., $D[i,j]-D[i–1,j–1] \in \{0,2\}$. Next note that with an even number of indels one must end in an even numbered diagonal and an odd diagonal with an odd number of indels. Thus for this variation of the problem, an h-wave has $h+1$ points on every other diagonal, i.e., $L^h = \langle L^h(-h), L^h(-h+2), \ldots, L^h(h-2), L^h(h)\rangle$. Finally, in Lemma 2.8, one must drop the term $L^{h-1}(d)+1$ from the 3-way maximum as it represents the contribution of extension via a substitution. As a consequence, a point is either obtained from the *left* or from *above*.

We continue to define key values as in Definition 3.1. Note however that the diagonals on a new h wave do not contain old h points, and hence an in-between point p on L^h_{new} is between the old $h-1$ and the old $h+1$ wave. As a result of our definitions, a key value of a point p on a new h wave will assume one of the three values in $\{h-1, h+\frac{1}{2}, h+1\}$. In spirit, all the observations in section 3 continue to hold with the obvious modifications that follow from the fact that points can only be obtained in two ways. Theorem 3.2 becomes the following.

THEOREM 3.6. *Wave h in D_{new} (L^h_{new}) is the concatenation of (up to) three pieces:* (i) *a prefix of L^{h+1}_{old},* (ii) *an in-between point p with key$(p) = h+\frac{1}{2}$, and* (iii) *a suffix of L^{h-1}_{old}. Not all pieces must be present.*

The proof of Theorem 3.6 is in some sense a subset of the proof of Theorem 3.2. So rather than prove it formally, we sketch the main elements and leave the details as an exercise. The informal statement of the first key property remains the same, but its formal statement becomes the following.

First key property. For $d \in [-h+1, h-1]$, $\lfloor key(L^h_{new}(d-2))\rfloor \geq key(L^h_{new}(d))$, to account for the fact that only alternate diagonals are relevant. This first key property can similarly be proven by induction on h using the second key property and its immediate consequence, the analogue of Lemma 3.4.

Second key property. If $key(L^h_{new}(d)) = h+\frac{1}{2}$, then $L^{h+1}_{old}(d)$ was obtained from above.

Because the proof in this case is simpler, we combine the proof of the second key property and of the analogue of Lemma 3.4 in Lemma 3.7.

LEMMA 3.7. *If the first key property holds up to wave h, and if key$(L^h_{new}(d)) = h+\frac{1}{2}$, then* (1) *key$(L^{h+1}_{old}(d))$ was obtained from above, and key$(L^{h+1}_{new}(d+1)) = h$.*

Proof (sketch). The proof is by induction.

BASIS: We need to show that if $key(L^0_{new}(-1)) = \frac{1}{2}$, then $L^1_{old}(-1)$ was obtained from above and $key(L^1_{new}(0)) = 0$. $L^1_{old}(-1)$ (whether it collides with $L^0_{new}(-1)$ or not) was obtained from the (only) old zero point $L^0_{old}(0)$, i.e., from above. In addition, if $key(L^0_{new}(-1)) = \frac{1}{2}$, then $L^0_{new}(-1)$ must be $\leq L^0_{old}(0)$; hence $L^1_{new}(0)$ will be equal to $L^0_{old}(0)$.

INDUCTION: Assume that Lemma 3.7 holds up to wave h. Consider an in-between point $L^h_{new}(d)$, for which $key(L^h_{new}(d)) = h+\frac{1}{2}$. We need to show that $L^{h+1}_{old}(d)$ could not have been obtained from the left and that $key(L^{h+1}_{new}(d+1)) = h$. $key(L^h_{new}(d)) = h+\frac{1}{2}$ implies that one of the two points $L^{h-1}_{new}(d-1)$, $L^{h-1}_{new}(d+1)$ must have a key value of $h-\frac{1}{2}$ or h, and since $key(L^{h-1}_{new}(d-1)) \geq key(L^{h-1}_{new}(d+1))$, it must be that $key(L^{h-1}_{new}(d-1)) \in \{h-\frac{1}{2}, h\}$. $key(L^{h-1}_{new}(d-1)) = h-\frac{1}{2}$ can be ruled out, since it

Procedure Construct_new_LCS_wave(h, p^h, p^{h+1})
1. $L^{h+1}_{new}[-h-2...p^h-1] \leftarrow L^{h+2}_{old}[-h-2...p^h-1]$
2. Compute_LCS($L^{h+1}_{new}(p^h+1)$)
3. $p^{h+1} \leftarrow \begin{cases} p^h-1 & \text{if } L^{h+1}_{new}(p^h+1) < L^{h+2}_{old}(p^h+1) \\ p^h+1 & \text{otherwise} \end{cases}$
4. $L^{h+1}_{new}[p^h+3..h] \leftarrow L^h_{old}[p^h+3...h]$
5. Double_Link($L^{h+1}_{new}(p^h+3)$, $L^{h+1}_{new}(p^h+1)$)

Procedure Compute_LCS($L^h_x(d)$)
1. **if** $x = new$ **then** $\delta \leftarrow 1$ **else** $\delta \leftarrow 0$
2. $L^h_x(d) \leftarrow Slide_d\left(\max \left\{ \begin{array}{ll} L^{h-1}_x(d+1)+1 & \text{if } d < h-\delta \\ L^{h-1}_x(d-1) & \text{if } d > -h-\delta \end{array} \right\} \right)$
3. **if** $h > 0$ **and** $d > -h-\delta$ **then**
4. { Double_Link($L^h_x(d)$, $L^h_x(d-2)$)
5. **if** $d < h-\delta$ **then** Double_Link($L^h_x(d)$, $L^{h-1}_x(d+1)$)
6. }

FIG. 9. *Computation of $L^h_{new}(d)$ or $L^h_{old}(d)$ and update of all relevant pointers.*

contradicts the inductive hypotheses, which says that in this case $key(L^h_{new}(d)) = h-1$. If $L^{h+1}_{old}(d)$ was obtained from $L^{h-1}_{new}(d-1)$ (i.e., the left) and $key(L^{h-1}_{new}(d-1)) = h$, we would have $key(L^h_{new}(d)) = h+1$; again a contradiction. Hence $L^{h+1}_{old}(d)$ was obtained from $L^h_{old}(d+1)$ (i.e., from above). This in turn implies that $L^h_{old}(d+1) \geq L^h_{new}(d)$. If $L^{h+1}_{new}(d+1)$ was obtained from $L^h_{new}(d)$, then the above inequality would imply that $L^{h+1}_{new}(d+1) \leq L^h_{old}(d+1)$, but since $L^{h+1}_{new}(d+1) \geq L^h_{old}(d+1)$ (always), it follows in this case that $L^{h+1}_{new}(d+1) = L^h_{old}(d+1)$. On the other hand by the first key property on wave h, $key(L^h_{new}(d+2)) = h-1$; hence if $L^{h+1}_{new}(d+1)$ was obtained from $L^h_{new}(d+2)$, we also have $L^{h+1}_{new}(d+1) = L^h_{old}(d+1)$. Hence regardless of how $L^{h+1}_{new}(d+1)$ was obtained, $key(L^{h+1}_{new}(d+1)) = h$. □

Given the second key property and Lemma 3.7, the proof of the first key property, and hence Theorem 3.6, is outlined in a nutshell as follows. Given a pair of consecutive points on wave h, $L^h_{new}(d-2)$ and $L^h_{new}(d)$, we consider the point $L^{h-1}_{new}(d-1)$. If $key(L^{h-1}_{new}(d-1)) = g$, $(g \in \{h-2, h\})$, then $key(L^h_{new}(d-2)) \geq g+1$, while $key(L^h_{new}(d)) \leq g+1$. If $L^{h-1}_{new}(d-1)$ is an in-between point, then $key(L^{h-1}_{new}(d-1)) = h-\frac{1}{2}$, and by Lemma 3.7 $key(L^h_{new}(d)) = h-1$, while $key(L^h_{new}(d-2))$ is always greater than or equal to $h-1$.

3.3. Explicit algorithm for LCS. The explicit algorithm given in Figures 8, 9, and 10 is similar to and simpler than the one for edit distance. Waves are still doubly linked lists, with $L^h(d)$ doubly linked to $L^h(d-2)$ and $L^h(d+2)$. Diagonal-links will be slightly different in that $L^h(d+1)$ is linked to $L^{h+1}(d)$ (as L^{h+1} does not have a point on diagonal $d+1$). p^h is defined as the largest (rightmost) diagonal on L^h_{new} for which $key(L^h_{new}(p^h)) = h+1$ and is set to $-h-2$ if there is no such diagonal.

4. Four applications. The power of the incremental algorithm of the proceeding section is that it delivers an encoding of the dynamic programming solution for each and every problem so obtained. In the context of the four applications of this section, this feature of the method allows the algorithm to completely explore the space of solutions to each subproblem. In the case of some of the applications, this

Procedure New_LCS_Wave
1. $L^0_{new}(-1) \leftarrow Slide_{-1}(0)$
2. **if** $L^0_{new}(-1) < L^1_{old}(-1)$ **then** $p^0 \leftarrow -2$ **else** $p^0 \leftarrow -1$

FIG. 10. *Construction of $L^0_{new} \dots L^k_{new}$ from the corresponding old waves.*

is essential to their efficient solution, and in others it provides leverage not found in previous algorithms that can only keep track of the best solution to a set of subproblems. For each application, we show how to apply the incremental algorithm as a subprocedure and focus on how its wave structure is processed at each stage to provide the desired solutions.

Before proceeding with the description of the applications, we introduce a notation for the wave structure that is different from the one introduced in section 3 but is convenient for the discussion of applications. In section 3 we showed how to compute the $k+1$ waves $L^0_{new}, \dots, L^k_{new}$ of the edit-distance matrix $D_{new}[i,j]$ of A and bB, when given the $k+1$ *waves* $L^0_{old}, \dots, L^k_{old}$ of the matrix $D_{old}[i,j]$ of A versus B. In all of our applications the overall outline of the algorithm is to start with a k-thresholded solution for A versus some suffix B_s of B. (Recall that B^r_l is the substring $b_{l+1}b_{l+2}\dots b_r$, and that $B_l = B^n_l$ and $B^r = B^r_0$.) When $s = n$ this is the trivial solution of A versus the empty string, and when $s < n$ the initial solution can be computed with the standard $O(n + k^2)$ algorithm. Thereafter, the application algorithm incrementally computes the solutions to A versus B_l for $l = s-1, s-2, \dots, 0$ using the incremental algorithm of section 3 as a subroutine.

At any moment we will have $k+1$ waves L^0, L^1 ... L^k modeling the solution to a comparison between some suffix B_l of B and A. Let the *origin diagonal* for this problem be l, and denote by D_l the dynamic programming matrix of the comparison of A with B_l. Further let $C^h(d) = L^h(l+d)$ denote the wave value that is at diagonal d of the matrix D_l. In this way $L^h = \langle C^h(-h), C^h(-(h-1)), \dots, C^h(h-1), C^h(h)\rangle$ regardless of the suffix of B at hand. Recall from the preliminaries that, in order to be compliant with the recursion for computing L^h in terms of L^{h-1}, it was convenient to sometimes set $L^h(d)$ to ∞ even though the extreme point on diagonal d in D had value h. But in the context of our applications, it is now convenient to reset these ∞ values so that C^h always holds the furthest h point on the corresponding diagonal, *within the boundary of* D, if such an h point exists. Formally if $L^h(l+d) = \infty$ while $L^{h-1}(l+d) \neq p_{last}(d)$, where $p_{last}(d) = \min\{m, n-l-d\}$ is the row number of the last point on diagonal d in matrix D, then set $C^h(d) = p_{last}(d)$. Note that the D value of $p_{last}(d)$ on diagonal d is indeed equal to h in this case. It is easy to see that this "adjustment" of values can be done $O(k)$ time per D_l matrix.

Recall from the previous section that each wave is implemented as a doubly linked list so that given a pointer to $C^h(d)$ one can move to $C^h(d-1)$ or $C^h(d+1)$ in constant time, and each diagonal across the waves is in a doubly linked list so that given a pointer to $C^h(d)$ one can move to $C^{h+1}(d)$ or $C^{h-1}(d)$ in constant time.

4.1. Approximate string matching and longest prefix. The approximate string matching problem was used in the introduction as an example of how our incremental alignments algorithm could be used to find *all* matching substrings in $O(nk)$ time. We begin by exploring in greater detail how our incremental algorithm

is applied to the following slightly more general problem and the leverage it provides over other algorithms. Consider first finding for each position $l \in [0, n]$ of a text B the length $m(l)$ of the longest prefix $A^{m(l)}$ of A that can be matched to some prefix of B_l with no more than k differences. Formally, $m(l) = \max\{p \in [0, m] : \exists r \in [l, n],\ ED(A^p, B_l^r) \leq k\}$. Further consider finding for each l the set of all r such that the substring B_l^r of the text B and the prefix $A^{m(l)}$ are within edit distance k of each other. When $m(l) = m$ we call such a substring of the text a *k-match*, and otherwise a *longest prefix k-match*. In summary, the *longest prefix approximate match problem* is, given strings A, B, and threshold k, to find for each l the length $m(l)$ and the set of indices r such that $ED(A^{m(l)}, B_l^r) \leq k$. The problem obviously generalizes the approximate string matching problem which seeks all (l, r) for which $m(l) = m$.

We start by building the trivial k-thresholded solution for A versus B_n $(= \varepsilon)$ and then proceed incrementally. First observe that constructing the trivial solution for A versus B_n simply requires building an initial cross-linked wave structure and setting $C^h(d)$ to h if $d = -h$ and to ∞ otherwise. The algorithm then proceeds to produce solutions for A versus progressively longer suffixes of B taking $O(k)$ time per incremental shift using our central result. The only remaining detail is to show how, given the k-thresholded solution for A versus some suffix B_l, one finds the longest prefix of A and all r and h such that $ED(A^{m(l)}, B_l^r) = h \leq k$. Note that when $m(l) < m$ the corresponding edit distance is always k, since we would otherwise choose a longer prefix of A. Even when $m(l) = m$ there is at least one diagonal d for which $C^k(d)$ is exactly m. This is easily seen by observing that the least possible number of differences on diagonal $-k$ is k; hence $D_l[m, m-k]$ is always $\geq k$, and hence $C^k(-k) \leq m$. For $d < 0$, $C^k(d) < m$ implies that $C^{k-1}(d+1) < m$ and hence $C^k(d+1) \leq m$. Hence even if $C^k(d) = \infty$ for some $d \leq 0$, we have $C^k(d') = m$ for some diagonal d' between $-k$ and d. We can therefore determine $m(l)$ by examining all non-∞ values on wave k; hence $m(l) = \max_d\{C^k(d) \mid C^k(d) \leq m\}$, and we wish to find d and h such that $C^h(d) = m(l)$, for this will give us all points $(m(l), m(l)+d)$ for which $D_l[m(l), m(l)+d] = h$.

It suffices to first traverse wave C^k to determine $m(l)$ and thereafter traverse the wave structure in order of diagonals, moving up or down along a diagonal list to find the entry on that diagonal equal to $m(l)$, if any. The algorithm fragment in Figure 11 gives the details. Note that we start by looking for a match with k differences on diagonal $-k$. Thereafter d and h are advanced in unit increments to suggest the pointer-based traversal of the cross-linked structure. The traversal again takes advantage of the fact that adjacent D-values never differ by more than one, implying that if we move from a best point on wave h and diagonal d to the adjacent wave point on the next diagonal, at most one move up or down to wave $h+1$ or wave $h-1$ along that diagonal will reach a point on row $m(l)$ if there is one.

Figure 11 clearly takes $O(k)$ time which is no more expensive than the time to produce the wave structure for the given index l. Thus the overall algorithm takes $O(nk)$ time. Note that a corollary is that there are at most $O(nk)$ k-matches to A. While there are other algorithms for approximate string matching that take only $O(nk)$ time, none delivers or can be trivially extended to deliver the longest prefix of A that can be matched with k differences to some substring of B and to deliver all the k-matching substrings and their associated edit distances. Finding the longest prefix that can be matched to a given string turns out to be crucial in an algorithm for finding approximate repeats, i.e., adjacent substrings whose edit distance is no more than k [LS-93] and is almost certain to find additional applications. Finding all matching substrings is crucial if one has some secondary criteria that is a non-linear function of match length and edit distance. In this case one needs to examine

```
1.   m(l) ← max_d{C^k(d) | C^k(d) ≤ m}
2.   h ← k
3.   for d = −k to k by 1 do
4.    {    if h < k and C^{h+1}(d) ≤ m(l) then
5.              h ← h + 1
6.         else if C^h(d) = ∞ then
7.              h ← h − 1
8.         if C^h(d) = m(l) then
9.              Report A^{m(l)} matches B_l^{l+m(l)+d} with h differences
10.   }
```

FIG. 11. *Reporting matching substrings.*

all matches and not simply the best one ending or beginning at a given index. For example, if $A = aaaacbbbbccccc$ and $B = xxxxxaaaaccccccbbbbccccxxxx\ldots$, then both B_5^{15} and B_{14}^{24} match A (of length 14) with 4 differences but B_5^{24} matches with 5 differences. The last match is conceivably more significant than the two others, (involving 14 identical symbols versus 10), but would not be revealed by previous algorithms. These algorithms can only determine the match(es) with the minimum number of differences ending at a given character of B, or (in a backward solution) the match(es) with the minimum number of differences starting at a given character of B. That is, previous algorithms only detect the difference 4 match B_{14}^{24} to the suffix of B^{24} when run left-to-right over B, and the difference 4 match B_5^{15} to the prefix of B_5 when run right-to-left over B. The difference 5 match B_5^{24} is missed in both directions.

The next application treats this issue in more detail.

4.2. Approximate overlap. Our second example comes from a problem in molecular biology that arises in sequencing DNA. Current methods for determining sequence allow the direct determination of the DNA sequence of a string of length less than 1,000. To determine the sequence of a very long DNA strand, say 50,000 symbols in length, an experimentalist employing the "shotgun" sequencing method randomly extracts fragments of sufficiently small length from the subject strand and determines the sequence of these fragments via a direct experimental method. The resulting *fragment assembly problem* is to determine the subject strand given the collected set of fragments.

The first step in solving the fragment assembly problem is to compare every sequence against every other sequence to see if a suffix of one matches a prefix of another.[4] Such detected overlaps indicate the possibility (but not the certainty) that the two fragments came from overlapping regions of the subject stand. Detecting the overlaps is complicated by the fact that direct sequencing experiments are imperfect and so do not produce the exact sequence. Typically, the error rate runs at about a 1–10% difference between the reported string and the true fragment sequence. Thus, fragments must be compared to determine if there is an *approximate overlap* between them. A fast method is essential for this fundamental subproblem since it must be solved for a quadratic number of fragment pairs.

More precisely, given a threshold k (reflective of the length of the fragments and the error rate of the sequencing method), and two fragments A and B, we say A

[4] [GLS-92] describes an algorithm that finds the exact (0 differences) matches between prefixes and suffixes of a set of strings.

approximately overlaps B within threshold k if either (a) a prefix of A aligns with a suffix of B with not more than k differences, or (b) A aligns with a substring of B with not more than k differences. Matches of type (a) are called *dovetail* matches and those of type (b) are *containment* matches. Unfortunately, whenever A and B approximately overlap within k-difference, there are typically a number of possible ways to do so. One way to compare the significance of different alignments is to choose the overlap which is the least likely to occur by chance, as suggested in [KM-94]. Let $\Pr_\Sigma(m, n, k)$ be the probability, or some approximation thereof, that two strings of respective lengths m and n formed by random Bernoulli trials over a Σ symbol alphabet can be aligned with k-or-less differences. For this discussion, let us assume a precomputed table containing values $Pr_\Sigma[m, n, k]$ between 0 and 1 for the relevant range of m, n, and k (e.g., $0 \leq m, n \leq 2{,}000$, and $0 \leq k \leq 400$ for most DNA sequencing projects). Note that Pr_Σ is typically a nonlinear function of m, n, and k.

Given a threshold k and strings A and B of length m and n, the *approximate overlap problem* can now be stated as finding three indices l, r, and p such that

(a) $r = n$ or $p = m$, and
(b) $ED(A^p, B_l^r) = h \leq k$, and
(c) $Pr_\Sigma[p, r - l, h]$ is minimal.

When $r = n$ the approximate overlap is of the dovetail variety (prefix A^p versus suffix B_l), and when $p = m$ it is of the containment type (A versus substring B_l^r).

As for the approximate match problem, the approximate overlap problem is solved by incrementally computing the solution for A versus B_l for $l = n, n - 1, \ldots, 0$. As before, the initial solution for B_n versus A is easy to compute and $O(k)$ time is spent thereafter incrementally delivering each additional k-thresholded solution as cross-threaded lists of the $k + 1$ waves, $L^0, L^1, \ldots, L^k$. For each suffix B_l, one traverses the wave structure finding all p and r that satisfy conditions (a) and (b) above. We term such a triple, (l, r, p), a *candidate*. As each candidate is discovered, its Pr_Σ "score" is compared against the minimum scoring triple (L, R, P) of probability score S encountered thus far in the algorithm and entered as the new best if its score is lower. Thus, at the end of the algorithm the indices delimiting a minimum scoring approximate overlap and its probability score are delivered. The algorithm is shown in Figure 12.

As for approximate match, the tricky detail is the discovery of the candidates within a given solution. Suppose we have the k-thresholded solution for A versus B_l. Like approximate match, containment candidates correspond to those d and h for which $C^h(d) = m$ for this implies $ED(A, B_l^{l+m+d}) = h$. Dovetail candidates correspond to those furthest points in the structure that reach the extreme column $n - l$ of D_l, the dynamic programming matrix for the problem of comparing A and B_l. That is, we seek d and h for which $C^h(d) = n - l - d$ and is therefore a point on the extreme column of D_l, for this implies $D_l[n - l - d, n - l] = h$ which in turn implies $ED(A^{n-l-d}, B_l) = h$.

Observe that the algorithm given in Figure 12 has exactly the same wave-traversal logic as the one given in Figure 11. The modifications are related to differences between the applications: lines 1 and 8–9 in Figure 11 versus lines 2, 11–14, and 17 in Figure 12. As a consequence, it is clear the algorithm takes $O(nk)$ time.

The algorithm can be further refined to deliver not only the indices of the best approximate overlap in $O(nk)$ time but an alignment achieving it as well. An alignment can of course be produced in all applications but it is particularly appealing here since we output only the "best matching substring" with respect to our scoring function, and we can produce $O(1)$ alignments per substring B_l in the desired time

```
1.  Compute initial solution for A versus B_n.
2.  (L, R, P, S) ← (n, n, 0, 1)    # B_n^n overlaps A^0 with 0 errors with probability 1.
3.  for l = n − 1 downto 0 by 1 do
4.    { Incrementally compute solution for A versus B_l.
5.      h ← k
6.      for d = −k to k by 1 do
7.        { if h < k and C^{h+1}(d) < ∞ then
8.              h ← h + 1
9.          else if C^h(d) = ∞ then
10.             h ← h − 1
11.         if C^h(d) = m or C^h(d) + d = n − l then
12.             s ← Pr_Σ[C^h(d), d + C^h(d), h]
13.             if s < S then
14.                 (L, R, P, S) ← (l, l + d + C^h(d), C^h(d), s)
15.       }
16.   }
17. Best overlap is A^P with B_L^R with score S.
```

FIG. 12. *Approximate overlap algorithm.*

bound. During the traversal of the k-thresholded solution for A versus B_l, record the best candidate encountered in the traversal and if it becomes the best candidate seen thus far in the algorithm, then take $O(k)$ additional time to record the alignment of the overlap modeled by the candidate. In order to take only $O(k)$ additional time, the alignment must be recorded as the ordered sequence of its $O(k)$ *differences*, often called a Δ-encoding of the alignment. Building this encoding simply requires tracing back from the entry $C^h(d)$ corresponding to the candidate. Specifically, from $C^h(d)$ trace back to whichever entry yields the maximum of $C^{h-1}(d-1)$, $C^{h-1}(d)+1$, or $C^{h-1}(d+1)+1$ (by Lemma 2.8), and then trace back from that entry recursively until $C^0(0)$ is reached. If $u = C^{h-1}(d-1)$ gave the maximum, then append "Insert b_{l+u+d}" to the Δ-encoding. If $v = C^{h-1}(d)$ gave the maximum, then append "Substitute $b_{l+v+d+1}$ for a_{v+1}." Finally, if $w = C^{h-1}(d+1)$ gave the maximum, then append "Delete a_{w+1}." Upon completion of the algorithm, the Δ-encoding of the best approximate overlap will have been recorded, and one can use it to produce a display of the alignment in $O(n+m)$ time if desired.

4.3. Cyclic string comparison. Yet another variation of traditional string comparison involves considering *cyclic shifts* of the two strings A and B in question. Let $cycle(a_1a_2\ldots a_m) = a_2\ldots a_ma_1$, and let $cycle^p(A)$ be the result of applying *cycle* exactly p times. The *cyclic string comparison problem* is to determine p and q such that $e = ED(cycle^p(A), cycle^q(B))$ is minimal. It is quite easy to see that if the minimum is obtained for $cycle^p(A)$ and $cycle^q(B)$, then by simply cyclically shifting an alignment one obtains an equally good alignment between A and $cycle^r(B)$ for some r. Thus the problem really reduces to the simpler one of finding q such that $ED(A, cycle^q(B))$ is minimal. This problem was introduced by Mathias Maes [Ma-90] and he gives an $O(mn\log m)$ algorithm for the problem that permits arbitrarily weighted edit costs. Our incremental alignment algorithm leads to a more efficient $O(ne)$ time algorithm for the case of unit cost editing operations.

First we present an $O(n^2)$ algorithm, and later show how to refine it to give an $O(ne)$ algorithm. Consider comparing A and $\overline{B} = B\cdot B$ (B concatenated with itself).

Let the threshold $k = n$ so that for any threshold structure computed $C^k(n-m) \geq m$. Begin by computing the threshold structure for A versus $\overline{B}_n$ $(=B)$ using the greedy algorithm in $O(n^2)$ time. Then incrementally compute the thresholded structure for A versus $\overline{B}_l$, for $l = n-1, n-2 \ldots 0$. We examine each threshold structure to find $ED(A, cycle^l(B))$ in $O(k)$ time. Specifically, it is that h for which $C^h(n-m) = m$ and this is easily found by starting with $C^k(n-m)$ and walking the diagonal list until h is encountered. Note that because k was chosen to be n it follows that h is always on the diagonal list. It takes $O(k)$ time to compute each incremental solution and $O(k)$ additional time to find the edit distance for the given cyclic shift of B. Thus the algorithm takes $O(kn) = O(n^2)$ time to find the minimum edit distance, e, over all possible cyclic shifts.

To bring the complexity down to $O(ne)$ time, consider running the algorithm with a threshold $k < n$. If for a given cyclic shift, $C^k(n-m) < m$, then the edit distance for that cyclic shift of B cannot be determined. On the other hand, if $C^k(n-m) \geq m$ then the edit distance can be computed and k upper bounds the answer e to the overall problem. So consider running the algorithm with $k = 1$, and then with $k = 2$, and $k = 4$, and so on in geometric sequence until the edit distance for at least one cyclic shift is determined in a given trial. Of course, in this last trial, the best edit distance obtained in the trial is the answer, e, to the cyclic string comparison problem. Since k is doubled with each trial, the total time complexity is bounded by the time of the last trial and $k = O(e)$ in that trial. Thus the algorithm takes $O(ne)$ time.

4.4. Text screen updating. Screen oriented programs maintain a representation of an object and present a view of it on the screen. For example, screen editors keep an internal edit buffer and display a block of lines from the buffer. The screen must be updated when the object is changed. In one solution, procedures that modify the object must also update the view or at least specify how the view has changed. A cleaner approach lets an autonomous screen manager module determine how to update the screen by comparing its record of the screen contents with views of the modified object. The interface to the screen manager is then a single routine, *refresh*, that updates the screen with respect to the current object. It is given no information other than the object and screen contents. Unfortunately, the simplicity of the interface requires the screen manager to solve a difficult comparison problem.

The feasibility of this design is demonstrated by the UNIX EMAC editor [Go-81] and the Maryland Window System [Ws-85]. In a two level approach, sequences of lines are compared to decide at the top level which lines to delete, insert, and replace. At the bottom level, the sequences of characters in two lines are compared to appraise and perform line or row replacements. The approach is not guaranteed to update the screen with a minimal set of terminal commands but nonetheless performs well. However, a number of improvements are possible at both levels. At the lower level, Myers and Miller [MM-89] developed algorithms that account for the nonuniformity of terminal command costs and produce optimal update command sequences for the row replacement subproblem. At the top level, a weakness of the earlier approach is the assumption that the screen-sized segment of buffer lines that is to replace the current screen contents is known a priori. More realistically, the screen manager should determine the optimal *window position*, i.e., the screen-sized segment of the buffer that most closely resembles the current screen contents subject to the constraint that the current cursor position be in this segment. A useful approximation to the theoretically optimal choice can be computed economically with our incremental algorithm by finding a window position minimizing the number of screen rows that need to be updated, inserted, or removed.

Suppose B is the current buffer contents, c is the current cursor position, and S is the current screen contents, where B and S are viewed as strings over the infinite alphabet of lines of ASCII text. Suppose B is n lines long and that the screen displays m lines. Formally, the *window positioning problem* is to find a position $p \in [c-m, c-1]$ that minimizes $e = ED(B_p^{p+m}, S)$. Given the cursor position c it is clear that we can restrict our attention to the substring $\overline{B} = B_{c-m}^{c+m-1}$ of B because the window B_p^{p+m} must contain line c. Now observe that this problem is very similar to the one we solved for the cyclic string comparison problem. Namely, we compute solutions for $\overline{B}_l$ for $l = m-1, m-2, \ldots 0$, and for each determine $ED(\overline{B}_l^{l+m}, S)$ which is the value h for which $C^h(0) = m$. Using the same geometric progression of threshold increases, as in the cyclic string comparison problem, gives an $O(me)$ algorithm for the window positioning problem.

Acknowledgment. We would like to thank Esko Ukkonen for bringing the Cyclic String Comparison problem to our attention.

LOCALIZING A ROBOT WITH MINIMUM TRAVEL*

GREGORY DUDEK†, KATHLEEN ROMANIK‡, AND SUE WHITESIDES†

Abstract. We consider the problem of localizing a robot in a known environment modeled by a simple polygon P. We assume that the robot has a map of P but is placed at an unknown location inside P. From its initial location, the robot sees a set of points called the visibility polygon V of its location. In general, sensing at a single point will not suffice to uniquely localize the robot, since the set H of points in P with visibility polygon V may have more than one element. Hence, the robot must move around and use range sensing and a compass to determine its position (i.e., localize itself). We seek a strategy that minimizes the distance the robot travels to determine its exact location.

We show that the problem of localizing a robot with minimum travel is NP-hard. We then give a polynomial time approximation scheme that causes the robot to travel a distance of at most $(k-1)d$, where $k = |H|$, which is no greater than the number of reflex vertices of P, and d is the length of a minimum length tour that would allow the robot to verify its true initial location by sensing. We also show that this bound is the best possible.

1. Introduction.

Numerous tasks for a mobile robot require it to have a map of its environment and knowledge of where it is located in the map. Determining the position of the robot in the environment is known as the *robot localization problem*. To date, mobile robot research that supposes the use of a map generally assumes either that the position of the robot is always known or that it can be estimated using sensor data acquired by displacing the robot only small amounts [4, 24, 30]. However, self-similarities between separate portions of the environment prevent a robot that has been dropped into or activated at some unknown place from uniquely determining its exact location without moving around. This motivates a search for strategies that direct the robot to travel around its environment and to collect additional sensory data [5, 25, 14] to deduce its exact position.

In this paper, we view the general robot localization problem as consisting of two phases: hypothesis generation and hypothesis elimination. The first phase is to determine the set H of *hypothetical locations* that are consistent with the sensing data obtained by the robot at its initial location. The second phase is to determine, in the

case that H contains two or more locations (see Fig. 2.1), which location is the true initial position of the robot; i.e., to eliminate the incorrect hypotheses.

Ideally, the robot should travel the minimum distance necessary to determine its exact location. This is because the time the robot takes to localize itself is proportional to the distance it must travel (assuming sensing and computation time are negligible in comparison). Also, the most common devices for measuring distance, and hence position, on actual mobile robots are relative measurement tools such as odometers. Therefore, they yield imperfect estimates of orientation, distance, and velocity, and the errors in these estimates accumulate disastrously with successive motions [13]. Our strategy is well suited to handling the accumulation of error problem via simple recalibration, as we will point out later.

A solution to the hypothesis generation phase of robot localization has been given by Guibas, Motwani, and Raghavan in [19]. We describe this further in the next section after making more precise the definitions of the two phases of robot localization. Our paper is concerned with minimizing the distance traveled in the hypothesis elimination phase of robot localization. It begins where [19] left off. Together, the two papers give a solution to the general robot localization problem.

In this paper, we define a natural algorithmic variant of the problem of localizing a robot with minimum travel and show that this variant is NP-hard. We then solve the hypothesis elimination phase with what we call a *greedy localization strategy*. To measure the performance of our strategy, we employ the framework of competitive analysis for on-line algorithms introduced by Sleator and Tarjan [29]. That is, we examine the ratio of the distance traveled by a robot using our strategy to the length d of a minimum length tour that allows the robot to verify its true initial position. The worst case value of this ratio over all maps and all starting points is called the *competitive ratio* of the strategy. If this ratio is no more than k, then the strategy is called *k-competitive*. Since our strategy causes the robot to travel a distance no more than $(k-1)d$, where $k = |H|$ ($|H|$ is no greater than the number of reflex vertices of P), our strategy is $(k-1)$-competitive. We also show that *no* on-line localization strategy has a competitive ratio better than $k-1$, and thus our strategy is optimal.

The rest of this paper is organized as follows. In section 2 we give a formal definition of the robot localization problem, we define some of the terms used in the paper, and we comment on previous work. In section 3 we prove that, given a solution set H to the hypothesis generation phase of the localization problem that contains more than one hypothetical location, the hypothesis elimination phase, which localizes the robot by using minimum travel distance, is NP-hard. In section 4 we define the geometric structures that we use to set up our greedy localization strategy. In section 5 we give our greedy localization strategy and prove the previously mentioned performance guarantee of $k-1$ times optimum. We also give an example of a map polygon for which no on-line localization strategy is better than $(k-1)$-competitive. Section 6 summarizes and comments on open problems.

2. Localization through traveling and probing. In this section, we describe our robot abstraction and give some key definitions.

The most common application domain for mobile robots is indoor "structured" environments. In such environments it is often possible to construct a map of the environment, and it is acceptable to use a polygonal approximation P of the free space [26] as a map. A common sensing method used by mobile robots is range sensing (for example, sonar sensing or laser range sensing).

2.1. Assumptions about the robot. We assume the following throughout this paper.

1. The robot moves in a static two-dimensional, obstacle-free environment for which it has a map. The robot has the ability to make error-free motions between arbitrary locations in the environment.[1] We model the movement of the robot in the environment by a point p moving inside and along the boundary of an n-vertex simple polygon P positioned somewhere in the plane.

2. The robot has a compass and a range sensing device. It is essential that the robot be able to determine its orientation (with the compass); otherwise it can never uniquely determine its exact location in an environment with nontrivial symmetry (such as a square).

3. The robot's sensor can detect the distances to those points on walls for which the robot has an unobstructed straight line of sight, and the robot's observations at a particular location determine a polygon V of points that it can see (see the next subsection for a definition of V). This is analogous to what can be extracted by various real sensors such as laser range finders. The robot also knows its location in V.

2.2. Some definitions and an example. Two points in P are *visible* to each other or *see* each other if the straight line segment joining them does not intersect the exterior of P. The *visibility polygon* $V(p)$ for a point $p \in P$ is the polygon consisting of all points in P that are visible from p. The data received from a range sensing device is modeled as a visibility polygon. The visibility polygon of the initial location of the robot is denoted by V, and the number of its vertices is denoted by m. Since the robot has a compass, we assume that P and V have a common reference direction.

We break the general problem of localizing a robot into two phases as follows.

The robot localization problem.

HYPOTHESIS GENERATION: Given P and V, determine the set H of all points $p_i \in P$ such that the visibility polygon of p_i is congruent under translation to V (denoted by $V(p_i) = V$).

HYPOTHESIS ELIMINATION: Devise a strategy by which the robot can correctly eliminate all but one hypothesis from H, thereby determining its exact initial location. Ideally, the robot should travel a distance as small as possible to achieve this.

As previously mentioned, the hypothesis generation phase has been solved by Guibas, Motwani, and Raghavan. We describe their results in the next subsection. This paper is concerned with the hypothesis elimination phase.

Consider the example illustrated in Fig. 2.1. The robot knows the map polygon P and the visibility polygon V representing what it can "see" in the environment from its present location. Suppose also that it knows that P and V should be oriented as shown. The black dot represents the robot's position in the visibility polygon. By examining P and V, the robot can determine that it is at either point p_1 or point p_2 in P, i.e., $H = \{p_1, p_2\}$. It cannot distinguish between these two locations because $V(p_1) = V(p_2) = V$. However, by traveling out into the "hallway" and taking another probe, the robot can determine its location precisely.

An optimal strategy for the hypothesis elimination phase would direct the robot to follow an optimal verification tour, defined as follows.

[1] In practice, position estimation errors accrue in the execution of such motions; however, the strategy we present here is exceptionally well suited to various methods for limiting these errors using sensor feedback (see section 5.1).

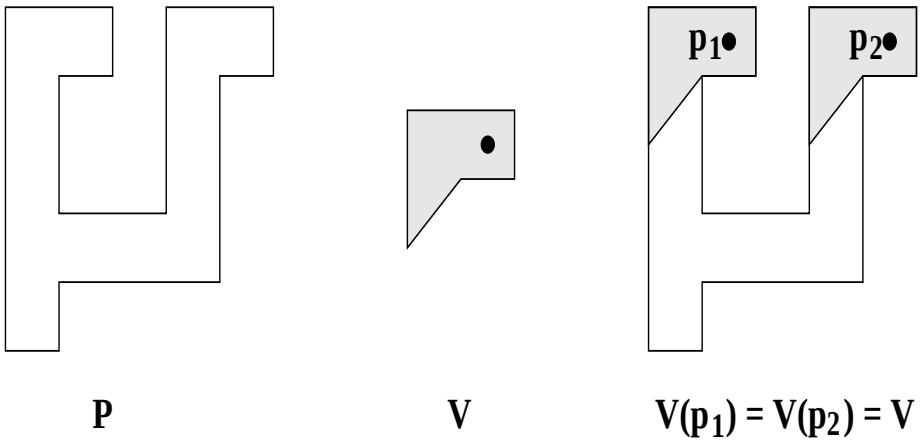

FIG. 2.1. *Given a map polygon P (left) and a visibility polygon V (center), the robot must determine which of the* 2 *possible initial locations p_1 and p_2 (right) is its actual location in P.*

DEFINITION 2.1. *A* verification tour *is a tour along which a robot that knows its initial position* a priori *can travel to verify this information by probing and then return to its starting position. An* optimal verification tour *is a verification tour of minimum length d.*

Since we do not assume *a priori* knowledge of which hypothetical location in H is correct, an optimal verification tour for the hypothesis elimination phase cannot be precomputed. Even if we did have this knowledge, computing an optimal verification tour would be NP-hard. This can be proven using a construction similar to that in section 3 and a reduction from hitting set [16]. For these reasons, we seek an interactive probing strategy to localize the robot. In each step of such a strategy, the robot uses its range sensors to compute the visibility polygon of its present position and from this information decides where to move next to make another probe. To be precise, the type of strategy we seek can be represented by a localizing decision tree, defined as follows.

DEFINITION 2.2. *A* localizing decision tree *is a tree consisting of two kinds of nodes and two kinds of weighted edges. The nodes are either sensing nodes (S-nodes) or reducing nodes (R-nodes), and the node types alternate along any path from the root to a leaf. Thus, tree edges directed down the tree either join an S-node to an R-node (SR-edges) or join an R-node to an S-node (RS-edges).*

1. *Each S-node is associated with a position defined relative to the initial position of the robot. The robot may be instructed to probe the environment from this position.*

2. *Each R-node is associated with a set $H' \subseteq H$ of hypothetical initial locations that have not yet been ruled out. The root is an R-node associated with H, and each leaf is an R-node associated with a singleton hypothesis set.*

3. *Each SR-edge represents the computation that the robot does to rule out hypotheses in light of the information gathered at the S-node end of the edge. An SR-edge does not represent physical travel by the robot and hence has weight* 0.

4. *Each RS-edge has an associated path defined relative to the initial location of the robot. This is the path along which the robot is directed to travel to reach its next sensing point. The weight of an RS-edge is the length of its associated path.*

Since we want to minimize the distance traveled by the robot, we define the weighted height of a localizing decision tree as follows.

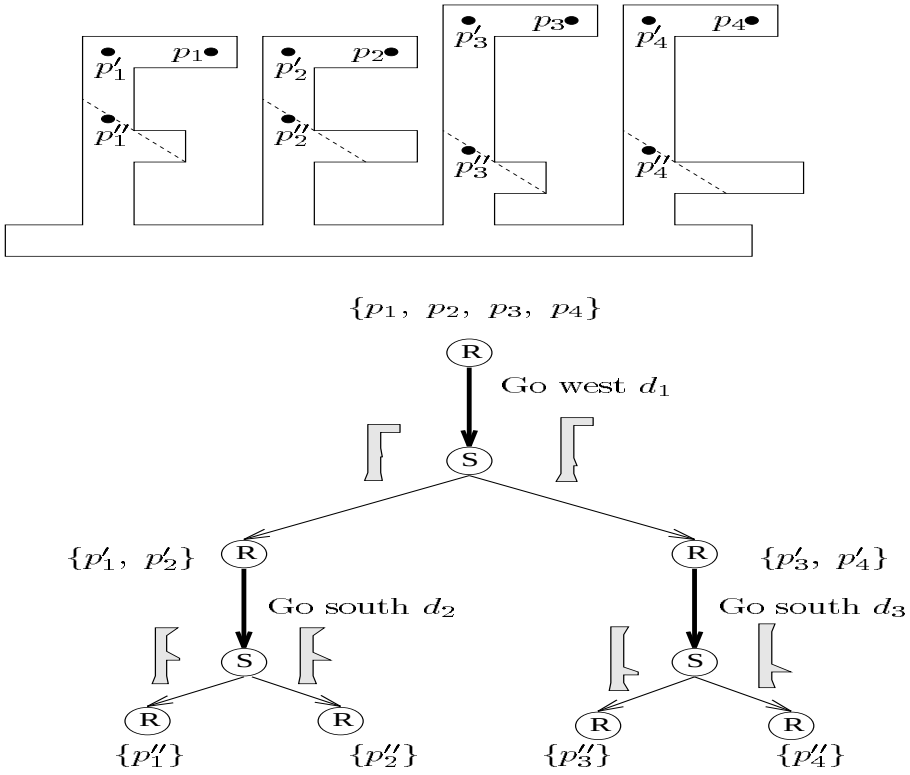

FIG. 2.2. *A map polygon and* 4 *hypothetical locations* $\{p_1, p_2, p_3, p_4\}$ *(above) with a localizing decision tree for determining the true initial position of the robot (below).*

DEFINITION 2.3. *The* weight *of a root-to-leaf path in a localizing decision tree is the sum of the weights on the edges in the path. The* weighted height *of a localizing decision tree is the weight of a maximum-weight root-to-leaf path. An* optimal localizing decision tree *is a localizing decision tree of minimum weighted height.*

In the next section, we show that the problem of finding an optimal localizing decision tree is NP-hard.

We call a localization strategy that can be associated with a localizing decision tree a *localizing decision tree strategy.* As an example of such a strategy, consider the map polygon P shown in Fig. 2.2.

Imagine that, from the visibility polygon sensed by the robot at its initial location, it is determined that the set of hypothetical locations is $H = \{p_1, p_2, p_3, p_4\}$. Hence the root of the localizing decision tree (shown in Fig. 2.2) is associated with H. In the figure, the SR-edges are labeled with the visibility polygons seen by the robot at the S-node endpoints of these edges. Assuming that north points straight up, the strategy given by the tree directs the robot first to travel west a distance d_1, which is the distance between p_i and p'_i, for $1 \leq i \leq 4$, and then to take another probe at its new location. Depending on the outcome of the probe, the robot knows it is located either at one of $\{p'_1, p'_2\}$ or at one of $\{p'_3, p'_4\}$. If it is located at p'_1 or p'_2, then the strategy directs it to travel south a distance d_2, which is the distance between p'_i and p''_i, for $1 \leq i \leq 2$, to a position just past the dotted line segment shown in P. By taking a probe from below this line segment, it will be able to see the vertex at

the end of the segment if it is at location p_1'', and it will not see this vertex if it is at location p_2''. Thus after this probe it will be able to determine its unique location in P. Similarly, if the robot is located at p_3' or p_4', then the strategy directs it to travel south a distance d_3 and take another probe to determine its initial position. The farthest that the robot must travel to determine its location is $d_1 + d_3$, so the weighted height of this decision tree is $d_1 + d_3$.

2.3. Previous work. Previous work on robot localization by Guibas, Motwani, and Raghavan [19] showed how to preprocess a map polygon P so that, given the visibility polygon V that a robot sees, the set of points in P whose visibility polygon is congruent to V, and oriented the same way, can be returned quickly. Their algorithm preprocesses P in $O(n^5 \log n)$ time and $O(n^5)$ space, and it answers queries in $O(m + \log n + k)$ time, where n is the number of vertices of P, m is the number of vertices of V, and k is the size of the output (the number of places in P at which the visibility polygon is V). They also showed how to answer a single localization query in $O(mn)$ time with no preprocessing.

Kleinberg [23] has independently given an interactive strategy for localizing a robot in a known environment. As in our work, he seeks to minimize the ratio of the distance traveled by a robot using his strategy to the length of an optimal verification path (i.e., the competitive ratio). Kleinberg's model differs from ours in several ways. First of all, he models the robot's environment as a geometric tree rather than a simple polygon. A *geometric tree* is a pair (V, E), where V is a finite point set in $\mathbb{R}^d$ and E is a set of line segments whose endpoints all lie in V. The edges E do not intersect except at points of V and do not form cycles. Kleinberg only considers geometric trees with bounded degree Δ. Also, his robot can make no use of vision other than to know the orientation of all edges incident to its current location. Using this model, Kleinberg gives an $O(n^{2/3})$-competitive algorithm for localizing a robot in a geometric tree with bounded degree Δ, where n is the number of branch vertices (vertices of degree greater than two) of the tree.

The competitive ratio of Kleinberg's algorithm appears to be better than the lower bound illustrated by Fig. 5.2 in section 5.3. However, if this map polygon were modeled as a geometric tree it would have degree n, where n is the number of branch vertices, rather than a constant degree, and the distance traveled by a robot using Kleinberg's algorithm can be linear in the degree of the tree. If Kleinberg's algorithm ran on this example, it would only execute step 1, which performs a spiral search, and it would cause the robot to travel a distance almost $4n$ times the length of an optimal verification path. Our algorithm causes the robot to travel a distance less than $2n$ times the length of an optimal verification path on this example. Our algorithm is similar to step 3 of Kleinberg's algorithm, and he gives a lower bound example (Fig. 3 of [23]) illustrating that an algorithm using only steps 1 and 3 of his algorithm is no better than $O(n)$-competitive. Although this example does not directly apply to our model since the robot in our model has the ability to see to the end of the hallway, by adding small jogs in the hallway a similar example can be constructed where our strategy is no better than $O(n)$-competitive. In this example, the number of branch vertices of the geometric tree represented by P would be n and the number of vertices of P would be $O(n)$. However, in this example $|H| = n$, so this does not contradict our results.

Other theoretical work on localizing a robot in a known environment has also been done. Betke and Gurvits [8] gave an algorithm that uses the angles subtended

by landmarks in the robot's environment to localize a robot. Their algorithm runs in time linear in the number of landmarks, and it assumes that a correspondence is given between each landmark seen by the robot and a point in the map of the environment. Avis and Imai [2] also investigated the problem of localizing a robot using angle measurements, but they did not assume any correspondence between the landmarks seen by the robot and points in the environment. Instead they assumed that the environment contains n identical markers, and the robot takes k angle measurements between an unknown subset of these markers. They gave polynomial time algorithms to determine all valid placements of the robot, both in the case where the robot has a compass and where it does not. In addition they showed that, with polynomial-time preprocessing, location queries can be answered in $O(\log n)$ time.

Theoretical work with a similar flavor to ours has also been done on navigating a robot through an unknown environment. In this work a point robot must navigate from a point s to a target t, which is either a point or an infinite wall, where the Euclidean distance from s to t is n. There are obstacles in the scene, which are not known *a priori*, but which the robot learns about only as it encounters them. The goal is to optimize (i.e., minimize) the ratio of the distance traveled by the robot to the length of a shortest obstacle-free path from s to t. As with localization strategies, the worst case ratio over all environments where s and t are distance n apart is called the competitive ratio of the strategy.

Papadimitriou and Yannakakis [28] gave a deterministic strategy for navigating between two points, where all obstacles are unit squares, that achieves a competitive ratio of 1.5, which they show is optimal. For squares of arbitrary size they gave a strategy achieving a ratio of $\sqrt{26}/3$. They also showed, along with Eades, Lin, and Wormald [15], that when t is an infinite wall and the obstacles are oriented rectangles, there is a lower bound of $\Omega(\sqrt{n})$ on the ratio achievable by any deterministic strategy.

Blum, Raghavan, and Schieber [9] gave a deterministic strategy that matched the $\Omega(\sqrt{n})$ lower bound for navigating between two points with oriented, rectangular obstacles. Their strategy combines strategies for navigating from a point to an infinite wall and from a point on the wall of a room to the center of the room, with competitive ratios of $O(\sqrt{n})$ and $O(2^{\sqrt{3 \log n}})$, respectively. The competitive ratio for the problem of navigating from a corner to the center of a room was improved to $O(\ln n)$ by a strategy of Bar-Eli et al. [3], who also showed that this ratio is a lower bound for any deterministic strategy. Berman et al. [7] gave a randomized algorithm for the problem of navigating between two points with oriented, rectangular obstacles with a competitive ratio of $O(n^{4/9} \log n)$.

Several people have studied the problem of navigating from a vertex s to a vertex t inside an unknown simple polygon. They assume that at every point on its path the robot can get the visibility polygon of that point. Klein [21] proved a lower bound of $\sqrt{2}$ on the competitive ratio and gave a strategy achieving a ratio of 5.72 for the class of street polygons. A *street* is a simple polygon such that the clockwise chain L and the counterclockwise chain R from s to t are mutually weakly visible. That is, every point on L is visible to some point on R and vice versa. Kleinberg [22] gave a strategy that improved Klein's ratio to $2\sqrt{2}$, and Datta and Icking [12] gave a strategy with a ratio of 9.06 for a more general class of polygons called *generalized streets*, where every point on the boundary is visible from a point on a horizontal line segment joining L and R. They also showed a lower bound of 9 for this class of polygons.

Previous work in the area of geometric probing has examined the complexity of constructing minimum height decision trees to uniquely identify one of a library of

polygons in the plane using point probes. Such probes examine a single point in the plane to determine if an object is located at that point. If each polygon in the library is given a fixed position, orientation and scale, then it has been shown that both the problem of finding a minimum cardinality probe set (for a noninteractive probing strategy) [6] and the problem of constructing a minimum height decision tree for probing (for an interactive strategy) [1] are NP-complete. Arkin et al. [1] give a greedy strategy that builds a decision tree of height at most $\lceil \log k \rceil$ times that of an optimal decision tree, where k is the number of polygons in the library. The minimum height decision tree used for probing in [1] is different than our localizing decision tree. It is a binary decision tree whose internal nodes represent point probes whose outcome is either positive or negative and whose edges are unweighted. The height of such a decision tree is the number of levels of the tree, and it represents the maximum number of probes necessary to identify any polygon in the library.

3. Hardness of localization. In this section we show that the problem of constructing an optimal localizing decision tree, as defined in the previous section, is NP-hard. To do this, we first formulate the problem as a decision problem.

Robot Localizing Decision Tree (RLDT).

INSTANCE: A simple polygon P and a star-shaped polygon V, both with a common reference direction, the set H of all locations $p_i \in P$ such that $V(p_i) = V$, and a positive integer h.

QUESTION: Does there exist a localizing decision tree of weighted height less than or equal to h that localizes a robot with initial visibility polygon V in the map polygon P?

We show that this problem is NP-hard by giving a reduction from the Abstract Decision Tree problem, proven NP-complete by Hyafil and Rivest in [20]. The Abstract Decision Tree problem is stated as follows.

Abstract Decision Tree (ADT).

INSTANCE: A set $X = \{x_1, \ldots, x_k\}$ of objects, a set $\mathcal{T} = \{T_1, \ldots, T_n\}$ of subsets of X representing binary tests, where test T_j is positive on object x_i if $x_i \in T_j$ and is negative otherwise, and a positive integer $h' \leq n$.

QUESTION: Does there exist an abstract decision tree of height less than or equal to h', where the height of a tree is the maximum number of edges on a path from the root to a leaf, that can be constructed to identify the objects in X?

An abstract decision tree has a binary test at all internal nodes and an object at every leaf. To identify an unknown object, the test at the root is performed on the object, and if it is positive the right branch is taken, otherwise the left branch is taken. This procedure is repeated until a leaf is reached, which identifies the unknown object.

Theorem 3.1. *RLDT is NP-hard.*

Proof. Given an instance of ADT, we create an instance of RLDT as follows. We construct P to be a staircase polygon, with a stairstep for each object $x_i \in X$ (see Fig. 3.1). For each stairstep we construct $n = |\mathcal{T}|$ protrusions, one for each test in $\mathcal{T}$ (see Fig. 3.2). If test T_j is a positive test for object x_i, then protrusion T_j on stairstep x_i has an extra hook on its end (such as T_3, T_4, and T_n in Fig. 3.2). The length of a protrusion is denoted by l and the distance between protrusions T_1 and T_n is denoted by d, where d and l are chosen so that $dh' < l$. The vertical piece between adjacent stairsteps is longer than $(2l + d)h'$, and the width w of each stairstep is much smaller than the other measurements. The polygon P has $O(nk)$ vertices, where $n = |\mathcal{T}|$ and $k = |X|$.

Consider a robot that is initially located at the shaded circle shown in Fig. 3.2 on one of the k stairsteps. The visibility polygon V at this point has $O(n)$ vertices and is

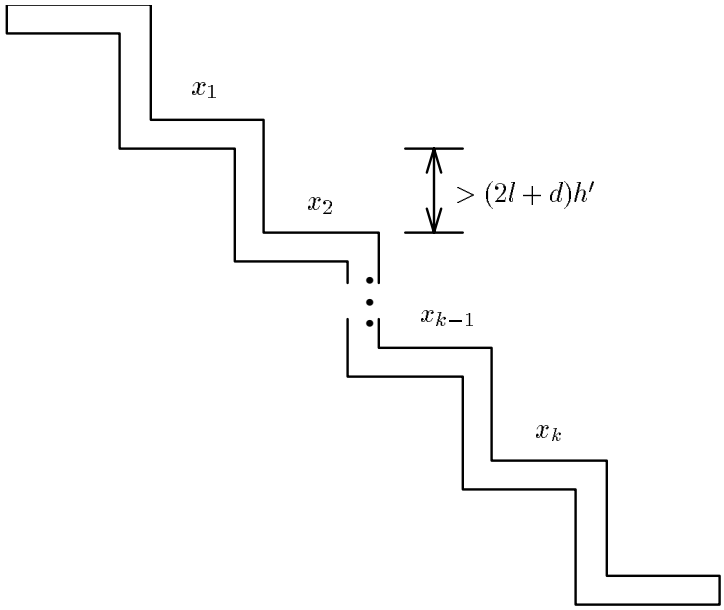

FIG. 3.1. *Construction showing localization is NP-hard.*

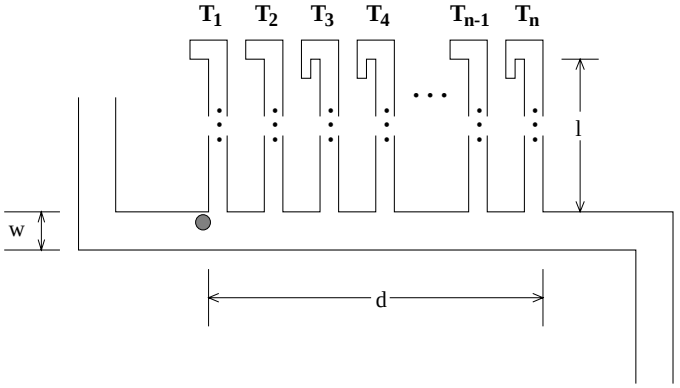

FIG. 3.2. *Close-up of a stairstep x_i in NP-hard construction. Not to scale: $l >> d >> w$.*

the same at an analogous point on any internal stairstep x_i. We output the polygons P and V, which can be constructed in polynomial time, the k locations $p_i \in P$ such that $V(p_i) = V$, and weighted height $h = (2l + d)h'$ as an instance of RLDT.

In order for the robot to localize itself, it must either travel to one of the "ends" of P (either the top or the bottom stairstep) to discover on which stairstep it was located initially, or it must examine a sufficient number of the n protrusions on the stairstep where it is located to distinguish that stairstep from all the others. Since the vertical piece of each stairstep is longer than $h = (2l + d)h'$, only a strategy that directs the robot to remain on the same stairstep can lead to a decision tree of weighted height less than or equal to h.

Any decision tree that localizes the robot by examining protrusions on the stairstep corresponds to an equivalent abstract decision tree to identify the objects of X using

tests in $\mathcal{T}$, and vice versa. Each time the robot travels to the end of protrusion T_j to see if it has an extra hook on its end, it corresponds to performing binary test T_j on an unknown object to observe the outcome. The robot must travel $2l$ to perform this test, and it travels at most d in between tests. Therefore, if the robot can always localize itself by examining no more than h' protrusions, then it has a decision tree of weighted height no more than $h = (2l + d)h'$, which corresponds to an abstract decision tree of height h' for the ADT problem. Since $dh' < l$, in a localizing decision tree of weighted height $\leq h$ the robot cannot examine more than h' protrusions on any root-to-leaf path. □

4. Using a visibility cell decomposition for localization. In this section we discuss the geometric issues involved in building a data structure for our greedy localization strategy.

4.1. Visibility cells and the overlay arrangement. When we consider positions where the robot can move to localize itself, we reduce the infinite number of locations in P to a finite number by first creating a visibility cell decomposition of P [10, 11, 19]. A *visibility cell* (or *visibility region*) C of P is a maximally connected subset of P with the property that any two points in C see the same subset of vertices of P [10, 11]. A *visibility cell decomposition* of P is simply a subdivision of P into visibility cells. This decomposition can be computed in $O(n^3 \log n)$ using techniques in [10, 11]. It is created by introducing $O(nr)$ line segments, called *visibility edges*, into the interior of P, where r is the number of reflex vertices[2] of P. Each line segment starts at a reflex vertex u, ends at the boundary of P, and is collinear with a vertex v that is either visible from u or is adjacent to it. The number of cells in this decomposition, as well as their total complexity, is $O(n^2 r)$ (see [19] for a proof).

Although two points p and q in the same visibility cell C see the same subset of vertices of P, they may not have the same visibility polygon (i.e., it may be that $V(p) \neq V(q)$). This is because some edges of $V(p)$ may not actually lie on the boundary of P (these edges are collinear with p and are produced by visibility lines), so these edges may be different in $V(q)$. Therefore, in order to represent the portion of P visible to a point p in a visibility cell C in such a way that all points in C are equivalent, we need a different structure than the visibility polygon. The structure that we use is the *visibility skeleton* of p.

DEFINITION 4.1. *The* visibility skeleton $V^*(p)$ *of a location $p \in P$ is the skeleton of the visibility polygon $V(p)$. That is, it is the polygon induced by the nonspurious vertices of $V(p)$, where a* spurious *vertex of $V(p)$ is one that lies on an edge of $V(p)$ that is collinear with p, and the other endpoint of this edge is closer to p. The nonspurious vertices of $V(p)$ are connected to form $V^*(p)$ in the same cyclical order that they appear in $V(p)$. The edges of the skeleton are labeled to indicate which ones correspond to real edges from P and which ones are* artificial *edges induced by the spurious vertices. If p is outside P, then $V^*(p)$ is equal to the special symbol $\emptyset$.*

For a complete discussion of visibility skeletons and a proof that $V^*(p) = V^*(q)$ for any two points p and q in the same visibility cell, see [10, 11, 19].

As stated in section 2, the hypothesis generation phase of the robot localization problem generates a set $H = \{p_1, p_2, \ldots p_k\} \subset P$ of *hypothetical locations* at which the robot might be located initially. The number k of such locations is bounded above by r (see [19] for a proof). From this set H, we can select the first location p_1 (or any arbitrary location) to serve as an origin for a local coordinate system. For each

[2] A *reflex vertex* of P is a vertex that subtends an angle greater than 180°.

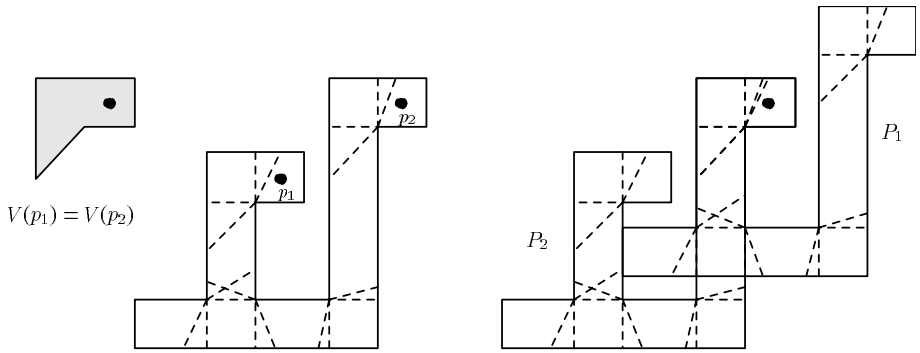

FIG. 4.1. *A visibility polygon, a map polygon and the corresponding overlay arrangement.*

location p_j, $1 \leq j \leq k$, we define the *translation vector* $t_j = p_1 - p_j$ that translates location p_j to location p_1, and we define P_j to be the *translate* of P by vector t_j. We thus have a set $\{P_1, P_2, \ldots, P_k\}$ of translates of P corresponding to the set H of hypothetical locations. The point in each P_j corresponding to the hypothetical location p_j is located at the origin.

In order to determine the hypothetical location corresponding to the true initial location of the robot, we construct an *overlay arrangement* A that combines the k translates P_j that correspond to the hypothetical locations, together with their visibility cell decompositions. More formally, we define A as follows.

DEFINITION 4.2. *The* overlay arrangement *A for the map polygon P corresponding to the set of hypothetical locations H is obtained by taking the union of the edges of each translate P_j as well as the visibility edges in the visibility cell decomposition of P_j.*

See Fig. 4.1 for an example of an overlay arrangement. Since each visibility cell decomposition is created from $O(nr)$ line segments introduced into the interior of P_j, a bound on the total number of cells in the overlay arrangement as well as their total complexity is $O(k^2n^2r^2)$, which may be $O(n^6)$.

4.2. Lower bound on the size of the overlay arrangement. Figure 4.2 shows a map polygon P whose corresponding overlay arrangement for the visibility polygon shown in Fig. 4.3(a) has $\Omega(n^5)$ cells. This polygon has a long horizontal "hallway" with k identical, equally spaced "rooms" on the bottom side of it ($k = 4$ in Fig. 4.2). Each room has width 1 unit, and the distance between rooms is $2k - 1$ units. If the robot is far enough inside one of these rooms so that it cannot see any of the rooms on the top of the hallway, then its visibility polygon is the same no matter which room it is in. The $k - 1$ rooms on the top side of the hallway are identical, have width 1 unit, and are spaced $2k + 1$ units apart. Each top room is between two bottom rooms. The ith top room from the left has its left edge a distance $2i - 1$ to the right of the right edge of the bottom room to its left, and it has its right edge a distance $2(k - i) - 1$ to the left of the left edge of the bottom room to its right (see Fig. 4.2).

Consider the visibility edges starting from the reflex vertices of the bottom rooms that are generated by (i.e., collinear with) the reflex vertices of the top rooms. The ith bottom room from the left will have $2(k - i)$ such visibility edges starting from its right reflex vertex and $2(i - 1)$ starting from its left reflex vertex. Due to the spacing of the top rooms, the visibility edges starting from the reflex vertices of one bottom

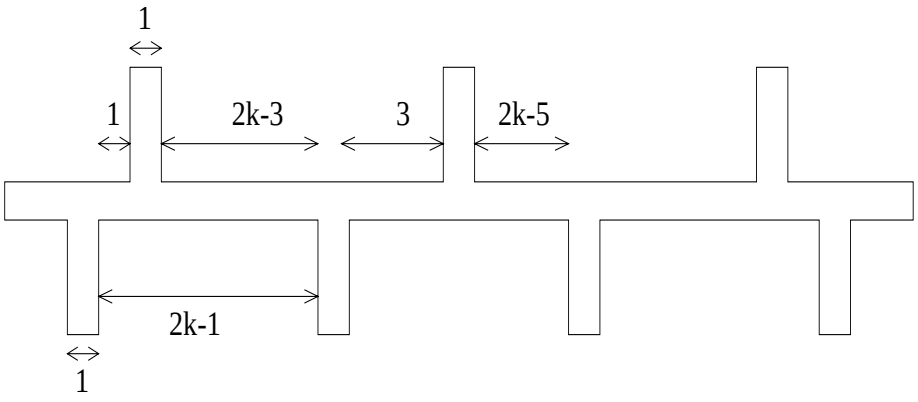

FIG. 4.2. *A map polygon whose overlay arrangement contains* $\Omega(n^5)$ *cells.*

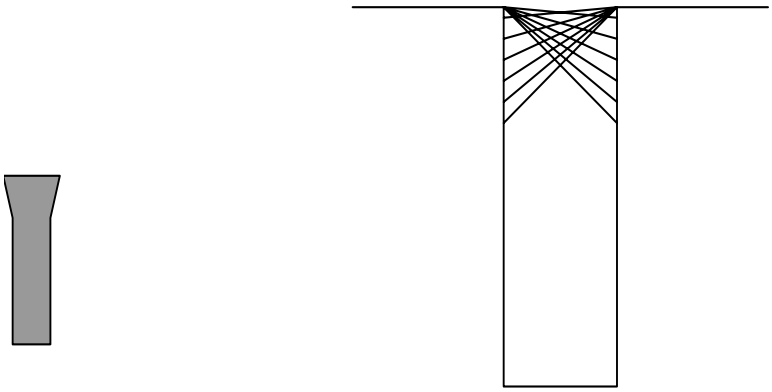

FIG. 4.3. (a) *A visibility polygon.* (b) *Visibility cells in a bottom room.*

room will be at different angles than those in any other bottom room. See the picture in Fig. 4.3(b) for an illustration of the visibility cells inside a bottom room.

When the overlay arrangement A for the visibility polygon shown in Fig. 4.3(a) is constructed, it will consist of k translates, one for each of the bottom rooms of P. Since these rooms are identical and equally spaced, A will have $2k-1$ rooms on its bottom side. Since the visibility edges inside each bottom room are at different angles, these edges will not coincide when bottom rooms from two different translates overlap in A. This means that A will have $\Omega(k)$ bottom rooms with $\Omega(k^2)$ visibility edges starting from the left reflex vertex, and $\Omega(k^2)$ visibility edges starting from the right reflex vertex, resulting in $\Omega(k^4)$ cells inside each of these bottom rooms of A. Therefore, A will have $\Omega(k^5)$ cells in total. Since the number of vertices of P is $8k$, A has $\Omega(n^5)$ cells.

Closing the gap between the upper and lower bounds on the size of the arrangement is an open problem.

4.3. The reference point set Q. Each cell in the overlay arrangement A represents a potential probe position, which can be used to distinguish between different hypothetical locations of the robot. For each cell C of A and for each translate P_j

that contains C, there is an associated visibility skeleton $V_j^*(C)$. If two translates P_i and P_j have different skeletons for cell C, or if C is outside of exactly one of P_i and P_j, then C distinguishes p_i from p_j.

For our localization strategy we choose a set Q of *reference points* in A that will be used to distinguish between different hypothetical locations. For each cell C in A that lies in at least one translate of P, and for each translate P_j that contains C, let $q_{C,j}$ denote the point on the boundary of C that is closest to the origin. Here, the distance $d_j(q_{C,j})$ from the origin to the closest point in C is measured inside P_j. We choose $Q = \{q_{C,j}\}$. In the remainder of this paper we drop the subscripts from $q_{C,j}$ when they are not necessary.

Computing the reference points in Q involves computing Euclidean shortest paths in P_j from the origin to each cell C. To compute these paths we can use existing algorithms in the literature for shortest paths in simple polygons. We first compute for each hypothetical initial location p_j the shortest path tree from the origin to all of the vertices of P_j in linear time using the algorithm given in [18]. This algorithm also gives a data structure for storing the shortest path tree so that the length of the shortest path from the origin to any point $x \in P_j$ can be found in time $O(\log n)$ and the path from the origin to x can be found in time $O(\log n + l)$, where l is the number of segments along this path. We can use this data structure later to extract the shortest path to any cell C in A within any translate P_j.

We use $\pi(p_j, x)$ to denote the shortest path from the origin to x in P_j. To find the shortest path from the origin to a segment $\overline{xy}$ contained in P_j we use the following theorem.

THEOREM 4.3. *If P is a simple polygon, then the Euclidean shortest path $\pi(s, \overline{xy})$ from a point s in P to a line segment $\overline{xy}$ in P is either the shortest path $\pi(s, x)$ from s to x, the shortest path $\pi(s, y)$ from s to y, or a polygonal path with l edges such that the first $l-1$ edges are the first $l-1$ edges on either $\pi(s, x)$ or $\pi(s, y)$, and the last edge is perpendicular to $\overline{xy}$.*

Proof. The theorem follows from standard geometry results. We sketch the proof here. It is shown in [27] that the shortest paths $\pi(s, x)$ and $\pi(s, y)$ are polygonal paths whose interior vertices are vertices of P, and if v is the last common point on these two paths, then $\pi(v, x)$ and $\pi(v, y)$ are both *outward-convex* (i.e., the convex hull of each of these subpaths lies outside the region bounded by $\pi(v, x)$, $\pi(v, y)$ and the segment $\overline{xy}$). As in [27] we call the union $\pi(v, x) \cup \pi(v, y)$ the *funnel* associated with $\overline{xy}$, and we call v the *cusp* of the funnel. See Fig. 4.4 for an example of a simple polygon with edges of this funnel shown as dashed line segments.

The shortest path $\pi(s, \overline{xy})$ has $\pi(s, v)$ as its initial subpath. To complete the shortest path $\pi(s, \overline{xy})$ we must find a shortest path $\pi(v, \overline{xy})$. If v has a perpendicular line of sight to $\overline{xy}$, then this visibility line will be $\pi(v, \overline{xy})$. If v does not have a perpendicular line of sight to $\overline{xy}$, then consider the edge e adjacent to v on the funnel that is the closest to perpendicular. Without loss of generality, assume e is the first edge on $\pi(v, y)$. The path $\pi(v, \overline{xy})$ will follow $\pi(v, y)$ until it reaches y or it reaches a vertex that has a perpendicular line of sight to $\overline{xy}$. □

Using this theorem we can in $O(n)$ time determine the length of the shortest path in P_j from the origin o to $\overline{xy}$ and the closest point on $\overline{xy}$ to o. We first use the data structure in [18] to determine in $O(\log n)$ time the length d_x and the last edge e_x on the shortest path $\pi(o, x)$, and the length d_y and the last edge e_y on the shortest path $\pi(o, y)$. For each of these edges we check its angle with respect to $\overline{xy}$. Note that both of these angles cannot be 90° or greater, or else it would be impossible to form

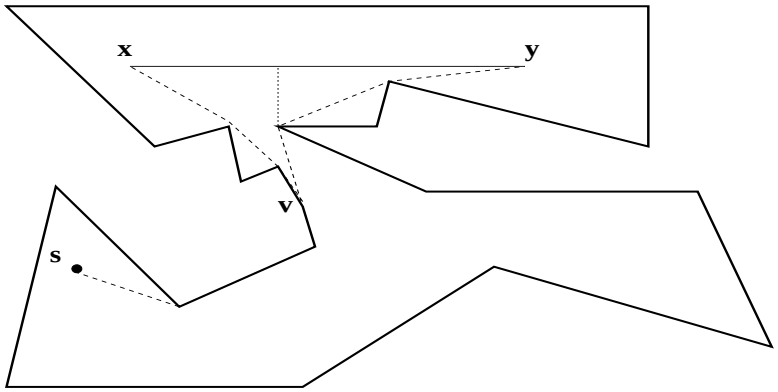

FIG. 4.4. *A simple polygon with shortest paths from s to x, y, and $\overline{xy}$ shown.*

a funnel with $\pi(o,x)$ and $\pi(o,y)$. If the angle between e_x (e_y) and $\overline{xy}$ is at least 90°, then we return d_x (d_y) as the shortest distance to $\overline{xy}$ and x (y) as the closest point on $\overline{xy}$.

If both the angles formed by e_x and e_y with $\overline{xy}$ are less than 90°, then the last edge on the shortest path $\pi(o,\overline{xy})$ will be a perpendicular drawn from one of the vertices on the funnel associated with $\overline{xy}$. To find this edge we again use the data structure in [18] to examine the edges of the funnel in order, starting with e_x. For each edge we calculate the angle formed by its extension with $\overline{xy}$. That is, for each edge (u,w) whose extension intersects $\overline{xy}$ at point z, we calculate the angle $\angle uzy$. As we move around the funnel these angles increase. When the angle becomes greater than 90°, we have found the vertex from which to drop a perpendicular to $\overline{xy}$. It takes $O(n)$ time to find this vertex, and an additional $O(\log n)$ time to calculate the distance to $\overline{xy}$ and the closest point (this is the time it takes to determine the length of the shortest path from o to this vertex).

To compute the reference point $q_{C,j}$, we compute the shortest path distance in P_j from the origin to each edge of C. We then choose the smallest distance as the distance to the cell C. For each cell C we will have up to k reference points $\{q_{C,1},\ldots,q_{C,k}\}$ and their corresponding distances $\{d_1(q_{C,1}),\ldots,d_k(q_{C,k})\}$. We define $d_j(q)=\infty$ for all points q not within P_j.

Partition of H. For each cell C we compute a *partition of H* that represents which hypothetical locations can be distinguished from one another by probing from inside C. If two translates P_i and P_j have the same visibility skeleton for cell C, or if C is outside of both P_i and P_j, then p_i and p_j are in the same subset of the partition of H corresponding to cell C.

Since the visibility polygon and the visibility skeleton for a point $p \in P$ can be computed in $O(n)$ time (see [17]) and we can compare two visibility skeletons with m vertices in $O(m)$ time to see if they are identical, we can compute the partition of H for C in $O(kn+k^2m)$ time, where m is the maximum number of vertices on any of the k visibility skeletons.

Although there may be $O(n^6)$ cells in the overlay arrangement A, yielding up to $O(kn^6)$ reference points, we show in section 5.4 that only $O(k^2)$ reference points are needed for our localization strategy, so we do not need to compute a partition of H for all $O(n^6)$ cells.

5. A greedy strategy for localization. In this section we present a localizing decision tree strategy, called *Minimum Distance Localization Strategy* or *Strategy MDL* for short, for completing the solution of the hypothesis elimination phase of the robot localization problem. Our strategy, which has a greedy flavor, uses the set Q of reference points described in the previous section for choosing probing locations. Strategy MDL has a competitive ratio of $k-1$, where $k = |H|$.

In devising a localizing decision tree strategy, there are two main criteria to consider when deciding where the robot should make the next probe: (1) the distance to the new probe position, and (2) the information to be gained at the new probe position. It is easy to see that a strategy that only considers the second criterion can do arbitrarily worse than an optimal localizing decision tree strategy. Strategy MDL considers (2) only to the extent that it never directs the robot to make a useless probe. Nevertheless, its performance is the best possible. Although it would seem beneficial to weight each possible probe location with the amount of information that could be gained in the worst case by probing at that location, this change will not improve the worst case behavior of Strategy MDL, as the lower bound example given in section 5.3 illustrates.

Even a strategy that considers both the distance and the information criteria when choosing the next probe position can do poorly. For example, if the robot employs an incremental strategy that at each step tells it to travel to the closest probe location that yields some information, then a map polygon can be constructed such that in the worst case the robot will travel distance $2^k d$.

Using Strategy MDL for hypothesis elimination, a strategy for the complete robot localization problem can be obtained as follows. Preprocess the map polygon P using a method similar to that in [19]. This preprocessing yields a data structure that stores for each equivalence class of visibility polygons either the location in P yielding that visibility polygon, if there is only one location, or a localizing decision tree that tells the robot how to travel to determine its true initial location.

5.1. Strategy MDL. In this subsection we present the details of Strategy MDL. Using the results of section 4, it is possible to precompute Strategy MDL's entire decision tree. However, for ease of exposition we will only describe how the strategy directs the robot to behave on a root-to-leaf path in the tree. In practice, it may also sometimes be preferable *not* to precompute the entire tree, but rather to compute the robot's next move on an interactive basis, as the robot carries out the strategy.

Strategy MDL uses the map polygon P, the set H generated in the hypothesis generation phase, and the set Q of reference points defined in section 4.3. Also, for each point $q_{C,j} \in Q$ the strategy uses the distance $d_j(q_{C,j})$ of $q_{C,j}$ from the origin, a path $path_j(q_{C,j})$ within P_j of length $d_j(q_{C,j})$, and the partition of H associated with cell C, as defined in section 4.3.

Next we describe how Strategy MDL directs the robot to behave. Initially, the set of hypothetical locations used by Strategy MDL is the given set H. As the robot carries out the strategy, hypothetical locations are eliminated from H. Thus in our description of Strategy MDL, we abuse notation and use H to denote the shrinking set of *active hypothetical locations*; i.e., those that have not yet been ruled out. Similarly, we use Q to denote the shrinking set of *active reference points*; i.e., those that nontrivially partition the set of active hypothetical locations. We call a path $path_j(q)$ *active* if $p_j \in H$ and $q \in Q$ are both active. We let $d_*(q*)$ denote the minimum of $\{\, d_j(q) \mid q \in Q$ and $p_j \in H$ are active $\}$ and let $path_*(q*)$ denote an active path of length $d_*(q*)$.

Using the initial H and Q, an initial $path_*(q*)$ can be selected. The strategy directs the robot to travel along this path and to make a probe at its endpoint. The robot then uses the information gained at the probe position to update H and Q. The strategy then directs the robot to retrace its path back to the origin and repeat the process until the size of H shrinks to 1.

Note that Strategy MDL is well suited to handling the problem of accumulation of errors caused by successive motions in the estimates of orientation, distance, and velocity made by the robot's sensors. This is because the robot always returns to the origin after making a probe, so it can recalibrate its sensors.

5.2. A performance guarantee for Strategy MDL. The following theorems show that Strategy MDL is correct and has a competitive ratio of $k-1$. First we show that Strategy MDL never directs the robot to pass through a wall. Then we show that Strategy MDL eliminates all hypothetical locations except the valid one while directing the robot along a path no longer than $k-1$ times the length of an optimal verification tour. A corollary of Theorem 5.2 is that the localizing decision tree associated with Strategy MDL has a weighted height that is at most $2(k-1)$ times the weighted height of an optimal localizing decision tree.

THEOREM 5.1. *Strategy MDL never directs the robot to pass through a wall.*

Proof. The proof is by contradiction. Suppose that p_j is the true initial location of the robot and x_j is the point on the boundary of P_j where the robot would first hit a wall. Furthermore, suppose that when the robot attempts to pass through the wall at x_j, the path it has been directed to follow is $path_i(q)$. Let C denote the cell of arrangement A that contains the portion of $path_i(q)$ just before x_j. Since cell C is contained in P_j, it contributes a reference point $q_{C,j}$ to the set Q of reference points.

In order to arrive at a contradiction, it suffices to show that $q_{C,j}$ is active at the time Strategy MDL chooses $path_i(q)$ for the robot to follow. This is because $d_j(q_{C,j}) \le d_j(x_j)$ by definition of $q_{C,j}$, $d_j(x_j) \le d_i(x_j)$ since the portion of $path_i(q)$ from the origin to x_j is contained within P_j, and $d_i(x_j) < d_i(q)$ because x_j is an intermediate point on $path_i(q)$. Thus $d_j(q_{C,j}) < d_i(q)$, so Strategy MDL would choose $path_j(q_{C,j})$ rather than $path_i(q)$ if $q_{C,j}$ is active.

Point $q_{C,j}$ is active when $path_i(q)$ is selected because cell C distinguishes between the two active hypothetical locations p_i and p_j. This is because the skeleton $V_j^*(C)$ associated with C relative to P_j has a real edge through the point x_j, whereas the skeleton $V_i^*(C)$ associated with C relative to P_i does not have a real edge through x_j. □

THEOREM 5.2. *Strategy MDL localizes the robot by directing it along a path whose length is at most $(k-1)d$, where $k = |H|$ and d is the length of an optimal verification tour for the robot's initial position.*

Proof. Let p_t denote the true initial location of the robot. First we show by contradiction that Strategy MDL eliminates all hypothetical initial locations in H except p_t. Suppose Q becomes empty before the size of H shrinks to one, and let p_i be an active hypothetical location different from p_t at the time Q becomes empty. Translates P_i and P_t are not identical, so there is some point x_t on the boundary of P_t that does not belong to the boundary of P_i. Let C be the cell of arrangement A contained in P_t and containing x_t. C distinguishes between p_i and p_t, so $q_{C,t}$ is still in the active set Q — a contradiction.

Next we establish an upper bound on the length of the path determined by Strategy MDL. Because the strategy always directs the robot to a probing site that eliminates one or more elements from H, the robot makes at most $k-1$ trips from its

initial location to a sensing point and back. To show that each round trip has length at most d, we consider how a robot traveling along an optimal verification tour L would rule out an arbitrary incorrect hypothetical location p_i. Then we consider how Strategy MDL would rule out p_i.

Consider a robot traveling along tour L that eliminates each invalid hypothetical location at the first point x on L where the visibility skeleton of x relative to the invalid hypothetical location differs from the visibility skeleton of x relative to P_t.

Let x be the first point on L where the robot can eliminate p_i. The point x must lie on the boundary of some cell C in the arrangement A that distinguishes p_i from p_t. Cell C generates a reference point $q_{C,t} \in Q$, and $d_t(q_{C,t}) \leq d_t(x)$. Since p_t is the true initial location of the robot, the distance $d_t(x)$ is no more than the distance along L of x from the origin, as well as the distance along L from x back to the origin. Thus $d_t(q_{C,t})$ is no more than half the length of L.

At the moment Strategy MDL directs the robot to move from the origin to the probing site where it eliminates p_i, both p_i and p_t are active, so point $q_{C,t}$ is active since it distinguishes between them. At this time Strategy MDL directs the robot to travel along $path_*(q*)$. By definition, the length $d_*(q*)$ of this path is the minimum over all $d_j(q)$ for active $p_j \in H$ and $q \in Q$. In particular, since point $q_{C,t}$ is still active, $d_*(q*) \leq d_t(q_{C,t})$, which is no more than half the length of L. Therefore, Strategy MDL directs the robot to travel along a loop from the origin to some probing position where the robot eliminates p_i and back, and the length of this loop is at most d. □

Using the definition of competitive ratio given in section 1, Theorem 5.2 can be stated as "Strategy MDL is $(k-1)$-competitive, where $k = |H|$." Note that if a verifying path is not required to return to its starting point, the bound for Theorem 5.2 becomes $2(k-1)d$. Note also that even if the robot were continuously sensing rather than just taking a probe at the end of each path $path_*(q*)$, a better bound could not be achieved. This is because the robot always goes to the closest point that yields useful information, so no point on $path_*(q*)$ before $q*$ will allow it to eliminate any hypothetical locations.

COROLLARY 5.3. *The weighted height of the localizing decision tree constructed by Strategy MDL is at most* $2(k-1)$ *times the weighted height of an optimal localizing decision tree for the same problem.*

Proof. Consider the decision tree of Strategy MDL. Let p_h denote the initial location associated with the leaf that defines the weighted height of the tree. The weighted height of the tree is thus the distance Strategy MDL will direct the robot to travel to determine that p_h is the correct initial location, and by Theorem 5.2 this distance is at most $k-1$ times the minimum verification tour length for p_h. But the minimum verification tour length for p_h is at most twice the weight of a path from the root to p_h in an optimal localizing decision tree, which is at most the weighted height of the tree. The result follows from these inequalities. □

If the robot is required to return to its initial position, the bound on the weighted height of the localizing decision tree constructed by Strategy MDL drops to $k-1$.

It should be clear from the discussions in sections 4 and 5 that Strategy MDL can be computed and executed in polynomial time. In this paper, we do not comment further on computation time as there are many ways to implement Strategy MDL. Also, if travel times are large compared to computation times, the importance of our results is that they obtain good path lengths.

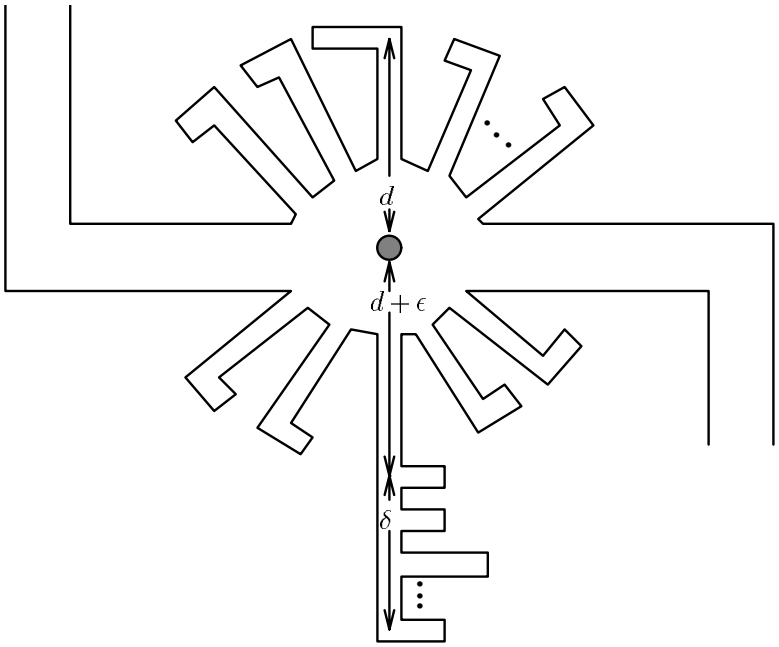

FIG. 5.1. *Part of the map polygon that gives lower bound. Not to scale:* $d >> \epsilon, \delta$.

5.3. Lower bounds. In Corollary 5.3 we proved that the weighted height of the localizing decision tree built by Strategy MDL is no greater than $2(k-1)d$, where $k = |H|$ and d is the weighted height of an optimal localizing decision tree. This bound is also a lower bound for Strategy MDL, as illustrated in Fig. 5.1. Consider a map polygon that is a staircase polygon with $k+2$ stairs, such as the one in Fig. 3.1, where each stairstep except the first and last one is similar to the one shown in Fig. 5.1. Each such stairstep has k protrusions placed in a circle, with the end of each protrusion a distance d from the center of the circle. In each stairstep a different protrusion has its end extended, which uniquely identifies the stairstep. Each stairstep also has a longer protrusion, with k smaller protrusions sticking out of it. One of these smaller protrusions is extended to uniquely identify the stairstep. The first small protrusion is a distance $d+\epsilon$ from the center of the circle, and the last one is a distance $d+\epsilon+\delta$ from the center of the circle.

For this map polygon, if the robot is initially placed in the center of the circle on one stairstep, Strategy MDL will direct it to travel up the k protrusions of length d until it finds one that has a longer piece at the end, or until it has examined all but one of these protrusions. In the worst case the robot will travel a distance $2(k-1)d$. An optimal strategy would direct the robot to travel down the protrusion of length $d+\epsilon+\delta$ and examine all the small protrusions coming out of it until it found one that was longer. In the worst case the robot would travel a distance $d+\epsilon+\delta$. Since ϵ and δ can be made arbitrarily small, in the worst case Strategy MDL travels $\Omega(k)$ times as far as the optimal strategy. Even if we used a strategy that weighted each potential probe location with the amount of information that could be gained from that location in the worst case, we would still build the same decision tree because any probe location in the stairstep yields at most one piece of information in the worst case.

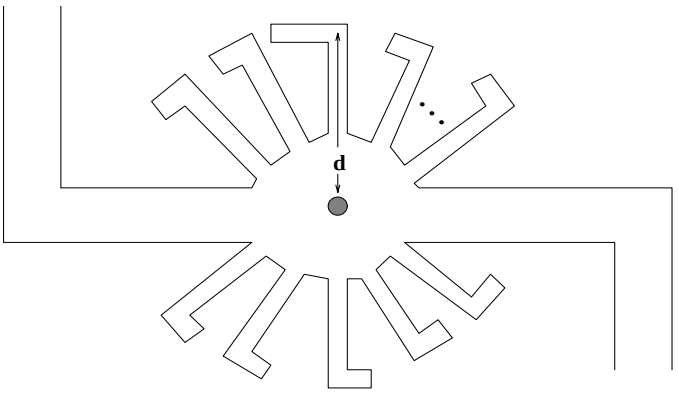

FIG. 5.2. *Part of the map polygon that shows Strategy MDL is best possible.*

Although there are map polygons for which Strategy MDL builds a localizing decision tree whose weighted height is $\Omega(k)$ times the weighted height of an optimal localizing decision tree, there are other map polygons for which any localizing decision tree strategy builds a tree with weighted height at least $k-1$ times the length of an optimal verification tour. Consider a map polygon that is a staircase polygon with $k+2$ stairs, such as the one in Fig. 3.1, where each stairstep except the first and last one is similar to the one shown in Fig. 5.2. Each such stairstep has k protrusions placed in a circle, with the end of each protrusion a distance d from the center of the circle, and has one protrusion extended at the end to uniquely identify the stairstep. The vertical piece between adjacent stairsteps is longer than $2(k-1)d$.

As with the map polygon shown in Fig. 5.1, Strategy MDL will direct the robot to explore the k protrusions of length d, and in the worst case the robot will travel a distance $2(k-1)d$. Consider any other localizing decision tree strategy. If it directs the robot to travel to any stairstep besides the one where it starts, then the localizing decision tree that it builds will have weighted height greater than $2(k-1)d$. The only way to localize the robot while remaining on the initial stairstep is to direct it to examine the protrusions, and in the worst case the robot must travel a distance $2(k-1)d$ before it has localized itself (assuming that it must return to the origin at the end).

Since no localizing decision tree strategy can build a tree with weighted height less than $k-1$ times the length of an optimal verification tour for all map polygons, Strategy MDL is the best possible strategy.

5.4. Creating a reduced set of reference points. The set Q of reference points has size upper bounded by k times the number of cells in the arrangement A, which may be very large as shown in section 4.2. In this subsection, we show that when Strategy MDL is run with only a small subset $Q' \subseteq Q$ of the original reference points, the $(k-1)d$ performance guarantee of section 5.2 still holds. The size of Q' will be no more than $k(k-1)$.

Set Q' is defined as the union of subsets $Q_i \subseteq Q$, where there is one Q_i for each $p_i \in H$ and $|Q_i| \leq k-1$. Ignoring implementation issues, we define Q_i as follows. Initially Q_i is empty, and the subset of Q consisting of reference points $q_{C,i}$ generated for translate P_i is processed in order of increasing $d_i(q_{C,i})$. For each successive point $q_{C,i}$, the partition of H induced by $Q_i \cup \{q_{C,i}\}$ is compared to that induced by Q_i

alone. If the subset of H containing location p_i is further subdivided by the additional reference point $q_{C,i}$, then $q_{C,i}$ is added to Q_i. Conceptually, the reference point $q_{C,i}$ is added if it distinguishes another hypothetical initial location from p_i. This process continues until p_i is contained in a singleton in the partition of H induced by Q_i. Since there are only $k-1$ initial locations to be distinguished from p_i, Q_i will contain at most $k-1$ points.

We denote by *Strategy MDLR*, which stands for *Minimum Distance Localization with Reduced reference point set*, the strategy obtained by replacing set Q with Q' in Strategy MDL.

THEOREM 5.4. *Strategy MDLR, which uses a set of at most $k(k-1)$ reference points, localizes the robot by directing it along a path whose length is at most $(k-1)d$, where $k = |H|$ and d is the length of an optimal verification tour for the robot's initial position.*

Proof. Both the proof that Strategy MDLR directs the robot along a path that determines its initial location and the proof of the $(k-1)d$ bound are essentially the same as the proofs of the corresponding results in Theorems 5.1 and 5.2 of section 5.2. The only additional observation needed is that if a reference point $q_{C,i}$ is used in one of the previous proofs to distinguish between two hypothetical initial locations, and if $q_{C,i}$ does not belong to set Q', then Q' contains some reference point $q_{C',j}$ that distinguishes the same pair of locations and that satisfies $d_j(q_{C',j}) \leq d_i(q_{C,i})$. Hence, set Q' always contains an adequate substitute for any reference point of Q required by the proofs of Theorems 5.1 and 5.2. □

6. Conclusions and future research. We have shown that the problem of localizing a robot in a known environment by traveling a minimum distance is NP-hard, and we have given an approximation strategy that achieves a competitive ratio of $k-1$, where k is the number of possible initial locations of the robot. We have also shown that this bound is the best possible.

The work in this paper is one part of a strategy for localizing a robot. The complete strategy will preprocess the map polygon and store the decision trees for ambiguous initial positions so that the robot only needs to follow a predetermined path to localize itself.

There are many variations to this problem which can be considered. If the robot must localize itself in an environment with obstacles, then the map of the environment can be represented as a simple polygon with holes. If these obstacles are moving, then the problem becomes more difficult.

In this paper we assigned a cost of zero for the robot to take a probe and analyze it. In a more general setting we would look for an optimal decision tree, where the edges of a decision tree associated with the outcome of a probe would be weighted with the cost to analyze that probe. A pragmatic variation of the problem would weight reference locations so that those that produce more reliable percepts would be selected first.

LISTING ALL MINIMAL SEPARATORS OF A GRAPH*

T. KLOKS† AND D. KRATSCH‡

Abstract. An efficient algorithm listing all minimal vertex separators of an undirected graph is given. The algorithm needs polynomial time per separator that is found.

Key words. graph, algorithm, listing algorithm, minimal separator, good pair, minimal pair

1. Introduction. Given a graph, one is often interested in listing certain subsets of vertices, or their cardinality, which possess a certain property. For example, the CLIQUE NUMBER of a graph G is the maximum cardinality of a subset S such that $G[S]$ is complete. Similar questions are the INDEPENDENCE NUMBER, the DOMINATION NUMBER, or the CHROMATIC NUMBER. For many of these problems, it would be convenient if one could use a decomposition of the graph by means of certain *separators*.

This is perhaps best illustrated by the recent results for classes of graphs of bounded treewidth. For these classes, linear time algorithms exist for many NP-complete problems *exactly* because a decomposition can be made using *separators of bounded size* [1, 2, 3, 4, 12]. A decomposition of this type can be found in linear time [5, 12]; however, the huge constants involved in these algorithms do not make them of much practical use.

A closely related but somewhat different approach was surveyed in [19]. In that paper (see also [8]) it is shown that for many classes of graphs (for example chordal graphs, clique separable graphs, and edge intersection graphs of paths in a tree (EPT-graphs)) a decomposition by *clique separators* is possible, and it is illustrated that such a decomposition can also be used to solve efficiently many NP-complete problems like MINIMUM FILL-IN, MAXIMUM CLIQUE, GRAPH COLORING, and MAXIMUM INDEPENDENT SET. In [20] an algorithm is given for finding clique separators efficiently (the algorithm uses $O(nm)$ time to find one clique separator). Recent results have shown how the above-mentioned results can be generalized in the sense that at least the NP-complete problems TREEWIDTH and MINIMUM FILL-IN can be solved by polynomial time algorithms for many more graph classes, i.e., certain graph classes for which the number of minimal separators is polynomial bounded [6, 7, 12, 13, 14, 15, 17].

In [11] an algorithm is given which finds all of what the authors call *minimum size separators*. By this they mean that, given a graph which is k-connected, the algorithm finds all separators with k vertices. Moreover, they show in this paper that the number of these separators is bounded by $O(2^k \frac{n^2}{k})$. Their algorithm, which lists all minimum size separators, runs in $O(2^k n^3)$ time. We call a subset of vertices S a

minimal separator if there are nonadjacent vertices x and y such that the removal of S separates x and y into disjoint connected components in such a way that no proper subset of S also does this (see Definition 1). A closely related concept which we call *inclusion minimal separators* lies more or less between the minimum size separators and the minimal separators, i.e., all minimum size separators are inclusion minimal and all inclusion minimal separators are minimal separators.

The following example shows that the minimum size separators and the inclusion minimal separators are only of limited use. Consider any graph G. Take a new vertex x and make this adjacent to all vertices of G. Take another new vertex y and make this adjacent to x. Call this new graph H. The only inclusion minimal separator which is also the only minimum size separator of H is $\{x\}$. However, if S is some minimal separator of G, then $S \cup \{x\}$ is a minimal separator in H. Hence H has at least as many minimal separators as G.

In [6, 12, 13, 14, 15] it is shown that many important classes of graphs have a polynomial number of minimal vertex separators. These graph classes include permutation graphs, circular permutation graphs, trapezoid graphs, circle graphs, circular arc graphs, distance hereditary graphs, chordal bipartite graphs, cocomparability graphs of bounded dimension, and weakly triangulated graphs. For some of these graph classes there are efficient algorithms listing all minimal vertex separators, often using so-called "scanlines" (see, e.g., [6, 12, 17]). In this paper we present an algorithm for listing all minimal vertex separators of any given graph. Notice that, in general, the number of minimal separators can be exponential, as the following example shows. Consider the graph consisting of two nonadjacent vertices s and t and a set of $\frac{n-2}{2}$ (internally) vertex disjoint paths of length 3 from s to t. The number of minimal s,t-separators in this graph is $2^{(n-2)/2}$.

Our listing algorithm has been applied as an important subroutine in $O(n^5R + n^3R^3)$ algorithms computing the treewidth and minimum fill-in of a given asteroidal triple-free graph with n vertices and R minimal separators [16, 17]. (Notice that asteroidal triple-free graphs are a relatively large class of graphs containing cocomparability graphs and permutation graphs.) Furthermore, it has been suggested in [18] to use a so-called "separator graph" for obtaining polynomial time treewidth and minimum fill-in algorithms. Thereby the vertex set of the separator graph is the set of all minimal separators of the given graph. Typically, applications require our listing algorithm.

For listing other types of combinatorial structures we refer to [9].

2. Preliminaries. If $G = (V, E)$ is a graph and $W \subseteq V$ is a subset of vertices, then we use $G[W]$ as a notation for the subgraph of G *induced* by the vertices of W. For a vertex $x \in V$ we use $N(x)$ to denote the neighborhood of x.

The following definition can be found, for example, in [10].

DEFINITION 1. *Given a graph $G = (V, E)$ and two nonadjacent vertices a and b, a subset $S \subset V$ is an* a,b-separator *if the removal of S separates a and b in distinct connected components. If no proper subset of S is an a,b-separator, then S is a* minimal a,b-separator. *A* minimal separator *is a set of vertices S for which there exist nonadjacent vertices a and b such that S is a minimal a,b-separator.*

The following lemma appears, for example, as an exercise in [10]. It provides an easy test of whether or not a given set S of vertices is a minimal separator.

LEMMA 2. *Let S be a separator of the graph $G = (V, E)$. Then S is a minimal separator if and only if there are two different connected components of $G[V - S]$ such that every vertex of S has a neighbor in both of these components.*

Proof. Let S be a minimal a,b-separator and let C_a and C_b be the connected components containing a and b, respectively. Let $x \in S$. Since S is a *minimal* a,b-separator, there is a path between a and b passing through x but using no other vertex in S. Hence x must have a neighbor in C_a and C_b.

Now let S be a separator and let C_a and C_b be two connected components such that every vertex of S has a neighbor in C_a and C_b. Let $a \in C_a$ and $b \in C_b$. Then, clearly, S is a minimal a,b-separator, for if $x \in S$, then there is a path between a and b which uses no vertices of $S \setminus \{x\}$. □

Notice that this also proves the following. Let S be a minimal separator and let C_1 and C_2 be two connected components of $G[V-S]$ such that every vertex of S has a neighbor in both C_1 and C_2. If a is a vertex of C_1 and b is a vertex of C_2, then S is a minimal a,b-separator.

It may be a bit surprising at first to see that it is very well possible for one minimal separator to be contained in another. An example of this can be found in [10]. However, for minimal a,b-separators things are different since, by definition, one minimal a,b-separator cannot be properly contained in another.

We now show that at least some of the minimal separators are easy to find.

DEFINITION 3. *Let a and b be nonadjacent vertices. If S is a minimal a,b-separator which contains only neighbors of a, then S is called* close to a.

LEMMA 4. *If a and b are nonadjacent, then there exists exactly one minimal a,b-separator close to a.*

Proof. Let S be a minimal a,b-separator close to a. For every vertex in S there is a path to b which does not use any other neighbors of a, since S is minimal. On the other hand, if x is a neighbor of a such that there is a path to b without any other neighbors of a, then x must be an element of S; otherwise, there is a path between x and b which avoids S and this is a contradiction since x is in the component of $G[V-S]$ that contains a. □

Notice that a minimal separator close to a can easily be computed as follows. Start with $S = N(a)$. Clearly, since a and b are nonadjacent, S separates a and b. Let C_b be the connected component of $G[V-S]$ containing b. Let $S' \subseteq S$ be the set of those vertices of S which have at least one neighbor in C_b. By Lemma 2, S' is a minimal a,b-separator, and since it only contains neighbors of a, it is close to a.

LEMMA 5. *Let S be a minimal a,b-separator close to a and let C_a and C_b be the connected components containing a and b, respectively. Let $S^* \neq S$ be another minimal a,b-separator. Then $S^* \subset S \cup C_b$.*

Proof. Since S^* is a minimal a,b-separator, $S^* \subset C_a \cup C_b \cup S$. Assume S^* has a vertex $x \in C_a$. $S^* \setminus \{x\}$ does not separate a and b; hence there is a path P between a and b using x but no other vertex of S^*. Since S is a minimal separator, P goes through a vertex $y \in S$. Since S is close to a, y is adjacent to a. Hence there is a path $P' \subset P$ between a and b that does not contain x. This is a contradiction since P' contains no vertex of S^*. □

In sections 3 and 4 we show how to obtain new minimal a,b-separators from a given one using so-called minimal pairs. A minimal pair is in some sense the smallest step to go from one minimal a,b-separator to the next one. The main difficulty is to prove that we indeed obtain all minimal separators by using small steps only.

In section 5 we describe an algorithm that computes all minimal a,b-separators for a given pair of nonadjacent vertices a and b in a breadth-first-search manner; we prove that it is correct and we analyze its time complexity. We end with some concluding remarks and open problems.

3. Good pairs. Let $G = (V, E)$ be a graph and let a and b nonadjacent vertices in G. Let S be a minimal a, b-separator and let C_a and C_b be the connected components containing a and b, respectively.

DEFINITION 6. *Let $\Delta \subseteq C_a \setminus \{a\}$ and let C'_a be the connected component of $G[C_a - \Delta]$ that contains a. Let $N \subseteq S$ be the set of vertices in S that do not have a neighbor in C'_a. The pair (Δ, N) is called* good *for S if the following conditions are satisfied:*

1. *$N \neq \emptyset$.*
2. *Each $\delta \in \Delta$ has at least one neighbor in C'_a.*
3. *Each $\delta \in \Delta$ either has a neighbor in N or there exists a vertex $x \in N$ and a connected component D of $G[C_a - \Delta]$ such that both x and δ have at least one neighbor in D.*

LEMMA 7. *If S is close to a, then there is no good pair.*

Proof. Assume (Δ, N) is a good pair. Hence $\Delta \subseteq C_a \setminus \{a\}$. Let C'_a be the connected component of $G[C_a - \Delta]$ that contains a. The set N is defined as the subset of S that does not contain any neighbor in C'_a. Then $N = \emptyset$ since S contains only neighbors of a, but by definition $N \neq \emptyset$. □

Theorem 8 shows that a good pair defines a new separator. In Theorem 9 we show that each minimal a, b-separator can be obtained by a good pair for the separator that is close to b. In section 4 we show that only a restricted type of good pairs, called minimal pairs, has to be considered.

THEOREM 8. *Let (Δ, N) be a good pair. Define $S^* = (S \cup \Delta) \setminus N$. Then S^* is a minimal a, b-separator.*

Proof. Let C'_a be the connected component of $G[C_a - \Delta]$ that contains a. Clearly, S^* separates a and b, since vertices of N do not have neighbors in C'_a. Let C'_b be the connected component of $G[V - S^*]$ that contains b. Notice that $C_b \subset C'_b$, and since each vertex of N has a neighbor in C_b, $N \subset C'_b$.
