4.1. Computing the node set. In this subsection we describe the node set V and an efficient algorithm for computing it. We set $V = \{I, F\} \cup V_1 \cup V_2 \cup V_3$, where each subset V_i corresponds to a specific type of positions. The first set V_1 corresponds to positions located at the vertices of Ω. More precisely, for each vertex v of Ω with feasible domain $[\alpha_v, \beta_v]$, we add the positions $(v, \alpha_v + i\delta)$ for $0 \le i < \lceil(\beta_v - \alpha_v)/\delta\rceil$ and (v, β_v) to V_1. V_1 can be constructed in $O(n/\delta)$ time in a straightforward manner.

The second set V_2 corresponds to deeply anchored C-segments. For a pair of nonparallel edges e_1, e_2, if the unit-radius circle C tangent to e_1 and e_2 does not intersect any other edge of Ω, we add four positions $(p_1, \theta_1), (p_1, \theta_1 + \pi), (p_2, \theta_2)$, and $(p_2, \theta_2 + \pi)$ to V_2, where p_i is the point at which C is tangent to e_i, and θ_i is the angle between e_i and the x-axis. Using an algorithm of Kedem et al. [29], the set of unit-radius circles tangent to two edges and not intersecting any other edge can be computed in $O(n \log^2 n)$ time, and so can be the set V_2.

The third set V_3 corresponds to semifree C-segments and shallowly anchored C-segments. For each edge $e \in \Omega$, we first mark a portion $\hat{e}$ of it, as described below, and then choose those points on e that are at distance $i\delta$ from its left endpoint for any integer $i \ge 0$, such that the semi-open interval $[i\delta, (i+1)\delta)$ intersects $\hat{e}$. Let S^e denote the set of points selected on e. Assuming that the angle between e and the x-axis is θ, for each point $p \in S^e$, we add two positions (p, θ) and $(p, \theta + \pi)$ to V_3.

We now describe which portion of each edge is marked. We mark the edges in two stages. First, for each edge e, we mark the portion that lies within distance 30 from any of its endpoints. Next, for each vertex $v \in \Omega$, let D_v be the disk of radius 15 centered at v. Let E_v be the set of edges that contain at least one unmarked point

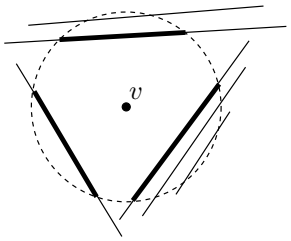

FIG. 4.1. *Segments in E_v; fat edges denote the portion of E_v E_v-visible from v.*

inside D_v, i.e., $e \in E_v$ if $e \cap D_v$ contains at least one point whose distance to both endpoints of e is more than 30. A point is E_v-visible from v if it is visible from v with respect to the edge set E_v (i.e., we ignore the edges in the set $E \setminus E_v$). For each edge $e \in E_v$, we mark the portion of $e \cap D_v$ that is E_v-visible from v. We repeat this step for all vertices of Ω.

LEMMA 4.1. *Let p be a point on an edge $e \in \Omega$ so that there is a vertex v of Ω visible from p and so that $d(p, v) \leq 15$. Then there is a point $q \in S^e$ within distance δ from p.*

Proof. It suffices to show that every such point p lies on $\hat{e}$ because, by construction, for every point $q \in \hat{e}$, there is a point $q' \in S^e$ such that $d(q, q') \leq \delta$. Since $d(p, v) \leq 15$ and v is visible from p, the above algorithm would have been marked p, implying that $p \in \hat{e}$. ∎

LEMMA 4.2. *Suppose Π is an optimal path from I to F, and let $\langle X_1, \ldots, X_k \rangle$ be the sequence of positions on Π such that $\text{LOC}(X_i) \in \partial\Omega$ for every $1 \leq i \leq k$. For each $1 \leq i \leq k$, there exist two (not necessarily distinct) nodes $Y_i^-, Y_i^+ \in V$ such that*

(i) *if $\text{LOC}(X_i)$ is a vertex v of Ω, then $\text{LOC}(Y_i^-), \text{LOC}(Y_i^+) = v$, $\text{VEC}(Y_i^-) \leq \text{VEC}(X_i) \leq \text{VEC}(Y_i^+)$, and $|\text{VEC}(Y_i^-) - \text{VEC}(X_i)|, |\text{VEC}(Y_i^+) - \text{VEC}(X_i)| \leq \delta$; or*

(ii) *if $\text{LOC}(X_i)$ is an interior point of an obstacle edge e, then $\text{LOC}(Y_i^-), \text{LOC}(Y_i^+) \in e$, Y_i^-, X, and Y_i^+ appear in that order along e,*

$$d(\text{LOC}(Y_i^-), \text{LOC}(X_i)), d(\text{LOC}(Y_i^+), \text{LOC}(X_i)) \leq \delta,$$

and $\text{VEC}(Y_i^-) = \text{VEC}(Y_i^+) = \text{VEC}(X_i)$.

Proof. If $\text{LOC}(X_i)$ is a vertex, the lemma follows from the definition of V_1. If $p = \text{LOC}(X_i)$ lies in the interior of an obstacle edge e, then p lies on a semifree C-segment, a shallow anchored C-segment, or a deep anchored C-segment. In the last case, X_i is a node in V_2. In the first two cases, there is a vertex $v \in \Omega$ so that v is visible from p and that $d(p, v) \leq 15$. By Lemma 4.1 and the definition of V_3, there exist two nodes $Y_i^-, Y_i^+ \in V_3$ so that $d(\text{LOC}(Y_i^-), \text{LOC}(X_i)), d(\text{LOC}(Y_i^+), \text{LOC}(X_i) \leq \delta$ and $\text{VEC}(Y_i^-) = \text{VEC}(Y_i^+) = \text{VEC}(X_i)$. This completes the proof of the lemma. ∎

Next, we prove that the size of V is $O(n/\delta)$. Since $|V_1| = O(n/\delta)$ and $|V_2| = O(n)$, it suffices to bound the size of V_3.

LEMMA 4.3. $\sum_e |S^e| = O(n/\delta)$.

Proof. For each edge $e \in \Omega$, let $\hat{e}$ denote the marked portions of e, $\#\hat{e}$ the number of connected components of $\hat{e}$, and $\|\hat{e}\|$ the total length of $\hat{e}$. For each connected component γ of $\hat{e}$, the algorithm chooses $2 + \|\gamma\|/\delta$ points. Therefore, $|S^e| \leq 2\#\hat{e} + \|\hat{e}\|/\delta$.

The total measure of points marked in the first stage is at most $60n$. Recall that for each vertex v, $e \in E_v$ if $e \cap D_v$ contains at least one point whose distance to both

endpoints of e is more than 30. Thus none of the endpoints of E_v lie inside D_v. This implies that the set of points in $(\bigcup E_v) \cap D_v$ that are E_v-visible from v form a set of disjoint chords of D_v (see Figure 4.1), and therefore its measure is bounded by the length of the perimeter of D_v, which is 30π. Therefore,

$$\sum_{e \in \Omega} \|\hat{e}\| \leq 60n + 30\pi n = O(n).$$

Next, for each connected component $\gamma \in \hat{e}$, if γ is the first or the last connected component of $\hat{e}$, then we charge γ to e itself. Otherwise, charge γ to any of the vertices that marked it in the second stage. We will prove in Lemma 4.4 that each vertex is charged by at most ten connected components, so

$$\sum_{e \in \Omega} \#\hat{e} = 2n + 10n = O(n).$$

This completes the proof. ∎

LEMMA 4.4. *Each obstacle vertex is charged by at most ten connected components.*

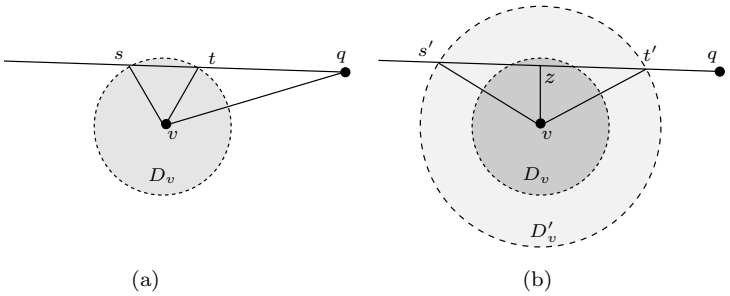

FIG. 4.2. $d(s,t) < 15$ *and* $\angle s'vt' > \pi/2$.

Proof. Since the edges of E_v are disjoint and do not contain any of its endpoints inside D_v and the visibility is taken with respect to the edge set E_v, v marks at most one connected component of each edge in E_v; see Figure 4.1. That is, for each edge $e \in E_v$, either v marks the entire chord $e \cap D_v$, or it does not mark any point of e. Hence, the number of connected components charged to v is bounded by the number of edges in E_v that are E_v-visible from v.

Partition the set of edges that are E_v-visible from v into two subsets Γ_1 and Γ_2. An edge e is in Γ_1 if the length of the chord $e \cap D_v$ is at least 15, and in Γ_2 otherwise. Each edge $e \in \Gamma_1 \cup \Gamma_2$ splits the circle ∂D_v into two circular arcs; we refer to the shorter one as the *cap* induced by e. Since the edges in $\Gamma_1 \cup \Gamma_2$ are E_v-visible from v, the caps induced by them are pairwise disjoint.

Each cap induced by an edge of Γ_1 spans an angle of at least $\pi/3$ because the length of the chord $e \cap D_v$ is at least 15 and the radius of D_v is 15. Since the caps are disjoint, $|\Gamma_1| \leq 6$.

Next, let e be an edge of Γ_2. Let p (resp., q) denote the left (resp., right) endpoint of e, and let s (resp., t) denote the left (resp., right) endpoint of $e \cap D_v$; see Figure 4.2(a). By definition, $d(s,t) < 15$, and therefore $\angle stv, \angle tsv > \pi/3$ and $d(t,q) > 15$. Since $e \in E_v$, $e \cap D_v = st$ contains a point u such that $d(u,p), d(u,q) > 30$. Hence,

$d(s,q) = d(s,u) + d(u,q) > 30$, and

$$\begin{aligned} d(v,q) &= \sqrt{d(v,s)^2 + d(s,q)^2 - 2\,d(s,q)\,d(v,s)\cos(\angle vst)} \\ &= \sqrt{d(v,s)^2 + d(s,q)^2 - 2\,d(s,q)\,d(v,s)\frac{d(s,t)}{2d(v,s)}} \\ &= \sqrt{d(v,s)^2 + d(s,q)(d(s,q) - d(s,t))} \\ &= \sqrt{d(v,s)^2 + d(s,q)d(q,t)} \\ &> \sqrt{15^2 + 30 \cdot 15} = 15\sqrt{3}. \end{aligned}$$

Similarly, one can show that $d(v,p) > 15\sqrt{3}$.

Draw a disk D'_v of radius $15\sqrt{3}$ centered at v. Since $d(v,p), d(v,q) > 15\sqrt{3}$, the endpoints of every edge in Γ_2 lie outside D'_v. Moreover, each edge of Γ_2 is E_v-visible from v, the caps of $\partial D'_v$ induced by the edges of Γ_2 are also pairwise disjoint. For an edge e, let s', t' be the endpoints of $e \cap D'_v$, and let z be the midpoint of the segment $s't'$. See Figure 4.2(b). Since $d(v,z) \le 15$ and $d(v,t') = 15\sqrt{3}$,

$$\angle s'vt' = 2\angle zvt' = 2 \cdot \cos^{-1}\frac{d(v,z)}{d(v,t')} \ge 2 \cdot \cos^{-1}\frac{1}{\sqrt{3}} > \pi/2.$$

Hence, the cap of $\partial D'_v$ induced by $e \in \Gamma_2$ spans an angle of at least $\pi/2$, which implies $|\Gamma_2| \le 4$. This completes the proof of the lemma. □

We now show that the node set V_3 can be computed in time $O(n^2 \log n + n/\delta)$. For every vertex v, the set E_v can be computed in $O(n)$ time in a straightforward manner. Let $E'_v = \{e \cap D_v \mid e \in E_v\}$. An edge e' of $E'v$ is marked if it is E_v-visible from v. Recall that either every point on e' is E_v-visible from v, or no point on e is E_v-visible from v. This set can be computed in $O(n \log n)$ time by performing an angular sweep around v. Let $\rho(\theta)$ be the ray emanating from v in direction θ. Let $\theta_1, \ldots, \theta_k$ be the orientations such that $\rho(\theta)$ passes through an endpoint of an edge in E'_v. We sweep the plane with the ray $\rho(\theta)$ by varying θ from 0 to 2π. For each θ, we maintain the edges of E'_v intersecting $\rho(\theta)$, sorted in the order they intersect $\rho(\theta)$. Since the segments of E'_v are pairwise disjoint, the ordering changes only at θ_i's. Let $e_i \in E'_v$ be the first edge in this ordering in the interval $[\theta_i, \theta_{i+1})$. We mark e_i. At each θ_i, we can update the ordering in time $O(\log n)$. Repeating this process for all the vertices of Ω, V_3 can be computed in time $O(n^2 \log n + n/\delta)$. Hence, we conclude the following lemma.

LEMMA 4.5. *$|V| = O(n/\delta)$ and V can be computed in time $O(n^2 \log n + n/\delta)$.*

4.2. Computing the edge set. We now describe how to compute the edge set E. For each pair of positions $X, Y \in V$, we compute all $O(1)$ Dubins paths from X to Y, check which of them are feasible, and select the one with the minimum arc length. The only nontrivial step is to determine whether a given Dubins path is feasible. We will consider CCC and CLC paths separately.

Testing CCC paths. CCC paths can be further classified into two subcategories: $C^+C^-C^+$ and $C^-C^+C^-$. We consider only $C^+C^-C^+$ paths; $C^-C^+C^-$ paths can be handled in a similar manner.

For each position X, let C_X denote the clockwise oriented circle passing through X, and let ϕ_X^+ (resp., ϕ_X^-) be the intersection point of C_X and $\partial\Omega$ immediately after (resp., before) $\text{LOC}(X)$, so the interiors of the arcs $C_X[\text{LOC}(X), \phi_X^+]$ and $C_X[\phi_X^-, \text{LOC}(X)]$ do not intersect $\partial\Omega$ (see Figure 4.3(a)); ϕ_X^+ and ϕ_X^- can be computed in $O(n)$ time.

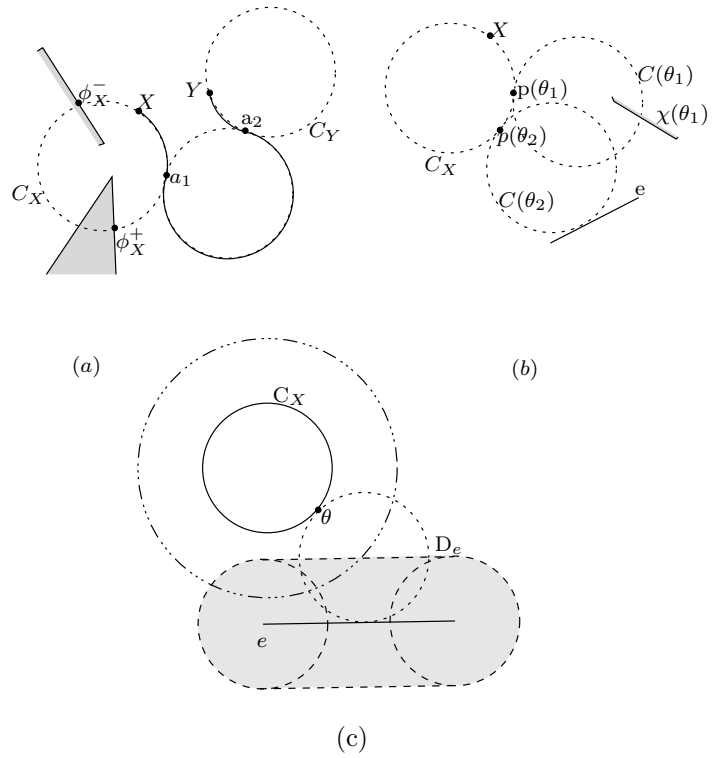

FIG. 4.3. (a) $C^+C^-C^+$ *path;* (b) $p(\theta), C(\theta)$, *and a critical orientation* θ_2; (c) *the center of* C_θ *is an intersection point of* ∂D_e *and* C'_X.

Let $w_1w_2w_3$ be a $C^+C^-C^+$ path from a position X to another position Y, with a_i being the common endpoint of w_i and w_{i+1} for $i = 1, 2$. Obviously, w_1 (resp., w_3) does not intersect Ω if and only if $a_1 \in C_X[\text{LOC}(X), \phi_X^+]$ (resp., $a_2 \in C_Y[\phi_Y^-, \text{LOC}(Y)]$); see Figure 4.3(a). After computing ϕ_X^+ and ϕ_X^- for all $O(n/\delta)$ positions in time $O(n^2/\delta)$, given a $C^+C^-C^+$ path, we can check in $O(1)$ time whether its first and last C-segments intersect Ω. Next, we describe how to test whether the middle C-segment of a $C^+C^-C^+$ path intersects Ω.

Fix a position X. We construct a linear-size data structure, in $O(n \log n)$ time, which, given a position Y, can determine in $O(\log n)$ time whether the middle C-segment of the $C^+C^-C^+$ path from X to Y intersects any obstacle edge.

For an orientation θ, $0 \le \theta < 2\pi$, let $p(\theta)$ be the point on C_X such that the length of the arc $C_X[\text{LOC}(X), p(\theta)]$ is θ. Let $C(\theta)$ be the counter-clockwise-directed circle tangent to C_X at $p(\theta)$. Set $\chi(\theta)$ to be the first edge of Ω intersected by $C(\theta)$, as one walks along it (in the counter-clockwise direction) starting from $p(\theta)$. If there is no such edge, then $\chi(\theta)$ is undefined (see Figure 4.3(b)).

We call an orientation θ *critical* (with respect to X) if $C(\theta)$ is either tangent to an obstacle edge or it passes through an obstacle vertex. Let $\langle \theta_1, \theta_2, \ldots, \theta_k \rangle$ be the sequence of critical angles sorted in the increasing order. Using a simple continuity argument and the fact that the obstacle edges have pairwise disjoint interiors, we can prove the following.

LEMMA 4.6. *For all orientations* θ *in any interval* (θ_i, θ_{i+1}), *the set of obstacle edges that intersect* $C(\theta)$ *and the order in which they intersect* $C(\theta)$ *remain the same.*

This lemma implies that the value of $\chi(\theta)$ remains the same for all orientations within each interval $[\theta_i, \theta_{i+1})$.

LEMMA 4.7. *For a fixed position X, there are $O(n)$ critical orientations, and they can be computed in $O(n)$ time.*

Proof. For an edge $e \in \Omega$, let D_e be the Minkowski sum of e and the unit-radius disk. Let C'_X be the circle concentric with C_X and of radius 2. $C(\theta)$ is tangent to e or passes through an endpoint of e if and only if $C(\theta)$ is centered at an intersection point of C'_X and ∂D_e (see Figure 4.3(c)). There are at most 4 intersection points between C'_X and ∂D_e. Thus an edge e can contribute at most $O(1)$ critical orientations, resulting in $O(n)$ critical orientations for all edges. These critical orientations can easily be computed in $O(n)$ time. □

By sweeping the circle $C(\theta)$ for $\theta \in [0, 2\pi)$, we can compute the values of χ for all $O(n)$ intervals (θ_i, θ_{i+1}) in $O(n \log n)$ time as follows. For each θ, we maintain the set of edges intersecting $C(\theta)$, sorted in the order in which they intersect $C(\theta)$. By Lemma 4.6, this ordering changes only at critical orientations. At each critical orientation, we can update the ordering in $O(\log n)$ time, thus spending a total of $O(n \log n)$ time. We record the value of χ for each interval $[\theta_i, \theta_{i+1})$.

Now, given a $C^+C^-C^+$ Dubins path $w_1w_2w_3$, we first compute the orientation θ of a_1, the common endpoint of w_1 and w_2. Using the above data structure, we can determine $e = \chi(\theta)$ in $O(\log n)$ time by a binary search. Finally, we check in $O(1)$ time whether w_2 intersects the edge e (That is, we check whether a_2, the common endpoint of w_2 and w_3, lies before the intersection point of $C(\theta)$ and e, in which case w_2 does not intersect any edge of Ω.) This completes the description of the data structure.

We can thus determine in time $O((n^2/\delta^2) \log n)$ all pairs $X, Y \in V$ for which there is a feasible CCC-path from X to Y.

Testing CLC paths. There are four types of CLC paths, namely, C^+LC^+, C^+LC^-, C^-LC^+, and C^-LC^-. Consider C^+LC^+ paths. Let $w_1w_2w_3$ be a C^+LC^+ path. After $O(n^2/\delta)$ preprocessing as above, we can easily determine whether w_1 or w_3 intersects Ω. As for w_2, we construct a similar data structure. Fix a position X. For a given θ, we now define $\ell(\theta)$ to be the ray tangent to C_X and emanating from $p(\theta)$, and we define $\chi(\theta)$ to be the first edge of Ω intersected by $\ell(\theta)$. An orientation θ is *critical* if $\ell(\theta)$ passes through a vertex of Ω. We can again construct a linear-size data structure in $O(n \log n)$ time that, given a position Y, can determine in $O(\log n)$ time whether the line segment of the C^+LC^+ path from X to Y intersects Ω.

Hence, we can compute in $O((n^2/\delta^2) \log n)$ time all pairs $X, Y \in V$ that admit a feasible C^+LC^+ path from X to Y. Repeating this procedure for other types of CLC paths, we can compute in $O((n^2/\delta^2) \log n)$ time all the pairs $X, Y \in V$ for which there is a feasible CLC path from X to Y.

After having computed the vertices and edges of G, we can compute a shortest path in G, using any standard shortest-path algorithm [19]. Putting everything together, we obtain the following result.

THEOREM 4.8. *The graph G, as described above, can be constructed in time $O((n^2/\delta^2) \log n)$, and a shortest path from I to F in G can be computed in an additional $O(n^2/\delta^2)$ time.*

5. Error analysis. In this section we prove that our algorithm computes an $(1 + \varepsilon)$-approximation to an optimal path provided that we choose $\delta = c\varepsilon^2$, where c is a sufficiently small constant independent of ε, and the optimal path is δ-robust. We first bound the change in the length of a Dubins path, whose end-positions lie on

obstacle boundaries, as we perturb the parameters of its end-positions, and then we bound the length of the path computed by the above algorithm.

5.1. Error induced by a single Dubins path. To give an error bound for our approximation algorithm, we need to answer the following question: given two Dubins paths of the same type whose end-positions differ by a small amount, what is the difference in length of these two paths? Let X and X' be two positions on an obstacle feature (vertex or edge) φ. We define $\Delta(X', X)$ to be the distance between X and X' in the configuration space. If φ is a vertex, then $\textsc{loc}(X') = \textsc{loc}(X)$ and we define $\Delta(X', X) = |\textsc{vec}(X') - \textsc{vec}(X)|$. If φ is an edge, i.e., $\textsc{vec}(X') = \textsc{vec}(X)$, then we define $\Delta(X', X) = \|\textsc{loc}(X') - \textsc{loc}(X)\|$. For two paths Π and Π', let $\Delta(\Pi', \Pi)$ be the difference in length of these two paths, i.e., $\Delta(\Pi', \Pi) = |\|\Pi'\| - \|\Pi\||$.

LEMMA 5.1. *Let φ_1 and φ_2 be two obstacle features, and let Π be a CLC path from a position I on φ_1 to a position F on φ_2. Let I' and F' be positions on φ_1 and φ_2, respectively, such that $\Delta(I', I) = \delta_I$ and $\Delta(F', F) = \delta_F$ for any reals $0 \le \delta_I, \delta_F \le 1$. Let Π' be the path from I' to F' of the same type as Π. If Π and Π' are neighbors, then*

$$\Delta(\Pi', \Pi) = O(\delta_I + \delta_F).$$

Proof. We will prove that if $\delta_F = 0$ (i.e., $F' = F$), then $\Delta(\Pi', \Pi) = O(\delta_I)$. By reversing the direction of Π, this also implies that $\Delta(\Pi', \Pi) = O(\delta_F)$ if $\delta_I = 0$. If both $\delta_I, \delta_F > 0$, then let Π'' be the CLC path from I' to F of the same type as Π; the existence of Π'' follows from the fact that Π and Π' are neighbors. Then

$$\Delta(\Pi', \Pi) \le \Delta(\Pi'', \Pi) + \Delta(\Pi', \Pi'') = O(\delta_I + \delta_F),$$

as claimed. We now assume $F' = F$, and set $\delta = \delta_I$.

We will first prove the claim for the case in which φ_1 is an obstacle vertex u, i.e., $I = (u, \theta_I)$ and $|\textsc{vec}(I') - \textsc{vec}(I)| = \delta$. Let C_1 (resp., C_2) be the unit-radius circle containing the initial (resp., final) C-segment of Π, and let o_i (for $i = 1, 2$) denote the centers of C_i. Let C_1' be the circle containing the initial C-segment of Π', and let o_1' be the center of C_1'. If Π is a C^+LC^+ or C^-LC^- type path, then

$$\|\Pi\| = |\textsc{vec}(I) - \textsc{vec}(F)| + d(o_1, o_2),$$

in which case,

$$\Delta(\Pi', \Pi) \le |\textsc{vec}(I') - \textsc{vec}(I)| + |d(o_1, o_2) - d(o_1', o_2)| \le \delta + d(o_1, o_1').$$

By applying the cosine law to $\Delta o_1 u o_1'$ (see Figure 5.1(b)),

$$d(o_1, o_1') = \sqrt{1 + 1 - 2\cos\delta} = 2\sin(\delta/2) \le \delta. \tag{5.1}$$

Therefore, $\Delta(\Pi', \Pi) \le 2\delta$.

In the following we prove the lemma for the case when Π is a C^+LC^- type path; the other case, when Π is a C^-LC^+ type path, is symmetric. Let p (resp., q) be the initial (resp., final) point of the L-segment of Π, i.e., it is the point at which the common tangent of C_1^+ and C_2^- touches C_1 (resp., C_2). Let s be the point on C_1 such that $so_1 \perp o_1o_2$ and $\angle so_1p < \pi/2$, and let S be the position on C_1 corresponding to s, i.e., $\textsc{loc}(S) = s$ and $\textsc{vec}(S)$ is the orientation of the tangent to C_1 (assuming that C_1 is clockwise oriented) at s. We define a similar point t and position T on

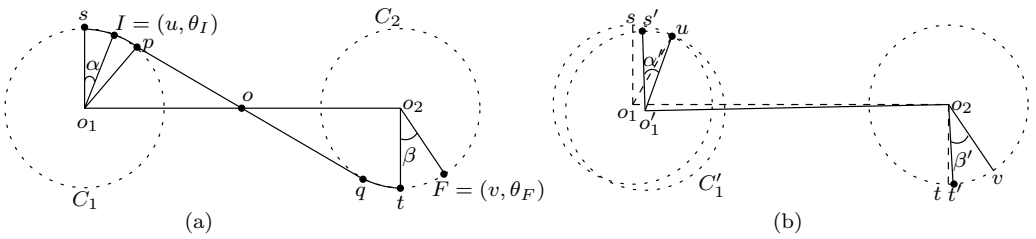

FIG. 5.1. *Bounding the difference in path length for CLC paths.*

C_2; see Figure 5.1(a). Instead of considering Π, we consider the C^+LC^- path from S to T and let ρ be the length of this path. Let $\alpha = \angle so_1u \in [-\angle po_1s, 2\pi - \angle po_1s)$ and $\beta = \angle to_2v \in [-\angle qo_2t, 2\pi - \angle qo_2t)$, measured in the counter-clockwise direction. Then

$$\|\Pi\| = \rho + \alpha + \beta;$$

see Figure 5.1(a). We define ρ', α', and β' corresponding to Π'. Then $\|\Pi'\| = \rho' + \alpha' + \beta'$, and

$$\Delta(\Pi', \Pi) \leq |\rho' - \rho| + |\alpha' - \alpha| + |\beta' - \beta|. \tag{5.2}$$

We first bound $|\alpha' - \alpha|$. Applying the sine law to $\triangle o_1o_2o'_1$,

$$\frac{\sin \angle o_1o_2o'_1}{d(o_1, o'_1)} = \frac{\sin \angle o'_1o_1o_2}{d(o_1, o_2)}.$$

Therefore $\sin \angle o_1o_2o'_1 \leq d(o_1, o'_1)/d(o_1, o_2)$. Using (5.1), the fact that $d(o_1, o_2) \geq 2$, and the inequality $\sin^{-1} x \leq 2x$ for any $0 \leq x \leq 1$, we obtain

$$\angle o_1o_2o'_1 \leq \sin^{-1} \frac{\delta}{2} \leq \delta.$$

Let w be the intersection point of lines supporting the segments so_1 and $s'o'_1$. Since $so_1 \perp o_1o_2$ and $s'o'_1 \perp o'_1o_2$, $\angle o_1wo'_1 = \angle o_1o_2o'_1 \leq \delta$; see Figure 5.2. Moreover,

$$\alpha' + \angle o_1uo'_1 = \alpha + \angle o_1wo'_1,$$

and therefore,

$$|\alpha' - \alpha| \leq \angle o_1uo'_1 + \angle o_1wo'_1 \leq 2\delta. \tag{5.3}$$

Similarly, we can show that $|\beta' - \beta| = 2\delta$.

Next, we bound $|\rho' - \rho|$. Notice that

$$\rho = 2\left(d(o, p) + \|C_1[s, p]\|\right).$$

Let $\mu = d(o_1, o) = d(o_1, o_2)/2$; then $\angle so_1p = \angle poo_1 = \sin^{-1}(1/\mu)$, and we have

$$\rho = 2\left(\sin^{-1}\left(\frac{1}{\mu}\right) + \sqrt{\mu^2 - 1}\right).$$

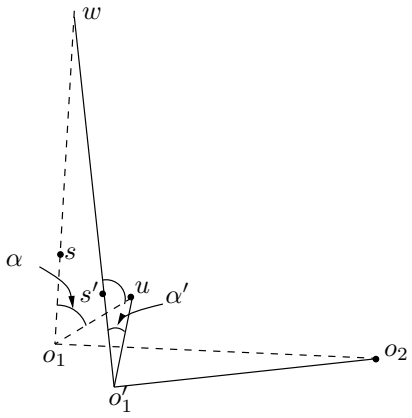

FIG. 5.2. *Bounding* $|\alpha' - \alpha|$.

Similarly, if we let $\nu = d(o_1', o_2)/2$, then

$$\rho' = 2\left(\sin^{-1}\left(\frac{1}{\nu}\right) + \sqrt{\nu^2 - 1}\right).$$

As in (5.1), $d(o_1', o_1) \leq \delta$, which implies that $|\nu - \mu| \leq \delta/2 \leq \delta$. Consider the function

$$f(x) = \sin^{-1}\left(\frac{1}{x}\right) + \sqrt{x^2 - 1}.$$

Then $|\rho' - \rho| = 2|f(\nu) - f(\mu)|$. Since both $f(x)$ and its derivative are monotonically increasing,

$$|\rho' - \rho| \leq 2(f(\mu + \delta) - f(\mu))$$

and $|\rho' - \rho|$ maximizes as μ tends to infinity. Using Taylor expansion, one can write

$$f(x) = x + \sum_{i=1}^{\infty} \frac{c_i}{x^{2i-1}},$$

where $|c_i|$'s are monotonically decreasing with i. Thus

$$|\rho' - \rho| \leq \lim_{\mu \to \infty} 2\left(\mu + \delta + \sum_{i=1}^{\infty} \frac{c_i}{(\mu + \delta)^{2i-1}} - \left(\mu + \sum_{i=1}^{\infty} \frac{c_i}{\mu^{2i-1}}\right)\right) = 2\delta. \tag{5.4}$$

Combining together (5.3) and (5.4), we obtain that

$$\Delta(\Pi', \Pi) \leq 6\delta = O(\delta).$$

If I is located in the interior of an obstacle edge, then $\|\text{LOC}(I') - \text{LOC}(I)\| = \delta$. Let o_1' be the same as defined before. Notice that $d(o_1, o_1') = \delta$. If Π is of C^+LC^+ or C^-LC^- type,

$$\Delta(\Pi', \Pi) = |d(o_1, o_2) - d(o_1', o_2)| < d(o_1, o_1') = \delta.$$

If Π is a C^+LC^- or C^-LC^+ path, we also bound the difference in path lengths by

$$\Delta(\Pi', \Pi) \leq |\rho' - \rho| + |\alpha' - \alpha| + |\beta' - \beta|,$$

where the notations are the same as defined before. It will be easy to see that $|\alpha' - \alpha| = \angle o_1 o_2 o_1'$. If we look at the triangle $\triangle o_1 o_2 o_1'$, using the facts that $d(o_1, o_1') = \delta$ and $d(o_1, o_2) \geq 2$, we can derive that $\angle o_1 o_2 o_1' \leq \delta$ as we did earlier for the case in which $\text{LOC}(I)$ is an obstacle vertex. Therefore, $|\alpha' - \alpha| \leq \delta$. Similarly, $|\beta' - \beta| \leq \delta$. Again using the fact that $d(o_1', o_1) = \delta$, $|\rho' - \rho| \leq 2\delta$ can be shown in a way similar to the one given above. This completes the proof of the lemma. □

LEMMA 5.2. *Let φ_1 and φ_2 be two obstacle features, and let Π be a CCC path from a position I on φ_1 to a position F on φ_2. Let I' and F' be positions on φ_1 and φ_2, respectively, such that $\Delta(I', I) = \delta_I$ and $\Delta(F', F) = \delta_F$ for any reals $0 \leq \delta_I, \delta_F \leq 1$. Let Π' be the path from I' to F' of the same type as Π. If Π and Π' are neighbors, then*

$$\Delta(\Pi', \Pi) = O(\sqrt{\delta_I} + \sqrt{\delta_F}).$$

Proof. As in the proof of Lemma 5.1, we need only to prove the lemma for the case in which $\delta_I > 0$ and $\delta_F = 0$. Let $\delta = \delta_I$. We assume that I is located at an obstacle vertex; thus $\text{LOC}(I') = \text{LOC}(I)$ and $|\text{VEC}(I') - \text{VEC}(I)| = \delta$. We prove the lemma for the case when Π is a $C^-C^+C^-$ path; the other case, when Π is a $C^+C^-C^+$ path, is symmetric.

Let p (resp., q) be the initial (resp., final) location of the path Π. Let o_i be the center of the unit circle containing the ith C-segment of Π. Consider the triangle $\Delta o_1 o_2 o_3$; see Figure 5.3(a). Without loss of generality, assume that $p, q \notin \triangle o_1 o_2 o_3$; other cases can be handled similarly. Let b_i be the angle of the triangle at o_i. Then

$$\begin{aligned}
\|\Pi\| &= b_1 + \angle p o_1 o_3 + 2\pi - b_2 + b_3 + \angle o_1 o_3 q \\
&= (b_1 + b_3) + 2\pi - b_2 + \angle p o_1 o_3 + \angle o_1 o_3 q \\
&= \pi - b_2 + 2\pi - b_2 + \angle p o_1 o_3 + \angle o_1 o_3 q \\
&= 3\pi - 2b_2 + \angle p o_1 o_3 + \angle o_1 o_3 q.
\end{aligned}$$

Let o_1', o_2', and o_3 be the centers of circles containing the C-segments of Π'. Notice that $\angle o_1' p o_1 = \delta$; see Figure 5.3(b). Let o_3' be the intersection point of the line supporting the segment $o_1' p$ and the line supporting the segment $o_2' o_3$; assume that o_1' is situated so that o_3 lies between o_2' and o_3', and consider the triangle $\Delta o_1' o_2' o_3'$. Let r_i be the angle of the triangle at o_i' and $\gamma = \angle o_2' o_3 o_1 - r_3$ (see Figure 5.3). Then

$$\begin{aligned}
\|\Pi'\| &= r_1 + 2\pi - r_2 + \angle o_2' o_3 o_1 + \angle o_1 o_3 q \\
&= r_1 + 2\pi - r_2 + r_3 + \gamma + \angle o_1 o_3 q \\
&= r_1 + 2\pi - r_2 + r_3 + \angle o_1' p o_1 + \angle p o_1 o_3 + \angle o_1 o_3 q \\
&= (r_1 + r_3) + 2\pi - r_2 + \delta + \angle p o_1 o_3 + \angle o_1 o_3 q \\
&= 3\pi - 2r_2 + \delta + \angle p o_1 o_3 + \angle o_1 o_3 q.
\end{aligned}$$

Thus

$$\Delta(\Pi', \Pi) = |\delta + 2b_2 - 2r_2| \leq \delta + 2|b_2 - r_2|.$$

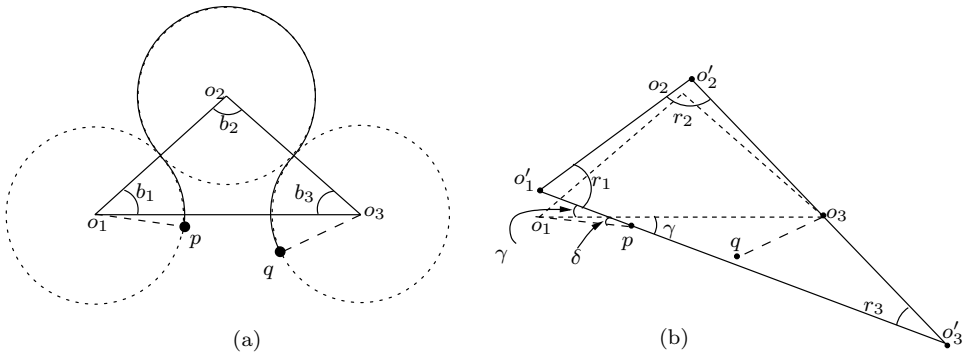

FIG. 5.3. *Bounding the difference in path length for CCC paths.*

Let $\rho = d(o_1, o_3)$ and $\rho' = d(o_1', o_3)$. Applying the cosine law to $\Delta o_1 o_2 o_3$ and $\Delta o_1' o_2' o_3$, and using the fact that $d(o_1, o_2) = d(o_2, o_3) = d(o_1', o_2') = d(o_2', o_3) = 2$, we obtain

$$b_2 = \cos^{-1}\left(\frac{2^2 + 2^2 - \rho^2}{2 \cdot 2 \cdot 2}\right) = \cos^{-1}\left(1 - \frac{\rho^2}{8}\right),$$
$$r_2 = \cos^{-1}\left(\frac{2^2 + 2^2 - \rho'^2}{2 \cdot 2 \cdot 2}\right) = \cos^{-1}\left(1 - \frac{\rho'^2}{8}\right).$$

Define a function

$$f(x) = \cos^{-1}\left(1 - \frac{x^2}{8}\right).$$

Then $|b_2 - r_2| = |f(\rho) - f(\rho')|$. Since $f(x)$ is monotonically increasing for $x \geq 0$,

$$|b_2 - r_2| \leq f(\rho) - f(\rho - \delta).$$

Moreover,

$$\frac{df}{dx} = 1 \Big/ \sqrt{4 - \frac{x^2}{4}}$$

is also monotonically increasing for $x \geq 0$ and $\rho \leq 4$; therefore, $|b_2 - r_2|$ maximizes at $\rho = 4$. Thus

$$\begin{aligned}
|b_2 - r_2| &\leq \cos^{-1}\left(1 - \frac{4^2}{8}\right) - \cos^{-1}\left(1 - \frac{(4-\delta)^2}{8}\right) \\
&\leq \pi - \cos^{-1}(-1 + \delta) \\
&= \pi - 2\cos^{-1}\left(\sqrt{\frac{\delta}{2}}\right) \\
&\leq \pi - 2\left(\frac{\pi}{2} - \sin^{-1}\sqrt{\frac{\delta}{2}}\right) \\
&= 2\sin^{-1}\sqrt{\frac{\delta}{2}} \leq 2\sqrt{2\delta}.
\end{aligned}$$

The last inequality follows froms the fact that $\sin^{-1}(x/2) \le x$ if $x \le 1$. Since $\delta \le 1$, the above inequalities hold.

For $\delta \le 1$, $\delta < \sqrt{\delta}$, and therefore,

$$\Delta(\Pi', \Pi) \le \delta + 2|b_2 - r_2| \le \sqrt{\delta} + 4\sqrt{2}\sqrt{\delta} = (4\sqrt{2}+1)\sqrt{\delta},$$

as desired. ∎

Remark 5.3. (i) Notice that $\Delta(\Pi, \Pi') = O(\sqrt{\delta})$ only if the distance between the centers o_1 and o_3 is almost 4. If $d(o_1, o_3) \le 4 - c$ for some constant $c > 0$, then $\Delta(\Pi, \Pi') \approx \delta/\sqrt{c}$.

(ii) Let φ_I, φ_F be two obstacle features, and for $i = 1, 2$, let Π_1 be a path from a position I_i on φ_I to a position F_i on φ_F. If $\Delta(I_1, I_2), \Delta(F_1, F_2) \le \delta$ for some $\delta < 1$ and Π_1 and Π_2 are neighbors, then the analysis in this section implies Π_2 lies in a tube of width $O(\sqrt{\delta})$ around Π_1.

5.2. Goodness of our approximation.

LEMMA 5.4. *Let $\delta = c\varepsilon^2$, where c is a sufficiently small constant. If there exists an optimal path Π from I to F that is δ-robust, then there exists a path from I to F in the graph G computed in section 4 whose length is at most $(1+\varepsilon)\|\Pi\|$.*

Proof. Let $\Pi = \Pi_1 \| \dots \| \Pi_k$, where each Π_i is a Dubins path of type $\sigma_i \in \mathcal{T}$ from a position X_{i-1} to a position X_i, such that $X_0 = I$, $X_k = F$, and $\text{LOC}(X_i) \in \partial\Omega$ for $0 < i < k$. Since Π is δ-robust, there exist $\chi_0, \dots, \chi_k \in \{+, -\}$ so that Π_i is $\delta^{\chi_{i-1}\chi_i}$-robust. Then, by Lemma 4.2 and the robustness of Π_i, there exist graph nodes $Y_i^{\chi_i}$ for $0 \le i \le k$ such that $\Delta(X_i, Y_i^{\chi_i}) \le \delta$ and such that the Dubins path from $Y_i^{\chi_i}$ to $Y_{i+1}^{\chi_{i+1}}$ of type σ_i is feasible. Therefore, there is an edge from $Y_i^{\chi_i}$ to $Y_i^{\chi_{i+1}}$ in G. Let Π_i' be the path corresponding to this edge in G. $\Pi' = \Pi_1' \| \dots \| \Pi_k'$ is the desired path from I to F in G. To prove the lemma, it suffices to show that $\|\Pi_i'\| \le (1+\varepsilon)\|\Pi_i\|$ for $1 \le i \le k$, provided we choose $\delta = c\varepsilon^2$ small enough.

If Π_i is a CLC path, by Lemma 5.1, $\Delta(\Pi_i', \Pi_i) \le O(\delta)$. Since Π_i is an ε-robust path, its length is at least ε. Therefore,

$$\|\Pi_i'\| \le \|\Pi_i\| + O(\delta) \le \|\Pi_i\| + \varepsilon^2 \le (1+\varepsilon)\|\Pi_i\|,$$

provided the constant c is chosen sufficiently small. If Π_i is a CCC path, by Lemma 5.2, $\Delta(\Pi_i', \Pi_i) \le O(\sqrt{\delta})$. But the length of a CCC path is at least π; therefore,

$$\|\Pi_i'\| \le \|\Pi_i\| + O(\sqrt{\delta}) \le \|\Pi_i\| + \varepsilon \le \left(1 + \frac{\varepsilon}{\pi}\right)\|\Pi_i\| \le (1+\varepsilon)\|\Pi_i\|,$$

provided c is chosen small enough. This completes the proof of the lemma. ∎

Plugging $\delta = O(\varepsilon^2)$ in Theorem 4.8, we obtain the following result.

THEOREM 5.5. *Given a polygonal obstacle environment Ω, an initial position I, a final position F, and a parameter ε, so that there exists an optimal path from I to F that is ε-robust. We can compute in time $O((n^2/\varepsilon^4)\log n)$ a feasible path from I to F whose arc length is at most $(1+\varepsilon)$ times the length of an optimal path.*

Remark 5.6. Recall that the running time of the algorithm is $O((n^2/\varepsilon^4)\log n)$ because we choose $\delta = O(\varepsilon^2)$, and the graph G has $O((n/\delta))$ vertices and in the worst-case every pair of vertices is connected by an edge. If the distance between the centers of initial and final circles of CCC type paths for most pairs of vertices is not close to 4, one can show that it suffices to add edges between $O((n^2/\delta)\log(1/\delta))$ pairs of vertices, and that these pairs can be computed in time $O((n^2/\delta^2)\log(1/\delta))$. In this case the time complexity improves to $O((n^2/\varepsilon^2)\log n \log(1/\varepsilon))$.

6. Computing near optimal robust paths. The path computed by the above algorithm is not necessarily robust because some of the edges in G may not correspond to robust paths. We can compute a graph $G' = (V, E')$, where E' is the set of edges corresponding to $(\varepsilon/2)$-robust paths. An easy argument shows that if δ is chosen correctly, there is an $(\varepsilon/2)$-robust path in G whose length is at most $(1+\varepsilon)$ times the length of an optimal path from I to F if the optimal path is ε-robust.

Next we show that E' can be computed in $O((n^{2.5}/\varepsilon^4)\log n)$ time. For each pair of positions $X, Y \in V$, we compute all $O(1)$ Dubins paths from X to Y, check which of them are $(\varepsilon/2)$-robust, and select the one with the minimum arc length. Recall that a canonical Dubins path is δ-robust if it is $\delta^{\chi\chi'}$-robust for some $\chi, \chi' \in \{-, +\}$. We will show how to determine which of the Dubins paths are $(\varepsilon/2)^{++}$-robust.

Let $\Pi = (\tau_1, \tau_2, \sigma)$ be a canonical Dubins path from an obstacle feature ϕ_1 to another obstacle feature ϕ_2. Let $[\alpha_i, \beta_i]$ denote the feasible domain of ϕ_i for $i = 1, 2$, and let $r_i = \min\{\tau_i + \varepsilon/2, \beta_i\}$. Set $R_\Pi = \{(\tau_1', \tau_2', \sigma) \mid \tau_i \le \tau_i' \le r_i\}$ to be the rectangle in the configuration space. Π is $(\varepsilon/2)^{++}$-robust if R_Π does not contain a singular or infeasible point in its interior. We can check in $O(1)$ time whether R_Π contains a singular point, so it suffices to check whether R_Π contains any infeasible point. Let γ_Π be the union of paths (regarding each path as a set of points) corresponding to the points in R_Π, i.e., the area swept by the paths $(\tau_1', \tau_2', \sigma)$, as we vary $\tau_i' \in [\tau_i, r_i]$. Roughly speaking, γ_Π is the union of at most three regions, each of which is the area swept by a line segment or a circular arc as it moves along an algebraic arc of constant degree. Therefore, the boundary of γ_Π consists of $O(1)$ x-monotone algebraic arcs, each of $O(1)$ degree, and they can be computed in $O(1)$ time. R_Π does not contain any infeasible point if and only if γ_Π does not intersect the interior of Ω. Since the endpositions of Π lie on the obstacle boundary, γ_Π intersects the interior of any obstacle if and only if any of the obstacle edges intersect the interior of γ_Π. We thus have the following intersection-detection problem at hand: Let $\Gamma = \{\gamma_1, \ldots, \gamma_m\}$ be a set of m regions, each of whose boundary consists of $O(1)$ algebraic arcs of constant degrees, and let S be a set of n disjoint line segments in the plane. Report all regions in Γ whose interiors do not intersect any segment of S. We present an $O((m\sqrt{n} + n)\log n)$-time algorithm to report such a subset. Since $m = O(n^2/\varepsilon^4)$ in our case, we conclude that we can compute all $(\varepsilon/2)$-robust paths in time $O((n^{2.5}/\varepsilon^4)\log n)$.

We now present an algorithm for the intersection-detection problem just described. It suffices to describe an $O(n \log n)$-time algorithm for the case when $m = \sqrt{n}$, for otherwise we can partition Γ into $\lceil m/\sqrt{n} \rceil$ subsets, $\Gamma_1, \ldots, \Gamma_s$, each of size at most $\sqrt{n}$, and solve the intersection-detection problem for each Γ_i and S separately. The total running time is obviously $O((m\sqrt{n} + n)\log n)$.

Let E be the set of x-monotone arcs bounding the regions in Γ. A segment $e \in S$ intersects the interior of a region $\gamma \in \Gamma$ if at least one of the following two conditions is satisfied. (i) An endpoint of e lies in the interior of γ, or (ii) e intersects the boundary of γ. It is possible to check both of these conditions for all regions in Γ in $O(n \log n)$ time, using a single sweep-line algorithm. But for the sake of clarity, we explain how to check each of the two conditions separately. The first condition can be checked in $O(n \log n)$ time by a variant of the batched point-location algorithm by Preparata [42]. It basically sweeps a vertical line from left to right and maintains the subset of regions that intersect the sweep-line. Whenever the sweep-line encounters an endpoint p of S, it reports and deletes all the regions of Γ whose interior contains p. These steps can be implemented efficiently using interval trees or segment trees [5]. We omit the rather easy and standard details from here. The total running time of

the algorithm is $O((m^2 + n + k)\log(m + n))$, where k is the number of regions in Γ that contain an endpoint of S. Since $m = \sqrt{n}$, and each region of Γ is a semialgebraic region of constant description complexity, $k = O(m) = O(\sqrt{n})$. Hence, the total time spent is $O(n \log n)$.

Next, we explain how to detect condition (ii). This can be done by modifying the Bentley–Ottman [4] algorithm for segment-intersection reporting, as follows. We sweep a vertical line from left to right and store the arcs of $E \cup S$ intersecting the sweep-line in a height balanced tree T, sorted in y-direction. The algorithm maintains the invariant that none of the arcs of E intersecting the sweep-line intersects any segment of S to the left of the sweep line. A region γ is deleted from Γ as soon as we detect an intersection between $\partial\gamma$ and S; all the boundary arcs of γ are deleted from E as well. The sweep-line stops at the endpoints of $E \cup S$ and the intersection points of arcs in E. At the left (resp., right) endpoint of an arc $e \in E$, we insert e into T (resp., delete e from T). We do the same at the endpoints of S. At an intersection point σ of two arcs $\rho_1, \rho_2 \in E$, we swap the order of ρ_1 and ρ_2 in T. Whenever one of the adjacent element of an active arc $\rho \in E$ changes (because of insertion, deletion, or swapping of two arcs), we check whether the new adjacent element is a segment $e \in S$. If e and ρ intersect, we delete ρ from E and T. Let γ be the region bounded by ρ. We report and delete γ from Γ, and we delete all the edges bounding γ. Note that deletion of these arcs from T may change the adjacent elements of other arcs stored in T, so we have to check for their intersections, but this time can be charged to the arcs deleted. Since each arc of Γ is deleted only once and there are $m = \sqrt{n}$ arcs, the total time spent in this step is $O(\sqrt{n}\log(m + n))$. The sweep-line stops in at most $O(m^2 + n)$ points; hence the overall time spent is also $O(n \log n)$. Putting all the steps together, we obtain the following theorem.

THEOREM 6.1. *Given a polygonal obstacle environment Ω, an initial position I, a final position F so that there exists an optimal path from I to F that is robust, and a parameter ε, we can compute in time $O((n^{2.5}/\varepsilon^4)\log n)$ a feasible $(\varepsilon/2)$-robust path from I to F whose arc length is at most $(1 + \varepsilon)$ times the length of an optimal path.*

7. Conclusion. In this paper we presented an efficient and simple approximation algorithm for computing a curvature-constrained shortest path. The main ingredients of our algorithm are a stronger characterization of curvature-constrained shortest paths, by exploiting their geometry, and a fast and simple algorithm for constructing the graph. We conclude this paper by suggesting a few open problems.

(i) Can one improve the running time of our algorithm to almost linear? Since we are interested only in computing approximate shortest paths, it may be sufficient to construct a small subset of the edges of G. Such techniques have been used to compute approximate unconstrained shortest paths amid obstacles, e.g., [16].

(ii) How fast can one compute an approximate curvature-constrained shortest path in 3-space, especially in view of the recent result by Sussmann [49]?

(iii) Can one develop simple and efficient algorithms for more general constraints, exploiting the geometry of paths?

Acknowledgments. The authors thank John Reif for valuable discussions and Sylvian Lazard and an anonymous referee for several useful comments and for pointing out a few errors in an earlier version of the paper.

ON BIPARTITE DRAWINGS AND THE LINEAR ARRANGEMENT PROBLEM*

FARHAD SHAHROKHI†, ONDREJ SÝKORA‡, LÁSZLÓ A. SZÉKELY§, AND IMRICH VRŤO¶

Abstract. The bipartite crossing number problem is studied and a connection between this problem and the linear arrangement problem is established. A lower bound and an upper bound for the optimal number of crossings are derived, where the main terms are the optimal arrangement values. Two polynomial time approximation algorithms for the bipartite crossing number are obtained. The performance guarantees are $O(\log n)$ and $O(\log^2 n)$ times the optimal, respectively, for a large class of bipartite graphs on n vertices. No polynomial time approximation algorithm which could generate a provably good solution had been known. For a tree, a formula is derived that expresses the optimal number of crossings in terms of the optimal value of the linear arrangement and the degrees, resulting in an $O(n^{1.6})$ time algorithm for computing the bipartite crossing number.

The problem of computing a maximum weight biplanar subgraph of an acyclic graph is also studied and a linear time algorithm for solving it is derived. No polynomial time algorithm for this problem was known, and the unweighted version of the problem had been known to be NP-hard, even for planar bipartite graphs of degree at most 3.

Key words. bipartite drawing, bipartite crossing number, biplanar graph, linear arrangement, approximation algorithms

1. Introduction.

The crossing number problem calls for placing the vertices of a graph in the plane and drawing the edges with Jordan curves, so that the number of edge crossings is minimized. This problem has been extensively studied in graph theory [27], combinatorial geometry [17], and theory of VLSI [12]. Moreover, this problem has also been studied by the graph drawing community, since one of the most important aesthetic objectives in graph drawing is reducing the number of crossings [18]. In this paper we study the *bipartite crossing number* problem which is an important variation of the crossing number problem. The problem of obtaining drawings of graphs on multiple layers with a small number of edge crossings frequently

arises in graph drawing and the design of VLSI [3, 4, 14, 24]. When the number of layers is two, the underlying problem is called the *bipartite drawing* or the *two-layer drawing* problem. Throughout this paper $G = (V_0, V_1, E)$ denotes a connected bipartite graph, where V_0, V_1 are the two classes of independent vertices, and E is the edge set. We will assume that $|V_0 \cup V_1| = n$ and $|E| = m$. A bipartite drawing of G consists of placing the vertices of V_0 and V_1 into distinct points on two parallel lines and then drawing each edge using a straight line segment connecting the points representing the endvertices of the edge. Let $bcr(G)$ denote the *bipartite crossing number* of G, that is, $bcr(G)$ is the minimum number of edge crossings over all bipartite drawings of G.

Computing $bcr(G)$ is NP-hard [8] even when the ordering of vertices in V_0 is fixed [4]. Integer programming methods for computing $bcr(G)$ have been studied by various researchers [10, 15, 26]. These methods, however, do not guarantee polynomial time running times. Moreover, although a polynomial time approximation algorithm with the performance guarantee of $O(\log^4 n)$ times the optimal is known for the crossing number of degree bounded graphs [13], no polynomial time approximation algorithm whose performance is guaranteed has been known for approximating $bcr(G)$. A nice result in this area is a fast polynomial time algorithm which approximates the bipartite crossing number by a factor of 3, when the positions of vertices in V_0 are fixed [4].

In this paper we explore an important relationship between the bipartite crossing number problem and the linear arrangement problem which is another well-known problem in the theory of VLSI [1, 2, 11, 23]. Let δ_G denote the minimum degree of G, a_G denote the arboricity of G, i.e., the minimum number of acyclic graphs that G can be decomposed to, and let $L(G)$ denote the optimal value for the linear arrangement problem. We show (Theorem 3.3) that $bcr(G)$ plus the sum of the square of degrees in G is $\Omega(\delta_G L(G))$. Moreover, we show (Theorem 3.6) that $bcr(G)$ is $O(a_G L(G))$. Our general method for constructing the upper bound is shown to provide for an optimal solution and an exact formula, resulting in an $O(n^{1.6})$ time algorithm for computing $bcr(G)$ when G is a tree (Theorem 5.1). A direct consequence of our results is to obtain the first polynomial time approximation algorithm for $bcr(G)$ with a performance guarantee of $O(\log n)$ from the optimal for a large class of graphs. This class contains all regular graphs, all degree bounded graphs, and all genus bounded graphs, provided that these graphs are not too sparse. We also obtain a polynomial time divide and conquer approximation algorithm in which the divide phase approximately separates the graph, and show that it has the performance guarantee of $O(\log^2 n)$ from the optimal for a variety of graphs. Both algorithms produce drawings in which the coordinates of all vertices are integers so that the sums of edge lengths are also provably near-optimal, with the same approximation factors as for the number of edge crossings. This property of our drawings makes them very appealing to the graph drawing and theory of VLSI.

We also settle the open problem of computing a largest *biplanar* subgraph of an acyclic graph in polynomial time. A bipartite graph $G = (V_0, V_1, E)$ is called a *biplanar* graph if it has a bipartite drawing in which no two edges cross each other. It is known that the problem of determining a largest biplanar subgraph is NP-hard, even when G is planar and the vertices in V_0 and V_1 have degrees at most 3, and at most 2, respectively [5]. No polynomial time algorithm for solving this problem on acyclic graphs had been known, and the proposed heuristics for computing a large biplanar subgraph of an acyclic graph such as the one in [25] would not necessarily compute a largest one. Thus, the question of whether or not a largest biplanar subgraph of an

acyclic graph can be computed in polynomial time had been an open one. Indeed, since the NP-hardness result was shown for very sparse planar graphs [5], it was suggesting that the problem may also be NP-hard for acyclic graphs. Surprisingly, in this paper we present a linear time algorithm for solving the weighted version of this problem in any acyclic graph (Theorem 6.2). The weighted version was first introduced in [15].

Section 2 contains preliminaries and the basic notations. Section 3 contains our main results and explores the relation between $bcr(G)$ and the linear arrangement problem. Section 4 contains the applications and includes several observations on the separator based lower bounds and also contains the approximation algorithms for $bcr(G)$. In particular, a lower bound of $\Omega(\delta_G n b_\beta(G))$ for $bcr(G)$ is derived, where $b_\beta(G)$, $\beta < 1/2$ is the size of the β-separator in G. This lower bound is crucial in verifying the performance guarantee of the divide and conquer algorithm. Section 5 contains our result regarding the bipartite crossing number of a tree T which is expressed exactly in terms of $L(T)$ and the degrees of the vertices, resulting in an $O(n^{1.6})$ time algorithm for computing $bcr(T)$. Finally, section 6 contains our linear time algorithm for computing a largest biplanar subgraph of an acyclic graph.

2. Preliminaries. With the exception of section 6 we consider the connected graphs only under the term graph. Let $G = (V_0, V_1, E)$, $V = V_0 \cup V_1$, and $v \in V$. We denote by d_v the degree of v, and denote by d_v^* the number of vertices of degree 1 which are adjacent to v. We denote by δ_G the minimum degree of G. A bipartite drawing of G is obtained by placing the vertices of V_0 and V_1 into distinct points on two horizontal lines y_0, y_1, respectively, and drawing each edge with one straight line segment. We will assume that y_0 is the line $y = 0$ and y_1 is the line $y = 1$. Any bipartite drawing of G is identified by a coordinate function $h : V_0 \cup V_1 \to \mathbb{R}$, where for any $v \in V_0 \cup V_1$, $h(v)$ is the x coordinate of the vertex v in the drawing. If h is a coordinate function of a bipartite drawing, then the restrictions $h_{|_{V_0}}$ and $h_{|_{V_1}}$ are injections and determine the order in which the vertices are placed on the lines y_0 and y_1, respectively. Conversely, any function $h : V_0 \cup V_1 \to \mathbb{R}$, whose restrictions to V_0 and V_1 are injections, gives rise to a bipartite drawing whose coordinate function is h. Throughout this paper we do not distinguish between a bipartite drawing and its coordinate function and refer to a drawing by referring to its coordinate function.

Let h be a bipartite drawing of $G = (V_0, V_1, E)$. For any $e \in E$, let $bcr_h(e)$ denote the number of crossings of the edge e with other edges. Let $bcr(h)$ denote the total number of edge crossings in h, i.e., $bcr(h) = \frac{1}{2}\sum_e bcr_h(e)$. The bipartite crossing number of G, denoted by $bcr(G)$, is the minimum number of edge crossings over all bipartite drawings of G. Clearly, $bcr(G) = \min_h bcr(h)$.

Given an arbitrary graph $G = (V, E)$, and a function $f : V \to \mathbb{R}$, define the *length* of f, denoted by L_f, to be

$$\sum_{uv \in E} |f(u) - f(v)|.$$

The *linear arrangement* problem is to determine a bijection $f : V \to \{1, 2, 3, \ldots, |V|\}$ of minimum length. This minimum value whose computation is NP-hard [8] will be denoted by $L(G)$. Let h be a bipartite drawing of $G = (V_0, V_1, E)$. Note that the *length* of h, denoted by L_h, is defined as

$$\sum_{uv \in E} |h(u) - h(v)|.$$

Let h be a bipartite drawing of $G = (V_0, V_1, E)$, and let $u_1, u_2, \ldots, u_{d_v}$ be the neighbors of a vertex $v \in V_1$ satisfying $h(u_1) < h(u_2) < \cdots < h(u_{d_v})$. Define the *median vertex* of v, denoted by $med(v)$, to be $u_{\lfloor \frac{d_v}{2} \rfloor}$ if $d_v \geq 2$, and to be u_1 if $d_v = 1$ [4]. We say that h has the *median property* if the following properties hold:

(i) h is an injection;
(ii) $h(V_0) = \{1, 2, \ldots, |V_0|\}$;
(iii) $h(med(v)) + \epsilon \geq h(v) > h(med(v))$, for any $v \in V_1$, where the value of ϵ is positive but "infinitesimally small";
(iv) if $med(x) = med(y)$ for $x \in V_1$ of odd degree and $y \in V_1$ of even degree, then $h(x) < h(y)$.

If a bipartite drawing h does not have the median property, then it can be converted to a drawing which has the property using a process which is called the *median construction*. This process consists of placing the vertices of V_0 in the same order in which they appear in h into the locations $(1, 0), (2, 0), \ldots, (|V_0|, 0)$, and then placing each $v \in V_1$ on a proper position so that the median property holds. Eades and Wormald [4] showed the following remarkable result.

THEOREM 2.1 (see [4]). *Let h be a bipartite drawing of $G = (V_0, V_1, E)$. If h' is obtained from h by the application of the median construction, then*

$$bcr(h') \leq 3bcr(h).$$

3. Linear arrangement and bipartite crossings. In this section we explore the relationship between $bcr(G)$ and $L(G)$.

3.1. Lower bounds. Let h be a bipartite drawing of $G = (V_0, V_1, E)$. Let $e = ab \in E$, and let u be a vertex in $V_0 \cup V_1$ so that $u \notin \{a, b\}$. We say e *covers* u in h if the line parallel to the y axis passing through u has a point in common with the edge e. Note that for any $e = ab$, $a \in V_0, b \in V_1$, neither a nor b are covered by e. However, a vertex $c \in V_1$ with $h(c) = h(a)$ is covered by e. Let $N_h(e)$ denote the number of those vertices in V_1 which are covered by e in h. We will use the following two lemmas later.

LEMMA 3.1. *Let h be a bipartite drawing of $G = (V_0, V_1, E)$.*

(i) *Assume that for any $v \in V_0$, $h(v)$ is an integer. Then there is a bijection $f^* : V_0 \cup V_1 \to \{1, 2, \ldots, n\}$ so that for any $e = ab \in E$*

$$|f^*(a) - f^*(b)| \leq N_h(e) + |h(a) - h(b)| + 1.$$

(ii) *Assume that h has the median property. Then the bijection f^* that satisfies* (i) *also satisfies*

$$L_{f^*} \leq \frac{8bcr(h)}{\delta_G} + L_h + \sum_{a \in V_0} d_a d_a^* + m.$$

Proof. To prove (i), we construct f^* by moving all vertices in V to integer locations. Formally, let $w_1, w_2, \ldots, w_n$ be the order of vertices of $V_0 \cup V_1$ such that $h(w_1) \leq h(w_2) \leq \cdots \leq h(w_n)$. Define $f^*(w_i) = i$, $1 \leq i \leq n$; then (i) easily follows.

For (ii), let $e = ab \in E$, $a \in V_0, b \in V_1$. Consider the case $h(a) > h(b)$. Let $v \in V_1$ be covered by e in h. If $d_v = 1$, then v generates one crossing on e, since v and $med(v)$ are separated by the line segment e in h. On the other hand, if $d_v \geq 2$, then at least $\lfloor d_v/2 \rfloor \geq d_v/4$ of vertices adjacent to v are separated from v in h by the straight line

segment e, since h has the median property. We conclude that any $v \in V_1$ which is covered by e generates at least $\delta_G/4$ crossings on e. Thus, $bcr_h(e) \geq N_h(e)\frac{\delta_G}{4}$.

Now consider the case that $h(a) < h(b)$, and let $v \in V_1$ be a vertex covered by e. Then v generates at least $d_v - \lfloor \frac{d_v}{2} \rfloor \geq d_v/2$ crossings on e provided that v is not a vertex of degree 1 which is adjacent only to a. Consequently, in this case, $bcr_h(e) \geq (N_h(e) - d_a^*)\delta_G/2$.

We conclude that in either case, $bcr_h(e) \geq \frac{1}{4}(N_h(e) - d_a^*)\delta_G$, and hence $N_h(e) \leq \frac{4bcr(e)}{\delta_G} + d_a^*$. Consequently, using (i),

$$|f^*(a) - f^*(b)| \leq \frac{4bcr(e)}{\delta_G} + d_a^* + |h(a) - h(b)| + 1.$$

To finish the proof of (ii) take the sum over all $e = ab \in E$. □

LEMMA 3.2. *Let h be a bipartite drawing of $G = (V_0, V_1, E)$. If h has the median property, then*

$$L_h \leq \epsilon + \sum_{\substack{uv \in E, u \in V_0, v \in V_1 \\ d_v \geq 2}} |h(u) - h(v)|,$$

with an arbitrary small $\epsilon > 0$.

Proof. To prove the claim, let $uv \in E$ with $v \in V_1$ so that $d_v = 1$. Since h has the median property, $med(v) = u$, and thus v is placed arbitrarily close to u in h. Therefore we may assume that $|h(v) - h(u)| \leq \frac{\epsilon}{V_1}$. Thus, the sum of the contributions of all edges which are incident to vertices of degree one in V_1 to L_h is at most $|V_1|\frac{\epsilon}{|V_1|} = \epsilon$, and the claim follows. □

We now prove the main result of this section.

THEOREM 3.3. *Let $G = (V_0, V_1, E)$; then*

$$bcr(G) + \frac{1}{12}\sum_{v \in V} d_v^2 \geq \frac{1}{36}\delta_G L(G).$$

Proof. Let h be a bipartite drawing of G. We will construct an appropriate bijection $f^* : V_0 \cup V_1 \to \{1, 2, \ldots, n\}$. Let h' be a drawing which is obtained by applying the median construction to h. Let $v \in V_1$ with $d_v \geq 2$, and let $u_1, u_2, \ldots, u_{d_v}$ be its neighbors with $h'(u_1) < h'(u_2) < \cdots < h'(u_{d_v})$. Let i be an integer, $1 \leq i \leq \lfloor d_v/2 \rfloor$, and let u be a vertex in V_0 so that $h'(u_i) < h'(u) < h'(u_{d_v - i + 1})$. Observe that u generates d_u crossings on the edges $u_i v$ and $u_{d_v - i + 1} v$ if it is not adjacent to v. Similarly, u generates $d_u - 1$ crossings on the edges $u_i v$ and $u_{d_v - i + 1} v$ if it is adjacent to v. Thus,

$$\begin{aligned} bcr_{h'}(u_i v) + bcr_{h'}(u_{d_v - i + 1} v) &\geq (h'(u_{d_v - i + 1}) - h'(u_i) - 1)\delta_G - d_v \\ &= (h'(u_{d_v - i + 1}) - h'(v) + h'(v) - h'(u_i) - 1)\delta_G - d_v. \end{aligned} \tag{3.1}$$

Note that h' has the median property; thus for $i = 1, 2, \ldots, \lfloor d_v/2 \rfloor$,

$$h'(u_i) < h'(v) < h'(u_{d_v - i + 1})$$

and hence (3.1) implies

$$\begin{aligned} bcr_{h'}(u_i v) + bcr_{h'}(u_{d_v - i + 1} v) \geq (&|h'(v) - h'(u_{d_v - i + 1})| + |h'(v) \\ &- h'(u_i)| - 1)\delta_G - d_v. \end{aligned} \tag{3.2}$$

Using (3.2) observe that for any $v \in V_1$ with $d_v \geq 2$,

$$\sum_{i=1}^{\lfloor \frac{d_v}{2} \rfloor} (bcr_{h'}(u_i v) + bcr_{h'}(u_{d_v - i+1} v))$$

$$\geq \delta_G \sum_{i=1}^{\lfloor \frac{d_v}{2} \rfloor} (|h'(v) - h'(u_i)| + |h'(v) - h'(u_{d_v-i+1})|) - \delta_G \left\lfloor \frac{d_v}{2} \right\rfloor - \left\lfloor \frac{d_v}{2} \right\rfloor d_v. \tag{3.3}$$

It follows using (3.3) that if $d_v \geq 2$ is even, then

$$\sum_{i=1}^{d_v} bcr_{h'}(u_i v) = \sum_{i=1}^{\lfloor \frac{d_v}{2} \rfloor} (bcr_{h'}(u_i v) + bcr_{h'}(u_{d_v-i+1} v))$$

$$\geq \delta_G \sum_{i=1}^{\lfloor \frac{d_v}{2} \rfloor} (|h'(v) - h'(u_i)| + |h'(v) - h'(u_{d_v-i+1})|) - \delta_G \left\lfloor \frac{d_v}{2} \right\rfloor - \left\lfloor \frac{d_v}{2} \right\rfloor d_v$$

$$= \delta_G \sum_{i=1}^{d_v} |h'(v) - h'(u_i)| - \delta_G \left\lfloor \frac{d_v}{2} \right\rfloor - \left\lfloor \frac{d_v}{2} \right\rfloor d_v. \tag{3.4}$$

Moreover, if $d_v \geq 2$ is odd, then

$$bcr_{h'}(u_{\lfloor \frac{d_v}{2} \rfloor} v) + bcr_{h'}(u_{\lceil \frac{d_v}{2} \rceil} v) \leq \sum_{i=1}^{d_v} bcr_{h'}(u_i v)$$

and

$$bcr_{h'}(u_{\lfloor \frac{d_v}{2} \rfloor} v) + bcr_{h'}(u_{\lceil \frac{d_v}{2} \rceil} v) \geq (h'(u_{\lceil \frac{d_v}{2} \rceil}) - h'(u_{\lfloor \frac{d_v}{2} \rfloor}) - 1)\delta_G,$$

where the upper bound is obvious, and the lower bound holds since no vertex adjacent to v is between $u_{\lceil \frac{d_v}{2} \rceil}$ and $u_{\lfloor \frac{d_v}{2} \rfloor}$. Consequently, if $d_v \geq 2$ is odd, then

$$\sum_{i=1}^{d_v} bcr_{h'}(u_i v) \geq bcr_{h'}(u_{\lfloor \frac{d_v}{2} \rfloor} v) + bcr_{h'}(u_{\lceil \frac{d_v}{2} \rceil} v)$$

$$\geq \delta_G |h'(v) - h'(u_{\lceil \frac{d_v}{2} \rceil})| - \delta_G,$$

where the last line is obtained by observing that $h'(u_{\lceil \frac{d_v}{2} \rceil}) > h'(v) > h'(med(v)) = h'(u_{\lfloor \frac{d_v}{2} \rfloor})$. Combining this with (3.3), for odd d_v, we obtain,

$$2\sum_{i=1}^{d_v} bcr_{h'}(u_i v) \geq \delta_G \sum_{i=1}^{d_v} |h'(v) - h'(u_i)| - \delta_G - \delta_G \left\lfloor \frac{d_v}{2} \right\rfloor - \left\lfloor \frac{d_v}{2} \right\rfloor d_v. \tag{3.5}$$

We note that since (3.5) is weaker than (3.4), it must also hold when d_v is even, and conclude by summing (3.5) over all $v \in V_1$ with $d_v \geq 2$, that

$$4bcr(h') \geq \delta_G \sum_{\substack{uv \in E, v \in V_1 \\ d_v \geq 2}} |h'(v) - h'(u)|$$

$$- \delta_G |V_1| - \delta_G \sum_{v \in V_1} \left\lfloor \frac{d_v}{2} \right\rfloor - \sum_{v \in V_1} \left\lfloor \frac{d_v}{2} \right\rfloor d_v$$

$$\geq \delta_G \sum_{\substack{uv \in E, v \in V_1 \\ d_v \geq 2}} |h'(v) - h'(u)| - 2\sum_{v \in V_1} d_v^2.$$

Using Lemma 3.2, the above inequality gives

$$4bcr(h') \geq \delta_G L_{h'} - \epsilon - 2\sum_{v\in V_1} d_v^2. \tag{3.6}$$

Since h' has the median property, the bijection f^* in Part (ii) of Lemma 3.1 satisfies

$$\delta_G L_{h'} \geq \delta_G L_{f^*} - 8bcr(h') - \delta_G m - \delta_G \sum_{v\in V_0} d_v d_v^*.$$

Observe that if $\delta_G \geq 2$, then $\sum_{v\in V_0} d_v d_v^* = 0$. Hence, the above inequality can be rewritten as

$$\delta_G L_{h'} \geq \delta_G L_{f^*} - 8bcr(h') - \delta_G m - \sum_{v\in V_0} d_v d_v^*.$$

Usage of the above inequality in (3.6) gives

$$12bcr(h') \geq \delta_G L_{f^*} - \delta_G m - \epsilon - \sum_{v\in V_0} d_v d_v^* - 2\sum_{v\in V_1} d_v^2. \tag{3.7}$$

Observing that $L_{f^*} \geq L(G)$, $bcr(h') \leq 3bcr(h)$, $\delta_G m + \epsilon = \epsilon + \sum_{v\in V_0} d_v \delta_G \leq \sum_{v\in V} d_v^2$, and $\sum_{v\in V_0} d_v d_v^* + 2\sum_{v\in V_1} d_v^2 \leq 2\sum_{v\in V} d_v^2$, we obtain

$$36bcr(h) + 3\sum_{v\in V} d_v^2 \geq \delta_G L(G),$$

which finishes the proof. □

Next, we investigate the cases for which the error term $\sum_{v\in V} d_v^2$ can be eliminated from Theorem 3.3.

COROLLARY 3.4. *Let $G = (V_0, V_1, E)$ so that $m \geq (1+\gamma)n$ and $\sum_{v\in V} (d_v - d_v^*)^2 \geq \alpha \sum_{v\in V} d_v^2$, where γ and α are positive constants. Then*

$$bcr(G) \geq C_{\alpha,\gamma}\delta_G L(G), \quad \textit{where} \quad C_{\alpha,\gamma} = \frac{1}{36}\cdot\frac{1}{1+\frac{8+4\gamma}{3\alpha}}.$$

Proof. To prove the result we will first show that for any bipartite drawing h of G,

$$bcr(h) \geq \frac{\sum_{v\in V}(d_v - d_v^*)^2}{16} - m. \tag{3.8}$$

For now assume that (3.8) holds. Since $bcr(G) \geq m - n + 1$ [14] and $n \leq \frac{\gamma}{1+\gamma}m$, we conclude that $m \leq (\gamma+1)bcr(G)$. Combining this inequality with (3.8) gives $(2+\gamma)bcr(G) \geq \frac{1}{16}\sum_{v\in V}(d_v - d_v^*)^2 \geq \frac{\alpha}{16}\sum_{v\in V} d_v^2$, and thus

$$\frac{16(2+\gamma)}{\alpha} bcr(G) \geq \sum_{v\in V} d_v^2,$$

and the claim follows from Theorem 3.3.

To prove (3.8), let h be any bipartite drawing of G, and let $v \in V_0$ so that $d_v - d_v^* \geq 2$. Let $u_1, u_2, \ldots, u_{d_v - d_v^*}$ be the set of vertices of degree at least 2 which are adjacent to v, and assume with no loss of generality that $h(u_1) < h(u_2) < \cdots <$

$h(u_{d_v-d_v^*})$. Let i be an integer, $1 \le i \le \lfloor \frac{d_v-d_v^*}{2} \rfloor$, and note that any vertex u_j, $d_v - d_v^* - i + 1 > j > i$, generates at least one crossing on the edges $u_i v$ and $u_{d_v-i+1}v$. Thus $bcr(vu_i) + bcr(vu_{d_v-d_v^*-i+1}) \ge d_v - d_v^* - 2i$, $1 \le i \le \lfloor \frac{d_v-d_v^*}{2} \rfloor$, and therefore

$$\begin{aligned}\sum_{i=1}^{\lfloor \frac{d_v-d_v^*}{2} \rfloor} bcr_h(u_i v) + bcr_h(u_{d_v-i-d_v^*+1}v) &\ge \sum_{i=1}^{\lfloor \frac{d_v-d_v^*}{2} \rfloor} d_v - d_v^* - 2i \\ &\ge (d_v - d_v^*)\frac{d_v - d_v^* - 1}{2} - \frac{d_v - d_v^*}{2} \cdot \frac{d_v - d_v^* + 2}{2} \\ &\ge \frac{1}{4}(d_v - d_v^*)^2 - d_v. \qquad (3.9)\end{aligned}$$

It follows by summing (3.9) over all $v \in V_1$ that

$$2bcr(h) \ge \frac{\sum_{v\in V_1} (d_v - d_v^*)^2}{4} - 2m.$$

Similarly, we can show that $2bcr(h) \ge (\sum_{v\in V_0}(d_v - d_v^*)^2/4) - 2m$, and hence the claim follows. ∎

3.2. An upper bound. We now derive an upper bound on $bcr(G)$. We need the following obvious lemma.

LEMMA 3.5. *Let h be a bipartite drawing of $G = (V_0, V_1, E)$. Let $e = uv$ and $\bar{e} = ab$ be two edges which cross in h, $u, a \in V_0, v, b \in V_1$. If $|h(v) - h(u)| \ge |h(a) - h(b)|$, then either a or b is covered by e in h. Moreover, if a is covered by e, then*

$$|h(b) - h(u)| \le |h(v) - h(u)|,$$

whereas if b is covered by e, then

$$|h(a) - h(v)| \le |h(v) - h(u)|.$$

Let H be a subgraph of G. We denote by V_H and E_H, respectively, the vertex set and the edge set of H. The arboricity of G, denoted by a_G, is $\max_H \lceil \frac{|E_H|}{|V_H|-1} \rceil$, where the maximum is taken over all subgraphs H, with $|V_H| \ge 2$. Note that $\delta_G/2 \le a_G \le \Delta_G$, where Δ_G denotes the maximum degree of G. A well-known theorem of Nash-Williams [16] asserts that a_G is the minimum number of edge disjoint acyclic subgraphs to which edges of G can be decomposed.

THEOREM 3.6. *Let $G = (V_0, V_1, E)$, and let $f : V_0 \cup V_1 \to \{1, 2, \ldots, n\}$ be a bijection; then*

$$bcr(f) \le 5a_G L_f.$$

In particular,

$$bcr(G) \le 5a_G L(G).$$

Proof. The mapping f is the coordinate function of a bipartite drawing.

Let $e = uv \in E$, $u \in V_0$, $v \in V_1$, and let I_e denote the set of those edges crossing e in the drawing f so that for any $ab \in I_e$,

$$|f(a) - f(b)| \le |f(v) - f(u)|.$$

Observe that if any edge $e' \notin I_e$ crosses e, then $e \in I_{e'}$. Hence, in this case the crossing of e and e' contributes one to $|I_{e'}|$. We conclude that

$$bcr(f) \leq \sum_{e \in E} |I_e|,$$

and will show that $|I_e| \leq a_G(4|f(u) - f(v)| + 1)$. For $e = uv \in E$, with $u \in V_0, v \in V_1$, let V_0^e be the set of all those vertices y of V_0 so that $|f(y) - f(v)| \leq |f(u) - f(v)|$. Similarly, let V_1^e be the set of all those vertices y of V_1 so that $|f(y) - f(u)| \leq |f(u) - f(v)|$. Note that $|V_i^e| \leq 2|f(u) - f(v)| + 1$, $i = 0, 1$, since the coordinates of all vertices are integers. Therefore, we have $|V_0^e \cup V_1^e| \leq 4|f(u) - f(v)| + 2$. Let $\bar{e} = ab \in I_e$, $a \in V_0, b \in V_1$, and observe that by Lemma 3.5, $a \in V_0^e$ and $b \in V_1^e$. Consequently, $|I_e| \leq |E_H|$, where H is the induced subgraph of G on the vertex set $V_0^e \cup V_1^e$. Clearly,

$$|I_e| \leq |E_H| \leq a_G(4|f(u) - f(v)| + 2 - 1) = a_G(4|f(u) - f(v)| + 1)$$

by the definition of a_G, and thus, observing that $L_f \geq m$, we obtain

$$bcr(f) \leq \sum_{e \in E} I_e \leq 5 a_G L_f.$$

To complete the proof we take f to be the optimal solution to the linear arrangement problem, that is, $L_f = L(G)$, and note that $bcr(G) \leq bcr(f)$. ∎

4. Applications. It is easy to provide examples of graphs G for which $bcr(G) = \Theta(\delta_G L(G))$.

PROPOSITION 4.1. *Let $G = (V_0, V_1, E)$ so that $m \geq (1 + \gamma)n$ for a fixed γ. Then*

$$bcr(G) = \Theta(\delta_G L(G)),$$

provided that G satisfies any of the following conditions:

(i) *$\delta_G \geq 2$ and $\delta_G = \Theta(a_G)$,*

(ii) *G is connected and has bounded degrees.*

Proof. If (i) holds, the claim easily follows from Corollary 3.4 and Theorem 3.6. Assume that (ii) holds and k is a constant upper bound on the degrees. Note that $d_v - d_v^* \geq 1$ for any $v \in V$, since G is connected and is not a star, and thus $\sum_{v \in V}(d_v - d_v^*)^2 \geq n$. (Note that the star is excluded by the density condition $m \geq (1 + \gamma)n$.) Now let $\alpha = \frac{1}{k^2}$, then, $n \geq \frac{1}{k^2} \sum_{v \in V} d_v^2$. Hence this graph satisfies the conditions of Corollary 3.4; moreover, it is easy to see that $a_G \leq k = O(1)$, and we conclude using Theorem 3.6 that $bcr(G) = \Theta(L(G))$. ∎

4.1. Bipartite crossings, separators, genus, and page number. The appearance of a_G in the upper bound of Theorem 3.6 relates $bcr(G)$ to other important topological properties of G such as genus of G, denoted by g_G, and page number of G denoted by p_G [27].

PROPOSITION 4.2. *Let $G = (V_0, V_1, E)$, and assume that $\delta_G \geq 2$ and $m \geq (1 + \gamma)n$, for a fixed $\gamma > 0$. Then $bcr(G) = \Theta(L(G))$, provided that either $p_G = O(1)$, or $g_G = O(1)$.*

Proof. Assume that $a_G = O(1)$ is added to the conditions for G; then $\delta_G = O(1)$, and one can conclude using Proposition 4.1 that $bcr(G) = \Theta(L(G))$. To prove the claim, one has to observe that if either $p_G = O(1)$, or $g_G = O(1)$, then $a_G = O(1)$. ∎

Let $0 < \beta \leq \frac{1}{2}$ be a constant and denote by $b_\beta(G)$ size of a smallest β-separator of G. That is,

$$b_\beta(G) = \min_{\beta n \leq |A| \leq (1-\beta)n} |(A, \bar{A})|,$$

where $(A, \bar{A})$ denotes a cut which partitions V into A and $\bar{A}$. Leighton [12] proved that for any degree bounded graph G, $cr(G) + n = \Omega(b^2_{\frac{1}{3}}(G))$, where $cr(G)$ is the planar crossing number of G. Another very interesting consequence of Theorem 3.3 is providing a stronger version of Leighton's result for $bcr(G)$.

THEOREM 4.3. *Let $G = (V_0, V_1, E)$; then, for any constant $0 < \beta < \frac{1}{2}$,*

$$bcr(G) + \sum_{v \in V} d_v^2 = \Omega(\delta_G n b_\beta(G)).$$

Proof. The claim follows from the lower bound in Theorem 3.3 and the well-known observation that $L(G) \geq (1 - 2\beta) n b_\beta(G)$. (See, for instance, [9].) □

Remark. After submission of this paper we derived a weaker version of Theorem 4.3 using Menger's theorem [22].

4.2. Approximation algorithms. Let $G = (V_0, V_1, E)$. The *bipartite arrangement problem* is to find a bipartite drawing h of G with smallest L_h, so that for any $v \in V_0 \cup V_1$, $h(v)$ is an integer. We denote this minimum value by $\bar{L}(G)$. Note that coordinate function h for a bipartite drawing need not to be an injection, since it may be that $h(a) = h(b)$, for some $a \in V_0$, and some $b \in V_1$. Thus, in general $\bar{L}(G) \neq L(G)$. Our approximation algorithms construct bipartite drawings in which all vertices have integer coordinates, so that the number of edge crossings, and at the same time, the length of the drawings are small. We need the following lemma.

LEMMA 4.4. *Let $G = (V_0, V_1, E)$; then*

$$\bar{L}(G) \geq \frac{L(G) - 1}{4}.$$

Proof. Let h be a feasible solution to the bipartite arrangement problem. Let $e = ab \in E$, and note that $N_h(e) \leq |h(a) - h(b)|$, since any vertex in $V_0 \cup V_1$ has an integer x coordinate. Let f^* be the bijection in (i) of Lemma 3.1; then $|f^*(a) - f^*(b)| \leq 2|h(a) - h(b)| + 1$, and hence it follows by taking the sum over all edges, that $L_{f^*} \leq 2L_h + m$. To prove the lemma, we claim that there are at least $\frac{m-1}{2}$ edges $e = ab$, so that $h(a) \neq h(b)$, and consequently $L_h \geq \frac{m-1}{2}$, which implies the result. To prove our claim, note that there are at most $\frac{n}{2}$ edges ab, so that $h(a) = h(b)$, and hence there are at least $m - \frac{n}{2} \geq \frac{m-1}{2}$ edges ab, with $h(a) \neq h(b)$, since G is connected and therefore has at least $n - 1$ edges. □

Even et al. [6] presented polynomial time approximation algorithms with the performance guarantees of $O(\log n \log\log n)$ times the optimal for several NP-hard problems, including the linear arrangement problem. Rao and Richa improved the quality of the approximation to $O(\log n)$ for the linear arrangement problem [19]. Combining the result in [19] with ours, we obtain the following.

THEOREM 4.5. *Let $G = (V_0, V_1, E)$, and let $f : V_0 \cup V_1 \to \{1, 2, \ldots, n\}$ be a bijection which is a $O(\log n)$ times optimal approximate solution to the linear arrangement problem. Then $L_f = O(\bar{L}(G) \log n)$. Moreover, if G meets any of the conditions in Proposition 4.1, then $bcr(f) = O(bcr(G) \log n)$.*

Proof. Note that $L_f = O(L(G) \log n)$ and thus the claim regarding L_f follows from Lemma 4.4. To finish the proof, note that Theorem 3.6 gives $bcr(f) =$

$O(a_G L(G) \log n)$, and the claim regarding $bcr(f)$ is verified by the application of Proposition 4.1. □

A nice algorithmic consequence of the lower bound presented in Theorem 4.3 is that a standard divide and conquer algorithm gives a good approximation for $bcr(G)$ in polynomial time. The divide stage of the algorithm uses a pseudoapproximation algorithm for computing a graph separator [7, 13]. Such a pseudoapproximation algorithm generates a 0.3-separator whose value is $O(\log n)$ times the optimal value of a 1/3-separator [7, 13].

THEOREM 4.6. *Let A be a polynomial time pseudoapproximation algorithm for computing a 0.3-separator with a performance guarantee of $O(\log n)$ times the optimal value of a 1/3-separator. Consider a divide and conquer algorithm which* (a) *recursively separates the graph G in to subgraphs G_1 and G_2, using A,* (b) *obtains the bipartite drawings of G_1 and G_2, and then* (c) *inserts the edges of the separator between these two drawings to obtain a drawing for G. This algorithm generates, in polynomial time, a bipartite drawing h of G with integer coordinates, so that $L_h = O(\bar{L}(G) \log^2 n)$. Moreover, if G meets the conditions in Proposition 4.1, then $bcr(h) = O(bcr(G) \log^2 n)$.*

Proof. Let $\bar{b}(G)$ denote the number of those edges having one endpoint in the vertex set of G_1 and the other in the vertex set of G_2. Let h_1 and h_2 be the bipartite drawings that are obtained for G_1 and G_2, respectively. Let h denote the drawing of G which is obtained by placing h_1 to the left of h_2 and then inserting the edges between G_1, and G_2. The claim for L_h can be verified using arguments similar to those in [9] and employing Lemma 4.1. To verify the claim regarding $bcr(h)$, note that

$$bcr(h) \leq bcr(h_1) + bcr(h_2) + \bar{b}^2(G) + \bar{b}(G)m.$$

Now observing that $m \leq a_G n$, $\bar{b}(G) = O(\log n b_{\frac{1}{3}}(G))$, and that $n b_{\frac{1}{3}}(G) \leq 3L(G)$, we obtain

$$bcr(h) \leq bcr(h_1) + bcr(h_2) + O(a_G L(G) \log n)$$

which implies

$$bcr(h) = O(a_G L(G) \log^2 n).$$

Note that by Proposition 4.1, $bcr(G) = \Theta(a_G L(G))$, and the claim follows. □

Remark. Note that since a_G can be computed in polynomial time, the class of graphs with $a_G \leq c\delta_G$ is recognizable in polynomial time, when c is a given constant. Hence, those graphs which meet the required conditions in Proposition 4.1 can be recognized in polynomial time. Also, note that many important graphs such as those introduced in Proposition 4.2 meet the conditions, and hence for these graphs the performances of both algorithms are guaranteed. Finally note that the lower bound of $\Omega(n\delta_G b_{\frac{1}{3}}(G))$ for $bcr(G)$ has been crucial to verify the suboptimality of the solution in Theorem 4.6.

5. Bipartite crossings in trees. We note that if a_G is small, then the gap between the upper bound in Theorem 3.6 and the lower bound in Theorem 3.3 is small, and hence, it is natural to investigate the case $a_G = 1$, that is, when G is acyclic. In fact, in this case the method in the proof of Theorem 3.6 provides for an optimal bipartite drawing.

THEOREM 5.1. *Let T be a tree on the vertex set $V = V_0 \cup V_1$, where V_0 and V_1 are the partite sets, and $|V| = n$. Let f^* be a bijection utilizing an optimal solution to the linear arrangement problem. Then*

$$bcr(f^*) = bcr(T) = L(T) - n + 1 - \sum_{v \in T} \left\lfloor \frac{d_v}{2} \right\rfloor \left\lceil \frac{d_v - 2}{2} \right\rceil . \tag{5.1}$$

Proof. We prove the theorem by induction on n. The result is true for $n = 1, 2$. Let $n \geq 3$. Assume that the theorem is true for all l-vertex trees, $l < n$, and let T be a tree on n vertices. We first show that the right-hand side (RHS) of (5.1) is a lower bound on $bcr(T)$. We then show that $bcr(f^*)$ is equal to the RHS of (5.1). Consider an optimal bipartite drawing h of T. It is not difficult to see that one of the leftmost (rightmost) vertices is a leaf. Denote the left leaf by v_0, the right leaf by v_k, and let $P = v_0 v_1 \dots v_k$ be the path between v_0 and v_k. Note that P will cross any edge in T which is not incident to v_i, $0 \leq i \leq k$. It follows that path P will generate at least

$$c_P = n - 1 - k - \sum_{i=1}^{k-1} (d_{v_i} - 2) \tag{5.2}$$

crossings, where c_P counts exactly the number of edges in T which are not incident to any vertex on P. By deleting the edges of P we obtain trees T_i, on the vertex sets $V^i = V_0^i \cup V_1^i$, rooted in $v_i, i = 1, 2, \dots, k-1$. Consider the optimal bipartite drawings of T_i, $i = 1, 2, \dots, k-1$, and place them consecutively such that the edges in the drawing of T_i do not cross the edges in the drawing of T_j, for $i \neq j$. Then draw the path P without self crossings such that v_0 (v_k) is placed to the left (right) of the drawing of $T_1(T_{k-1})$. Clearly the number of crossings in this new drawing is $\sum_{i=1}^{k-1} bcr(T_i) + c_P$; therefore we conclude that

$$bcr(h) = \sum_{i=1}^{k-1} bcr(T_i) + c_P = \left(\sum_{i=1}^{k-1} bcr(T_i) \right) + n - 1 - k - \sum_{i=1}^{k-1} (d_{v_i} - 2),$$

for otherwise h is not an optimal drawing. For any $v \in V$, let d_v^i denote the degree of v in T_i; applying the inductive hypothesis to T_i, $i = 1, 2, \dots, k-1$, we obtain

$$\begin{aligned} bcr(T) &= \sum_{i=1}^{k-1} \left(L(T_i) - |V^i| + 1 - \sum_{v \in V^i} \left\lfloor \frac{d_v^i}{2} \right\rfloor \left\lceil \frac{d_v^i - 2}{2} \right\rceil \right) \\ &\quad + n - 1 - k - \sum_{i=1}^{k-1} (d_{v_i} - 2) \\ &= \sum_{i=1}^{k-1} \left(L(T_i) - \sum_{v \in V^i} \left(\left\lfloor \frac{d_{v_i}}{2} \right\rfloor \left\lceil \frac{d_{v_i} - 2}{2} \right\rceil + d_{v_i} - 2 \right) \right). \end{aligned} \tag{5.3}$$

Now observe that for $v \in V^i$, $d_v^i = d_v$ if $v \neq v_i$; otherwise $d_v^i = d_v - 2$, $i = 1, 2, \dots, k-1$. Consequently,

$$\begin{aligned} \sum_{v \in V^i} \left\lfloor \frac{d_v^i}{2} \right\rfloor \left\lceil \frac{d_v^i - 2}{2} \right\rceil + d_{v_i} - 2 &= \left\lfloor \frac{d_{v_i} - 2}{2} \right\rfloor \left\lceil \frac{d_{v_i} - 4}{2} \right\rceil + d_{v_i} - 2 \\ &\quad + \sum_{v \in V^i - v_i} \left\lfloor \frac{d_v}{2} \right\rfloor \left\lceil \frac{d_v - 2}{2} \right\rceil \end{aligned}$$

$$= \sum_{v \in V^i} \left\lfloor \frac{d_v}{2} \right\rfloor \left\lceil \frac{d_v - 2}{2} \right\rceil,$$

where the last line is obtained by observing that

$$\left\lfloor \frac{d_{v_i} - 2}{2} \right\rfloor \left\lceil \frac{d_{v_i} - 4}{2} \right\rceil + d_{v_i} - 2 = \left\lfloor \frac{d_{v_i}}{2} \right\rfloor \left\lceil \frac{d_{v_i} - 2}{2} \right\rceil.$$

Thus it follows using (5.3) that

$$bcr(h) = \sum_{i=1}^{k-1} L(T_i) - \sum_{v \in V} \left\lfloor \frac{d_v}{2} \right\rfloor \left\lceil \frac{d_v - 2}{2} \right\rceil. \tag{5.4}$$

Now consider the optimal linear arrangements of the trees T_i, specified by the bijections f_i, $0 \le i \le k$. Place $V^0, V^1, \ldots, V^k$ consecutively on a line so that the vertices in each V^i are placed in the order specified by f_i, $0 \le i \le k$. Let $g : V \to \{1, 2, \ldots, n\}$ denote the bijection associated with this arrangement; then $L_g = \sum_{i=1}^{k-1} L(T_i) + n - 1$. Using this fact (5.4) implies

$$bcr(T) \ge L(T) - n + 1 - \sum_{v \in T} \left\lfloor \frac{d_v}{2} \right\rfloor \left\lceil \frac{d_v - 2}{2} \right\rceil,$$

since $L_g \ge L(T)$.

To finish the proof we will show that $bcr(f^*)$ is equal to the RHS of (5.1). Consider an optimal linear arrangement f^* of the tree T. It is not difficult to see that ${f^*}^{-1}(1)$ and ${f^*}^{-1}(n)$ are leaves [1, 20]. Let $P = v_0 v_1 \ldots v_k$ be the path between $v_0 = {f^*}^{-1}(1)$ and $v_k = {f^*}^{-1}(n)$ in T, and let T_i, $1 \le i \le k-1$ be the trees defined in the first part of the proof. Let g be the bijection described earlier; then $L_g = \sum_{i=1}^{k-1} L(T_i) + n - 1$, and thus we conclude that

$$L_{f^*} = L(T) = \sum_{i=1}^{k-1} L(T_i) + n - 1, \tag{5.5}$$

and note that the above equation implies that P does not cross itself, in the arrangement associated with f^*. It follows that P does not cross itself in the bipartite drawing f^*. Let f_i^* be the restriction of f^* to V^i, $i = 1, 2, \ldots, k-1$. Note that $bcr(f^*) = \sum_{i=1}^{k-1} bcr(f_i^*) + c_P$. By applying the induction hypothesis to f_i^*, $i = 1, 2, \ldots, k-1$, we obtain

$$bcr(f^*) = \sum_{i=1}^{k-1} \left(L(T_i) - |V_i| + 1 - \sum_{v \in V_i} \left\lfloor \frac{d_v}{2} \right\rfloor \left\lceil \frac{d_v - 2}{2} \right\rceil \right) + c_P. \tag{5.6}$$

Substituting c_P its value from (5.2), and repeating the same steps used in deriving (5.4), we obtain

$$bcr(f^*) = \sum_{i=1}^{k-1} L(T_i) - \sum_{v \in V} \left\lfloor \frac{d_v}{2} \right\rfloor \left\lceil \frac{d_v - 2}{2} \right\rceil. \tag{5.7}$$

To complete the proof, we use (5.5) in (5.7) and obtain

$$bcr(f^*) = L(T) - n + 1 - \sum_{v \in T} \left\lfloor \frac{d_v}{2} \right\rfloor \left\lceil \frac{d_v - 2}{2} \right\rceil. \qquad \square$$

Remark. Since the optimal linear arrangement of an n-vertex tree can be found in $O(n^{1.6})$ time [1], Theorem 5.1 implies that computing $bcr(T)$ can also be done in $O(n^{1.6})$ time.

6. Largest biplanar subgraphs in acyclic graphs. Throughout this section $T = (V, E)$ denotes a tree, where $V = V_0 \cup V_1$. Let w_{ij} denote the weight assigned to an edge $ij \in E$. Let $w(B)$ denote the sum of weights for all edges in a subgraph B of T. In this section we present a linear time algorithm to compute a biplanar subgraph of T of largest weight.

A tree is called a *caterpillar* if it consists of a path to which some vertices of degree 1 (leaves) are attached. The path is called the *backbone* of the caterpillar. There are four categories of vertices in a caterpillar. First, consider those caterpillars which are not stars. They have a backbone on at least two vertices, and any vertex on the backbone is of degree at least 2. An endvertex of the backbone is called an *endbone*, any internal vertex of the backbone is called a *midbone*, and any leaf attached to an endbone is called an *endleaf*. Any leaf attached to a midbone is called a *midleaf*.

For a star with at least three vertices, the nonleaf vertex is considered an endbone, the backbone consists of this single endbone, and all leaves are endleaves. If a star has two vertices, then we treat these vertices as endbones. We would not concern ourselves with a star on only one vertex, as it does not play any role in the nontrivial instances of our problem.

Let $T = (V, E)$ and $r \in V$. We may view r as the root of T, and for any $x \in V,\ x \neq r$, define the *parent* of x to be the vertex adjacent to x on the unique path between x and r. For any $x \in V$, the set of *children* of x, denoted by N_x, are those vertices of T whose parent is x. For any $x \in V,\ x \neq r$, let T_x denote the component of T containing x, which is obtained by removing the parent of x from T. We define T_r to be T.

It is well known and easy to show that any graph is biplanar iff all of its connected components are caterpillars. It is further easy to check that any acyclic graph is a caterpillar iff it does not contain a double claw (a star on four vertices whose edges are subdivided) as a subgraph. Hence, any graph is biplanar iff it does not contain a double claw as a subgraph. Let B be a biplanar subgraph of $T = (V, E)$. We say that a caterpillar is in B if this caterpillar is a connected component of B. We say that B *spans* a vertex $a \in V$ if there is an edge ab in B.

For any $x \in V$, let B_x denote the set of all biplanar subgraphs of T_x and $w^*(T_x)$ denote the maximum weight of any biplanar subgraph in B_x. Our goal is to determine $w^*(T_r)$. To achieve this goal, for any $x \in V$, we define five additional related optimization problems as follows:

$$w^1(T_x) = \max_{B \in B_x} \{w(B) : \ \ x \text{ is endleaf of a caterpillar in } B\},$$
$$w^2(T_x) = \max_{B \in B_x} \{w(B) : \ x \text{ is midleaf of a caterpillar in } B\},$$
$$w^3(T_x) = \max_{B \in B_x} \{w(B) : \ x \text{ is endbone of a caterpillar in } B\},$$
$$w^4(T_x) = \max_{B \in B_x} \{w(B) : \ x \text{ is midbone of a caterpillar in } B\},$$
$$w^5(T_x) = \max_{B \in B_x} \{w(B) : \ B \text{ does not span } x\}.$$

It is obvious that for any $x \in V$, $w^*(T_x) = \max_{1 \leq i \leq 5} w^i(T_x)$, and therefore solving all five problems for T_x determines $w^*(T_x)$. For any leaf $v \in V$, we define $w^1(T_v) =$

$w^5(T_v) = 0$, $w^*(T_v) = 0$, and $w^i(T_v) = -\infty$ for $i = 2, 3, 4$. To avoid long displayed equations, for any $x \in V$ and any $u \in N_x$, we denote $w_{xu} + w^5(T_u)$ by $g(u)$ and denote $\max\{w_{ux} + w^5(T_u), w^*(T_u)\}$ by $f(u)$.

LEMMA 6.1.

$$w^1(T_x) = \max_{y \in N_x} \left\{ \left(\sum_{y' \in N_x \setminus \{y\}} w^*(T_{y'}) \right) + w_{xy} + \max_{i=1,3} w^i(T_y) \right\}, \tag{6.1}$$

$$w^2(T_x) = \max_{y \in N_x} \left\{ w_{xy} + w^4(T_y) + \sum_{y' \in N_x \setminus \{y\}} w^*(T_{y'}) \right\}, \tag{6.2}$$

$$\begin{aligned} w^3(T_x) = \max \Bigg\{ & \max_{\substack{y_1, y_2 \in N_x \\ y_1 \neq y_2}} \Bigg\{ w_{xy_1} + \max_{i=1,3} w^i(T_{y_1}) + g(y_2) \\ & + \sum_{y' \in N_x \setminus \{y_1, y_2\}} f(y') \Bigg\}, \max_{y \in N_x} \left\{ g(y) + \sum_{y' \in N_x \setminus \{y\}} f(y') \right\} \Bigg\}, \end{aligned} \tag{6.3}$$

$$\begin{aligned} w^4(T_x) = & \max_{\substack{y_1, y_2 \in N_x \\ y_1 \neq y_2}} \Bigg\{ w_{xy_1} + w_{xy_2} + \max_{i=1,3} w^i(T_{y_1}) + \max_{i=1,3} w^i(T_{y_2}) \\ & + \sum_{y' \in N_x \setminus \{y_1, y_2\}} f(y') \Bigg\}, \end{aligned} \tag{6.4}$$

$$w^5(T_x) = \sum_{y \in N_x} w^*(T_y). \tag{6.5}$$

Proof (sketch). The basic idea for the recurrence relations is to describe how an optimal solution for T_x can be constructed from the optimal solutions for the trees rooted in N_x. Indeed, (6.1), (6.2), and (6.5) are not difficult to see. For (6.3), let x be an endbone of a caterpillar C in $B \in B_x$, $w(B) = w^3(T_x)$. First, consider the case that C is not a star. Since x is an endbone of C, it has at least two neighbors in C, and all but one of its neighbors are leaves in C. Let y_1 be the nonleaf neighbor of x in C and y_2 be an endleaf in C. Then y_1 is either an endbone or an endleaf in $C \setminus \{x\}$, for otherwise B will contain a double claw. This justifies the first two terms in the first inner curly bracket. To justify the third and the fourth terms note that the leaf y_2 will contribute $g(y_2)$, and any $y' \in N_x \setminus \{y_1, y_2\}$ will contribute $f(y')$, respectively, to $w(B)$. To justify the terms in the second inner bracket, consider the case that C is a star. Then C must contain at least one vertex of degree 1, y, which will contribute $g(y)$ to $w(B)$. Furthermore, any $y' \in N_x \setminus y$ is a leaf of C only if $w_{xy'} + w^5(T_{y'}) > w^*(T_{y'})$; otherwise B must contain a maximum biplanar subgraph of T_y which has the weight $w^*(T_y)$. Thus, any $y' \in N_x \setminus y$ will contribute $f(y')$ to $w(B)$. For (6.4), let x be a midbone of a caterpillar C in $B \in B_x$, $w(B) = w^4(T_x)$. Then x has two neighbors y_1 and y_2 which are located on the backbone of C. By deleting x from C, we obtain exactly two caterpillars C_1 and C_2 so that y_i is either an endbone or an endleaf for C_i, $i = 1, 2$, for otherwise B will contain a double claw. Now follow arguments similar to those for deriving (6.3). □

THEOREM 6.2. *For an edge-weighted acyclic graph $T = (V, E)$, a biplanar subgraph of largest weight can be computed in $O(|V|)$ time.*

Proof (sketch). With no loss of generality assume that T is connected, for otherwise we apply our arguments to the connected components of T. We select a root r

for T, perform a post order traversal, and show that for any $x \in V$, $w^i(T_x)$, $1 \leq i \leq 5$, and $w^*(T_x)$ can be computed in $O(|N_x|)$ time if all these quantities are already known for the children of x. This is obvious for $w^*(T_x)$, and it is obvious for $w^5(T_x)$ using (6.5). For $w^1(x)$ and $w^2(x)$ we use (6.1) and (6.2), and note that the expressions in the curly braces can be computed in $O(N_x)$ time if a maximizing y^* is known. Therefore the issue is to find a maximizing vertex $y^* \in N_x$ in $O(N_x)$ time. It is easy to see that for (6.1), y^* must maximize $w_{xy} + \max_{i=1,3} w^i(T_y) - w^*(T_y)$, and for (6.2), $y^* \in N_x$ must maximize $w_{xy} + w^4(T_y) - w^*(T_y)$; these can be computed in $O(|N_x|)$ time.

For computing $w^3(x)$ using (6.3), first note that $y_1^*, y_2^* \in N_x$ can be found in $O(|N_x|)$ time which maximizes $w_{xy_1} + \max_{i=1,3} w^i(T_{y_1}) + g(y_2) + \sum_{y' \in N_x \setminus \{y_1, y_2\}} f(y') = w_{xy_1} + \max_{i=1,3} w^i(T_{y_1}) - f(y_1) + g(y_2) - f(y_2) + \sum_{y' \in N_x} f(y')$. To do so, select distinct vertices $y_1^*, y_2^* \in N_x$ in $O(|N_x)$ time which maximize $w_{xy_1} + \max_{i=1,3} w^i(T_{y_1}) - f(y_1) + g(y_2) - f(y_2)$. This can be done by observing that for any two sequences of numbers, $a_1, a_2, \ldots, a_l$ and $b_1, b_2, \ldots, b_l$, the value of $\max_{i \neq j} a_i + b_j$ can be computed in $O(l)$ time. Finally, note that $y^* \in N_x$ can be computed in $O(|N_x|)$ time to maximize $g(y) + \sum_{y' \in N_x \setminus \{y\}} f(y') = g(y) - f(y) + \sum_{y' \in N_x} f(y')$. To do so, select $y^* \in N_x$ which maximizes $g(y) - f(y)$.

For $w^4(x)$ employ (6.4), and use arguments similar to those employed for computing $w^3(x)$.

It is easy to maintain for every x not just the values $w^i(T_x)$, $w^*(T_x)$, but also the edge sets which realize these values; therefore, we can store the edge set of a maximum-weight biplanar subgraph as well. □

EDGE-DISJOINT PATHS IN EXPANDER GRAPHS*

ALAN M. FRIEZE†

Abstract. Given a graph $G = (V, E)$ and a set of κ pairs of vertices in V, we are interested in finding, for each pair (a_i, b_i), a path connecting a_i to b_i such that the set of κ paths so found is edge-disjoint. For arbitrary graphs the problem is $\mathcal{NP}$-complete, although it is in $\mathcal{P}$ if κ is fixed.

We present a polynomial time randomized algorithm for finding edge-disjoint paths in an r-regular expander graph G. We show that if G has sufficiently strong expansion properties and r is sufficiently large, then *all* sets of $\kappa = \Omega(n/\log n)$ pairs of vertices can be joined. This is within a constant factor of best possible.

1. Introduction.

Given a graph $G = (V, E)$ with n vertices and a set of κ pairs of vertices in V, we are interested in finding, for each pair (a_i, b_i) a path connecting a_i to b_i such that the set of κ paths so found is edge-disjoint. This problem has numerous algorithmic applications—in VLSI, for example, or in the context of virtual circuit routing.

For arbitrary graphs the related decision problem is $\mathcal{NP}$-complete, even for planar graphs, although Robertson and Seymour [19], as part of their monumental work on graph minors, have shown that the problem is in $\mathcal{P}$ if κ is fixed. The algorithm of Robertson and Seymour is not considered to be practical and so there has been a lot of work on developing algorithms in various cases, such as planar graphs and grids, where there are restrictions on the placement of the endpoints; see, for example, Frank [5], Wagner and Weihe [21], or Zhou, Tamura, and Nishizeki [22]. Approximation algorithms have been developed for some classes of planar graphs by Kleinberg and Tardos [13].

Another class of graphs which has yielded positive results is expanders. Peleg and Upfal [18] presented a polynomial time algorithm for the case where G is a (sufficiently strong) bounded degree expander graph, and $\kappa \le n^{\epsilon}$ for a small constant ϵ that depends on the expansion property of the graph. This result has been improved and extended by Broder, Frieze, and Upfal [2, 3], Frieze [6], Leighton and Rao [14], and Leighton, Rao, and Srinivasan [15, 16]. In these papers G has to be a (sufficiently strong) bounded degree expander and κ can grow as fast as $n/(\log n)^{\theta}$, where θ depends only on the expansion properties of the input graph, but is at least 2. Also, Kleinberg and Rubinfeld [12] have developed an on-line approximation algorithm.

Let D be the median distance between pairs of vertices in G. Clearly it is not possible to connect more than $O(m/D)$ pairs of vertices by edge-disjoint paths, for all choices of pairs, since some choice would require more edges than all the edges available. In the case of an r-regular expander, this absolute upper bound on κ is $O(n/\log n)$ (assuming r is independent of n). In this paper, we show that if G has

sufficiently strong *edge* expansion properties and r is sufficiently large, then *all* sets of $\kappa = \Omega(n/\log n)$ pairs of vertices can be joined. This, therefore, is within a constant factor of the optimum. The precise definition of "sufficiently strong" is given after the theorem.

THEOREM 1.1. *Let $G = (V, E)$ be an n-vertex, r-regular graph. Suppose that G is a sufficiently strong edge expander. Then there exist $\epsilon_1, \epsilon_2 > 0$ such that G has the following property: For all sets of pairs of vertices $\{(a_i, b_i) \mid i = 1, \dots, \kappa\}$ satisfying*

(i) $\kappa = \lceil \epsilon_1 rn/\log n \rceil$.

(ii) *For each vertex v, $|\{i : a_i = v\}| + |\{i : b_i = v\}| \le \epsilon_2 r$.*

There exist edge-disjoint paths in G, each of length $O(\log n)$, joining a_i to b_i, for each $i = 1, 2, \dots, \kappa$. Furthermore, there is a polynomial time randomized algorithm for constructing these paths.

ϵ_1, ϵ_2 depend only on certain expansion parameters α, β, γ defined below. They do not depend on n or r. (For example, conditions (1.3) *with $\epsilon = \alpha$,* (2.1), (3.1), *and* (4.1) *suffice.)*

REMARK 1. *The algorithm is a simplification of an algorithm of* [8] *for finding edge-disjoint paths in random regular graphs. There we have a slightly stronger result in that we can take $\kappa = \lceil \epsilon_1 rn/\log_r n \rceil$, i.e., an increase by a factor $\log r$. This is due to the fact that a random r-regular graph has strong vertex expansion. If G has sufficiently strong vertex expansion properties, then we can also take $\kappa = \lceil \epsilon_1 rn/\log_r n \rceil$; see Remark* 2 *below.*

1.1. Preliminaries. We define expanders in terms of edge expansion (a weaker property than vertex expansion).

Let $G = (V, E)$ be a graph and let $n = |V|$. For $S \subset V$ let $\mathrm{out}(S) = \mathrm{out}_G(S)$ be the number of edges with one endpoint in S and one endpoint in $V \setminus S$, that is,

$$\mathrm{out}(S) = \left| \left\{ \{u, v\} \mid \{u, v\} \in E, u \in S, v \notin S \right\} \right|.$$

Similarly,

$$\mathrm{in}(S) = \left| \left\{ \{u, v\} \mid \{u, v\} \in E, u, v \in S \right\} \right|.$$

A graph $G = (V, E)$ is a θ-expander if for every set $S \subset V$, $|S| \le n/2$, we have $\mathrm{out}(S) \ge \theta |S|$.

An r-regular graph $G = (V, E)$ is called an (α, β, γ)-expander if for every set $S \subset V$

$$\mathrm{out}(S) \ge \begin{cases} (1-\alpha) r|S| & \text{if } |S| \le \gamma n, \\ \beta r |S| & \text{if } \gamma n < |S| \le n/2. \end{cases}$$

We naturally assume that $\beta < 1 - \alpha$.

By "sufficiently strong" in Theorem 1.1, we mean that β, γ are arbitrary and α is sufficiently small. Then everything will work provided r is sufficiently large.

Since $2\mathrm{in}(S) + \mathrm{out}(S) = r|S|$ we see that in an (α, β, γ)-expander

$$\mathrm{in}(S) \le \alpha r |S|/2 \qquad \text{when } |S| \le \gamma n. \tag{1.1}$$

In particular, random regular graphs and the (explicitly constructible) Ramanujan graphs of Lubotsky, Phillips and Sarnak [17] are (α, β, γ)-expanders. (See the discussion in [2].)

We have made no real attempt to optimize constants, and, in general, we claim only that inequalities dependent on n or r hold for n or r sufficiently large.

For a graph $G = (V, E)$ and $v \in V$ we let $d_G(v)$ denote the degree of v in G. We use $\delta(G)$ and $\Delta(G)$ to denote the smallest and largest degrees, respectively. For a set $S \subseteq V$ we let $\bar{S} = V \setminus S$ and define its neighbor set, $N_G(S)$, as

$$N_G(S) = \{v \in \bar{S} : \exists w \in S \text{ such that } \{v, w\} \in E\}.$$

For $v \in V$ and $S \subseteq V$ we let $d_G(v, S) = |N_G(v) \cap S|$.

Let $\Phi_S = \text{out}(S)/|S|$ and let the (edge-)expansion $\Phi = \Phi(G)$ of G be defined by

$$\Phi = \min_{\substack{S \subseteq V \\ |S| \le n/2}} \Phi_S.$$

We need an algorithm for splitting a strong expander into nine expander graphs. We could use the algorithm of [2] or [7]. The latter gives a better split and we arbitrarily choose to use it. $\epsilon > 0$ is a small constant. The expansion requirements for the algorithm are

$$\frac{r}{\log r} \ge 63\epsilon^{-2} \text{ and } \Phi \ge 36\epsilon^{-2} \log r, \tag{1.2}$$

which for us means

$$\beta \ge 36\epsilon^{-2} r^{-1} \log r. \tag{1.3}$$

The result we need from [7, Theorem 2] is as follows.

THEOREM 1.2. *Suppose that* (1.2), (1.3) *hold and that G is an r-regular (α, β, γ)-expander, r constant. Then there is a randomized polynomial time algorithm which with probability at least $1 - \delta$ constructs $E_1, E_2, \dots, E_9$ such that the edge-expansion Φ_i of $G_i = (V, E_i)$ satisfies*

$$\Phi_i \ge (1 - \epsilon)\frac{\Phi}{9} - (\alpha + 2\epsilon)\, r$$

for $i = 1, 2, \dots, 9$. This theorem is useful only if Φ is at least a constant multiple of r and α is sufficiently small. This is the case discussed in this paper.

The algorithm of [7] runs in $O(n^{O(\log r)} \log \delta^{-1})$ expected time. The focus of this paper is r constant. If $O(n^{O(\log r)})$ seems excessive, then we can use the linear time algorithm of [2] at the expense of more stringent expansion requirements.

2. The algorithm.

Our algorithm divides naturally into the four phases.

2.1. Phase 0.

Partition G into nine edge-disjoint graphs $G_i = (V, E_i)$, $1 \le i \le 9$. Phase 1 will use the graphs G_1, G_2 to replace the a_i, b_i by randomly chosen $\tilde{a}_i, \tilde{b}_i$; Phase 2 will use the graphs G_3 and G_4. G_3 will be used to try to connect $\tilde{a}_i$ to $\tilde{b}_i$ by a short path. Sometimes we will need G_4 for this task and sometimes we will fail; Phase 3 will use the graphs G_5–G_9 to handle the failures of Phase 2.

The input to our algorithm is a sufficiently strong (α, β, γ)-expander graph G and a set of pairs of vertices $\{(a_i, b_i) \mid i = 1, \dots, \kappa\}$ satisfying the premises of Theorem 1.1. The output is a set of κ edge-disjoint paths, $P_1, \dots, P_\kappa$ such that P_i connects a_i to b_i.

2.2. Phase 0. We start by partitioning G into nine edge-disjoint graphs $G_i = (V, E_i)$, for $1 \le i \le 9$. We use the algorithm SPLIT of Theorem 1.2. We take $\epsilon = \alpha$ in the theorem and assume that

$$\beta > 63\alpha. \tag{2.1}$$

Then each G_i satisfies

$$\Phi_i = \Phi(G_i) \ge \beta_0 r, \tag{2.2}$$

$$\beta_0 r \le \delta(G_i) \le \Delta(G_i) < r, \tag{2.3}$$

where

$$\beta_0 = \frac{\beta}{9} - 4\alpha > 3\alpha > 0. \tag{2.4}$$

2.3. Phase 1. Let $\tilde{A}, \tilde{B}$ be two randomly chosen *disjoint* κ-subsets of V. We are going to replace the problem of finding paths from a_i to b_i by that of finding paths from $\tilde{a}_i$ to $\tilde{b}_i$, where $\tilde{a}_i \in \tilde{A}$ and $\tilde{b}_i \in \tilde{B}$. Let A denote the set $\{a_1, a_2, \ldots, a_\kappa\}$ and $B = \{b_1, b_2, \ldots, b_\kappa\}$.

We connect A to $\tilde{A}$ via edge-disjoint paths in the graph G_1 using network flow techniques. We construct a network as follows:

- Each undirected edge of G_1 gets capacity 1.
- Each $v \in V$ becomes a source of capacity $|\{i : a_i = v\}|$ and each member of $\tilde{A}$ becomes a sink of capacity 1.

Then we find a flow from A to $\tilde{A}$ that satisfies all demands. Since the maximum flow has integer values, it decomposes naturally into $|A|$ edge-disjoint paths (together perhaps with some cycles). If a path joins a_i to $z \in A$, then we let $\tilde{a}_i = z$.

We connect B to $\tilde{B}$ by edge-disjoint paths in a similar manner using G_2.

Thus Phase 1 finds edge-disjoint paths $P_i^{(1)}$ from a_i to $\tilde{a}_i$ and $P_i^{(3)}$ from $\tilde{b}_i$ to b_i, $1 \le i \le \kappa$, where the vertex sets $\tilde{A}, \tilde{B}$ are chosen uniformly at random.

2.4. Phase 2.

2.4.1. Algorithm GENPATHS**.** Our aim is to join $\tilde{a}_i$ and $\tilde{b}_i$ for $i = 1, 2, \ldots, \kappa$ by a *short* path in G_3. After constructing a path, we remove its edges. It is important to ensure that short paths exist. This would not be a problem if we could ensure that G_3 remains an expander throughout. We have to be satisfied with identifying *large* subgraphs $\Gamma_t = (V_t, F_t)$ of $G_t, t = 3, 4$ which are expanders. Initially $\Gamma_3 = G_3, \Gamma_4 = G_4$, and V_3, V_4 lose vertices as the algorithm progresses. We ensure that Γ_3, Γ_4 remain expanders by keeping the degrees of vertices in the Γ_t close to their degree in G_t. This may involve deleting some (low degree) vertices after the construction of a path. We use the routine REMOVE to do this.

If the proposed start vertex v of a walk on Γ_3 does not lie in V_3, then we try to *connect it back* to V_3 by a path in Γ_3. The terminal endpoint of this walk is denoted by v'. We use a subroutine CONNECTBACK for this purpose. We do not expect to succeed all the time and our failures are kept in a set L for later consideration.

The walk from a_i to b_i is then the catenation of paths $P_i^{(t)}$, $t = 1, \ldots, 3$. These walks may each include a short walk W_{CB} at the beginning provided by CONNECTBACK.

1. **Algorithm** GenPaths
2. **begin**
3. $\Gamma_i \leftarrow G_i$, $i = 3, 4$.
4. **for** $i = 1$ **to** κ **do**
5. **Execute** REMOVE(Γ_3)
6. **Execute** ConnectBack($V_3, \tilde{a}_i, \tilde{a}'_i, i, W_{CB}^{(3a)}$)
7. **Execute** ConnectBack($V_3, \tilde{b}_i, \tilde{b}'_i, i, W_{CB}^{(3b)}$)
8. **if** $i \notin L$ **then**
9. Construct a shortest path Q_i from $\tilde{a}'_i$ to $\tilde{b}'_i$ in Γ_3.
10. $P_i^{(2)} \leftarrow (W_{CB}^{(3a)}, Q_i, W_{CB}^{(3b)})$
11. $\Gamma_3 \leftarrow \Gamma_3 \setminus E(P_i^{(2)})$
12. **fi**
13. **od**
14. **end** GenPaths

2.4.2. Subroutine REMOVE. The purpose of REMOVE is to delete vertices which might prevent a graph from being an expander. In GENPATHS we apply REMOVE to Γ_3 or Γ_4.

In step 4 we remove the set of vertices R_0 which have so far lost more than $\beta_0 r/4$ edges through the deletion of shortest paths. We then iteratively (steps 5–12) remove vertices which have at least $\beta_0 r/4$ neighbors among previously removed vertices. We therefore see that for $t = 3, 4$

$$v \in V_t \text{ implies } d_{\Gamma_t}(v) \geq d_{G_t}(v) - \beta_0 r/2 \geq \beta_0 r/2. \tag{2.5}$$

1. **Algorithm** REMOVE(Γ_t)
2. **begin**
3. $R_0 = \{v \in V_t : \ d_{\Gamma_t}(v) < d_{G_t}(v) - \beta_0 r/4\}$.
4. $\ell \leftarrow 0$.
5. **begin**
6. $\bar{R}_\ell \leftarrow V_t \setminus R_\ell$.
7. $d \leftarrow \max_v \{d_{\Gamma_t}(v, R_\ell) : \ v \in \bar{R}_\ell\}$.
8. **if** $d \leq \beta_0 r/4$ **terminate** REMOVE, otherwise
9. $R_\ell \leftarrow R_\ell \cup \{w\}$; $V_t \rightarrow V_t \setminus \{w\}$ where $w \in \bar{R}_\ell$ is such that $d_{\Gamma_t}(w, R_\ell) = d$.
10. $\ell \leftarrow \ell + 1$
11. **goto** 6.
12. **end**
13. **end** REMOVE

We can see from (2.5) that throughout the algorithm

$$\Phi_{\Gamma_t} \geq \Phi_t - \beta_0 r/2 \geq \beta_0 r/2 \qquad \text{for } t = 3, 4. \tag{2.6}$$

Indeed, (2.5) implies that for $S \subseteq V_t$ we have

$$\text{out}_{\Gamma_t}(S) \geq \text{out}_{G_t}(S) - \beta_0 r|S|/2 \geq (\Phi_t - \beta_0 r/2)|S|.$$

2.4.3. Subroutine ConnectBack**.** The purpose of ConnectBack is to connect a vertex x to V_3 by means of a random walk. (If $x \in V_3$ already, then ConnectBack does nothing except to relabel x as x'.) All walks are done on V_4 and in step 5 we check that the start point x lies in V_4. If not, we put i into L, where $x = \tilde{a}_i$ or $\tilde{b}_i$. Edge-disjoint paths for the pairs $(a_i, b_i), i \in L$ are found in Phase 3. Let

$$\omega = \lceil \log \log n \rceil^2.$$

We do a random walk W_{CB} from x until we reach V_3 or make ω steps. In the latter case we add the corresponding i to L.

1. **subroutine** ConnectBack(V_3, x, x', i, W_{CB})
2. **begin**
3. **if** $x \in V_3$ **then** $x' \leftarrow x$ **exit fi else**
4. **Execute** remove(Γ_4)
5. **if** $x \notin V_4$ **then** $L \leftarrow L \cup \{i\}$ **exit fi else**
6. Do a random walk W_{CB} starting at x in Γ_4, until V_3 is reached or ω steps have been taken.
7. In the latter case $L \leftarrow L \cup \{i\}$ and we **exit else**
8. $\Gamma_4 \leftarrow \Gamma_4 \setminus W_{CB}$
9. **end** ConnectBack

2.5. Phase 3. There is still the set L of pairs (a_i, b_i) which have not been connected by paths. We will show later that with probability at least $1 - o(1)$, $|L|$ is at most $n/(\log n)^4$. As such, these pairs can be dealt with by the algorithm of [6], using graphs G_5–G_9. It is convenient to join the $\tilde{a}_i, \tilde{b}_i$ as then we are guaranteed to have distinct endpoints.

3. Analysis of Phase 1. In this section we show that if (2.2) holds and

$$\beta_0 r \geq 1 \text{ and } \epsilon_2 \leq \beta_0, \tag{3.1}$$

then after we run Split, we can find edge-disjoint paths from a_i to $\tilde{a}_i$ in G_1 and edge-disjoint paths from b_i to $\tilde{b}_i$ in G_2, for $1 \leq i \leq \kappa$, for *any* choice of $a_1, \ldots, b_\kappa$ consistent with the premises of Theorem 1.1, and every choice for $\tilde{a}_1, \ldots, \tilde{a}_\kappa, \tilde{b}_1, \ldots, \tilde{b}_\kappa$.

Let A and $\tilde{A}$ be as defined in section 2.3. For $S \subseteq V$, let

$$\alpha(S) = |\{i : \ a_i \in S\}| \text{ and } \xi(S) = |S \cap \tilde{A}|.$$

For sets $S, T \subseteq V$, let $e_{G_1}(S, T)$ denote the number of edges of G_1 with an endpoint in S and the other endpoint in T. It suffices to prove that

$$e_{G_1}(S, \bar{S}) \geq \xi(\bar{S}) - \alpha(\bar{S}) \qquad \forall S \subseteq V. \tag{3.2}$$

Given (3.2), the existence of the required flow in G_1 is a special case of a theorem of Gale [9] (see Bondy and Murty [1, Theorem 11.8], in which case we see that (3.2) implies a successful run of Phase 2.

Now

$$\alpha(\bar{S}) = \kappa - \alpha(S) \geq \kappa - \epsilon_2 r|S|$$

and so

$$\xi(\bar{S}) - \alpha(\bar{S}) \leq |\tilde{A} \cap \bar{S}| - \kappa + \epsilon_2 r|S| \leq \epsilon_2 r|S|.$$

Thus (2.2) verifies (3.2) for $|S| \leq n/2$ provided we have $\epsilon_2 \leq \beta_0$. For $|S| > n/2$ we have $\Phi_1 \geq 1$ and then

$$e_{G_1}(S, \bar{S}) = e_{G_1}(\bar{S}, S) \geq \Phi_1|\bar{S}| \geq |\tilde{A} \cap \bar{S}| \geq |\tilde{A} \cap \bar{S}| - \kappa + \alpha(S) = \xi(\bar{S}) - \alpha(\bar{S});$$

and so Phase 1 succeeds with respect to $A, \tilde{A}$. The same argument applies to $B, \tilde{B}$. To ensure these paths are of length $O(\log n)$ we can solve a minimum cost maximum flow problem as indicated in Kleinberg and Rubinfeld [12].

4. Analysis of Phase 2. We first prove that V_3 stays large.

LEMMA 4.1. *Throughout the algorithm*

$$|V_3| \geq (1-\gamma_0)n,$$

where

$$\gamma_0 = \frac{\beta_0\gamma}{10}.$$

Proof. We know from (2.6) that Γ_3 is a $(\beta_0 r/2)$-expander throughout the execution of Phase 2. We can use the strong edge-expansion of Γ_3 to prove some vertex-expansion and conclude the diameter of Γ_3 is at most $\tau_0 = \lceil 2\log_{1+\beta_0/2} n\rceil + 1$. Indeed, in a θr-expander, every set S, $|S| \leq n/2$ has at least $\theta|S|$ neighbors. Thus the total number of edges in the paths that are removed from G_3 is $\leq \kappa\tau_0$. Hence the vertices B_1 of G_3 which are incident with $\beta_0 r/4$ edges of these paths satisfy

$$|B_1| \leq \frac{4\kappa\tau_0}{\beta_0 r} \leq \frac{\gamma_0 n}{3}$$

provided

$$\epsilon_1 \leq \frac{\beta_0^2\gamma}{250}\log\left(1+\frac{\beta_0}{2}\right), \tag{4.1}$$

where ϵ_1 is as in the statement of Theorem 1.1.

Let $X = \{x_1, x_2, \dots,\}$ be the remaining vertices removed by REMOVE. We claim that if $|B_1| \leq \frac{\gamma_0}{3}n$, then $|X| \leq 2|B_1| \leq \frac{2\gamma_0}{3}n$ implying that $|V_3| \geq (1-\gamma_0)n$ and the lemma follows.

Indeed, if $X_i = \{x_1, x_2, \dots, x_i\}$, then $X_i \cup B_1$ has $i + |B_1|$ vertices and contains at least $i\beta_0 r/4$ edges. The existence of x_i, $i = 2|B_1|$ contradicts (1.1) with $S = X_i \cup B_1$. Therefore

$$\text{in}(S) \geq |B_1|\beta_0 r/2 \geq |S|\beta_0 r/6 > |S|\alpha r/2$$

using (2.4). □

Our next task is to bound the size of the set L of pairs of vertices which are left to Phase 3. For this we need to establish some facts about random walks on graphs.

4.1. Random walks. A *random walk* on an undirected graph $G = (V, F)$ is a Markov chain $\{X_t\}$ on V associated with a particle that moves from vertex to vertex according to the following rule: The probability of a transition from vertex v, of degree d_v, to a vertex w is $1/(2d)_v$ if $\{v, w\} \in E$ and 0 otherwise. The particle stays at v with probability 1/2. This removes the possibility of periodicity and allows us to use the conductance bound of Jerrum and Sinclair. Its stationary distribution, denoted by π, is given by $\pi(v) = \frac{d_v}{2|E|}$ for $v \in V$.

Let P be the transition matrix of the associated Markov chain. Let λ be the second largest eigenvalue of P. According to Sinclair and Jerrum [20]

$$\lambda \leq 1 - \frac{\Psi^2}{2}, \tag{4.2}$$

where Ψ denotes the *conductance* of a random walk on G.

Here

$$\begin{aligned}\Psi &= \min_{\pi(S)\le 1/2} \frac{1}{\pi(S)} \sum_{\substack{v\in S\\ w\notin S}} \pi(v)P(v,w)\\ &\ge \min_{\pi(S)\le 1/2} \frac{1}{\pi(S)} \sum_{\substack{v\in S\\ w\notin S}} \frac{d_v}{\Delta|V|}\cdot\frac{1}{2d_v}\\ &= \min_{\pi(S)\le 1/2} \frac{\mathrm{out}(S)}{2\Delta|V|\pi(S)}\\ &\ge \frac{\Phi\delta}{2\Delta^2}. \qquad (4.3)\end{aligned}$$

Another fact we will need is

$$|P^t(v,w)-\pi(w)| \le \sqrt{\frac{\Delta}{\delta}}\lambda^t. \qquad (4.4)$$

A proof of this can be found, for example, in [20].

We also need a large deviation result. This can be taken from the works of Dinwoodie [4], Gillman [10] and Kahale [11]. We quote the consequences of Theorem 2.1 of [10]: Let q be the distribution of the start vertex of a random walk on a graph G. Let S be a set of vertices of G. Let Y denote the number of visits to S in the first t steps.

$$\mathbf{Pr}(Y - t\pi(S) \le -u) \le \left(1+\frac{(1-\lambda)u}{10t}\right) N_q e^{-(1-\lambda)u^2/(20t)}, \qquad (4.5)$$

where

$$N_q = \left(\sum_{v\in V}\frac{q(v)^2}{\pi(v)}\right)^{1/2}.$$

4.2. Analysis of CONNECTBACK**.** Arguing as in Lemma 4.1 we see that since $\kappa\omega = o(n)$ we will have $|V_4| = n - o(n)$ throughout the algorithm. Furthermore the minimum and maximum degrees of Γ_4 will satisfy

$$\beta_0 r/2 \le \delta \le \Delta \le r.$$

Consequently Γ_4 has at least $(1-o(1))\beta_0 rn/2$ edges and then for sufficiently large n, the steady state for a random walk on Γ_4 will always satisfy

$$\frac{\beta_0}{3n} \le \pi(v) \le \frac{3}{\beta_0 n} \qquad \forall v\in V_4.$$

From (2.6) and (4.3) we see that the conductance Ψ satisfies

$$\Psi \ge \frac{\beta_0^2}{8}. \qquad (4.6)$$

Let $L = L_5 \cup L_7$, where L_θ consists of the indices added to L in step θ of CONNECTBACK.

To probabilistically bound $|L_5|$ we first bound the expected value of the number M_t of vertices which are incident with five or more CONNECTBACK walks in Step t of

GENPATHS, $t = 6, 7$. Fix a t and enumerate these walks as $W_1, W_2, \dots, W_m$, $m \le \kappa$. Then for $c = 9/\beta_0^2$,

$$\begin{aligned}\mathbf{E}(M_t) &\le \sum_{i_1,\dots,i_5,v} \mathbf{Pr}(W_{i_t},\, t = 1,\dots,5 \text{ go through } v)\\ &\le \binom{\kappa}{5} n \left(\frac{c\,\omega}{n - o(n)}\right)^5 = O\left(\frac{\omega^5 n}{(\log n)^5}\right). \qquad (4.7)\end{aligned}$$

It is important to note here that regardless of the history of Phase 1, $\tilde{A}$ is a random set and we can assume that $\tilde{a}_1, \tilde{a}_2, \dots, \tilde{a}_\kappa$ is a random ordering of its elements. (Phase 1 may cause some correlation between the orderings of $\tilde{A}, \tilde{B}$, but we compute the contribution of each set separately.)

Explanation of (4.7). We first show that $c\omega/(n - o(n))$ bounds the probability that walk $W_{i_t} = (x_1, x_2, \dots, x_m)$ passes through v, given $W_{i_s}, 1 \le s < t$ pass through v. Observe that x_1 is chosen randomly from $V_3 \setminus X$, where X is the set of start vertices of $W_{i_s}, 1 \le u < t$. Therefore

$$\mathbf{Pr}(x_1 = v) \le \frac{1}{n - o(n)} \le \frac{3}{\beta_0}\pi(v).$$

Then by induction on j we get

$$\mathbf{Pr}(x_j = v) = \sum_{w \in V_4} \mathbf{Pr}(x_{j-1} = w)P(w, v) \le \sum_{w \in V_4} \frac{3}{\beta_0}\pi(w)P(w, v) = \frac{3}{\beta_0}\pi(v) \le \frac{9}{\beta_0^2 n}$$

and we have the claimed bound of $\frac{9\omega}{\beta_0^2 n}$ for the (conditional) probability that W_{i_s} goes through v. There are at most $\binom{\kappa}{t}$ choices for $W_{i_s}, 1 \le s < t$ and n choices for v and (4.7) follows.

It follows from (4.7) and the Markov inequality that

$$\mathbf{Pr}\left(M_t \ge \frac{n}{8(\log n)^4}\right) = o(1).$$

In addition to these $M = M_6 + M_7$ vertices we consider those vertices which are removed by REMOVE(Γ_4). Arguing as in Lemma 4.1 we see that if $M = o(n)$, then $|L_5| \le 3M$. We deduce that

$$\mathbf{Pr}\left(|L_5| \ge \frac{3n}{4(\log n)^4}\right) = o(1). \qquad (4.8)$$

We now estimate the probability that $i \in L_7$. We apply (4.5) with $G = \Gamma_4$, $S = V_3 \cap V_4$, and $q(v) = \frac{1}{|V_4|}$ for $v \in V_4$. Then we have

$$1 - \lambda \ge \frac{\beta_0^4}{64},\ N_q \le \left(\frac{3}{\beta_0}\right)^{1/2},\ \text{and } \pi(S) \ge 1 - \frac{3\gamma_0}{\beta_0} \ge \frac{1}{2}.$$

Putting $t = \omega$ and $u = t\pi(S)$ we get

$$\mathbf{Pr}(W \cap V_3 = \emptyset) = O(e^{-\beta_0^4\omega/5120})$$

and so

$$\mathbf{E}(|L_7|) = O(e^{-\beta_0^4\omega/5120}\kappa)$$

and

$$\mathbf{Pr}\left(|L_7| \geq \frac{n}{4(\log n)^4}\right) = o(1).$$

Combining this with (4.8) we see that $\mathbf{Pr}(|L| \geq n/(\log n)^4) = o(1)$.

REMARK 2. *Suppose G has the following vertex expansion property for small sets: $S \subseteq V$, $|S| \leq \frac{\gamma}{r}n$ implies that $|N_G(S)| \geq (1-\alpha)r|S|$. The algorithm of [7] can be modified to split the graph so that each subgraph G_i satisfies $|N_{G_i}(S)| \geq \frac{1-10\alpha}{8}r|S|$. Then the shortest paths in Γ_3 will be of length $O(\log_r n)$ and the claim in Remark 1 will follow.*

5. Analysis of Phase 3. We join the pairs in L using the algorithm of [6]. The algorithm is capable of joining $\Omega(n/(\log n)^{2+o(1)})$ *distinct* pairs, provided the graph has sufficient edge-expansion. Notice that $\tilde{a}_i, \tilde{b}_i$ are chosen as distinct vertices. We briefly describe how we can make this algorithm route $m \leq \frac{n}{(\log n)^4}$ pairs using the graphs G_5–G_9, assuming only that $\Phi_5, \ldots, \Phi_9 \geq 1$. Let $\lambda = \lceil \log n \rceil$.

(a) The aim here is to choose w_j, W_j, $1 \leq j \leq 2m$ such that (i) $w_j \in W_j$, (ii) $|W_j| = \lambda + 1$, (iii) the sets $W_j, 1 \leq j \leq 2m$ are pairwise disjoint, and (iv) W_j induces a connected subgraph of G_6.

As in [14] we partition an arbitrary spanning tree T of G_6. Since T has maximum degree at most r we can find $2m$ vertex disjoint subtrees T_j, $1 \leq j \leq 2m$ of T, each containing between $\lambda+1$ and $(r-1)\lambda+2$ vertices. We can find T_1 as follows: choose an arbitrary root ρ and let $Q_1, Q_2, \ldots, Q_\sigma$ be the subtrees of ρ. If there exists l such that Q_l has between $\lambda+1$ and $(r-1)\lambda+2$ vertices, then we take $T_1 = Q_l$. Otherwise we can search for T_1 in any Q_ℓ with more than $(r-1)\lambda+2$ vertices. Since $T \setminus T_1$ is connected, we can choose all of the T_j's in this way. Finally, W_j is the vertex set of an arbitrary $\lambda+1$ vertex subtree of T_j and w_j is an arbitrary member of W_j for $j = 1, 2, \ldots, 2m$.

(b) Let S_A, S_B denote the set of sources and sinks that need to be joined. Using a network flow algorithm in G_5 connect in an arbitrary manner the vertices of $S_A \cup S_B$ to $W = \{w_1, \ldots, w_{2m}\}$ by $2m$ edge-disjoint paths. The expansion properties of G_5 ensure that such paths always exist.

Let $\hat{a}_k$ (resp., $\hat{b}_k$) denote the vertex in W_i that was connected to the original end-point $\tilde{a}_k$ (resp., $\tilde{b}_k$). Our problem is now to find edge-disjoint paths joining $\hat{a}_k$ to $\hat{b}_k$ for $1 \leq k \leq m$.

(c) If w_t has been renamed as $\hat{a}_k$ (resp., $\hat{b}_k$), then rename the elements of W_t as $\hat{a}_{k,\ell}$ (resp., $\hat{b}_{k,\ell}$), $1 \leq \ell \leq \lambda$. Choose $\xi_j, 1 \leq j \leq \lambda m$ and $\eta_j, 1 \leq j \leq \lambda m$ independently at random from the steady state distribution π of a random walk on G_9. Using a network flow algorithm as in (b), connect $\{\hat{a}_{k,\ell} : 1 \leq k \leq m, 1 \leq \ell \leq \lambda\}$ to $\{\xi_j : 1 \leq j \leq \lambda m\}$ by edge-disjoint paths in G_7. Similarly, connect $\{\hat{b}_{k,\ell} : 1 \leq k \leq m, 1 \leq \ell \leq \lambda\}$ to $\{\eta_j : 1 \leq j \leq \lambda m\}$ by edge-disjoint paths in G_8. Rename the other endpoint of the path starting at $\hat{a}_{k,\ell}$ (resp., $\hat{b}_{k,\ell}$) as $a^*_{k,\ell}$ (resp., $b^*_{k,\ell}$). Once again the expansion properties of G_7, G_8 ensure that flows exist.

(d) Choose $x^*_{k,\ell}, 1 \leq k \leq m, 1 \leq \ell \leq \lambda$ independently at random from the steady state distribution π of a random walk on G_9. Let $W'_{k,\ell}$ (resp., $W''_{k,\ell}$) be a random walk of length $\tau = \theta \log n$ from $a^*_{k,\ell}$ (resp., $b^*_{k,\ell}$) to $x^*_{k,\ell}$. Here θ is sufficiently large that a random walk of this length on G_9 is "well mixed," e.g., until the variational distance between the τ-step distribution and the steady state is $O(n^{-3})$. That $\theta = O(1)$ follows from (4.4). The use of this intermediate vertex $\hat{x}_{k,\ell}$ helps to break some conditioning caused by the pairing up of the flow algorithm.

Let B'_k (resp., B''_k) denote the *bundle* of walks $W'_{k,\ell}, 1 \le \ell \le \lambda$ (resp., $W''_{k,\ell}, 1 \le \ell \le \lambda$). Following [16] we say that $W'_{k,\ell}$ is *bad* if there exists $k' \neq k$ such that $W'_{k,\ell}$ shares an edge with a walk in a bundle $B'_{k'}$ or $B''_{k'}$. Each walk starts at an independently chosen vertex and moves to an (almost) independently chosen destination. The steady state of a random walk is uniform on edges and so at each stage of a walk, each edge is equally likely to be crossed. Thus

$$\mathbf{Pr}(W'_{k,\ell} \text{ is bad}) \le \frac{2\lambda m\theta^2(\log n)^2}{\beta_0 rn} = O\left(\frac{1}{\log n}\right).$$

We say that index k is bad if either B'_k or B''_k contain more than $\lambda/3$ bad walks. If index k is not bad, then we can find a walk from $a^*_{k,\ell}$ to $b^*_{k,\ell}$ through $x^*_{k,\ell}$ for some ℓ which is edge-disjoint from all other walks. This gives a walk

$$a_k - \tilde{a}_k - \hat{a}_k - \hat{a}_{k,\ell} - a^*_{k,\ell} - x^*_{k,\ell} - b^*_{k,\ell} - \hat{b}_{k,\ell} - \hat{b}_k - \tilde{b}_k - b_k,$$

which is edge-disjoint from all other such walks.

The probability that index k is bad is at most

$$2\,\mathbf{Pr}(B(\lambda, O(1/(\log n)) \ge \lambda/3) = O(n^{-2}).$$

Therefore with probability 1-o(1) there are no bad indices. □

Acknowledgment. We thank Aravind Srinivasan for a careful reading of an earlier version of the paper.

EFFICIENT DYNAMIC TRAITOR TRACING*

OMER BERKMAN†, MICHAL PARNAS†, AND JIŘÍ SGALL‡

Abstract. The notion of traitor tracing was introduced by Chor, Fiat, and Naor [*Tracing Traitors*, Lecture Notes in Comput. Sci. 839, 1994, pp. 257–270] in order to combat piracy scenarios. Recently, Fiat and Tassa [*Tracing Traitors*, Lecture Notes in Comput. Sci. 1666, 1999, pp. 354–371] proposed a dynamic traitor tracing scenario, in which the algorithm adapts dynamically according to the responses of the pirate. Let n be the number of users and p the number of traitors.

Our main result is an algorithm which locates p traitors, even if p is unknown, using a watermarking alphabet of size $p+1$ and an optimal number of $\Theta(p^2 + p \log n)$ rounds. This improves the exponential number of rounds achieved by Fiat and Tassa in this case. We also present two algorithms that use a larger alphabet: for an alphabet of size $p+c+1$, $c \geq 1$, an algorithm that uses $O(p^2/c + p \log n)$ rounds; for an alphabet of size $pc+1$, an algorithm that uses $O(p \log_c n)$ rounds.

Our final result is a lower bound of $\Omega(p^2/c + p \log_{c+1} n)$ rounds for any algorithm that uses an alphabet of size $p+c$, assuming that p is not known in advance.

1. Introduction.

In the electronic world, where information is easily copied and retransmitted, the issue of protecting intellectual property becomes a great concern. While owners of such information are interested in selling it, they need to protect themselves. There are two ways to protect such property. One option is to prevent the redistribution. Another option is to devise means to detect misconduct once redistribution has occurred. The second issue is the one addressed by traitor tracing (of course, the existence of such a scheme may also deter piracy from even occurring).

An excellent example is the world of Pay-TV systems. The owners of a Pay-TV system would like to broadcast only to their paying customers, and to be able to add and delete viewers as needed, while ensuring that this process happens in a timely manner. In order to protect the material that is being broadcast, encryption is utilized and keys are changed periodically, in addition to the existence of secure hardware. The goal of the pirate is to enable nonpaying persons to view the broadcasts. The pirate, registered as a legitimate subscriber of the system, can achieve this goal by transferring the decryption keys or by rebroadcasting the entire content. In order to make tracing difficult, the pirate can control several subscriptions and alternate between them. We refer to each such subscription as a *traitor*.

We assume from now on that the pirate operates by rebroadcasting the content. Our algorithms can be easily adapted to deal with the other mode of piracy, where

keys are published.

Traitor tracing schemes should be capable of detecting the traitors, so that they can be disconnected from the system without harming any legitimate user. Furthermore, such schemes should supply legal evidence of the pirate's identity.

Chor, Fiat, and Naor [3] introduced the notion of traitor tracing and provided a solution to this problem. They use a static approach, which means that all security measures are applied once at the onset of the protocol. As there is a single opportunity for applying these measures, they must suffice in order to locate the traitors once piracy is observed. If the number of traitors in reality is larger than that assumed by the static scheme, then the algorithm has no way of tracing the traitors, and the traitors may even frame an innocent user. Other related work can be found in [2, 5, 6, 9, 8, 10, 11]. For a comprehensive overview of static schemes and related work, see [7].

A basic tool used by many traitor tracing schemes is cryptographic fingerprinting (e.g., [13, 1, 2, 7]), which allows the schemes to generate different versions of the same content and send them to subsets of users. This can be done, for example, by watermarking each version, with no noticeable degradation in quality. A basic assumption of both previous schemes and our schemes is that the pirate cannot remove the watermarks or combine different versions into a new one; see, e.g., [4].

In a typical static scheme that uses fingerprinting, the content is divided into segments, and each segment is watermarked. The number of different versions that can be generated from a segment is referred to as the *watermarking alphabet size*. It is possible, of course, to use an alphabet whose size equals the number of subscribers and locate the traitors immediately. However, this requires an enormous bandwidth. Therefore, a smaller alphabet is used, so that the same version of a given segment is sent to many subscribers.

1.1. Dynamic traitor tracing schemes. Recently, Fiat and Tassa [7] introduced *dynamic* traitor tracing schemes. Their schemes adapt themselves throughout the algorithm in order to force the pirate to reveal more and more information. Eventually, the algorithm locates all traitors (or stops piracy). An additional nice feature of the dynamic schemes of [7] is that there is no need for an a priori bound on the possible number of traitors, as the algorithms adapt themselves when a new traitor is discovered.

The static schemes described above are modified by [7] to fit the dynamic setting as follows: In each round, the algorithm divides the set of users into disjoint subsets, where the number of subsets is bounded by the watermarking alphabet size. Then different versions of the content are transmitted by the system to these subsets of users, one version per subset. Whenever the pirate broadcasts one of these versions, it is evidence that the corresponding subset contains a traitor. When this happens, the algorithm changes the allocation of versions to the users, thus starting a new *round*. (Otherwise the pirate could continue to broadcast the same version with no further knowledge gained by the algorithm.) Eventually, if the pirate keeps rebroadcasting, the information gathered allows the algorithm to locate and disconnect all traitors.

A *segment* in the dynamic setting is defined as the part of the content transmitted to the users within the duration of a round. We note that sending a distinct version securely to each subset can be done by encryption. See section 2.1 in [7] for a discussion of the bandwidth overhead required for sending the encrypted versions.

We are interested in the following two complexity measures of such a dynamic traitor tracing scheme:

- the *number* of different versions used (i.e., the size of the watermarking alphabet), which is proportional to the bandwidth requirements, and
- the *time* or *number of rounds* needed, which is proportional to the number of segments used.

We ignore the computation performed by the traitor tracing algorithm, but we note that all proposed algorithms, both previous and ours, are efficient.

Let n be the number of all subscribers and p the number of traitors. It is shown in [7] that

(A) any deterministic algorithm must use at least $p+1$ versions in order to locate even a single traitor, regardless of the number of rounds, and even if p is known in advance;
(B) using $2p+1$ versions, it is possible to locate all p traitors in $O(p \log n)$ rounds;
(C) using $p+1$ versions, it is possible to locate all p traitors in $O(3^p p \log n)$ rounds.

1.2. Our results. We present a family of deterministic algorithms which locate all p traitors in a polynomial number of rounds. The exact bounds depend on the size of the watermarking alphabet. Specifically, we show the following:

(1) Using $p+1$ versions, it is possible to locate all p traitors in an optimal number of $\Theta(p^2 + p \log n)$ rounds (see lower bound (4) below). This improves the exponential bound in (C), thus solving an open problem raised in [7]. Note that the algorithm in (B) runs in a polynomial number of rounds but uses twice as many versions as our algorithm. By (A), the minimal number of versions needed is $p+1$. Thus our algorithm achieves the optimal time for the minimal alphabet size.
(2) Using $p+c+1$ versions, for any $1 \le c \le p$, it is possible to locate p traitors in $O(p^2/c + p \log n)$ rounds. For example, if $c = \Omega(p)$, the time is $O(p \log n)$.
(3) Using $pc+1$ versions, for any $c \ge 2$, it is possible to locate p traitors in $O(p \log_c n)$ rounds. For example, if $c = n^\epsilon$ for a constant $\epsilon > 0$, the time is $O(p)$.

All our algorithms, similar to algorithms (B) and (C) of [7], apply even if the number of traitors p is not known in advance. This means that, for example, if the algorithm is allowed to use $p+1$ versions, then the algorithm uses only $t+1$ versions when only $t \le p$ traitors are known to exist. As noted before, the computation performed by the algorithms between consecutive rounds is efficient.

In addition, we provide the following lower bound for the time needed to locate p traitors:

(4) The time needed to locate all p traitors, when p is not known in advance and $p+c$ versions are used, is $\Omega(p^2/c + p \log_{c+1} n)$.

This bound is tight when c is a constant (result (2) above) and when $c \ge p^{1+\varepsilon}$ for a constant $\varepsilon > 0$ (result (3) above). Otherwise the gap is very small—only a factor of $\log c$. It remains an open problem to close this gap.

Organization. The remainder of this paper is organized as follows. In section 2 we describe the problem and the general strategy that will be used by our algorithms. In section 3 we describe an algorithm that uses $p+1$ versions and $O(p^3 \log n)$ rounds. This algorithm is used as a building block by later algorithms. The optimal algorithm that uses $p+1$ versions is presented in section 4, thus establishing (1). In section 5 we present two algorithms that use more than the minimal number of versions required and prove bounds (2) and (3). In section 6 we present another algorithm that uses $p+1$ versions and runs in time $O(p^3 \log n)$. While this is not optimal, it is interesting that the same bound as that given in section 3 can be obtained using a different

approach. Finally, in section 7 we prove lower bound (4). We conclude with a few open problems in section 8.

2. Preliminaries.

2.1. The model. We now describe a combinatorial game which is an abstraction of the dynamic scenario described in the introduction and serves as a model for the rest of the paper.

Denote by U the set of users, and let $n = |U|$. Let $T \subseteq U$ be the set of traitors controlled by the pirate and let $p = |T|$.

In each *round*, the algorithm assigns to each user a version of the current segment from a set of versions C. If we give version $c \in C$ to a subset of users, then the subset is said to be *colored* by c. Then the pirate broadcasts one of the colors as an *answer*. If the pirate broadcasts color c, this implies that one of the users colored by c is a traitor. A traitor is *located* if only a single user is colored by c, and c is given as an answer. Since the number of traitors is not known in advance, this is the only way to locate a traitor. A traitor that has been located is *disconnected*, i.e., removed from U.

We assume that the pirate always gives an answer, as long as he has active traitors. The pirate loses the game when he does not answer (meaning that he goes out of business because the algorithm located all traitors). We measure the maximal number of colors used in any single round and the number of rounds needed in the worst case. The goal of the algorithm is to minimize these numbers in the worst case; more precisely, to achieve some given tradeoff between the two measures.

In fact, the pirate does not have to decide in advance who the p traitors are (as we implicitly assumed above). Instead, the pirate can choose the traitors in an adaptive manner throughout the game. However, once he decides to corrupt a user, he is committed to this decision until the end of the game. (This is similar to the general situation in the area of on-line algorithms and other adversary arguments. Since the algorithms are deterministic, the adversary can simulate the algorithm in advance, and thus committing to the set T in advance does not pose any restriction.)

2.2. A simplified model. The following lemma shows that locating a single traitor is as hard as locating all p traitors in the worst case. Specifically, we show that this seemingly easier problem of locating only one traitor saves at most $p-1$ rounds. This may be somewhat counterintuitive at first, and so we try to give some intuition.

Let us call a pirate's strategy *reasonable* if it never answers by a color given to a single user, unless he has no choice (when each one of the traitors received a unique color given only to him). For reasonable strategies, the statement holds trivially, since the algorithm can locate a traitor only when all traitors have a unique color. Then it is easy to locate the remaining traitors in additional $p-1$ rounds, as claimed.

It remains to prove that reasonable strategies result in the maximal number of rounds for a given fixed number of colors. If the goal of the algorithm is to locate one traitor, this is trivial, since it brings no advantage for the pirate to lose the game before he must. However, when the goal of the algorithm is to locate all p traitors, then it is not clear in advance that a reasonable strategy is the pirate's best resort. It may be better in this case for the pirate to reveal one traitor and keep a bigger uncertainty about the location of the remaining traitors. We thus have to prove that the statement is true for any strategy, not necessarily reasonable strategies.

LEMMA 2.1. *There exists an algorithm that locates one of the p traitors in m rounds if and only if there exists an algorithm that locates all p traitors in $m+p-1$*

rounds. The bound on the number of colors is the same for both algorithms.

Proof. If we have an algorithm that locates all traitors, it must eventually get p answers that allow it to locate all traitors. If we stop after the first traitor is located, we have an algorithm that locates one traitor, takes at most m rounds instead of $m + p - 1$, and does not use more colors.

Now suppose that we have an algorithm A that locates a single traitor in at most m rounds. We devise an algorithm B that uses algorithm A as a black box in order to locate all traitors. To do this, algorithm B runs algorithm A and passes to algorithm A the pirate's answers with the following exception: whenever a color c that was given by algorithm A to a single user is given as an answer by the pirate, algorithm B disconnects that user (which is clearly a traitor), but *does not* pass the pirate's answer to algorithm A. Thus, as far as algorithm A is concerned, it still waits for an answer from the pirate, and the user that was colored by c is still a part of the user set U. However, since this user has been disconnected, the pirate cannot give the color c that was given only to this user as an answer in the next round.

As far as algorithm B is concerned a round has occurred, and we charge this round in which a traitor was located to algorithm B. All other rounds are charged to algorithm A, including the final round in which a traitor is located. Algorithm B stops when all traitors are located, that is, when no more answers are received from the pirate. Clearly, the number of colors used by algorithm B is the same as the number of colors used by algorithm A.

To finish the proof we show that algorithm B performs at most $m+p-1$ rounds, assuming that algorithm A performs at most m rounds. Indeed, we charged $p - 1$ rounds to algorithm B (the rounds in which the first $p - 1$ traitors were located). Also, the sequence of answers that are passed by algorithm B to algorithm A is valid, and thus algorithm A locates a single traitor (the last traitor located) in at most m rounds. Thus the total number of rounds performed by algorithm B is at most $m + p - 1$ as claimed. □

We will assume from now on that any algorithm stops after locating one traitor. Thus, without mentioning it explicitly in the algorithm, we assume that the pirate never broadcasts a color given to a single user (otherwise the algorithm stops immediately). By Lemma 2.1 the change in the number of rounds is at most $p - 1$, which is insignificant compared to the bounds that we show. In fact, locating all p traitors requires $\Omega(p)$ rounds no matter how many colors are used.

In practice it may be desired to reduce the number of colors used after a traitor is located. It is easy to modify our algorithms to achieve this as well.

2.3. Graph notation. The algorithms that we present partition the set of all users into disjoint subsets and give all users in the same subset a common color. We represent the current state of the algorithm by an undirected graph $G = (V, E)$. Each vertex of G represents a subset of users, and each user belongs to exactly one vertex. An edge (X, Y) means that the subset $X \cup Y$ contains a traitor, i.e., in some previous round, the answer was the color of $X \cup Y$ or (less frequently) the color of some subset of $X \cup Y$. A special vertex I represents the subset of "innocent users" (i.e., the subset of users not known at the present stage to contain a traitor). A vertex is called a *singleton* if it contains exactly one user.

2.4. A basic algorithm. Two of the schemes presented in [7] are based on the following basic algorithm, which is formulated here using our graph notation. In this algorithm the graph consists of $2t + 1$ vertices, one of which is the special vertex I, and t disjoint edges, none of which is adjacent to I. Recall that each edge implies

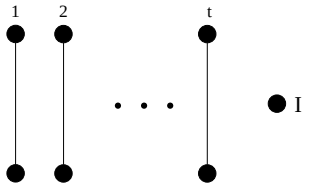

FIG. 2.1. *An example of the graph G used by the basic algorithm.*

that at least one of its endpoints contains a traitor. Since the graph has t disjoint edges, there exist at least t traitors. See Figure 2.1.

BASIC ALGORITHM. Start with a graph $G = (V, E)$ with $I = U$, $V = \{I\}$, $E = \emptyset$, and $t = 0$. Repeat forever:

(1) Find a vertex X that contains a traitor.
(2) If $X = I$: Split I into two new vertices of equal size (or differing in size by 1 if $|X|$ is odd), and connect them by an edge. Set $I = \emptyset$ and $t = t + 1$.
(3) Otherwise: Let Y be the vertex that is connected to X by an edge. Set $I = I \cup Y$, split X into two vertices of (almost) equal size, and connect them by an edge.

The first algorithm in [7] uses $2t + 1$ colors, giving each vertex a distinct color. Thus, in each round the pirate has to broadcast the color of some vertex X, and all p traitors are located in $O(p \log n)$ rounds. The second algorithm in [7] uses only $t + 1$ colors, but step (1) requires an exponential time in t, and thus the algorithm is impractical.

2.5. Generalized graph notation. In order to decrease the number of colors needed, our algorithms use graphs that generalize the above structure. Instead of the t pairs of connected vertices, we have disjoint cliques and possibly some additional edges. More formally, we define the following graphs.

DEFINITION 2.2. *Let $t \geq k \geq 0$ be two integers. A graph $G = (V, E)$ is a* (t, k)-graph *if*

(1) *G contains $t+k+1$ vertices, one of which is the special vertex I. The vertices are subsets of U, all of them except possibly I are nonempty, and every user belongs to exactly one vertex;*
(2) *for any edge $(X, Y) \in E$, the subset $X \cup Y$ contains a traitor;*
(3) *the vertices in $V \setminus \{I\}$ are partitioned into k disjoint cliques $\{Q_1, \ldots, Q_k\}$, where $|Q_i| = t_i \geq 2$ for each $1 \leq i \leq k$.*

Note that a (t, k)-graph may contain additional edges between the cliques. Further constraints on the structure of the graph will be described in each one of the algorithms. The following lemma is easy to verify if we remember that two vertices are connected by an edge if at least one of them contains a traitor.

LEMMA 2.3. *Let G be a (t, k)-graph. A clique Q_i of t_i vertices contains at least $t_i - 1$ traitors, and the graph G contains at least t traitors. The number of vertices of a (t, k)-graph is at most $2t + 1$.*

3. The clique algorithm. In this section we describe an algorithm that uses $p+1$ colors. The algorithm runs in $O(p^3 \log n)$ rounds and is not optimal. In the next section this algorithm is used to derive an algorithm that uses $(p+1)$ colors and runs in an optimal number of $\Theta(p^2 + p \log n)$ rounds.

We start with an overview of the clique algorithm. By Lemma 2.3, a (t, k)-graph is known to contain at least t traitors. Therefore we are allowed to use $t + 1$ colors.

Since a (t,k)-graph can contain up to $2t+1$ vertices, we may not have enough colors to give each vertex a distinct color. Thus our algorithm pairs the k cliques and forces the pirate in each round to either transmit a color given to only one vertex or to disclose an edge connecting a pair of cliques. If a color given to only one vertex is transmitted, then we split this vertex into two vertices (producing a new clique of size 2), and thus advance towards locating at least one of the traitors. Disclosed edges, on the other hand, are added to the graph in order to merge eventually each pair of cliques into one larger clique (containing all but one of the vertices of the two cliques). This process is repeated until the graph contains exactly one clique of size $t+1$. Then we can give each one of the vertices a distinct color and force the pirate to transmit a color given to only one vertex (allowing us again to split this vertex).

3.1. Data structures and invariants.

The graph. We maintain a (t,k)-graph $G=(V,E)$ with a special vertex I and cliques Q_i of size t_i.

Zones and blocks. The vertices of the graph G are partitioned into Zones Z_1, Z_2. The vertices in Zone Z_1 are partitioned into blocks. There are no edges connecting vertices from different blocks or zones. The zones and the blocks are defined as follows:

- ($\mathbf{Z_1}$) The vertices in this zone are partitioned into blocks. Each block is a graph induced by the vertices of two cliques Q_i and Q_j, of sizes t_i and t_j, respectively. The block does not contain a clique of size t_i+t_j-1. Equivalently, this means that there are four distinct vertices $X_1, X_2 \in Q_i$ and $Y_1, Y_2 \in Q_j$ such that $(X_1,Y_1),(X_2,Y_2) \notin E$.
- ($\mathbf{Z_2}$) This zone contains the special vertex I. In addition it may contain one clique Q_i of size t_i. The vertex I and the clique Q_i do not form a clique of size t_i+1. Equivalently, this means that there exists a vertex $X \in Q_i$ such that $(X,I) \notin E$.

See Figure 3.1 for an example of the data structures used by the clique algorithm.

3.2. Description of the algorithm. Start with a $(0,0)$-graph $G=(V,E)$ with $I=U$, $V=\{I\}$, $E=\emptyset$, and $t=0$. Repeat the following two phases:

Phase 1: Distributing the colors to the vertices of G.

Allocate t_i-1 colors to each clique Q_i, for a total of t colors. The last color is allocated to I. We now describe how to distribute these allocated colors in each zone and block of G.

(1) Color each block in Zone Z_1 separately, using the colors allocated to the pair of cliques in it: Let B be a block in Zone Z_1 and let Q_i and Q_j be the two cliques in B. By the definition of the blocks in Zone Z_1, there exist four distinct vertices $X_1, X_2 \in Q_i$ and $Y_1, Y_2 \in Q_j$ such that $(X_1,Y_1),(X_2,Y_2) \notin E$. Color $X_1 \cup Y_1$ with one color and $X_2 \cup Y_2$ with another color. Color the remaining t_i+t_j-4 vertices of Q_i, Q_j using the remaining t_i+t_j-4 colors allocated to these two cliques, one color per vertex.

(2) If Zone Z_2 contains only the vertex I, then color I using the color allocated to it. Otherwise Zone Z_2 contains also a clique Q_i and there exists a vertex $X \in Q_i$ such that $(X,I) \notin E$. Use one color for $X \cup I$ and color the remaining t_i-1 vertices of Q_i using t_i-1 colors, one color per vertex. (If I is empty, all vertices of Q_i are colored with distinct colors.) Therefore t_i colors are used, which is the total number of colors allocated to Q_i and I.

See Figure 3.1 for an example of the distribution of colors.

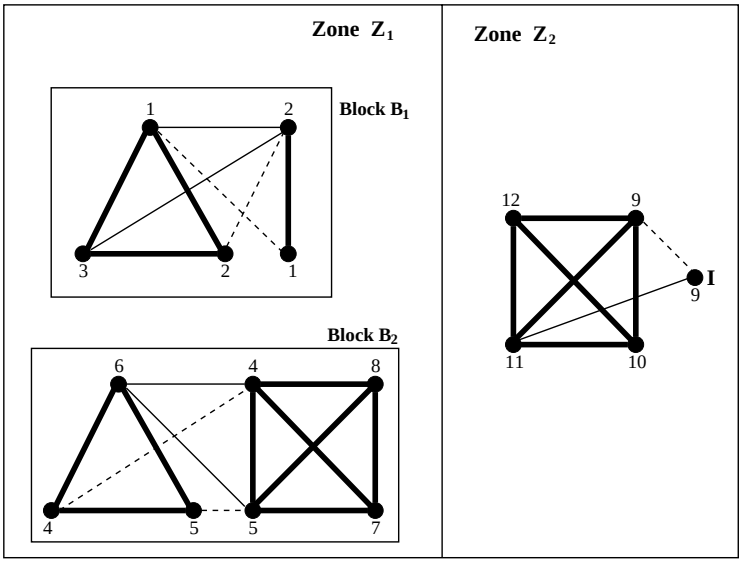

FIG. 3.1. *An example of the data structures used by the clique algorithm. This is a* (t, k)*-graph, where* $t = 11$ *and* $k = 5$*. The bold lines represent clique edges, and the thin lines represent edges between cliques, or between a clique and* I*. This is also an example of the distribution of colors in Phase* 1 *of the clique algorithm. The labels denote the colors given to the vertices. The dashed lines denote the pairs of nonadjacent vertices that received the same color.*

Phase 2: Reorganizing the graph following the pirate's response.

(1) If the pirate broadcasts a color given to only one vertex X: Remove X and the edges incident with it from G. Split X into two new vertices X_1, X_2 of equal size (or differing in size by one if $|X|$ is odd), and add the edge (X_1, X_2).
  (1.1) If $X = I$: Define a new clique Q consisting of the two vertices X_1, X_2. Set $I = \emptyset$, $t = t + 1$, and $k = k + 1$. Incorporate the clique Q into the zones (see step (3)).
  (1.2) Otherwise: Let Q_i be the clique to which X belongs. Set $Q_i = Q_i \setminus \{X\}$.
    (1.2.1) If $|Q_i| = 1$, then remove all edges incident with the vertex remaining in Q_i. Remove this vertex from Q_i and add it to I. Place X_1 and X_2 into Q_i. The clique Q_i now consists of the two vertices X_1, X_2.
    (1.2.2) Otherwise Q_i is still a legal clique. In this case the two sets X_1, X_2 will form a new clique Q. Set $k = k + 1$ and incorporate the new clique Q into the zones (see step (3)).

(2) If the pirate broadcasts a color given to a pair of vertices X, Y: Add the edge (X, Y) to G, and
  (2.1) if this edge connects vertices belonging to a pair of cliques Q_i, Q_j in some block B, and after adding this edge, the block B contains a large clique Q of size $t_i + t_j - 1$: Let Z be the remaining vertex in B that does not belong to this large clique (i.e., $Z \notin Q$). Remove Z and all edges incident with it from its clique and add Z to I. Furthermore, set $k = k - 1$, remove the cliques Q_i, Q_j and their block B. Incorporate the new clique Q into the zones (see step (3)). See Figure 3.2 for an example.
  (2.2) If this edge connects I and a vertex of the clique Q_i in Zone Z_2, and

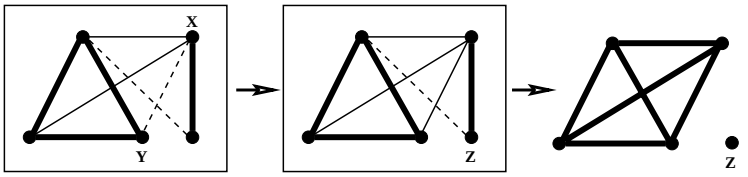

FIG. 3.2. *An example of merging a pair of cliques in step* (2.1) *of Phase* 2 *of the clique algorithm. On the left: A block of Zone* Z_1*, in which* X *and* Y *received the same color. In the middle: The block after the pirate answered with the joint color of* X *and* Y*, and the edge* (X, Y) *was added. Finally, on the right: The two cliques were merged into one big clique, and all edges incident with* Z *were removed.*

after adding this edge, Q_i and I form a clique on $t_i + 1$ vertices: Add I as a vertex to Q_i and create a new special vertex $I = \emptyset$. Set $t = t + 1$ (since t_i was increased by 1).

(3) If a new clique Q was created during one of the above steps, reorganize the zones as follows to incorporate Q: If Zone Z_2 contains only I, place Q in Zone Z_2. Otherwise, Zone Z_2 contains a clique R in addition to I. In this case, remove all edges incident with I, remove R from Zone Z_2, pair it with the new clique Q, and create in Zone Z_1 a new block containing the cliques Q and R.

Remark. In step (3) of Phase 2, we removed all edges incident with the vertex I. Removing these edges makes the structure of G simpler, but in practice we may want to leave them in the graph, since they provide more information. Since the number of these edges is $O(p)$, it turns out that the analysis of the algorithm (Theorem 3.3 below) is valid whether these edges are removed or not.

3.3. Correctness and efficiency.

LEMMA 3.1. *The invariants of the algorithm are preserved at all times.*

Proof.

The graph. An edge is added only if we got an answer from the pirate corresponding to that edge, and thus one of its endpoints must contain a traitor. Whenever the structure of the cliques is changed in steps (1) or (2) of Phase 2, we verify that every clique has at least two vertices and that the values of t and k are updated properly, so that the new graph is a (t, k)-graph for the new values. Step (3) of Phase 2 only removes edges incident with I, which maintains the structure of a (t, k)-graph.

Zone constraints. If adding a new edge would violate the zone invariants, i.e., it would create a big clique, then we reorganize the cliques in step (2) of Phase 2. In steps (1) and (3) of Phase 2, no edges are added between cliques. Reorganizing the cliques does not violate the zone constraints. If two cliques are placed in the same block, then there are no edges between them (since they were in different blocks or zones before). Similarly if a clique is placed in Zone Z_2, then there are no edges between this clique and I.

Edges between different zones and blocks. Whenever the cliques are reorganized or a new clique is created, all the edges that would connect vertices from different zones or blocks are removed. □

In order to bound the number of rounds used by the algorithm, we first need to bound the number of split operations performed throughout the algorithm. Define a *split* to be any round in which a vertex of G is split (i.e., a round in which step (1) in Phase 2 is performed).

LEMMA 3.2. *The total number of splits is* $O(p^2 \log n)$.

Proof. Whenever the set I is split, t increases. During the algorithm t never decreases and its value is at most p. Thus the set I can be split at most p times.

For every traitor i, define x_i as follows. If traitor i is in I, then $x_i = 0$. Otherwise traitor i is in a vertex $X \neq I$ and $x_i = \lceil \log |X| \rceil$. Each x_i is an integer between 0 and $\lceil \log n \rceil$. Between any two consecutive splits of I, x_i does not increase. It may be set to zero (if the corresponding vertex is added to I), decrease by one or two (if the corresponding vertex is split), or remain the same (otherwise). At each split of a vertex $X \neq I$, we know that X contains a traitor. It follows that when a spilt occurs, then for some traitor i, x_i is decreased by at least one. Thus there are at most $p\lceil \log n \rceil$ splits between any two consecutive splits of I, and the total number of splits is $O(p^2 \log n)$. □

THEOREM 3.3. *The clique algorithm locates a traitor in* $O(p^3 \log n)$ *rounds, using* $p + 1$ *colors. Hence, all* p *traitors can be located in* $O(p^3 \log n)$ *rounds, using* $p + 1$ *colors.*

Proof. By Lemma 3.1, the algorithm maintains a (t, k)-graph, and thus Lemma 2.3 implies that $t \leq p$. It is immediate from the allocation of colors in Phase 1 that the algorithm uses $t + 1 \leq p + 1$ colors.

We now analyze the number of rounds needed. In each round some progress is made: either a set is split, or an edge is added to the graph (since we assumed that the pirate always gives an answer as long as he has active traitors). We show that the number of such events is at most $O(p^3 \log n)$, and thus the algorithm must terminate and its running time is $O(p^3 \log n)$. This also proves that the algorithm eventually finishes by locating a traitor. By Lemma 2.1, all p traitors can be located in the worst case in at most $O(p^3 \log n + (p - 1)) = O(p^3 \log n)$ rounds.

By Lemma 3.2, the total number of splits is $O(p^2 \log n)$. It remains to bound the number of edges added during the algorithm. The final graph is a (t, k)-graph for some k, where $t \leq p$. Such a graph can contain at most $2t + 1 \leq 2p + 1$ vertices and thus at most $O(p^2)$ edges. However, in some rounds edges may be removed. We show below that the number of edges removed during the algorithm is $O(p^3 \log n)$. It implies that at most $O(p^2 + p^3 \log n) = O(p^3 \log n)$ edges are added during the algorithm and the theorem follows.

Edges are removed when (i) a set is split or (ii) two cliques are merged into a larger clique. Each time such an event happens, at most $O(p)$ edges are removed (including the edges that are possibly removed in step (3) of Phase 2). Event (i) can happen at most $O(p^2 \log n)$ times by Lemma 3.2. The number of times two cliques are merged is bounded from above by the number of times the number of cliques increases, and this happens only when a vertex is split. Thus event (ii) can happen at most $O(p^2 \log n)$ times. Therefore, at most $O(p^3 \log n)$ edges are removed during the algorithm. □

It may seem at first that a more careful analysis can show that the number of splits is $O(p \log n)$, which would improve the overall running time by a factor of p. However, it is possible to demonstrate a run of the algorithm where indeed $\Theta(p^2 \log n)$ splits occur and $\Theta(p^3 \log n)$ rounds are needed.

4. An optimal algorithm. In this section we describe an algorithm that uses $p + 1$ colors and runs in an optimal number of $\Theta(p^2 + p \log n)$ rounds. We start with an overview of the algorithm.

The clique algorithm loses efficiency because of the high number of $O(p^2 \log n)$ splits, and due to the fact that whenever we split a vertex, we may remove $O(p)$ edges.

We solve these problems as follows:

The users are partitioned into two areas, Areas 1 and 2. In Area 1 the users are organized into cliques of singletons (recall that a vertex is called a singleton if it contains exactly one user). Here we allow cliques of any size and use the clique algorithm. Since all vertices are singletons, there are no split operations. It follows that the total number of rounds in Area 1 is $O(p^2)$.

Initially, all the users are placed in Area 2. The only case when users are moved from Area 2 to Area 1 is when we find a set of two users containing a traitor. Then we add them to Area 1 as a clique of two singletons. Area 2 is divided into blocks, each with a constant number of known traitors. This allows us to achieve an amortized cost of $O(1)$ rounds per split and an amortized cost of $O(\log n)$ rounds until we pin down a traitor to a set of two users. Thus, at an amortized cost of $O(\log n)$, we increase the number of traitors in Area 1 (by placing there the new clique of two singletons that we found in Area 2). The number of known traitors can increase at most p times, and thus the resulting number of rounds is $O(p^2 + p \log n)$, exactly matching our lower bound. See Figure 4.1 for a sketch of the two areas.

This grand plan has some difficulties. The main obstacle is that the clique algorithm cannot be used on the blocks of Area 2, since we are not allowed to create large cliques on nonsingleton vertices (as this may result in many splits). An additional problem is that in each block of Area 2 we cannot use more colors than the number of traitors known to exist in the block (otherwise we would violate the bound of $p+1$ colors). We now sketch briefly the solutions used in Area 2 to overcome these difficulties.

Most of Area 2 is organized into blocks containing at least three known traitors each (Zone Z_4 below). In each such block, our goal is to either (i) find a set of two users containing a traitor, or (ii) split the block into two parts, one part with three known traitors and one part with one known traitor. In case (i), we can place these two users as a clique of two singletons in Area 1. In case (ii), the number of known traitors in Area 2 has increased, while maintaining the invariant of blocks with a constant number of known traitors in this area. Since our means are very limited, it may happen that we can show that there are four traitors in the block, but we are not able to partition them into two parts as required in (ii). In such a case we continue with a block known to contain more traitors. Eventually, when the number of traitors known to exist in the block raises to seven, we are able to achieve the required partition, using the basic algorithm from section 2.4 with seven colors.

Note that even if we know that there are seven traitors in the block, we do not necessarily know their exact location among the two parts into which the block was partitioned. Hence, the total number of traitors known to exist in some particular block may decrease (this never happens in the clique algorithm).

Another major problem is that we cannot treat the two areas, Area 1 and Area 2, as two completely independent processes. If we did, we would need in each of the two areas one more color than the number of traitors known to exist in that area. This would add up to $p + 2$ colors instead of the desired $p + 1$ colors. To solve this, we distinguish between the total number of traitors known to exist and the number of traitors known to exist in each one of the areas. Using a single additional color for both areas we are able to prove the existence of an additional traitor without knowing to which area it belongs. (Technically this is done by using the concept of *marking* of vertices in the algorithm.) Once we know that an additional traitor exists, we can safely use one extra color and continue the algorithm with one additional color in each

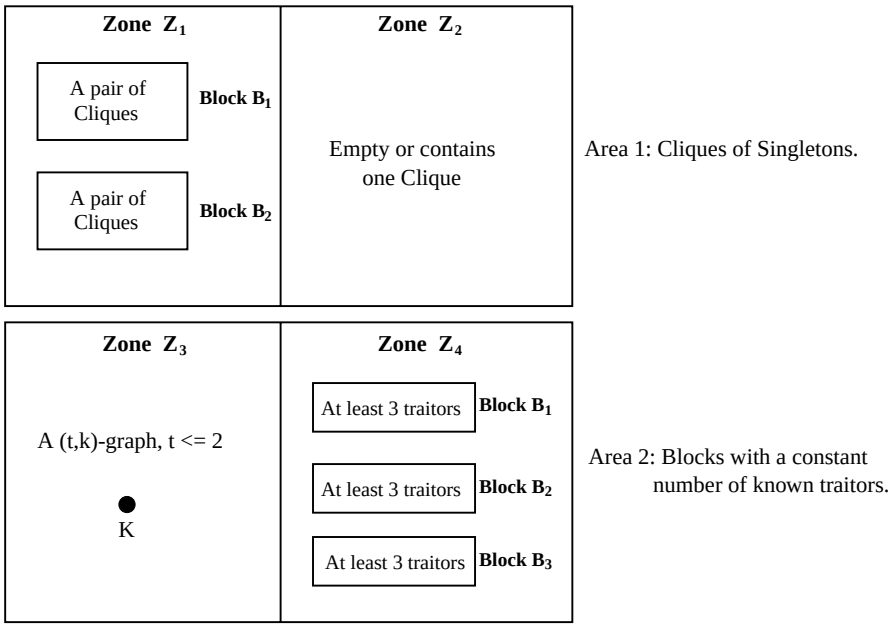

FIG. 4.1. *An example of the data structures and the graph used by the optimal algorithm.*

area.

4.1. Data structures and invariants.

The graph. We maintain an undirected graph $G = (V, E)$. The vertices are subsets of the user set U and form a partition of U. If there is an edge $(X, Y) \in E$, then $X \cup Y$ contains a traitor.

Zones and blocks. The vertices of the graph G are partitioned into Zones Z_1, Z_2, Z_3, Z_4. Furthermore, the vertices in Zones Z_1 and Z_4 are partitioned into blocks B_i. There are no edges connecting vertices from different zones or from different blocks. Let b_i be the number of traitors known to exist in block B_i, and z_i the number of traitors known to exist in Zone Z_i. The value of z_1 and z_4 is always the sum of all b_i's over the blocks of the corresponding zone. The zones and the blocks are defined as follows:

Area 1 (cliques of singletons).

- ($\mathbf{Z_1}$) This zone is partitioned into blocks B_i, where the number of vertices in B_i is $b_i + 2$, and all vertices are singletons. The vertices of block B_i can be partitioned into two cliques, each containing at least two vertices (therefore, the number of traitors known to exist in B_i is b_i). However, B_i does not contain a clique of size $b_i + 1$.
- ($\mathbf{Z_2}$) This zone either is empty or contains a clique of size $z_2 + 1 \geq 2$ whose vertices are all singletons.

Area 2 (blocks with a constant number of known traitors).

- ($\mathbf{Z_3}$) This zone is a (t, k)-graph, where $t \leq 2$. The number of traitors known to exist in Zone Z_3 is $z_3 = t \leq 2$. The special vertex I that contains "innocent users" is denoted here by K. Users from other zones may be added to the set K during the algorithm.

($\mathbf{Z_4}$) This zone is partitioned into blocks B_i, where the number of traitors known to exist in B_i is $3 \leq b_i \leq 7$.

See Figure 4.1 for an example of the data structures used by the optimal algorithm.

Number of traitors. Let $z = z_1 + z_2 + z_3 + z_4$. The value of z is updated automatically, according to the values of b_i and z_i in the individual blocks and zones. The value z is a lower bound on the number of traitors known to exist; however, it may increase or decrease. We can always use safely $z + 1$ colors.

We define another value T. Similar to z, the value T is a lower bound on the number of traitors known to exist. However, T never decreases and always $T \geq z$. Whenever z increases so that we would have $T < z$, we set $T = z$. (T may be larger than z, if we know that there exist additional traitors, but we do not know to which zone they belong. The practical implication is that the algorithm may use in this case $z + 2$ colors.)

Marks. The vertices in Zones Z_1 and Z_2 are all singletons, and they may be *marked*. The invariant is that either the marked user is a traitor, or that the total number of traitors is at least $T + 1$ (but we do not know which is the case). Additionally, in no clique in Zones Z_1 and Z_2 are all vertices marked. As a rule, whenever T increases, all marks are removed.

4.2. Description of the algorithm. We describe the algorithm with respect to each block and zone separately. When the pirate broadcasts a color given to the vertices in one of the blocks or zones, we advance the corresponding algorithm and do not change the coloring in the remaining zones.

We now describe in detail the algorithm with respect to each one of the zones. The initial graph is $G = (V, E)$, where $K = U$, $V = \{K\}$ and $E = \emptyset$ (hence, at the beginning all zones are empty except Zone Z_3). Set $T = z = 0$.

Zone Z_1. We run the clique algorithm. We need only z_1 colors, since the number of cliques in Zone Z_1 is even (as they are paired into blocks and there is no vertex I in Zone Z_1). Since all vertices are singletons, every step creates a new edge (unless we locate a traitor).

Eventually, two cliques in some block B_i are merged into one clique Q of size $b_i + 1$. Let Z be the remaining vertex in B_i that does not belong to this large clique Q. Remove all edges incident with Z and add Z to K in Zone Z_3. Reorganize the zones as follows: If Zone Z_2 is empty, the clique Q is placed in Zone Z_2. Otherwise we pair the clique in Zone Z_2 with Q into a new block in Zone Z_1, and Zone Z_2 becomes empty.

Zones Z_2 and Z_3. We use $z_2 + z_3 + 1$ colors for these two zones if $z = T$ and $z_2 + z_3 + 2$ colors if $z < T$.

(1) In Zone Z_3 we do the following:
  (1.1) We run the clique algorithm on Zone Z_3, until we know that it contains $z_3 = 3$ traitors. To do this in only $O(\log n)$ rounds, let c be a constant such that if there were only two traitors among the users, then the clique algorithm would run for at most $c \log n$ steps. If the clique algorithm runs for more than $c \log n$ steps without reaching $z_3 = 3$, we conclude that there are three traitors in the zone and we set $z_3 = 3$.
  (1.2) When $z_3 = 3$, all vertices in Zone Z_3 are placed as a block in Zone Z_4. Zone Z_3 is now empty, and we set $z_3 = 0$ and $K = \emptyset$.
(2) If Zone Z_2 is not empty and $z < T$: Use a separate color for each vertex of Zone Z_2.

(3) If Zone Z_2 is not empty and $z = T$: If the algorithm for Zone Z_3 uses at the current round only z_3 colors (out of the $z_3 + 1$ colors allocated to it), use a separate color for each vertex of Zone Z_2.
Otherwise, modify the algorithm for Zone Z_3 as follows. Suppose that the algorithm for Zone Z_3 would use at this round $q = z_3 + 1$ colors for coloring the subsets $X_1, \ldots, X_q$ (note that $q \leq 3$). Replace this round by the following q rounds. Fix an unmarked vertex S in Zone Z_2. In round k, $k = 1, \ldots, q$, color the subsets $X_1, \ldots, X_q$ in Zone Z_3 as before, color S with the color of X_k, and color the remaining vertices of Zone Z_2 with distinct colors. (The number of colors used in this case is $q + z_2 = z_2 + z_3 + 1$ as required.) Then
(3.1) if the pirate broadcasts the color of X_j, for some $j \neq k$: Advance the algorithm in step (1) above of Zone Z_3.
(3.2) Otherwise the pirate eventually broadcasts the q colors of all pairs $X_k \cup S$. In this case mark S. If all the vertices in Z_2 are marked, set $T = T + 1$ (and remove all marks).

Remark. Recall that the clique in Zone Z_2 may be moved to Zone Z_1, and in a later stage may be moved back to Zone Z_2 as part of a larger clique (after two cliques are merged). Therefore there may be marks on vertices of both Zones Z_1 and Z_2.

The algorithm used for the blocks in Zone Z_4 is fairly complex. The main building block used here is the following Algorithm (X). We now provide the specification of Algorithm (X) and then describe the algorithm for Zone Z_4. The description and analysis of Algorithm (X) is postponed to section 4.4.

Specification of Algorithm (X). *The input is a block containing at least three traitors. In each step the algorithm uses q colors, where q is the number of traitors currently known to exist in the block. At all times $3 \leq q \leq 7$. The algorithm is allowed to discard some users; in the context of the whole algorithm these users are added to the set K in Zone Z_3.*

After $O(\log n)$ rounds the algorithm either (i) *finds a subset of two users (in the block) that contains a traitor, or* (ii) *finds two disjoint subsets of the input block, one containing at least three traitors and one containing at least one traitor.*

Zone Z_4. We run Algorithm (X) on each of the blocks in this zone, thus using z_4 colors. When Algorithm (X) finishes in one of the blocks B_i, we have one of the following two cases.

(1) Block B_i is split into two subsets, one with at least one traitor and the second with at least three traitors: The first subset is added to Zone Z_3 (see step (3)). The second subset remains in this zone as a block of itself.
(2) We have a subset of two users in B_i that contains a traitor: We create a new clique Q of size 2, with two singleton vertices containing these two users, and reorganize the zones as follows. If Zone Z_2 is empty, we place the clique Q in Zone Z_2. Otherwise, we remove the single clique in Zone Z_2, pair it with the new clique Q, and create in Zone Z_1 a new block containing these two cliques; Zone Z_2 is now empty. The rest of block B_i is added to Zone Z_3 (see step (3)).
(3) In each of the above cases, some subset X of block B_i, known to contain at least one traitor, is added to Zone Z_3. This is done as follows: Remove the edges incident with X, divide X into two (almost) equal vertices connected by an edge, and add them as a clique of size 2 to Zone Z_3. Restructure the cliques of Zone Z_3 as necessary, in a similar way to step 3 in Phase 2 of the clique algorithm. Set $z_3 = z_3 + 1$. If $z_3 = 3$, go to step (1.2) in Zone Z_3.

4.3. Correctness and efficiency.

LEMMA 4.1. *The invariants of the algorithm are preserved, assuming that the same holds for Algorithm* (X).

Proof.

The graph, zone constraints, and edges between different zones and blocks. In Area 1 and Zone Z_3 these invariants are maintained because of the properties of the clique algorithm. In Zone Z_4 they are maintained because of the properties of Algorithm (X). One additional invariant is that $z_3 \leq 2$. If this invariant is violated, then the zones are restructured appropriately in step (1.2) of Zone Z_3. At all times the vertices in Area 1 are singletons: this is true when new vertices are created in step (2) of Zone Z_4 and maintained by the clique algorithm.

We need to check that the invariants are not violated when adding users to Zone Z_3 from other zones. If some users are added to K in Zone Z_3, then edges incident with K are still valid since the corresponding set of users can only become bigger. If a 2-clique is added to Zone Z_3 by step (3) of Zone Z_4, then the structure of Zone Z_3 is changed consistently with the clique algorithm. If $z_3 > 2$, then the zones are restructured.

The marks. The vertices are only marked in step (3.2) of Zones Z_2 and Z_3. If a vertex is marked and is not a traitor, it follows that all the $q = z_3 + 1$ sets $X_1, \ldots, X_q$ described there contain a traitor. This would imply that there are at least $z + 1$ traitors overall as required. Since this step is invoked only when $z = T$, the vertex is marked consistently with the invariant. The invariant of the marked vertices is maintained as long as T is unchanged, and as soon as T increases, all marks are removed.

It cannot happen that all vertices in some clique are marked. If this happens upon marking a new vertex in Zone Z_2, then the value of T is increased and all marks are removed. A new clique is created when two cliques in Zone Z_1 are merged. In this case the new clique contains all the vertices of one of the merged cliques, and thus they cannot be all marked.

The number of traitors. We need to check that there are always at least T traitors. The value T is changed in two cases—first, when z increases so that $z > T$. In this case the existence of T traitors is guaranteed by the invariants of the individual blocks and zones.

The second case is in step (3.2) of Zones Z_2 and Z_3 when all vertices in Zone Z_2 are marked. If some vertex in Zone Z_2 is not a traitor, then by the marking invariant there are at least $T + 1$ traitors, and the increase of T is justified. Otherwise all the vertices in Zone Z_2 are traitors, for a total of $z_2 + 1$ traitors. Thus, the total number of traitors is at least $z + 1$, and since $T = z$ in this step, the increase of T is justified as well. □

THEOREM 4.2. *The algorithm locates a traitor in* $O(p^2 + p \log n)$ *rounds, using* $p+1$ *colors. Hence, all* p *traitors can be located in* $O(p^2 + p \log n)$ *rounds, using* $p+1$ *colors.*

Proof. The number of colors used is at most $z_1 + z_2 + z_3 + z_4 + 1 = z + 1$ if $z = T$, and $z_1 + z_2 + z_3 + z_4 + 2 = z + 2$ if $z < T$. In both cases, at most $T + 1 \leq p + 1$ colors are used.

We now analyze the number of rounds needed by the algorithm. After at most $q = 3$ rounds in step (3) of Zones Z_2 and Z_3, we either mark a vertex or advance one of the other algorithms (most often the clique algorithm used in step (1) of Zone Z_3, but it may happen that one of the other algorithms changes z, in which case we

cannot continue the series of rounds in step (3) of Zones Z_2 and Z_3). In the first case we charge these rounds to marking a vertex. The second case adds at most $q-1$ steps per one step of the other algorithms, so the total number of rounds may increase by a factor of 3.

Let $s = z_1 + z_2$ be the number of traitors known to exist in Zones Z_1 and Z_2 (which contain only singleton vertices). Let $r = z_1 + z_2 + z_3 + 3b$, where b is the number of blocks in Zone Z_4. Note that r is a lower bound on the number of traitors in all zones, since the blocks of Zone Z_4 contribute only three traitors each instead of b_i (which may be as large as 7).

The values of T, s, and r are between 0 and p at all times. The values of s and T never decrease, and thus each of them increases at most p times. The value of r decreases only when a subset of two users containing a traitor is found in a block in Zone Z_4. In such a case s increases by 1 and r decreases by 2 (since b decreases by 1 and z_3 increases by 1). It follows that r may increase at most $3p$ times.

The value of r increases after each (amortized) $O(\log n)$ rounds in a block in Zones Z_4 and Z_3, not counting the rounds charged to marking of vertices in Zone Z_2. Thus the number of these rounds is $O(p \log n)$.

Each of the remaining rounds either is charged to marking a vertex or creates an edge between two cliques of singletons. We unmark vertices or remove edges when T increases or when two cliques are merged. We increase T at most p times, and each time $O(p)$ vertices are unmarked. This accounts for $O(p^2)$ rounds. A clique of singletons is never split. Therefore we get a new clique only when s increases, which happens at most p times. Thus two cliques are merged at most p times. Each time we remove at most p edges and one marked vertex. This accounts for $O(p^2)$ rounds. At the end we have $O(p)$ marked vertices and $O(p^2)$ edges. This accounts for $O(p^2)$ rounds as well. Thus the total number of rounds needed to locate one traitor is $O(p^2 + p \log n)$. Again, by Lemma 2.1, all p traitors can be located in the worst case in at most $O(p^2 + p \log n + (p-1)) = O(p^2 + p \log n)$ rounds. □

4.4. Algorithms for blocks in zone Z_4. Algorithm (X) described in this section receives as an input a block known to contain at least three traitors. Its goal is to either (i) find a subset of two users containing a traitor, or (ii) partition the block into two parts, one with three traitors and one with a single traitor. This is achieved in $O(\log n)$ rounds.

The plan is to first partition the block into a constant number of $q \geq 3$ parts, where each part contains at least one traitor. Then we either halve one of these q parts, and thus come closer to achieving goal (i), or we prove that the block contains at least $q+1$ traitors and thus advance towards goal (ii).

Since we cannot use more colors than the number of traitors known to exist in this block, the pirate can confuse our algorithm if there are in fact more traitors. We found the following conditional invariant extremely useful in achieving our aims.

DEFINITION 4.3. *A block is q-good if it is partitioned into $q+1$ sets of users $A_1, \ldots, A_q$, and J with the property that either each of the sets A_i contains one traitor or the block contains more than q traitors.*

In other words, either a q-good block contains exactly q traitors located in q disjoint sets, or there are more than q traitors, but we have no knowledge about their location. (Such a block is good in the sense that the algorithm is making progress in the desired direction.)

Thus, instead of finding an unconditional partitioning of the block into three parts, each containing a traitor, we try to find a partition which demonstrates that

the block is 3-good. However, this may not succeed, and instead we might just learn that there are four traitors. Then we try to find a 4-good block, etc. Eventually, when we are able to prove that there are at least seven traitors in the block, we can partition the block unconditionally as required in (ii), using the basic algorithm of section 2.4 with seven colors.

The main part of the algorithm is how to halve one of the sets A_i in a q-good block (and still remain with a q-good block), or to deduce that there are at least $q+1$ traitors in the block. Our algorithm is motivated by the exponential algorithm of Fiat and Tassa [7]. Their method is as follows: Split each one of the sets $A_1, \ldots, A_q$ into two (almost) equal parts. Choose one part from each one of the sets A_i, and color these q chosen parts with q unique colors. Use an additional color for all the remaining users (consisting of the parts of the sets A_i that did not receive a unique color and of the set J). Try all 2^q combinations of choosing q parts from each one of the sets A_i. If we get an answer in one of the parts that were colored by a unique color, then we have achieved the required split of the corresponding set A_i. Otherwise we can conclude that there are more than q traitors. However, this method uses $q+1$ colors, and we can only use q colors. Thus our algorithm is modified to use one common color for two of the q chosen parts of the sets A_i. After trying all of the $\binom{q}{2}2^q$ combinations and analyzing the answers, we are able to halve a set or prove that there are at least $q+1$ traitors. Since q is a constant, the number of combinations and rounds needed is also a constant.

4.4.1. Description of the algorithms. Algorithms (I) through (IV) described below are used as building blocks for Algorithm (X), which is then used by the algorithm for Zone Z_4 in section 4.2.

Algorithms (I)–(IV) and Algorithm (X) stop whenever they find *a subset of two users that contains a traitor*. In fact, this event always stops not only the current algorithm but also stops Algorithm (X) in the current block. We do not mention this in the descriptions of the algorithms explicitly. This also means that when we have an edge in this part of the graph, at least one of its endpoints is not a singleton. Similarly, recall that the algorithm stops upon locating a traitor. Therefore, if we get a vertex as an answer, it is not a singleton.

The algorithms are allowed to *discard* some users. In the context of the optimal algorithm described in section 4.2, these users are added to the set K in Zone Z_3.

The correctness of the individual algorithms follows immediately from the remarks in their description. After the description of each algorithm we argue briefly to bound its running time.

Algorithm (I). *The input is a constant $q \geq 3$ and a q-good block. Using q colors and $O(\log n)$ rounds, the algorithm proves that there are more than q traitors in this block. (The algorithm also stops upon finding a set of two users containing a traitor. It never discards any users.)*

Throughout the algorithm, we maintain a q-good block. Additionally, each set A_i is split into two disjoint sets $A_{i,0}$ and $A_{i,1}$ of equal size (more exactly, their cardinalities may differ by one and if A_i is a singleton, then one of the sets may be empty).

(1) In successive $\binom{q}{2}2^q = O(1)$ rounds, use all $\binom{q}{2}2^q$ colorings of the following form. For any $a_1, \ldots, a_q \in \{0,1\}$, and $1 \leq j < j' \leq q$: Use one color for the set $A_{j,a_j} \cup A_{j',a_{j'}}$ and $q-2$ colors for the sets A_{i,a_i}, $i \notin \{j, j'\}$, one color per set. The last color is given to the union of the remaining $q+1$ sets (including J).

(2) If the pirate ever broadcasts a color given to only one (nonsingleton) set $A_{i,a}$:

Add $A_{i,1-a}$ to J, set $A_i = A_{i,a}$, split A_i into $A_{i,0}$ and $A_{i,1}$, and go to step (1).

(3) If in the above $\binom{q}{2}2^q$ rounds the pirate broadcasts the colors of all possible 2^q sets containing J, each at least once, then the block contains more than q traitors and we are done.

(4) Otherwise we may suppose after renumbering that the pirate never broadcasts the color of $J \cup A_{1,1} \cup \cdots \cup A_{q,1}$. This means that the pirate broadcasts the color of $A_{j,0} \cup A_{j',0}$ for all $j \neq j'$. If two of the sets A_j and $A_{j'}$ are singletons, then $A_{j,0} \cup A_{j',0} \subseteq A_j \cup A_{j'}$ is a subset of cardinality at most two that contains a traitor, and we are done.

Otherwise there is at most one singleton set. Renumber the sets so that A_1 and A_2 are not singletons (using $q \geq 3$). The sets $A_{1,0}, \ldots, A_{q,0}$ form a clique of size q and therefore contain at least $q-1$ traitors. Below we find a set $A_{j,1}$ that does not contain a traitor, assuming that there are only q traitors. Given such a set $A_{j,1}$, we add it to J, set $A_j = A_{j,0}$, and go to step (1).

In order to find such a set $A_{j,1}$, we distinguish between two subcases. Let us examine the answer given by the pirate in the round when we used one color for the set $J \cup A_{1,0} \cup A_{2,1} \cup \cdots \cup A_{q,1}$ and one color for the set $A_{1,1} \cup A_{2,0}$.

(4.1) If the answer was $A_{1,1} \cup A_{2,0}$: Assuming that there are only q traitors, $A_{2,1}$ does not contain a traitor. Otherwise $A_{2,0}$ has no traitor, and thus $A_{1,1}$ contains a traitor; it follows that there are more than q traitors (together with the $q-1$ traitors in $A_{1,0} \cup \cdots \cup A_{q,0}$).

(4.2) If the answer was $J \cup A_{1,0} \cup A_{2,1} \cup \cdots \cup A_{q,1}$: Assuming that there are only q traitors, $A_{1,1}$ does not contain a traitor. Otherwise $A_{1,0}$ does not contain a traitor, and thus either J or some $A_{j,1}$, $j \neq 1$ contains a traitor; it follows that there are more than q traitors.

After $O(1)$ rounds, if the algorithm is not done, one of the nonsingleton sets is split and half of it is added to J. Thus the total number of rounds is $O(q \log n) = O(\log n)$ (since $q = O(1)$).

Algorithm (II). *The input is a constant $q \geq 3$ and a block known to contain at least q traitors. Using q colors and $O(\log n)$ rounds, the algorithm either* (i) *proves that there are more than q traitors in the block or* (ii) *finds a subset of the input block which consists of k cliques with a total of $k+q$ vertices (i.e., q of the vertices have to contain a traitor) for some odd number k. (The algorithm also stops upon finding a set of two users containing a traitor.)*

We run the clique algorithm on this block, with its own special set I. Initially, I contains all the users. Let c be a constant such that if there were only q traitors among the users, then the clique algorithm would run for at most $c \log n$ rounds. If the clique algorithm does not finish in $c \log n$ steps, we conclude that there exist more than q traitors and we are done by (i).

If the clique algorithm needs $q+1$ colors, then there are k cliques with a total of $k+q$ vertices for some k. If k is odd, we are done. Otherwise we discard the set I and continue running the clique algorithm with only q colors, since we do not need the color for I. Whenever a vertex is supposed to be added to I, it is discarded (this happens when a vertex in a clique of size two is split, or when two cliques are merged). Eventually, either two cliques are merged, or a vertex contained in a clique of size at least 3 is split. In either case we get an odd number of cliques and we are done by (ii).

The number of rounds of this algorithm is $O(\log n)$ as claimed because we explic-

itly restricted it.

Algorithm (III). *The input is a block consisting of a clique Q on five vertices. Using four colors and $O(\log n)$ rounds, the algorithm either* (i) *finds a 4-good block which is a subset of the input block or* (ii) *finds two disjoints subsets of the input block, one containing at least three traitors and one containing at least one traitor. (The algorithm also stops upon finding a set of two users containing a traitor.)*

(1) Let A be a nonsingleton vertex of Q. Remove the edges incident with A and split A into two vertices A_1 and A_2 of (almost) equal size. The block now contains the clique $Q \setminus \{A\}$ and the vertices A_1 and A_2.
(2) Find two disjoint nonedges, one containing A_1 and one containing A_2. Use two colors for these nonedges and two colors for the remaining two vertices. (A *nonedge* is a pair of vertices in this block that are not connected by an edge in the graph G.)
(3) If the pirate broadcasts a color given to one vertex: We are done by (ii), since this vertex is a subset with one traitor and the remaining four vertices contain three traitors.
(4) If the pirate broadcasts a color given to two vertices: Add that edge and repeat step (2). If the two disjoint nonedges in step (2) do not exist, one of the following cases occurs:
  (4.1) We have a 5-clique containing one of A_1 and A_2: Discard the other set A_i and go back to step (1).
  (4.2) We have a graph on the six vertices containing all edges except for those in the triangle A_1, A_2, B, for some vertex B: This is a 4-good block with $J = \emptyset$, one of the sets being $A_1 \cup A_2 \cup B$ and the other three sets being the remaining vertices. Thus we are done by (i).

After a constant number of rounds, if the algorithm does not end, it goes back to step 1 with a 5-clique in which one of the vertices is halved. Thus after $O(\log n)$ rounds we obtain a clique with two singletons and the algorithm stops.

Algorithm (IV). *The input is a block consisting of a clique Q on four vertices. Using three colors and $O(\log n)$ rounds, the algorithm finds a 3-good block which is a subset of the input block. (The algorithm also stops upon finding a set of two users containing a traitor.)*

(1) Let A be a nonsingleton vertex of Q. Remove the edges incident with A and split A into two vertices A_1 and A_2 of (almost) equal size.
(2) Find two disjoint nonedges, one containing A_1 and one containing A_2. Use two colors for these nonedges and one color for the remaining vertex.
(3) If the pirate broadcasts a color given to only one (nonsingleton) vertex B, one of the following cases occurs:
  (3.1) If the edge (A_1, A_2) does not exist: Unite back $A = A_1 \cup A_2$ and split B into (almost) equal parts B_1 and B_2 connected by an edge. The remaining three vertices form a clique, and there are no other edges. Set $A_1 = B_1$ and $A_2 = B_2$ and go to step (2).
  (3.2) Otherwise: We have a 3-good block with $J = \emptyset$, and the three sets are A, B, and the union of the remaining two vertices. Thus we are done.
(4) If the pirate broadcasts a color given to two vertices: Add that edge and repeat step (2). If the two disjoint nonedges in step (2) do not exist, one of the following cases occurs:
  (4.1) We have a 4-clique containing one of A_1 and A_2. Discard the other set A_i and go back to step (1).

(4.2) We have a graph on the five vertices containing all edges except for those in the triangle A_1, A_2, B, for some vertex B. This is a 3-good block with $J = \emptyset$, one of the sets is $A_1 \cup A_2 \cup B$, and the other two sets are the remaining vertices. Thus we are done.

After a constant number of steps, if the algorithm does not end, it goes back to step 1 with a 4-clique in which one of the vertices is halved (note that step (3.1) may occur only once). Thus after $O(\log n)$ rounds we obtain a clique with two singletons and the algorithm stops.

Algorithm (X). *The input is a block containing at least three traitors. In each step the algorithm uses q colors, where q is the number of traitors currently known to exist in the block. After $O(\log n)$ rounds the algorithm finds two disjoint subsets of the input block, one containing at least three traitors and one containing at least one traitor. (The algorithm also stops upon finding a set of two users containing a traitor.)*

(1) Prove that the block contains at least four traitors (or finish): Run Algorithm (II) with $q = 3$. If it proves that there are four traitors, go to step (2). Otherwise we have k cliques with a total of $k + 3$ vertices, where $k \in \{1, 3\}$. If $k = 3$, then the block is 3-good (with $J = \emptyset$ and the three sets each being the union of one clique). If $k = 1$, we have a 4-clique: Run Algorithm (IV) to find a 3-good block. In either case we get a 3-good block. Run Algorithm (I) to prove that the block contains four traitors, and go to step (2).

(2) Prove that the block contains at least five traitors (or finish): Now we have a block with four traitors. Run Algorithm (II) with $q = 4$. If it proves that there are five traitors, go to step (3). Otherwise we have k cliques with a total of $k + 4$ vertices, where $k \in \{1, 3\}$.

(2.1) If $k = 3$, then the number of traitors in the three cliques is 1, 1, and 2. We split the block into a clique with one traitor and a subset containing the remaining two cliques with three traitors, and we are done.

(2.2) If $k = 1$, then we have a 5-clique, and we run Algorithm (III). If we get two subsets with one and three traitors, we are done. Otherwise we have a 4-good block. We run Algorithm (I) with $q = 4$ to prove that the block contains five traitors, and go to step (3).

(3) Now we have a block with five traitors. Run Algorithm (II) with $q = 5$.

(3.1) If we get cliques, we split the block into two subsets—one with at least one traitor and one with at least three traitors—and we are done. This is done as follows: If there are at least three cliques, one subset is the smallest clique and the other one is the rest. If there is a single clique, one subset is the union of two of the vertices of the clique, and the other subset contains the remaining vertices.

(3.2) If we get a block with six traitors: Run Algorithm (II) with $q = 6$. If we get cliques, we split them as in step (3.1). Otherwise we have a block with seven traitors. We run the basic algorithm described in section 2.4 (for locating p traitors with $2p+1$ colors) until it needs more than seven colors. This happens when it finds four disjoint subsets each containing a traitor (the pairs in the basic algorithm). Split the block into one of these subsets and the remaining subsets.

Algorithm (X) runs Algorithms (I)–(IV) $O(1)$ times, and each of them takes $O(\log n)$ rounds. Step (3.2) also needs $O(\log n)$ rounds. Thus the total number of rounds is $O(\log n)$.

5. Using more colors. In this section we extend our results and present two algorithms which use more than $p+1$ colors. The number of rounds needed to locate all traitors is reduced as the number of colors grows.

5.1. Using $p+c+1$ colors. We modify the optimal algorithm from section 4 to use $p+c+1$ colors for any $1 \le c \le p$. The additional colors are used for cliques of singletons with more than p/c vertices. This ensures that all cliques have at most $O(p/c)$ vertices, and therefore the number of edges removed in each round is smaller. The additional colors allow us not to use marks on the vertices in the corresponding part of the optimal algorithm. (Recall that the marks were used to decrease the number of colors from $p+2$ to $p+1$.)

5.1.1. Data structures and invariants. The basic structure is similar to that of the optimal algorithm with the following modifications.

Zones and blocks.

($\boldsymbol{Z_1, Z_2}$) As in the optimal algorithm. Additionally, any clique in these zones is required to have at most T/c vertices.

($\boldsymbol{Z_3, Z_4}$) As in the optimal algorithm.

($\boldsymbol{Z_5}$) This new zone is partitioned into blocks B_i, where each B_i contains one clique of singletons of size b_i+1, such that $T/c < b_i + 1 \le 2T/c$.

Marks. There are no marks on the vertices.

5.1.2. Description of the algorithm.

Zone $\boldsymbol{Z_1}$. As in the optimal algorithm (i.e., run the clique algorithm using z_1 colors). If a new clique with more than T/c vertices is produced by merging two cliques, add it as a new block in Z_5 (instead of incorporating it into Z_1, Z_2).

Zones $\boldsymbol{Z_2}$ and $\boldsymbol{Z_5}$. Each vertex gets a unique color. If the size of a clique in Z_5 becomes $\le T/c$ (because T increased), incorporate this clique into Z_1 and Z_2 (similarly as a new clique in the clique algorithm).

Zone $\boldsymbol{Z_3}$. Run the clique algorithm as in the optimal algorithm, using z_3+1 colors, with no modifications due to marks in Z_2.

Zone $\boldsymbol{Z_4}$. As in the optimal algorithm, using z_4 colors. If $T/c < 2$ and a new clique of two singletons is created, add it as a new block in Z_5 (instead of incorporating it into Z_1, Z_2).

5.1.3. Correctness and efficiency.

LEMMA 5.1. *The invariants of the algorithm are preserved at all times.*

Proof. Each clique added to Zone Z_5 is produced by merging two cliques, each of size at most T/c, so its size is at most $2T/c$ as required. The bounds on the size of the cliques are maintained; to verify this we also use the fact that T never decreases. All other invariants are maintained similarly as in the optimal algorithm. ∎

THEOREM 5.2. *The algorithm locates a traitor in $O(p^2/c + p\log n)$ rounds, using $p+c+1$ colors, for any $1 \le c \le p$. Hence, all p traitors can be located in $O(p^2/c + p\log n)$ rounds, using $p+c+1$ colors.*

Proof. Compared to the optimal algorithm, we need one extra color for each clique in Zones Z_2 and Z_5. Let m be the number of these cliques, where $m-1$ of these cliques belong to Zone Z_5. Thus $T \ge z_2 + z_5 \ge 1 + (m-1)T/c$. It follows that $m \le c$ and thus the number of colors used is at most $p+c+1$.

The analysis of the number of rounds is the same as in Theorem 4.2, with the following differences in the area of singletons. First, we have no marks, so we do not charge any work to marking and unmarking vertices. Second, the degree of any

vertex in Zones Z_1 and Z_2 is $O(p/c)$. Thus, the number of edges removed during the algorithm and the final number of edges in G is bounded by $O(p^2/c)$ instead of $O(p^2)$. Hence, the total number of rounds needed to locate a traitor is $O(p^2/c + p \log n)$, and the theorem follows by using Lemma 2.1. □

5.2. Using $pc + 1$ colors. Now we allow for the use of $tc + 1$ colors when t traitors are known to exist for any integer $c \geq 2$. The algorithm is an immediate extension of the basic algorithm described in section 2.4.

In each stage of the algorithm we keep t disjoint sets S_i, each known to contain a traitor. Furthermore, each set is partitioned into c subsets $S_{i,j}$ of almost equal sizes. In addition we have the set I of innocent users, which at the beginning contains all users.

(1) Distribute the colors as follows: For each set S_i, color the c subsets $S_{i,j}$ using c colors, one color per subset. Color I with an additional color. The total number of colors used is thus $tc + 1$.
(2) If the pirate broadcasts the color of I: Create a new set $S_{t+1} = I$ and partition it into c (almost) equal subsets. Set $I = \emptyset$ and $t = t + 1$.
(3) If the pirate broadcasts the color of a subset $S_{i,j}$: Add all subsets $S_{i,j'}$, $j' \neq j$, to I. Set $S_i = S_{i,j}$ and partition S_i into c new (almost) equal subsets.

THEOREM 5.3. *The algorithm locates a traitor in $O(p \log_c n)$ rounds, using $pc+1$ colors, for $c \geq 2$. Hence, all p traitors can be located in $O(p \log_c n)$ rounds, using $pc+1$ colors.*

Proof. A subset is split at each round of the algorithm. Since a split divides a subset into c equal parts, each subset other than I can be split at most $O(\log_c n)$ times. The subset I may be split an additional p times. Thus the algorithm finishes in $O(p \log_c n)$ rounds. □

6. The degree algorithm. In this section we present an algorithm based on a different idea. This algorithm uses $p + 1$ colors and runs in time $O(p^3 \log n)$. Thus the bounds are the same as for the clique algorithm.

The knowledge of the algorithm is represented by a similar graph as before. That is, vertices represent disjoint subsets of users from U, and an edge between vertices X and Y represents the fact that the subset $X \cup Y$ contains a traitor.

The main idea here is to eliminate vertices with a large degree. To do that, note that if the degree of a vertex is larger than p, then this vertex must contain a traitor (otherwise each of its neighbors would contain a traitor, resulting in more than p traitors). Therefore, if we knew p in advance, we would know that such a vertex contains a traitor and the algorithm could have split it.

Since p is unknown, we maintain a value T (as in the previous algorithms), which is the number of traitors known by the algorithm to exist. Whenever a vertex of a large degree appears, we *suspect* that it contains a traitor. (The notion of a large degree will be defined later.) Note that our knowledge about these vertices is conditional only: we know that either the vertex contains a traitor, or that the actual number of traitors is greater than T (however, we do not know which is the case). Consequently, when T is increased, we have no information about any traitor in these suspected vertices and we have to treat the users as innocent.

Among the remaining vertices, we distribute the colors so that each color is used by one vertex or by two vertices not connected by an edge. An existence of such a coloring is implied by the fact that the degree of these vertices is small. In each round progress is made by adding a new edge, splitting a vertex, or finding a vertex of a large degree.

6.1. Data structures and invariants.

The graph. We maintain an undirected graph $G = (V, E)$. The vertices are subsets of the user set U and form a partition of U. If there is an edge $(X, Y) \in E$, then $X \cup Y$ contains a traitor.

The zones. The vertices of the graph G are partitioned into Zones Z_1, Z_2. There are no edges adjacent to vertices in Zone Z_1. We also maintain a value T, which is the number of traitors known to exist. The zones are defined as follows:

- (**Z_1**) This zone contains z_1 vertices. The invariant is that if the actual number of traitors is exactly T, then each vertex in Z_1 contains a traitor. As stated above, the degree of all vertices in this zone is 0.
- (**Z_2**) This zone is a (z_2, z_2)-graph, i.e., a graph on $2z_2 + 1$ vertices containing z_2 disjoint cliques of size 2 each, and the special vertex I (there may be edges between the cliques). The invariant is that all vertices in this zone have degree at most $T - z_1$.

Number of traitors. Let $z = z_1 + z_2$. Thus z is the number of traitors known to exist in distinct vertices of G, assuming that the actual number of traitors is T. The invariant is that the total number of traitors is at least T and that $T \geq z$. This implies that the algorithm may use $T + 1$ colors. As a rule, T never decreases. Note that the total number of vertices in the graph is $|V| = z_1 + 2z_2 + 1 = z + z_2 + 1$.

6.2. Description of the algorithm. Before describing the algorithm we give a lemma about the existence of a large matching, and show how it is applied to find a proper coloring in the algorithm. A *matching* in a graph is a set of disjoint edges. The *size* of the matching is the number of edges in the matching. The proof of the following lemma is standard and can be found in Appendix A.

LEMMA 6.1. *Let H be a graph with at least $2d$ vertices with degree at least d each. Then there exists a matching in H of size at least d.*

Let G' be the complement graph of G restricted to Zone Z_2, i.e., the vertices of G' are the vertices in Zone Z_2, and two distinct vertices are connected by an edge in G' if and only if they are not connected by an edge in G. Zone Z_2 contains $2z_2 + 1$ vertices, each with degree at most $T - z_1$. Thus the minimum degree of the graph G' is $2z_2 - (T - z_1) = z_2 + z - T$. By taking $d = z_2 + z - T$ in Lemma 6.1, there exists a matching of size at least $z_2 + z - T$ in G'.

We now describe the algorithm. The initial graph is $G = (V, E)$ with $I = U$, $V = \{I\}$, and $E = \emptyset$. Zone Z_1 is empty and Zone Z_2 contains the single vertex I. Set $T = z = 0$. Repeat the following two phases:

Phase 1: Distributing the colors to the vertices of G.

Find a matching of size at least $z_2 + z - T$ in G' (which exists by Lemma 6.1 and the above discussion). Use one color for each edge in the matching (i.e., for the two vertices of the edge). Use a distinct color for every remaining vertex, including the vertices of Zone Z_1. The number of colors used is at most $|V| - (z_2 + z - T) = (z + z_2 + 1) - (z_2 + z - T) = T + 1$.

Phase 2: Reorganizing the graph following the pirate's response.

(1) If the pirate transmitted a color given to a single vertex X: Remove X and all edges incident with X. Split X into two (almost) equal subsets X_1 and X_2, and add the edge (X_1, X_2). Place X_1 and X_2 as a new clique in Zone Z_2.
  (1.1) If X was in Zone Z_1: Set $z_1 = z_1 - 1$ and $z_2 = z_2 + 1$.

(1.2) If X was in Zone Z_2 in a clique with Y: Remove Y and all edges incident with Y, and set $I = I \cup Y$.

(1.3) If X was in Zone Z_2 and $X = I$: Create a new special vertex $I = \emptyset$ and set $z_2 = z_2 + 1$.

(2) If the pirate transmitted a color given to a pair of vertices (X, Y) (necessarily in Zone Z_2): Add the edge (X, Y) to G, and

(2.1) for any vertex $Z \in Z_2$ of degree larger than $T - z_1$ do the following: Move Z to Zone Z_1, remove all edges incident with Z, and set $z_1 = z_1 + 1$. If $Z = I$, create a new special vertex $I = \emptyset$.

(2.2) Repeat step (2.1) until all vertices have degree at most $T - z_1$. (Note that after step (2.1) the value of $T - z_1$ decreases, which may cause some more vertices to have a large degree.)

(2.3) Add to the special vertex I all the vertices which remain in Zone Z_2 and do not belong to a clique of size 2 (i.e., the vertex I will contain all the vertices who had a neighbor Z (in their clique) that was moved to Zone Z_1. The vertex I will also contain the old I if it was not moved to Zone Z_1). Update z_2 to reflect the current number of cliques of size 2 in Zone Z_2.

(3) If after one of the previous steps $z > T$: Set $T = T + 1$ and add to I all the vertices that belong to Zone Z_1. Zone Z_2 remains unchanged.

6.3. Correctness and efficiency.

LEMMA 6.2. *The invariants of the algorithm are preserved at all times.*

Proof.

The graph. An edge is added only if we got an answer from the pirate corresponding to that edge.

Zone Z_1. First consider the moment when we decide to place a vertex X in Zone Z_1. At that point X is in Zone Z_2 and its degree is larger than $T - z_1$. Assume that the invariant is violated, i.e., X does not contain a traitor and the actual number of traitors is exactly T. It follows that there are more than $T - z_1$ traitors in the neighbor vertices of X in Zone Z_2. Also, Zone Z_1 contains z_1 traitors, by the invariant of the zone. Thus the total number of traitors is strictly larger than T, a contradiction. We conclude that the invariant is maintained when a vertex is placed in Zone Z_1.

As long as a vertex remains in Zone Z_1, the value of T does not change, by step (3) of the algorithm. Thus the invariant is maintained at all times.

Zone Z_2. Whenever one vertex of a clique is removed in step (2.1), the other vertex is also removed in step (2.3), and the value of z_2 is updated accordingly. Thus, the (z_2, z_2)-graph is maintained. No vertex in Zone Z_2 has degree larger than $T - z_1$ after a round because we remove in step (2.2) all such vertices from Zone Z_2.

The number of traitors. T is increased only in step (3). Assume to the contrary that there are only T traitors when T is increased. Then there are z_1 traitors in Zone Z_1 by its invariant and z_2 traitors in Zone Z_2. However, then the total number of traitors is at least $z_1 + z_2 = z > T$, a contradiction. We conclude that there are at least $T + 1$ traitors and the increase of T is justified. Thus, there are at least T traitors at all times.

Note that we cannot conclude that there are z traitors, since a vertex in Zone Z_1 is known to contain a traitor only if the actual number of traitors is exactly T. Since this was found to be untrue as T has increased, we cannot assume any more that the vertices in Zone Z_1 contain traitors. □

THEOREM 6.3. *The degree algorithm locates a traitor in $O(p^3 \log n)$ rounds, using at most $p+1$ colors. Hence, all p traitors can be located in $O(p^3 \log n)$ rounds, using at most $p+1$ colors.*

Proof. The algorithm always uses at most $T+1 \leq p+1$ colors, by the calculation in Phase 1 of the algorithm.

We now estimate the number of rounds. The value of T is increased at most p times and never decreases. Therefore it is sufficient to prove that for each value of T, the number of rounds is at most $O(T^2 \log n)$. Since $T \leq p$, the total number of rounds until a traitor is located is $O(p^3 \log n)$.

When T does not increase, the algorithm takes one of the following actions: either (1) a vertex is split or moved to Zone Z_1 and at most $2T$ edges are removed or (2) an edge is added to G. Note that (1) may happen more than once during a single round. Zone Z_1 has at most T vertices at the end, so the number of times a vertex is moved to Zone Z_1 is at most T plus the number of splits. Similarly, as in the previous algorithms, there are at most $O(T \log n)$ splits before T increases. Consequently, the number of steps of type (2) is bounded by the number of edges of G at the end, plus the number of edges removed during the algorithm. This gives the bound of $O(T^2 \log n)$ rounds before T increases. ∎

7. Lower bounds. We now prove a lower bound on the number of rounds needed by any algorithm that uses $p+c$ colors, assuming that p is not known in advance.

LEMMA 7.1. *Using $p+c$ colors, at least $\Omega(p^2/c)$ rounds are needed to locate p traitors, when p is not known in advance.*

Proof. If $c \geq p$, the bound is true, since at least p rounds are needed to locate p traitors. Let $c < p$ and let $n = p + c + 1$ be the number of users, i.e., there are $c+1$ innocent users. In any coloring with $p+c$ colors there are at least two users with the same color.

We use an adversary argument. In each round, the pirate transmits a color given to (at least) two users. We prove that the pirate can continue for at least $\Omega(p^2/c)$ rounds, consistently with the fact that there are p traitors. We maintain a graph G with users as vertices, initially with no edges. In each round we add an edge between the two users whose color was given as an answer (if the algorithm colors more than two users by the same color, we choose any two of them; this can only decrease the number of rounds). The pirate can continue as long as there is an independent set of size $c+1$ in G. (Recall that an independent set is a set of vertices with no edges between them.) In this case the pirate's answers are consistent with the p traitors being the vertices not in the independent set.

Let H be the graph on n vertices consisting of c disjoint cliques, each with $\lfloor n/c \rfloor$ or $\lceil n/c \rceil$ vertices, and no other vertices and edges. By Turan's theorem (see [12]) used for the complement graph of G, if G does not contain an independent set of size $c+1$, then G has at least as many edges as H. The number of edges in H is $\Theta(p^2/c)$ (the cliques are nontrivial, since $c < p$). Thus the pirate can always continue for at least $\Omega(p^2/c)$ rounds. ∎

THEOREM 7.2. *Using $p+c$ colors, at least $\Omega(p^2/c + p \log_{c+1} n)$ rounds are needed to locate p traitors if p is not known in advance and $n \geq (1+\varepsilon)c$ for some constant $\varepsilon > 0$.*

Proof. We use an adversary argument which proceeds in phases. In phase t, $t = 1, \ldots, p$, the pirate has already chosen the location of the first $t-1$ traitors and is revealing the location of the next traitor. The algorithm knows about the existence of only t traitors and thus can use $t+c$ colors. The pirate keeps a set A of candidates for

the next traitor. At the beginning of each phase, the set A contains all users except for the first $t-1$ traitors. If any of the first $t-1$ traitors does not get a unique color, then the pirate broadcasts that color. Otherwise A is colored by at most $c+1$ colors. Then the pirate broadcasts the color given to most users in A and removes all the other users from A. When the size of A is at most $c+1$, the pirate fixes one user in A as the next traitor, and a new phase begins. No traitor is located until the end of phase p.

Assume, without loss of generality, that $\varepsilon < 1$. The number of rounds in phase t is at least $\lceil \log_{c+1}(n+1-t) \rceil - 1$. For $t < \varepsilon p/2 \le \varepsilon n/2$, we have $n+1-t > c+1$ and $n+1-t > n/2$. Therefore, the number of rounds in phase t is at least $\Omega(\log_{c+1} n)$ and the total number of rounds is at least $\varepsilon p/2 \cdot \Omega(\log_{c+1} n) = \Omega(p \log_{c+1} n)$. Together with Lemma 7.1 this proves the theorem. ∎

8. Open problems. We conclude with a few open problems. First it would be nice to close the small gap of $O(\log c)$ between the lower and upper bound in the case that $p+c$ colors are used, and p is not known in advance.

We achieve an asymptotically optimal number of rounds in the optimal algorithm described in section 4. However, it is very complex and the hidden constants are large. From a more practical viewpoint, it would be desired to find a simpler optimal algorithm for the $p+1$ case, with possibly better constants.

It may be interesting to investigate randomized algorithms. The first question is what is the proper model in this case. In the deterministic case, the pirate is able to simulate the algorithm. Thus, for example, the pirate can deduce completely the distribution of the colors. In the randomized case, it is not realistic to assume this, and the game needs to be specified precisely.

Appendix A. Proof of Lemma 6.1.

LEMMA 6.1. *Let H be a graph with at least $2d$ vertices with degree at least d each. Then there exists a matching in H of size at least d.*

Proof. The proof is by induction. Given a matching of size $c < d$, we show how to find a matching of size $c+1$. Starting at $c = 0$ and repeating this process, we find a matching of size d.

Let v and w be two unmatched vertices of degree at least d each. If some neighbor of v or w is unmatched, then we extend the matching trivially. Otherwise, let $x_1, \ldots, x_d$ be d distinct neighbors of v in H, and $y_1, \ldots, y_d$ their respective neighbors in the matching of cardinality c. Some vertices y_j may be equal to some x_i, but in any case all the vertices y_j are distinct. Out of the $2c$ vertices of the matching of size c there are $2c-d$ vertices that are distinct from all the vertices y_j. Since $c < d$, we have $2c-d < d$. As all the neighbors of w are matched and its degree is at least d, it follows that w is connected to y_j for some j. Replace the edge (x_j, y_j) in the matching by the edges (v, x_j) and (y_j, w). ∎

Acknowledgments. We are in debt to Amos Fiat, Aria Lev, Tal Rabin, and Tamir Tassa for useful discussions and comments. We would especially like to thank the anonymous referees for the many suggestions and comments they made, which helped to improve the presentation of this paper.

QUANTUM ENTANGLEMENT AND COMMUNICATION COMPLEXITY*

HARRY BUHRMAN†, RICHARD CLEVE‡, AND WIM VAN DAM§

Abstract. We consider a variation of the communication complexity scenario, where the parties are supplied with an extra resource: particles in an entangled quantum state. We note that "quantum nonlocality" can be naturally expressed in the language of communication complexity. These are communication complexity problems where the "output" is embodied in the correlations between the outputs of the individual parties. Without entanglement, the parties must communicate to produce the required correlations; whereas, with entanglement, *no* communication is necessary to produce the correlations. In this sense, nonlocality proofs can also be viewed as communication complexity problems where the presence of quantum entanglement reduces the amount of necessary communication. We show how to transform examples of nonlocality into more traditional communication complexity problems, where the output is explicitly determined by each individual party. The resulting problems require communication with or without entanglement, but the required communication is less when entanglement is available. All these results are a noteworthy contrast to the well-known fact that entanglement cannot be used to actually simulate or compress classical communication between remote parties.

1. Introduction and summary of results.

One of the most remarkable aspects of quantum physics is the notion of *quantum entanglement*. If two particles are in an entangled state, then, even if the particles are physically separated by a great distance, they behave in some respects as a single entity. The entangled particles exhibit what physicists call *nonlocal* effects. Informally, these are effects that cannot occur in a world governed by the laws of "classical" physics unless communication occurs between the particles. Moreover, if the physical separation between the particles is large and the time between the observations is small, then this entailed communication may exceed the speed of light! Nonlocal effects were alluded to in a famous 1935 paper by Einstein, Podolsky, and Rosen [13]. Einstein later referred to this as *spukhafte Fernwirkungen* (spooky actions at a distance) (see [12, 25, 30] for more historical background). In 1964, Bell [3] formalized the notion of two-particle nonlocality in terms of correlations among probabilities in a scenario where one of a number of a measurements are performed on each particle. He showed that the results of the measurements that occur quantum physically can be correlated in a way that cannot occur classically unless the type of measurement selected to be per-

formed on one particle affects the result of the measurement performed on the other particle.

In reality—which is quantum physical—the nonlocal effects exhibited by entangled particles do not involve any communication (consequently, nonlocality does not entail communication faster than the speed of light). In operational terms, the "spooky actions at a distance" that Einstein referred to cannot be used to simulate a communication channel. More precisely, if two physically separated parties, Alice and Bob, initially possess entangled particles and then Alice is given an arbitrary n-bit string x, there is no way for Alice to manipulate her particles in order to convey any information about x to Bob (unless she explicitly sends that information to him). Moreover, entanglement cannot even be used to *compress* the information in x: for Alice to convey x to Bob, she must in general send n bits—any smaller number will not suffice. The proof of this is based on a fundamental theorem in quantum information theory due to Holevo [17] (see also [16, 10]). Similar results apply to communication involving more than two parties.

Now consider the *communication complexity* scenario introduced by Yao [33]. Alice obtains an n-bit string x and Bob obtains an n-bit string y, and the goal is for them to determine $f(x, y)$, for some function $f : \{0,1\}^n \times \{0,1\}^n \to \{0,1\}$, with as little communication between them as possible. Clearly, $n + 1$ bits of communication always suffice (Alice sends all her n bits to Bob, Bob computes $f(x, y)$ and sends the one-bit answer to Alice), but for some functions fewer bits suffice. This scenario and variations of it have been widely studied (see [23] for an extensive survey).

In one variation of the above communication complexity scenario, there are more than two parties, each of which is given a subset of the input data. In another variation, all parties have access to a common "public" string of random bits. This string can be assumed to have been communicated during a "set up" stage prior to the parties being given their input data. For some functions, this prior random string reduces the communication complexity for a worst-case input if a small error probability is permitted (here, a worst-case input is understood to be chosen independently of the random string).

The first variation of the communication complexity scenario that incorporates quantum information was proposed by Yao [34]. In this model, Alice and Bob are allowed to communicate with *quantum bits (qubits)* rather than classical bits. Kremer [22] includes many important definitions and basic results for this model, including a proof that for the Inner Product function $f(x, y) = x_0 \cdot y_0 + x_1 \cdot y_1 + \cdots + x_{n-1} \cdot y_{n-1} \bmod 2$, the qubit communication must be $\Omega(n)$ qubits. These works leave open the question of whether quantum information can ever be advantageous over classical information for a communication complexity problem.

In the present paper, we consider an alternate way of incorporating quantum information into the communication complexity scenario. Here Alice and Bob's communication is with classical bits, but they are provided with a priori information that is entangled. On the face of it, it may appear that a prior quantum entanglement cannot reduce communication complexity because of the aforementioned theorem of Holevo. Consider the following informal argument, where Alice and Bob are given input strings x and y, and their goal is to collectively determine $f(x, y)$:

1. Assume that the classical communication complexity of function $f(x, y)$ is k. That is, k bits of communication are necessary for Alice and Bob to acquire the answer.

2. By Holevo's Theorem [17], the prior entanglement cannot simulate or even compress any particular message in a classical communication protocol.
3. Ergo, even with prior entanglement, the communication complexity of $f(x, y)$ is k.

A similar informal argument could be made for three-party scenarios. We shall demonstrate that this conclusion is incorrect for both scenarios.

Our first counterexample is in a three-party setting. We give an example of a function $f : \{0,1\}^2 \times \{0,1\}^2 \times \{0,1\}^2 \to \{0,1\}$, where, without prior quantum entanglement, four bits of communication are *necessary* to compute $f(x, y, z)$; whereas, with prior quantum entanglement, three bits of communication are *sufficient* to compute $f(x, y, z)$. The function is actually a partial function, defined on a subset of $\{0,1\}^2 \times \{0,1\}^2 \times \{0,1\}^2$ (i.e., the input data (x, y, z) obeys a certain "promise"). If we want to allow any input combination, then f can be defined as a relation (rather than a function). The protocol employing quantum entanglement uses less communication than necessary by any classical protocol by manipulating the entanglement so as to *circumvent* (rather than simulate) communication. Our technique is based on an interesting example of tripartite nonlocality due to Mermin [26]. Mermin's result is a refinement (from four components to three) of a similar result by Greenberger, Horne, and Zeilinger [14].

We also give an example of a two-party probabilistic communication complexity scenario with a function $g : \{0,1\}^2 \times \{0,1\}^2 \to \{0,1\}$ for which, with a classical shared random string but no prior entanglement, three bits of communication are *necessary* to compute $g(x, y)$ with probability at least $\cos^2(\frac{\pi}{8}) = 0.853\ldots$; whereas, with prior entanglement, two bits of communication are *sufficient* to compute $g(x, y)$ with the same probability. Unlike the previous three-party example, this function does not require a promise on the input data (x, y). The correlations in this two-party scenario are based on an example of nonlocality due to Clauser et al. [8].

Although, in both of the above cases, the savings in communication are not in an asymptotic setting, these results demonstrate that quantum entanglement can change the nature of communication complexity. After the initial announcement of these results and those of [9], several stronger quantum vs. classical separations appeared, and these are briefly reviewed in section 5.

2. Three-party deterministic scenarios. Let us begin by considering the following scenario, which is a reformulation of the one in [26] but cast in terms of data processing. Alice, Bob, and Carol receive input bits x, y, and z, respectively, which are arbitrary subject to the condition that $x \oplus y \oplus z = 0$. Once they receive their input data, they are forbidden from having any communication between them. Their goal is to produce output bits a, b, and c, respectively, such that

$$a \oplus b \oplus c = \begin{cases} 0 & \text{if } xyz = 000, \\ 1 & \text{if } xyz \in \{011, 101, 110\}. \end{cases} \tag{2.1}$$

Let us consider whether or not the trio can accomplish the above in terms of classical information. Since Alice cannot receive any information from Bob or Carol, her output bit a can depend only on the value of her input bit x. Let a_0 (respectively, a_1) be Alice's output when her input bit is 0 [1]. Similarly, let b_0, b_1 and c_0, c_1 be Bob and Carol's outputs for their respective input values. Note that the six bits $a_0, a_1, b_0, b_1, c_0, c_1$ completely characterize any (deterministic) strategy of Alice, Bob, and Carol (and probabilistic strategies will not help here since no error probability is

permitted). The conditions of the problem translate into the equations

$$\begin{aligned} a_0 \oplus b_0 \oplus c_0 &= 0, \\ a_0 \oplus b_1 \oplus c_1 &= 1, \\ a_1 \oplus b_0 \oplus c_1 &= 1, \\ a_1 \oplus b_1 \oplus c_0 &= 1. \end{aligned} \tag{2.2}$$

It is impossible to satisfy all four equations simultaneously. This is because summing the four equations (modulo two) yields $0 = 1$. Therefore, for any strategy, there exists an input configuration $xyz \in \{000, 011, 101, 110\}$ for which it fails.

Now consider the same problem, but where Alice, Bob, and Carol are supplied with qubits Q_A, Q_B, and Q_C, respectively, where the state of $\mathsf{Q}_A\mathsf{Q}_B\mathsf{Q}_C$ is initialized to

$$\tfrac{1}{2}(|000\rangle - |011\rangle - |101\rangle - |110\rangle). \tag{2.3}$$

The parties are allowed to apply unitary transformations and perform measurements on their individual qubits, but communication between the parties is still forbidden. It turns out that now the parties *can* produce a, b, c satisfying (2.1). This is achieved by the following procedures:

Procedure for Alice:
if $x = 1$ **then apply** H **to** Q_A
measure Q_A **yielding bit** a

Procedure for Bob:
if $y = 1$ **then apply** H **to** Q_B
measure Q_B **yielding bit** b

Procedure for Carol:
if $z = 1$ **then apply** H **to** Q_C
measure Q_C **yielding bit** c

In the above, H is the Hadamard transform, which is represented in the standard basis ($|0\rangle$ and $|1\rangle$) as

$$H = \tfrac{1}{\sqrt{2}} \begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix}, \tag{2.4}$$

and the measurements are performed in the standard basis.

We claim that the described procedure produces three output bits a, b, and c, satisfying (2.1). To see why this is so, first consider the case where $xyz = 000$. In this case, no H transform is applied to any of the three qubits. Therefore $\mathsf{Q}_A\mathsf{Q}_B\mathsf{Q}_C$ is measured directly in state (2.3), so the results will satisfy $a \oplus b \oplus c = 0$.

Next, in the case where $xyz = 011$, a Hadamard transform is applied to Q_B and to Q_C but not to Q_A. Therefore $\mathsf{Q}_A\mathsf{Q}_B\mathsf{Q}_C$ is measured in state

$$I \otimes H \otimes H \left(\tfrac{1}{2}(|000\rangle - |011\rangle - |101\rangle - |110\rangle)\right) = \tfrac{1}{2}(|001\rangle + |010\rangle - |100\rangle + |111\rangle), \tag{2.5}$$

so $a \oplus b \oplus c = 1$. The remaining cases where $xyz = 101$ and 110 are similar by the symmetry of state (2.3).

Note that a, b, and c by themselves are just random bits, uncorrelated with xyz. It is only the *trivariate correlations* among a, b, and c that are related to the input data xyz. Although the above task has some of the flavor of a communication complexity problem, it is technically different in that individual parties acquire no information.

We now construct a function based on the above where the presence of entanglement reduces its communication complexity.

Consider the function f defined on all triples $(x, y, z) \in \{0, 1, 2, 3\} \times \{0, 1, 2, 3\} \times \{0, 1, 2, 3\}$ which satisfy the condition

$$x + y + z \equiv 0 \pmod 2 \tag{2.6}$$

for which its value is given as

$$f(x, y, z) = \frac{(x + y + z) \bmod 4}{2} \tag{2.7}$$

(the value is always 0 or 1 by (2.6)). We represent the numbers x, y, and z in binary notation as x_1x_0, y_1y_0, and z_1z_0. In terms of these bits, the condition of (2.6) is

$$x_0 \oplus y_0 \oplus z_0 = 0, \tag{2.8}$$

and the function of (2.7) for inputs satisfying (2.8) is

$$f(x, y, z) = x_1 \oplus y_1 \oplus z_1 \oplus (x_0 \vee y_0 \vee z_0). \tag{2.9}$$

We assume the standard multiparty communication channel, where each bit that a party sends is broadcast to all other parties. Also, at the conclusion of the protocol, *all* parties must be able to determine the value of the function.

In the following two subsections, we show that with a prior entanglement, three bits of communication are sufficient to compute $f(x, y, z)$, whereas, without a prior entanglement, four bits of communication are necessary to compute $f(x, y, z)$.

2.1. The communication complexity with quantum entanglement is three bits. We now show that if Alice, Bob, and Carol initially share qubits Q_A, Q_B, and Q_C, respectively, in state (2.3), then there is a protocol for f where each party broadcasts only a single classical bit. The idea is based on applying the procedures at the beginning of this section using $x_0y_0z_0$ as the input. This requires no communication and provides Alice, Bob, and Carol with bits a, b, and c, respectively, such that $a \oplus b \oplus c = x_0 \vee y_0 \vee z_0$ (by (2.1)). Next Alice broadcasts the bit $(x_1 \oplus a)$, Bob broadcasts $(y_1 \oplus b)$, and Carol broadcasts $(z_1 \oplus c)$. At this point, each party knows $(x_1 \oplus a)$, $(y_1 \oplus b)$, and $(z_1 \oplus c)$, from which they can each determine the bit

$$\begin{aligned}(x_1 \oplus a) \oplus (y_1 \oplus b) \oplus (z_1 \oplus c) &= x_1 \oplus y_1 \oplus z_1 \oplus (a \oplus b \oplus c) \\ &= x_1 \oplus y_1 \oplus z_1 \oplus (x_0 \vee y_0 \vee z_0) \\ &= f(x, y, z),\end{aligned} \tag{2.10}$$

as required.

2.2. The communication complexity without quantum entanglement is four bits. In this section, we show that in the classical setting, four bits of communication are necessary to compute $f(x, y, z)$.

One can view any k-bit protocol as a binary tree of depth k, where each node that is not a leaf is labeled A(lice), B(ob), or C(arol). This labeling indicates which party will broadcast the next bit. An execution of the protocol corresponds to a path from the root of the tree to a leaf. Each leaf node is labeled 0 or 1, indicating the common output that results from the execution leading to that leaf. To establish our lower

bound, it suffices to show that no protocol-tree of depth three correctly computes $f(x, y, z)$.

We use the following lemma, which implies that in any correct protocol, all three parties must broadcast at least one bit.

LEMMA 2.1. *For any correct protocol-tree, on every path from its root to a leaf, each of A, B, and C must occur as a label at least once.*

Proof. Suppose that there exists a path along which one party, say, A, does not occur as a label. Let the leaf of that path be labeled $l \in \{0, 1\}$. Since this path does not include any reference to Alice's data, the same path is taken if x_1 is negated and all other input bits are held constant. However, by (2.9), negating x_1 also negates the value of $f(x, y, z)$, so the protocol cannot be correct for both possible values of x_1. □

Next suppose we have a protocol-tree of depth three for $f(x, y, z)$. Assume, without loss of generality, that the root of the tree is labeled A. The bit that Alice broadcasts is some function $\phi : \{0, 1\}^2 \to \{0, 1\}$ of her input data x alone. The function ϕ partitions $\{0, 1\}^2$ into two classes, $\phi^{-1}(0)$ and $\phi^{-1}(1)$. Call these two classes S_0 and S_1 and assume (without loss of generality) that $00 \in S_0$.

Next assume for the moment that the two children of the root of the protocol-tree are both labeled B (we shall see later that the other cases can be handled similarly). Then, by Lemma 2, the four children of B are all labeled C. Therefore, after Alice and Bob each send a bit, Carol must have enough information to determine the value of $f(x, y, z)$, since Carol broadcasts the third bit and does not gain any information from doing this. We shall show that this is impossible whatever S_0 and S_1 are.

There are two cases (the second of which has three subcases).

Case 1. $|S_0| = 1$. Recall that $00 \in S_0$, so $01, 10, 11 \in S_1$. Now, should the bit that Alice broadcasts specify that $x \in S_1$, Bob must follow this by broadcasting one bit from which Carol can completely determine the value of $f(x, y, z)$. Suppose that Bob sends the bit consistent with $y = 01$. If $z = 00$, then, from Carol's perspective, the possible values of (x, y, z) include $(01, 01, 00)$ and $(11, 01, 00)$ for which the respective values of $f(x, y, z)$ are 1 and 0. Therefore Carol cannot determine the value of $f(x, y, z)$ in this case.

Case 2. $|S_0| \geq 2$. There are three subcases where S_0 contains 01, 10, or 11 in addition to 00.

Case 2.1. S_0 *contains* 00 *and* 01. Here we consider the case where Alice broadcasts the bit specifying that $x \in S_0$. Bob must follow this by broadcasting one bit from which Carol can completely determine the value of $f(x, y, z)$. The bit that Bob broadcasts induces a partition of the possible values for y into two classes. If $z = 00$, then, from Carol's perspective, after receiving Alice's bit but before receiving Bob's bit, the possible values of (x, y, z) include $(00, 00, 00)$, $(00, 10, 00)$, $(01, 01, 00)$, and $(01, 11, 00)$, and the respective values of $f(x, y, z)$ on these points are 0, 1, 1, and 0. Therefore, for the protocol to be successful in this case, the partition that Bob's bit induces on y must place 00 and 11 in one class and 01 and 10 in the other class (otherwise Carol would not be able to determine $f(x, y, z)$ when $z = 00$). On the other hand, if $z = 01$, then, from Carol's perspective, the possible values of (x, y, z) include $(00, 01, 01)$, $(00, 11, 01)$, $(01, 00, 01)$, and $(01, 10, 01)$, and the respective values of $f(x, y, z)$ on these points are 1, 0, 1, and 0. Since we have established that Bob's bit does not distinguish between $y = 00$ and $y = 11$, Bob's bit is not sufficient information for Carol to determine $f(x, y, z)$ in this case.

Case 2.2. S_0 *contains* 00 *and* 10. The argument is similar to that in Case 1. Assume that Alice sends the bit specifying that $x \in S_0$. If Bob follows this by sending the bit consistent with $y = 00$ and $z = 00$, then, from Carol's perspective, the possible values of (x, y, z) include $(00, 00, 00)$ and $(10, 00, 00)$, and the respective values of $f(x, y, z)$ on these points are 0 and 1. Thus Carol cannot determine the value of $f(x, y, z)$ in this case.

Case 2.3. S_0 *contains* 00 *and* 11. The argument is similar to Case 2.1. Suppose that Alice broadcasts the bit specifying that $x \in S_0$. Consider Carol's perspective. If $z = 00$, then the possible values of (x, y, z) include $(00, 00, 00)$, $(00, 10, 00)$, $(11, 01, 00)$, and $(11, 11, 00)$, and the respective values of $f(x, y, z)$ on these points are 0, 1, 0, and 1; whereas, if $z = 01$, then the possible values of (x, y, z) include $(00, 01, 10)$, $(00, 11, 01)$, $(11, 00, 01)$, and $(11, 10, 01)$, and the respective values of $f(x, y, z)$ on these points are 1, 0, 0, 1. No binary partitioning of y will work for both possibilities.

The cases where the two children of the root of the protocol-tree are CC, CB, and BC have an analogous proof as above with the roles of B and C possibly reversed.

This completes the proof of the lower bound of four bits. The following deterministic four-bit protocol shows that this bound is tight.

A classical four bit protocol. First, Bob and Carol start by broadcasting the bits y_0, y_1 (Bob) and z_1 (Carol). After that, Alice now knows—by the promise of (2.8)—the bit $z_0 = x_0 \oplus y_0$ and hence all six bit values involved. The fourth and last bit of communication is therefore the announcement of the answer $f(x, y, z)$ by Alice to Bob and Carol.

3. Two-party probabilistic scenarios. The following scenario can be viewed as a reformulation of the nonlocality proof in [8] into data processing terminology. Alice and Bob receive input bits x and y, respectively, and, after this, they are forbidden from communicating with each other. Their goal is to produce output bits a and b, respectively, such that

$$a \oplus b = x \wedge y, \tag{3.1}$$

or, failing that, to satisfy this condition with as high a probability as possible.

To analyze the situation in terms of classical information, first consider the case of deterministic strategies. For these, Alice's output bit depends solely on her input bit x and similarly for Bob. Let a_0, a_1 be the two possibilities for Alice and b_0, b_1 be the two possibilities for Bob. These four bits completely characterize any deterministic strategy. Condition (3.1) translates into the equations

$$\begin{aligned} a_0 \oplus b_0 &= 0, \\ a_0 \oplus b_1 &= 0, \\ a_1 \oplus b_0 &= 0, \\ a_1 \oplus b_1 &= 1. \end{aligned} \tag{3.2}$$

It is impossible to satisfy all four equations simultaneously (since summing them modulo two yields $0 = 1$). Therefore it is impossible to satisfy condition (3.1) absolutely.

By using a probabilistic strategy, Alice and Bob can satisfy condition (3.1) with probability $\frac{3}{4}$. For such a strategy, we allow Alice and Bob to have a priori classical random variables, whose distribution is independent of that of the inputs x and y. Note that any three of the four equations of (3.2) *can* be simultaneously satisfied. The probabilistic strategy now works as follows. Alice and Bob have random variables

R_A and R_B, respectively, which are each uniformly distributed over $\{0,1,2,3\}$ and completely correlated with each other (i.e., $R_A = R_B$). These variables specify to both of them one of the four equations to violate while satisfying the other three. Alice and Bob then follow the deterministic procedure corresponding to a preagreed a_0, a_1, b_0, b_1 which satisfy the three equations determined by R_A and R_B. It is easy to see that (a) for any input xy, the resulting outputs satisfy condition (3.1) with probability $\frac{3}{4}$, and (b) this is optimal in that no probabilistic strategy can attain a success probability greater than $\frac{3}{4}$.

Now consider the same problem but where Alice and Bob are supplied with qubits Q_A and Q_B, respectively (instead of random variables), where the state of $\mathsf{Q}_A\mathsf{Q}_B$ is initialized to

$$\tfrac{1}{\sqrt{2}}(|00\rangle - |11\rangle). \tag{3.3}$$

It turns out that now the parties can produce data that satisfies condition (3.1) with probability $\cos^2(\frac{\pi}{8}) = 0.853\ldots$, which is higher than what is possible in the classical case. This is achieved by the following procedures:

Procedure for Alice:	Procedure for Bob:
if $x = 0$ **then**	**if** $y = 0$ **then**
apply $R(-\frac{\pi}{16})$ to Q_A	**apply** $R(-\frac{\pi}{16})$ to Q_B
else	**else**
apply $R(\frac{3\pi}{16})$ to Q_A	**apply** $R(\frac{3\pi}{16})$ to Q_B
measure Q_A **yielding bit** a	**measure** Q_B **yielding bit** b

In the above, $R(\theta)$ is the rotation by angle θ which is represented in the standard basis as

$$R(\theta) = \begin{pmatrix} \cos\theta & -\sin\theta \\ \sin\theta & \cos\theta \end{pmatrix}, \tag{3.4}$$

and the measurements are performed in the standard basis. If Alice rotates by θ_1 and Bob rotates by θ_2, then the state of $\mathsf{Q}_A\mathsf{Q}_B$ becomes

$$\tfrac{1}{\sqrt{2}}\left(\cos(\theta_1+\theta_2)(|00\rangle - |11\rangle) + \sin(\theta_1+\theta_2)(|01\rangle + |10\rangle)\right), \tag{3.5}$$

and, after the measurements, the probability that $a \oplus b = 0$ is $\cos^2(\theta_1 + \theta_2)$. It is now straightforward to verify that condition (3.1) is satisfied with probability $\cos^2(\frac{\pi}{8})$ for all input possibilities.

From the above, we can construct a function for which the presence of entanglement reduces its communication complexity in a probabilistic sense. Define $g : \{0,1\}^2 \times \{0,1\}^2 \to \{0,1\}$ as

$$g(x,y) = x_1 \oplus y_1 \oplus (x_0 \wedge y_0). \tag{3.6}$$

An execution of a probabilistic protocol for g is considered successful if and only if the value determined by Alice and the value determined by Bob are *both* correct.

In the following two subsections, we show that, with a prior quantum entanglement and two bits of communication, the probability of success can be at least $\cos^2(\frac{\pi}{8}) = 0.853\ldots$, whereas, with a shared random string instead of quantum entanglement and two bits of communication, the probability of success cannot exceed $\frac{3}{4}$. Thus, without prior entanglement, to achieve a success probability of at least $\cos^2(\frac{\pi}{8})$, *three* bits of communication are necessary.

TABLE 3.1
The values of $g(x, y)$. The columns are indexed by x and the rows are indexed by y.

$g(x,y)$	00	01	10	11
00	0	0	1	1
01	0	1	1	0
10	1	1	0	0
11	1	0	0	1

3.1. With quantum entanglement. Here we show that if Alice and Bob initially share qubits Q_A and Q_B, respectively, in state (3.3), then there is a protocol which successfully computes g with probability $\cos^2(\frac{\pi}{8})$. Alice and Bob first apply the procedures at the beginning of this section using x_0y_0 as input. This requires no communication and provides Alice and Bob with bits a and b, respectively, such that $\Pr[a \oplus b = x_0 \wedge y_0] = \cos^2(\frac{\pi}{8})$. Then Alice sends $(a \oplus x_1)$ to Bob, and Bob sends $(b \oplus y_1)$ to Alice. At this point, each party can determine the bit

$$(a \oplus x_1) \oplus (b \oplus y_1) = x_1 \oplus y_1 \oplus (a \oplus b), \tag{3.7}$$

which equals $x_1 \oplus y_1 \oplus (x_0 \wedge y_0) = g(x, y)$ with probability $\cos^2(\frac{\pi}{8})$, as required.

3.2. With shared classical random bits but no quantum entanglement. We now show that if Alice and Bob initially share classical random bits but no quantum entanglement, then there is no two-bit protocol in which both parties output the correct value of $g(x, y)$ with probability greater than $\frac{3}{4}$. By Theorem 3.20 of [23], it is sufficient to prove the lower bound on the error probability for all deterministic protocols with respect to *random inputs* from $\{0,1\}^2 \times \{0,1\}^2$ (which we can take to be uniformly distributed). As noted in section 2.2, we can represent any two-bit protocol as a binary tree of depth two with nonleaf nodes labeled A(lice) and B(ob).

Assume, without loss of generality, that the root of the protocol-tree is labeled A. The first bit that Alice sends is some function $\phi : \{0,1\}^2 \to \{0,1\}$ of her input data x alone. The function ϕ partitions $\{0,1\}^2$ into two classes $S_0 = \phi^{-1}(0)$ and $S_1 = \phi^{-1}(1)$. Let the first and second children of the root correspond to the paths traversed when the first bit sent (by Alice) indicates that $x \in S_0$ and $x \in S_1$, respectively. We must consider all partitions S_0 and S_1 in combination with all cases where the two children of the root are BB, AB, or AA (the case BA can be omitted by symmetry).

LEMMA 3.1. *If the child corresponding to S_i is labeled B, then, conditioned on $x \in S_i$, the probability that Bob correctly determines $g(x, y)$ is at most 1 if $|S_i| = 1$; $\frac{3}{4}$ if $|S_i| = 2$; $\frac{2}{3}$ if $|S_i| = 3$; and $\frac{1}{2}$ if $|S_i| = 4$. There is no well-defined probability for the empty set $|S_i| = 0$.*

Proof. The case where $|S_i| = 1$ is trivial.

For the case where $|S_i| = 2$, first consider the subcase where $S_i = \{00, 01\}$. Under the condition $x \in S_i$, (x, y) is a position in one of the first two columns of Table 3.1, and Alice's bit to Bob indicates this to him. From Bob's perspective, if $y = 00$, then $g(x, y) = 0$, so Bob can determine the correct answer. Similarly, if $y = 10$, then $g(x, y) = 1$, so Bob can determine the correct answer. However, if $y = 01$, then, since the first two columns of the table differ in this row, whatever function of Alice's message and y Bob computes, the probability that it will match $g(x, y)$ is at most $\frac{1}{2}$. Similarly, if $y = 01$, then Bob computes the correct answer with probability at most $\frac{1}{2}$. Since these four values of y are equiprobable, the probability that Bob correctly computes $g(x, y)$ conditioned on $x \in S_i$ is at most $\frac{1}{4} \cdot 1 + \frac{1}{4} \cdot 1 + \frac{1}{4} \cdot \frac{1}{2} + \frac{1}{4} \cdot \frac{1}{2} = \frac{3}{4}$. The other five subcases in which $|S_i| = 2$ are handled similarly.

For the case where $|S_i| = 3$, first consider the subcase where $S_i = \{00, 01, 10\}$. Under the condition $x \in S_i$, (x, y) is a position in one of the first three columns of Table 3.1, and Alice's bit to Bob indicates this to him. By looking at these three columns of Table 3.1, we observe that, from Bob's perspective, whatever the value of y, the probability of Bob determining $g(x, y)$ is at most $\frac{2}{3}$. The other two subcases in which $|S_i| = 3$ are handled similarly.

The last case $|S_i| = 4$ immediately implies $S_i = \{00, 01, 10, 11\}$, where Bob receives no information about the the string x of Alice. For all possible y's, the probability that Bob guesses $g(x, y)$ correctly is therefore $\frac{1}{2}$.

As the probabilities are conditioned on x being an element of S_i, the case of the empty set $|S_i| = 0$ is not well-defined. □

Now, by Lemma 3.1, if the two children of the root are BB, then the probability that Bob correctly determines $g(x, y)$ is at most $\frac{1}{4} \cdot 1 + \frac{3}{4} \cdot \frac{2}{3} = \frac{3}{4}$ if $|S_0| \neq |S_1|$, and $\frac{1}{2} \cdot \frac{3}{4} + \frac{1}{2} \cdot \frac{3}{4} = \frac{3}{4}$ if $|S_0| = |S_1|$.

Next, we show that for protocol-trees in which the two children of the root are *not* BB, the correctness probability is actually less than $\frac{3}{4}$.

LEMMA 3.2. *If the child corresponding to S_i is labeled A, then, conditioned on $x \in S_i$, the probability that Alice correctly determines $g(x, y)$ is at most $\frac{1}{2}$.*

Proof. If the condition $x \in S_i$ occurs, then Alice receives no information from Bob. Therefore, from Alice's perspective, the value of $g(x, y)$ is either y_1, $y_1 \oplus y_0$, $1 \oplus y_1$, or $1 \oplus y_1 \oplus y_0$ (corresponding to the cases $x = 00$, 01, 10, and 11, respectively). The result now follows from the fact that, from Alice's perspective, y is uniformly distributed over $\{0, 1\}^2$. □

By Lemma 3.2, it follows that if the two children of the root are AA, then the probability that Bob correctly determines $g(x, y)$ is at most $\frac{1}{2}$. The remaining case is where the two children of the root are AB. By applying Lemma 3.2 for the first child and Lemma 3.1 for the second child, the probability that both Alice and Bob correctly determine $g(x, y)$ is at most

- $\frac{1}{4} \cdot \frac{1}{2} + \frac{3}{4} \cdot \frac{2}{3} = \frac{5}{8}$ if $|S_0| = 1$ and $|S_1| = 3$,
- $\frac{1}{2} \cdot \frac{1}{2} + \frac{1}{2} \cdot \frac{3}{4} = \frac{5}{8}$ if $|S_0| = 2$ and $|S_1| = 2$,
- $\frac{3}{4} \cdot \frac{1}{2} + \frac{1}{4} \cdot 1 = \frac{5}{8}$ if $|S_0| = 3$ and $|S_1| = 1$.

This completes the proof that no two-bit protocol is correct with probability more than $\frac{3}{4}$. There is a straightforward errorless three-bit protocol.

4. The qubit model of communication complexity. In the previous two sections, novel protocols were obtained in the *entanglement model* for communication complexity, where communication is with classical bits, but the parties have an a priori supply of entangled qubits. In the *qubit model* (introduced by Yao [34] and Kremer [22]), the parties have no entanglement but are allowed to communicate with qubits in place of classical bits. Qubits cannot be broadcast [32], so in a multiparty setting a qubit of communication must be sent to a specific party.

In this section, we show how to translate the protocols from sections 2 and 3 in the entanglement model into protocols in the qubit model. By doing so we also prove the same separation between qubit communication complexity and classical communication complexity.

4.1. A deterministic three-party qubit protocol. The following protocol requires only two qubits plus one classical bit of communication to compute f from section 2 with the one-qubit rotation R that we used earlier.

Procedure for Alice:
initialize qubit Q **to state** $|0\rangle$
apply $R(x \cdot \frac{\pi}{4})$ **to** Q
send Q **to Bob**

Procedure for Bob:
receive Q **from Alice**
apply $R(y \cdot \frac{\pi}{4})$ **to** Q
send Q **to Carol**

Procedure for Carol:
receive Q **from Bob**
apply $R(z \cdot \frac{\pi}{4})$ **to** Q
measure Q**, yielding bit** m
announce the answer m

It is straightforward to verify that the final state of qubit Q is

$$\begin{aligned} R(z \cdot \tfrac{\pi}{4}) \cdot R(y \cdot \tfrac{\pi}{4}) \cdot R(x \cdot \tfrac{\pi}{4})|0\rangle &= \cos((x+y+z) \cdot \tfrac{\pi}{4})|0\rangle + \sin((x+y+z) \cdot \tfrac{\pi}{4})|1\rangle \\ &= |f(x,y,z)\rangle, \end{aligned} \tag{4.1}$$

which implies that the answer as announced by Carol is indeed correct.

4.2. A probabilistic two-party qubit protocol. Also the two-party problem of section 2 can be translated to the qubit model. The following protocol computes g from section 2 with correctness probability $0.853\ldots$ using only one qubit and one bit of communication:

Procedure for Alice:
initialize qubit Q **to state** $|0\rangle$
apply $R((2x_1 + x_0 - \frac{1}{2}) \cdot \frac{\pi}{4})$ **to** Q
send Q **to Bob**

Procedure for Bob:
receive Q **from Alice**
apply $R((2y_1 + y_0) \cdot \frac{\pi}{4})$ **to** Q
measure Q**, yielding bit** m
announce the answer m

For any combination of input x and y, this final answer m will be the correct value $g(x,y)$ with probability $\cos^2(\frac{\pi}{8}) = 0.853\ldots$, which is identical to the success rate of the entanglement protocol of section 3.1.

5. Discussion of subsequent work. After the publication of [9] and the announcement of this article in 1997, several other results in quantum communication complexity were obtained. In [6] the three-party problem of Chapter 2 was generalized into a k-party problem for which the separation between quantum and classical communication complexity is k versus $\Theta(k \log k)$ bits. For the one-round, three-party setting this article also proved a difference of $n+1$ versus $(3/2)n+1$ bits between communication with and without initial entanglement.

A lower bound of $\Omega(n)$ on the quantum communication complexity of the (two-party) Inner Product function in [10] showed that the entanglement model does not always allow an improvement over the classical scenario. On the other hand, a significant decrease in communication complexity was established for the Disjoint function

$$\textsc{Disjoint}(x,y) = \begin{cases} 0 & \text{if there exists an } i \text{ such that } x_i = y_i = 1, \\ 1 & \text{otherwise.} \end{cases} \tag{5.1}$$

This well-studied problem has a classical probabilistic communication complexity of $\Omega(n)$ [18, 28], while the authors of [5] gave a qubit protocol requiring only $O(\sqrt{n} \log n)$ qubits of communication. The question whether there exists a more efficient quantum protocol for Disjoint is still an important open problem. This is especially relevant as

DISJOINT is a complete problem for the communication class "co-NP" [2]. The same article [5] also contained the first exponential separation for the exact distributed computation of a partial two-party function that is related to the Deutsch–Jozsa problem of [11].

In [27] Raz improved on these results by establishing an exponential separation between classical and quantum communication in the bounded-error probabilistic setting. The problem involved is the question for Alice whether her normalized n-dimensional vector $\vec{v} \in \mathbf{C}^n$, after Bob's unitary transformation U, lies in a particular subspace $S \subset \mathbf{C}^n$ or in the orthogonal complement $S^\perp$. (The promise here is that the vector $U\vec{v}$ is close to either S or $S^\perp$.) It is clear that this can be solved with only $2 \log n$ qubits of communication if we store the coefficients of $\vec{v}$ (and $U\vec{v}$) in the amplitudes of a $\log n$ qubit message. The classical lower bound, on the other hand, was proved to be polynomial in n. It is currently still an open problem if it is possible to have an exponential quantum vs. classical reduction in communication complexity for a *total* function.

The "sampling complexity" of a function f and a probability distribution μ is the amount of communication that is required to create a mixture of the possible states $(f(x, y), x, y)$ according to the distribution $\mu(x, y)$ over the input states. In [1] it was shown that we can have an exponential gap between the quantum and the classical sampling complexity of the DISJOINT function.

Separations for nondeterministic (quantum) communication complexity are exhibited in the articles [31] and [24]. In [7], there is a general framework for establishing lower bounds on exact communication complexity with entanglement. For the zero-error (Las Vegas) model, Klauck [20] has given a polynomial difference between the quantum and the classical setting. The question whether quantum information, in general, can reduce the number of rounds is addressed in [21]. (See [29, 19] for spectacular examples of such a reduction in the context of interactive proof systems.)

The preliminary communication complexity results that appear in this article were inspired by examples of quantum nonlocality. Conversely, in [4] new powerful examples of nonlocality are given that follow from the results in [5].

Acknowledgments. We would like to thank Charles Bennett, Lance Fortnow, Richard Jozsa, and Lev Vaidman for helpful discussions.

NOGA ALON†, MICHAEL KRIVELEVICH‡, ILAN NEWMAN§, AND MARIO SZEGEDY¶

Abstract. We continue the study of combinatorial property testing, initiated by Goldreich, Goldwasser, and Ron in [*J. ACM*, 45 (1998), pp. 653–750]. The subject of this paper is testing regular languages. Our main result is as follows. For a regular language $L \in \{0,1\}^*$ and an integer n there exists a randomized algorithm which always accepts a word w of length n if $w \in L$ and rejects it with high probability if w has to be modified in at least ϵn positions to create a word in L. The algorithm queries $\tilde{O}(1/\epsilon)$ bits of w. This query complexity is shown to be optimal up to a factor polylogarithmic in $1/\epsilon$. We also discuss the testability of more complex languages and show, in particular, that the query complexity required for testing context-free languages cannot be bounded by any function of ϵ. The problem of testing regular languages can be viewed as a part of a very general approach, seeking to probe testability of properties defined by logical means.

Key words. property testing, regular languages, context-free languages

1. Introduction.

Property testing deals with the question of deciding whether a given input x satisfies a prescribed property P or is "far" from any input satisfying it. Let P be a property, i.e., a nonempty family of binary words. A word w of length n is called ϵ-far from satisfying P if no word w' of the same length, which differs from w in no more than ϵn places, satisfies P. An *ϵ-test* for P is a randomized algorithm, which, given the quantity n and the ability to make queries about the value of any desired bit of an input word w of length n, distinguishes with probability at least $2/3$ between the case of $w \in P$ and the case of w being ϵ-far from satisfying P. Finally, we say that property P is *(c,ϵ)-testable* if for every $\epsilon > 0$ there exists an ϵ-test for P whose total number of queries is bounded by c.

Property testing was defined by Goldreich, Goldwasser, and Ron [7] (inspired by [13]). It emerges naturally in the context of PAC learning, program checking [6, 3, 10, 13], probabilistically checkable proofs [2], and approximation algorithms [7].

In [7], the authors mainly consider graph properties, such as bipartiteness, and they show (among other things) the quite surprising fact that testing bipartiteness can be done by randomly testing a polynomial in $1/\epsilon$ number of edges of the graph, answering the above question with constant probability of failure. They also raise the question of obtaining general results as to when there is, for every $\epsilon > 0$, an ϵ-test for a property using $c = c(\epsilon)$ queries (i.e., c is a function of ϵ but independent of n) with constant probability of failure. We call properties of this type ϵ-*testable*. So far, such answers are quite sparse; some interesting examples are given in [7], and several additional ones can be obtained by applying the regularity lemma as we show in a subsequent paper [1].

In this paper we address testability of formal languages (see [8] as a general reference). A language $L \subseteq \{0,1\}^*$ is a property which is usually viewed as a sequence of Boolean functions $f_n : \{0,1\}^n \to \{0,1\}$, with $f_n^{-1}(1) = L \cap \{0,1\}^n = L_n$. Our main result states that all regular languages are ϵ-testable with a query complexity of only $\tilde{O}(1/\epsilon)$. We also show that this complexity is optimal up to a factor polylogarithmic in $1/\epsilon$. This positive result cannot be extended to context-free languages, for there is an example of a very simple context-free language which is not testable.

Since regular languages can be characterized using second order monadic logic, we thus obtain a large set of logically defined objects which are testable. In [1] we provide testable graph properties described by logical means as well. These results indicate a strong interrelation between testability and logic. Although our result on regular languages can be viewed as a separate result having no logical bearing at all, our opinion is that logic does provide the right context for testability problems, which may lead to the discovery of further classes of testable properties.

The rest of this paper is organized as follows. In section 2 we present the proof of the main result showing that every regular language is testable. In section 3 we show that the upper bound of $\tilde{O}(1/\epsilon)$ for the query complexity of testing regular languages, obtained in Theorem 2.9, is tight up to a polylogarithmic factor. Section 4 is devoted to the discussion of testability of context-free languages. There we show, in particular, that there exist nontestable context-free languages. We also discuss testability of the Dyck languages. Section 5 contains some concluding remarks and outlines new research directions.

2. Testing regular languages. In this section we prove the main result of the paper, namely, that regular languages are $(\tilde{O}(\frac{1}{\epsilon}), \epsilon)$-testable. As this result is asymptotic, we assume that n is big enough with respect to $\frac{1}{\epsilon}$ (and with respect to any other constant that depends only on the fixed language we are working with). All logarithms are binary unless stated explicitly otherwise.

We start by recalling the standard definition of a regular language, based on finite automata. This definition is convenient for algorithmic purposes.

DEFINITION 2.1. *A deterministic finite automaton (DFA) M over $\{0,1\}$ with states $Q = \{q_1, \ldots, q_m\}$ is given by a function $\delta : Q \times \{0,1\} \to Q$ together with a set $F \subseteq Q$. One of the states, q_1, is called the initial state. The states belonging to the set F are called accepting states, and δ is called the transition function.*

We can extend the transition function δ to $\{0,1\}^*$ recursively as follows. Let γ denote the empty word. Then

$$\begin{aligned} \delta(q, \gamma) &= q, \\ \delta(q, u0) &= \delta(\delta(u, q), 0), \\ \delta(q, u1) &= \delta(\delta(u, q), 1). \end{aligned}$$

Thus, if M starts in a state q and processes string u, then it ends up in a state $\delta(q,u)$.

We then say that M accepts a word u if $\delta(q_1,u) \in F$. M rejects u means that $\delta(q_1,u) \in Q \setminus F$. Finally, the language accepted by M, denoted by L_M, is the set of all $u \in \{0,1\}^*$ accepted by M. We use the following definition of regular languages.

DEFINITION 2.2. *A language is regular iff there exists a finite automaton that accepts it.*

Therefore, we assume in this section that a regular language L is given by its automaton M so that $L = L_M$.

A word w of length n defines a sequence of states $(q_{i_0}, \dots, q_{i_n})$ in the following natural way: $q_{i_0} = q_1$, and for $1 \le j \le n$, $q_{i_j} = \delta(q_1, w[1] \dots w[j])$. This sequence describes how the automaton M moves while reading w. Later in the paper we will occasionally refer to this sequence as the *traversal path* of w.

A finite automaton M defines a directed graph $G(M)$ by $V(G(M)) = Q$ and $E(G(M)) = \{(q_i,q_j) \mid \delta(q_i,0) = q_j\} \cup \{(q_i,q_j) \mid \delta(q_i,1) = q_j\}$. The *period* $g(G)$ of a directed graph G is the greatest common divisor of cycle lengths in G. If G is acyclic, we set $g(G) = \infty$.

We will use the following lemma about directed graphs.

LEMMA 2.3. *Let $G = (V,E)$ be a nonempty, strongly connected directed graph with a finite period $g(G)$. Then there exist a partition $V(G) = V_0 \cup \dots \cup V_{g-1}$ and a constant $m = m(G)$ which does not exceed $3|V|^2$ such that the following hold.*

1. *For every $0 \le i, j \le g-1$ and for every $u \in V_i$, $v \in V_j$ the length of every directed path from u to v in G is $(j-i) \bmod g$.*
2. *For every $0 \le i, j \le g-1$, for every $u \in V_i$, $v \in V_j$, and for every integer $r \ge m$, if $r = (j-i) \pmod g$, then there exists a directed path from u to v in G of length r.*

Proof. To prove part 1, fix an arbitrary vertex $z \in V$ and for each $0 \le i \le g-1$, let V_i be the set of all those vertices which are reachable from v by a directed (not necessarily simple) path of length $i \bmod g$. Note that since any closed (directed) walk in G is a disjoint union of cycles, the length of each such walk is divisible by g. This implies that the sets V_i are pairwise disjoint. Indeed, assume this is false, and suppose w lies in $V_i \cap V_j$ with $i \ne j$. As G is strongly connected, there is a path p_1 from w to z, and by definition there are a path p_2 of length $i \bmod g$ from z to w as well as a path p_3 of length $j \bmod g$ from z to w. Now the number of edges of either $p_1 \cup p_2$ or $p_1 \cup p_3$ is not divisible by g, which is impossible. Therefore, the sets V_i form, indeed, a partition of V. For $u \in V_i$ and $v \in V_j$, the union of any (directed) path from z to u with a (directed) path from u to v forms a path from z to v, and as any such path must have length $j \bmod g$; the assertion of part 1 follows.

We next prove part 2. Consider any set of positive integers $\{a_i\}$ whose greatest common divisor is g. It is well known that there is a smallest number t such that every integer $s \ge t$ which is divisible by g is a linear combination with nonnegative integer coefficients of the numbers a_i. Moreover, it is known (see [9, 5]) that t is smaller than the square of the maximal number a_i. Fix a closed (directed) walk in G that visits all vertices and whose length is at most $|V|^2$. (This is easily obtained by numbering the vertices of G arbitrarily as $v_0, v_1, \dots, v_{k-1}$ and by concatenating directed paths from v_i to v_{i+1} for each $0 \le i \le k-1$, where the indices are taken modulo k.) Now associate the set of cycle lengths in this walk with the set of positive integers $\{a_i\}$ as above. Then, following this closed walk and traversing each directed cycle as many times as desired, we conclude that every integer divisible by g and exceeding $2|V|^2$ is the length of a closed walk passing through all vertices of the graph. Given now a

vertex $u \in V_i$, a vertex $v \in V_j$, and an integer $r > 3|V|^2$ satisfying $r = (j-i) \bmod g$, fix a shortest path p from u to v, and note that its length l satisfies $l = (j-i) \bmod g$ and $l < |V| (\leq |V|^2)$. Adding to p a closed walk of length $r-l$ from v to itself, we obtain the required path, completing the proof. □

We call the constant m from the above lemma the *reachability constant* of G and denote it by $m(G)$. In what follows we assume that m is divisible by g.

If $L_M \cap \{0,1\}^n = \emptyset$, a testing algorithm can reject any input without reading it at all. Therefore, we can assume that we are in the nontrivial case $L_M \cap \{0,1\}^n \neq \emptyset$.

We now introduce a key definition for what follows.

DEFINITION 2.4. *Given a word $w \in \{0,1\}^n$, a subword (run) w' of w starting at position i is called* feasible *for language L_M if there exists a state $q \in Q$ such that q is reachable from q_1 in G in exactly $i-1$ steps, and there is a path of length $n - (|w'| + i - 1)$ in G from the state $\delta(q, w')$ to at least one of the accepting states. Otherwise, w' is called* infeasible.

Of course, finding an infeasible run in w proves that $w \notin L$. Our aim is to show that if a given word w of length n is far from any word of length n in L, then many short runs of w are infeasible. Thus a choice of a small number of random runs of w almost surely contains an infeasible run. First we treat the following basic case.

DEFINITION 2.5. *We call an automaton M* "essentially strongly connected" *if*

(1) *M has a unique accepting state q_{acc};*
(2) *the set of states of the automaton, Q, can be partitioned into two parts, C and D, so that*
   - *$q_1, q_{acc} \in C$,*
   - *the subgraph of $G(M)$ induced on C is strongly connected, and*
   - *no edges in $G(M)$ go from D to C (but edges can go from C to D).*

   (Note that D may be empty.)

LEMMA 2.6. *Assume that the language $L = L_M$ contains some words of length n and that M is essentially strongly connected with C and D being the partition of the states of M as in Definition 2.5. Let m be the reachability constant of $G[C]$. Assume also that $\epsilon n \geq 64m \log(4m/\epsilon)$. Then if, for a word w of length $|w| = n$, $dist(w, L) \geq \epsilon n$, then there exists an integer $1 \leq i \leq \log(4m/\epsilon)$ such that the number of infeasible runs of w of length 2^{i+1} is at least $\frac{2^{i-4}\epsilon n}{m \log(4m/\epsilon)}$.*

Proof. Our intention is to construct a sequence $(R_j)_{j=1,\ldots}$ of disjoint infeasible runs, each being minimal in the sense that each of their prefixes is feasible, and so that each is a subword of the given word w. We then show that we can concatenate these subwords to form a word in the language that is not too far from w. ("Not too far" will essentially depend on the number of runs that we have constructed.) This in turn will show that if $dist(w, L) \geq \epsilon n$, then there is a lower bound on the number of these infeasible runs.

For reasons to become obvious later, we also want these runs to be in the interval $[m+1, n-m]$.

A natural way to construct such a sequence is to repeat the following procedure starting from coordinate $m+1$. Let R_1 be the shortest infeasible run starting from $w[m+1]$ and ending before $w[n-m+1]$. If there is no such run we stop. Assume that we have constructed so far $R_1, \ldots, R_{j-1}$ ending at $w[c_{j-1}]$; next we construct R_j by taking the minimal infeasible run starting at $w[c_{j-1}+1]$ and ending before $w[n-m+1]$. Again, if there is no such run, we stop.

Assume we have constructed in this way runs $R_1, \ldots, R_h$. Note that each run is a subword of w, the runs are pairwise disjoint, and their concatenation in order

forms a (continuous) subword of w. Also note that by the definition of each run, R_j being minimal infeasible, its prefix $R_j^{(-)}$, obtained by discarding the last bit of R_j, is feasible. This, in turn, implies that R'_j, which is obtained from R_j by flipping its last bit, is feasible. In addition, by Definition 2.4, this means that for each R'_j there is a state $q_{i_j} \in C$ so that $\delta(q_{i_j}, R'_j) \in C$ and such that q_{i_j} is reachable from q_1 in $c_{j-1}+1$ steps.

Next we inductively construct a word $w^* \in L$ such that $dist(w, w^*) \leq hm+2m+2$. Assuming that $dist(w, L) \geq \epsilon n$, this will imply a lower bound on h. The general idea is to "glue" together the R'_j for $j = 1, \ldots, h$, each being feasible and yet very close to a subword of w (except for the last bit in each). The only concern is to glue the pieces together so that as a whole word they will be feasible. This will require an extra change of m bits per run, plus some additional $2m$ bits at the end of the word.

We maintain during the induction that, for $j = 0, \ldots$, the word w_j we construct is feasible starting from position 1, and it ends in position c_j. For the base case, let $c_0 = m$, and let w_0 be any word of length m which is feasible starting from position 1. Assume we have already defined a word w_{j-1} feasible from position 1 and ending in position c_{j-1}. Let $\delta(q_1, w_{j-1}) = p_j$. As both p_j and q_{i_j} are reachable from q_1 by a path of length c_{j-1}, according to Lemma 2.3 we can change the last m bits in w_{j-1} so that we get a word u_j for which $\delta(q_1, u_j) = q_{i_j}$. We now define w_j as a concatenation of u_j and R'_j. Let w_h be the final word that is defined in this way, ending at place c_h. There are two possible reasons we have stopped with R_h. One possible reason is that there is no infeasible run starting at $c_h + 1$, in which case, changing the last m bits of w_h and concatenating to it the remaining suffix of w (that starts at position $c_h + 1$), exactly as in the case of adding R'_j, yields the required w^*. The other possible reason for stopping the growth of R_h is when there is a minimal infeasible run that starts at $c_h + 1$ and ends after position $n - m + 1$. Let R be that run, and let R' be the run obtained by flipping the last bit of R. As was the case with any R'_j, R' is feasible from position $c_h + 1$. Hence there is a feasible word u of which R' is a prefix and u is of length $n - c_h$ so that $\delta(q_{i_h}, u) = q_{acc}$. We can construct w^* from w_h and u exactly as we have constructed w^* from w_h and the suffix of w in the previous case.

By the definition of w^*, $w^* \in L$. Following the inductive construction of w^*, we have that for $1 \leq j \leq h$, $dist(w_j, w[1, c_j]) \leq jm + 1$. Then to get from w_h to w^* we start with R', which is either a subword of w (as in the first case previously discussed) or a subword of w where one bit was changed (as in the second case), and we continue by changing m bits at the end of w_h and possibly additional m bits at the end of u. Therefore, $dist(w, w^*) \leq hm + 2m + 2$, as we claimed.

Recalling that $dist(w, L) \geq \epsilon n$, we conclude that $h \geq \frac{\epsilon n - 2}{m} - 2 \geq \epsilon n/(2m)$. (The last inequality is by our assumptions that $\epsilon n \geq 64m \log(4m/\epsilon)$.) This already shows that if $dist(w, L) \geq \epsilon n$, then there are $\Omega(\epsilon n)$ many disjoint infeasible runs in w. However, we need a stronger dependence, as stated in the lemma. We achieve this in the following way.

Let $a = \log(4m/\epsilon)$. For $1 \leq i \leq a$, denote by s_i the number of runs in $\{R_j\}_{j=1}^h$ whose length falls in the interval $[2^{i-1} + 1, 2^i]$. As $|\{R_j : 1 \leq j \leq h, |R_j| > 4m/\epsilon\}| < \epsilon n/(4m)$, we get $\sum_{i=1}^a s_i \geq h - \epsilon n/(4m) \geq \epsilon n/(4m)$. Therefore, there exists an index i for which $s_i \geq \epsilon n/(4am)$. Consider all infeasible runs R_j with $|R_j| \in [2^{i-1} + 1, 2^i]$. Note that if a run contains an infeasible subrun, then it is infeasible by itself. Now, each infeasible run of length between $2^{i-1} + 1$ and 2^i is contained in at least 2^i infeasible runs of length 2^{i+1}, except maybe for the first two and the last two runs (those with the two smallest j's and those with the two largest j's). As R_j are

disjoint, each infeasible run of length 2^{i+1} contains at most three of the R_j's of length at least $2^{i-1}+1$. Thus, we a get a total of at least $(2^i/3)(s_i-4)$ infeasible runs of length at most 2^{i+1}. By our assumption on the parameters, this number is $(2^i/3)(s_i-4) \geq \frac{2^i}{3}(\frac{\epsilon n}{4am}-4) = 2^{i-4}(\frac{\epsilon n}{am}+\frac{1}{3}\frac{\epsilon n-64am}{am}) \geq \frac{2^{i-4}\epsilon n}{m\log(4m/\epsilon)}$, as claimed. ∎

Now our aim is to reduce the general case to the above described case. For a given DFA M with a graph $G=G(M)$, we denote by $\mathcal{C}(G)$ the *graph of components* of G, whose vertices correspond to maximal by inclusion strongly connected components of G and whose directed edges connect components of G, which are connected by some edge in G. Note that some of the vertices of $\mathcal{C}(G)$ may represent single vertices of G with no self loops that do not belong to any strongly connected subgraph of G with at least two vertices. All other components have nonempty paths inside them and will be called *truly connected*. From now on we reserve k for the number of vertices of $\mathcal{C}(G)$ and set $V=V(G)$. We may assume that all vertices of G are reachable from the initial state q_1. Then $\mathcal{C}(G)$ is an acyclic graph in which there exists a directed path from a component C_1, containing q_1, to every other component. Denote $m=\max_j(m(C_j))$, $l=lcm(\{g(G[C_j])\})$, where j runs over all truly connected components of G, corresponding to vertices of $\mathcal{C}(G)$. We will assume in what follows that the following relations are satisfied between the parameters.

Condition (*).

- $\frac{\epsilon n}{2k} \geq 64m\log\frac{8mk}{\epsilon}$.
- $\epsilon n > 8km$.
- $\epsilon\log(1/\epsilon) < \frac{1}{258k^2|V|^2m(l+m)}$.

Clearly, for any fixed k,m,l for ϵ small enough, and n large enough, condition (*) holds.

Our next step is to describe how a word $w \in L_M$ of length n can move along the automaton. If a word w belongs to L, it traverses G, starting from q_1 and ending in one of the accepting states. Accordingly, w traverses $\mathcal{C}(G)$, starting from C_1 and ending in a component containing an accepting state. For this reason, we call a path A in $\mathcal{C}(G)$ *admissible* if it starts at C_1 and ends at a component with an accepting state. Given an admissible path $A=(C_{i_1},\dots,C_{i_t})$ in $\mathcal{C}(G)$, a sequence $P=(p_j^1,p_j^2)_{j=1}^t$ of pairs of vertices of G (states of M) is called an *admissible sequence of portals* if it satisfies the following restrictions.

1. $p_j^1,p_j^2 \in C_{i_j}$ for every $1 \leq j \leq t$.
2. $p_1^1 = q_1$.
3. $p_t^2 \in F$ (i.e., p_t^2 is an accepting state of M).
4. For every $2 \leq j \leq t$ one has $(p_{j-1}^2,p_j^1) \in E(G)$.

The idea behind the above definition of admissible portals is simple: Given an admissible path A, an admissible sequence P of portals defines how a word $w \in L$ moves from one strongly connected component of A to the next one, starting from the initial state q_1 and ending in an accepting state. The pair (p_j^1,p_j^2) is the first and last states that are traversed in C_{i_j}.

Now, given an admissible path A and a corresponding admissible sequence P of portals, we say that an increasing sequence of integers $\Pi=(n_j)_{j=1}^{t+1}$ forms an *admissible partition* with respect to (A,P) if the following hold.

1. $n_1=0$.
2. For every $1 \leq j \leq t$, there exists a path from p_j^1 to p_j^2 in C_{i_j} of length $n_{j+1}-n_j-1$.
3. $n_{t+1}=n+1$.

The meaning of the partition $\Pi=(n_j)_{j=1}^{t+1}$ is as follows. If $w \in L$ and w traverses M

in accordance with (A, P), then, for each $1 \le j \le t$, the value of n_j indicates that w arrives to component C_{i_j} for the first time after n_j bits. For convenience we also set $n_{t+1} = n + 1$. Thus, for each $1 \le j \le t$, the word w stays in C_{i_j} in the interval $[n_j + 1, n_{j+1} - 1]$. Note that it is possible in principle that for a given admissible path A and a corresponding admissible sequence of portals P there is no corresponding admissible partition Π. (This could happen if the path A and the set of portals P correspond to no word of length n.)

A triplet (A, P, Π), where A is an admissible path, P is a corresponding admissible sequence of portals, and Π is a corresponding admissible partition, will be called an *admissible triplet*. It is clear from the definition of an admissible triplet that a word $w \in L$ traverses G in accordance with a scenario suggested by one of the admissible triplets. Therefore, in order to get convinced that $w \notin L$, it is enough to check that w does not fit any admissible triplet.

Fix an admissible triplet (A, P, Π), where $A = (C_{i_1}, \dots, C_{i_t})$, $P = (p_j^1, p_j^2)_{j=1}^t$, and $\Pi = (n_j)_{j=1}^{t+1}$. For all $1 \le j \le t$, we define a language L_j that contains all words that traverse in M from p_j^1 to p_j^2. This is done formally by defining an automaton M_j as follows. The set of states of M_j is obtained by adding to C_{i_j} a new state f_j. The initial state of M_j and its unique accepting state are p_j^1 and p_j^2, respectively. For each $q \in C_{i_j}$ and $\alpha \in \{0, 1\}$, if $\delta_M(q, \alpha) \in C_{i_j}$, we set $\delta_{M_j}(q, \alpha) = \delta_M(q, \alpha)$. Otherwise, $\delta_{M_j}(q, \alpha) = f_j$. We also define $\delta_{M_j}(f_j, 0) = \delta_{M_j}(f_j, 1) = f_j$. Namely, in M_j all transitions within C_{i_j} remain the same. All transitions going to other components now go to f_j, which has a loop to itself. Thus, M_j is essentially strongly connected, as in Definition 2.5, with $D = \{f_j\}$. Then L_j is the language accepted by M_j.

Given the fixed admissible triplet (A, P, Π) and a word w of length $|w| = n$, we define t subwords of it, $w^1, \dots, w^t$, by setting $w^j = w[n_j + 1] \dots w[n_{j+1} - 1]$, where $1 \le j \le t$. Note that $|w^j| = n_{j+1} - n_j - 1$. Namely, if w were to pass through M according to the partition Π, then the substring w_j would correspond to the portion of the traversal path of w that lies within the component C_{i_j}.

LEMMA 2.7. *Let (A, P, Π) be an admissible triplet , where $A = (C_{i_1}, \dots, C_{i_t})$, $P = (p_j^1, p_j^2)_{j=1}^t$, and $\Pi = (n_j)_{j=1}^{t+1}$. Let w be a word of length n satisfying $dist(w, L) \ge \epsilon n$. Define languages $(L_j)_{j=1}^t$ and words $(w_j)_{j=1}^t$ as described above. Then there exists an index j, $1 \le j \le t$, for which $dist(w^j, L_j) \ge \frac{\epsilon n - k}{k}$.*

Proof. Assume this is not the case. Let $\Pi = (n_j)_{j=1}^{t+1}$ be the partition, and recall that $t \le k$. For every $1 \le j \le t$, if $n_{j+1} - n_j \ge 2$, let $w^{j*} \in L_j$ be a word of length $n_{j+1} - n_j - 1$ for which $dist(w^j, w^{j*}) < (\epsilon n - k)/k$. If $n_{j+1} - n_j = 1$, we set $w^{j*} = \gamma$ (the empty word). Also, for $1 \le j \le t - 1$, choose $\alpha_j \in \{0, 1\}$ so that $\delta_M(p_j^2, \alpha_j) = p_{j+1}^1$. Then by construction the word $w^* = w^{1*}\alpha_1 w^{2*} \dots \alpha_{t-1} w^{t*}$ belongs to L and $dist(w, w^*) \le t - 1 + \sum_{j=1}^t dist(w^j, w^{j*}) \le t - 1 + t(\epsilon n - k)/k < \epsilon n$, which is a contradiction. ∎

Now we present a key idea of the proof. Ideally, we would like to test whether an input word w of length n fits any admissible triplet. In the positive case, i.e., when $w \in L_M$, the traversal path of w in M defines naturally an admissible triplet which w will obviously fit. In the negative case, i.e., when $dist(w, L) \ge \epsilon n$, Lemma 2.7 implies that for every admissible triplet (A, P, Π), at least one of the subwords w^j is very far from the corresponding language L_j. Then by Lemma 2.6 w^j contains many short infeasible runs, and thus sampling a small number of random runs will catch one of them with high probability. However, the problem is that the total number of admissible triplets clearly depends on n, which makes the task of applying directly

the union bound on the probability of not catching an infeasible run impossible.

We circumvent this difficulty in the following way. We place evenly in $1, \ldots, n$ a bounded number (depending only on ϵ and the parameters of M) of *transition intervals* T_s of a bounded length and postulate that a transition between components of $\mathcal{C}(G)$ should happen inside these transition intervals. Then we show that if $w \in L$, it can be modified slightly to meet this restriction, whereas if $dist(w, L) \geq \epsilon n$, for any choice of such an admissible triplet, w is far from fitting it. As the number of admissible triplets under consideration is bounded by a function of ϵ only, we can apply the union bound to estimate the probability of failure.

Recall that $m = \max_j(m(C_j))$, $l = lcm(\{g(G[C_j])\})$, where j runs over all truly connected components of G, corresponding to vertices of $\mathcal{C}(G)$. Let $S = 129km\log(1/\epsilon)/\epsilon$. We place S transition intervals $\{T_s = [a_s, b_s]\}_{s=1}^{S}$ evenly in $[n]$, where the length of each transition interval T_s is $|T_s| = (k-1)(l+m)$. For $1 \leq i \leq \log(8km/\epsilon)$ define $r_i = \frac{2^{8-i}k^2 m \log^2(\frac{1}{\epsilon})}{\epsilon}$.

ALGORITHM.

Input: a word w of length $|w| = n$;

1. For each $1 \leq i \leq \log(8km/\epsilon)$ choose r_i random runs in w of length 2^{i+1} each;
2. For each admissible triplet (A, P, Π) with $A = (C_{i_1}, \ldots, C_{i_t})$, $P = (p_j^1, p_j^2)_{j=1}^t$, $\Pi = (n_j)_{j=1}^{t+1}$ such that for all $2 \leq j \leq t$ one has $n_j \in T_s$ for some $1 \leq s \leq S$, do the following:
   - Form the automata M_j, $1 \leq j \leq t$, as described above.
   - Discard those chosen runs which end or begin at place p for which $|p - n_j| \leq \epsilon n/(128km\log(1/\epsilon))$. Namely, those runs which have one of their ends closer than $\epsilon n/(128km\log(1/\epsilon))$ from some $n_j \in \Pi$.
   - For each remaining run R, if R falls between n_j and n_{j+1}, check whether it is feasible for the automaton M_j starting at $b - n_j + 1$, where b is the first coordinate of R in w. Namely, $b - n_j + 1$ is the place where R starts relative to n_j, which is the place w "enters" M_j.
3. If for some admissible triplet all checked runs turned out to be feasible, output "YES." Otherwise (i.e., in the case where for all admissible triplets at least one infeasible run has been found) output "NO."

LEMMA 2.8. *If $dist(w, L) \geq \epsilon n$, then the above algorithm outputs "NO" with probability at least $3/4$. If $w \in L$, then the algorithm always outputs "YES."*

Proof. The proof contains two independent parts. In the first we consider the case of an input w with $dist(w, L) \geq \epsilon n$, on which the algorithm should answer "NO" (with high probability). The other part treats the case where $w \in L$, for which the algorithm should answer "YES."

Let us first assume that $dist(w, L) \geq \epsilon n$. The number of admissible triplets (A, P, Π) for which all partition points fall into the union of transition intervals $\bigcup_{s=1}^{S} T_s$ can be estimated from above by

$$2^k |V|^{2k} \left(S(k-1)(l+m)\right)^{k-1}.$$

(First choose an admissible path in $\mathcal{C}(G)$; the number of admissible paths is at most 2^k as any subset of vertices of $\mathcal{C}(G)$ defines at most one path spanning it. Then choose portals; the total number of chosen portals is at most $2k$, and therefore there are at most $|V|^{2k}$ possible choices for portals; then for a fixed pair (A, P) there are at most $S|T_s|$ choices for each n_j, where $2 \leq j \leq t$ and $t \leq k$.) For ϵ satisfying condition (*) and S as above, this expression is at most $(1/\epsilon)^{2k}$. Thus we need to check at most $(1/\epsilon)^{2k}$ admissible triplets.

Let (A, P, Π) be an admissible triplet satisfying the restriction formulated in step 2 of the above algorithm. Write $A = (C_{i_1}, \ldots, C_{i_t})$, $P = (p_j^1, p_j^2)_{j=1}^t$, $\Pi = (n_j)_{j=1}^{t+1}$. Then the triplet defines automata $(M_j)_{j=1}^t$ and languages $(L_j)_{j=1}^t$ as described before. By Lemma 2.7 for some $1 \le j \le t$ one has $dist(w^j, L_j) \ge (\epsilon n - k)/k > \epsilon n/(2k)$. Then by Lemma 2.6 there exists an i, $1 \le i \le \log(8km/\epsilon)$ so that w^j contains at least $2^{i-4}\epsilon n/(2km\log(8km/\epsilon)) \ge 2^{i-6}\epsilon n/(km\log(1/\epsilon))$ infeasible runs of length 2^{i+1}. At most $\alpha = \epsilon n/(128km\log(1/\epsilon))$ of them may touch the last α bits of the interval $[n_j, n_{j+1} - 1]$, and at most α of them may touch the first α bits of this interval. Hence there are at least $2^{i-6}\epsilon n/(km\log(1/\epsilon)) - 2\alpha \ge (2^{i-7}\epsilon n)/(km\log(1/\epsilon))$ of them that touch neither the first nor the last $\epsilon n/(128km\log(1/\epsilon))$ bits of the interval $[n_j, n_{j+1} - 1]$. Obviously, if a random sample contains one of these infeasible runs, then it provides a certificate for the fact that w does not fit this admissible triplet. A random sample of r_i runs of length 2^{i+1} misses all of these infeasible runs with probability at most

$$\left(1 - \frac{1}{n}\frac{2^{i-7}\epsilon n}{km\log(\frac{1}{\epsilon})}\right)^{r_i} < e^{-2k\log(\frac{1}{\epsilon})} < \frac{1}{4}\left(\frac{1}{\epsilon}\right)^{-2k}.$$

Thus by the union bound we conclude that in this case a random sample does not contain a "witness" for each feasible triplet with probability at most 1/4. This completes the proof for the case of $dist(w, L) \ge \epsilon n$.

We now address the case for which $w \in L$. We need to show that in this case the algorithm answers "YES." For this is enough to show that if $w \in L$, then there exists an admissible triplet which passes successfully the test of the above algorithm. A traversal of w in M naturally defines a triplet (A, P, Π) as follows: $A = (C_{i_1}, \ldots, C_{i_t})$, where $C_{i_1}, \ldots, C_{i_t}$ are components from $\mathcal{C}(G)$, ordered according to the order of their traversal by w; $P = (p_j^1, p_j^2)_{j=1}^t$, where p_j^1 (resp., p_j^2) is the first (resp., the last) state of C_{i_j} visited by w; $\Pi = (n_j)_{j=1}^{t+1}$, where $n_1 = 0$, $n_{t+1} = n + 1$, and for $2 \le j \le t$, n_j is set to be the first time w enters C_{i_j} while traversing M. However, this partition does not necessarily meet the requirement stated in step 2 of the algorithm. In the true traversal of w in M the transitions from C_{i_j} to $C_{i_{j+1}}$ might occur outside the transition intervals T_s. We show that the desired triplet can be obtained from the actual triplet, (A, P, Π), of w by modifying only the third component of it. This modified triplet would then correspond to a different word $w' \in L$ (which is quite close to w) that makes all the transitions inside the postulated transition intervals. In addition, we will take care that no query is made to bits in which w' differs from w. Hence, the algorithm will actually be consistent with both. This is in fact the reason for discarding the runs that are too close to some n_j in step 2 of the algorithm. Intuitively, this is done as follows. Assume n_j is not in a transition interval; then we either make the traversal in $C_{i_{j-1}}$ longer so as to end in p_{j-1}^2 in a transition interval, or we shorten the traversal in $C_{i_{j-1}}$ so as to enter a transition interval, depending on where the closest transition interval is. Formally, this is done as follows. Define a new partition $\Pi' = (n'_j)_{j=1}^{t+1}$, where $n'_1 = n_1 = 0$. For each $2 \le j \le t$ choose a transition interval T_s closest to n_j. If C_{i_j} is a truly connected component, we choose n'_j as the leftmost coordinate in T_s satisfying the following restrictions: (a) $n'_j \equiv n_j \bmod l$; (b) $n'_j - n'_{j-1} > m$. If C_{i_j} is a singleton without loops, we set $n'_j = n'_{j-1} + 1$. As $|T_s| = (k-1)(l+m)$, such an n'_j always exists. Finally, we set $n'_{t+1} = n_{t+1} = n + 1$.

Note that the obtained triplet (A, P, Π') is admissible. Indeed, for every $1 \le j \le t$ we have $n'_{j+1} - n'_j \equiv n_{j+1} - n_j \bmod l$, thus implying $n'_{j+1} - n'_j \equiv n_{j+1} - n_j \bmod g(G[C_{i_j}])$ if C_{i_j} is truly connected. As there exists a path from p_j^1 to p_j^2 in

C_{i_j} of length $n_{j+1} - n_j - 1$, there also exists a path of length $n'_{j+1} - n'_j - 1$. This implies the admissibility of Π' and hence the admissibility of (A, P, Π').

Now let R be a run of w inside $[n'_j + \epsilon n/(128km\log(1/\epsilon)), n'_{j+1} - \epsilon n/(128km\log(1/\epsilon))]$, and let b be its first coordinate. Since we placed S transition intervals $\{T_s\}$ evenly in $[n]$, we have $|n'_j - n_j| \le n/S + |T_s| = \epsilon n/(129km\log(1/\epsilon)) + (k-1)(l+m)$. Therefore, R falls also completely inside $[n_j + m, n_{j+1} - 1]$. (We remark at this point that the purpose of discarding marginal runs at step 2 of the algorithm is to achieve that each one of the remaining runs will fall completely not only within $[n'_j, n'_{j+1}]$ but also within $[n_j, n_{j+1}]$. As we will see immediately, this guarantees that R will be feasible for the corresponding automaton M_j. Without this deletion, with positive probability one of the sampled runs R may start in a place where w is in $C_{i_{j-1}}$ and end in a place where w is in C_{i_j}, thus making it impossible to attribute R to one particular automaton M_j. Therefore, with positive probability the algorithm would fail in the positive case. Discarding marginal runs allows us to get a one-sided error algorithm.)

As $w \in L$, there exists a state $q \in C_{i_j}$ so that $\delta(q, R) \in C_{i_j}$. Also, q is reachable from p^1_j (the initial state of C_{i_j}) in $b - n_j \ge m$ steps (b is the first coordinate of R). According to the choice of n'_j, we have $n'_j \equiv n_j \bmod g_j$, where g_j is the period of C_{i_j}. But then by Lemma 2.3 q is reachable from p^1_j in $b - n'_j$ ($\ge m$) steps. This shows that R is feasible for M_j, starting at $b - n'_j + 1$. Thus, if $w \in L$, the above algorithm always outputs "YES." □

Finally, the number of bits of w queried by our algorithm is at most

$$\sum_{i=1}^{\log(8km/\epsilon)} 2^{i+1} r_i = \sum_{i=1}^{\log(8km/\epsilon)} 2^{i+1} \frac{2^{8-i} k^2 m \log^2(\frac{1}{\epsilon})}{\epsilon} < \frac{2^{10} k^2 m \log^3(\frac{1}{\epsilon})}{\epsilon} .$$

We have thus proven the following theorem.

THEOREM 2.9. *For every regular language L, every integer n, and every small enough $\epsilon > 0$, there exists a one-sided error ϵ-testing algorithm for $L \cap \{0,1\}^n$, whose query complexity is $c\log^3(1/\epsilon)/\epsilon$, where the constant $c > 0$ depends only on L.*

A final note about the dependence of the complexity on the parameters is in place here. In the proof M is considered fixed, as the algorithm is tailored for a fixed given language. However, in the calculation above we have kept the dependence of the query complexity on the parameters of M explicit. One has to keep in mind, though, that the estimates hold only when condition (*) holds. In particular, we require (third item in (*)) that $1/(\epsilon\log(1/\epsilon)) = \Omega(k^2|V|^2 m(l+m))$.

Another note is about the running time of the algorithm (rather than just its query complexity). The dominating term in step 1 and the first two subsets of step 2 of the algorithm is the query complexity. In the last substeps, each run has to be checked against M_j. Each such check involves checking whether there is a word u and a word v (of suitable lengths) so that $uRv \in L$. Checking whether there are such u, v is done directly by Lemma 2.3 in case the length of u and v are longer than m, or by checking all 2^m words if one of them is shorter than m.

3. Lower bound for regular languages. In many testability questions, it is quite natural to expect a lower bound of order $1/\epsilon$ for the query complexity of testing. This is usually proven by taking a positive example of size n and perturbing it in randomly chosen ϵn places to create a negative instance which is hard to distinguish from the positive one. Regular languages are not an exception in this respect, as shown by the next proposition and its fairly simple proof.

PROPOSITION 3.1. *Let L be the regular language over the alphabet $\{0,1\}$ defined by $L = \{1^n \mid n \geq 1\}$. For any n an ϵ-test for $L \cap \{0,1\}^n$ has query complexity at least $\frac{1}{3\epsilon}$.*

Proof. Our proof is based on the following reformulation of the renowned principle of Yao [14], saying that if there exists a probability distribution on the union Ω of positive and negative examples such that any *deterministic* testing algorithm of query complexity d is correct with probability less than $2/3$ for an input randomly chosen from Ω according to this distribution, then d is a lower bound on the query complexity of any randomized testing algorithm.

Define a distribution on the set of positive and negative instances of length n as follows. The word 1^n gets probability $1/2$. Next we partition the index set $[1,n]$ into $t = 1/\epsilon$ parts $I_1, \ldots, I_t$, each of size ϵn, and for each $1 \leq i \leq t$ we give probability $1/(2t)$ to the vector y_i created from 1^n by flipping all bits in I_i from 1 to 0. Note that $dist(y_i, L) = \epsilon n$; hence all y_i are negative instances. Now we apply the above-mentioned principle of Yao. Let A be a deterministic ϵ-testing algorithm with query complexity d. If A is incorrect on the word 1^n, then it is already incorrect with probability at least $1/2$. Otherwise, it should accept the input if all d tested bits equal to 1. Therefore, it accepts as well at least $t - d$ of the inputs y_i. This shows that A gives an incorrect answer with probability at least $(t-d)/(2t) < 1/3$, implying that $d > t/3$. □

The main idea of the proof of the above proposition can be used to get an $\Omega(1/\epsilon)$ lower bound on the query complexity of testing any nontrivial regular language, with a natural definition of nontrivial. This is proven in the next proposition. A somewhat paradoxical feature of its proof is that our main positive result (Theorem 2.9) and its proof are used here to get a negative result.

For a language L let $L_n = L \cap \{0,1\}^n$.

DEFINITION 3.2. *A language L is nontrivial if there exists a constant $0 < \epsilon_0 < 1$, so that for infinitely many values of n the set L_n is nonempty, and there exists a word $w \in \{0,1\}^n$ so that $dist(w, L_n) \geq \epsilon_0 n$.*

PROPOSITION 3.3. *Let L be a nontrivial regular language. Then for all sufficiently small $\epsilon > 0$, any ϵ-testing algorithm for L requires $\Omega(1/\epsilon)$ queries.*

Proof. The proof here is essentially a generalization of the proof of Proposition 3.1. We thus present it in a somewhat abridged form.

Let n be large enough. Assume $L_n \neq \emptyset$, and $w \in \{0,1\}^n$ is such that $dist(w, L_n) \geq \epsilon_0 n$. We may clearly assume that the constant ϵ_0 is as small as needed for our purposes. Our main result, Theorem 2.9, and its proof imply that with probability at least $2/3$, a random choice of a set of runs, built as described at step 1 of the testing algorithm of Theorem 2.9, and having total length $\tilde{O}(1/\epsilon_0)$, will cause the algorithm to reject w. As we have noticed, the testing algorithm has a one-sided error, i.e., it always accepts a word from L. Thus, if we choose a random set of runs as above, it will cause a rejection of w with probability $2/3$ and it will not coincide with any word $u \in L_n$ (for otherwise, it would reject u too).

Each such random set of runs is just a random set of intervals in $\{1, \ldots, n\}$ (of length as defined in step 1 of the testing algorithm) of total length bounded by $\tilde{O}(1/\epsilon_0)$. Notice that two such random sets intersect with probability $\tilde{O}(1/(\epsilon_0^2 n))$. Therefore, if we choose $\tilde{\Omega}(\epsilon^2 n)$ such subsets at random, then we expect that $\tilde{O}(\epsilon_0^2 n)$ pairs of them will intersect, and that $2/3$ of the members will reject w. This implies that there exists a family $\mathcal{S}$ of $\tilde{\Omega}(\epsilon_0^2)n$ pairwise disjoint sets of runs so that for each member of $\mathcal{S}$, no word of L_n coincides with w on this set. Fix now ϵ_0 and let $\epsilon > 0$

be small enough compared to ϵ_0. We partition the family $\mathcal{S}$ into $t = (c/\epsilon)$ subfamilies $\mathcal{S}_1, \ldots, \mathcal{S}_t$, each of cardinality ϵn, where the constant c depends on ϵ_0 only and is thus independent of ϵ. Let u be a word in L_n. For each $1 \leq i \leq t$, the word w_i is obtained from u by changing the bits of u, corresponding to $\mathcal{S}_i$, to those from w. It follows then that $dist(w_i, L_n) \geq \epsilon n$. Indeed, to transform w_i into a word in L_n, at least one bit has to be changed in every member of $\mathcal{S}_i$.

Now, as in the proof of Proposition 3.1, we define a probability distribution on the union of positive and negative examples. The word u gets probability $1/2$, and each one of the t words $w_1, \ldots, w_t$ gets probability $1/(2t)$. A simple argument, essentially identical to that in the proof of Proposition 3.1, shows that any deterministic algorithm needs to query at least $\Omega(t) = \Omega(1/\epsilon)$ bits of the input word to be successful with probability at least $2/3$ on the defined probability distribution. Applying Yao's principle, we get the desired result. □

4. Testability of context-free languages. Having essentially completed the analysis of testability of regular languages, it is quite natural to try to go one step further and to address testability of the much more complex class of context-free languages (see, e.g., [8] for background information). It turns out that the general situation changes drastically here as compared to the case of regular languages. We show that there exist quite simple context-free languages which are *not* ϵ-testable. Then we turn our attention to one particular family of context-free languages—the so-called Dyck languages. We prove that the first language in this family, D_1, is testable in time polynomial in $1/\epsilon$, while all other languages in the family are already nontestable. All relevant definitions and proofs follow.

4.1. Some context-free languages are nontestable. As we have already mentioned, not all context-free languages are testable. This is proven in the following proposition.

THEOREM 4.1. *Any ϵ-testing algorithm for the context-free language $L = \{vv^R uu^R\}$, where w^R denotes the reversal of a word w, requires $\Omega(\sqrt{n})$ queries in order to have an error of at most $1/3$.*

Proof. Let n be divisible by 6. We again define a distribution D on the union of positive and negative inputs in the following way. A negative instance is chosen uniformly at random from among all negative instances (i.e., those words $w \in \{0,1\}^n$ which are at distance at least ϵn from L). We refer to this distribution as N. Positive instances are generated according to a distribution P defined as follows. We pick uniformly at random an integer k in the interval $[n/6+1, n/3]$ and then select a positive example uniformly among words $vv^R uu^R$ with $|v| = k$. Finally, the distribution D on all inputs is defined as follows: with probability $1/2$ we choose a positive input according to P and with probability $1/2$ we choose a negative input according to N. We note that a positive instance is actually a pair (k, w). (The same word w may be generated using different k's.)

We use the above-mentioned Yao's principle again. Let A be a deterministic ϵ-testing algorithm for L. We show that for any such A, if its maximum number of queries is $d = o(\sqrt{n})$, then its expected error with respect to D is at least $\frac{1}{2} - o(1)$. Indeed, let A be such an algorithm. We can view A as a binary decision tree, where each node represents a query to a certain place, and the two outgoing edges, labeled with 0 or 1, represent possible answers. Each leaf of A represents the end of a possible computation and is labeled "positive" or "negative" according to the decision of the algorithm. Tracing the path from the root to a node of A, we can associate with each node t of A a pair (Q_t, f_t), where $Q_t \subseteq \{1, \ldots, n\}$ is a set of queries to the input

word, and $f_t : Q_t \to \{0,1\}$ is a vector of answers received by the algorithm. We may obviously assume that A is a full binary tree of height d and has thus 2^d leaves. Then $|Q_t| = d$ for each leaf t of A.

We will use the following notation. For a subset $Q \subseteq \{1,\dots,n\}$ and a function $f : Q \to \{0,1\}$, let

$$E^-(Q,f) = \{w \in \{0,1\}^n, dist(w,L) \geq \epsilon n,\ w \text{ coincides with } f \text{ on } Q\},$$
$$E^+(Q,f) = \{w \in \{0,1\}^n \cap L :\ w \text{ coincides with } f \text{ on } Q\},$$

i.e., $E^-(Q,f)$ ($E^+(Q,f)$) is the set of all negative (resp., positive) instances of length n consistent with the pair (Q,f). Also, if D is a probability distribution on the set of binary strings of length n and $E \subseteq \{0,1\}^n$ is a subset, we define $\Pr^D[E] = \sum_{w \in E} \Pr^D[w]$.

Let T_1 be the set of all leaves of A labeled "positive," and let T_0 be the set of all leaves of T labeled "negative." Then the total error of the algorithm A on the distribution D is

$$\sum_{t \in T_1} \Pr^D[E^-(Q_t, f_t)] + \sum_{t \in T_0} \Pr^D[E^+(Q_t, f_t)] \ .$$

The theorem follows from the following two claims.

CLAIM 4.2. *For every subset $Q \subset \{1,\dots,n\}$ of cardinality $|Q| = o(n)$ and for every function $f : Q \to \{0,1\}$,*

$$\Pr^D[E^-(Q,f)] \geq \left(\frac{1}{2} - o(1)\right) 2^{-|Q|} \ .$$

CLAIM 4.3. *For every subset $Q \subset \{1,\dots,n\}$ of cardinality $|Q| = o(\sqrt{n})$ and for every function $f : Q \to \{0,1\}$,*

$$\Pr^D[E^+(Q,f)] \geq \left(\frac{1}{2} - o(1)\right) 2^{-|Q|} \ .$$

Based on Claims 4.2 and 4.3, we can estimate the error of the algorithm A by

$$\sum_{t \in T_1} \Pr^D[E^-(Q_t, f_t)] + \sum_{t \in T_0} \Pr^D[E^+(Q_t, f_t)] \geq \sum_{t \in T_1} \left(\frac{1}{2} - o(1)\right) 2^{-|Q_t|}$$
$$+ \sum_{t \in T_0} \left(\frac{1}{2} - o(1)\right) 2^{-|Q_t|} = \left(\frac{1}{2} - o(1)\right) \frac{|T_1| + |T_0|}{2^d} \geq \frac{1}{2} - o(1) \ .$$

The theorem follows. □

We now present the proofs of Claims 4.2 and 4.3.

Proof of Claim 4.2. Notice first that L has at most $2^{n/2} n/2$ words of length n. (First choose a word of length $n/2$, and then cut it into two parts v and u, thus getting a word $w = vv^R uu^R \in L$.) Therefore, the number of words of length n at a distance less than ϵn from L is at most $|L \cap \{0,1\}^n| \sum_{i=0}^{\epsilon n} \binom{n}{i} \leq 2^{n/2 + 2\epsilon \log(1/\epsilon) n}$. We get

$$|E^-(Q,f)| \geq |\{w \in \{0,1\}^n : w(Q) = f\}| - |\{w \in \{0,1\}^n : dist(w,L) < \epsilon n\}|$$
$$\geq 2^{n-|Q|} - 2^{n/2 + 2\epsilon \log(1/\epsilon) n} = (1 - o(1)) 2^{n-|Q|} \ .$$

It follows then from the definition of D that

$$\Pr^D[E^-(Q,f)] = \frac{1}{2} \Pr^N[E^-(Q,f)] \geq \frac{1}{2} \frac{|E^-(Q,f)|}{2^n} \geq \left(\frac{1}{2} - o(1)\right) 2^{-|Q|} \ . \qquad \square$$

Proof of Claim 4.3. It follows from the definition of the distribution D that, for a word $w \in L \cap \{0,1\}^n$,

$$\Pr^D(w) = \frac{1}{2}\Pr^P(w) = \frac{1}{2}\,\frac{|\{w = vv^Ruu^R : \ |v| = k, \frac{n}{6}+1 \le k \le \frac{n}{3}\}|}{\frac{n}{6}2^{n/2}} \ .$$

Recall that $E^+(Q,f)$ is the set of words in L which is consistent with f on the set of queries Q. Hence,

$$\Pr^D[E^+(Q,f)] = \frac{1}{\frac{n}{6}2^{n/2+1}} \sum_{k=n/6+1}^{n/3} |\{w \in \{0,1\}^n : w(Q) = f, w = vv^Ruu^R, |v| = k\}| \ .$$

Now observe that for each of the $\binom{d}{2}$ pairs of places in Q there are at most two choices of k for which the pair is symmetric with respect to k or to $n/2+k$. This implies that for $n/6 - 2\binom{d}{2} = (1-o(1))n/6$ choices of k, the set Q does not contain a pair symmetric with respect to k or $n/2+k$. For each such k,

$$|\{w \in \{0,1\}^n : w(Q) = f, w = vv^Ruu^R, |v| = k\}| = 2^{n/2-|Q|} \ .$$

Therefore,

$$\Pr^D[E^+(Q,f)] \ge \frac{(1-o(1))\frac{n}{6}2^{n/2-|Q|}}{\frac{n}{6}2^{n/2+1}} = \left(\frac{1}{2} - o(1)\right)2^{-|Q|} \ . \qquad \square$$

As a concluding remark to this subsection we would like to note that in the next subsection (Theorem 4.10) we will give another proof to the fact that not all context-free languages are testable by showing the nontestability of the Dyck language D_2. However, we preferred to give Theorem 4.1 as well due to the following reasons. First, the language discussed in Theorem 4.1 is simpler and more natural than the Dyck language D_2. Second, the lower bound of Theorem 4.1 is better than that of Theorem 4.10. The proofs of these two theorems have many common points, so the reader may view Theorem 4.1 as a "warm-up" for Theorem 4.10.

4.2. Testability of the Dyck languages. It would be extremely nice to determine exactly which context-free languages are testable. At present we seem to be very far from fulfilling this task. However, we are able to solve this question completely for one family of context-free languages—the so-called Dyck languages.

For an integer $n \ge 1$, the *Dyck language of order* n, denoted by D_n, is the language over the alphabet of $2n$ symbols $\{a_1, b_1, \ldots, a_n, b_n\}$, grouped into n ordered pairs $(a_1,b_1), \ldots, (a_n,b_n)$. The language D_n is defined by the following productions:

1. $S \to a_i S b_i$ for $i = 1, \ldots, n$,
2. $S \to SS$, and
3. $S \to \gamma$,

where γ denotes the empty word. Though the words of D_n are not binary according to the above definition, we can easily encode them and the grammar describing them using only 0's and 1's. Thus we may still assume that we are in the framework of languages over the binary alphabet. We can interpret D_n as the language with n distinct pairs of brackets, where a word w belongs to D_n iff it forms a balanced bracket expression. The most basic and well-known language in this family is D_1, where we have only one pair of brackets. Dyck languages play an important role in the theory

of context-free languages (see, e.g., [4] for a relevant discussion), and therefore the task of exploring their testability is interesting.

Our first goal in this subsection is to show that the language D_1 is testable. Let us introduce a suitable notation. First, for the sake of simplicity we denote the brackets a_1, b_1 of D_1 by $0, 1$, respectively. Assume that n is a large enough even number. (Obviously, for odd n we have $D_1 \cap \{0,1\}^n = \emptyset$, and thus there is nothing to test in this case.) Let w be a binary word of length n. For $1 \le i \le n$, we denote by $x(w,i)$ the number of 0's in the first i positions of w. Also, $y(w,i)$ stands for the number of 1's in the first i positions of w. We have the following claims.

CLAIM 4.4. *The word w belongs to D_1 iff the following two conditions hold:* (a) $x(w,i) \ge y(w,i)$ *for every* $1 \le i \le n$; (b) $x(w,n) = y(w,n)$.

Proof. The proof follows easily from the definition of D_1—for example, by induction on the length of w. We omit a detailed proof. □

CLAIM 4.5. *If w satisfies* (a) $y(w,i) - x(w,i) \le s_1$ *for every* $1 \le i \le n$, *and* (b) $x(w,n) - y(w,n) \le s_2$, *then* $dist(w, D_1) \le s_1 + s_2/2 + 1$.

Proof. Observe first that by Claim 4.4 a word w is in D_1 iff we can partition its letters into pairwise disjoint pairs, so that the left letter in each pair is a 0, and the right letter is a 1. Consider the bipartite graph, whose two classes of vertices are the set of indices i for which $w[i] = 0$ and the set of indices i for which $w[i] = 1$, respectively, where each i with $w[i] = 1$ is connected to all $1 \le j < i$ for which $w[j] = 0$. By assumption (a) and the defect form of Hall's theorem, this graph contains a matching of size at least $y(w,n) - s_1$. By assumption (b), $y(w,n) \ge n/2 - s_2/2$. Therefore, there are at least $n/2 - s_2/2 - s_1$ disjoint pairs of letters in w, where in each pair there is a 0 on the left and a 1 on the right. Let us pair the remaining elements of w arbitrarily, where all pairs but at most one consist of either two 0's or two 1's. By changing, now, when needed, the left entry of each such pair to 0 and its right entry to 1 we obtain a word in D_1, and the total number of changes performed is at most $(s_2 + 2s_1 - 2)/2 + 2 = s_1 + s_2/2 + 1$, completing the proof. □

CLAIM 4.6. (a) *If for some $1 \le i \le n$ one has $y(w,i) - x(w,i) \ge s$, then $dist(w, D_1) \ge s/2$.* (b) *If $x(w,n) - y(w,n) \ge s$, then $dist(w, D_1) \ge s/2$.*

Proof. The proof follows immediately from Claim 4.4. □

We conclude from the above three claims that a word w is far from D_1 iff for some coordinate i it deviates significantly from the necessary and sufficient conditions provided by Claim 4.5. This observation is used in the analysis of an algorithm for testing D_1, proposed below.

Set

$$d = \frac{C \log\left(\frac{1}{\epsilon}\right)}{\epsilon^2},$$

$$\Delta = \frac{C \log\left(\frac{1}{\epsilon}\right)}{8\epsilon},$$

where $C > 0$ is a sufficiently large constant, whose value will be chosen later, and assume that d is an even integer. In what follows we omit all floor and ceiling signs to simplify the presentation.

ALGORITHM.

Input: a word w of length $|w| = n$;

1. Choose a sample S of bits in the following way. For each bit of w, independently and with probability $p = d/n$ choose it to be in S. Then, if S contains more than $d + \Delta/4$ bits, answer "YES" without querying any bit. Else,

2. If $dist(S, D_1 \cap \{0,1\}^{d'}) < \Delta$, where $d' = |S|$, output "YES"; otherwise, output "NO."

LEMMA 4.7. *The above algorithm outputs a correct answer with probability at least* 2/3.

Proof. As we have already mentioned, we set

$$p = \frac{d}{n} = \frac{C \log\left(\frac{1}{\epsilon}\right)}{\epsilon^2 n} .$$

The proof contains two independent parts; in the first we prove that the algorithm is correct (with probability 2/3) for $w \in D_1$, and in the second part we prove that the algorithm has a bounded error for words w for which $dist(w, D_1) \geq \epsilon n$.

Consider first the positive case $w \in D_1$. Set $t = C/\epsilon$, and assume for simplicity that t as well as n/t are integers. For $1 \leq j \leq t$, let X_j be the number of 0's in S, sampled from the interval $[1, nj/t]$. Let also Y_j denote the number of 1's in S, sampled from the same interval. Both X_j and Y_j are binomial random variables with parameters $x(w, nj/t)$ and p, and $y(w, nj/t)$ and p, respectively. As $w \in D_1$, we get by Claim 4.4 that $x(w, nj/t) \geq y(w, nj/t)$, implying $EX_j \geq EY_j$. Applying standard bounds on the tails of binomial distribution, we obtain

$$\Pr\left[Y_j \geq X_j + \frac{\Delta}{2}\right] \leq \Pr\left[X_j \leq EX_j - \frac{\Delta}{4}\right] + \Pr\left[Y_j \geq EY_j + \frac{\Delta}{4}\right] \leq 2^{-\Omega(\Delta^2/np)}$$

$$= 2^{-\Omega(C \log(1/\epsilon))}. \tag{4.1}$$

For $1 \leq j \leq t-1$, set $Z_j = Y_{j+1} - Y_j$. Note that $EZ_j \leq np/t$. Using similar argumentation as above, we get

$$\Pr\left[Z_j \geq \frac{2np}{t}\right] \leq 2^{-\Omega(np/t)} = 2^{-\Omega(\log(1/\epsilon)/\epsilon)}. \tag{4.2}$$

As $w \in D_1$, we have by Claim 4.4 $x(w, n) = y(w, n) = n/2$. Hence

$$\Pr\left[X_t \geq \frac{np}{2} + \frac{\Delta}{8}\right] \leq 2^{-\Omega(\Delta^2/np)} = 2^{-\Omega(C \log(1/\epsilon))}. \tag{4.3}$$

Finally, we have the following estimate on the distribution of the sample size $|S|$:

$$\Pr\left[||S| - np| \geq \frac{\Delta}{4}\right] \leq 2^{-\Omega(\Delta^2/np)} = 2^{-\Omega(C \log(1/\epsilon))}. \tag{4.4}$$

Choosing C large enough and recalling the definition of t, we derive from (4.1)–(4.4) that with probability at least 2/3 the following events hold simultaneously:

1. $\max_{1 \leq j \leq t}(Y_j - X_j) \leq \frac{\Delta}{2}$,
2. $\max_{1 \leq j \leq t} Z_j \leq \frac{2np}{t}$,
3. $X_t \leq \frac{np}{2} + \frac{\Delta}{8}$,
4. $|S| \geq np - \frac{\Delta}{4}$.

Assume that the above four conditions are satisfied. Then we claim that $dist(S, D_1) < \Delta$. Indeed, the first two conditions guarantee that for all $1 \leq i \leq |S|$ we have $y(S, i) - x(S, i) \leq \Delta/2 + 2np/t \leq 2\Delta/3$. The last two conditions provide $x(S, |S|) - y(S, |S|) = X_t - Y_t = 2X_t - |S| \leq \Delta/2$. Therefore, by Claim 4.5 $dist(S, D_1) < \Delta$.

Thus, if $w \in D_1$, our algorithm will accept w with probability at least $2/3$, as required. This ends the first part of the proof.

Let us now consider the negative case. Assume that $dist(w, D_1 \cap \{0,1\}^n) \geq \epsilon n$. By Claim 4.5 we have then that at least one of the following two conditions holds: (a) there exists an index $1 \leq i \leq n$ for which $y(w,i) - x(w,i) \geq \epsilon n/2$; (b) $x(w,n) - y(w,n) \geq \epsilon n/2$. In the former case, let X, Y be the number of 0's, 1's, respectively, of S, sampled from the interval $[1,i]$. Let also k be the number of elements from $[1,i]$ chosen to S. Then $X = x(S,k)$, $Y = y(S,k)$. Both X and Y are binomially distributed with parameters $x(w,i)$ and p, and $y(w,i)$ and p, respectively. It follows from the definition of i that $EY - EX \geq \epsilon np/2$. But then we have

$$\begin{aligned}\Pr[y(S,k) - x(S,k) \leq 2\Delta] &= \Pr[Y - X \leq 2\Delta] \\ &\leq \Pr\left[X \geq EX + \left(\frac{\epsilon np}{4} - \Delta\right)\right] \\ &\quad + \Pr\left[Y \leq EY - \left(\frac{\epsilon np}{4} - \Delta\right)\right] \\ &= 2^{-\Omega((\epsilon np/4 - \Delta)^2/(np))}.\end{aligned}$$

Choosing the constant C to be sufficiently large and recalling the definitions of p and Δ, we see that the above probability is at most $1/6$. But if $y(S,k) - x(S,k) \geq 2\Delta$, it follows from Claim 4.6 that $dist(S, D_1) \geq \Delta$.

If $x(w,n) - y(w,n) \geq \epsilon n/2$, we obtain, using similar arguments,

$$\Pr[x(S,|S|) - y(S,|S|) \leq 2\Delta] = 2^{-\Omega((\epsilon np/4 - \Delta)^2/(np))}.$$

The above probability can be made at most $1/6$ by the choice of C. But if $x(S,|S|) - y(S,|S|) \geq 2\Delta$, it follows from Claim 4.6 that $dist(S, D_1) \geq \Delta$. Thus in both cases we obtain that our algorithm accepts w with probability at most $1/6$. In addition, the algorithm may accept w (in each of the cases) when $|S| > d + \Delta/4$ (first item in the algorithm). However, by (4.4) this may be bounded by $1/6$ (choosing C as in the first part). Hence the algorithm rejects w with probability at least $2/3$. This completes the proof of Lemma 4.7. □

By Lemma 4.7 we have the following result about the testability of the Dyck language D_1.

THEOREM 4.8. *For every integer n and every small enough $\epsilon > 0$, there exists an ϵ-testing algorithm for $D_1 \cap \{0,1\}^n$, whose query complexity is $C \log(1/\epsilon)/\epsilon^2$ for some absolute constant $C > 0$.*

The reader has possibly noticed one significant difference between the algorithm of section 2 for testing regular languages and our algorithm for testing D_1. While the algorithm for testing regular languages has a one-sided error, the algorithm of this section has a two-sided error. This is not a coincidence. We can show that there is *no* one-sided error algorithm for testing membership in D_1, whose number of queries is bounded by a function of ϵ only. Indeed, assume that A is a one-sided error algorithm for testing D_1. Consider its execution on the input word $u = 0^{n/2+\epsilon n}1^{n/2-\epsilon n}$. It is easy to see that $dist(u, D_1) \geq \epsilon n$. Therefore, A must reject u with probability at least $2/3$. Fix any sequence of coin tosses which makes A reject u, and denote by Q the corresponding set of queried bits of u. We claim that if $|Q \cap [1, n/2 + \epsilon n]| \leq n/2 - \epsilon n$, then there exists a word w of length n from D_1 for which $w[i] = u[i]$ for all $i \in Q$. To prove this claim, we may clearly assume that $|Q \cap [1, n/2 + \epsilon n]| = n/2 - \epsilon n$. Define w as follows. For all $i > n/2 + \epsilon n$ we set $w[i] = 1$. Now, we take the first ϵn indices i in

$[1, n/2+\epsilon n] \setminus Q$ and set $w[i] = 0$. For the last ϵn indices i in $[1, n/2+\epsilon n] \setminus Q$ we set $w[i] = 1$. Also, $w[i] = u[i]$ for all $i \in Q$. Now, w satisfies the sufficient condition for the membership in D_1, given by Claim 4.4. Indeed, at any point j in $[1, n/2+\epsilon n]$, the number of 0's in the first j bits of w is at least as large as the number of 1's. Also, for $j \geq n/2+\epsilon n$ we have $x(w, j) = n/2$ and $y(w, j) = \epsilon n + (j - n/2 - \epsilon n) = j - n/2$. Therefore, $w \in D_1$. As A is assumed to be a one-sided error algorithm, it should always accept every $w \in D_1$. But then we must have $|Q \cap [1, n/2+\epsilon n]| > n/2 - \epsilon n$, implying that A queries a number of bits linear in n. We have proven the following statement.

PROPOSITION 4.9. *Any one-sided error ϵ-test for membership in D_1 queries $\Omega(n)$ bits on words of length n.*

Our next goal is to prove that all other Dyck languages, namely, D_k for all $k \geq 2$, are nontestable. We will present a detailed proof of this statement only for $k = 2$, but this clearly implies the result for all $k \geq 3$.

For the sake of clarity of exposition we replace the symbols a_1, b_1, a_2, b_2 in the definition of D_2 by $0, 1, 2, 3$, respectively. Then D_2 is defined by the following context-free grammar: $S \to 0S1 \mid 2S3 \mid SS \mid \gamma$, where γ is the empty word. Having in mind the above-mentioned bracket interpretation of the Dyck languages, we will sometimes refer to $0, 2$ as left brackets and to $1, 3$ as right brackets. Note that we do not use an encoding of D_2 as a language over $\{0, 1\}$ but rather as a language over an alphabet of size 4. Clearly, nontestability of D_2 as defined above will imply nontestability of any binary encoding of D_2 that is obtained by a fixed binary encoding of $\{0, 1, 2, 3\}$.

THEOREM 4.10. *The language D_2 is not ϵ-testable.*

Proof. Let n be a large enough integer, divisible by 8. We denote $L_n = D_2 \cap \{0, 1, 2, 3\}^n$. Using Yao's principle, we assign a probability distribution on inputs of length n and show that any deterministic algorithm probing $d = O(1)$ bits outputs an incorrect answer with probability $0.5 \pm o(1)$. Both positive and negative words will be composed of three parts. The first is a sequence of matching 0/1 (brackets of the first kind) followed by a sequence of 0/2 (left brackets) and a sequence of 1/3 (right brackets).

Positive instances are generated according to the distribution P as follows: choose k uniformly at random in the range $n/8, \ldots, n/4$. Given k, the word of length n is $w = 0^k 1^k v$, where v is of length $n-2k$ generated by the following. For $i = 1, \ldots, (n-2k)/2$ choose $v[i]$ at random from $0, 2$, and then set $v[n-2k+1-i] = v[i]+1$.

Negative instances are chosen as follows: the process is very similar to the positive case except that we do not have the restriction on $v[n-2k+1-i] = v[i]+1$. Namely, we choose k at random in the range $n/8, \ldots, n/4$. Given k, a word of length n is $w = 0^k 1^k v$, where v is of length $n-2k$ generated by the following. For $i = 1, \ldots, (n-2k)/2$ choose $v[i]$ at random from $0, 2$, and for $i = 1, \ldots, (n-2k)/2$ choose $v[n-2k+1-i]$ at random from $1, 3$. Let us denote by N the distribution at this stage. Note that the words that are generated may be of distance less than ϵn from L_n. (In fact, some words in L_n are generated too.) Hence we further condition N on the event that the word is of distance at least ϵn from L_n.

The probability distribution over all inputs of length n is now defined by choosing with probability 1/2 a positive instance, generated as above, and with probability 1/2 a negative instance, chosen according to the above-described process. □

CLAIM 4.11. *The probability that an instance generated according to N is ϵn-close to some word in L_n is exponentially small in n.*

Proof. Fix k, and let $w = 0^k 1^k v$ be a word of length n generated by N. For such

fixed k the three parts of w are the first part of matching 0/1 of length $2k$, the second part of which is a random sequence of 0/2 of length $\frac{n-2k}{2}$ and the third part of which is a random sequence of 1/3 of length $\frac{n-2k}{2}$. Let us denote by N_1, N_2, N_3 these three disjoint sets of indices of w.

We will bound from above the number of words w of length n of the form $w = 0^k 1^k (0/2)^{\frac{n-2k}{2}} (1/3)^{\frac{n-2k}{2}}$ which are at distance at most ϵn from L_n. First, we choose the value of w on N_2, which gives $2^{\frac{n-2k}{2}}$ possibilities. Then we choose (at most) ϵn bits of w to be changed to get a word from L_n ($\binom{n}{\epsilon n}$ choices) and set those bits ($4^{\epsilon n}$ possibilities). At this point, the only part of w still to be set is its value of N_3, where we are allowed to use only right brackets $1, 3$. The word to be obtained should belong to L_n. It is easy to see that there is at most one way to complete the current word to a word in L_n using right brackets only. Hence the number of such words altogether is at most $2^{\frac{n-2k}{2}} \binom{n}{\epsilon n} 4^{\epsilon n}$. The total number of words w of the form $0^k 1^k (0/2)^{\frac{n-2k}{2}} (1/3)^{\frac{n-2k}{2}}$ is 2^{n-2k}, and each such word gets the same probability in the distribution N. Therefore, the probability that a word chosen according to N is ϵn-close to L_n can be estimated from above by

$$\sum_{k=n/8}^{n/4} \frac{8}{n} \cdot \frac{2^{\frac{n-2k}{2}} \binom{n}{\epsilon n} 4^{\epsilon n}}{2^{n-2k}} \leq \max_k (2^{O(\epsilon \log(\frac{1}{\epsilon}))n + 2\epsilon n - \frac{n}{2} + k}) \leq 2^{-n/5}$$

for small enough $\epsilon > 0$ as promised. □

CLAIM 4.12. *Let $S \subseteq [n], |S| = d$, be a fixed set of places, and let k be chosen uniformly at random in the range $n/8, \ldots, n/4$. Then S contains a pair $i < j$ symmetric with respect to $(n-2k)/2$ with probability at most $\binom{d}{2}\frac{8}{n}$.*

Proof. For each distinct pair $i, j \in S$ there is a unique k for which i, j are symmetric with respect to the above point. Hence the above probability is bounded by $\binom{d}{2}\frac{8}{n}$. □

Proof. We now return to the proof of Theorem 4.10. Let A be an algorithm for testing L_n that queries at most $d = O(1)$ queries. As $d = O(1)$, we may assume that A is nonadaptive; namely, it queries some fixed set of places S of size d (as every adaptive A can be made nonadaptive by querying ahead at most 2^d possible queries defined by two possible branchings after each adaptive query. We then look at these $2^d = O(1)$ queries as our S). For any possible set of answers $f : S \longrightarrow \{0, 1, 2, 3\}$ and an input w let f_w denote the event that w is consistent with f on S. Let $NoSym$ be the event in which S contains no symmetric pair with respect to $(n-2k)/2$. Also, let F_0 denote all these f's on which the algorithm answers "NO," and let F_1 be all these f's on which it answers "YES." Finally, denote by (w *positive*) and (w *negative*) the events that a random w is a positive instance and a negative instance, respectively.

The total error of the algorithm is

$$\begin{aligned}
&\sum_{f \in F_0} \Pr[f_w \wedge (w \text{ positive})] + \sum_{f \in F_1} \Pr[f_w \wedge (w \text{ negative})] \\
&\geq \Pr[NoSym] \Bigg(\sum_{f \in F_0} \Pr[f_w \wedge (w \text{ positive}) | NoSym] \\
&\qquad + \sum_{f \in F_1} \Pr[f_w \wedge (w \text{ negative}) | NoSym] \Bigg).
\end{aligned}$$

However, given that S contains no symmetric pairs, for a fixed f, $\Pr[f_w \wedge (w \textit{ is negative})]$ is essentially equal to $\Pr[f_w \wedge (w \textit{ is positive})]$. (These probabilities would be exactly equal if negative w would be generated according to N. Claim 4.11 asserts that N is exponentially close to the real distribution on negative instances.) Hence each is of these probabilities is $0.5 \Pr[f_w|NoSym] \pm o(1)$.

Plugging this into the sum above and using Claim 4.12, we get that the error probability is bounded from below by $\Pr(NoSym) \sum_f (0.5 \pm o(1)) \Pr[f_w|NoSym] \geq (1 - \binom{d}{2}\frac{8}{n})(0.5 \pm o(1)) \geq 0.5 - o(1)$. □

5. Concluding remarks. The main technical achievement of this paper is a proof of testability of regular languages. A possible continuation of the research is to describe other classes of testable languages and to formulate sufficient conditions for a context-free language to be testable. (Recall that in Theorem 4.1 we have shown that not all context-free languages are testable.)

One of the most natural ways to describe large classes of testable combinatorial properties is by putting some restrictions on the logical formulas that define them. In particular, we can restrict the arity of the participating relations, the number of quantifier alternations, the order of the logical expression (first order, second order), etc.

The result of the present paper is an example to this approach, since regular languages are exactly those that can be expressed in second order monadic logic with a unary predicate and an embedded linear order. Another example can be found in a sequel of this paper [1], which addresses testability of graph properties defined by sentences in first order logic with binary predicates and which complements the class of graph properties shown to be testable by Goldreich, Goldwasser, and Ron [7]. Analogous results for predicates of higher arities would be desirable to obtain, but technical difficulties arise when the arity is greater than two.

As a long-term goal we propose a systematic study of the testability of logically defined classes. Since many different types of logical frameworks are known, to find out which one is suited for this study is a challenge. Virtually all single problems that have been looked at so far have the perspective of being captured by a more general logically defined class with members that have the same testability properties.

A very different avenue is to try to develop general *combinatorial* techniques for proving lower bounds for the query complexity of testing arbitrary properties, possibly by finding analogues to the block sensitivity [12] and the Fourier analysis [11] approaches for decision tree complexity. At present we have no candidates for combinatorial conditions that would be both necessary and sufficient for ϵ-testability.

Acknowledgments. We would like to thank Oded Goldreich for helpful comments. We are also grateful to the anonymous referees for their careful reading.

THE APPROXIMABILITY OF CONSTRAINT SATISFACTION PROBLEMS*

SANJEEV KHANNA†, MADHU SUDAN‡, LUCA TREVISAN§, AND DAVID P. WILLIAMSON¶

Abstract. We study optimization problems that may be expressed as "Boolean constraint satisfaction problems." An instance of a Boolean constraint satisfaction problem is given by m constraints applied to n Boolean variables. Different computational problems arise from constraint satisfaction problems depending on the nature of the "underlying" constraints as well as on the goal of the optimization task. Here we consider four possible goals: MAX CSP (MIN CSP) is the class of problems where the goal is to find an assignment maximizing the number of satisfied constraints (minimizing the number of unsatisfied constraints). MAX ONES (MIN ONES) is the class of optimization problems where the goal is to find an assignment satisfying all constraints with maximum (minimum) number of variables set to 1. Each class consists of infinitely many problems and a problem within a class is specified by a finite collection of finite Boolean functions that describe the possible constraints that may be used.

Tight bounds on the approximability of every problem in MAX CSP were obtained by Creignou [*J. Comput. System Sci.,* 51 (1995), pp. 511–522]. In this work we determine tight bounds on the "approximability" (i.e., the ratio to within which each problem may be approximated in polynomial time) of every problem in MAX ONES, MIN CSP, and MIN ONES. Combined with the result of Creignou, this completely classifies all optimization problems derived from Boolean constraint satisfaction. Our results capture a diverse collection of optimization problems such as MAX 3-SAT, MAX CUT, MAX CLIQUE, MIN CUT, NEAREST CODEWORD, etc. Our results unify recent results on the (in-)approximability of these optimization problems and yield a compact presentation of most known results. Moreover, these results provide a formal basis to many statements on the behavior of natural optimization problems that have so far been observed only empirically.

Key words. approximation algorithms, approximation classes, approximation-preserving reductions, complete problems, Boolean constraint satisfaction problems, hardness of approximation

1. Introduction.

The approximability of an optimization problem is the best possible performance ratio that is achieved by a polynomial time approximation algorithm for the problem. The approximability is studied as a function of the input size and is always a function bounded from below by 1. Research in the 1990s has led to dramatic progress in our understanding of the approximability of many central optimization problems. The results cover a large number of optimization problems,

deriving tight bounds on the approximability of some, while deriving "asymptotically" tight bounds on many more.[1]

In this paper we study optimization problems derived from "Boolean constraint satisfaction problems" and present a complete classification of these problems based on their approximability. Our work is motivated by an attempt to unify this recent progress on the (in-)approximability of combinatorial optimization problems. In the case of positive results, i.e., bounding the approximability from above, a few paradigms have been used repeatedly and these serve to unify the results nicely. In contrast, there is a lack of similar unification among negative or inapproximability results. Inapproximability results are established by approximation-preserving reductions from hard problems, and such reductions tend to exploit every feature of the problem whose hardness is being shown, rather than isolating the "minimal" features that would suffice to obtain the hardness result. As a result inapproximability results are typically isolated and are not immediately suited for unification.

The need for a unified study is, however, quite essential at this stage. The progress in the understanding of optimization problems has shown large amounts of diversity in their approximability. Despite this diversity, natural optimization problems do seem to exhibit some noticeable trends in their behavior. However, in the absence of a terse description of known results, it is hard to extract the trends, let alone trying to provide them with a formal basis. Some such trends are described below:

- There exist optimization problems that are solvable exactly, that admit polynomial time approximation schemes (PTAS) (i.e., for every constant $\alpha > 1$, there exists a polynomial time α-approximation algorithm), that admit constant factor approximation algorithms, that admit logarithmic factor approximation algorithms, and that admit polynomial factor approximation algorithms. However, this list appears to be nearly exhaustive, raising the question, "Are there 'natural' optimization problems with intermediate approximability?"[2]
- A number of minimization problems have an approximability of logarithmic factors. However, so far no natural maximization problem has been shown to have a similar approximability, raising the question, "Are there any 'natural' maximization problems which are approximable to within polylogarithmic factors, but no better?"
- Papadimitriou and Yannakakis [39] define a class of optimization problems called MAX SNP. This class has played a central role in many of the recent inapproximability results, and yet even now the class does not appear to be fully understood. The class contains a number of NP-hard problems, and for all such known problems it turns out to be the case that the approximability is bounded away from 1! This raises the natural question, "Are there any NP-hard problems in MAX SNP that admit polynomial time approximation schemes?"

In order to study such questions, or even to place them under a formal setting,

[1] We say that the approximability of an optimization is known asymptotically if we can determine a function $f : \mathcal{Z} \to \mathcal{Z}$ and constants c_1, c_2 such that the approximability is between $1 + f(n)$ and $1 + c_1 f(n^{c_2})$. This choice is based on the common choice of an approximation preserving reduction. See Definition 2.7.

[2] There are problems such as the *minimum feedback arc set* for which the best known approximation factor is $O(\log n \log\log n)$ [16] and the *asymmetric p-center problem,* where the best known approximation factor is $O(\log^* n)$ [38]. However, no matching inapproximability results are known for such problems.

one needs to first specify the optimization problems in some uniform framework. Furthermore, one has to be careful to ensure that the task of determining whether the optimization problem studied is easy or hard (to, say, compute exactly) is decidable. Unfortunately, barriers such as Rice's theorem (which says this question may not in general be decidable) or Ladner's theorem (which says problems may not be just easy or hard [35]) force us to severely restrict the class of problems which can be studied in such a manner.

Schaefer [42] isolates one class of decision problems which can actually be classified completely. He obtains this classification by restricting his attention to "Boolean constraint satisfaction problems." A problem in this class is specified by a finite set $\mathcal{F}$ of Boolean functions on finitely many variables, referred to as the constraints. (These functions are specified by, say, a truth table.) A function $f : \{0,1\}^k \to \{0,1\}$, when applied to k variables $x_1, \ldots, x_k$, represents the constraint $f(x_1, \ldots, x_k) = 1$. An instance of a constraint satisfaction problem specified by $\mathcal{F}$ consists of m "constraint applications" on n Boolean variables, where each constraint application is the application of one of the constraints from $\mathcal{F}$ to some ordered subset of the n variables. The language $\textsc{Sat}(\mathcal{F})$ consists of all instances which have an assignment satisfying all m constraints. Schaefer describes six classes of function families such that if $\mathcal{F}$ is a subset of one of these classes, then the decision problem is in P; otherwise he shows that the decision problem is NP-hard.

Our setup. In this paper we consider four different optimization versions of Boolean constraint satisfaction problems. In each case the problem is specified by a family $\mathcal{F}$ and the instance by m constraints from $\mathcal{F}$ applied to n Boolean variables. The goals for the four versions vary as follows: In the problem $\textsc{Max CSP}(\mathcal{F})$ the goal is to find an assignment that maximizes the number of satisfied constraints. Analogously in the problem $\textsc{Min CSP}(\mathcal{F})$ the goal is to find an assignment that minimizes the number of unsatisfied constraints. Notice that while the problems are equivalent w.r.t. exact computation, their approximability may be (and often is) very different. In the problem $\textsc{Max Ones}(\mathcal{F})$ ($\textsc{Min Ones}(\mathcal{F})$) the goal is to find an assignment satisfying all constraints while maximizing (minimizing) the number of variables set to 1. We also consider the weighted version of all the above problems. In the case of $\textsc{Weighted Max CSP}(\mathcal{F})$ ($\textsc{Weighted Min CSP}(\mathcal{F})$) the instance includes a nonnegative weight for every constraint and the goal is to maximize (minimize) the sum of the weights of the satisfied (unsatisfied) constraints. In the case of $\textsc{Weighted Max Ones}(\mathcal{F})$ ($\textsc{Weighted Min Ones}(\mathcal{F})$) the instance includes a nonnegative weight for every variable and the goal is to find an assignment satisfying all constraint maximizing (minimizing) the weight of the variables set to 1. The collection of problems $\{\textsc{Max CSP}(\mathcal{F}) \mid \mathcal{F} \text{ finite}\}$ yields the class Max CSP, and similarly we get the classes (Weighted) Min CSP, Max Ones, Min Ones.

Together these classes capture a host of interesting optimization problems. Max CSP is a subset of MAX SNP and forms a combinatorial core of the problems in MAX SNP. It also includes a number of well-studied MAX SNP-complete problems, including MAX 3-SAT, MAX 2-SAT, and Max Cut. Max Ones shows more varied behavior among maximization problems and includes Max Clique and a problem equivalent to Max Cut. Min CSP and Min Ones are closely related to each other capturing very similar problems. The list of problems expressible as one of these includes the *s-t* Min Cut problem, Vertex Cover, Hitting Set with bounded size sets, integer programs with two variables per inequality [25], Min UnCut [20], Min 2CNF Deletion [33], and Nearest Codeword [2]. The ability to study

all these different problems in a uniform framework and extract the features that make the problems easier/harder than the others shows the advantage of studying optimization problems under the constraint satisfaction framework.

We provide a complete characterization of the asymptotic approximability of every optimization problem in the classes mentioned above. For the class MAX CSP such a classification was obtained by Creignou [11], who shows that every problem in the class is either solvable to optimality in polynomial time or has a constant approximability bounded away from 1. For the remaining classes we provide complete characterizations. The detailed statement of our results, comprising 22 cases, appear in Theorems 2.11–2.14. (This includes a technical strengthening of the results of Creignou [11].) In short the results show that every MAX ONES problem either is solvable optimally in P, or has constant factor approximability or polynomial approximability, or it is hard to find feasible solutions. For the minimization problems, the results show that the approximability of every problem lies in one of at most seven levels. However, it does not pin down the approximability of every problem but rather highlights a number of open problems in the area of minimization that deserve further attention. In particular, it exposes a class of problems for which MIN UNCUT is complete, a class for which MIN 2CNF DELETION is complete, and a class for which NEAREST CODEWORD is complete. The approximability of these problems is not yet resolved.

Our results do indeed validate some of the observations about trends exhibited by optimization problems. We find that when restricted to constraint satisfaction problems, the following can be formally established. The approximability of optimization problems does come from a small number of levels; maximization problems do not have a log-approximable representative while minimization problems may have such representatives (e.g., MIN UNCUT). NP-hard MAX CSP problems are also MAX SNP-hard. We also find that weights do not play any significant role in the approximability of combinatorial optimization problems, a thesis in the work of Crescenzi, Silvestri, and Trevisan [15].[3]

Finally, we conclude with some thoughts on directions for further work. We stress that while constraint satisfaction problems provide a good collection of core problems to work with, they are by no means an exhaustive or even near-exhaustive collection of optimization problems. Our framework lacks such phenomena as PTAS; it does not capture several important optimization problems such as the traveling salesman problem and numerous scheduling, sequencing, and graph partitioning problems. One possible reason for the nonexistence of PTAS is that in our problems the input instances have no restrictions in the manner in which constraints may be imposed on the input variables. Significant insight may be gleaned by restricting the problem instances. A widely prescribed condition is that the incidence graph on the variables and the constraints should form a planar graph. This restriction has been studied by Khanna and Motwani [28] and they show that it leads to PTAS for a general class of constraint satisfaction problems. Another input restriction of interest could be that variables are allowed to participate only in a bounded number of constraints. We are unaware of any work on this front. An important extension of our work would be to consider constraint families which contain constraints of unbounded arity (such as

[3]Our definition of an unweighted problem is more loose than that of Crescenzi, Silvestri, and Trevisan. In their definition they disallow instances with repeated constraints, while we do allow them. We believe that it may be possible to remove this discrepancy from our work by a careful analysis of all proofs. We do not carry out this exercise here.

those included in the class MIN $F^+\Pi_1$ studied by Kolaitis and Thakur [34]). Such an extension would allow us to capture problems such as SET COVER. Other directions include working with larger domain sizes (rather than Boolean domains for the variables) and working over spaces where the solution space is the set of all permutations of $[n]$ rather than $\{0,1\}^n$.

Related work. The works of Schaefer [42] and Creignou [11] have already been mentioned above. We reproduce some of the results of Creignou in Theorem 2.11 with some technical strengthenings. This strengthening is described in section 2.5. Another point of difference with the result of Creignou is that our techniques allow us to directly work with the approximability of optimization problems, while in her case the results formally establish NP-hardness and the hardness of approximation can in turn be derived from them. A description of these techniques appear in section 2.6. Among other works focusing on classes showing dichotomy is that of Feder and Vardi [17], who consider the "largest" possible class of natural problems in NP that may exhibit a dichotomy. They motivate constraint satisfaction problems over larger domains and highlight a number of central open questions that lie on the path to the resolution of the complexity of deciding them. Creignou and Hermann [12] show a dichotomy result analogous to Schaefer's for counting versions of constraint satisfaction problems. In the area of approximability, the works of Lund and Yannakakis [37] and Zuckerman [45] provide two instances where large classes of problems are shown to be hard to approximate simultaneously—to the best of our knowledge these are the only cases where the results provide hardness for many problems simultaneously. Finally we mention a few results that are directly related to the optimization problems considered here. Trevisan et al. [43] provide an algorithm for finding optimal implementations (or "gadgets" in their terminology) reducing between MAX CSP problems. Karloff and Zwick [27] describe generic methods for finding "semidefinite relaxations" of MAX CSP problems and use these to provide approximation algorithms for these problems. These results further highlight the appeal of the "constraint satisfaction" framework for studying optimization problems.

2. Definitions and results.

2.1. Constraints, constraint applications, and constraint families. We start by formally defining constraints and constraint satisfaction problems. Schaefer's work [42] proposes the study of such problems as a generalization of 3-satisfiability (3-SAT). We will use the same example to illustrate the definitions below.

A constraint is a function $f : \{0,1\}^k \to \{0,1\}$. A constraint f is satisfied by an input $s \in \{0,1\}^k$ if $f(s) = 1$. A constraint family $\mathcal{F}$ is a finite collection of constraints $\{f_1, \ldots, f_l\}$. For example, constraints of interest for 3-SAT are described by the constraint family $\mathcal{F}_{3\text{SAT}} = \{\text{OR}_{k,j} : 1 \le k \le 3, 0 \le j \le k\}$, where $\text{OR}_{k,j} : \{0,1\}^k \to \{0,1\}$ denotes the constraint $\neg x_1 \bigvee \cdots \bigvee \neg x_j \bigvee x_{j+1} \bigvee \cdots \bigvee x_k$. A constraint application, of a constraint f to n Boolean variables, is a pair $\langle f, (i_1, \ldots, i_k)\rangle$, where the indices $i_j \in [n]$ select k of the n Boolean variables to whom the constraint is applied. (Here and throughout the paper we use the notation $[n]$ to denote the set $\{1, \ldots, n\}$.) For example, to generate the clause $(x_5 \bigvee \neg x_3 \bigvee x_2)$, we could use the constraint application $\langle \text{OR}_{3,1}, (3,5,2)\rangle$ or $\langle \text{OR}_{3,1}, (3,2,5)\rangle$. Note that the applications allow the constraint to be applied to different ordered sets of variables but *not literals*. This distinction is an important one and is the reason that we need all the constraints $\text{OR}_{3,0}, \text{OR}_{3,1}$, etc. to describe 3-SAT. In a constraint application $\langle f, (i_1, \ldots, i_k)\rangle$, we require that $i_j \neq i_{j'}$ for $j \neq j'$, i.e., the variables are not allowed to be replicated

within a constraint application. This is why we need both the functions $\mathrm{OR}_{2,0}$ as well as $\mathrm{OR}_{3,0}$ in 3-SAT.

Constraints and constraint families are the ingredients that specify an optimization *problem*. Thus it is necessary that their description be finite. (Notice that the description of $\mathcal{F}_{3\mathrm{SAT}}$ is finite.) Constraint applications are used to specify *instances* of optimization problems (as well as instances of Schaefer's generalized satisfiability problems) and the fact that their description lengths grow with the instance size is crucially exploited here. (Notice that the description size of a constraint application used to describe a 3-SAT clause will be $\Omega(\log n)$.) While this distinction between constraints and constraint applications is important, we will often blur this distinction in the rest of this paper. In particular we may often let the constraint application $C = \langle f, (i_1, \ldots, i_k)\rangle$ refer only to the constraint f. In particular, we will often use the expression "$C \in \mathcal{F}$" when we mean "$f \in \mathcal{F}$, where f is the first component of C." We now describe Schaefer's class of satisfiability problems and the optimization problems considered in this paper.

Definition 2.1 (Sat($\mathcal{F}$)).

Instance. *A collection of m constraint applications of the form $\{\langle f_j, (i_1(j), \ldots, i_{k_j}(j))\rangle\}_{j=1}^{m}$ on Boolean variables $x_1, x_2, \ldots, x_n$, where $f_j \in \mathcal{F}$ and k_j is the arity of f_j.*

Objective. *Decide if there exists a Boolean assignment to the x_i's which satisfies all the constraints.*

For example, the problem Sat($\mathcal{F}_{3\mathrm{SAT}}$) is the classical 3-SAT problem.

Definition 2.2 (Max CSP($\mathcal{F}$) (Min CSP($\mathcal{F}$))).

Instance. *A collection of m constraint applications of the form $\{\langle f_j, (i_1(j), \ldots, i_{k_j}(j))\rangle\}_{j=1}^{m}$ on Boolean variables $x_1, x_2, \ldots, x_n$, where $f_j \in \mathcal{F}$ and k_j is the arity of f_j.*

Objective. *Find a Boolean assignment to x_i's so as to maximize (minimize) the number of satisfied (unsatisfied) constraints.*

In the weighted problem Weighted Max CSP($\mathcal{F}$) *(*Weighted Min CSP($\mathcal{F}$)*) the input instance includes m nonnegative weights $w_1, \ldots, w_m$, and the objective is to find an assignment which maximizes (minimizes) the sum of the weights of the satisfied (unsatisfied) constraints.*

Definition 2.3 (Max Ones($\mathcal{F}$) (Min Ones($\mathcal{F}$))).

Instance. *A collection of m constraint applications of the form $\{\langle f_j, (i_1(j), \ldots, i_{k_j}(j))\rangle\}_{j=1}^{m}$ on Boolean variables $x_1, x_2, \ldots, x_n$, where $f_j \in \mathcal{F}$ and k_j is the arity of f_j.*

Objective. *Find a Boolean assignment to x_i's which satisfies all the constraints and maximizes (minimizes) the total number of variables assigned true.*

In the weighted problem Weighted Max Ones($\mathcal{F}$) *(*Weighted Min Ones($\mathcal{F}$)*) the input instance includes n nonnegative weights $w_1, \ldots, w_n$, and the objective is to find an assignment which satisfies all constraints and maximizes (minimizes) the sum of the weights of variables assigned true.*

The class (Weighted) Max CSP is the set of all optimization problems (Weighted) Max CSP($\mathcal{F}$) for every constraint family $\mathcal{F}$. The classes (Weighted) Max Ones, Min CSP, Min Ones are defined similarly.

The optimization problem Max 3 Sat is easily seen to be equivalent to Max CSP($\mathcal{F}_{3\mathrm{SAT}}$). This and the other problems Max Ones($\mathcal{F}_{3\mathrm{SAT}}$), Min CSP($\mathcal{F}_{3\mathrm{SAT}}$), and Min Ones($\mathcal{F}_{3\mathrm{SAT}}$) are considered in the rest of this paper. More interesting examples of Max Ones, Min CSP, and Min Ones problems are described in sec-

tion 2.3. We start with some preliminaries on approximability that we need to state our results.

2.2. Approximability, reductions, and completeness. A *combinatorial optimization* problem is defined over a set of *instances* (admissible input data); a finite set $\mathsf{sol}(x)$ of *feasible solutions* is associated with any instance. An *objective function* attributes an integer value to any solution. The *goal* of an optimization problem is, given an instance x, to find a solution $y \in \mathsf{sol}(x)$ of *optimum* value. The optimum value is the largest one for *maximization* problems and the smallest one for *minimization* problems. A combinatorial optimization problem is said to be an NP optimization (NPO) problem if instances and solutions can be recognized in polynomial time, solutions are polynomial-bounded in input size, and the objective function can be computed in polynomial time (see, e.g., [10]).

DEFINITION 2.4 (performance ratio). *A solution s to an instance $\mathcal{I}$ of an* NPO *problem A is r-approximate if it has a value V satisfying*

$$\max\left\{\frac{V}{\mathrm{OPT}(\mathcal{I})}, \frac{\mathrm{OPT}(\mathcal{I})}{V}\right\} \leq r.$$

An approximation algorithm for an NPO *problem A has* performance ratio $\mathcal{R}(n)$ *if, given any instance $\mathcal{I}$ of A with $|\mathcal{I}| = n$, it outputs an $\mathcal{R}(n)$-approximate solution.*

We say that an NPO problem is approximable to within a factor $\mathcal{R}(n)$ if it has a polynomial time approximation algorithm with performance ratio $\mathcal{R}(n)$.

DEFINITION 2.5 (approximation classes). *An* NPO *problem A is in the class* PO *if it is solvable to optimality in polynomial time. A is in the class* APX *(resp.,* log-APX*/*poly-APX*) if there exists a polynomial time algorithm for A whose performance ratio is bounded by a constant (resp., logarithmic/polynomial factor in the size of the input).*

Completeness in approximation classes can be defined using the appropriate approximation-preserving reducibilities. In this paper, we use two notions of reducibility: A-reducibility and AP-reducibility. We discuss the difference between the two and the need for having two different notions after the definitions.

DEFINITION 2.6 (A-reducibility [14]). *An* NPO *problem A is said to be A-reducible to an* NPO *problem B, denoted $A \leq_{\mathrm{A}} B$, if two polynomial time computable functions F and G and a constant α exist such that*

1. *for any instance $\mathcal{I}$ of A, $F(\mathcal{I})$ is an instance of B;*
2. *for any instance $\mathcal{I}$ of A and any feasible solution $\mathcal{S}'$ for $F(\mathcal{I})$, $G(\mathcal{I}, \mathcal{S}')$ is a feasible solution for $\mathcal{I}$;*
3. *for any instance $\mathcal{I}$ of A and any $r \geq 1$, if $\mathcal{S}'$ is an r-approximate solution for $F(\mathcal{I})$, then $G(\mathcal{I}, \mathcal{S}')$ is an (αr)-approximate solution for $\mathcal{I}$.*

DEFINITION 2.7 (AP-reducibility [13]). *For a constant $\alpha > 0$ and two* NPO *problems A and B, we say that A is α-AP-reducible to B, denoted $A \leq_{\mathrm{AP}} B$, if two polynomial time computable functions F and G exist such that the following holds:*

1. *For any instance $\mathcal{I}$ of A, $F(\mathcal{I})$ is an instance of B.*
2. *For any instance $\mathcal{I}$ of A, and any feasible solution $\mathcal{S}'$ for $F(\mathcal{I})$, $G(\mathcal{I}, \mathcal{S}')$ is a feasible solution for $\mathcal{I}$.*
3. *For any instance $\mathcal{I}$ of A and any $r \geq 1$, if $\mathcal{S}'$ is an r-approximate solution for $F(\mathcal{I})$, then $G(\mathcal{I}, \mathcal{S}')$ is an $(1 + (r-1)\alpha + o(1))$-approximate solution for $\mathcal{I}$, where the $o()$-notation is with respect to $|\mathcal{I}|$.*

We say that A is AP-reducible to B if a constant $\alpha > 0$ exists such that A is α-AP-reducible to B.

Remark.

(1) Notice that conditions (3) of both reductions preserve only the quality of an approximate solution in absolute terms (to within the specified limits) and not as functions of the instance size. For example, an A-reduction from Π to Π' which blows up instance size by quadratic factor and an $O(n^{1/3})$ approximation algorithm for Π' combine to give only an $O(n^{2/3})$ approximation algorithm for Π.

(2) The difference between the two reductions is the level of approximability that is preserved by them (conditions (3) in the definitions). A-reductions preserve constant factor approximability or higher, i.e., if Π is A-reducible to Π' and Π' is approximable to within a factor of $r(n)$, then Π is approximable to within $\alpha r(n^c)$ for some constants α, c. This property suffices to preserve membership in APX (log-APX, poly-APX), i.e., if Π is in APX (log-APX, poly-APX), then Π' is also in APX (resp., log-APX, poly-APX). However, it does not preserve membership in PO or PTAS, as can be observed by setting $r = 1$.

(3) AP-reductions are more sensitive than A-reductions. Thus if Π is AP-reducible to Π, then an r-approximate solution is mapped to an $h(r)$-approximate solution where $h(r) \to 1$ as $r \to 1$. Thus AP-reductions preserve membership in PTAS as well. However, they need not preserve membership in PO (due to the $o(1)$-term in their preservation of approximability).

(4) Condition (3) of the definition of AP-reductions is strictly stronger than the corresponding condition in the definition of A-reductions. Thus, every AP-reduction is also an A-reduction. Unfortunately, neither one of these reductions on their own suffice for our purposes. We need AP-reductions to show APX-hardness of problems, but we need the added flexibility of A-reductions for other hardness results.

(5) The original definitions of AP-reducibility and A-reducibility of [14] and [13] were more general. Under the original definitions, the A-reducibility does not preserve membership in log-APX, and it is not clear whether every AP-reduction is also an A-reduction. The restricted versions defined here are more suitable for our purposes. In particular, it is true that the VERTEX COVER problem is APX-complete under our definition of AP-reducibility.

DEFINITION 2.8 (APX, log-APX, and poly-APX-completeness). *An* NPO *problem* Π *is* APX*-hard if every* APX *problem is AP-reducible to* Π. *An* NPO *problem* Π *is* log-APX*-hard (*poly-APX*-hard) if every* log-APX *(*poly-APX*) problem is A-reducible to* Π. *A problem* Π *is* APX*(*log-APX*,* poly-APX*)-complete if it is in* APX *(resp.,* log-APX*,* poly-APX*) and it is* APX *(resp.,* log-APX*,* poly-APX*)-hard.*

The class APX contains the class MAX SNP as defined by Papadimitriou and Yannakakis [39]. The containment is strict in a syntactic sense (e.g., MAX SNP does not contain any minimization problems); however, when one takes the closure of APX under AP-reductions, one obtains the class MAX SNP [29]. The notion of reductions used here is also less stringent than the notion of reduction used in [39]. Thus APX, APX-hardness, and APX-completeness are (mild) generalizations of the notions of MAX SNP, MAX SNP-hardness, and MAX SNP-completeness.

Most problems we consider are known/shown to be in PO or else are APX-complete or poly-APX-complete. However, in some cases, we will not be able to establish the exact approximability of a given problem. However, we will nevertheless be able to compile all problems into a finite number of equivalence classes with some equivalence classes being defined as "problems equivalent to Π" for some problem Π

of unknown approximability. The following definition captures this concept.

DEFINITION 2.9 (Π-completeness). *For* NPO *problems* Π *and* Π′, Π′ *is said to be* Π*-complete if* $\Pi \leq_{\mathrm{A}} \Pi'$ *and* $\Pi' \leq_{\mathrm{A}} \Pi$.

2.3. Problems captured by MAX CSP, MAX ONES, MIN CSP, and MIN ONES. We first specify our notation for commonly used functions.

- **0** and **1** are the functions which are always satisfied and never satisfied, respectively. Together these are the trivial functions. We will assume that all our function families do not have any trivial functions.
- T and F are unary functions given by $T(x) = x$ and $F(x) = \neg x$.
- For a positive integer i and nonnegative integer $j \leq i$, $\mathrm{OR}_{i,j}$ is the function on i variables given by $\mathrm{OR}_{i,j}(x_1, \ldots, x_i) = \neg x_1 \bigvee \cdots \bigvee \neg x_j \bigvee x_{j+1} \bigvee \cdots \bigvee x_i$. $\mathrm{OR}_i = \mathrm{OR}_{i,0}$; $\mathrm{NAND}_i = \mathrm{OR}_{i,i}$; $\mathrm{OR} = \mathrm{OR}_2$; $\mathrm{NAND} = \mathrm{NAND}_2$.
- Similarly, $\mathrm{AND}_{i,j}$ is given by $\mathrm{AND}_{i,j}(x_1, \ldots, x_i) = \neg x_1 \bigwedge \cdots \bigwedge \neg x_j \bigwedge x_{j+1} \bigwedge \cdots \bigwedge x_i$. $\mathrm{AND}_i = \mathrm{AND}_{i,0}$; $\mathrm{NOR}_i = \mathrm{AND}_{i,i}$; $\mathrm{AND} = \mathrm{AND}_2$; $\mathrm{NOR} = \mathrm{NOR}_2$.
- The function XOR_i is given by $\mathrm{XOR}(x_1, \ldots, x_i) = x_1 \oplus \cdots \oplus x_i$. $\mathrm{XOR} = \mathrm{XOR}_2$.
- The function XNOR_i is given by $\mathrm{XNOR}(x_1, \ldots, x_i) = \neg(x_1 \oplus \cdots \oplus x_i)$. $\mathrm{XNOR} = \mathrm{XNOR}_2$.

Now we enumerate some interesting maximization and minimization problems which are "captured" by (i.e., are equivalent to some problem in) MAX CSP, MAX ONES, MIN CSP, and MIN ONES. The following list is interesting for several reasons. First, it highlights the importance of these classes as ones that contain interesting optimization problems and shows the diversity of the problems captured by these classes. Furthermore, each of these problems turn out to be "complete" problems for the partitions they belong to. Some are even necessary for a full statement of our results. Finally, for several of the minimization problems listed below, their approximability is not yet fully resolved. We feel that these problems are somehow representative of the lack of our understanding of the approximability of minimization problems. We start with the maximization problems.

- For any positive integer k, MAX kSAT = MAX CSP($\{\mathrm{OR}_{i,j} | i \in [k], 0 \leq j \leq i\}$). MAX kSAT is a well-studied problem and known to be MAX SNP-complete [39] for $k \geq 2$. Every MAX SNP-complete problem is in APX (i.e., approximable to within a constant factor in polynomial time) [39] (see also [6, 21, 44]). Also for MAX SNP-complete problem there exists a constant α greater than 1 such that the problem is not α-approximable unless NP = P [3, 4, 24] .
- For any positive integer k, MAX EkSAT = MAX CSP($\{\mathrm{OR}_{k,j} | 0 \leq j \leq k\}$). The problem MAX E$k$SAT is a variant of MAX kSAT restricted to have clauses of length exactly k.
- MAX CUT = MAX CSP($\{\mathrm{XOR}\}$). MAX CUT is also MAX SNP-complete [39], and the best known approximation algorithm for this problem, due to [22], achieves a performance ratio of $1.14 \approx 1/.878$
- MAX CLIQUE = MAX ONES(NAND). MAX CLIQUE is known to be approximable to within a factor of $O(n/\log^2 n)$ in an n-vertex graph [9] and is known to be hard to approximate to within a factor of $\Omega(n^{1-\epsilon})$ for any $\epsilon > 0$ unless NP = RP [18, 23].

We now go on to the minimization problems.

- The well-known minimum s-t cut problem in directed graphs is equivalent to WEIGHTED MIN CSP($\mathcal{F}$) for $\mathcal{F} = \{\mathrm{OR}_{2,1}, T, F\}$. This is shown in section 5.1.

This problem is well known to be solvable exactly in polynomial time.

- The HITTING SET problem, restricted to instances in which all sets are of size at most B, can be captured as MIN ONES($\mathcal{F}$) for $\mathcal{F} = \{\mathrm{OR}_k | k \leq B\}$. Also, of interest to our paper is a slight generalization of this problem which we call the implicative HITTING SET-B problem (MIN IHS-B) which is MIN CSP($\{\mathrm{OR}_k : k \leq B\} \cup \{\mathrm{OR}_{2,1}, F\}$). The MIN ONES version of this problem will be of interest to us as well. The HITTING SET-B problem is well known to be approximable to within a factor of B. We show that MIN IHS-B is approximable to within a factor of $B + 1$.
- MIN UNCUT = MIN CSP($\{\mathrm{XOR}\}$). This problem has been studied previously by Klein et al. [32] and Garg, Vazirani, and Yannakakis [20]. The problem is known to be MAX SNP-hard and hence not approximable to within some constant factor greater than 1. On the other hand, the problem is known to be approximable to within a factor of $O(\log n)$ [20].
- MIN 2CNF DELETION = MIN CSP($\{\mathrm{OR}, \mathrm{NAND}\}$). This problem has been studied by Klein et al. [33]. They show that the problem is MAX SNP-hard and that it is approximable to within a factor of $O(\log n \log \log n)$.
- NEAREST CODEWORD = MIN CSP($\{\mathrm{XOR}_3, \mathrm{XNOR}_3\}$). This is a classical problem for which hardness of approximation results have been shown by Arora et al. [2]. The MIN ONES version of this problem is essentially identical to this problem. For both problems, the hardness result of Arora et al. [2] shows that approximating this problem to within a factor of $\Omega(2^{\log^{1-\epsilon} n})$ is hard for every $\epsilon > 0$, unless NP $\subseteq$ QP. No nontrivial approximation guarantees are known for this problem (the trivial bound being a factor of m, which is easily achieved since deciding if all equations are satisfiable amounts to solving a linear system).
- Finally we also mention one more problem which is required to present our main theorem. MIN HORN DELETION = MIN CSP($\{\mathrm{OR}_{3,1}, T, F\}$). The currently known bounds on the approximability of this problem are similar to those of the NEAREST CODEWORD, i.e., it is in poly-APX and hard to approximate to within a factor of $2^{\Omega(\log^{1-\epsilon} n)}$ (see Lemma 7.21).

2.4. Properties of function families. We start with the six properties defined by Schaefer:

- A constraint f is 0-*valid* (resp., 1-*valid*) if $f(0, \ldots, 0) = 1$ (resp., $f(1, \ldots, 1) = 1$).
- A constraint is *weakly positive* (resp., *weakly negative*) if it can be expressed as a CNF-formula having at most one negated variable (resp., at most one unnegated variable[4]) in each clause.
- A constraint is *affine* if it can be expressed as a conjunction of linear equalities over $\mathcal{Z}_2$.
- A constraint is 2*cnf* if it is expressible as a 2CNF-formula.

The above definitions extend to constraint families naturally. For instance, a constraint family $\mathcal{F}$ is 0-*valid* if *every* constraint $f \in \mathcal{F}$ is 0-valid. The above definitions are central to Schaefer's main theorem, restated below.

THEOREM 2.10 (Schaefer's theorem [42]). *For any constraint family $\mathcal{F}$,* SAT($\mathcal{F}$) *is in* P *if $\mathcal{F}$ is* 0*-valid or* 1*-valid or weakly positive or weakly negative or affine or* 2*cnf; otherwise deciding* SAT($\mathcal{F}$) *is* NP*-hard.*

[4]Such clauses are usually called Horn clauses.

We use the shorthand "$\mathcal{F}$ is (not) decidable" to say that deciding membership in $\text{SAT}(\mathcal{F})$ is solvable in P (is NP-hard). Abusing our vocabulary slightly, we say MAX ONES($\mathcal{F}$) (or MIN ONES($\mathcal{F}$)) is not decidable to indicate that determining if a given instance of this problem has a feasible solution is NP-hard.

We need to define some additional properties to describe the approximabilities of the optimization problems we consider:

- f is 2-*monotone* if $f(x_1, \ldots, x_k)$ is expressible as
$$(x_{i_1} \bigwedge \cdots \bigwedge x_{i_p}) \bigvee (\neg x_{j_1} \bigwedge \cdots \bigwedge \neg x_{j_q})$$
for some $p, q \geq 0$, $(p, q) \neq (0, 0)$ (i.e., f is expressible as a DNF-formula with at most two terms—one containing only positive literals and the other containing only negative literals).
- A constraint is *width*-2 *affine* if it is expressible as a conjunction of linear equations over $\mathcal{Z}_2$ such that each equation has at most two variables.
- A constraint is *strongly* 0-*valid* if it is satisfied by all assignments with at most one variable set to 1. (Note that a strongly 0-valid constraint is also 0-valid.)
- A constraint f is *IHS-B+* (for *implicative hitting set-bounded+*) if it is expressible as a CNF formula, where the clauses are of one of the following types: $x_1 \bigvee \cdots \bigvee x_k$ for some positive integer $k \leq B$, or $\neg x_1 \bigvee x_2$, or $\neg x_1$. IHS-$B-$ constraints and constraint families are defined analogously (with every literal being replaced by its complement). A family is an IHS-B family if the family is an IHS-$B+$ family or an IHS-$B-$ family.

We use the following shorthand for the above families: (1) $\mathcal{F}_0$ is the family of 0-valid constraints; (2) $\mathcal{F}_1$ is the family of 1-valid constraints; (3) $\mathcal{F}_{\text{S0}}$ is the family of strongly 0-valid constraints; (4) $\mathcal{F}_{\text{2M}}$ is the family of 2-monotone constraints; (5) $\mathcal{F}_{\text{IHS}}$ is the family of IHS-B constraints; (6) $\mathcal{F}_{\text{2A}}$ is the family of width-2 affine constraints; (7) $\mathcal{F}_{\text{2CNF}}$ is the family of 2CNF constraints; (8) $\mathcal{F}_{\text{A}}$ is the family of affine constraints; (9) $\mathcal{F}_{\text{WP}}$ is the family of weakly positive constraints; (10) $\mathcal{F}_{\text{WN}}$ is the family of weakly negative constraints.

2.5. Main results. We now present the main results of this paper. A pictorial representation is available in Appendices B.1, B.2, B.3, and B.4. All theorems are stated assuming that $\mathcal{F}$ has no trivial constraints, i.e., constraints that are always satisfied or never satisfied. The first theorem is a minor strengthening of Creignou's theorem [11] so as to cover problems such as MAX EkSAT. The remaining theorems cover MAX ONES, MIN CSP, and MIN ONES, respectively.

THEOREM 2.11 (MAX CSP classification). *For any constraint set $\mathcal{F}$, the problem (*WEIGHTED*)* MAX CSP($\mathcal{F}$) *is always either in* PO *or is* APX*-complete. Furthermore, it is in* PO *if and only if $\mathcal{F}$ is* 0*-valid or* 1*-valid or* 2*-monotone.*

THEOREM 2.12 (MAX ONES classification). *For any constraint set $\mathcal{F}$, the problem (*WEIGHTED*)* MAX ONES($\mathcal{F}$) *is either in* PO *or is* APX*-complete or* poly-APX*-complete or decidable but not approximable to within any factor or not decidable. Furthermore,*

1. *if $\mathcal{F}$ is* 1*-valid or weakly positive or affine with width-*2*, then (*WEIGHTED*)* MAX ONES($\mathcal{F}$) *is in* PO*;*
2. *otherwise if $\mathcal{F}$ is affine, then (*WEIGHTED*)* MAX ONES($\mathcal{F}$) *is* APX*-complete;*
3. *otherwise if $\mathcal{F}$ is strongly* 0*-valid or weakly negative or* 2*CNF, then (*WEIGHTED*)* MAX ONES($\mathcal{F}$) *is* poly-APX*-complete;*
4. *otherwise if $\mathcal{F}$ is* 0*-valid, then* SAT($\mathcal{F}$) *is in* P *but finding a solution of positive value is* NP*-hard;*

(5) *otherwise finding a feasible solution to (*Weighted*)* Max Ones($\mathcal{F}$) *is* NP*-hard.*

Theorem 2.13 (Min CSP classification). *For any constraint set $\mathcal{F}$, the problem (*Weighted*)* Min CSP($\mathcal{F}$) *is in* PO *or is* APX*-complete or* Min UnCut*-complete or* Min 2CNF Deletion*-complete or* Nearest Codeword*-complete or* Min Horn Deletion*-complete or even deciding if the optimum is zero is* NP*-hard. Furthermore,*

(1) *if $\mathcal{F}$ is* 0*-valid or* 1*-valid or* 2*-monotone, then (*Weighted*)* Min CSP($\mathcal{F}$) *is in* PO*;*
(2) *otherwise if $\mathcal{F}$ is IHS-B, then (*Weighted*)* Min CSP($\mathcal{F}$) *is* APX*-complete;*
(3) *otherwise if $\mathcal{F}$ is width-*2 *affine, then (*Weighted*)* Min CSP($\mathcal{F}$) *is* Min UnCut*-complete;*
(4) *otherwise if $\mathcal{F}$ is 2CNF, then (*Weighted*)* Min CSP($\mathcal{F}$) *is* Min 2CNF Deletion*-complete;*
(5) *otherwise if $\mathcal{F}$ is affine, then (*Weighted*)* Min CSP($\mathcal{F}$) *is* Nearest Codeword*-complete;*
(6) *otherwise if $\mathcal{F}$ is weakly positive or weakly negative, then (*Weighted*)* Min CSP($\mathcal{F}$) *is* Min Horn Deletion*-complete;*
(7) *otherwise deciding if the optimum value of an instance of (*Weighted*)* Min CSP($\mathcal{F}$) *is zero is* NP*-complete.*

Theorem 2.14 (Min Ones classification). *For any constraint set $\mathcal{F}$, the problem (*Weighted*)* Min Ones($\mathcal{F}$) *is either in* PO *or* APX*-complete or* Nearest Codeword*-complete or* Min Horn Deletion*-complete or* poly-APX*-complete or inapproximable to within any factor or not decidable. Furthermore,*

(1) *if $\mathcal{F}$ is* 0*-valid or weakly negative or width-*2 *affine, then (*Weighted*)* Min Ones($\mathcal{F}$) *is in* PO*;*
(2) *otherwise, if $\mathcal{F}$ is 2CNF or IHS-B, then (*Weighted*)* Min Ones($\mathcal{F}$) *is* APX*-complete;*
(3) *otherwise if $\mathcal{F}$ is affine, then* Min Ones($\mathcal{F}$) *is* Nearest Codeword*-complete;*
(4) *otherwise if $\mathcal{F}$ is weakly positive, then (*Weighted*)* Min Ones($\mathcal{F}$) *is* Min Horn Deletion*-complete;*
(5) *otherwise if $\mathcal{F}$ is* 1*-valid, then* Min Ones($\mathcal{F}$) *is* poly-APX*-complete and* Weighted Min Ones($\mathcal{F}$) *is decidable but hard to approximate to within any factor;*
(6) *otherwise finding any feasible solution to (*Weighted*)* Min Ones($\mathcal{F}$) *is* NP*-hard.*

2.6. Techniques. Two simple ideas play an important role in this paper. First is the notion of an *implementation* which shows how to use the constraints of a family $\mathcal{F}$ to enforce constraints of a different family $\mathcal{F}'$, thereby laying the groundwork of a reduction among problems. The notion of an implementation is inspired by the notion of gadgets formalized by Bellare, Goldreich, and Sudan [8], who in our language define implementations for specific pairs of function families $(\mathcal{F}, \mathcal{F}')$. In this work we unify their definition, so as to make it work for arbitrary pairs of function families. This definition of implementation also finds applications in the work of Trevisan et al. [43], who, in our language, show uniform methods for searching for efficient implementations for pairs of function families $(\mathcal{F}, \mathcal{F}')$.

A second simple idea we exploit here is that of working with weighted versions of optimization problems. Even though our primary concerns were only the approximability of the unweighted versions of problems, many of our results use as intermediate steps the weighted versions of these problems. The weights allow us to manipulate

problems more locally. However, simple and well-known ideas eventually allow us to get rid of the weights, thereby yielding hardness of the unweighted problem as well. As a side-effect we also show that the unweighted and weighted problems are equally hard to approximate in all the relevant optimization problems. This extends to minimization problems the results of Crescenzi, Silvestri, and Trevisan [15].

The definitions of implementations and weighted problems follow in section 3. Section 4 shows some technical results showing how we exploit the fact that we have functions which don't exhibit some property. The results of this section play a crucial role in all the hardness results. This sets us up for the proofs of our main theorems. In section 5 we show the containment results and hardness results for Max CSP. Similarly sections 6, 7, and 8 deal with the classes Max Ones, Min CSP, and Min Ones, respectively.

3. Implementations. We now describe the main technique used in this paper to obtain hardness of approximation results. Suppose we want to show that for some constraint set $\mathcal{F}$, the problem Max CSP($\mathcal{F}$) is APX-hard. We will start with a problem that is known to be APX-hard, such as Max Cut, which turns out to be Max CSP($\{\text{XOR}\}$). We will then wish to reduce this problem to Max CSP($\mathcal{F}$). The main technique we use to do this is to "implement" the constraint XOR using constraints from the constraint set $\mathcal{F}$. We show how to formalize this notion next and then show how this translates to approximation-preserving reductions.

Definition 3.1 (implementation). *A collection of constraint applications $C_1, \ldots, C_m$ over a set of variables $\mathbf{x} = \{x_1, \ldots, x_p\}$ called* primary variables *and $\mathbf{y} = \{y_1, \ldots, y_q\}$ called* auxiliary variables *is an* α-implementation *of a constraint $f(\mathbf{x})$ for a positive integer α if the following conditions are satisfied:*

1. *For any assignment to $\mathbf{x}$ and $\mathbf{y}$, at most α constraints from $C_1, \ldots, C_m$ are satisfied.*
2. *For any $\mathbf{x}$ such that $f(\mathbf{x}) = 1$, there exists $\mathbf{y}$ such that exactly α constraints are satisfied.*
3. *For any $\mathbf{x}, \mathbf{y}$ such that $f(\mathbf{x}) = 0$, at most $(\alpha - 1)$ constraints are satisfied.*

Definition 3.2 (strict/perfect implementations). *An α-implementation is a* strict α-implementation *if for every $\mathbf{x}$ such that $f(\mathbf{x}) = 0$, there exists $\mathbf{y}$ such that exactly $(\alpha - 1)$ constraints are satisfied. An α-implementation (not necessarily strict) is a* perfect *implementation if $\alpha = m$.*

We say that a constraint set $\mathcal{F}$ (strictly/perfectly) implements a constraint f if there exists a (strict/perfect) α-implementation of f using constraints of $\mathcal{F}$ for some $\alpha < \infty$. We use the notation $\mathcal{F} \Longrightarrow_\alpha f$ to denote that $\mathcal{F}$ α-implements f, and $\mathcal{F} \Longrightarrow f$ to denote that $\mathcal{F}$ implements f. Similarly we use the notation $\mathcal{F} \overset{s/p}{\Longrightarrow} f$ to denote that $\mathcal{F}$ implements f strictly/perfectly. The above notation is also extended to allow the target to be a family of functions. For instance, $\mathcal{F} \Longrightarrow \mathcal{F}'$ denotes that $\mathcal{F}$ implements every function in $\mathcal{F}'$.

Remark. The definition of [8] defined (nonstrict and nonperfect) implementations for specific choices of f and $\mathcal{F}$. For each choice they provided a separate definition. We unify their definitions into a single one. Furthermore, as we will show later, the use of strictness and/or perfectness greatly enhance the power of implementations. These aspects are formalized for the first time here.

A constraint f 1-implements itself strictly and perfectly ($\{f\} \overset{s/p}{\Longrightarrow}_1 f$). Some more examples of strict and/or perfect implementations are given below.

Proposition 3.3. $\{\text{XOR}\} \overset{s/p}{\Longrightarrow}_2 \text{XNOR}$.

Proof. The constraints $\mathrm{XOR}(x, z_{\mathrm{AUX}})$ and $\mathrm{XOR}(y, z_{\mathrm{AUX}})$ perfectly and strictly implement the constraint $\mathrm{XNOR}(x, y)$. □

PROPOSITION 3.4. *If* $f(\mathbf{x}) = f_1(\mathbf{x}) \bigwedge \cdots \bigwedge f_k(\mathbf{x})$, *then* $\{f_1, \ldots, f_k\} \stackrel{p}{\Longrightarrow}_k f$.

Proof. The collection $\{f_1(\mathbf{x}), \ldots, f_k(\mathbf{x})\}$ is a perfect (but not necessarily strict) k-implementation of $f(\mathbf{x})$. □

The following lemma shows that the implementations of constraints compose together if they are strict or perfect.

LEMMA 3.5. *If* $\mathcal{F}_a \stackrel{s}{\Longrightarrow} \mathcal{F}_b$ *and* $\mathcal{F}_b \stackrel{s}{\Longrightarrow} \mathcal{F}_c$, *then* $\mathcal{F}_a \stackrel{s}{\Longrightarrow} \mathcal{F}_c$. *An analogous result also holds for perfect implementations.*

Proof. It suffices to consider the case when $\mathcal{F}_c$ consists of a single function f. Furthermore, we observe that it suffices to prove the following simpler assertion (to prove the lemma): If $\mathcal{F} \stackrel{s}{\Longrightarrow} g$ and $\mathcal{F} \cup \{g\} \stackrel{s}{\Longrightarrow} f$, then $\mathcal{F} \stackrel{s}{\Longrightarrow} f$. To see that this suffices, let $\mathcal{F}_b = \{g_1, \ldots, g_l\}$. Define $\mathcal{F}_0 = \mathcal{F}_a$, $\mathcal{F}_i = \mathcal{F}_a \cup \{g_1, \ldots, g_i\}$. Note that by hypothesis we have $\mathcal{F}_l \stackrel{s}{\Longrightarrow} f$ and $\mathcal{F}_i \stackrel{s}{\Longrightarrow} g_{i+1}$ and $\mathcal{F}_l \stackrel{s}{\Longrightarrow} f$. The assertion above says that if $\mathcal{F}_{i+1} \stackrel{s}{\Longrightarrow} f$, then $\mathcal{F}_i \stackrel{s}{\Longrightarrow} f$. Thus by induction $\mathcal{F}_0 \stackrel{s}{\Longrightarrow} f$.

We now prove the assertion: If $\mathcal{F} \stackrel{s}{\Longrightarrow} g$ and $\mathcal{F} \cup \{g\} \stackrel{s}{\Longrightarrow} f$, then $\mathcal{F} \stackrel{s}{\Longrightarrow} f$. Let $C_1, \ldots, C_{m_1}$ be constraint applications from $\mathcal{F} \cup \{g\}$ on variables $\mathbf{x}, \mathbf{y}$ giving an α_1-implementation of $f(\mathbf{x})$ with $\mathbf{x}$ being the primary variables. Let $C'_1, \ldots, C'_{m_2}$ be constraint applications from $\mathcal{F}$ on variable set $\mathbf{x}', \mathbf{z}'$ yielding an α_2-implementation of $g(\mathbf{x}')$. Furthermore, let the first β constraints of $C_1, \ldots, C_{m_1}$ be applications of the constraints g.

We create a collection of $m_1 + \beta(m_2 - 1)$ constraints from $\mathcal{F}$ on a set of variables $\mathbf{x}, \mathbf{y}, \mathbf{z'}_1, \ldots, \mathbf{z'}_\beta$, where $\mathbf{x}$ and $\mathbf{y}$ are the original variables and $\mathbf{z}'_1, \ldots, \mathbf{z}'_\beta$ are new sets of disjoint auxiliary variables, i.e., the vectors $\mathbf{z'}_i$ and $\mathbf{z'}_j$ do not share any variables if $i \neq j$.

The $m_1 + \beta(m_2 - 1)$ constraints introduced are as follows. We include the constraint applications $C_{\beta+1}, \ldots, C_{m_1}$ on variables $\mathbf{x}, \mathbf{y}$ and for every constraint application C_j, for $j \in \{1, \ldots, \beta\}$, on variables $\mathbf{v}_j$ (which is a subset of variables from $\mathbf{x}, \mathbf{y}$), we place the constraints $C'_{1,j}, \ldots, C'_{m_2,j}$ on variable set $\mathbf{v}_j, \mathbf{z'}_j$ with $\mathbf{z'}_j$ being the auxiliary variables.

We now show that this collection of constraints satisfies properties (1)–(3) from Definition 3.1 with $\alpha = \alpha_1 + \beta(\alpha_2 - 1)$. Additionally we show that perfectness and/or strictness is preserved. We start with properties (1) and (3).

Consider any assignment to $\mathbf{x}$ satisfying f. Then any assignment to $\mathbf{y}$ satisfies at most α_1 constraints from the set $C_1, \ldots, C_{m_1}$. Let γ of these be from the set $C_1, \ldots, C_\beta$. Now for every $j \in \{1, \ldots, \beta\}$ any assignment to $\mathbf{z'}_j$ satisfies at most α_2 of the constraints $C'_{1,j}, \ldots, C'_{m_2,j}$. Furthermore, if the constraint C_j was not satisfied by the assignment to $\mathbf{x}, \mathbf{y}$, then at most $\alpha_2 - 1$ constraints are satisfied. Thus the total number of constraints satisfied by any assignment is at most $\gamma\alpha_2 + (\beta - \gamma)(\alpha_2 - 1) + (\alpha_1 - \gamma) = \alpha_1 + \beta(\alpha_2 - 1)$. This yields property (1). Property (3) is achieved similarly.

We now show that if the α_1- and α_2-implementations are perfect we get property (2) with perfectness. In this case, for any assignment to $\mathbf{x}$ satisfying f, there exists an assignment to $\mathbf{y}$ satisfying $C_1, \ldots, C_{m_1}$. Furthermore, for every $j \in \{1, \ldots, \beta\}$, there exists an assignment to $\mathbf{z'}_j$ satisfying all the constraints $C'_{1,j}, \ldots, C'_{m_2,j}$. Thus there exists an assignment to $\mathbf{x}, \mathbf{y}, \mathbf{z'}_1, \ldots, \mathbf{z'}_\beta$ satisfying all $m_1 + \beta(m_2 - 1)$ constraints. This yields property (2) with perfectness.

Finally we consider the case when the α_1- and α_2-implementations are strict (but not necessarily perfect) and show that in this case the collection of constraints above

also satisfies property (2) with strictness. Given an assignment to $\mathbf{x}$ satisfying f there exists an assignment to $\mathbf{y}$ satisfying α_1 constraints from $C_1, \ldots, C_{m_1}$. If this assignment satisfied γ clauses from the set $C_1, \ldots, C_\beta$ and $\alpha_1 - \gamma$ constraints from the set $C_{\beta+1}, \ldots, C_{m_1}$, then for every $j \in \{1, \ldots, \beta\}$ such that the clauses C_j is satisfied by this assignment to $\mathbf{x}, \mathbf{y}$, there exists an assignment to $\mathbf{z'}_j$ satisfying α_2 clauses from the set $C'_{1,j}, \ldots, C'_{m_2,j}$. Furthermore, for the remaining values of $j \in \{1, \ldots, \beta\}$ there exists an assignment to the variables $\mathbf{z'}_j$ satisfying $\alpha_2 - 1$ of the constraints $C'_{1,j}, \ldots, C'_{m_2,j}$ (here we are using the strictness of the α_2-implementations). This setting to $\mathbf{y}, \mathbf{z'}_1, \ldots, \mathbf{z'}_\beta$ satisfies $\gamma\alpha_2 + (\beta - \gamma)(\alpha_2 - 1) + \alpha_1 - \gamma = \alpha_1 + \beta(\alpha_2 - 1)$ of the m constraints. This yields property (2). A similar analysis can be used to show the strictness. □

Next we show a simple monotonicity property of implementations.

LEMMA 3.6. *For integers α, α' with $\alpha \leq \alpha'$, if $\mathcal{F} \Longrightarrow_\alpha f$, then $\mathcal{F} \Longrightarrow_{\alpha'} f$. Furthermore, strictness and perfectness are preserved under this transformation.*

Proof. Let constraint applications $C_1, \ldots, C_m$ from $\mathcal{F}$ on $\mathbf{x}, \mathbf{y}$ form an α-implementation of $f(\mathbf{x})$. Let g be any constraint from $\mathcal{F}$ and let k be the arity of g. Let $C_{m+1}, \ldots, C_{m+\alpha'-\alpha}$ be $\alpha' - \alpha$ applications of the constraint g on new variables $\mathbf{z} = \{z_1, \ldots, z_k\}$. Then the collection of constraints $C_1, \ldots, C_{m+\alpha'-\alpha}$ on variable set $\mathbf{x}, \mathbf{y}, \mathbf{z}$ form an α'-implementation of f. Furthermore, the transformation preserves strictness and perfectness. □

3.1. Reduction from strict implementations. Here we show how strict implementations are useful in establishing AP-reducibility among MAX CSP problems. However, first we need a simple statement about the approximability of MAX CSP problems.

PROPOSITION 3.7 (see [39]). *For every constraint family $\mathcal{F}$ there exists a constant k such that given any instance $\mathcal{I}$ of* WEIGHTED MAX CSP($\mathcal{F}$) *with constraints of total weight W, a solution satisfying constraints of weight W/k can be found in polynomial time.*

Proof. The proposition follows from the proof of Theorem 1 in [39] which shows the above for every MAX SNP problem. (Note, in particular, that a random assignment satisfies a constant fraction of WEIGHTED MAX CSP($\mathcal{F}$) instance, and such an assignment can be found deterministically by using the method of conditional probabilities.) □

LEMMA 3.8. *If $\mathcal{F}' \stackrel{s}{\Longrightarrow} \mathcal{F}$, then* MAX CSP($\mathcal{F}$) $\leq_{\text{AP}}$ MAX CSP($\mathcal{F}'$).

Proof. The reduction uses Proposition 3.7 above. Let β be a constant such that given an instance $\mathcal{I}$ of MAX CSP($\mathcal{F}$) with m constraints, an assignment satisfying $\frac{m}{\beta}$ constraints can be found in polynomial time.

Recall that we need to show polynomial time computable functions F and G such that F maps an instance $\mathcal{I}$ of MAX CSP($\mathcal{F}$) to an instance of MAX CSP($\mathcal{F}'$), and G maps a solution to $F(\mathcal{I})$ back to a solution of $\mathcal{I}$.

Given an instance $\mathcal{I}$ on n variables and m constraints, the mapping F simply replaces every constraint in $\mathcal{I}$ (which belongs to $\mathcal{F}$) with a strict α-implementation using constraints of $\mathcal{F}'$ for some constant α. (Notice that by Lemma 3.6 some such α does exist.) The mapping retains the original n variables of $\mathcal{I}$ as primary variables and uses m independent copies of the auxiliary variables—one independent copy for every constraint in $\mathcal{I}$.

Let $\langle \mathbf{x}, \mathbf{y} \rangle$ be an r-approximate solution to the instance $F(\mathcal{I})$, where $\mathbf{x}$ denotes the original variables of $\mathcal{I}$ and $\mathbf{y}$ denotes the auxiliary variables introduced by F. The mapping G uses two possible solutions and takes the better of the two: the first

solution is x; and the second solution x' is the solution which satisfies at least m/β of the constraints in $\mathcal{I}$. G outputs the solution which satisfies more constraints.

We now show that an r-approximate solution leads to an r'-approximate solution, where $r' \leq 1+\gamma(r-1)$ for some constant γ. Let OPT denote the value of the optimum to $\mathcal{I}$. Then the optimum of $F(\mathcal{I})$ is exactly $\text{OPT}+m(\alpha-1)$. This computation uses the fact that for every satisfied constraint in the optimal assignment to $\mathcal{I}$, we can satisfy α constraints of its implementation by choosing the auxiliary variables appropriately (from properties (1) and (2) of Definition 3.1); and for every unsatisfied constraint exactly $\alpha-1$ constraints of its implementation can be satisfied (from property (3) and strictness of the implementation). Thus the solution $\langle \mathbf{x}, \mathbf{y} \rangle$ satisfies at least $\frac{1}{r}(\text{OPT} + m(\alpha-1))$ constraints of $F(\mathcal{I})$. Thus $\mathbf{x}$ satisfies at least $\frac{1}{r}(\text{OPT}+m(\alpha-1)) - m(\alpha-1)$ constraints in $\mathcal{I}$. (Here we use properties (1) and (3) of Definition 3.1 to see that there must be at least $\frac{1}{r}(\text{OPT} + m(\alpha-1)) - m(\alpha-1)$ constraints of $\mathcal{I}$ in whose implementations exactly α constraints must be satisfied.) Thus the solution output by G satisfies at least

$$\max\left\{\frac{1}{r}(\text{OPT} + m(\alpha-1)) - m(\alpha-1), \frac{m}{\beta}\right\}$$

constraints. Using the fact that $\max\{a,b\} \geq \lambda a + (1-\lambda)b$ for any $\lambda \in [0,1]$ and using $\lambda = \frac{r}{r+\beta(\alpha-1)(r-1)}$, we lower bound the above expression by

$$\frac{\text{OPT}}{r+\beta(\alpha-1)(r-1)}.$$

Thus

$$r' \leq \frac{\text{OPT}}{\text{OPT}/(r+\beta(\alpha-1)(r-1))} = r+\beta(\alpha-1)(r-1) = 1+(\beta(\alpha-1)+1)(r-1).$$

Thus we find that G maps r-approximate solutions of $F(\mathcal{I})$ to $(1+\gamma(r-1))$-approximate solutions to $\mathcal{I}$ for $\gamma = \beta(\alpha-1)+1 < \infty$ as required. ∎

3.2. Reductions from perfect implementations. We now show how to use perfect implementations to get reductions. Specifically we obtain reductions among Weighted Max Ones, Weighted Min Ones, and Min CSP problems.

Lemma 3.9. *If $\mathcal{F}' \stackrel{p}{\Longrightarrow} \mathcal{F}$, then* Weighted Max Ones($\mathcal{F}$) *(*Weighted Min Ones($\mathcal{F}$)*) is AP-reducible to* Weighted Max Ones($\mathcal{F}'$) *(resp.,* Weighted Min Ones($\mathcal{F}'$)*).*

Proof. Again we need to show polynomial time computable functions F and G such that F maps an instance $\mathcal{I}$ of Weighted Max Ones($\mathcal{F}$) (Weighted Min Ones($\mathcal{F}$)) to an instance of Weighted Max Ones($\mathcal{F}'$) (Weighted Min Ones($\mathcal{F}$)), and G maps a solution to $F(\mathcal{I})$ back to a solution of $\mathcal{I}$.

Given an instance $\mathcal{I}$ on n variables and m constraints, the mapping F simply replaces every constraint in $\mathcal{I}$ (which belongs to $\mathcal{F}$) with a perfect α-implementation using constraints of $\mathcal{F}'$ for some constant α. (Notice that by Lemma 3.6 some such α does exist.) The mapping retains the original n variables of $\mathcal{I}$ as primary variables and uses m independent copies of the auxiliary variables—one independent copy for every constraint in $\mathcal{I}$. Furthermore, $F(\mathcal{I})$ retains the weight of the primary variables from $\mathcal{I}$ and associates a weight of zero with all the newly created auxiliary variables. Given a solution to $F(\mathcal{I})$, the mapping G is simply the projection of the solution back to the primary variables. It is clear that every feasible solution to $\mathcal{I}$ can be extended

into a feasible solution to $F(\mathcal{I})$ such that $\text{OPT}(\mathcal{I}) = \text{OPT}(F(\mathcal{I}))$. Furthermore, the mapping G maps feasible solutions to $F(\mathcal{I})$ into feasible solutions to $\mathcal{I}$ with the same objective. (This is where the perfectness of the implementations is being used.) Thus the optimum of $F(\mathcal{I})$ equals the value of the optimum of $\mathcal{I}$ and given an r-approximate solution to $F(\mathcal{I})$, the mapping G yields an r-approximate solution to $\mathcal{I}$. □

LEMMA 3.10. *If* $\mathcal{F}' \stackrel{p}{\Longrightarrow} \mathcal{F}$, *then* MIN CSP($\mathcal{F}$) $\leq_{\text{A}}$ MIN CSP($\mathcal{F}'$).

Proof. Let α be large enough so that any constraint from $\mathcal{F}$ has a perfect α-implementation using constraints from $\mathcal{F}'$. Let $\mathcal{I}$ be an instance of MIN CSP($\mathcal{F}$) and let $\mathcal{I}'$ be the instance of MIN CSP($\mathcal{F}'$) obtained by replacing each constraint of $\mathcal{I}$ with the respective α-implementation. Once again each implementation uses the original set of variables for its primary variables and uses its own independent copy of the auxiliary variables. Note that the optimum of $\mathcal{I}'$ may be as high as αo if o is the optimum of $\mathcal{I}$ (since the implementations are not strict). It is easy to check that any assignment for $\mathcal{I}'$ of cost V yields an assignment for $\mathcal{I}$ whose cost is between V/α and V. In particular, if the solution is an r-approximate solution to $\mathcal{I}'$, then $V \geq \frac{o}{\alpha r}$ and thus it induces a solution that is at least an (αr)-approximate solution to $\mathcal{I}$. (Note that if the implementations were strict, we would have obtained an AP-reduction by the above.) □

3.3. Weighted vs. unweighted problems. Lemma 3.9 crucially depends on its ability to work with weighted problems to obtain reductions. The following lemma shows that in most cases showing hardness for weighted problems is sufficient. Specifically it shows that as long as a problem is weakly approximable, its weighted and unweighted versions are equivalent. The result uses a similar result from Crescenzi, Silvestri, and Trevisan [15], who prove that for a certain class of problems in poly-APX that they term "nice," weighted problems AP-reduce to problems with polynomially bounded integral weights. (We include a sketch of their proof, specialized to our case for the sake of completeness.) Using this result we scale all weights down to small integers and then simulate the small integral weights by replication of clauses and/or variables. (We note that the little-oh slackness in the definition of AP-reduction is exploited in this step.)

LEMMA 3.11. *For every family* $\mathcal{F}$, *if* WEIGHTED MAX ONES($\mathcal{F}$) *is in* poly-APX, *then* WEIGHTED MAX ONES($\mathcal{F}$) *AP-reduces to* MAX ONES($\mathcal{F}$). *Analogous results hold for* MIN CSP($\mathcal{F}$), MAX CSP($\mathcal{F}$), *and* MIN ONES($\mathcal{F}$).

Proof. Fix a family $\mathcal{F}$. We first reduce WEIGHTED MAX ONES($\mathcal{F}$) to WEIGHTED MAX ONES($\mathcal{F}$) restricted to instances with polynomially bounded positive integer weights, provided WEIGHTED MAX ONES($\mathcal{F}$) is in poly-APX. This step uses a scaling idea as in [15, Theorem 4]. Essentially the same proof also works for the cases of WEIGHTED MAX CSP($\mathcal{F}$), WEIGHTED MIN CSP($\mathcal{F}$), or WEIGHTED MIN ONES($\mathcal{F}$). Given an instance $\mathcal{I} = (\mathbf{x}, \mathbf{C}, \mathbf{w})$ of WEIGHTED MAX ONES($\mathcal{F}$), we will define a new vector of weights $\mathbf{w}'$ and use this to define a new instance $\mathcal{I}' = (\mathbf{x}, \mathbf{C}, \mathbf{w}')$ of WEIGHTED MAX ONES($\mathcal{F}$) with polynomially bounded weights. Let A be an $p(n)$-approximation algorithm for WEIGHTED MAX ONES($\mathcal{F}$), and let t be the value of the solution returned by A on $\mathcal{I}$. We let $N = n^2(p(n))^2 + np(n)$, and let $w_i'' = \left\lfloor \frac{w_i \cdot N}{t} \right\rfloor + 1$, and finally let $w_i' = \min\{w_i'', N \cdot p(n) + 1\}$. It is clear that the weights w_i' are polynomially bounded. Furthermore, note that if $w_i' < w_i''$, then no feasible solution to $\mathcal{I}$ (or $\mathcal{I}'$) can have x_i set to 1, since any such solution would have value at least $w_i > t \cdot p(n)$, contradicting the assumption that A is a $p(n)$-approximation algorithm. Thus, in particular, we have $\text{OPT}(\mathcal{I}') \geq (N/t) \cdot \text{OPT}(\mathcal{I})$. Given an r-approximate solution s' to $\mathcal{I}'$ we return the better of the solutions s' and the solution

returned A as the solution to $\mathcal{I}$. It is clear that if $r \geq p(n)$, then the returned solution is still an r-approximate solution. Below we see that an r-approximate solution to $\mathcal{I}'$, with $r \leq p(n)$, is also an $(r + 1/n)$-approximate solution to $\mathcal{I}$ of value at least

$$\begin{aligned}(t/N) \cdot (\text{OPT}(\mathcal{I}')/r) - n) &\geq \text{OPT}(\mathcal{I})/r - (nt/N) \\ &\geq \text{OPT}(\mathcal{I})/r - (n \cdot \text{OPT}(\mathcal{I})/N) \\ &\geq \text{OPT}(\mathcal{I}) \left(\frac{1}{r} - \frac{1}{nr^2 + r}\right) \\ &= \text{OPT}(\mathcal{I})/(r + 1/n).\end{aligned}$$

This concludes the first step of the reduction. In the next step we give an AP-reduction from the class of problems with polynomially bounded weights to the unweighted case.

We start with the case of Weighted Max CSP($\mathcal{F}$) first. Given an instance of Weighted Max CSP($\mathcal{F}$) on variables $x_1, \ldots, x_n$, constraints $C_1, \ldots, C_m$, and polynomially bounded integer weights $w_1, \ldots, w_m$, we reduce it to the unweighted case by replication of constraints. Thus the reduced instance has variables $x_1, \ldots, x_n$ and constraint $\{\{C_i^j\}_{j=1}^{w_i}\}_{i=1}^m$, where constraint $C_i^j = C_i$. It is clear that the reduced instance is essentially the same as the instance we started with. Similarly we reduce Weighted Min CSP($\mathcal{F}$) to Min CSP($\mathcal{F}$).

Given an instance $\mathcal{I}$ of Weighted Max Ones($\mathcal{F}$) on variables $x_1, \ldots, x_n$, constraints $C_1, \ldots, C_m$, and weights $w_1, \ldots, w_n$, we create an instance $\mathcal{I}'$ of Max Ones($\mathcal{F}$) on variables $\{\{y_i^j\}_{j=1}^{w_i}\}_{i=1}^n$. For every constraint C_j of $\mathcal{I}$ of the form $f(x_{i_1}, \ldots, x_{i_k})$, and for every $j \in \{1, \ldots, k\}$ and $n_j \in \{1, \ldots, w_{i_j}\}$, we impose the constraints $f(y_{i_1}^{n_1}, \ldots, y_{i_k}^{n_k})$. We now claim that the reduced instance is essentially equivalent to the instance we started with. To see this, notice that given any feasible solution $\mathbf{y}$ to the instance $\mathcal{I}'$, we may convert it to another feasible solution $\mathbf{y}'$ in which, for every i, all the variables $\{(\mathbf{y}')_i^j | j = 1, \ldots, w_i\}$ have the same assignment by setting $(\mathbf{y}')_i^j$ to 1 if any of the variables $y_i^{j'}$, $j' = 1, \ldots, w_i$, is set to 1. Notice that this preserves feasibility and increases only the contribution to the objective function. The assignment $\mathbf{y}'$ now induces an assignment to $\mathbf{x}$ with the same value of the objective function. Thus the reduced instance is essentially equivalent to the original one. This concludes the reduction from Weighted Max Ones($\mathcal{F}$) to Max Ones($\mathcal{F}$). The reduction from Weighted Min Ones($\mathcal{F}$) to Min Ones($\mathcal{F}$) is similar. □

4. Characterizations: New and old. In this section we characterize some of the properties of functions that we study. Most of the properties are defined so as to describe how a function behaves if it exhibits the property. For the hardness results, however, we need to see how to exploit the fact that a function does not satisfy some given property. For this we would like to see some simple witness to the fact that the function does not have a given property. As an example consider the affineness property. If a function is affine, it is easy to see how to use this property. What will be important to us is whether there exists a simple witness to the fact that a function f is not affine. Schaefer [42] provides such a characterization: If a function is not affine, then there exist assignments s_1, s_2, and s_3 that satisfy f such that $s_1 \oplus s_2 \oplus s_3$ does not satisfy f. This is exploited by Schaefer in his classification theorem (and by us, in our classifications). In this section, we describe other such characterizations and the implementations that are obtained from them. First we introduce some more definitions and notations that we will be used in the rest of the paper.

4.1. Definitions and notations. For $s \in \{0,1\}^k$, we let $\bar{s} \in \{0,1\}^k$ denote the bitwise complement of s. For a constraint f of arity k, let f^- be the constraint

$f^-(s) = f(\bar{s})$. For a constraint family $\mathcal{F}$, let $\mathcal{F}^- = \{f^- : f \in \mathcal{F}\}$. For $s_1, s_2 \in \{0,1\}^k$, $s_1 \oplus s_2$ denotes the bitwise exclusive-or of the assignments s_1 and s_2. For $s \in \{0,1\}^k$, $Z(s)$ denotes the subset of indices $i \in [k]$, where s is zero and $O(s)$ denotes the subset of indices where s in one.

For a constraint f of arity k, $S \subseteq [k]$ and $b \in \{0,1\}$, $f|_{(S,b)}$ is the constraint of arity $k' = k - |S|$ defined as follows: For variables $x_{i_1}, \ldots, x_{i_{k'}}$, where $\{i_1, \ldots, i_{k'}\} = [k] - S$, we define $f|_{(S,b)}(x_{i_1}, \ldots, x_{i_{k'}}) = f(x_1, \ldots, x_k)$, where $x_i = b$ for $i \in S$. We will sometimes use the notation $f|_{(i,b)}$ to denote the function $f|_{(\{i\},b)}$. For a constraint family $\mathcal{F}$, the family $\mathcal{F}|_0$ is the family $\{f|_{S,0} | f \in \mathcal{F}, S \subseteq [\text{arity}(f)]\}$. The family $\mathcal{F}|_1$ is defined analogously. The family $\mathcal{F}|_{0,1}$ is the family $(\mathcal{F}|_0)|_1$ (or equivalently the family $(\mathcal{F}|_1)|_0$).

DEFINITION 4.1 (C-closed). *A constraint f is C-closed (complementation-closed) if for every assignment s, $f(s) = f(\bar{s})$.*

DEFINITION 4.2 (existential zero/existential one). *A constraint f is an existential zero constraint if $f(\mathbf{0}) = 1$ and $f(\mathbf{1}) = 0$. A constraint f is an existential one constraint if $f(\mathbf{0}) = 0$ and $f(\mathbf{1}) = 1$.*

The terminology above is motivated by the fact that an existential zero constraint application $f(x_1, \ldots, x_k)$ forces at least one of the variables to be zero (while an all zero assignment definitely satisfies the application).

Every constraint f can be expressed as the conjunction of disjuncts. This representation of a function is referred to as the conjunctive normal form (CNF) representation of f. Alternately, a function can also be represented as a disjunction of conjuncts and this representation is called the disjunctive normal form (DNF) representation.

A partial setting to the variables of f that fixes the value of f to 1 is called a *term* of f. A partial setting that fixes f to 0 is called a *clause* of f. We refer to the terms and clauses in a functional form, i.e., we say $\text{OR}_{3,1}(x_1, x_2, x_3) = x_1 \bigvee x_2 \bigvee \neg x_3$ is a clause of $f(x_1, \ldots, x_p)$ if setting $x_1 = x_2 = 0$ and $x_3 = 1$ fixes f to being 0. Similarly we use the $\text{AND}_{i,j}$ to denote the terms. Notice that a DNF (CNF) representation of f can be obtained by expressing as the conjunction (disjunction) of its terms (clauses).

DEFINITION 4.3 (minterm/maxterm). *A partial setting to a subset of the variables of f is a minterm if it is a term of f and no restriction of the setting to any strict subset of the variables fixes the value of f. Analogously a clause of f is a maxterm if it is a minimal setting to the variables of f so as to fix its value to* 0.

As in the case of terms and clauses, we represent minterms and maxterms functionally, i.e., using $\text{OR}_{i,j}$ and $\text{AND}_{i,j}$.

DEFINITION 4.4 (basis). *A constraint family $\mathcal{F}'$ is a basis for a constraint family $\mathcal{F}$ if any constraint of $\mathcal{F}$ can be expressed as a conjunction of constraints drawn from $\mathcal{F}'$.*

Thus, for example, the basis for affine constraints is the set $\{\text{XOR}_p | p \geq 1\} \cup \{\text{XNOR}_p | p \geq 1\}$. The basis for width-2 affine constraints is the set $\mathcal{F} = \{\text{XOR}, \text{XNOR}, T, F\}$, and the basis for 2CNF constraints is the set $\mathcal{F} = \{\text{OR}_{2,0}, \text{OR}_{2,1}, \text{OR}_{2,2}, T, F\}$. The definition of a basis is motivated by the fact that if $\mathcal{F}'$ is a basis for $\mathcal{F}$, then $\mathcal{F}'$ can perfectly implement every function in $\mathcal{F}$ (see Proposition 3.4).

4.2. 0-validity and 1-validity. The characterization of 0-valid and 1-valid functions is obvious. We now show what can be implemented with functions that are not 0-valid and not 1-valid.

LEMMA 4.5. *Let f be a nontrivial constraint which is C-closed and is not* 0*-valid (or equivalently not* 1*-valid).*[5] *Then* $\{f\} \stackrel{s/p}{\Longrightarrow}$ XOR.

Proof. Let k denote the arity of f and let k_0 and k_1, respectively, denote the maximum number of 0's and 1's in any satisfying assignment for f; clearly $k_0 = k_1$. Now let $S_x = \{x_1, \ldots, x_{3k}\}$ and $S_y = \{y_1, \ldots, y_{3k}\}$ be two disjoint sets of $3k$ variables each. In the first phase of the proof, we place a large number of constraints on the variables of S_x and S_y that ends up implementing perfectly, but not necessarily strictly, the constraints $\mathrm{XOR}(x_i, y_j)$ for every i and j. In the second phase, we will introduce two new variables x and y and augment the constraints so as to implement the constraint $\mathrm{XOR}(x, y)$ perfectly and strictly.

We start by placing the constraint f on a large collection of inputs as follows: For every satisfying assignment s, we place $\binom{3k}{i}\binom{3k}{k-i}$ constraints on the variable set $S_x \cup S_y$ such that every i-variable subset of S_x appears in place of 0's in s and every $(k-i)$ variable subset of S_y appears in place of 1's in the assignment s, where i denotes the number of 0's in s. Let this collection of constraints be denoted by $\mathcal{I}$. We will first show that $\mathcal{I}$ gives a perfect (but possibly nonstrict) implementation of the constraint $\mathrm{XOR}(x_i, y_j)$.

Clearly, any solution which assigns identical values to all variables in S_x and the complementary value to all variables in S_y satisfies all the constraints in $\mathcal{I}$. We will show the converse, i.e., every assignment satisfying all the above constraints assigns identical values to all variables in S_x and the complementary value to every variable in S_y.

Fix any assignment satisfying all the constraints and let Z and O, respectively, denote the set of variables set to 0 and 1, respectively. We claim that any solution which satisfies all the constraints must satisfy either $Z = S_x$ and $O = S_y$ or $Z = S_y$ and $O = S_x$.

Note first that at least one of the conditions $|S_x \cap Z| \geq k$ or $|S_x \cap O| \geq k$ must hold. Consider the case where $|S_x \cap Z| \geq k$. In this case, we will show that $S_x = Z$ and $S_y = O$. (A similar argument for the other case will show $S_x = O$ and $S_y = Z$.)

- First we claim that $|S_y \cap Z| < k$ and thus $|S_y \cap O| > 2k$. Assume for contradiction that $|S_y \cap Z| \geq k$. Then there exists a constraint application in $\mathcal{I}$ with all its input variables coming from the sets $S_x \cap Z$ and $S_y \cap Z$. By definition of Z all these variables are set to zero, and hence this constraint application is unsatisfied (by the 0-validity of f).
- Next we claim that every variable of S_x is set to 0: Assume otherwise and, without loss of generality (w.l.o.g.), let x_1 be set to 1. Let s be an assignment with minimal number of 0's. Assume w.l.o.g. that $s = 0^{k_0}1^{k-k_0}$. W.l.o.g., let $y_1, \ldots, y_{2k}$ be set to one. (We know $2k$ such variables exist since $|S_y \cap O| > 2k$.) By our choice of constraint applications, $f(x_1, \ldots, x_{k_0}, y_1, \ldots, y_{k-k_0})$ is one of the constraint applications. However, at most $k_0 - 1$ variables of this constraint are set to 0 and thus this application cannot be satisfied.
- Finally, similar to the above step, we can show that every variable in S_y is set to 1.

Thus we have shown that if $|S_x \cap Z| \geq k$, then $S_x = Z$ and $S_y = O$. The other case is similar, and this concludes the first phase.

We next augment the collection of constraints above as follows. Consider a least Hamming weight satisfying assignment s for f. W.l.o.g., we assume that $s =$

[5] Notice that C-closedness implies that f is 0-valid if and only if it is 1-valid.

$10^{k-k_1-1}1^{k_1}$. We add the constraints $f(x, x_1, \ldots, x_{k-k_1-1}, y_1, \ldots, y_{k_1})$ and $f(y, x_1, \ldots, x_{k-k_1-1}, y_1, \ldots, y_{k_1})$. We now argue that the resulting collection of constraints yields a perfect and strict implementation of the constraint $\mathrm{XOR}(x, y)$.

Clearly $s' = 0^{k-k_1}1^{k_1}$ is not a satisfying assignment (since it has smaller Hamming weight than s). Since f is C-closed, we have the following situation:

		$\overbrace{\quad}^{k-k_1-1}$	$\overbrace{\quad}^{k_1}$	$f()$
s'	0	00...0	11...1	0
s	1	00...0	11...1	1
$\bar{s}$	0	11...1	00...0	1
$\bar{s'}$	1	11...1	00...0	0

If $x = 1$, then to satisfy the first of the two constraints (in addition to all the earlier constraints) above, we must have $Z = S_x$, $O = S_y$ and thus must have $y = 0$. Similarly if $x = 0$, then we must have $O = S_x$, $Z = S_y$ and $y = 1$. Thus the given constraints do form a perfect implementation of $\mathrm{XOR}(x, y)$. Finally if $x = y$, then the setting $O = S_x$ and $Z = S_y$ satisfies all constraints except one (which is one of the last two additional constraints). Thus the implementation satisfies the strictness property as well. □

LEMMA 4.6. *Let f_0, f_1 and g be nontrivial constraints, possibly identical, which are not 0-valid, not 1-valid, and not C-closed, respectively. Then $\{f_0, f_1, g\} \overset{s/p}{\Longrightarrow} \{T, F\}$.*

Proof. We will describe only the implementation of constraint $T(\cdot)$; the implementation for the constraint $F(\cdot)$ is identical.

Assume, for simplicity, that all the three functions f_0, f_1, and g are of arity k. We use an implementation similar to the one used in the proof of Lemma 4.5. To implement $T(x)$, we use a set of $6k$ auxiliary variables $S_x = \{x_1, \ldots, x_{3k}\}$ and $S_y = \{y_1, \ldots, y_{3k}\}$. For each $h \in \{f_0, f_1, g\}$, for each satisfying assignment s of h, if j is the number of 0's in s we place the $\binom{3k}{j}\binom{3k}{k-j}$ constraints h with all possible subsets of S_x appearing in the indices in $Z(s)$ and all possible subsets of S_y appearing in $O(s)$. Finally we introduce one constraint involving the primary variable x. Let s be the satisfying assignment of minimum Hamming weight which satisfies f_0. Notice that s must include at least one 1. Assume, w.l.o.g., that $s = 10^{k-k_1-1}1^{k_1}$. Then we introduce the constraint application $f_0(x, x_1, \ldots, x_{k-k_1-1}, y_1, \ldots, y_{k_1})$.

It is clear that by setting all variables in S_x to 0 and all variables in S_y to 1 we get an assignment that satisfies all constraints except possibly the last constraint (which involves x). Furthermore, the last constraint is satisfied if and only if $x = 1$. Thus, to prove the lemma, it suffices to show that any solution which satisfies all the constraints above must set x to 1, all variables in S_x to 0, and all variables in S_y to 1.

Fix an assignment satisfying all the constraints. Let O be the set of variables in $S_x \cup S_y$ set to 1 and Z be the set of variables set to 0. We need to show that $S_x \cap O = \emptyset$ and we do so in stages.

- First, we consider the possibility $|S_x \cap O| \geq k$. We consider two cases.
  - Case. $|S_y \cap Z| \geq k$. Consider a satisfying assignment s such that $g(\bar{s}) = 0$. Such an assignment must exist since g is not C-closed. Note that the constraint applications include at least one where g is applied to variables where the positions corresponding to $O(s)$ come from $S_y \cap Z$ and positions corresponding to $Z(s)$ come from $S_x \cap O$. However, this constraint is not satisfied by the assignment (since $g(\bar{s}) = 0$).

– Case. $|S_y \cap O| > 2k$. Let s_1 be a satisfying assignment for f_1. Note that the application of the constraint f_1 with the positions corresponding to $O(s)$ coming from $S_y \cap O$ and the positions corresponding to $Z(s)$ coming from $S_x \cap O$ is one of the constraints imposed above and is not satisfied (since f_1 is not 1-valid).

Thus in either case, we find a constraint that is not satisfied and thus this possibility ($|S_x \cap O| \geq k$) cannot occur. Thus we conclude $|S_x \cap O| < k$.

- From the above, we have $|S_x \cap Z| > 2k$. If $|S_y \cap Z| \geq k$, then we can find an application of the constraint f_0 to the variables in the set Z that will not be satisfied. Thus we have $|S_y \cap Z| < k$ and thus $|S_y \cap O| > 2k$. This can now be used to conclude that $S_y \cap Z = \phi$ as follows. Consider a satisfying assignment with smallest number of ones. The number of ones in such an assignment is positive since f_0 is not 0-valid. If we consider all the constraints corresponding to this assignment with inputs from S_y and $S_x \cap Z$ only, it is easy to see that there will be at least one unsatisfied constraint if $S_y \cap Z \neq \phi$. Hence each variable in S_y is set to 1 in this case. Finally, using the constraints on the constraint f_1 which is not 1-valid, it is easy to conclude that in fact $Z = S_x$.

Having concluded that $S_x = Z$ and $S_y = O$, it is easy to see that the constraint $f_0(x, x_1, \ldots, x_{k-k_1-1}, y_1, \ldots, y_{k_1})$ is satisfied only if $x = 1$. Thus the set of constraints imposed above yields a strict and perfect implementation of $T(\cdot)$. The constraint $F(\cdot)$ can be implemented analogously. □

For the CSP classes, it suffices to consider the case when $\mathcal{F}$ is neither 0-valid nor 1-valid. For the MAX ONES and MIN ONES classes we also need to consider the case when $\mathcal{F}$ fails only to have one of these two properties. Therefore keeping these classes in mind we prove the following lemma, which shows how to obtain a weak version of T and F in these cases.

LEMMA 4.7. *If $\mathcal{F}$ is not C-closed and not* 1*-valid, then $\mathcal{F} \overset{s/p}{\Longrightarrow} f$ for some existential zero constraint f_0. Analogously, if $\mathcal{F}$ is not C-closed and not* 0*-valid, then $\mathcal{F} \overset{s/p}{\Longrightarrow} f_1$ for some existential one constraint f_1.*

Proof. We prove only the first part of the lemma. The second part is similar.

The proof reduces to two simple subcases. Let $f \in \mathcal{F}$ be a constraint that is not 1-valid. If f is 0-valid, then we are done since f is an existential zero constraint. If f is not 0-valid, then $\mathcal{F}$ has a non-C-closed function, a non-0-valid function, and a non-1-valid function, and hence by Lemma 4.6, $\mathcal{F}$ perfectly and strictly implements F which is an existential zero function. □

4.3. 2-monotone functions.

DEFINITION 4.8 (0/1-term). *A set $V \subseteq \{1, \ldots, k\}$ is a* 0-term (1-term) *for a k-ary constraint f if every assignment s with $Z(s) \supseteq V$ (resp., $O(s) \supseteq V$) is a satisfying assignment for f.*

The choice of the name reflects the fact that a 0-term is a term consisting of all negated variables (or variables set to 0) and a 1-term consists of all positive variables.

LEMMA 4.9. *A constraint f is a* 2*-monotone constraint if and only if all the following conditions are satisfied:*

(a) *for every satisfying assignment s of f, either $Z(s)$ is a* 0*-term or $O(s)$ is a* 1*-term;*

(b) *if V_1 and V_2 are* 1*-terms for f, then $V_1 \cap V_2$ is a* 1*-term; and*

(c) *if V_1 and V_2 are* 0*-terms for f, then $V_1 \cap V_2$ is also a* 0*-term.*

Proof. Recall that a 2-monotone constraint is one that can be expressed as a

disjunction of two terms. Every satisfying assignment must satisfy one of the two terms and this gives property (a). Properties (b) and (c) are obtained from the fact that the constraint has at most one term with all positive literals and at most one term with all negated literals.

Conversely, consider a constraint f which satisfies properties (a)–(c). Let $s_1, \ldots, s_l$ be the satisfying assignments of f such that $Z(s_i)$ is a 0-term for $i \in \{1, \ldots, l\}$. Let $t_1 \ldots, t_k$ be the satisfying assignments of f such that $O(t_j)$ is a 1-term for $j \in \{1, \ldots, k\}$. Then $Z = \cap_i Z(s_i)$ is a 0-term and $O = \cap_j O(t_j)$ is a 1-term for f, respectively (using (b) and (c)), and together they cover all satisfying assignments of f. Thus $f(\mathbf{x}) = (\wedge_{i \in Z} \neg x_i) \vee (\wedge_{j \in O} x_j)$, which is 2-monotone. □

We now use the characterization above to prove, in Lemma 4.11, that if a function f is not 2-monotone, then the family $\{f, T, F\}$ implements the function XOR. We first prove a simple lemma which shows implementations of XOR by some specific constraint families. This will be used in Lemma 4.11.

LEMMA 4.10.

(1) $\{\mathrm{AND}_{2,1}\} \stackrel{s}{\Longrightarrow} \mathrm{XOR}$.

(2) *For every* $p \geq 2$, *we have* $\{f_p, T, F\} \stackrel{s/p}{\Longrightarrow} \mathrm{XOR}$, *where* $f_p(x_1, \ldots, x_p) = \mathrm{OR}_p(x_1, \ldots, x_p) \bigwedge \mathrm{NAND}_p(x_1, \ldots, x_p)$.

(3) *For every* $p \geq 2$, *we have* $\{\mathrm{NAND}_p, T, F\} \stackrel{s}{\Longrightarrow} \mathrm{XOR}$.

Proof. For part (1) we observe that the constraints

$$\{\mathrm{AND}_{2,1}(x_1, x_2), \mathrm{AND}_{2,1}(x_2, x_1)\}$$

provide a strict (but not perfect) 1-implementation of $\mathrm{XOR}(x_1, x_2)$.

For part (2) notice that the claim is trivial if $p = 2$, since the function $f_2 = \mathrm{XOR}$. For $p \geq 3$, the constraints $\{f_p(x_1, \ldots, x_p), T(x_3), \ldots, T(x_p)\}$ perfectly and strictly implement $\mathrm{NAND}(x_1, x_2)$. Similarly the constraints $\{f_p(x_1, \ldots, x_p), F(x_3), \ldots, F(x_p)\}$ perfectly and strictly implement the constraint $\mathrm{OR}(x_1, x_2)$. Finally the constraints $\mathrm{OR}(x_1, x_2)$ and $\mathrm{NAND}(x_1, x_2)$ perfectly and strictly implement the constraint XOR (x_1, x_2). Part (2) follows from the fact that perfect and strict implementations compose (Lemma 3.5).

Finally for part (3), we first use the constraints

$$\{\mathrm{NAND}_p(x_1, \ldots, x_p), F(x_3), \ldots, F(x_p)\}$$

to implement, strictly and perfectly, the constraint $\mathrm{NAND}(x_1, x_2)$. Now we may use $\{\mathrm{NAND}(x_1, x_2), \mathrm{NAND}(x_1.x_2), T(x_1), T(x_2)\}$ to obtain a 3-implementation of the constraint $\mathrm{XOR}(x_1, x_2)$. (Note that in the case the implementation is not perfect.) □

LEMMA 4.11. *Let* f *be a constraint which is not* 2*-monotone. Then* $\{f, T, F\} \stackrel{s}{\Longrightarrow}$ XOR.

Proof. The proof is divided into three cases which depend on which of the three conditions defining 2-monotonicity is violated by f. We first state and prove the claims.

CLAIM 4.12. *If* f *is a function violating property* (a) *of Lemma* 4.9, *then* $\{f, T, F\} \stackrel{s}{\Longrightarrow}$ XOR.

Proof. There exists some assignment s satisfying f, and two assignments s_0 and s_1 such that $Z(s) \subseteq Z(s_0)$ and $O(s) \subseteq O(s_1)$, such that $f(s_0) = f(s_1) = 0$. Rephrasing slightly, we know that there exists a triple (s_0, s, s_1) with the following properties:

$$f(s_0) = f(s_1) = 0; f(s) = 1; \; Z(s_0) \supseteq Z(s) \supseteq Z(s_1). \tag{1}$$

Note that the condition $Z(s_0) \supseteq Z(s) \supseteq Z(s_1)$ implies that $O(s_0) \subseteq O(s) \subseteq O(s_1)$. We call property (1) the "sandwich property." Of all triples satisfying the sandwich property, pick one that minimizes $|Z(s_0) \cap O(s_1)|$.

W.l.o.g., assume that $Z(s_0) \cap O(s_1) = \{1, \ldots, p\}$, $Z(s_0) \cap Z(s_1) = \{p+1, \ldots, q\}$, and $O(s_0) \cap O(s_1) = \{q+1, \ldots, k\}$. (Notice that the sandwich property implies that $O(s_0) \cap Z(s_1) = \emptyset$.) Let f_1 be the constraint given by $f_1(x_1, \ldots, x_p) = f(x_1, \ldots, x_p, 0, \ldots, 0, 1, \ldots, 1)$. Notice that the constraint applications $f(x_1 \ldots x_k)$ and $T(x_i)$ for every $i \in O(s_0) \cap O(s_1)$ and $F(x_i)$ for every $i \in Z(s_0) \cap Z(s_1)$ implement the function f_1. Thus it suffices to show that $\{f_1, T, F\}$ implements XOR.

Below we examine some properties of the constraint f_1. We will use the characters t, t', t_i, t_i' to denote assignments to f_1, while we use the characters s, s', s_i, s_i' to denote assignments to f. Note that

(1) $f_1(\mathbf{0}) = f_1(\mathbf{1}) = 0$.
(2) f_1 has a satisfying assignment. Thus p (the arity of f_1) is at least 2.
(3) If $f_1(t_1) = 0$ for some $t \neq \mathbf{1}$, then for every assignment t such that $Z(t) \supseteq Z(t_1)$, it is the case that $f_1(t_1) = 0$: This follows from the minimality of $|Z(s_0) \cap O(s_1)|$ above. If not, then consider the assignments $s_0' = s_0$, $s' = t0^{q-p}1^{k-q}$, and $s_1' = t_1 0^{q-p} 1^{k-q}$. The triple (s_0', s', s_1') also satisfies the sandwich property and has a smaller value of $|Z(s_0') \cap O(s_1')|$.
(4) If $f_1(t_0) = 0$ for some $t_0 \neq \mathbf{0}$, then for every assignment t such that $O(t) \supseteq O(t_0)$, it is the case that $f_1(t) = 0$ (again from the minimality of $|Z(s_0) \cap O(s_1)|$).

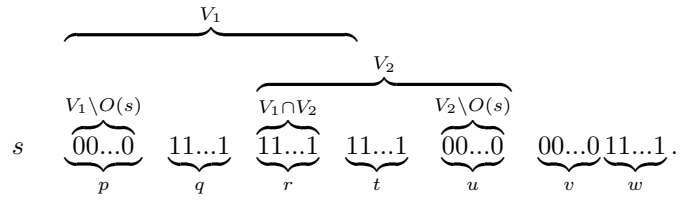
These properties of f_1 now allow us to identify f_1 almost completely. We show that either (a) $p = 2$ and $f_1(x_1 x_2)$ is either $\mathrm{AND}_{2,1}(x_1, x_2)$ or $\mathrm{AND}_{2,1}(x_2, x_1)$, or (b) f is satisfied by every assignment other than the all zeroes assignment and the all ones assignment. In either case $\{f_1, T, F\}$ strictly implements XOR by Lemma 4.10, parts (1) and (2). (Note that part (1) of Lemma 4.10 yields only a strict (but not perfect) implementation.) Thus proving that either (a) or (b) holds concludes the proof of the claim.

Suppose (b) is not the case. Thus, f_1 is left unsatisfied by some assignment t and $t \neq \mathbf{0}$ and $t \neq \mathbf{1}$. Then we will show that the only assignment that can satisfy f_1 is $\bar{t}$. However, this implies that t, $\bar{t}$, $\mathbf{0}$, and $\mathbf{1}$ are the only possible assignments to f_1, implying p must be 2, thereby yielding that (a) is true. Thus it suffices to show that if $f_1(t) = 0$, and $t' \neq \bar{t}$, then $f_1(t') = 0$. Since t' is not the bitwise complement of t, there must exist some input variable which shares the same assignment in t and t'. W.l.o.g. assume this is the variable x_1. Consider the case that this variable takes on the value 0 in the assignment t. Then we claim that the assignment $f_1(01 \ldots 1) = 0$. This is true since $O(01 \ldots 1) \supseteq O(t)$. Now notice that $f(t') = 0$ since $Z(t') \supseteq Z(01 \ldots 1)$. (In the case that the first variable takes on the value 1 in the assignment t, it is symmetric.) Thus we conclude that either (a) or (b) always holds and this concludes the proof of the claim. □

CLAIM 4.13. *Suppose f violates property* (b) *of Lemma* 4.9. *Then* $\{f, T, F\} \overset{s/p}{\Longrightarrow}$ XOR.

Proof. Let V_1 and V_2 be two 1-terms such that $V_1 \cap V_2$ is not a 1-term. Thus, there exists an assignment s such that (s.t.) $O(s) \supseteq V_1 \cap V_2$ and $f(s) = 0$. Among all such assignments let s be the one with the maximum number of 1's. The situation

looks as shown below:



In other words $s = 0^p 1^{q+r+t} 0^{u+v} 1^w$ and $f(s) = 0$. Furthermore, every assignment of the form $1^{p+q+r} *^{t+u+v+w}$ satisfies f and every assignment of the form $*^{p+q} 1^{r+t+u} *^{v+w}$ satisfies f (where the $*$'s above can be replaced by any of 0/1 independently). In particular this implies that $p, u \geq 1$. Consider the function f_1 on $p + u \geq 2$ variables obtained from f by restricting the variables in $O(s)$ to 1 and restricting the variables in $Z(s) - (V_1 \cup V_2)$ to 0. Notice that the constraint applications $f(x_1 \dots x_k)$, $T(x_i)$ for $i \in O(s)$ and $F(x_i)$ for $i \in Z(s) - (V_1 \cup V_2)$ strictly implement f_1. Thus it suffices to show that $\{f_1, T, F\}$ implements XOR. We do so by observing that $f_1(x_1 \dots x_{p+u})$ is the function NAND_{p+u}. Notice that $f_1(\mathbf{0}) = 0$. Furthermore, if $f_1(t) = 0$ for any other assignment t, then it contradicts the maximality of the number of 1's in s. The claim now follows from Lemma 4.10, part (3), which shows that the family $\{\text{NAND}_{p+u}, T, F\}$ implements XOR, provided $p + u \geq 2$. □

CLAIM 4.14. *Suppose f violates property* (c) *of Lemma* 4.9. *Then* $\{f, T, F\} \overset{s/p}{\Longrightarrow}$ XOR.

Proof. The proof is similar to the proof of the claim above. □

The lemma now follows from the fact that any constraint f_2 that is not 2-monotone must violate one of the properties (a), (b), or (c) from Lemma 4.9. □

4.4. Affine functions.

LEMMA 4.15 (see [42]). *f is an affine function if and only if for every three satisfying assignments s_1, s_2, and s_3 to f, $s_1 \oplus s_2 \oplus s_3$ is also a satisfying assignment.*

We first prove a simple consequence of the above which gives a slightly simpler sufficient condition for a function to be affine.

COROLLARY 4.16. *If f is not affine, then there exist two satisfying assignments s_1 and s_2 for f such that $s_1 \oplus s_2$ does not satisfy f.*

Proof. Assume otherwise. Then for any three satisfying assignments s_1, s_2, and s_3, we have that $f(s_1 \oplus s_2) = 1$, and hence $f((s_1 \oplus s_2) \oplus s_3) = 1$, thus yielding that f is affine. □

LEMMA 4.17. *If f is an affine constraint, then any function obtained by restricting some of the variables of f to constants and existentially quantifying over some other set of variables is also affine.*

Proof. We use Lemma 4.15 above. Let f_1 be a function derived from f as above. Consider any three assignments s_1', s_2', and s_3' which satisfy f_1. Let s_1, s_2, and s_3 be the respective extensions which satisfy f. Then the assignment $s_1 \oplus s_2 \oplus s_3$ extends $s_1' \oplus s_2' \oplus s_3'$ and satisfies f. Thus $s_1' \oplus s_2' \oplus s_3'$ satisfies f_1. Thus (using Lemma 4.15) again, we find that f_1 is affine. □

LEMMA 4.18. *If f is an affine function which is not of width-2, then* $\{f\} \overset{s/p}{\Longrightarrow}$ XOR_p *or* $\{f\} \overset{s/p}{\Longrightarrow} \text{XNOR}_p$ *for some $p \geq 3$.*

Proof. Let k be the arity of f. Define a dependent set of variables to be a set of variables $S \subseteq \{1, \dots, k\}$ such that not every assignment to the variables in S extends to a satisfying assignment of f. A dependent set S is a minimally dependent set if

no strict subset $S' \subset S$ is a dependent set. Notice that f can be expressed as the conjunction of constraints on its minimally dependent sets. Thus if f is not of width-2, then it must have a minimally dependent set S of cardinality at least 3. Assume $S = \{1, \ldots, p\}$, where $p \geq 3$. Consider the function

$$f_1(x_1 \ldots x_p) = \exists x_{p+1}, \ldots, x_k \text{ s.t. } f(x_1, \ldots x_k).$$

f_1 is affine (by Lemma 4.17), is not satisfied by every assignment, and has at least 2^{p-1} satisfying assignments. Thus f_1 has exactly 2^{p-1} assignments (since the number of satisfying assignments must be a power of 2). Thus f_1 is described by exactly one linear constraint and by the minimality of S this must be the constraint $\mathrm{XOR}(x_1 \ldots x_p)$ or the constraint $\mathrm{XNOR}(x_1 \ldots x_p)$. ∎

4.5. Horn Clauses, 2CNF, and IHS.

LEMMA 4.19. *If f is a weakly positive (weakly negative/IHS-B+/IHS-B−/*2CNF*) constraint, then any function obtained by restricting some of the variables of f to constants and existentially quantifying over some other set of variables is also weakly positive (resp., weakly negative/IHS-B+/IHS-B−/*2CNF*).*

Proof. It is easy to see that f remains weakly positive (weakly negative/IHS-$B+$/IHS-B−/2CNF) when some variable is restricted to a constant. Hence it suffices to consider the case where some variable y is quantified existentially. (Combinations of the possibilities can then be handled by a simple induction.) Thus consider the function $f_1(x_1, \ldots, x_k) \stackrel{\text{def}}{=} \exists y \text{ s.t. } f(x_1, \ldots, x_k, y)$. Let

$$f(x_1, \ldots, x_k, y) = \left(\bigwedge_{j=1}^{m} C_j(\bar{x}) \right) \bigwedge \left(\bigwedge_{j_0=1}^{m_0} (C^0_{j_0}(\bar{x}) \bigvee y) \right) \bigwedge \left(\bigwedge_{j_1=1}^{m_1} (C^1_{j_1}(\bar{x}) \bigvee \neg y) \right)$$

be a CNF expression for f which shows it is weakly positive (weakly negative/IHS-$B+$/IHS-B−/2CNF), where the clauses C_j, $C^0_{j_0}$, and $C^1_{j_1}$ involve literals on the variables $x_1, \ldots, x_k$.

We first show a simple transformation which creates a CNF expression for f_1. Later we show that f_1 inherits the appropriate properties of f.

Define $m_0 \times m_1$ clauses $C^{01}_{j_0 j_1}(\bar{x}) \stackrel{\text{def}}{=} C^0_{j_0}(\bar{x}) \bigvee C^1_{j_1}(\bar{x})$. Next, we note that $f_1(\bar{x})$ can be expressed as follows:

$$\begin{aligned} f_1(\bar{x}) &= f_1(\bar{x}, 0) \bigvee f_1(\bar{x}, 1) \\ &= \left(\left(\bigwedge_j C_j(\bar{x}) \right) \bigwedge \left(\bigwedge_{j_0} C^0_{j_0}(\bar{x}) \right) \right) \bigvee \left(\left(\bigwedge_j C_j(\bar{x}) \right) \bigwedge \left(\bigwedge_{j_1} C^1_{j_1}(\bar{x}) \right) \right) \\ &= \left(\bigwedge_j C_j(\bar{x}) \right) \bigwedge \left(\left(\bigwedge_{j_0} C^0_{j_0}(\bar{x}) \right) \bigvee \left(\bigwedge_{j_1} C^1_{j_1}(\bar{x}) \right) \right) \\ &= \left(\bigwedge_j C_j(\bar{x}) \right) \bigwedge \left(\bigwedge_{j_0} \bigwedge_{j_1} C^{01}_{j_0 j_1}(\bar{x}) \right). \end{aligned} \tag{2}$$

To conclude we need to verify that the right-hand side of (2) satisfies the same properties as f. Furthermore, we have only to consider clauses of the form $C^{01}_{j_0 j_1}(\bar{x})$ since all other clauses are directly from the expression for f. We verify this below:

- If f is weakly positive, then the clause $C^0_{j_0}$ involves at most one negated variable, and the clause $C^1_{j_1}$ involves no negated variable (since the clause participating in f is $(C^1_{j_1}(\bar{x}) \bigvee \neg y)$ which has a negated y involved in it). Thus the clause defining $C^{01}_{j_0 j_1}$ also has at most one negated variable.
- Similarly if f is weakly negative, then the clauses $C^{01}_{j_0 j_1}$ has at most one positive literal.
- If f is 2CNF, then the clauses $C^0_{j_0}$ and $C^1_{j_1}$ are of length 1, and hence the clause $C^{01}_{j_0 j_1}$ is of length at most 2.
- If f is IHS-$B+$, then the clause $C^0_{j_0}$ either has only one literal which is negated or has only positive literals. Furthermore, $C^1_{j_1}$ has at most one positive literal. Thus $C^{01}_{j_0 j_1}$ either has only positive literals or has at most two literals, one of which is negated. Hence $C^{01}_{j_0 j_1}$ is also IHS-$B+$.
- Similarly if f is IHS-$B-$, then the clause $C^{01}_{j_0 j_1}$ is also IHS-$B-$.

This concludes the proof of the lemma. □

LEMMA 4.20. *f is a weakly positive (weakly negative) constraint if and only if all its maxterms are weakly positive (weakly negative).*

Proof. We prove the lemma for the weakly positive case. The other case is similar. For the easy direction, recall that a function can be expressed as the conjunction of all its maxterms. If all maxterms are weakly positive, then this gives a weakly positive representation of f.

For the other direction, assume for contradiction that f is a weakly positive constraint that has $C = \neg x_1 \bigvee \cdots \bigvee \neg x_p \bigvee x_{p+1} \bigvee \cdots \bigvee x_q$ as a maxterm for some $p \geq 2$. Let the arity of f be k. Consider the function

$$f_1(x_1 x_2) \stackrel{\text{def}}{=} \exists x_{q+1}, \ldots, x_k \text{ s.t. } f(x_1 x_2 1^{p-2} 0^{q-p} x_{q+1} \ldots x_k).$$

Since C is an admissible clause in a CNF representation of f, we have that if we set $x_1, \ldots, x_p$ to 1 and setting $x_{p+1}, \ldots, x_q$ to 0, then no assignment to $x_{q+1}, \ldots, x_k$ satisfies f. Thus we find that $f_1(11) = 0$. By the fact that the clause is a maxterm we have that both the assignments $x_1 \ldots x_q = 01^{p-1}0^{q-p}$ and $x_1 \ldots x_q = 101^{p-2}0^{q-p}$ can be extended to satisfying assignments of f. Thus we find that $f_1(10) = f_1(01) = 1$. Thus f_1 is either the function NOR or XOR. It can be easily verified that neither of these is 2-monotone. (Every basic weakly positive function on two variables is unsatisfied on at least one of the two assignments 01 or 10.) However, this is in contradiction to Lemma 4.19 that showed that every function obtained by restricting some variables of f to constants and existentially quantifying over some others should yield a weakly positive function. □

LEMMA 4.21. *f is a* 2CNF *constraint if and only if all its maxterms are* 2CNF.

Proof. The "if" part is obvious. For the other direction we use Lemma 4.19. Assume for contradiction that f has a maxterm of the form

$$x_1 \bigvee x_2 \bigvee x_3 \bigvee \cdots \bigvee x_p \bigvee \neg x_{p+1} \bigvee \cdots \bigvee \neg x_q.$$

(For simplicity we assume $p \geq 3$. Other cases where one or more of the variables $x_1, \ldots, x_3$ are negated can be handled similarly.) Consider the function

$$f_1(x_1 x_2 x_3) \stackrel{\text{def}}{=} \exists x_{q+1}, \ldots, x_k \text{ s.t. } f(x_1, x_2, x_3, 0^{p-3}, 1^{q-p}, x_{q+1}, \ldots, x_k).$$

Then since $x_1 \bigvee x_2 \bigvee x_3 \ldots$ is a maxterm of f, we have that $f_1(000) = 0$ and $f_1(100) = f_1(010) = f_1(001) = 1$. We claim that f_1 cannot be a 2CNF function. If not, then

to make $f_1(000) = 0$, at least one of the clauses x_1, x_2, x_3, $x_1 \bigvee x_2$, $x_2 \bigvee x_3$, or $x_3 \bigvee x_1$ should be a clause of f_1 in any 2CNF representation. However, all these clauses are left unsatisfied by at least one of the assignments 100, 010, or 001. This validates our claim that f_1 is not a 2CNF constraint. However, f_1 was obtained from f by setting some variables to a constant and existentially quantifying over others, and by Lemma 4.19 f_1 must also be a 2CNF function. This yields the desired contradiction. □

LEMMA 4.22. *An affine function f is a width-2 affine function if and only if all its minimally dependent sets are of cardinality at most* 2.

Proof. We use the fact that $\mathcal{F}_{2A} \subseteq \mathcal{F}_{2CNF} \cap \mathcal{F}_A$. Suppose $f \in \mathcal{F}_{2A}$ has a minimally dependent set of size $p \geq 3$ and, say, the set is $x_1, \ldots, x_p$. Then by existential quantification over the variables $x_{p+1}, \ldots, x_k$ and by setting the variables $x_4, \ldots, x_p$ to 0, we obtain the function $f_1(x_1, x_2, x_3)$ which is an affine function (by Lemma 4.17) with x_1, x_2, x_3 as a minimally dependent set. Thus this function is either XOR_3 or XNOR_3. However, now notice that neither of these functions is a 2CNF function. However, since f is a 2CNF function Lemma 4.19 implies that f_1 must also be a 2CNF function. This yields the required contradiction. □

5. Classification of MAX CSP. The main results of this section are in sections 5.1 and 5.2. These results were originally obtained by Creignou [11]. Her focus, however, is on the the complexity of finding optimal solutions to the optimization problems. The proofs for hardness of approximation are left to the reader to verify. We give full proofs using the notions of implementations. Our proof is also stronger since it does not assume replication of variables as a basic primitive. This allows us to talk about problems such as MAX EkSAT. In section 5.3 we extend Schaefer's results to establish the hardness of satisfiable MAX CSP problems. Similar results, again with replication of variables being allowed, were first shown by Hunt, Marathe, and Stearns [26].

5.1. Containment results for MAX CSP. We start with the polynomial time solvable cases.

PROPOSITION 5.1. WEIGHTED MAX CSP($\mathcal{F}$) *(*WEIGHTED MIN CSP($\mathcal{F}$)*) is in* PO *if $\mathcal{F}$ is* 0*-valid (*1*-valid).*

Proof. Set each variable to zero (resp., one); this satisfies all of the constraints. □

Before proving the containment in PO of MAX CSP($\mathcal{F}$) for 2-monotone function families, we show that the corresponding WEIGHTED MIN CSP($\mathcal{F}$) is in PO. The containment for WEIGHTED MAX CSP($\mathcal{F}$) will follow easily.

LEMMA 5.2. WEIGHTED MIN CSP($\mathcal{F}$) *is in* PO *if $\mathcal{F}$ is* 2*-monotone.*

Proof. This problem reduces to the problem of finding s-t min-cut in directed weighted graphs. 2-monotone constraints have the following possible forms:

(a) $\mathrm{AND}_p(x_{i_1}, \ldots, x_{i_p})$,
(b) $\mathrm{NOR}_q(x_{j_1}, \ldots, x_{j_q})$, and
(c) $\mathrm{AND}_p(x_{i_1}, \ldots, x_{i_p}) \bigvee \mathrm{NOR}_q(x_{j_1}, \ldots, x_{j_q})$.

Construct a directed graph G with two special nodes, F and T, and a vertex v_i corresponding to each variable x_i in the input instance. Let ∞ denote an integer larger than the total weight of all constraints.

Now we proceed as follows for each of the above classes of constraints:

- For a constraint C of weight w of the form (a), create a new node e_C and add an edge from each v_{i_l}, $l \in [p]$, to e_C of capacity ∞ and an edge from e_C to T of capacity w.

- For a constraint C of weight w of the form (b), create a new node $\overline{e_C}$ and add an edge from $\overline{e_C}$ to each v_{j_l}, $l \in [q]$, of capacity ∞ and an edge from F to $\overline{e_C}$ of capacity w.
- Finally, for a constraint C of weight w of the form (c), we create two nodes e_C and $\overline{e_C}$. For every $l \in [p]$, we add an edge from v_{i_l} to e_C of capacity ∞, and for every $l \in [q]$, we add an edge from $\overline{e_C}$ to v_{j_l} of capacity ∞ and finally an edge from e_C to $\overline{e_C}$ of capacity w. (Note in this case there are no edges connecting F or T to any of the vertices.)

Notice that each vertex of type e_C or $\overline{e_C}$ can be associated with a term: e_C with a term on positive literals and $\overline{e_c}$ with a term on negated literals. We use this association to show that the value of the min F-T cut in this directed graph equals the weight of the minimum number of unsatisfied constraints in the given Weighted Min CSP($\mathcal{F}$) instance.

Given an assignment which fails to satisfy constraints of weight W, we associate a cut as follows: Vertex v_i is placed on the F side of the cut if and only if it is set to 0. A vertex e_C is placed on the T side if and only if the term associated with it is satisfied. A vertex $\overline{e_C}$ is placed on the F side if and only if the term associated with it is satisfied. It can be verified that such an assignment has no directed edges of capacity ∞ going from the F side of the cut to the T side of the cut. Furthermore, for every constraint C of weight w, the associated edge of capacity w crosses the cut if and only if the constraint is not satisfied. Thus the capacity of this cut is exactly W and thus we find that the min F-T cut value is at most W.

In the other direction, we show that given a F-T cut in this graph of cut capacity $W < \infty$, there exists an assignment which fails to satisfy constraints of weight at most W. Such an assignment is simply to assign $x_i = 0$ if and only if v_i is on the F side of the cut. Note that for any constraint C, the associated vertices e_C and $\overline{e_c}$ (whichever exist) may be placed on the T and F sides of the cut (respectively) only if the associated term is satisfied (otherwise there will be an edge of capacity ∞ crossing the cut). Thus, if a constraint C of capacity w is not satisfied by this assignment, then the edge of capacity w corresponding to C must cross the cut. Summing up we find that the assignment fails to satisfy constraints of total weight at most W.

Putting both directions together, we find that the min F-T cut in this graph has capacity exactly equal to the optimum of the Weighted Min CSP{XOR} instance, and thus the latter problem can be solved exactly in polynomial time. □

For the sake of completeness we also prove the converse direction to the above lemma. We show that the s-t min-cut problem can be phrased as a Min CSP($\mathcal{F}$) problem for a 2-monotone family $\mathcal{F}$.

Lemma 5.3. *The s-t min-cut problem is in* Weighted Min CSP($\{\mathrm{OR}_{2,1}, T, F\}$).

Proof. Given an instance $G = (V, E)$ of the s-t min-cut problem, we construct an instance of Weighted Min CSP($\mathcal{F}$) on variables $x_1, x_2, \ldots, x_n$, where x_i corresponds to the vertex $i \in V - \{s, t\}$:

- For each edge $e = (s, i)$ with weight w_e, we create the constraint $F(x_i)$ with weight w_e.
- For each edge $e = (i, t)$ with weight w_e, we create the constraint $T(x_i)$ with weight w_e.
- For each edge $e = (i, j)$ with weight w_e and such that $i, j \notin \{s, t\}$, we create the constraint $\mathrm{OR}_{2,1}(x_j, x_i)$ with weight w_e.

Given a solution to this instance of Weighted Min CSP($\mathcal{F}$), we construct an s-t cut by placing the vertices corresponding to the false variables on the s-side of

the cut and the remaining on the t-side of the cut. It is easy to verify that an edge e contributes to the cut if and only if its corresponding constraint is unsatisfied. Hence the optimal MIN CSP($\mathcal{F}$) solution and the optimal s-t min-cut solution coincide. □

Going back to our main objective, we obtain as a simple corollary to Lemma 5.2 the following corollary.

COROLLARY 5.4. *For every* $\mathcal{F} \subseteq \mathcal{F}_{2M}$, WEIGHTED MAX CSP($\mathcal{F}$)$\in$ PO.

Proof. The proof follows from the fact that given an instance $\mathcal{I}$ of WEIGHTED MAX CSP($\mathcal{F}$), the optimum solution to $\mathcal{I}$ viewed as an instance of WEIGHTED MIN CSP($\mathcal{F}$) is also an optimum solution to the WEIGHTED MAX CSP($\mathcal{F}$) version. □

Finally we prove a simple containment result for all of MAX CSP($\mathcal{F}$) which follows as an easy consequence of Proposition 3.7.

PROPOSITION 5.5. *For every* $\mathcal{F}$, WEIGHTED MAX CSP($\mathcal{F}$) *is in* APX.

Proof. The proof follows from Proposition 3.7 and the fact that the total weight of all constraints is an upper bound on the optimal solution. □

5.2. Negative results for MAX CSP. In this section we prove that if $\mathcal{F} \not\subseteq \mathcal{F}_0, \mathcal{F}_1, \mathcal{F}_{2M}$, then MAX CSP($\mathcal{F}$) is APX-hard. We start with a simple observation which establishes MAX CSP(XOR) as our starting point.

LEMMA 5.6. MAX CSP(XOR) *is* APX*-hard.*

Proof. We observe that MAX CSP(XOR) captures the MAX CUT problem shown to be APX-hard by [39, 3]. Given a graph $G = (V, E)$ with n vertices and m edges, create an instance $\mathcal{I}_G$ of MAX CSP($\{$XOR$\}$) with one variable x_u for every vertex $u \in V$ and with constraints XOR(x_u, x_v) corresponding to every edge $\{u, v\} \in E$. It is easily seen there is a one-to-one correspondence between (ordered) cuts in G and the assignments to the variables of $\mathcal{I}_G$ which maintains the values of the objective functions (i.e., the cut value and the number of satisfied constraints). □

We start with the following lemma which shows how to use the functions which are not 0-valid or 1-valid.

LEMMA 5.7. *If* $\mathcal{F} \not\subseteq \mathcal{F}_0, \mathcal{F}_1$, *then* MAX CSP($\mathcal{F} \cup \{T, F\}$) *is AP-reducible to* MAX CSP($\mathcal{F}$) *and* MIN CSP($\mathcal{F} \cup \{T, F\}$) *is A-reducible to* MIN CSP($\mathcal{F}$).

Proof. Let f_0 be the function from $\mathcal{F}$ that is not 0-valid and let f_1 be the function that is not 1-valid. If some function g in $\mathcal{F}$ is not C-closed, then by Lemma 4.6 $\mathcal{F}$ perfectly and strictly implements T and F. Hence, by Lemmas 3.8 and 3.10, MAX CSP($\mathcal{F} \cup \{T, F\}$) is AP-reducible to MAX CSP($\mathcal{F}$) and MIN CSP($\mathcal{F} \cup \{T, F\}$) is A-reducible to MIN CSP($\mathcal{F}$).

Otherwise, every function of $\mathcal{F}$ is C-closed, and hence by Lemma 4.5, $\mathcal{F}$ perfectly and strictly implements the XOR function and hence, by Proposition 3.3, the XNOR function. Thus it suffices to show that MAX CSP($\mathcal{F} \cup \{T, F\}$) is AP-reducible to MAX CSP($\mathcal{F} \cup \{$XOR, XNOR$\}$) (and MIN CSP($\mathcal{F} \cup \{T, F\}$) is A-reducible to MIN CSP($\mathcal{F} \cup \{$XOR, XNOR$\}$)) for C-closed families $\mathcal{F}$. Here we use an idea from [8] described next.

Given an instance $\mathcal{I}$ of MAX CSP($\mathcal{F} \cup \{T, F\}$) on variables $x_1, \ldots, x_n$ and constraints $C_1, \ldots, C_m$, we define an instance $\mathcal{I}'$ of MAX CSP($\mathcal{F} \cup \{$XOR, XNOR$\}$) (MIN CSP($\mathcal{F} \cup \{$XOR, XNOR$\}$)) whose variables are $x_1, \ldots, x_n$ and additionally one new auxiliary variable x_F. Each constraint of the form $F(x_i)$ (resp., $T(x_i)$) in $\mathcal{I}$ is replaced by a constraint XNOR(x_i, x_F) (resp., XOR(x_i, x_F)). All the other constraints are not changed. Thus $\mathcal{I}'$ also has m constraints. Given a solution $a_1, \ldots, a_n, a_F$ for $\mathcal{I}'$ that satisfies m' of these constraints, notice that the assignment $\neg a_1, \ldots, \neg a_n, \neg a_F$ also satisfies the same collection of constraints (since every function in $\mathcal{F}$ is C-closed). In

one of these cases the assignment to x_F is false and then we notice that a constraint of $\mathcal{I}$ is satisfied if and only if the corresponding constraint in $\mathcal{I}'$ is satisfied. Thus every solution to $\mathcal{I}'$ can be mapped to a solution to $\mathcal{I}$ with the same contribution to the objective function. □

The required lemma now follows as a simple combination of Lemmas 4.9 and 5.7.

LEMMA 5.8. *If* $\mathcal{F} \not\subseteq \mathcal{F}_0, \mathcal{F}_1, \mathcal{F}_{2M}$, *then* MAX CSP($\mathcal{F}$) *is* APX*-hard.*

Proof. By Lemma 4.11 $\mathcal{F} \cup \{T, F\}$ strictly implements the XOR function. Thus MAX CSP(XOR) AP-reduces to MAX CSP($\mathcal{F} \cup \{T, F\}$) which in turn (by Lemma 5.7) AP-reduces to MAX CSP($\mathcal{F}$). Thus MAX CSP($\mathcal{F}$) is APX-hard. □

5.3. Hardness at gap location 1. Schaefer's dichotomy theorem can be extended to show that in the cases where SAT($\mathcal{F}$) is NP-hard to decide, it is actually hard to distinguish satisfiable instances from instances which are not satisfiable in a constant fraction of the constraints. This is termed hardness at gap location 1 by Petrank [40], who highlights the utility of such hardness results in other reductions. The essential observation needed is that perfect implementations preserve hardness gaps located at 1 and that Schaefer's proof is based on perfect implementations.

However, Schaefer's proof of NP-hardness in his dichotomy theorem relies on the ability to replicate variables within a constraint application. Specifically, the following lemma can be abstracted from his paper.

LEMMA 5.9 (see [42]). *If* $\mathcal{F}$ *is not* 0*-valid or* 1*-valid or affine or bijunctive or weakly positive or weakly negative, then* $\mathcal{F} \cup \{\text{XNOR}\} \stackrel{p}{\Longrightarrow} \mathcal{F}_{3\text{SAT}}$.

In this section, we show that a family $\mathcal{F}$ that is not decidable also perfectly implements the XNOR constraint and thus the lemma above can be strengthened. We start with the following lemma that shows how to use functions that are not weakly negative.

LEMMA 5.10. *If* f *is not weakly negative, then* $\{f, T, F\} \stackrel{p}{\Longrightarrow}$ XOR *or* $\{f, T, F\} \stackrel{p}{\Longrightarrow}$ OR. *Similarly, if* f *is not weakly positive, then* $\{f, T, F\} \stackrel{p}{\Longrightarrow}$ XOR *or* $\{f, T, F\} \stackrel{p}{\Longrightarrow}$ NAND.

Proof. We prove only the first part—the second part follows by symmetry. By Lemma 4.20 we find that f has a maxterm with at least two positive literals. W.l.o.g. the maxterm is of the form $x_1 \bigvee x_2 \bigvee \cdots x_p \bigvee \neg x_{p+1} \bigvee \cdots \bigvee \neg x_q$ with $p \geq 2$. We consider the function f' which is f existentially quantified over all variables but $x_1, \ldots, x_q$. Furthermore, we set $x_3, \ldots, x_p$ to 0 and $x_{p+1}, \ldots, x_q$ to 1. Then the assignment $x_1 = x_2 = 0$ is a nonsatisfying assignment. The assignments $x_1 = 0 \neq x_2$ and $x_1 \neq 0 = x_2$ must be satisfying assignments by the definition of maxterm (and in particular by the minimality of the clause). The assignment $x_1 = x_2 = 1$ may go either way. Depending on this we get either the function XOR or OR. □

COROLLARY 5.11. *If* f_2 *is not weakly positive and* f_3 *is not weakly negative, then* $\{f_2, f_3, T, F\} \stackrel{p}{\Longrightarrow}$ XOR.

LEMMA 5.12. *If* $\mathcal{F}$ *is not* 0*-valid or* 1*-valid or weakly positive or weakly negative, then* $\mathcal{F} \stackrel{s/p}{\Longrightarrow} \{\text{XOR}, \text{XNOR}\}$.

Proof. If $\mathcal{F}$ is C-closed, then, by Lemma 4.5, we immediately get a strict and perfect implementation of XOR. If it is not C-closed, then, by Lemma 4.6, we get perfect and strict implementations of the constraints T and F. Applying Corollary 5.11 now, we get a perfect and strict implementation of XOR in this case also. Finally we use Proposition 3.3 to get a perfect and strict implementation of XNOR from the constraint XOR. □

Combining Lemma 5.9 and the above, we get the following corollary.

COROLLARY 5.13. *If $\mathcal{F}$ is not 0-valid or 1-valid or affine or bijunctive or weakly positive or weakly negative, then $\mathcal{F} \stackrel{p}{\Longrightarrow} \mathcal{F}_{3\mathrm{SAT}}$.*

Thus we get the following theorem.

THEOREM 5.14. *For every constraint set $\mathcal{F}$, either SAT($\mathcal{F}$) is easy to decide or there exists $\epsilon = \epsilon_{\mathcal{F}} > 0$ such that it is NP-hard to distinguish satisfiable instances of SAT($\mathcal{F}$) from instances where $1 - \epsilon$ fraction of the constraints are not satisfiable.*

6. Classification of MAX ONES. Again we will first prove the positive results and then show the negative results. However, before we do either, we will show a useful reduction between unweighted and weighted MAX ONES($\mathcal{F}$) problems which holds for most interesting function families $\mathcal{F}$.

6.1. Preliminaries. We begin with a slightly stronger notion of the definition of polynomial time solvability of SAT($\mathcal{F}$) (than that of [42]). We then show that given this stronger form of polynomial time decidability the weighted and unweighted cases of MAX ONES($\mathcal{F}$) are equivalent by showing that this stronger form of polynomial time decidability leads to a polynomial approximation algorithm. We conclude by showing that for the MAX ONES problems, which we hope to show to be APX-complete or poly-APX-complete, the strong form of decidability does hold.

DEFINITION 6.1. *We say that a constraint family $\mathcal{F}$ is* strongly decidable *if, given m constraints from $\mathcal{F}$ on n variables $x_1, \ldots, x_n$* and an index $i \in \{1, \ldots, n\}$, *there exists a polynomial time algorithm to find an assignment to $x_1, \ldots, x_n$ satisfying all m constraints and additionally satisfying the property $x_i = 1$ if one such exists.*

LEMMA 6.2. *For every strongly decidable constraint family $\mathcal{F}$,* WEIGHTED MAX ONES($\mathcal{F}$) *is in* poly-APX.

Proof. Consider an instance of WEIGHTED MAX ONES($\mathcal{F}$) with variables $x_1, \ldots, x_n$, constraint applications $C_1, \ldots, C_m$, and weights $w_1, \ldots, w_n$. Assume $w_1 \leq w_2 \leq \cdots \leq w_n$. Let i be the largest index such that there exists a feasible solution with $x_i = 1$. Notice that i can be determined in polynomial time due to the strong decidability of $\mathcal{F}$. We also use the strong decidability to find an assignment with $x_i = 1$. It is easily verified that this yields an n-approximate solution. (Weight of this solution is at least w_i, while weight of optimal is at most $\sum_{j=1}^{i} w_j \leq i w_i \leq n w_i$.) ∎

Before concluding we show that most problems of interest to us will be able to use the equivalence established above between weighted and unweighted problems.

LEMMA 6.3. *If $\mathcal{F} \subseteq \mathcal{F}'$ for any $\mathcal{F}' \in \{\mathcal{F}_1, \mathcal{F}_{\mathrm{S0}}, \mathcal{F}_{\mathrm{2CNF}}, \mathcal{F}_{\mathrm{A}}, \mathcal{F}_{\mathrm{WP}}, \mathcal{F}_{\mathrm{WN}}\}$, then $\mathcal{F}$ is strongly decidable.*

Proof. Recall that for $i \in [k]$, $f|_{(\{i\},1)}$ is the constraint obtained from f by restricting the ith input to 1. Define $\mathcal{F}^*$ to be the constraint set

$$\mathcal{F}^* \stackrel{\mathrm{def}}{=} \mathcal{F} \cup \{f|_{i,1} | f \in \mathcal{F}, i \in [k]\}.$$

First, observe that the problem of strong decidability of $\mathcal{F}$ reduces to the decision problem SAT($\mathcal{F}^*$). Furthermore, observe that if $\mathcal{F} \subseteq \mathcal{F}'$ for $\mathcal{F}' \in \{\mathcal{F}_1, \mathcal{F}_{\mathrm{2CNF}}, \mathcal{F}_{\mathrm{A}}, \mathcal{F}_{\mathrm{WP}}, \mathcal{F}_{\mathrm{WN}}\}$, then $\mathcal{F}^* \subseteq \mathcal{F}'$ as well. Finally, if $\mathcal{F}^* \subseteq \mathcal{F}_{\mathrm{S0}}$, then $\mathcal{F}^* \subseteq \mathcal{F}_0$. Thus in each case we end up with a problem from SAT($\mathcal{F}$) for a family $\mathcal{F}$ which is polynomial time decidable in Schaefer's dichotomy. ∎

LEMMA 6.4. *If $\mathcal{F} \stackrel{p}{\Longrightarrow} f_0$ for some existential zero constraint f_0, then $\mathcal{F} \stackrel{p}{\Longrightarrow} \mathcal{F}|_0$. Similarly, if $\mathcal{F} \stackrel{p}{\Longrightarrow} f_1$ for some existential one constraint f_1, then $\mathcal{F} \stackrel{p}{\Longrightarrow} \mathcal{F}|_1$.*

Proof. Let $f \in \mathcal{F}$. We show how to implement the constraint $f(0, x_1, \ldots, x_{k-1})$. The proof can be extended to other constraints in $\mathcal{F}|_0$ by induction. Let f_0 be an

existential zero constraint implementable by $\mathcal{F}$ and let K be the arity of f_0. Then the constraints $f(y_i, x_1, \ldots, x_{k-1})$, for $i \in [K]$, along with the constraint $f_0(y_1, \ldots, y_K)$ perfectly implement the constraint $f(0, x_1, \ldots, x_{k-1})$. (Observe that since at least one of the y_i's in the set $y_1, \ldots, y_K$ is zero, the constraint $f(0, x_1, \ldots, x_{k-1})$ is being enforced. Furthermore, we can always set all of $y_1, \ldots, y_K$ to zero, ensuring that any assignment to $x_1, \ldots, x_{k-1}$ satisfying $f(0, x_1, \ldots, x_{k-1})$ does satisfy all the constraints listed above.) □

6.2. Containment results.

LEMMA 6.5. *If $\mathcal{F}$ is* 1*-valid or weakly positive or width-*2 *affine, then* WEIGHTED MAX ONES($\mathcal{F}$) *is in* PO.

Proof. If $\mathcal{F}$ is 1-valid, then setting each variable to 1 satisfies all constraint applications with the maximum possible variable weight.

If $\mathcal{F}$ is weakly positive, consider the CNF formulae for the $f_i \in \mathcal{F}$ such that each clause has at most one negated variable. Clearly, clauses consisting of a single literal force the assignment of these variables. Setting these variables may create new clauses of a single literal; set these variables and continue the process until all clauses have at least two literals or until a contradiction is reached. In the latter case, no feasible assignment is possible. In the former case, setting the remaining variables to 1 satisfies all constraints, and there exists no feasible assignment with a greater weight of ones.

In the case that $\mathcal{F}$ is affine with width-2, we reduce the problem of finding a feasible solution to that of checking whether a graph is bipartite and then use the bipartition to find the optimal solution. Notice that each constraint corresponds to a conjunction of constraints of the form $X_i = X_j$ or $X_i \neq X_j$. Create a vertex X_j for each variable X_j and for each constraint $X_i \neq X_j$, add an edge (X_i, X_j). For each constraint $X_i = X_j$, identify the vertices X_i and X_j and associate the sum of their weights to the identified vertex; if this creates a self-loop, then clearly no feasible assignment is possible. Check whether the graph is bipartite; if not, then there is no feasible assignment. If it is bipartite, then for each connected component of the graph choose the larger weight side of the bipartition and set the corresponding variables to 1. □

LEMMA 6.6. *If $\mathcal{F}$ is affine, then* WEIGHTED MAX ONES($\mathcal{F}$) *is in* APX.

Remark. Our proof actually shows that MAX ONES($\mathcal{F}$) has a 2-approximation algorithm. Combined with the fact that the AP-reduction of Lemma 3.11 does not lose much in the approximation factor we essentially get the same factor for WEIGHTED MAX ONES($\mathcal{F}$) as well.

Proof. By Lemmas 3.11, 6.2, and 6.3 it suffices to consider the unweighted case. (Lemma 6.3 shows that $\mathcal{F}$ is strongly decidable; Lemma 6.2 uses this to show that WEIGHTED MAX ONES($\mathcal{F}$) is in poly-APX; and Lemma 3.11 uses this to provide an AP-reduction from WEIGHTED MAX ONES($\mathcal{F}$) to MAX ONES($\mathcal{F}$).)

Given an instance $\mathcal{I}$ of MAX ONES($\mathcal{F}$), notice that finding a solution which satisfies all constraints is the problem of solving a linear system of equations over GF [2]. Say the linear system is given by $Ax = b$, where A is an $m \times n$ matrix, and b is a $m \times 1$ column vector, and the x is an $n \times 1$ vector. Assume w.l.o.g. that the rows of A are independent. By simple row operations and reordering of the variables, we can set up the linear system as $[I|A']x = b'$. Thus if x' represents the vector $\langle x_1, \ldots, x_m \rangle$ and x'' represents the vector $\langle x_{m+1}, \ldots, x_n \rangle$, then the set of feasible solutions to the given linear system are given by

$$\{\langle x', x'' \rangle | x'' \in \{0,1\}^{n-m}, x' = -A'x'' + b'\}.$$

Pick a random element of this set by picking x'' at random and setting x' accordingly. Notice that for any $i \in \{m+1, \ldots, n\}$ $x_i = 1$ with probability (w.p.) $\frac{1}{2}$. Furthermore, for any $i \in [m]$, x_i is either forced to 0 in all feasible solutions, or x_i is forced to 1 in all feasible solutions, or $x_i = 1$ w.p. 1/2. Thus, if $S \subseteq [n]$ is the set of variables which are ever set to 1 in a feasible solution, then the expected number of 1's in a random solution is at least $|S|/2$. However, S is an upper bound on OPT. Thus the expected value of the solution is at least OPT/2, and hence the solution obtained is a 2-approximate solution. □

PROPOSITION 6.7. *If $\mathcal{F} \subseteq \mathcal{F}'$ for some $\mathcal{F}' \in \{\mathcal{F}_1, \mathcal{F}_{\mathrm{S0}}, \mathcal{F}_{\mathrm{2CNF}}, \mathcal{F}_{\mathrm{A}}, \mathcal{F}_{\mathrm{WP}}, \mathcal{F}_{\mathrm{WN}}\}$, then* WEIGHTED MAX ONES$(\mathcal{F}) \in$ poly-APX.

Proof. The proof follows immediately from Lemmas 6.2 and 6.3. □

PROPOSITION 6.8 (see [42]). *If $\mathcal{F} \subseteq \mathcal{F}_0$, then* SAT$(\mathcal{F})$ *is in* P.

6.3. Hardness results.

6.3.1. APX-hard case. We wish to show in this section that if $\mathcal{F}$ is an affine family but not width-2 affine, then MAX ONES$(\mathcal{F})$ is APX-hard. By Lemmas 6.2 and 3.11 it suffices to show this for WEIGHTED MAX ONES$(\mathcal{F})$. The basic APX-hard problems we work with in this section are described in the following lemma.

LEMMA 6.9. WEIGHTED MAX ONES(XNOR_3) *and* WEIGHTED MAX ONES $(\{\mathrm{XOR}, \mathrm{XNOR}_4\})$ *are* APX*-hard.*

Proof. We reduce the MAX CUT problem to the WEIGHTED MAX ONES(XNOR_3) problem as follows. Given a graph $G = (V, E)$ we create a variable x_v for every vertex $v \in V$ and a variable y_e for every edge $e \in E$. The weight w_v associated with the vertex variable x_v is 0. The weight w_e of an edge variable y_e is 1. For every edge e between u and v we create the constraint $y_e \oplus x_u \oplus x_v = 0$. It is clear that any 0/1 assignment to the x_v's define a cut and for an edge $e = \{u, v\}$, y_e is 1 if and only if u and v are on opposite sides of the cut. Thus solutions to the WEIGHTED MAX ONES problem correspond to cuts in G with the objective function being the number of edges crossing the cut. This shows the APX-hardness of WEIGHTED MAX ONES(XNOR_3).

The reduction for WEIGHTED MAX ONES$(\{\mathrm{XOR}, \mathrm{XNOR}_4\})$ is similar. Given a graph $G = (V, E)$, we create the variables x_v for every $v \in V$, y_e for every $e \in E$, and one global variable z (which is supposed to be zero) and $m \stackrel{\mathrm{def}}{=} |E|$ auxiliary variables y'_e for every $e \in E$. For every edge $e = \{u, v\}$ in G we impose the constraints $y_e \oplus x_u \oplus x_v \oplus z = 0$. In addition we throw in the constraints $z \oplus y'_e = 1$ for every $i \in \{1, \ldots, m\}$. Finally we make the weight of the vertex variables and z 0, and the weight of the edge variables y_e and the auxiliary variables y'_e is made 1. The optimum to this WEIGHTED MAX ONES problem is MAX CUT$(G) + m$. Given an r-approximate solution for the WEIGHTED MAX ONES$(\{\mathrm{XOR}_4, \mathrm{XOR}\})$ instance created above, we consider the two possible solutions (as usual): (1) the solution induced by the assignment with zero vertices on one side and one vertex on the other and (2) a cut with m/K edges crossing the cut (notice such a cut can be found based on Proposition 3.7). The better of these solutions has $\max\{(\frac{1}{r})(m + \text{MAX CUT}(G)) - m, \frac{m}{K}\} \geq \frac{1}{r(K(1-1/r)+1)}\text{MAX CUT}(G) \geq \frac{1}{1+K(r-1)}\text{MAX CUT}(G)$ edges crossing the cut. Thus an r-approximate solution to WEIGHTED MAX ONES$(\{\mathrm{XOR}, \mathrm{XNOR}_4\})$ yields a $(1+K(r-1))$-approximate solution to MAX CUT(G). Thus MAX CUT(G) AP-reduces to WEIGHTED MAX ONES$(\{\mathrm{XOR}, \mathrm{XNOR}_4\})$, and hence the latter is APX-hard. □

LEMMA 6.10. *If $\mathcal{F}$ is affine but neither width-2 affine nor 1-valid, then $\mathcal{F} \xrightarrow{p} \mathrm{XNOR}_3$ or $\mathcal{F} \xrightarrow{p} \{\mathrm{XOR}, \mathrm{XNOR}_4\}$.*

Proof. Since $\mathcal{F}$ is affine but not of width-2, it can perfectly (and strictly) implement the function XOR_p or XNOR_p for some $p \geq 3$ (Lemma 4.18). Let $f \in \mathcal{F}$ be an affine constraint that is not 1-valid. We consider two possible cases depending on whether $\mathcal{F}$ is C-closed or not. If $g \in \mathcal{F}$ is not C-closed, then we find (by Lemma 4.7) that $\{f, g\}$ (and hence $\mathcal{F}$) perfectly implements some existential zero constraint. This case is covered in Claim 6.11 and we show that in this case $\mathcal{F}$ perfectly implements XNOR_3. In the other case, $\mathcal{F}$ is C-closed, and hence (by Lemma 4.5) $\mathcal{F}$ perfectly implements the constraint XOR. This case is covered in Claim 6.12 and we show that in this case $\mathcal{F}$ perfectly implements either XNOR_3 or XNOR_4. This concludes the proof of Lemma 6.10 (modulo Claims 6.11 and 6.12). □

CLAIM 6.11. *If $\{f\}$ is an existential zero constraint and h is either the constraint XOR_p or XNOR_p for some $p \geq 3$, then $\{f, h\} \xrightarrow{p} \mathrm{XNOR}_3$.*

Proof. Since f is an existential zero constraint, the family $\{f, h\}$ can perfectly implement $\{f, h\}|_0$ (using Lemma 6.4). In particular, $\{f, h\}$ can implement the constraints $x_1 \oplus x_2 = b$ and $x_1 \oplus x_2 \oplus x_3 = b$ for some $b \in \{0, 1\}$. Notice finally that the constraints $x_1 \oplus x_2 \oplus y = b$ and $y \oplus x_3 = b$ form a perfect implementation of the constraint $x_1 \oplus x_2 \oplus x_3 = 0$. Thus $\{f, h\}$ perfectly implements the constraint XNOR_3. □

CLAIM 6.12. *If $f \in \{\mathrm{XOR}_p, \mathrm{XNOR}_p \mid p \geq 3\}$, then $\{f, \mathrm{XOR}\} \xrightarrow{p} \mathrm{XNOR}_3$ or $\{f, \mathrm{XOR}\} \xrightarrow{p} \mathrm{XNOR}_4$.*

Proof. Since XOR perfectly implements XNOR it suffices to prove this using the constraints $\{f, \mathrm{XOR}, \mathrm{XNOR}\}$.

W.l.o.g assume that f is the constraint XNOR, since otherwise $\mathrm{XOR}_p(x_1, \ldots, x_{p-1}, y)$ and $\mathrm{XOR}(y, x_p)$ perfectly implement the constraint $\mathrm{XNOR}_p(x_1, \ldots, x_p)$.

Now if p is odd, then the constraints $\mathrm{XNOR}_p(x_1, \ldots, x_p)$ and $\mathrm{XNOR}(x_4, x_5)$, $\mathrm{XNOR}(x_6, x_7)$, and so on up to $\mathrm{XNOR}(x_{p-1}, x_p)$ perfectly implement the constraint $\mathrm{XNOR}_3(x_1, x_2, x_3)$.

Now if p is even, then the constraints $\mathrm{XNOR}_p(x_1, \ldots, x_p)$ and $\mathrm{XNOR}(x_5, x_6)$, $\mathrm{XNOR}(x_7, x_8)$, and so on up to $\mathrm{XNOR}(x_{p-1}, x_p)$ perfectly implement the constraint $\mathrm{XNOR}_4(x_1, x_2, x_3, x_4)$. □

LEMMA 6.13. *If $\mathcal{F}$ is affine but neither width-2 affine nor 1-valid, then* MAX ONES($\mathcal{F}$) *is* APX*-hard.*

Proof. By Lemma 6.6 we have WEIGHTED MAX ONES($\mathcal{F}$) is in APX and thus (by Lemma 3.11) it suffices to show APX-hardness of WEIGHTED MAX ONES($\mathcal{F}$). This now follows from Lemmas 3.9, 6.9, and 6.10. □

6.3.2. The poly-APX-hard case. This part turns out to be long and the bulk of the work will be done in Lemmas 6.16–6.21. We first describe the proof of the hardness result modulo the above lemmas. (Hopefully, the proof will also provide some motivation for the rest of the lemmas.)

LEMMA 6.14. *If $\mathcal{F} \subseteq \mathcal{F}'$ for some $\mathcal{F}' \in \{\mathcal{F}_0, \mathcal{F}_{2\mathrm{CNF}}, \mathcal{F}_{\mathrm{WN}}\}$ but $\mathcal{F} \not\subseteq \mathcal{F}''$ for any $\mathcal{F}'' \in \{\mathcal{F}_1, \mathcal{F}_{\mathrm{A}}, \mathcal{F}_{\mathrm{WP}}\}$, then* MAX ONES($\mathcal{F}$) *is* poly-APX*-hard.*

Proof. As usual, by Lemmas 6.2 and 3.11, it suffices to show hardness of the weighted version. First we show in Lemma 6.15 that MAX ONES($\{\mathrm{NAND}_k\}$) is poly-APX-hard for every $k \geq 2$. Thus our goal is to establish that any non-1-valid, nonaffine, and nonweakly positive constraint family can implement some NAND_k constraint. We do so in three phases.

The main complication here is that we don't immediately have a non-0-valid constraint to work with and thus we can't immediately reduce MAX ONES($\mathcal{F} \cup \{T, F\}$) to MAX ONES($\mathcal{F}$). Therefore we go after something weaker and try to show that $\mathcal{F}$ can perfectly implement $\mathcal{F}|_{0,1}$. In Phase 3 (Lemmas 6.20 and 6.21) we show that this suffices. Lemma 6.20 uses the fact that $\mathcal{F}|_{0,1}$ is not weakly positive to implement either NAND_2 or XOR. In the former case we are done and in the latter case, Lemma 6.21 uses the fact that $\mathcal{F}|_{0,1}$ is not affine to implement NAND.

Thus our task reduces to that of showing that $\mathcal{F}$ can implement $\mathcal{F}|_{0,1}$. Part of this is easy. In Phase 1, we show that $\mathcal{F}$ implements every constraint in $\mathcal{F}|_0$. This is shown via Lemma 6.16 which shows that any family which is either 0-valid or 2CNF or weakly negative but not 1-valid or affine or weakly positive must have a non-C-closed constraint. This along with the non-1-valid constraint allows it to implement every constraint in $\mathcal{F}|_0$ (by Lemmas 4.7 and 6.4). The remaining task for Phase 2 is to show that $\mathcal{F}|_0$ can implement $\mathcal{F}|_1$. If $\mathcal{F}$ also has a non-0-valid constraint, then we are done since now we can implement all of $\mathcal{F}|_{0,1}$ (another application of Lemmas 4.7 and 6.4). Thus all lemmas in Phase 2 focus on $\mathcal{F}|_0$ for 0-valid constraint families $\mathcal{F}$. If $\mathcal{F}|_0$ is all 0-valid, then all we can show is that $\mathcal{F}|_0$ either implements NAND_k for some k or $\text{OR}_{2,1}$ (Lemmas 6.17 and 6.18). The former is good, but the latter seems insufficient. In fact we are unable to implement $\mathcal{F}|_{0,1}$ in this case. We salvage the situation by reverting back to reductions. We AP-reduce the problem WEIGHTED MAX ONES($\mathcal{F}|_0 \cup \{\text{OR}_{2,1}\}$) to WEIGHTED MAX ONES($\mathcal{F}|_{0,1}$) (Lemma 6.19). This suffices to establish the poly-APX-hardness of WEIGHTED MAX ONES($\mathcal{F}$) since

$$\begin{aligned}\text{WEIGHTED MAX ONES}(\mathcal{F}|_{0,1}) &\leq_{\text{AP}} \text{WEIGHTED MAX ONES}(\mathcal{F}|_0 \cup \{\text{OR}_{2,1}\}) \\ &\leq_{\text{AP}} \text{WEIGHTED MAX ONES}(\mathcal{F})\end{aligned}$$

and the problem WEIGHTED MAX ONES($\mathcal{F}|_{0,1}$) is poly-APX-hard. □

LEMMA 6.15. MAX ONES($\{\text{NAND}_k\}$) *is* poly-APX-*hard for every* $k \geq 2$.

Proof. We reduce from MAX CLIQUE, which is known to be poly-APX-hard. Given a graph G, construct a MAX ONES($\{f\}$) instance consisting of a variable for every vertex in G and the constraint f is applied to every subset of k vertices in G which does not induce a clique. It may be verified that the optimum number of ones in any satisfying assignment to the instance created in this manner is $\max\{k-1, \omega(G)\}$, where $\omega(G)$ is the size of the largest clique in G. Given a solution to the MAX ONES($\{f\}$) instance with $l \geq k$ ones, the set of vertices corresponding to the variables set to 1 form a clique of size l. If $l < k$, output any singleton vertex. Thus in all cases we obtain a clique of size at least $l/(k-1)$ vertices. Thus given an r-approximate solution to the MAX ONES($\{\text{NAND}_k\}$) problem, we can find a $(k-1)r$-approximate solution to MAX CLIQUE. Thus MAX CLIQUE is A-reducible to MAX ONES($\{\text{NAND}_k\}$). □

Phase 1. $\mathcal{F}$ implements $\mathcal{F}|_0$.

LEMMA 6.16. *If* $\mathcal{F} \subseteq \mathcal{F}'$ *for some* $\mathcal{F}' \in \{\mathcal{F}_0, \mathcal{F}_{2\text{CNF}}, \mathcal{F}_{\text{WN}}\}$ *but* $\mathcal{F} \not\subseteq \{\mathcal{F}_1, \mathcal{F}_{2\text{A}}, \mathcal{F}_{\text{WP}}\}$, *then there exists a constraint in* $\mathcal{F}$ *that is not C-closed constraint.*

Proof. Notice that a C-closed 0-valid constraint is also 1-valid. Thus if $\mathcal{F}$ is 0-valid, then the non-1-valid constraint is not C-closed.

Next we claim that a C-closed weakly positive constraint f is also weakly negative. To do so, consider the constraint $\bar{f}$ given by $\bar{f}(x) = f(\bar{x})$. Notice that for a C-closed constraint $f = \bar{f}$. Suppose $f(x) = \bigwedge_j C_j(x)$, where the C_j's are weakly positive clauses. Then $\bar{f}(x)$ can be described as $\bigwedge_j \bar{C}_j(x)$ (where $\bar{C}_j(x) = C_j(\bar{x})$). However, in this representation $\bar{f}$ (and thus f) is seen to be a weakly negative constraint,

thereby verifying our claim. Thus if $\mathcal{F}$ is weakly negative but not weakly positive, the nonweakly positive constraint is the non-C-closed constraint.

Finally we consider the case when f is a 2CNF formula. Again define $\bar{f}(x) = f(\bar{x})$ and $f'(x) = f(x)\bar{f}(x)$. Notice that $f' = f$ if f is C-closed. Again consider the CNF representation of $f = \bigwedge_j C_j(x)$, where the $C_j(x)$'s are clauses of f of length 2. Then $f'(x)$ can be expressed as $\bigwedge_j (C_j(x) \bigwedge \bar{C}_j(x))$. However, $C_j \bigwedge \bar{C}_j$ are affine constraints of width-2! Thus f', and hence f, is an affine width-2 constraint. Thus if $\mathcal{F}$ is 2CNF but not width-2 affine, the non-width-2 affine constraint is the non-C-closed constraint. □

Lemma 4.7 along with Lemma 6.4 suffice to prove that $\mathcal{F}$ implements $\mathcal{F}|_0$. We now move on to Phase 2.

Phase 2. From $\mathcal{F}|_0$ to $\mathcal{F}|_{0,1}$.

Recall that if $\mathcal{F}$ has a non-0-valid constraint, then by Lemmas 6.16, 4.7, and 6.4 it implements an existential one constraint and thus $\mathcal{F}|_{0,1}$. Thus all lemmas in this phase assume $\mathcal{F}$ is 0-valid.

LEMMA 6.17. *If f is 0-valid and not weakly positive, then $\{f\}|_0$ either perfectly implements* NAND_k *for some $k \geq 2$ or* $\mathrm{OR}_{2,1}$ *or* XNOR.

Proof. Let $C = \neg x_1 \bigvee \cdots \bigvee \neg x_p \bigvee y_1 \bigvee \cdots \bigvee y_q$ be a maxterm in f with more than one negation, i.e., $p \geq 2$. Since f is not weakly positive, Lemma 4.20 shows that such a maxterm exists. Substituting a 0 in place of variables $y_1, y_2, \ldots, y_q$ and existentially quantifying over all variables not in C, we get a constraint g such that $\neg x_1 \bigvee \neg x_2 \bigvee \cdots \bigvee \neg x_p$ is a maxterm in g. Consider an unsatisfying assignment s for g with the smallest number of 1's and let k denote the number of 1's in s; we know $k > 0$ since the original constraint is 0-valid. W.l.o.g. assume that s assigns value 1 to the variables $x_1, x_2, \ldots, x_k$ and 0 to the remaining variables. It is easy to see that by fixing the variables $x_{k+1}, x_{k+2}, \ldots, x_p$ to 0, we get a constraint $g' = (\neg x_1 \bigvee \neg x_2 \bigvee \cdots \bigvee \neg x_k)$. If $k > 1$, then this perfectly implements the constraint $\mathrm{NAND}_k(x_1, \ldots, x_k)$ and we are done.

Otherwise $k = 1$, i.e., there exists an unsatisfying assignment s which assigns value 1 to exactly one of the x_i's, say, x_1. Now consider a satisfying assignment s' which assigns 1 to x_1 and has a minimum number of 1's among all assignments which assign 1 to x_1. The existence of such an assignment follows from C being a maxterm in g. For instance, the assignment $1^{p-1}0$ is a satisfying assignment which satisfies such a property. W.l.o.g. assume that $s' = 1^i 0^{p-i}$. Thus the constraint g looks as follows:

	x_1	x_2	$x_3 ... x_i$	$x_{i+1} ... x_p$	$g()$
s_1	0	0	00...0	00...0	1
s_2	1	0	00...0	00...0	0
$s' = s_3$	1	1	11...1	00...0	1
s_4	0	1	_..._	00...0	?

Existential quantification over the variables $x_3, x_4, \ldots, x_i$ and fixing the variables x_{i+1} through x_p to 0 yields a constraint g' which is either $\mathrm{OR}_{2,1}(x_2, x_1)$ or $\mathrm{XNOR}(x_1, x_2)$. The lemma follows. □

Now we consider the case where we can implement the function XNOR and show that in this case we can perfectly implement either NAND or $\mathrm{OR}_{2,1}$. In the former case we are done, and for the latter case we show in Lemma 6.19 that WEIGHTED MAX ONES($\mathcal{F}|_1$) is AP-reducible to WEIGHTED MAX ONES($\mathcal{F} \cup \{\mathrm{OR}_{2,1}\}$).

LEMMA 6.18. *If f is 0-valid but not affine, then $\{f\}|_0 \cup \{\mathrm{XNOR}\}$ perfectly implements either* NAND *or the constraint* $\mathrm{OR}_{2,1}$.

Proof. Corollary 4.16 shows that if f is not affine, then there exist two satisfying assignments s_1 and s_2 such that $s_1 \oplus s_2$ is not a satisfying assignment for f. Reorder the variables such that $Z(s_1) \cap Z(s_2) = \{x_1, \ldots, x_p\}$, $Z(s_1) \cap O(s_2) = \{x_{p+1}, \ldots, x_q\}$, $O(s_1) \cap Z(s_2) = \{x_{q+1}, \ldots, x_r\}$, and $O(s_1) \cap O(s_2) = \{x_{r+1}, \ldots, x_k\}$. Using the fact that f is 0-valid, we find that f looks as follows:

	$x_1 \ldots x_p$	$x_{p+1} \ldots x_q$	$x_{q+1} \ldots x_r$	$x_{r+1} \ldots x_k$	$g(\mathbf{x})$
	00...0	00...0	00...0	00...0	1
s_1	00...0	00...0	11...1	11...1	1
s_2	00...0	11...1	00...0	11...1	1
$s_1 \oplus s_2$	00...0	11...1	11...1	00...0	0

Consider the following collection of constraints:

(1) $f(0, \ldots, 0, x_{p+1}, \ldots, x_k)$.
(2) $\mathrm{XNOR}(x, x_i)$ for $i \in Z(s_1) \cap O(s_2)$.
(3) $\mathrm{XNOR}(y, x_i)$ for $i \in O(s_1) \cap Z(s_2)$.
(4) $\mathrm{XNOR}(z, x_i)$ for $i \in O(s_1) \cap O(s_2)$.

Existentially quantifying over the variables $x_{p+1}, \ldots, x_k$ we obtain an implementation of a constraint $h(x, y, z)$ such that $h(000) = h(011) = h(101) = 1$ and $h(110) = 0$. Furthermore, by restricting more of the variables in (1) above to 0, we get a perfect implementation of any constraint in $\{h\}|_0$. Using Claim 6.22 again we get that $\{h\}|_0$ can implement either NAND or $\mathrm{OR}_{2,1}$, and thus we are done. ∎

Finally we show how to use $\mathrm{OR}_{2,1}$ constraints.

LEMMA 6.19. *If $\mathcal{F}$ is 0-valid, then* WEIGHTED MAX ONES$(\mathcal{F}|_1)$ *AP-reduces to* WEIGHTED MAX ONES$(\mathcal{F} \cup \{\mathrm{OR}_{2,1}\})$.

Proof. We show something stronger, namely, WEIGHTED MAX ONES$(\mathcal{F} \cup \{T\})$ AP-reduces to WEIGHTED MAX ONES$(\mathcal{F} \cup \{\mathrm{OR}_{2,1}\})$. This suffices since T is an existential one constraint and thus $\mathcal{F} \cup \{T\}$ can perfectly implement $\mathcal{F}|_1$.

Given an instance $\mathcal{I}$ of WEIGHTED MAX ONES$(\mathcal{F} \cup \{T\})$ construct an instance $\mathcal{I}'$ of WEIGHTED MAX ONES$(\mathcal{F} \cup \{\mathrm{OR}_{2,1}\})$ as follows. The variable set of $\mathcal{I}'$ is the same as that of $\mathcal{I}$. Every constraint from $\mathcal{F}$ in $\mathcal{I}$ is also included in $\mathcal{I}'$. The only remaining constraints are of the form $T(x_i)$ for some variables x_i. We simulate this constraint in $\mathcal{I}'$ with $n-1$ constraints of the form $\mathrm{OR}_{2,1}(x_j, x_i)$ (i.e., $\neg x_j \bigvee x_i$) for every $j \in [n]$, $j \neq i$. Every nonzero solution to the resulting instance $\mathcal{I}'$ is also a solution to $\mathcal{I}$, since the solution must have $x_i = 1$ or else have $x_j = 0$ for every $j \neq i$. Thus the resulting instance of MAX ONES$(\mathcal{F} \cup \{\mathrm{OR}_{2,1}\})$ has the same objective function and the same feasible space and hence is at least as hard as the original problem. ∎

This concludes Phase 2.

Phase 3. $\mathcal{F}|_{0,1}$ implements NAND.

LEMMA 6.20. *If f is not weakly positive, then $\{f\}|_{0,1}$ perfectly implements either* XOR *or* NAND.

Proof. Let $C = (\neg x_1 \bigvee \cdots \bigvee \neg x_p \bigvee y_1 \bigvee \cdots \bigvee y_q)$ be a maxterm in f with more than one negation, i.e., $p \geq 2$. Substituting a 1 for variables $x_3, \ldots, x_p$, a 0 for variables $y_1, \ldots, y_q$, and existentially quantifying over all variables not in C, we get a constraint f' such that $f'(11) = 0$, $f'(01) = f'(10) = 1$. (These three properties follow from the definition of a maxterm.) Depending on whether $f'(00)$ is 0 or 1 we get the function XOR or NAND, respectively. ∎

LEMMA 6.21. *If g is a nonaffine constraint, then* $\{g, \mathrm{XOR}\}|_{0,1} \stackrel{p}{\Longrightarrow}$ NAND.

Proof. Again it suffices to consider $\{g, \mathrm{XOR}, \mathrm{XNOR}\}|_{0,1}$. Let g be of arity k. By Lemma 4.15 we find that there must exist assignments s_1, s_2, and s_3 satisfying g such

	S_{000}	S_{001}	S_{010}	S_{011}	S_{100}	S_{101}	S_{110}	S_{111}	$g(\mathbf{x})$
s_1	0...0	0...0	0...0	0...0	1...1	1...1	1...1	1...1	1
s_2	0...0	0...0	1...1	1...1	0...0	0...0	1...1	1...1	1
s_3	0...0	1...1	0...0	1...1	0...0	1...1	0...0	1...1	1
$s_1 \oplus s_2 \oplus s_3$	0...0	1...1	1...1	0...0	1...1	0...0	0...0	1...1	0

FIG. 1. *Partition of inputs to g.*

that $s_1 \oplus s_2 \oplus s_3$ does not satisfy g. Partition the set $[k]$ into up to eight equivalence classes $S_{b_1b_2b_3}$ for $b_1, b_2, b_3 \in \{0,1\}$ such that for any index $i \in S_{b_1b_2b_3}$, $(s_j)_i = b_j$ for every $j \in \{1,2,3\}$ (refer to Figure 1).

W.l.o.g. assume that $S_{000} = \{1, \ldots, p\}$ and $S_{111} = \{q+1, \ldots, k\}$. Notice that the assignment of a variable in $S_{b_1b_2b_3}$ under assignment $s_1 \oplus s_2 \oplus s_3$ is also fixed (to $b_1 \oplus b_2 \oplus b_3$). Now consider the following collection of constraints:

(1) $g(0, \ldots, 0, x_{p+1} \ldots, x_q, 1, \ldots, 1)$.
(2) $\mathrm{XNOR}(x, x_i)$ for $i \in S_{001}$.
(3) $\mathrm{XNOR}(y, x_i)$ for $i \in S_{010}$.
(4) $\mathrm{XNOR}(z, x_i)$ for $i \in S_{011}$.
(5) $\mathrm{XOR}(z, x_i)$ for $i \in S_{100}$.
(6) $\mathrm{XOR}(y, x_i)$ for $i \in S_{101}$.
(7) $\mathrm{XOR}(x, x_i)$ for $i \in S_{110}$.

By existentially quantifying over the variables $x_{p+1}, \ldots, x_q$ we perfectly implement a constraint $h(x,y,z)$ with the following properties: $h(000) = h(011) = h(101) = 1$ and $h(110) = 0$. Furthermore, by restricting more variables in condition (1) above, we can actually implement any function in the set $\{h\}|_{0,1}$. Claim 6.22 now shows that for any such function h, the set $\{h\}|_0$ perfectly implements either $\mathrm{OR}_{2,1}$ or NAND. In the latter case, we are done. In the former case, notice that the constraints $\mathrm{OR}_{2,1}(x,z)$ and $\mathrm{XOR}(z,y)$ perfectly implement the constraint $\mathrm{NAND}(x,y)$; so in this case too we are done (modulo Claim 6.22). □

CLAIM 6.22. *If h is ternary function such that* $h(000) = h(011) = h(101) = 1$ *and* $h(110) = 0$*, then* $\{h\}|_0 \xRightarrow{p} \mathrm{NAND}$ *or* $\{h\}|_0 \xRightarrow{p} \mathrm{OR}_{2,1}$.

Proof. Figure 2 describes the truth table for the function h. The undetermined values of interest to us are indicated in the table by A and B. The following analysis shows that for every possible value of A and B, we can perfectly implement either NAND or $\mathrm{OR}_{2,1}$:

$$\begin{aligned} A = 0 &\implies \exists\, x\ h(x,y,z) = \neg y \bigvee z, \\ B = 0 &\implies \exists\, y\ h(x,y,z) = \neg x \bigvee z, \\ A = 1, B = 1 &\implies h(x,y,0) = \neg x \bigvee \neg y. \end{aligned}$$

Thus in each case we perfectly implement either the constraint NAND or $\mathrm{OR}_{2,1}$. □

6.3.3. Remaining cases. We now prove that if $\mathcal{F}$ is not strongly decidable, then deciding if there exists a nonzero solution is NP-hard. This is shown in Lemma 6.23. The last of the hardness results, claiming that finding a feasible solution is NP-hard if $\mathcal{F}$ is not 0-valid or 1-valid or 2cnf or weakly positive or weakly negative or linear, follows directly from Schaefer's theorem (Theorem 2.10).

LEMMA 6.23. *If* $\mathcal{F} \not\subseteq \mathcal{F}'$*, for any* $\mathcal{F}' \in \{\mathcal{F}_{\mathrm{S0}}, \mathcal{F}_1, \mathcal{F}_{\mathrm{2CNF}}, \mathcal{F}_{\mathrm{A}}, \mathcal{F}_{\mathrm{WP}}, \mathcal{F}_{\mathrm{WN}}\}$*, then the problem of finding solutions of nonzero value to a given instance of (unweighted)*

x \ yz	00	01	11	10
0	1	-	1	A
1	B	1	-	0

FIG. 2. *Truth table of the constraint* $h(x, y, z)$.

MAX ONES($\mathcal{F}$) *is NP-hard.*

Proof. Assume, for simplicity, that all constraints of $\mathcal{F}$ have arity k. Given a constraint $f : \{0,1\}^k \to \{0,1\}$ and an index $i \in [k]$, let $f{\downarrow_i}$ be the constraint mapping $\{0,1\}^{k-1}$ to $\{0,1\}$ given by

$$f{\downarrow_i}(x_1, \ldots, x_k) \stackrel{\text{def}}{=} f(x_1, \ldots, x_{i-1}, 1, x_{i+1}, \ldots, x_k) \wedge f(x_1, \ldots, x_{i-1}, 0, x_{i+1}, \ldots, x_k).$$

Let $\mathcal{F}'$ be the set of constraints defined as follows:

$$\mathcal{F}' \stackrel{\text{def}}{=} \mathcal{F} \cup \{f{\downarrow_i} \quad | \quad f \in \mathcal{F}, i \in [k]\}.$$

We will show that deciding SAT($\mathcal{F}'$) is NP-hard and that the problem of deciding SAT($\mathcal{F}'$) reduces to finding nonzero solutions to MAX ONES($\mathcal{F}$).

First observe that $\mathcal{F}' \not\subseteq \mathcal{F}''$ for any $\mathcal{F}'' \in \{\mathcal{F}_0, \mathcal{F}_1, \mathcal{F}_{2\text{CNF}}, \mathcal{F}_{\text{A}}, \mathcal{F}_{\text{WP}}, \mathcal{F}_{\text{WN}}\}$. In particular it is not 0-valid, since $\mathcal{F}$ is not strongly 0-valid. Hence, once again applying Schaefer's result, we find that deciding SAT($\mathcal{F}'$) is NP-hard.

Given an instance of SAT($\mathcal{F}'$) on n variables $\mathbf{x}$ with m constraints $\mathbf{C}$, with $C_1, \ldots, C_{m'} \in \mathcal{F}$ and $C_{m'+1}, \ldots, C_m \in \mathcal{F}' \setminus \mathcal{F}$, consider the instance of MAX ONES($\mathcal{F}$) defined on variable set

$$w_1, \ldots, w_{k+1}, y_1, \ldots, y_n, z_1, \ldots, z_n$$

with the following constraints:

(1) Let f be a non-1-valid constraint in $\mathcal{F}$. We introduce the constraint $f(w_1, \ldots, w_k)$.
(2) For every constraint $C_i(v_{i_1}, \ldots, v_{i_k})$, $1 \le i \le m'$, we introduce two constraints $C_i(y_{i_1}, \ldots, y_{i_k})$ and $C_i(z_{i_1}, \ldots, z_{i_k})$.
(3) For every constraint $C_i(v_{i_1}, \ldots, v_{i_{k-1}})$, $m' + 1 \le i \le m$, we introduce $2(n + k + 1)$ constraints. For simplicity of notation, let $C_i(v_{i_1}, \ldots, v_{i_{k-1}}) = g(1, v_{i_1}, \ldots, v_{i_{k-1}}) \wedge g(0, v_{i_1}, \ldots, v_{i_{k-1}})$, where $g \in \mathcal{F}$. The $2(n+k+1)$ constraints are
   - $g(w_j, y_{i_1}, \ldots, y_{i_{k-1}})$ for $1 \le j \le k+1$,
   - $g(z_j, y_{i_1}, \ldots, y_{i_{k-1}})$ for $1 \le j \le n$,
   - $g(w_j, z_{i_1}, \ldots, z_{i_{k-1}})$ for $1 \le j \le k+1$,
   - $g(y_j, z_{i_1}, \ldots, z_{i_{k-1}})$ for $1 \le j \le n$.

We now show that the instance of MAX ONES($\mathcal{F}$) created above has a nonzero satisfying assignment if and only if the instance of SAT($\mathcal{F}'$) has a satisfying assignment. Let $s = s_1 s_2 \ldots s_k$ be a satisfying assignment for the non-1-valid constraint f chosen above. First if $v_1, \ldots, v_n$ form a satisfying assignment to the instance of SAT($\mathcal{F}'$), then we claim that the assignment $w_j = s_j$ for $1 \le j \le k$, $w_{k+1} = 1$ and $y_j = z_j = v_j$ for $1 \le j \le n$ is a satisfying assignment to the instance of MAX ONES($\mathcal{F}$) which has at least one 1 (namely, w_{k+1}). Conversely, let some nonzero setting $w_1, \ldots, w_{k+1}, y_1, \ldots, y_n, z_1, \ldots, z_n$ satisfy the instance of MAX ONES($\mathcal{F}$). W.l.o.g.

assume that one of the variable $w_1, \ldots, w_{k+1}, y_1, \ldots, y_n$ is a 1. Then we claim that the setting $v_j = z_j$, $1 \leq j \leq n$, satisfies the instance of SAT($\mathcal{F}'$). It is easy to see that the constraints $C_i(v_{i_1}, \ldots, v_{i_k})$, $1 \leq i \leq m'$, are satisfied. Now consider a constraint $C_i(v_{i_1}, \ldots, v_{i_{k-1}}) = g(0, v_{i_1}, \ldots, v_{i_{k-1}}) \wedge g(1, v_{i_1}, \ldots, v_{i_{k-1}})$. Since at least one of the variables in the set $w_1, \ldots, w_k$ is a 0 and at least one of the variables in the set $w_1, \ldots, w_{k+1}, y_1, \ldots, y_n$ is 1, we know that both $g(0, z_{i_1}, \ldots, z_{i_{k-1}})$ and $g(1, z_{i_1}, \ldots, z_{i_{k-1}})$ are satisfied, and hence $C_i(v_{i_1}, \ldots, v_{i_{k-1}}) = 1$. Thus the reduced instance of MAX ONES($\mathcal{F}$) has a nonzero satisfying assignment if and only if the instance of SAT($\mathcal{F}'$) is satisfiable. □

7. Classification of MIN CSP.

7.1. Preliminary results. We start with a simple equivalence between the complexity of the (WEIGHTED) MIN CSP problem for a function family and the family of functions obtained by complementing the 0's and 1's in its domain. Recall that for a function f, we defined f^- to be the function $f^-(\mathbf{x}) = f(\mathbf{1} - \mathbf{x})$, and for a function family $\mathcal{F}$, we defined $\mathcal{F}^- = \{f^- \mid f \in \mathcal{F}\}$.

PROPOSITION 7.1. *For every constraint family $\mathcal{F}$,* (WEIGHTED) MIN CSP($\mathcal{F}$) *is AP-reducible to* (WEIGHTED) MIN CSP($\mathcal{F}^-$).

Proof. The reduction substitutes every constraint $f(\mathbf{x})$ from $\mathcal{F}$ with the constraint $f^-(\mathbf{x})$ from $\mathcal{F}^-$. A solution for the latter problem is converted into a solution for the former one by complementing the value of each variable. The transformation preserves the cost of the solution. □

PROPOSITION 7.2. *If $\mathcal{F}$ is decidable, then* WEIGHTED MIN CSP($\mathcal{F}$) *is in* poly-APX *and is AP-reducible to* MIN CSP($\mathcal{F}$).

Proof. Given an instance $\mathcal{I}$ of WEIGHTED MIN ONES($\mathcal{F}$) with constraints $C_1, \ldots, C_m$ sorted in order of decreasing weight $w_1 \geq \cdots \geq w_m$. Let j be the largest index such that the constraints $C_1, \ldots, C_j$ are simultaneously satisfiable. Notice that j is computable in polynomial time and an assignment $\mathbf{a}$ satisfying $C_1, \ldots, C_j$ is computable in polynomial time. Then the solution $\mathbf{a}$ is an m-approximate solution to $\mathcal{I}$, since every solution must fail to satisfy at least one of the constraints $C_1, \ldots, C_{j+1}$ and thus have an objective of at least w_{j+1}, while $\mathbf{a}$ achieves an objective of at most $\sum_{i=j+1}^{m} w_i \leq m w_{j+1}$. Thus we conclude that WEIGHTED MIN CSP($\mathcal{F}$) is in poly-APX. The second part of the proposition follows by Lemma 3.11. □

7.2. Containment results (algorithms) for MIN CSP. We now show the containment results described in Theorem 2.13. Most results described here are simple containment results which follow easily from the notion of a "basis." The more interesting result here is a constant factor approximation algorithm for IHS-B which is presented in Lemma 7.3.

Recall that the classes contained in PO have already been dealt with in section 5.1. We now move on to APX-containment results.

LEMMA 7.3. *If $\mathcal{F} \subseteq \mathcal{F}_{\text{IHS}}$, then* WEIGHTED MIN CSP($\mathcal{F}$) $\in$ APX.

Proof. By Propositions 3.4 and 7.1 it suffices to prove the lemma for the problem WEIGHTED MIN CSP(IHS-B), where IHS-$B = \{\text{OR}_k | k \in [B]\} \cup \{\text{OR}_{2,1}, F\}$. We will show that for every B, WEIGHTED MIN CSP(IHS-B) is $B+1$-approximable.

Given an instance $\mathcal{I}$ of WEIGHTED MIN CSP(IHS-B) on variables $x_1, \ldots, x_n$ with constraints $C_1, \ldots, C_m$ with weights $w_1, \ldots, w_m$, we create a linear program on variables $y_1, \ldots, y_n$ (corresponding to the Boolean variables $x_1, \ldots, x_n$) and variables $z_1, \ldots, z_m$ (corresponding to the constraints $C_1, \ldots, C_m$). For every constraint C_j in

the instance $\mathcal{I}$ we create an LP constraint using the following transformation rules:

$$\begin{array}{lcll} C_j & : & x_{i_1} \bigvee \cdots \bigvee x_{i_k} \text{ for } k \le B & \rightarrow \quad z_j + y_{i_1} + \cdots + y_{i_k} \ge 1, \\ C_j & : & \neg x_{i_1} \bigvee x_{i_2} & \rightarrow \quad z_j + (1 - y_{i_1}) + y_{i_2} \ge 1, \\ C_j & : & \neg x_{i_1} & \rightarrow \quad z_j + (1 - y_{i_1}) \ge 1. \end{array}$$

In addition we add the constraints $0 \le z_j, y_i \le 1$ for every i, j. It may be verified that any integer solution to the above LP corresponds to an assignment to the MIN CSP problem with the variable z_j set to 1 if the constraint C_j is not satisfied. Thus the objective function for the LP is to minimize $\sum_j w_j z_j$.

Given any feasible solution vector $y_1, \ldots, y_n, z_1, \ldots, z_m$ to the LP above, we show how to obtain a 0/1 vector $y_1'', \ldots, y_n'', z_1'', \ldots, z_m''$ that is also feasible such that $\sum_j w_j z_j'' \le (B+1) \sum_j w_j z_j$.

First we set $y_i' = \min\{1, (B+1)y_i\}$ and $z_j' = \min\{1, (B+1)z_j\}$. Observe that the vector $y_1', \ldots, y_n', z_1', \ldots, z_m'$ is also feasible and gives a solution of value at most $(B+1)\sum_j w_j z_j$. We now show how to get an *integral* solution whose value is at most $\sum_j w_j z_j' \le (B+1)\sum_j w_j z_j$. For this part we first set $y_i'' = 1$ if $y_i' = 1$ and $z_j'' = 1$ if $z_i' = 1$. Now we remove every constraint in the LP that is made redundant. Notice in particular that every constraint of type $z_j + y_{i_1} + \cdots + y_{i_k} \ge 1$ is now redundant (either z_j'' or one of the y_i'''s has already been set to 1, and hence the constraint will be satisfied by any assignment to the remaining variables). We now observe that, on the remaining variables, the LP constructed above reduces to the following:

$$\begin{array}{lcll} \text{Minimize} & \sum_j w_j z_j & & \\ \text{Subject to} & y_{i_2} - y_{i_1} + z_j & \ge & 0, \\ & y_{i_2} + z_j & \ge & 1, \\ & -y_{i_1} + z_j & \ge & 0 \end{array}$$

with the y_i''s and z_j''s forming a feasible solution to the above LP. Notice further that every z_j occurs in at most one constraint above. Thus the above LP represents s-t min-cut problem and therefore has an optimal integral solution. We set z_j'''s and y_i'' to such an integral optimal solution. Notice that the solution thus obtained is integral and satisfies $\sum_j w_j z_j'' \le \sum_j w_j z_j' \le (B+1)\sum_j w_j z_j$. ∎

LEMMA 7.4. *For any family* $\mathcal{F} \subseteq \mathcal{F}_{2A}$, WEIGHTED MIN CSP($\mathcal{F}$) *A-reduces to* MIN CSP(XOR).

Proof. First we will argue that the family $\mathcal{F}' = \{\text{XOR}, T, F\}$ perfectly implements $\mathcal{F}$. By Proposition 3.4 it suffices to implement the basic width-2 affine functions, namely, the functions XOR, XNOR, T, and F. Every function except XNOR is already present in $\mathcal{F}'$ and by Proposition 3.3 XOR perfectly implements XNOR.

We conclude by observing that the family {XOR} is neither 0-valid nor 1-valid and hence, by Lemma 5.7, WEIGHTED MIN CSP($\mathcal{F}'$) A-reduces to WEIGHTED MIN CSP(XOR). Finally the weights can be removed using Proposition 7.2. ∎

Lemmas 7.5–7.7 show reducibility to MIN 2CNF DELETION, NEAREST CODEWORD, and MIN HORN DELETION.

LEMMA 7.5. *For any family* $\mathcal{F} \subseteq \mathcal{F}_{2CNF}$, *the family* $\{\text{OR}, \text{NAND}\} \stackrel{p}{\Longrightarrow} \mathcal{F}$ *and hence* WEIGHTED MIN CSP($\mathcal{F}$)$\le_A$ MIN 2CNF DELETION.

Proof. Again it suffices to consider the basic constraints of $\mathcal{F}$ and this is some subset of

$$\{\text{OR}_{2,0}, \text{OR}_{2,1}, \text{OR}_{2,2}, T, F\}.$$

The family $\{\mathrm{OR}, \mathrm{NAND}\}$ contains the first and the third functions. Since it contains a non-0-valid function, a non-1-valid function and a non-C-closed function, it can also implement T and F (by Lemma 4.6). This leaves the function $\mathrm{OR}_{2,1}$ which is implemented by the constraints $\mathrm{NAND}(x, z_{\mathrm{AUX}})$ and $\mathrm{OR}(y, z_{\mathrm{AUX}})$ (on the variables x and y). The A-reduction now follows from Lemma 3.10. □

LEMMA 7.6. *For any family $\mathcal{F} \subseteq \mathcal{F}_{\mathrm{A}}$, the family $\{\mathrm{XOR}_3, \mathrm{XNOR}_3\}$ perfectly implements every function in $\mathcal{F}$. Thus* WEIGHTED MIN CSP$(\mathcal{F}) \leq_{\mathrm{A}}$ NEAREST CODEWORD.

Proof. It suffices to show implementation of the basic affine constraints, namely, constraints of the form XNOR_p and XOR_q for every $p, q \geq 1$. We focus on the former type, as the implementation of the latter is analogous. First, we observe that the constraint $\mathrm{XNOR}(x_1, x_2)$ is perfectly implemented by the constraints $\{\mathrm{XNOR}_3(x_1, x_2, z_1), \mathrm{XNOR}_3(x_1, x_2, z_2), \mathrm{XNOR}_3(x_1, x_2, z_3), \mathrm{XNOR}_3(z_1, z_2, z_3)\}$. Next, the constraint $F(x_1)$ can be perfectly implemented by $\{\mathrm{XNOR}(x_1, z_1), \mathrm{XNOR}(x_1, z_2), \mathrm{XNOR}(x_1, z_3), \mathrm{XNOR}_3(z_1, z_2, z_3)\}$. Finally, the constraint $\mathrm{XNOR}_p(x_1, \ldots, x_p)$ for any $p > 3$ can be implemented as follows. We introduce the following set of constraints using the auxiliary variables $z_1, z_2 \ldots, z_{p-2}$ and the set of constraints $\{\mathrm{XNOR}_3(x_1, x_2, z_1), \mathrm{XNOR}_3(z_1, x_3, z_2), \mathrm{XNOR}_3(z_2, x_4, z_3), \ldots, \mathrm{XNOR}_3(z_{p-2}, x_{p-1}, x_p)\}$ □

LEMMA 7.7. *For any family $\mathcal{F} \subseteq \mathcal{F}_{\mathrm{WP}}$, we have $\{\mathrm{OR}_{3,1}, T, F\} \overset{p}{\Longrightarrow} \mathcal{F}$ and thus* WEIGHTED MIN CSP$(\mathcal{F}) \leq_{\mathrm{A}}$ MIN HORN DELETION.

Proof. As usual, it suffices to perfectly implement every function in the basis $\{\mathrm{OR}_k \mid k \geq 1\} \cup \{\mathrm{OR}_{k,1} \mid k \geq 1\}$. The constraint $\mathrm{OR}(x, y)$ is implemented by the constraints $\mathrm{OR}_{3,1}(a, x, y)$ and $T(a)$. $\mathrm{OR}_{2,1}(x, y)$ is implemented by $\mathrm{OR}_{3,1}(x, y, a)$ and $F(a)$. The implementation of $\mathrm{OR}_3(x, y, z)$ is $\mathrm{OR}(x, a)$ and $\mathrm{OR}_{3,1}(a, y, z)$ (the constraint $\mathrm{OR}(x, a)$, in turn, may be implemented with the already shown method). Thus every k-ary constraint for $k \leq 3$ can be perfectly implemented by the family $\{\mathrm{OR}_{3,1}, T, F\}$). For $k \geq 4$, we use the textbook reduction from SAT to 3-SAT (see, e.g., [19, p. 49]) and we observe that when applied to k-ary weakly positive constraints it yields a perfect implementation using only 3-ary weakly positive constraints. □

To conclude this section we describe the trivial approximation algorithms for NEAREST CODEWORD and MIN HORN DELETION. They follow easily from Proposition 7.2 and the fact that both families are decidable.

COROLLARY 7.8 (to Proposition 7.2). MIN HORN DELETION *and* NEAREST CODEWORD *are in* poly-APX.

7.3. Hardness results (reductions) for MIN CSP.

LEMMA 7.9 (APX-hardness). *If $\mathcal{F} \not\subseteq \mathcal{F}'$, for $\mathcal{F}' \in \{\mathcal{F}_0, \mathcal{F}_1, \mathcal{F}_{2\mathrm{M}}\}$, then* MIN CSP$(\mathcal{F})$ *is* APX*-hard.*

Proof. The proof essentially follows from Lemma 5.8 in combination with Proposition 3.7. We show that for every $\mathcal{F}$, MAX CSP$(\mathcal{F})$ AP-reduces to MIN CSP$(\mathcal{F})$. Let $\mathcal{I}$ be an instance of MAX CSP$(\mathcal{F})$ on n variables and m constraints. Let $\mathbf{x}'$ be a solution satisfying m/k constraints that can be found in polynomial time (by Proposition 3.7). Let $\mathbf{x}''$ be an r-approximate solution to the same instance $\mathcal{I}$ viewed as an instance of MIN CSP$(\mathcal{F})$. If OPT is the optimum solution to the maximization problem $\mathcal{I}$, then $\mathbf{x}''$ satisfies at least $m - r(m - \mathrm{OPT}) = r\mathrm{OPT} - (r-1)m$ constraints. Thus the better of the two solutions is an r'-approximate solution to the instance $\mathcal{I}$ of MAX CSP$(\mathcal{F})$, where

$$\begin{aligned} r' &\le \frac{\text{OPT}}{\max\{m/k, r\text{OPT} - (r-1)m\}} \\ &\le \frac{((r-1)k+1)\text{OPT}}{(r-1)k(m/k) + r\text{OPT} - (r-1)m} \\ &= \frac{1+(r-1)k}{r} \\ &\le 1 + (r-1)k. \end{aligned}$$

Thus MAX CSP($\mathcal{F}$) AP-reduces to MIN CSP($\mathcal{F}$). The lemma follows from the APX-hardness of MAX CSP($\mathcal{F}$) (Lemma 5.8). □

LEMMA 7.10 (MIN UNCUT-hardness). *If $\mathcal{F} \not\subseteq \mathcal{F}'$, for $\mathcal{F}' \in \{\mathcal{F}_0, \mathcal{F}_1, \mathcal{F}_{2M}, \mathcal{F}_{IHS}\}$, and $\mathcal{F} \subseteq \mathcal{F}_{2A}$, then* MIN CSP($\mathcal{F}$) *is* MIN UNCUT*-hard.*

Proof. Recall that MIN UNCUT-hardness requires that MIN CSP(XOR) be A-reducible to MIN CSP($\mathcal{F}$).

Let $f \in \mathcal{F}$. Consider (all) the minimally dependent sets of f. By Lemma 4.22 all such sets are of cardinality at most 2. For a minimally dependent set $\{i, j\}$ let

$$f_{i,j}(x_i, x_j) \stackrel{\text{def}}{=} \exists x_1, \ldots, x_{i-1}, x_{i+1}, \ldots, x_{j-1}, x_{j+1}, \ldots, x_k \text{ s.t. } f(x_1, \ldots, x_k).$$

By Lemma 4.17 all the $f_{i,j}$'s are affine and thus must be one of the functions $T(x_i)$, $F(x_i)$, XOR(x_i, x_j), or XNOR(x_i, x_j). Furthermore, f can be expressed as the conjunction of $f_{i,j}$'s over all the minimally dependent sets. It follows that there exist i, j such that $f_{i,j}(x_i, x_j) = \text{XOR}(x_i, x_j)$. (Otherwise f would be a conjunction of T, F and XNOR functions, all of which are in $\mathcal{F}_{IHS}$, and thus f would also be in $\mathcal{F}_{IHS}$.) Thus we conclude that f implements XOR and by Lemma 3.10 we conclude that MIN CSP(XOR) is A-reducible to MIN CSP($\mathcal{F}$) as desired. □

For the MIN 2CNF DELETION-hardness proof, we need the following three simple lemmas.

LEMMA 7.11. *If f is a* 2CNF *function which is not width-2 affine, then $f \stackrel{p}{\Longrightarrow} \text{OR}_{2,l}$ for some $l \in \{0, 1, 2\}$.*

Proof. For $i, j \in [k]$, let

$$f_{i,j}(x_i, x_j) \stackrel{\text{def}}{=} \exists x_1, \ldots, x_{i-1}, x_{i+1}, \ldots, x_{j-1}, x_{j+1}, \ldots, x_k \text{ s.t. } f(x_1, \ldots, x_k).$$

Recall that if f can be expressed as the conjunction of $f_{i.j}$'s over all its maxterms and by Lemma 4.21, all the maxterms of f's have at most two literals in them. Thus $f(x_1, \ldots, x_k)$ can be expressed as $\bigwedge_{i,j \in [k]} f_{i,j}(x_i, x_j)$. It follows that some $f_{i,j}$ must be one of the functions $\text{OR}_{2,0}$, $\text{OR}_{2,1}$, or $\text{OR}_{2,2}$ (all other functions on two variables are affine). Thus existentially quantifying over all variables other than x_i and x_j, f perfectly implements $\text{OR}_{2,l}$ for some $l \in \{0, 1, 2\}$. □

LEMMA 7.12. *If $f \in \mathcal{F}_{2CNF}$ is not in IHS-B, then $f \stackrel{p}{\Longrightarrow}$ XOR.*

Proof. Once again we use the fact that f can be expressed as $\bigwedge_{i,j \in [k]} f_{i,j}(x_i, x_j)$, where $f_{i,j}$ is the function obtained from f by existentially quantifying over all variables other than x_i and x_j. It follows that one of the $f_{i,j}$'s must be NAND or XOR, since all the other functions on two variables are in IHS-$B+$. In the latter case we are done; otherwise we use the fact that f is not in IHS-$B-$ to conclude that f perfectly implements OR or XOR. In the latter case again we are done; otherwise we use the fact that f perfectly implements both the functions NAND and OR, and that NAND(x, y) and OR(x, y) perfectly implement XOR(x, y) to conclude that in this case too, the function f perfectly implements XOR. □

LEMMA 7.13. *If f is the function $\mathrm{OR}_{2,l}$ for some $l \in \{0,1,2\}$, then $\{f, \mathrm{XOR}\} \stackrel{p}{\Longrightarrow} \{\mathrm{OR}, \mathrm{NAND}\}$.*

Proof. The lemma follows from the fact that the function XOR essentially allows us to negate literals. For example, given the function $\mathrm{OR}_{2,1}(x,y)$ and XOR, the applications $\mathrm{OR}_{2,1}(x, z_{Aux})$ and $\mathrm{XOR}(z_{Aux}, y)$ perfectly and strictly implement the function $\mathrm{NAND}(x,y)$. Other implementations are obtained similarly. □

LEMMA 7.14 (MIN 2CNF DELETION-hardness). *If $\mathcal{F} \not\subseteq \mathcal{F}'$ for $\mathcal{F}' \in \{\mathcal{F}_0, \mathcal{F}_1, \mathcal{F}_{2\mathrm{M}}, \mathcal{F}_{\mathrm{IHS}}, \mathcal{F}_{2\mathrm{A}}\}$, and $\mathcal{F} \subseteq \mathcal{F}_{2\mathrm{CNF}}$, then* MIN CSP($\mathcal{F}$) *is* MIN 2CNF DELETION*-hard.*

Proof. By Lemmas 7.11 and 7.12, $\mathcal{F}$ implements one of the functions $\mathrm{OR}_{2,l}$ for $l \in \{0,1,2\}$ and the function XOR. By Lemma 7.13 this suffices to implement the family $\{\mathrm{NAND}, \mathrm{OR}\}$. Thus by Lemma 3.10 we conclude that MIN CSP($\{\mathrm{OR}, \mathrm{NAND}\}$) A-reduces to MIN CSP($\mathcal{F}$). □

LEMMA 7.15. *If $\mathcal{F} \subseteq \mathcal{F}_{\mathrm{A}}$, but $\mathcal{F} \not\subseteq \mathcal{F}'$ for any $\mathcal{F}' \in \{\mathcal{F}_0, \mathcal{F}_1, \mathcal{F}_{2\mathrm{M}}, \mathcal{F}_{\mathrm{IHS}}, \mathcal{F}_{2\mathrm{A}}\}$, then* MIN CSP($\mathcal{F}$) *is* NEAREST CODEWORD*-hard.*

Proof. By Lemma 4.18 we know that in this case $\mathcal{F}$ perfectly implements the constraint $x_1 \oplus \cdots \oplus x_p = b$ for some $p \geq 3$ and some $b \in \{0,1\}$. Thus the family $\mathcal{F} \cup \{T, F\}$ implements the functions $x \oplus y \oplus z = 0, x \oplus y \oplus z = 1$. Thus NEAREST CODEWORD =MIN CSP($\{x \oplus y \oplus z = 0, x \oplus y \oplus z = 1\}$ is A-reducible to MIN CSP($\mathcal{F} \cup \{F, T\}$). Since $\mathcal{F}$ is neither 0-valid nor 1-valid, we can use Lemma 5.7 to conclude that MIN CSP($\mathcal{F}$) is NEAREST CODEWORD-hard. □

The next lemma describes the best known hardness of approximation for the NEAREST CODEWORD problem. The result relies on an assumption stronger than NP ≠ P.

LEMMA 7.16 (see [2]). *For every $\epsilon > 0$,* NEAREST CODEWORD *is hard to approximate to within a factor of $\Omega(2^{\log^{1-\epsilon} n})$ unless* NP *has deterministic algorithms running in time $n^{\log^{O(1)} n}$.*

Proof. The required hardness of the NEAREST CODEWORD problem is shown by Arora et al. [2]. The NEAREST CODEWORD problem, as defined in Arora et al., works with the following problem: Given an $m \times n$ matrix A and an m-dimensional vector b, find an n-dimensional vector x which minimizes the Hamming distance between Ax and b. Thus this problem can be expressed as a MIN CSP problem with m affine constraints over n-variables. The only technical point to be noted is that these constraints have unbounded arity. In order to get rid of such long constraints, we replace a constraint of the form $x_1 \oplus \cdots \oplus x_l = 0$ into $l-2$ constraints $x_1 \oplus x_2 \oplus z_1 = 0$, $z_1 \oplus x_3 \oplus z_2 = 0$, etc. on auxiliary variables $z_1, \ldots, z_{l-3}$. (The same implementation was used in Lemma 7.6.) This increases the number of constraints by a factor of at most n but does not change the objective function. Thus if M represents the number of constraints in the new instance of the problem, then the approximation hardness which is $2^{\log^{1-\epsilon} m}$ can be expressed as $2^{\frac{1}{2}\log^{1-\epsilon} M}$ which is still growing faster than, say, $2^{\log^{1-2\epsilon} M}$. Since the result of [2] holds for every positive ϵ, we still get the desired result claimed above. □

It remains to see the MIN HORN DELETION-hard case. We will have to draw some nontrivial consequences from the fact that a family is not IHS-B.

LEMMA 7.17. *Assume $\mathcal{F} \not\subseteq \mathcal{F}_{\mathrm{IHS}}$ and either $\mathcal{F} \subseteq \mathcal{F}_{\mathrm{WP}}$ or $\mathcal{F} \subseteq \mathcal{F}_{\mathrm{WN}}$. Then $\mathcal{F}$ contains a function that is not C-closed.*

Proof. Let f be a C-closed function in $\mathcal{F}_{\mathrm{WP}}$ ($\mathcal{F}_{\mathrm{WN}}$). We claim that all of f's maxterms must be of the form $T(x_i)$, $F(x_i)$, or $\mathrm{OR}_{2,1}(x_i, x_j)$. If not, then since f is C-closed, the maxterm involving the complementary literals is also a maxterm of f,

x1 \ x2 x3	00	01	11	10
0	1	A	B	D
1	0	1	C	1

FIG. 3. *Truth table of the constraint f_2.*

but the complementary maxterm is not weakly positive (and by Lemma 4.20 every maxterm of f must be weakly positive). However, if all of f's maxterms are of the form $T(x_i)$, $F(x_i)$, or $\mathrm{OR}_{2,1}(x_i, x_j)$, then f is in IHS-B. The lemma follows from the fact that $\mathcal{F} \not\subseteq \mathcal{F}_{\mathrm{IHS}}$. □

LEMMA 7.18. *If f is a weakly positive function not expressible as IHS-$B+$, then $\{f, T, F\} \stackrel{p}{\Longrightarrow} \mathrm{OR}_{3,1}$. If f is a weakly negative function not expressible as IHS-$B-$, then $\{f, T, F\} \stackrel{p}{\Longrightarrow} \mathrm{OR}_{3,2}$.*

Proof. Let f be a weakly positive function. By Lemma 4.20 all maxterms of f are weakly positive. Since f is not IHS-$B+$, f must have a maxterm of the form $(\neg x_1 \bigvee x_2 \bigvee \cdots \bigvee x_p)$ for some $p \geq 3$. We first show that $\{f, F\}$ can perfectly implement the function XNOR. To get the former, consider the function

$$f_1(x_1, x_2) \stackrel{\mathrm{def}}{=} \exists x_{p+1}, \ldots, x_k \text{ s.t. } f(x_1, x_2, 0^{p-2}, x_{p+1}, \ldots, x_k).$$

The function f_1 satisfies the properties $f_1(10) = 0$, $f_1(00) = f_1(11) = 1$. Thus f_1 is either the function XNOR or $\mathrm{OR}_{2,1}$. Notice that the constraints $f(x_1, \ldots, x_k)$ and $F(x_i)$, $i \in \{3, \ldots, p\}$, perfectly implement f_1. Thus $\{f, F\}$ perfectly implement either the function XNOR or $\mathrm{OR}_{2,1}$. In the former case, we have the claim and in the latter case we use the fact that the constraints $\mathrm{OR}_{2,1}(x, y)$ and $\mathrm{OR}_{2,1}(y, x)$ perfectly implement $\mathrm{XNOR}(x, y)$.

Next, we show how the family $\{f, T, F, \mathrm{XNOR}\}$ (and hence $\{f, T, F\}$) can perfectly implement $\mathrm{OR}_{2,1}$. To do so, we consider the function

$$f_2(x_1, x_2, x_3) \stackrel{\mathrm{def}}{=} \exists x_{p+1}, \ldots, x_k \text{ s.t. } f(x_1, x_2, x_3, 0^{p-3}, x_{p+1}, \ldots, x_k).$$

Again $\{f, F\}$ implement f_2 perfectly. By the definition of a maxterm, we find that f_2 satisfies the following properties: $f_2(100) = 0$ and $f_2(000) = f_2(110) = f_2(101) = 1$. Figure 3 gives the truth table for f_2, where the unknown values are denoted by A, B, C, and D. If $C = 0$, then restricting $x_1 = 1$ gives the constraint $\mathrm{XOR}(x_2, x_3)$. However, notice that XOR is not a weakly positive function and by Lemma 4.19 every function obtained by setting some of the variables in a weakly positive function to constants and existentially quantifying over some other subset of variables is a weakly positive function. Thus $C = 1$. If $D = 1$, we implement the function $\mathrm{OR}_{2,1}(x_1, x_2)$ by the constraints $f_2(x_1, x_2, x_3)$ and $F(x_3)$. Otherwise we have $D = 0$, and the constraints $f_2(x_1, x_2, x_3)$ and $\mathrm{XNOR}(x_1, x_3)$ implement the constraint $\mathrm{OR}_{2,1}(x_2, x_1)$.

Finally we conclude by observing that the constraints $f_2(x, z^1, z^2)$, $\mathrm{OR}_{2,1}(z^1, y)$ and $\mathrm{OR}_{2,1}(z^2, z)$, perfectly implement the constraint $\mathrm{OR}_{3,1}(x, y, z)$.

This completes the proof for the first part. The proof if f is weakly negative is similar. □

LEMMA 7.19 (the MIN HORN DELETION-hard case). *If $\mathcal{F} \not\subseteq \mathcal{F}'$ for any $\mathcal{F}' \in \{\mathcal{F}_0, \mathcal{F}_1, \mathcal{F}_{2\mathrm{M}}, \mathcal{F}_{\mathrm{IHS}}, \mathcal{F}_{2\mathrm{A}}, \mathcal{F}_{2\mathrm{CNF}}\}$, and either $\mathcal{F} \subseteq \mathcal{F}_{\mathrm{WP}}$ or $\mathcal{F} \subseteq \mathcal{F}_{\mathrm{WN}}$, then* WEIGHTED MIN CSP($\mathcal{F}$) *is* MIN HORN DELETION*-hard.*

Proof. From Lemma 7.18 we have that either MIN CSP($\{\mathrm{OR}_{3,1}, T, F\}$ or MIN CSP($\{\mathrm{OR}_{3,2}, T, F\}$ is A-reducible to MIN CSP($\mathcal{F}$). Furthermore, since $\mathcal{F}$ is not 0-valid or 1-valid we have that MIN CSP($\mathcal{F} \cup \{T, F\}$) is A-reducible to MIN CSP($\mathcal{F}$). The lemma follows by an application of Proposition 7.1 which shows that the problems MIN CSP($\{\mathrm{OR}_{3,1}, T, F\}$) A-reduces to MIN CSP($\{\mathrm{OR}_{3,2}, T, F\}$). ∎

To show the hardness of MIN HORN DELETION we define a variant of the "label cover" problem. The original definition from [2] used a different objective function. Our variant is similar to the one used by Amaldi and Kann [1] under the name TOTAL LABEL COVER.

DEFINITION 7.20 (TOTAL LABEL COVER$_p$).

INSTANCE. *An instance is described by sets $\mathcal{R}$, $\mathcal{Q}$, and $\mathcal{A}$ and by p functions (given by their tables) $Q_1, \ldots, Q_p : \mathcal{R} \to \mathcal{Q}$ and a function* ACC $: \mathcal{R} \times (\mathcal{A})^p \to \{0, 1\}$.

FEASIBLE SOLUTIONS. *A solution is a collection of p functions $A_1, \ldots, A_p : \mathcal{Q} \to 2^{\mathcal{A}}$. The solution is feasible if for every $R \in \mathcal{R}$, there exists $a_1 \in A_1(Q_1(R)), \ldots, a_p \in A_p(Q_p(R))$ such that* ACC$(R, a_1, \ldots, a_p) = 1$.

OBJECTIVE. *The objective is to minimize* $\sum_{i=1}^{p} \sum_{q \in Q} |A_i(q)|$.

In Appendix A, we show how results from interactive proofs imply the hardness of approximating MIN LABEL-COVER to within a factor of $2^{\log^{1-\epsilon} n}$. We now use this result to show that hardness of MIN HORN DELETION.

LEMMA 7.21. *For every $\epsilon > 0$,* MIN HORN DELETION *is* NP*-hard to approximate to within a factor of $2^{\log^{1-\epsilon} n}$.*

Proof. Let p be such that MIN LABEL-COVER$_p$ is NP-hard to approximate to within a factor of $2^{\log^{1-\epsilon} n}$. (By Lemma A.3 such a p exists.) We now reduce MIN LABEL-COVER$_p$ to MIN HORN DELETION.

Let $(Q_1, \ldots, Q_p, \mathrm{ACC})$ be an instance of MIN LABEL-COVER$_p$, where $Q_i : \mathcal{R} \to \mathcal{Q}$ and ACC $: \mathcal{R} \times (\mathcal{A})^p \to \{0, 1\}$. For any $R \in \mathcal{R}$, we define $Acc(R) = \{(a_1, \ldots, a_p) : V(R, a_1, \ldots, a_p) = 1\}$.

We now describe the reduction. For any $R \in \mathcal{R}$, $a_1, \ldots, a_p \in \mathcal{A}$, we have a variable $v_{R,a_1,\ldots,a_p}$ whose intended meaning is the value of ACC$(R, a_1, \ldots, a_p)$. Moreover, for every $i \in [p]$, $Q \in \mathcal{Q}$, and $a \in A_i$ we have a variable $x_{i,Q,a}$ with the intended meaning being that its value is 1 if and only if $a \in A_i(Q)$. For any $x_{i,Q,a}$ we have the weight-one constraint $\neg x_{i,q,a}$. The following constraints (each with weight $(p \times |\mathcal{Q}| \times |\mathcal{A}|)$) enforce the variables to have their intended meaning. Due to their weight, it is never convenient to contradict them.

$$\begin{array}{ll} \forall R \in \mathcal{R}: & \bigvee_{(a_1,\ldots,a_p) \in Acc(R)} v_{R,a_1,\ldots,a_p} \\ \forall R \in \mathcal{R}, a_1, \ldots, a_p \in \mathcal{A}, i \in [p]: & v_{R,a_1,\ldots,a_p} \Rightarrow x_{i,Q_i(R),a_i}. \end{array}$$

The constraints of the first kind can be perfectly implemented with OR_3 and $\mathrm{OR}_{3,1}$ (see Lemma 7.7). It can be checked that this is an AP-reduction from MIN LABEL-COVER$_p$ to MIN HORN DELETION and thus the lemma follows. ∎

8. MIN ONES classification.

8.1. Preliminaries: MIN ONES vs. MIN CSP.

We start with the following easy relation between MIN CSP and MIN ONES problems. Recall that a family $\mathcal{F}$ is decidable if membership in SAT($\mathcal{F}$) is decidable in polynomial time.

PROPOSITION 8.1. *For any decidable constraint family $\mathcal{F}$,* WEIGHTED MIN ONES($\mathcal{F}$) *AP-reduces to* WEIGHTED MIN CSP($\mathcal{F} \cup \{F\}$).

Proof. Let $\mathcal{I}$ be an instance of WEIGHTED MIN ONES($\mathcal{F}$) over variables $x_1, \ldots, x_n$ with weights $w_1, \ldots, w_n$. Let $w_{\max}$ be the largest weight. We construct an instance $\mathcal{I}'$ of WEIGHTED MIN CSP($\mathcal{F} \cup \{F\}$) by leaving the constraints of $\mathcal{I}$ (each with weight $nw_{\max}$) and adding a constraint $F(x_i)$ of weight w_i for any $i = 1, \ldots, n$. Notice that whenever $\mathcal{I}$ is feasible, the optimum value for $\mathcal{I}$ equals the optimum value for $\mathcal{I}'$. Given an r-approximate solution to $\mathbf{x}$ to $\mathcal{I}'$, we check to see if $\mathcal{I}$ is feasible and if so find any feasible solution $\mathbf{x}'$ and output solution (from among $\mathbf{x}$ and $\mathbf{x}'$) that achieves a lower objective. It is clear that the solution is at least an r-approximate solution if $\mathcal{I}$ is feasible. □

Reducing a MIN CSP problem to a MIN ONES problem is slightly less general.

PROPOSITION 8.2. *For any function f, let f' and f'' denote the functions $f'(\mathbf{x}, y) = \mathrm{OR}(f(\mathbf{x}), y)$ and $f''(\mathbf{x}, y) = \mathrm{XOR}(f(\mathbf{x}), y)$, respectively. If constraint families $\mathcal{F}$ and $\mathcal{F}'$ are such that for every $f \in \mathcal{F}$, f' or f'' is in $\mathcal{F}'$, then* WEIGHTED MIN CSP($\mathcal{F}$) *AP-reduces to* WEIGHTED MIN ONES($\mathcal{F}'$).

Proof. Given an instance $\mathcal{I}$ of WEIGHTED MIN CSP($\mathcal{F}$) we create an instance $\mathcal{I}'$ of WEIGHTED MIN ONES($\mathcal{F}'$) as follows: For every constraint C_j we introduce an auxiliary variable y_j. The variable takes the same weight as the constraint C_j in $\mathcal{I}$. The original variables are retained with weight zero. If the constraint $C_j(\mathbf{x}) \bigvee y_j$ is a constraint of $\mathcal{F}'$ we apply that constraint; otherwise we apply the constraint $C_j(\mathbf{x}) \oplus y = 1$. Given an assignment to the variables of $\mathcal{I}$, notice that by setting $y_j = \neg C_j$, we get a feasible solution to $\mathcal{I}'$ with the same objective value; conversely, a feasible solution to $\mathcal{I}'$ when projected onto the variables $\mathbf{x}$ gives a solution with the same value to the objective function of $\mathcal{I}$. This shows that the optimum value to $\mathcal{I}'$ equals that of $\mathcal{I}$ and that an r-approximate solution to $\mathcal{I}'$ projects to give an r-approximate solution to $\mathcal{I}$. □

Finally the following easy proposition is invoked at a few places.

PROPOSITION 8.3. *If $\mathcal{F} \Longrightarrow f$, then $\mathcal{F}^- \Longrightarrow f^-$.*

8.2. Containment results for MIN ONES.

LEMMA 8.4 (PO containment). *If $\mathcal{F} \subseteq \mathcal{F}'$ for some $\mathcal{F}' \in \{\mathcal{F}_0, \mathcal{F}_{\mathrm{WN}}, \mathcal{F}_{\mathrm{2A}}\}$, then* WEIGHTED MIN ONES($\mathcal{F}$) *is solvable exactly in polynomial time.*

Proof. The proof follows from Lemma 6.5 and from the observation that for any family $\mathcal{F}$, solving WEIGHTED MIN ONES($\mathcal{F}$) to optimality reduces to solving WEIGHTED MAX ONES($\mathcal{F}^-$) to optimality. □

LEMMA 8.5. *If $\mathcal{F} \subseteq \mathcal{F}'$ for $\mathcal{F}' \in \{\mathcal{F}_{\mathrm{2CNF}}, \mathcal{F}_{\mathrm{IHS}}\}$, then* WEIGHTED MIN ONES($\mathcal{F}$) *is in* APX.

Proof. For the case $\mathcal{F} \subseteq \mathcal{F}_{\mathrm{2CNF}}$, a 2-approximate algorithm is given by Hochbaum et al. [25].

Now consider the case $\mathcal{F} \subseteq \mathcal{F}_{\mathrm{IHS}}$. From Proposition 3.4 it is sufficient to consider only basic IHS-B constraints. Since IHS-$B-$ constraints are weakly negative, we will restrict ourselves to basic IHS-$B+$ constraints. We use linear programming relaxations and deterministic rounding. Let k be the maximum arity of a function in $\mathcal{F}$; we will give a k-approximate algorithm. Let $\phi = \{C_1, \ldots, C_m\}$ be an instance of WEIGHTED MIN ONES($\mathcal{F}$) over variable set $X = \{x_1, \ldots, x_n\}$ with weights $w_1, \ldots, w_n$. The following is an integer linear programming formulation of finding the minimum weight satisfying assignment for ϕ.

$$\begin{array}{lll}
\text{Minimize} & \sum_i w_i y_i, & \\
\text{Subject to} & & \\
& y_{i_1} + \cdots + y_{i_h} \geq 1 & \forall (x_{i_1} \bigvee \cdots \bigvee x_{i_h}) \in \phi, \\
& y_{i_1} - y_{i_2} \geq 0 & \forall (x_{i_1} \bigvee \neg x_{i_2}) \in \phi, \qquad \text{(SCB)} \\
& y_i = 0 & \forall \neg x_i \in \phi, \\
& y_i = 1 & \forall x_i \in \phi, \\
& y_i \in \{0,1\} & \forall i \in \{1,\ldots,n\}.
\end{array}$$

Now consider the linear programming relaxation obtained by relaxing the $y_i \in \{0,1\}$ constraints into $0 \leq y_i \leq 1$. We first find an optimum solution $\mathbf{y}^*$ for the relaxation, and then we define a 0/1 solution by setting $y_i = 0$ if $y_i^* < 1/k$ and $y_i = 1$ if $y_i^* \geq 1/k$. It is easy to see that this rounding increases the cost of the solution at most k times and that the obtained solution is feasible for (SCB). □

LEMMA 8.6. *For any $\mathcal{F} \subseteq \mathcal{F}_{\mathrm{A}}$,* WEIGHTED MIN ONES($\mathcal{F}$) *is A-reducible to* NEAREST CODEWORD.

Proof. From Lemmas 7.6 and 3.9 we have that WEIGHTED MIN ONES($\mathcal{F}$) is A-reducible to WEIGHTED MIN ONES($\{\mathrm{XNOR}_3, \mathrm{XOR}_3\}$). From Proposition 8.1, we have that WEIGHTED MIN ONES($\mathcal{F}$) A-reduces to WEIGHTED MIN CSP($\{\mathrm{XOR}_3$, $\mathrm{XNOR}_3, F\}$). Notice further that the family $\{\mathrm{XNOR}_3, \mathrm{XOR}_3\}$ can implement F (by Lemma 4.6). Thus we have that WEIGHTED MIN ONES($\mathcal{F}$) A-reduces to WEIGHTED MIN CSP($\{\mathrm{XOR}_3, \mathrm{XNOR}_3, \}$) = NEAREST CODEWORD. □

LEMMA 8.7. *For any $\mathcal{F} \subseteq \mathcal{F}_{\mathrm{WP}}$,* WEIGHTED MIN ONES($\mathcal{F}$) *AP-reduces to* MIN HORN DELETION.

Proof. The proof follows from the following sequence of assertions:

(1) $\{\mathrm{OR}_{3,1}, T, F\}$ perfectly implements $\mathcal{F}$ (Lemma 7.7).

(2) WEIGHTED MIN ONES($\mathcal{F}$) AP-reduces to WEIGHTED MIN ONES($\{\mathrm{OR}_{3,1}, T, F\}$) (Lemma 3.9).

(3) WEIGHTED MIN ONES($\{\mathrm{OR}_{3,1}, T, F\}$) AP-reduces to WEIGHTED MIN CSP ($\{\mathrm{OR}_{3,1}, T, F\}$) = MIN HORN DELETION (Proposition 8.1). □

PROPOSITION 8.8. *If $\mathcal{F}$ is decidable, then* MIN ONES($\mathcal{F}$) *is in* poly-APX.

Proof. The proposition follows immediately from the fact that in this case it is easy to determine if the input instance is feasible and if so, if the optimum value is zero. If so we output the $\mathbf{0}$ as the solution; otherwise we output any feasible solution. Since the objective is at least 1 and the solution has value at most n, this is an n-approximate solution. □

8.3. Hardness results for MIN ONES. We start by considering the hardest problems first. The case when $\mathcal{F}$ is not decidable is immediate. We move to the case where $\mathcal{F}$ may be 1-valid but not in any other of Schaefer's easy classes.

LEMMA 8.9. *If $\mathcal{F} \not\subseteq \mathcal{F}'$ for any $\mathcal{F}' \in \{\mathcal{F}_0, \mathcal{F}_{2\mathrm{CNF}}, \mathcal{F}_{\mathrm{A}}, \mathcal{F}_{\mathrm{WP}}, \mathcal{F}_{\mathrm{WN}}\}$, then* WEIGHTED MIN ONES($\mathcal{F}$) *is hard to approximate to within any factor, and* MIN ONES($\mathcal{F}$) *is* poly-APX-*hard.*

Proof. We first show how to handle the weighted case. The hardness for the unweighted case will follow easily. Consider a function $f \in \mathcal{F}$ which is not weakly positive. For such an f, there exists assignments $\mathbf{a}$ and $\mathbf{b}$ such that $f(\mathbf{a}) = 1$ and $f(\mathbf{b}) = 0$ and $\mathbf{a}$ is zero in every coordinate where $\mathbf{b}$ is zero. (Such an input pair exists for every nonmonotone function f and every monotone function is also weakly positive.) Now let f' be the constraint obtained from f by restricting it to inputs where $\mathbf{b}$ is one and setting all other inputs to zero. Then f' is a satisfiable function which is not 1-valid. We can now apply Schaefer's theorem [42] to conclude that

SAT($\mathcal{F} \cup \{f'\}$) is hard to decide. We now reduce an instance of deciding SAT($\mathcal{F} \cup \{f'\}$) to approximating WEIGHTED MIN CSP($\mathcal{F}$). Given an instance $\mathcal{I}$ of SAT($\mathcal{F} \cup \{f'\}$) we create an instance which has some auxiliary variables $W_1, \ldots, W_k$ which are all supposed to be zero. This in enforced by giving them very large weights. We now replace every occurrence of the constraint f' in $\mathcal{I}$ by the constraint f on the corresponding variables with the W_i's in place which were set to zero in f to obtain f'. It is clear that if a "small" weight solution exists to the resulting WEIGHTED MIN CSP problem, then $\mathcal{I}$ is satisfiable; otherwise it is not. Thus we conclude it is NP-hard to approximate WEIGHTED MIN CSP to within any bounded factors.

For the unweighted case, it suffices to observe that by using polynomially bounded weights above, we get a poly-APX hardness. Furthermore, one can get rid of weights entirely by replicating variables. □

We may now restrict our attention to function families $\mathcal{F}$ that are 2CNF or affine or weakly positive or weakly negative or 0-valid. In particular, by the containment results shown in the previous section, in all such cases the problem WEIGHTED MIN ONES($\mathcal{F}$) is in poly-APX. We now give a weight-removing lemma which allows us to focus on showing the hardness of the weighted problems.

LEMMA 8.10. *If $\mathcal{F} \subseteq \mathcal{F}'$ for some $\mathcal{F}' \in \{\mathcal{F}_{2\text{CNF}}, \mathcal{F}_{\text{A}}, \mathcal{F}_{\text{WP}}, \mathcal{F}_{\text{WN}}, \mathcal{F}_0\}$, then* WEIGHTED MIN ONES($\mathcal{F}$) *AP-reduces to* MIN ONES($\mathcal{F}$).

Proof. By Lemma 3.11 it suffices to verify that WEIGHTED MIN ONES($\mathcal{F}$) is in poly-APX in all cases. If $\mathcal{F}$ is weakly negative or 0-valid, then this follows from Lemma 8.4. If $\mathcal{F}$ is 2CNF, then this follows from Lemma 8.5. If $\mathcal{F}$ is affine or weakly positive, then it A-reduces to NEAREST CODEWORD or MIN HORN DELETION, respectively, which are in poly-APX by Corollary 7.8. □

Before dealing with the remaining cases, we prove one more lemma that is useful in dealing with MIN ONES problems.

LEMMA 8.11. *For every constraint family $\mathcal{F}$ such that $\mathcal{F} \cup \{F\}$ is decidable,* WEIGHTED MIN ONES($\mathcal{F} \cup \{F\}$) *AP-reduces to* WEIGHTED MIN ONES($\mathcal{F}$).

Proof. Given an instance $\mathcal{I}$ of WEIGHTED MIN ONES($\mathcal{F} \cup \{F\}$) on n variables $x_1, \ldots, x_n$ with weights $w_1, \ldots, w_n$ we create an instance $\mathcal{I}'$ of WEIGHTED MIN ONES($\mathcal{F}$) on the variables $x_1, \ldots, x_n$ using all the constraints of $\mathcal{I}$ that are from $\mathcal{F}$; and for every variable x_i such that $F(x_i)$ is a constraint of $\mathcal{I}$, we increase the weight of the variable x_i to $nw_{\max}$, where $w_{\max}$ is the maximum of the weights $w_1, \ldots, w_n$. As in the proof of Proposition 8.1 we observe that if $\mathcal{I}$ is feasible, then the optima for $\mathcal{I}$ and $\mathcal{I}'$ are equal and given an r-approximate solution to $\mathcal{I}'$ we can find an r-approximate solution to $\mathcal{I}$. Furthermore, since $\mathcal{F} \cup \{F\}$ is decidable, we can decide whether or not $\mathcal{I}$ is feasible. □

We now deal with the affine problems.

LEMMA 8.12. *If $\mathcal{F}$ is affine but not width-2 affine or 0-valid, then* MIN ONES(XOR_3) *is AP-reducible to* WEIGHTED MIN ONES($\mathcal{F}$).

Proof. Notice that since $\mathcal{F}$ is affine, so is $\mathcal{F}^-$. Furthermore, $\mathcal{F}^-$ is neither width-2 affine nor 1-valid. Thus by Lemma 6.10 $\mathcal{F}^-$ perfectly implements either the family $\{\text{XNOR}_3\}$ or the family $\{\text{XOR}, \text{XNOR}_4\}$. Thus, by applying Proposition 8.3, we get that $\mathcal{F}$ implements either XOR_3 or the family $\{\text{XOR}, \text{XNOR}_4\}$. In the former case, we are done (by Lemma 3.9). In the latter case, notice that the constraints $\text{XNOR}_4(x_1, x_2, x_3, x_5)$ and $\text{XOR}(x_4, x_5)$ perfectly implement the constraint $\text{XOR}_4(x_1, x_2, x_3, x_5)$. Thus we conclude that WEIGHTED MIN ONES(XOR_4) is AP-reducible to WEIGHTED MIN ONES($\mathcal{F}$). Finally we use Lemma 8.11 to conclude that the family WEIGHTED MIN ONES($\mathcal{F}$)($\{\text{XOR}\}|_0$) is AP-reducible to WEIGHTED MIN

ONES($\mathcal{F}$). The lemma follows from the fact that $\mathrm{XOR}_3 \in \{\mathrm{XOR}_4\}|_0$. □

LEMMA 8.13. *If $\mathcal{F}$ is affine but not width-2 affine or 0-valid, then, for every $\epsilon > 0$,* MIN ONES($\mathcal{F}$) *is* NEAREST CODEWORD*-hard and hard to approximate to within a factor of $\Omega(2^{\log^{\epsilon} n})$.*

Proof. The proof follows from the following sequence of reductions:

NEAREST CODEWORD
$=$ WEIGHTED MIN CSP($\{\mathrm{XOR}_3, \mathrm{XNOR}_3\}$)
$\leq_{\mathrm{AP}}$WEIGHTED MIN ONES($\{\mathrm{XOR}_4, \mathrm{XNOR}_4\}$) (using Proposition 8.2)
$\leq_{\mathrm{AP}}$WEIGHTED MIN ONES($\{\mathrm{XOR}_3, \mathrm{XOR}\}$) (see below)
$\leq_{\mathrm{AP}}$WEIGHTED MIN ONES(XOR_3) (using Lemma 8.11)
$\leq_{\mathrm{AP}}$WEIGHTED MIN ONES($\mathcal{F}$) (using Lemmas 8.12 and 3.9)
$\leq_{\mathrm{AP}}$MIN ONES($\mathcal{F}$) (using Lemma 8.10).

The second reduction above follows by combining Lemma 3.9 with the observation that the family $\{\mathrm{XOR}_3, \mathrm{XOR}\}$ perfectly implement the functions XOR_4 and XNOR_4 as shown next. The constraints $\mathrm{XOR}_3(u, v, w)$ and $\mathrm{XOR}_3(w, x, y)$ perfectly implement the constraint $\mathrm{XNOR}_4(u, v, x, y)$; the constraints $\mathrm{XOR}_4(u, v, w, x)$ and $\mathrm{XOR}(w, y)$ perfectly implement $\mathrm{XOR}_4(u, v, x, y)$. The hardness of approximation of NEAREST CODEWORD is given by Lemma 7.16. □

LEMMA 8.14. *If $\mathcal{F}$ is weakly positive and not IHS-B (nor 0-valid), then* MIN ONES($\mathcal{F}$) *is* MIN HORN DELETION*-hard, and hence hard to approximate within $2^{\log^{1-\epsilon} n}$ for any $\epsilon > 0$.*

Proof. The proof follows from the following sequence of reductions:

MIN HORN DELETION
$=$ WEIGHTED MIN CSP($\{\mathrm{OR}_{3,1}, T, F\}$
$\leq_{\mathrm{AP}}$WEIGHTED MIN ONES($\{\mathrm{OR}_{4,1}, \mathrm{OR}_2, \mathrm{OR}_{2,1}\}$) (using Proposition 8.2)
$\leq_{\mathrm{AP}}$WEIGHTED MIN ONES($\{\mathrm{OR}_{3,1}, T, F\}$) (using Lemmas 7.7 and 3.9)
$\leq_{\mathrm{AP}}$WEIGHTED MIN ONES($\mathcal{F} \cup \{T, F\}$) (using Lemmas 7.18 and 3.9)
$\leq_{\mathrm{AP}}$WEIGHTED MIN ONES($\mathcal{F} \cup \{F\}$) (using Lemma 4.6 to perfectly implement T)
$\leq_{\mathrm{AP}}$WEIGHTED MIN ONES($\mathcal{F}$) (using Lemma 8.11)
$\leq_{\mathrm{AP}}$MIN ONES($\mathcal{F}$) (using Lemma 8.10).

The hardness of approximation follows from Lemma 7.21. □

LEMMA 8.15. MIN ONES(OR) *is* APX*-hard.*

Proof. We reduce VERTEX COVER to MIN ONES(OR). Given a graph G on n vertices, we construct an instance of MIN ONES(OR) on n variables $x_1, \ldots, x_n$. For every edge between vertex i and j of G, we create a constraint $\mathrm{OR}(x_i, x_j)$. We notice that there is a one-to-one correspondence between an assignment to the variables and vertex covers in G (with variables assigned 1 corresponding to vertices in the cover) and the minimum vertex cover minimizes the sum of the variables. The lemma follows from the fact that VERTEX COVER is APX-hard [39, 3]. □

LEMMA 8.16 (APX-hardness). *If $\mathcal{F} \not\subseteq \mathcal{F}'$ for any $\mathcal{F}' \in \{\mathcal{F}_0, \mathcal{F}_{\mathrm{WN}}, \mathcal{F}_{2\mathrm{A}}\}$, then* MIN ONES($\mathcal{F}$) *is* APX*-hard.*

Proof. We mimic the proof of Lemma 6.14. We assume that $\mathcal{F}$ is not affine—the case where $\mathcal{F}$ is affine is shown to be NEAREST CODEWORD-hard in Lemma 8.13. By

Lemma 8.10 it suffices to show that WEIGHTED MIN ONES($\mathcal{F}$) is APX-hard; and by Lemma 8.11 it suffices to show that WEIGHTED MIN ONES($\mathcal{F} \cup \{F\}$) is APX-hard. Since $\mathcal{F} \cup \{F\}$ is not 0-valid or 1-valid or C-closed, it implements every function in $\mathcal{F} \cup \{T, F\}$ and thus every function in $\mathcal{F}|_{0,1}$. We now shift focus on to the family $(\mathcal{F}|_{0,1})^-$. Furthermore, $(\mathcal{F}|_{0,1})^-$ is neither weakly positive nor affine and thus by Lemmas 6.20 and 6.21 it implements NAND. Using Proposition 8.3 we get that $\mathcal{F}_{0,1}$ implements OR. Using Lemma 8.15 we get that WEIGHTED MIN ONES(OR) is APX-hard. Thus we conclude that WEIGHTED MIN ONES($\mathcal{F}$) is APX-hard. ∎

Appendix A. Hardness of TOTAL LABEL COVER.

DEFINITION A.1. *$L \in \mathrm{MIP}_{c,s}[p, r, q, a]$ if there exists a polynomial time bounded probabilistic oracle machine V (verifier) such that on input $x \in \{0,1\}^n$, the verifier picks a random string $R \in \{0,1\}^{r(n)}$ and generates p queries $Q_1 = Q_1(x, R), \ldots, Q_p = Q_p(x, R) \in \{0,1\}^{q(n)}$ and sends query Q_i to prover Π_i and receives from prover Π_i an answer $A_i = A_i(Q_i) \in \{0,1\}^{a(n)}$ and then computes a verdict $\mathrm{ACC}(x, R, A_1, \ldots, A_p) \in \{0,1\}$ with the following properties:*

Completeness: *$x \in L \Rightarrow \exists A_1(\cdot), \ldots, A_p(\cdot)$ such that $\mathbf{E}_R[\mathrm{ACC}(x, R, A_1, \ldots, A_p)] \geq c(n)$.*

Soundness: *$x \notin L \Rightarrow \forall A_1(\cdot), \ldots, A_p(\cdot), \quad \mathbf{E}_R[\mathrm{ACC}(x, R, A_1, \ldots, A_p)] < s(n)$.*

We say V is uniform if for every x and i, there exists $d_{x,i}$ s.t. for every query $Q_i \in \{0,1\}^{q(n)}$, $|\{R \in \{0,1\}^{r(n)} | Q_i(R) = Q_i\}| = d_{x,i}$. We say L is in UNIFORM-$\mathrm{MIP}_{c,s}[p, r, q, a]$ *if there exists a uniform verifier V which places L in $\mathrm{MIP}_{c,s}[p, r, q, a]$.*

We use a recent result of Raz and Safra [41] (see also [5] for an alternate proof) which provides a strong UNIFORM-MIP containment result for NP.

LEMMA A.2 (see [41, 5]). *For every $\epsilon > 0$, there exist constants p, c_1, c_2, and c_3 such that*

$$\mathrm{NP} \subseteq \text{UNIFORM-MIP}_{1,2^{-\log^{1-\epsilon} n}}[p, c_1 \log n, c_2 \log n, c_3 \log n].$$

Remark.

(1) The result shown by [41, 5] actually has smaller answer sizes, but this turns out to be irrelevant to our application below; therefore we don't mention their stronger result.

(2) The uniformity property is not mentioned explicitly in the above papers. However, it can be verified from their proofs that this property does hold for the verifier constructed there.

The following reduction is essentially from [36, 7, 2].

LEMMA A.3. *For every $\epsilon > 0$, there exists a $p = p_\epsilon$ such that* TOTAL LABEL COVER$_p$ *is NP-hard to approximate to within a factor of $2^{\log^{1-\epsilon} n}$.*

Proof. We use Lemma A.2. Let L be an NP-complete language and for $\epsilon > 0$, let p, c_1, c_2, c_3 be such that $L \in \text{UNIFORM-MIP}_{1,2^{-\log^{1-\epsilon/2} n}}[p, c_1 \log n, c_2 \log n, c_3 \log n]$, and let V be the verifier that shows this containment. Given an instance $x \in \{0,1\}^n$ of L, we create an instance of TOTAL LABEL COVER$_p$ as follows: Set $Q_i(R)$ to be the query generated by V to prover Π_i on input x and random string R. For every $R, a_1, \ldots, a_p$ $\mathrm{ACC}(R, a_1, \ldots, a_p)$ is 1 if V accepts the answers $a_1, \ldots, a_p$ on random string R.

Let $\mathcal{Q} = \{0,1\}^{c_2 \log n}$ denote the set of all possible queries and let $\mathcal{R}$ denote the space of all possible random strings (i.e., $\mathcal{R} = \{0,1\}^{c_1 \log n}$). If $x \in L$, it is clear that there exists a feasible solution $A_1, \ldots, A_p$ such that for every query $q \in \mathcal{Q}$, and for

every $i \in \{1, \ldots, p\}$, it is the case that $|A_i(q)| = 1$. Thus the value of the optimum solution is at most $p \cdot |\mathcal{Q}|$.

Now we claim for a given x, if the mapped instance of TOTAL LABEL COVER has a solution of size $Kp|\mathcal{Q}|$, then there exist provers $\Pi_1, \ldots, \Pi_p$ such that V accepts with probability at least $K^{-1/p}/(p+1)^{p+1}$.

To see this let $\Pi_i(q)$ be a random element of $A_i(q)$. If $n_{i,q}$ denotes the cardinality of $A_i(q)$, then the probability that V accepts the provers response is given by

$$\frac{1}{|\mathcal{R}|} \sum_{R \in \mathcal{R}} \prod_i 1/n_{i,Q_i(R)}.$$

Define $\mathcal{R}_i$ to be $\{R \in \mathcal{R} | n_{i,Q_i(R)} \geq (p+1)K\}$. By Markov's inequality and the uniformity of the protocol $|\mathcal{R}_i|/|\mathcal{R}| \leq 1/(p+1)$.

Let $\mathcal{R}_0 = \mathcal{R} - \mathcal{R}_1 - \mathcal{R}_2 - \cdots - \mathcal{R}_p$. Then $|\mathcal{R}_0|/|\mathcal{R}| \geq 1/(p+1)$.

We go back to bounding the probability above:

$$\begin{aligned}
\frac{1}{|\mathcal{R}|} \sum_{R \in \mathcal{R}} \prod_i 1/n_{i,Q_i(R)} &\geq \frac{1}{|\mathcal{R}|} \sum_{R \in \mathcal{R}_0} \prod_i 1/n_{i,Q_i(R)} \\
&\geq \frac{1}{|\mathcal{R}|} \sum_{R \in \mathcal{R}_0} \prod_i 1/n_{i,Q_i(R)} \\
&\geq \frac{1}{|\mathcal{R}|} \sum_{R \in \mathcal{R}_0} (1/((p+1)K)^p) \\
&\geq K^{-1/p}/(p+1)^{p+1}.
\end{aligned}$$

It follows that if $K = K(n)$ is less than $2^{\log^{1-\epsilon} n}$, then for sufficiently large n, $K^{-1/p}/(p+1)^{p+1}$ is greater than $2^{\log^{1-\epsilon/2} n}$. Thus a K-approximation algorithm for TOTAL LABEL COVER$_p$ can be used to decide L. Thus TOTAL LABEL COVER$_p$ is NP-hard to approximate to within a factor of $2^{\log^{1-\epsilon} n}$. □

DUAL-ISSUE SCHEDULING FOR BINARY TREES WITH SPILLS AND PIPELINED LOADS*

WALEED M. MELEIS†

Abstract. We describe an algorithm that finds a minimum cost schedule, including spill code, for a register-constrained machine that can issue up to one arithmetic operation and one memory access operation at a time, under the restrictions that the dependence graph is a full binary tree, all arithmetic and store operations have unit latency, and all load operations have a latency of 1 or all load operations have a latency of 2. This problem is a generalization of two problems whose efficient solutions are well understood: optimal dual-issue scheduling without spills for binary expression trees, solved by Bernstein, Jaffe, and Rodeh [*SIAM J. Comput.*, 18 (1989), pp. 1098–1127], and optimal single-issue scheduling with spill code and delayed loads, solved by Kurlander, Proebsting, and Fischer [*ACM Transactions on Programming Languages and Systems*, 17 (1995), pp. 740–776], both assuming a fixed number of registers. We show that the algorithm's complexity is $O(nk)$ where n is the number of operations to be scheduled and k is the number of spills in the schedule. The cost of a "contiguous" schedule (i.e., its length) is shown to be $\rho + 2k + g + |A|$, where ρ is the number of registers used, $|A|$ is the number of arithmetic operations, k is the number of spills, and g is the number of empty slots in the associated single processor schedule. Therefore all contiguous schedules formed from optimal single processor schedules have minimum cost.

1. Introduction.

In modern processors, memory bandwidth is a major performance bottleneck due to increased processor issue widths and clock speeds relative to the limited number of ports and access latency to memory. Reducing memory traffic by improving data reuse at all levels of the memory hierarchy is therefore critical to improve system performance. In addition, the latency of pipelined memory operations is often larger than that of most arithmetic operations. One source of memory traffic is spilling, which moves data values from registers to memory and back. This data movement is necessary because the number of registers that instructions can access is limited. Reducing this traffic can be achieved through better register allocation and register sensitive scheduling and through the judicious use of spill code to minimize performance degradation. Processors that can issue more than one instruction per cycle can hide the latency of spill operations and other memory operations by overlapping them with instructions that do useful work.

Many scheduling problems for related processor architectures can be solved efficiently. Minimizing the number of registers needed to schedule operations without spill code on a single-issue machine when the dependence graph is a tree was first solved by Nakata [30] and Redziejowski [34]. These algorithms use a postorder evaluation of the expression tree and execute in time proportional to the number of operations to be scheduled. Sethi and Ullman [36] extended this result to minimize the amount of spill code needed to evaluate an expression tree. This algorithm also uses a postorder traversal of the expression tree and executes in linear time. Aho and John-

son [1] describe a dynamic programming solution to this problem that applies to a wider range of architectures. While the preceding results only apply to operations with unit latencies, Kurlander, Proebsting, and Fischer [28] describe an efficient algorithm for optimally scheduling expressions trees, with spills, for a delayed load architecture. This architecture assumes that all load operations have a latency of two cycles.

When the dependence graph is a directed acyclic graph (DAG), the related scheduling problems are usually NP-complete. In this case, more than one operation can depend on a particular operation. Minimizing the number of registers needed to schedule operations without spill code on a single-issue machine when the dependence graph is a DAG was shown to be NP-complete by Sethi [35]. Bruno and Sethi [11] show that when the dependence graph is a DAG, minimizing spill code is NP-complete even when only one register is available. This result assumes an accumulator-based architecture which is different than the load/store architecture we consider. The easier problem of inserting the minimum amount of spill code into a fixed schedule is also NP-complete when the underlying dependence graph is a DAG [13, 19]. Scheduling operations with arbitrary latencies on multiple identical machines was shown by Ullman to be NP-complete when the dependence graph is a DAG [37], by Bernstein, Rodeh, and Gertner when the dependence graph is a tree [5], and by Palem and Simons when the dependence graph is a collection of chains [31].

However, a number of related problems with unit-time operations can be solved efficiently in the absence of register constraints. If all latencies equal one, polynomial algorithms are described by Coffman and Graham that schedule operations on two processors when the dependence graph is a DAG [15] and by Hu for arbitrarily many processors when the dependence graph is a tree [27]. If all latencies are equal and the dependence graph is a tree, Bruno, Jones, and So give an efficient algorithm to schedule operations on multiple processors [10]. Finally, if all latencies equal 1 or 2, Bernstein and Gertner describe an efficient algorithm to schedule a single processor with arbitrary precedence [3].

Heuristics for the spill insertion problem based on dynamic programming and pruning rules are described by Horwitz et al. [25] and Hsu, Fischer, and Goodman [26]. More practical heuristics for register allocation and spill insertion are described and evaluated by Chaitin et al. [17, 18] and Chow and Hennessy [14]. More recently, improved allocation algorithms were evaluated by Callahan and Koblenz [12], Pinter [32], Briggs et al. [8, 9], Proebsting and Fischer [33], George and Appel [20], Lueh and Gross [29], and Bergner et al. [2]. These algorithms attempt to minimize the number of spills within a basic block or over an entire program, but without explicitly handling pipelines or instruction-level parallelism. The interdependency of code scheduling and register allocation in practical applications was described in [7] and [22]. These papers address the problem of efficient code generation for basic blocks on single-issue RISC processors and document the tradeoffs that exist between good data reuse in the register file and the minimization of pipeline interlocks. Other scheduling algorithms for pipelined processors were described by Hennessy and Gross [23, 24] and by Gibbons and Muchnick [21].

The algorithms described in this paper are the first to simultaneously optimize a schedule in the presence of multiple processors, and either spill code or instruction pipelines. (In fact, we solve the scheduling problem in the presence of both spills and instruction pipelines.) These results therefore increase the space of scheduling problems that can be solved efficiently along these important dimensions. Bernstein, Jaffe, and Rodeh [4] first described an efficient algorithm to schedule a dual-issue

processor with a limit on the number of available registers. They show that an optimal dual-issue schedule can be derived from an optimal single-issue schedule. However, this result does not apply when spill code must be inserted and the authors state that "... more work concerning store operations is needed."

In this paper we describe an efficient optimal scheduling algorithm that allocates registers and inserts spill code for a dual-issue processor with pipelined memory access operations. We show that an optimal single-issue schedule can be transformed into an optimal dual-issue schedule without increasing the number of spill operations. We then show that this transformation can be further generalized to apply to processors with pipelined memory operations, and we completely describe the structure of an optimal solution to this general problem. The dual-issue machine assumed in this paper is a simplified representation of a range of pipelined RISC microprocessors and supercomputers that have a limited number of registers. By solving the problem of scheduling with spills for a dual-issue processor with pipelined memory operations, we have solved the following two previously open subproblems: optimal scheduling for a dual-issue processor with spills and optimal scheduling for a dual-issue processor without spills with pipelined memory operations. Our main result represents a generalization of optimal algorithms described by Sethi and Ullman [36] and Bernstein, Jaffe, and Rodeh [4]. This result also represents an extension of the algorithm described by Kurlander, Proebsting, and Fischer [28]; however, their machine model also includes unary operations and literals which our algorithm does not handle. We summarize the main results of this paper below.

1. A sequential schedule with arbitrary load latencies and spills can be transformed into a dual-issue schedule with the same number of spills and idle cycles, and visa versa.

2. A dual-issue schedule with arbitrary load latencies and spills can be transformed into a contiguous dual-issue schedule by moving load operations earlier in the schedule and store operations later, without increasing the schedule's length or the number of spill operations.

3. We give an efficient algorithm that solves the dual-issue scheduling problem with spills for load latencies = 1 or load latencies = 2.

Our paper is organized as follows. In section 2 we describe our machine and computation model and define the sequential and parallel scheduling problems. In section 3 we describe some basic properties of parallel schedules. In sections 4 and 5 we show that we only need to consider contiguous schedules. In section 6 we describe the structure and cost of a contiguous schedule, and in section 7 we describe an algorithm that solves the parallel scheduling problem.

2. The machine/computation model. The notation used by Bernstein, Jaffe, and Rodeh in [4] formalizes the sequential and parallel scheduling problems without spills. We extend this notation to allow the use of spill code and nonunit latencies for loads. We consider a machine model that has access to R registers: $r_1\ r_2, \ldots, r_R$ and an arbitrarily large memory space. The machine has three types of operations: load operations which copy a data value from memory into a register, store operations which copy a data value from a register into memory, and binary arithmetic operations which read two data values from registers and write a new data value to a register. Arithmetic and store operations have unit latencies, and each load operation has a latency that is some positive integer. In the definitions below, we assume that an operation's latency gives the minimum number of cycles that must elapse before a dependent operation is scheduled. We also assume that all functional units are fully

pipelined, which allows an operation to be issued to each functional unit in each cycle. We let NOP indicate that no operation is scheduled at some time.

The dependence graph F is a rooted binary tree that contains leaf nodes that represent load operations and internal nodes that represent arithmetic operations. We assume that every internal node has exactly two predecessors. An edge between two nodes represents a data dependence between the two operations, and an operation must be scheduled after its predecessors. The set of *arithmetic operations* in F is denoted $A(F) = \{A_1, A_2, \ldots, A_{|A(F)|}\}$, where A_i may denote either the operation or its *arithmetic result* (or simply, *value*). An arithmetic operation is said to *use* a value that it directly depends on. The set of *load operations* is $L(F) = \{L_1, L_2, \ldots, L_{|L(F)|}\}$, where L_i represents a load of A_i if $1 \leq i \leq |A(F)|$, and L_i represents a leaf node of F if $|A(F)| < i \leq |L(F)|$. The latency of load operation L_i is denoted $latency(L_i)$. The set of *store operations* is denoted $S(F) = \{S_1, S_2, \ldots, S_{|A(F)|}\}$, where S_i represents a store of A_i. A load operation L_i or a store operation S_i is referred to as *spill code* if $1 \leq i \leq |A(F)|$. Note that if value A_i is spilled in an evaluation of F, S_i and later L_i will appear in the evaluation somewhere between A_i and the use of A_i; if A_i is not spilled, S_i and L_i will not appear at all.

For a given node v of F, F_v denotes the subtree of F with v as its root. If u is a predecessor of v in F, we say u is *used* by v.

A *sequential evaluation* P of a computation F is an ordered list of operations (including spill code and NOPs): $P = P_1, P_2, \ldots, P_n$, where P_i is executed at time i, and the following three conditions are satisfied:

1. Every arithmetic operation and load leaf is executed, i.e., for every node v, there exists a unique j such that $P_j = v$.

2. No dependences of F are violated, i.e., if P_i, P_j are nodes in F, and P_j is an arithmetic operation, then $P_j \in F_{P_i}$ implies $j \leq i - 1$. If P_j is a load operation, then $P_j \in F_{Pi}$ implies $j \leq i - latency(P_j)$. This implies that the latency of each arithmetic operation is one, and the latency of each load operation P_j is $latency(P_j)$.

3. If the value A_v corresponding to a nonleaf node P_i is used by P_j $(j > i)$, then A_v may be stored at time k_1 and loaded at time k_2, provided that $i < k_1 < k_2 \leq j - latency(P_{k_2})$. In this case, $P_{k_1} = S_v$ and $P_{k_2} = L_v$, and S_v and L_v are spill code.

Conditions 2 and 3 are collectively referred to as the *precedence constraints* of a sequential evaluation. An operation $P_i = NOP$ is called an *empty slot* of a sequential evaluation. The cost of P, $c(P)$, equals the number of operations in P, i.e., we define an evaluation's cost to be equal to its length.

We now extend the definitions in [4] to handle dual-issue processors. A *parallel evaluation* PQ of a computation F is an ordering of operation pairs: $PQ = PQ_1, PQ_2, \ldots, PQ_n$ where $PQ_i = (p_i, q_i)$ such that $p_i \in L(F) \cup S(F) \cup \{NOP\}$ and $q_i \in A(F) \cup \{NOP\}$. NOPs are used to indicate that no operation is scheduled in either or both operation pairs at some time. A parallel evaluation PQ must satisfy the following four conditions:

1. For every nonleaf node v, there exists a unique PQ_j such that $q_j = v$.

2. For every leaf node v, there exists a unique PQ_j such that $p_j = v$.

3. For every PQ_i, PQ_j, if $q_i \neq NOP$, then $p_j \in F_{q_i}$ implies $j \leq i - latency(q_i)$. Furthermore, $q_j \in F_{q_i}$ implies $j \leq i - 1$. Once again, the latency of each arithmetic operation is one, and the latency of load operation q_i is $latency(q_i)$.

4. For every PQ_i, PQ_j, if $q_i = A_v$ and q_j uses A_v $(j > i)$, then A_v may be stored at time k_1 and loaded at time k_2, provided that $i < k_1 < k_2 \leq j - latency(k_2)$. In this case, $PQ_{k_1} = (S_v, q_{k_1})$ and $PQ_{k_2} = (L_v, q_{k_2})$ are spill code.

(c) *A parallel evaluation of F.*

FIG. 1. *Examples of sequential and parallel evaluations for latency $= 2$ and $R = 3$.*

Conditions 3 and 4 are collectively referred to as the precedence constraints of a parallel evaluation. A pair (p_i, NOP) is called an *empty arithmetic slot* if p_i is not a NOP, and (NOP, q_i) is called an *empty load/store slot* if q_i is not a NOP. A pair (NOP, NOP) is called an *empty slot* of a parallel evaluation. Note that by definition the sets of empty arithmetic slots, empty load/store slots, and empty slots in an evaluation are disjoint. The cost of PQ, $c(PQ)$, equals the number of operation pairs in PQ, and note that we again define an evaluation's cost to be equal to its length.

Sequential and parallel evaluations defined in this way ensure that every operation is executed, the operations' latencies are not violated, and spills (if any) are properly placed in the evaluation. The limitations imposed by a register file of finite size are described below. The concatenation $P|P'$ (or simply PP') of two sequential evaluations represents the sequential evaluation formed by the operations in P followed by the operations in P'.

For a sequential or parallel evaluation E, $inreg_i$ is the set of all values that are in a register at time i, namely the set of all values v such that v is defined or loaded at time j, where $j \leq i$, and is neither used nor stored at any time k, where $j < k \leq i$.

A nonleaf value v is said to be *spilled* at time i if it is stored at time j, where $j \leq i$, and is loaded at time k, where $k > i$. Thus if v is spilled or used at time i, then v is not in a register at time i.

Each load operation adds one element to $inreg$, each store removes one, and each arithmetic operation adds one and removes two. Therefore, $|inreg_i|$ = the total number of loads, minus stores, minus arithmetic operations at time i or earlier. The number of values in registers at time i of an evaluation E, $|inreg_i|$, is denoted $\rho_i(E)$, and $\rho(E)$ denotes the maximum over all i of $\rho_i(E)$. That is, $\rho_i(E) = |inreg_i|$ and $\rho(E) = \max_i \rho_i(E)$. When all load latencies are equal, we let $latency = latency(L_i)$. An example is shown in Figure 1 in which $latency = 2$ and $R = 3$.

Given a computation F, the number of available registers R, and the latencies of the load operations, the sequential scheduling problem is to construct a sequential evaluation P such that $c(P)$ is minimized subject to $\rho(P) \leq R$. The parallel scheduling problem is to construct a parallel evaluation PQ such that $c(PQ)$ is minimized subject to $\rho(PQ) \leq R$. In each case, the evaluation constructed is said to *use R registers*. In this paper we describe algorithms that solve the parallel scheduling problem for $latency = 1$ and $latency = 2$.

3. Minimizing spill operations plus empty slots in a parallel evaluation. Given a tree F, the number of available registers R, and the latencies of the load operations, a solution to the parallel scheduling problem is found by using the sequential scheduling algorithm to construct a sequential evaluation that minimizes the number of spill operations plus empty slots, transforming this evaluation into a parallel evaluation, and then transforming this evaluation into a "contiguous" form. At each stage of the transformation the number of spill operations plus empty slots remains unchanged and the cost of the evaluation does not increase. In this section we show that for arbitrary load latencies, no parallel evaluation of F can have fewer spill operations plus empty slots than an optimal sequential evaluation of F, and that a minimum cost sequential evaluation can be transformed into a parallel evaluation that minimizes the number of spill operations plus empty slots. In the following sections, we show that every parallel evaluation PQ of F in contiguous form that contains k spilled values and g empty slots has a cost of $\rho(PQ) + 2k + g + |A(F)|$, and, for $latency = 1$ or $latency = 2$, that no parallel evaluation can cost less.

3.1. Minimizing spills in a sequential evaluation. An efficient algorithm that solves the sequential scheduling problem with $latency = 1$ was described by Aho, Sethi, and Ullman [1] and Sethi and Ullman [36]. In addition to the three types of operations described above, these algorithms include another binary arithmetic operator that reads one operand from a register and one operand from memory and writes its result to a register, causing no net change in $inreg_i$. Bose [6] describes an adaptation of the algorithm in [1] that solves the sequential scheduling problem without this fourth instruction class.

For a given vertex v, the algorithm first computes the minimum number of registers needed to evaluate the subtree rooted at v without spill code. The scheduling routine uses these quantities to optimally schedule the entire tree. Spill code is inserted when neither subtree can be scheduled using R or fewer registers. The operations that compute a particular subtree are executed consecutively. That is, the computation of a subtree is never interrupted by the computation of another subtree. The subtree with the higher register requirement at a particular vertex is always executed first. As argued in [6], this sequential scheduling algorithm finds a minimum cost evaluation of F that uses no more than R registers assuming $latency = 1$. Furthermore, it can be

shown that if the cheapest evaluation contains no spills, the algorithm minimizes the maximum number of values in registers. The proof of this, which we omit, is similar to the one given in [36].

An efficient algorithm to solve the sequential scheduling problem with $latency = 2$ was described by Kurlander, Proebsting, and Fischer [28]. They show that all nontrivial trees can be scheduled without empty slots or spill code if the number of available registers is at least one more than the minimum number of registers needed to evaluate the tree without spills. In this case the sequential scheduling algorithm for $latency = 1$ is first used to create an evaluation, and the ordering of the load operations and the ordering of the arithmetic operations becomes an invariant. The new evaluation then consists of a series of load operations, followed by an alternating series of arithmetic and load operations, and ending with a series of arithmetic operations. This algorithm therefore solves the sequential scheduling problem with $latency = 2$ for sufficiently large values of R.

For smaller values of R, spill code may need to be inserted in the evaluation. For each vertex v, the algorithm computes the *register pressure* caused by v by applying the unit load latency sequential scheduling algorithm to the subtree rooted at v. The register pressure caused by v is equal to the number of times during this evaluation that the number of live values equals the maximum number of live values. A vertex v is then spilled if the minimum number of registers needed to evaluate the subtree rooted at v equals R and v's register pressure is greater than two. If the minimum number of registers needed to evaluate v is greater than R, then a predecessor of v with the largest register pressure is spilled.

The cost of a sequential evaluation equals the number of nodes in F plus the number of spill operations and empty slots. Therefore an optimal sequential evaluation must contain the fewest spill operations plus empty slots among all sequential evaluations. Furthermore, if k values are spilled, there are $2k$ spill operations, i.e., k store/load pairs.

3.2. A lower bound on spill operations plus empty slots in a parallel evaluation. A simple transformation allows us to transform a k-spill, g-empty slot parallel evaluation with arbitrary load latencies and that uses R registers into a k-spill, g-empty slot sequential evaluation that uses R registers. Recall that for a parallel evaluation PQ and a time i, $PQ_i = (p_i, q_i)$.

Serial transformation. Given a k-spill parallel evaluation PQ with arbitrary load latencies that uses R registers, we construct a serial evaluation P as follows. For each time i, if $PQ_i = (L, A)$ for some load L and arithmetic operation A, let $J_i = A, L$. Similarly, if $PQ_i = (L, NOP)$, (S, NOP), or (NOP, A), let $J_i = L$, S, or A, respectively. If $PQ_i = (S, A)$, let $J_i = A, S$. Finally if $PQ_i = (NOP, NOP)$, let $J_i = NOP$. Then let $P' = J_1 J_2 \dots J_{|PQ|}$. In [4] a similar transformation is applied to parallel evaluations that do not contain spills and with $latency = 1$. We first show that when P is constructed in this manner it represents a sequential evaluation. Then we show that $\rho(P) \leq \rho(PQ)$ (Lemma 3.1).

If two operations v and w are scheduled $d \geq 1$ cycles apart in parallel evaluation PQ, these operations are scheduled d or more cycles apart after PQ is transformed into P. Therefore these operations cannot violate the precedence constraints in the serial evaluation P. If operations v and w are scheduled at the same time in PQ then by definition of a parallel evaluation they are not dependent on one another. Therefore these operations cannot violate the precedence constraints in P, and it follows that P represents a sequential evaluation.

LEMMA 3.1. *Given a k-spill parallel evaluation PQ of a computation F with arbitrary load latencies and R available registers, and given the serial evaluation P formed by applying the serial transformation to PQ, then $\rho(P) \leq \rho(PQ)$.*

Proof. Consider some arbitrary time j of the evaluation P. Suppose first that P_j contains an arithmetic operation, i.e., $P_j = q_i$ for some time i of PQ. By definition of the serial transformation, all operations scheduled earlier than q_i in P must have been scheduled at time $i-1$ or earlier in PQ. Therefore, the number of values in registers at time $j-1$ of P and at time $i-1$ of PQ is the same, i.e., $\rho_{j-1}(P) = \rho_{i-1}(PQ)$. Since q_i is an arithmetic operation, $\rho_j(P) = \rho_{j-1}(P) - 1 \leq \rho_{j-1}(P)$, which implies that $\rho_j(P) \leq \rho_{i-1}(PQ)$.

Now suppose that P_j contains a load/store operation, i.e., $P_j = p_i$ for some time i of PQ. By definition of the serial transformation, all operations scheduled at time j or earlier in P must have been scheduled at time i or earlier in PQ. Therefore, $\rho_j(P) \leq \rho_i(PQ)$. Finally if P_j contains a NOP, then $\rho_j(P) \leq \rho_{j-1}(P)$. □

Since P is a sequential evaluation of F that contains the same non-NOP operations as PQ, evaluations P and PQ contain the same number of spills. Furthermore, by construction both evaluations contain the same number of empty slots. We can now state the following lemmas whose proofs follow from the discussion above.

LEMMA 3.2. *Consider a computation F with arbitrary load latencies and R available registers. If an optimal sequential evaluation P of F that uses R registers contains $2k$ spill operations and g empty slots, then the number of spill operations plus empty slots in any parallel evaluation of F that uses R registers is not less than $2k+g$.*

LEMMA 3.3. *Consider a computation F with arbitrary load latencies and R available registers, and let minreg be the minimum number of registers needed to evaluate F without spills in a serial evaluation. Then all parallel evaluations of F that use fewer than minreg registers have at least one spill.*

3.3. Creating a minimum-spill operation plus empty slot parallel evaluation. An optimal serial evaluation of F thus directly yields a lower bound $2k+g$ on the number of spill operations plus empty slots in any parallel evaluation of F. We can achieve this lower bound through a straightforward transformation of an optimal sequential evaluation.

Parallel transformation. Given a k-spill, g-empty slot sequential evaluation $P = P_1, \ldots, P_n$ with arbitrary load latencies, then for each time i,

(i) if $P_i \in A(F)$, let $PQ_i = (NOP, P_i)$, and
(ii) if $P_i \in L(F) \cup S(F)$, let $PQ_i = (P_i, NOP)$,
(iii) if $P_i = NOP$, let $PQ_i = (NOP, NOP)$.

No precedence is violated by this transformation since the operations are executed in the same order, and all pairs of operations are the same number of cycles apart in both evaluations. Therefore PQ represents a k-spill, g-empty slot parallel evaluation of F that uses R registers. Note, however, that PQ is degenerate since there is a NOP scheduled in PQ for every time i; thus PQ is unlikely to have the minimum cost. The result of applying the parallel transformation to the sequential evaluation in Figure 1(b) is shown in Figure 2.

4. Load-contiguous parallel evaluations. We have shown that a parallel evaluation with the minimum number of spill operations plus empty slots can be constructed by applying the parallel transformation to an optimal sequential evaluation. We now describe the process of transforming this parallel evaluation into a contiguous form. We define a load-contiguous parallel evaluation and show that

FIG. 2. *The result of transforming the sequential evaluation in Figure* 1(b) *into a parallel evaluation for latency* $= 2$ *and* $R = 3$.

every parallel evaluation can be made load-contiguous without increasing its cost or the maximum number of values in registers. Furthermore, for load latencies ≤ 2 we show that the number of spill operations plus empty slots also does not increase. We then show in section 5 that a load-contiguous evaluation can be made contiguous, i.e., both load-contiguous and store-contiguous, without increasing its cost, the maximum number of values in registers, or the number of spill operations plus empty slots. Finally in sections 6 and 7 we show that for *latency* $= 1$ or *latency* $= 2$, a contiguous evaluation that minimizes the number of spill operations plus empty slots is necessarily optimal. That is, applying the contiguity transformations to a parallel evaluation with the minimum number of spill operations plus empty slots produces a minimum cost evaluation.

A parallel evaluation of a computation F is said to be *load-contiguous* if and only if no load operation is scheduled at a later time than an empty load/store slot, i.e., a pair (NOP, q) where q is not a NOP. Using this definition we can prove the following theorem and lemma.

THEOREM 4.1. *Given any* k*-spill parallel evaluation* PQ *of a computation* F *with arbitrary load latencies, there exists a* k'*-spill load-contiguous parallel evaluation* PQ' *of* F *such that*

(i) $c(PQ') \leq c(PQ)$,
(ii) $\rho(PQ') \leq \rho(PQ)$, *and*
(iii) $k' \leq k$.

Proof. Let PQ be a k-spill, g-empty slot parallel evaluation of a computation F that uses R registers, but is not load-contiguous. Consider the first empty load/store slot i. Let j be the first time after i where a load operation is scheduled. We create an evaluation PQ' that is the same as PQ, except one of of the following two transformations has been applied.

1. If the load scheduled at time j loads a value that is stored at time m such that $i < m < j$, both the load and store are deleted.

2. Otherwise, the load operation at time j is moved to i.

In both cases, $c(PQ') \leq c(PQ)$ and PQ' has no more spill operations than PQ. It remains to show that $\rho(PQ') \leq \rho(PQ)$, and that precedence is preserved.

Since no load/store operation is scheduled at time i, $\rho_i(PQ) = \rho_{i-1}(PQ) - 1$. From time i through $j-1$ by assumption there are no load operations, so the number of registers used as we progress forward can only stay the same or decrease. In particular, for all time s such that $i \leq s < j$, $\rho_s(PQ) \leq \rho_{i-1}(PQ) - 1$. We tentatively create a new evaluation PQ' that is identical to PQ except the load operation at time j is moved to time i. That is, $p'_i = p_j$, and $p'_j = NOP$. For all $m < i$, $\rho_m(PQ') = \rho_m(PQ)$. Similarly, for all $m \geq j$, $\rho_m(PQ') = \rho_m(PQ)$. However, $\rho_i(PQ') = \rho_i(PQ) + 1$ due to the new load operation at time i. Similarly, for all time

Slot $i =$	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20
$p_i =$	L_{18}	L_{19}	–	L_{20}	–	L_{21}	L_{22}	–	L_{14}	L_{15}	S_5	–	L_{16}	L_{17}	–	L_5	L_{24}	–	L_{25}	S_2
$q_i =$	–	–	–	A_{13}	–	A_9	–	–	A_{10}	A_5	–	–	A_7	–	–	A_8	A_4	–	A_2	–
$\rho_i =$	1	2	2	2	2	2	3	3	3	3	2	2	2	3	3	3	3	3	3	2

Slot $i =$	21	22	23	24	25	26	27	28	29	30
$p_i =$	–	L_{26}	L_{27}	–	L_{23}	L_2	–	–	–	–
$q_i =$	–	A_{11}	–	–	A_{12}	A_6	–	A_3	–	A_1
$\rho_i =$	2	2	3	3	3	3	3	2	2	1

FIG. 3. *The result of applying the load-contiguous transformation to the parallel evaluation in Figure* 2 *for latency* $= 2$ *and* $R = 3$.

s such that $i \leq s < j$, $\rho_s(PQ') = \rho_s(PQ) + 1$. But since $\rho_s(PQ) \leq \rho_{i-1}(PQ) - 1$ from above, we can conclude that for $i \leq s < j$, $\rho_s(PQ') = \rho_s(PQ) + 1 \leq \rho_{i-1}(PQ)$. Therefore if the load operation at time j is moved to i, $\rho(PQ') \leq \rho(PQ) \leq R$. By a similar argument we can show that if the load at time j and a store at time m are deleted, $\rho(PQ') \leq \rho(PQ) \leq R$.

Moving a load operation earlier in the evaluation cannot violate its precedence with respect to an arithmetic operation that uses the loaded value. If the load operation scheduled at time j loads a value that is stored at time m such that $i < m < j$, both the load and store operations are deleted. Note that the number of empty slots in the evaluation will increase if the load operation at time j or the store operation at time m is in an empty arithmetic slot.

The transformation described above can be applied iteratively until the evaluation is load-contiguous. The transformation does not affect any operation earlier than i, and each time the transformation is applied either a load operation is scheduled at time i or a spill is eliminated. Therefore the iterations will eventually terminate, giving an evaluation in which the initial portion of the evaluation contains load operations, store operations and empty slots, until the load operations are exhausted. □

We now extend this result by showing that for *latency* ≤ 2, the number of spill operations plus empty slots also does not increase.

LEMMA 4.2. *Given any* k*-spill,* g*-empty slot, parallel evaluation* PQ *of a computation* F *with latency* ≤ 2*, there exists a* k'*-spill,* g'*-empty slot, load-contiguous parallel evaluation* PQ' *of* F *such that*

(i) $c(PQ') \leq c(PQ)$,
(ii) $\rho(PQ') \leq \rho(PQ)$,
(iii) $k' \leq k$, *and*
(iv) $g' = g$.

Proof. Let PQ be a k-spill, g-empty slot parallel evaluation of a computation F that uses R registers, but is not load-contiguous. Consider the first empty load/store slot i. Let j be the first time after i where a load operation is scheduled. We apply the transformation described in Theorem 4.1 to either move the load operation at time j to i or delete the load operation at time j along with the store of the same value. In each case we show that an evaluation can be created that contains g empty slots.

If PQ_j originally contained an empty arithmetic slot, moving the load operation scheduled there to time i will create a new empty slot at time j. Deleting this empty slot does not violate precedence. Deleting an empty slot cannot violate precedence between two arithmetic operations, between an arithmetic operation and a store operation, or between a store operation and a load operation, because arithmetic and store operations have a latency of 1. Since the load latency is not larger than 2,

deleting an empty slot at time j could only violate precedence if PQ_{j-1} contains a load operation and PQ_{j+1} contains an arithmetic operation dependent on that load. However, by assumption there are no load operations scheduled between time i and time j in PQ. Therefore PQ_{j-1} does not contain a load operation, and precedence is not violated if an empty slot at time j is deleted.

A similar argument applies if the load operation scheduled at time j loads a value that is stored at time m such that $i < m < j$. Deleting both the load and store operations will create new empty slots if either operation was originally scheduled in an empty arithmetic slot. Precedence would be violated by deleting these empty slots if either operation was preceded by a load operation and followed by an arithmetic operation dependent on that load. However, by assumption there cannot be a load operation scheduled between the first empty load/store slot at time i and time j. Therefore any new empty slots can be deleted without violating precedence.

Furthermore by arguments similar to those used in the proof of Theorem 4.1 we can show that $c(PQ') \leq c(PQ)$, $\rho(PQ') \leq \rho(PQ)$, $k' \leq k$, and that this transformation can be applied iteratively until the evaluation is load contiguous. □

Load-contiguous transformation for load latencies ≤ 2. Given any parallel evaluation PQ of a computation F, we create a load-contiguous parallel evaluation PQ' using the transformation described in Lemma 4.2: we apply the transformation from Theorem 4.1 and delete any slots that are empty as a result of each phase of the transformation.

The result of applying the load-contiguous transformation to the parallel evaluation in Figure 2 is shown in Figure 3. We now extend the notion of load-contiguity to stores.

5. Store-contiguous parallel evaluations. We define a store-contiguous parallel evaluation and show that every load-contiguous parallel evaluation can be made store-contiguous as well. Given R available registers, a parallel evaluation of a computation F is *store-contiguous* if and only if for any i such that a store operation is scheduled at time i, $\rho_{i+1} = R$. This implies that store operations are scheduled as late as possible. Using this definition we can prove the following theorem.

THEOREM 5.1. *Given a k-spill, g-empty slot, load-contiguous, parallel evaluation PQ of a computation F with arbitrary load latencies and with $\rho(PQ) \leq R$, there exists a k'-spill, g'-empty slot, parallel evaluation PQ' of F such that*

(i) $c(PQ') \leq c(PQ)$,
(ii) $\rho(PQ') \leq R$,
(iii) $k' \leq k$,
(iv) $g' \geq g$,
(v) $2k' + g' \leq 2k + g$,
(vi) *PQ' is load-contiguous, and*
(vii) *PQ' is store-contiguous.*

Proof. Let PQ be a load-contiguous, k-spill, g-empty slot parallel evaluation of a computation F that uses R registers, but is not store-contiguous. We show that PQ can be transformed into an evaluation that is both load-contiguous and store-contiguous without increasing the evaluation's cost, the number of spill operations, or the number of spill operations plus empty slots, and without causing the number of empty slots to decrease or the maximum number of values in registers to exceed R. We begin by showing that the last store operation in the evaluation that violates the store-contiguous property cannot immediately precede another store operation. We then show that the parallel evaluation can be transformed so that the store operation

no longer violates the store-contiguous property. Finally we show that both load-contiguity and store-contiguity can be achieved for the entire evaluation.

Consider the largest time i such that a store operation is scheduled at time i and $\rho_{i+1}(PQ) < R$. We show by contradiction that there cannot be a store operation scheduled at time $i+1$. Suppose there is a store operation scheduled at time $i+1$. Then $\rho_{i+1}(PQ) < \rho_i(PQ)$ because the number of values in registers must decrease by at least 1 between time i and time $i+1$. Furthermore, since a store operation is scheduled at time i, $\rho_i(PQ) < \rho_{i-1}(PQ)$. Thus $\rho_{i+1}(PQ) \leq \rho_{i-1}(PQ) - 2$. The number of values in registers at any time can increase by at most one in the next time period, which occurs when the next time period contains *only* a load operation. Therefore, $\rho_{i+2}(PQ) \leq \rho_{i-1}(PQ) - 1$. Since $\rho_{i-1}(PQ) \leq R$, we have $\rho_{i+2} \leq R-1$. In this case, the store scheduled at time $i+1$ contradicts the assumption that the store scheduled at time i is the last store that precedes a time period with fewer than R values in registers. Therefore there is not a store operation scheduled at time $i+1$.

We now show that since $\rho_{i+1}(PQ) < R$, we can construct a new evaluation PQ' in which the store scheduled at time i is moved one time period later. We consider seven cases depending on the operations scheduled at times i and $i+1$. The transformation from PQ to PQ' is shown in Figure 4. For each case, the upper pairs of operations represent PQ_i and PQ_{i+1}, while the lower pairs represent PQ'_i and PQ'_{i+1}. For conciseness we let X and Y each represent either an arithmetic operation or an empty slot, and we let Z represent either a load operation or an empty slot. In each case it can be seen that $c(PQ') \leq c(PQ)$, $k' \leq k$, and $g' \geq g$.

The new evaluation does not violate the precedence constraints because in each case one or more of the following transformations is performed: a load operation is moved earlier in the evaluation, a store operation is moved later in the evaluation, an arithmetic operation is moved one slot later into a previously empty slot, or an arithmetic operation is moved before a store operation. None of these transformations can violate the precedence constraints, unless a load operation is moved earlier than a store operation of the same value. In this case deleting both operations does not violate precedence. We now show that in each case $\rho(PQ') \leq R$ and $2k' + g' \leq 2k + g$.

The transformations affect only operations scheduled at time i or $i+1$, so for all $j \leq i-1$ and $j \geq i+1$, $\rho_j(PQ) = \rho_j(PQ')$. As a result, showing that $\rho_i(PQ') \leq \rho_{i-1}(PQ')$ allows us to conclude that $\rho(PQ') \leq R$.

(i) Case 1 in Figure 4 such that S and L reference the same value: Delete the load and store operations, i.e., let $PQ'_i = (NOP, X)$ and $PQ'_{i+1} = (NOP, Y)$. Since $PQ'_i = (NOP, A)$ or (NOP, NOP), $\rho_i(PQ') \leq \rho_{i-1}(PQ')$. The number of empty slots does not decrease. The quantity $2k+g$ does not increase because the number of spills decreases by one and the number of empty slots increases by no more than two.

(ii) Cases 2–6 in Figure 4 such that S and L, if present, do not reference the same value: Since $\rho_{i-1}(PQ) \leq R$ and $\rho_{i-1}(PQ) = \rho_{i-1}(PQ')$, it can be seen in each case that $\rho_i(PQ') \leq R$. Also, the number of spill operations and empty slots is unchanged.

(iii) Case 7 in Figure 4 such that S and L do not reference the same value: In this case, $\rho_{i-1}(PQ) \leq R-1$. If this were not true, then $\rho_{i+1}(PQ) = R$, which contradicts the assumption that $\rho_{i+1}(PQ) < R$. Therefore $\rho_i(PQ') \leq R$. Again, the number of spill operations and empty slots is unchanged.

In each case we have shown that if a store operation is scheduled at time i and $\rho_{i+1}(PQ) < R$, it is always possible to move the store one time period later without violating precedence, without increasing the evaluation's cost, the number of spill

FIG. 5. *The result of applying the store-contiguous transformation to the load-contiguous evaluation in Figure* 3 *with $R = 3$.*

operations, or the number of spill operations plus empty slots, and without causing the number of empty slots to decrease or the maximum number of values in registers to exceed R. The transformation described above can be applied repeatedly to the same store, moving it one time period later in each case, until either it does precede a time period in which R values are in registers, or the store can be deleted (if it is moved later than the load of the same value). Then this transformation can be applied to the preceding store. Since the evaluation is of finite length, each store will eventually either precede a time period containing R values in a register or be deleted.

The movement of one store cannot affect the prior placement of a later store since, as we have shown, the last store to violate the store-contiguous property cannot immediately precede another store operation. Since there are finitely many stores, the sequence of transformations will eventually terminate with each remaining store preceding a time period with R values in registers.

It remains to show that it is possible to satisfy both load-contiguity and store-contiguity in an optimal evaluation. Notice that up to the point of deleting load/store pairs, any transformation that moves a load interchanges the load with a store. Thus load-contiguity is preserved. But empty load/store slots can be introduced wherever a load/store pair is deleted and these may destroy load-contiguity. In this case, however, the load-contiguous transformation can be reapplied. At worst, the transformation described above and the load-contiguous transformation are reapplied k times, i.e., each time a spill is eliminated. □

Store-contiguous transformation. Given a load-contiguous parallel evaluation PQ of a computation F, we create a parallel evaluation PQ' that is both load-contiguous and store-contiguous using the transformation described in Theorem 5.1.

An evaluation PQ' is said to be *contiguous* if it is both load-contiguous and store-contiguous, i.e., if no load operation is scheduled in a later time period than an empty load/store slot, and for any i such that a store operation is scheduled at

time i, $\rho_{i+1} = R$. The result of applying the store-contiguous transformation to the load-contiguous parallel evaluation in Figure 3 is shown in Figure 5.

6. Cost of a *k*-spill parallel evaluation. We have shown that given a k-spill, g-empty slot parallel evaluation of a computation F that uses R registers, there exists another parallel evaluation of F that costs no more, uses no more than R registers, and is contiguous. Furthermore, for load latencies ≤ 2 the contiguous evaluation has no more than $2k + g$ spill operations plus empty slots. We now examine the structure of such a k-spill, g-empty slot contiguous evaluation with a sequence of lemmas and show in Theorem 6.5 that its cost is $\rho(PQ)+2k+\mathrm{g}+|A(F)|$. The results in this section apply with arbitrary load latencies.

LEMMA 6.1 (each store operation and the following operation). *Consider a k-spill, g-empty slot contiguous parallel evaluation PQ of a computation F with arbitrary load latencies and R available registers. If PQ_i contains a store operation S, then $PQ_i = (S, NOP)$, and $PQ_{i+1} = (L, NOP)$ for some load operation L.*

Proof. Let PQ be a k-spill, g-empty slot contiguous parallel evaluation of a computation F such that $\rho(PQ) \leq R$, and consider an arbitrary store operation S in PQ_i. We show by contradiction that $PQ_i = (S, NOP)$, and show that $PQ_{i+1} = (L, NOP)$ for some load operation L. Assume that $PQ_i \neq (S, NOP)$, i.e., $PQ_i = (S, A)$. Then $\rho_i(PQ) = \rho_{i-1}(PQ) - 2$. The number of values in registers at some time can increase by at most one in the next time period, so $\rho_{i+1}(PQ) \leq \rho_i(PQ) + 1 = \rho_{i-1}(PQ) - 1 \leq R - 1$. Thus PQ is not store-contiguous, which is a contradiction. We conclude that $PQ_i = (S, NOP)$.

Now from the store contiguity of PQ we know that $\rho_{i+1}(PQ) = R$. We also know that $\rho_{i-1}(PQ) \leq R$ and therefore, since $PQ_i = (S, NOP)$, $\rho_i(PQ) \leq R - 1$. Thus $\rho_{i+1}(PQ) - \rho_i(PQ) \geq 1$ which implies that $PQ_{i+1} = (L, NOP)$ for some load operation L. ∎

LEMMA 6.2 (operations between two successive store operations). *Consider a k-spill, g-empty slot contiguous parallel evaluation PQ of a computation F with arbitrary load latencies and R available registers. If $PQ_i = (S, NOP)$ for some store operation S and the following store operation exists and is scheduled at time j, $j > i$, then for all m, $i + 1 < m < j$, PQ_m is of the form (L, A) or (NOP, NOP), and $\rho_m(PQ) = R$.*

Proof. Consider a store operation scheduled at time i of a contiguous parallel evaluation PQ with $\rho(PQ) \leq R$, and the following store operation scheduled at time j. We know from Lemma 6.1 that $PQ_{i+1} = (L, NOP)$ and from store-contiguity that $\rho_{i+1}(PQ) = R$. We now show by contradiction that for all m such that $i+1 < m < j$, $\rho_m(PQ) = R$. Assume that for some time m, $i+1 < m < j$, $\rho_m(PQ) < R$. Therefore the number of values in registers decreases by at least one between time $i + 1$ and m. Since there are, by assumption, no stores scheduled at these times, there must be at least one time m', $i + 1 < m' \leq m$ such that $PQ_{m'} = (NOP, A)$. However, there must be a load operation after time j that loads the value stored in slot j. Thus the empty load/store slot m' causes PQ not to be load-contiguous, which is a contradiction. Therefore, for all $i + 1 < m < j$, $\rho_m(PQ) = R$. This implies that for all m, $i + 1 < m < j$, PQ_m is of the form (L, A) or (NOP, NOP). ∎

LEMMA 6.3 (operations before the first store operation). *Consider a k-spill, g-empty slot contiguous parallel evaluation PQ of a computation F with arbitrary load latencies and R available registers. If the first store operation of PQ is scheduled at time i, then a load operation or an empty slot is scheduled at each time preceding time i, and exactly R empty arithmetic slots precede time i.*

Proof. Consider the first time i when a store operation S, if one exists, is scheduled in a contiguous parallel evaluation PQ with $\rho(PQ) \leq R$. Load-contiguity and the fact that there is a load operation scheduled at time $i+1$ imply that there can be no empty load/store slots before slot i, and since there are no stores there, there must be a load operation or an empty slot scheduled at each time before time i.

Store-contiguity implies that $\rho_{i+1}(PQ) = R$, so $\rho_{i-1} = R$ because $PQ_i = (S, NOP)$ and $PQ_{i+1} = (L, NOP)$ for some store operation S and load operation L. Therefore there are R more load operations than arithmetic operations scheduled before time i, which implies that there are exactly R empty arithmetic slots before time i. ∎

LEMMA 6.4 (operations after the last store operation). *Consider a k-spill, g-empty slot contiguous parallel evaluation PQ of a computation F with arbitrary load latencies and R available registers. If the last store operation of PQ is scheduled at time m, then there are no empty arithmetic slots after time $m+1$.*

Proof. Consider the last time m when a store operation S, if one exists, is scheduled in a contiguous parallel evaluation PQ with $\rho(PQ) \leq R$. We claim that there are no empty arithmetic slots after time $m+1$, and show this by contradiction. Note first that there can be no empty load/store slots between time m and the last load operation at time t. As argued above, if there is such an empty load/store slot, PQ would not be load-contiguous. Assume that PQ does contain an empty arithmetic slot m' such that $m+1 < m'$. If there is more than one such slot, we let m' be the first one. Therefore, there is an arithmetic operation or an empty slot scheduled at every time j, where $m+2 \leq j \leq m'-1$. (Recall that the operations scheduled at time $m+1$ have the form (L, NOP).) Since PQ is contiguous, there must be a load operation or an empty slot scheduled at every time j, where $m+1 \leq j \leq m'$. Therefore, $\rho_{m'-1}(PQ) = R$. Since $PQ_{m'} = (L, NOP)$ for some load operation L, $\rho_{m'}(PQ) = R+1$, which is a contradiction. Therefore, the empty arithmetic slot m' cannot exist. ∎

THEOREM 6.5 (cost of a contiguous parallel evaluation). *A k-spill, g-empty slot contiguous parallel evaluation PQ of a computation F with arbitrary load latencies and with $\rho(PQ) \leq R$ has cost $c(PQ) = \rho(PQ) + 2k + g + |A(F)|$.*

Proof. We have shown that in a contiguous parallel evaluation there are two empty arithmetic slots for each store operation (spill), namely, the slot with the store operation and the one immediately after. Furthermore there are no other empty arithmetic slots between a pair of store operations. If any stores exist, there are R empty arithmetic slots before the first store operation and there are no empty arithmetic slots after the last store, except for the slot immediately following the last store which is of the form (L, NOP). If there is at least one spill, $\rho(PQ) = R$ since PQ is contiguous. Therefore, the cost of a k-spill contiguous evaluation, where $k \geq 1$, is the sum of the number of slots containing arithmetic operations, plus the number empty arithmetic slots, plus the number of empty slots, i.e., $\rho(PQ) + 2k + g + |A(F)|$.

If there are no spills in a contiguous parallel evaluation PQ, the number of empty arithmetic slots can be seen to be $\rho(PQ)$. The number of values in registers only increases when operation pairs scheduled at some time are of the form (L, NOP). Since PQ contains no spills, the number of values in registers only decreases when operation pairs scheduled have the form (NOP, A). The number of values in registers is unchanged when operation pairs scheduled have the form (L, A) or (NOP, NOP). Since PQ is load-contiguous, each operation pair of the form (NOP, A) must follow all operation pairs of the form (L, NOP). Therefore, $\rho(PQ) =$ the number of

operation pairs of the form (L, NOP). Since arithmetic operations or empty slots are scheduled at all other times, the cost of a 0-spill contiguous evaluation is $\rho(PQ) + g + |A(F)|$. □

As a consequence of Theorem 6.5 and the preceding lemmas, a k-spill, g-empty slot contiguous evaluation that uses R registers has the following general form. The first store operation, if it exists, is preceded by a series of operation pairs of the form (L, A) interspersed with empty slots and R operation pairs of the form (L, NOP). Each of the k store operations is scheduled in an empty arithmetic slot, (S, NOP), and is followed by an operation pair of the form (L, NOP). Such pairs of load/store operations are followed by a series of operation pairs of the form (L, A) interspersed with empty slots. The evaluation ends with a series of operation pairs of the form (NOP, A), also interspersed with empty slots. It can be seen that the contiguous evaluation in Figure 5 satisfies Lemmas 6.1, 6.2, 6.3, and 6.4 and Theorem 6.5.

Note also that there are $R - 1$ final operations ($\rho(PQ) - 1$ operations if there are no stores) of the form (NOP, A) interspersed with empty slots. This will always be the case since there are R values in registers in the time period after the last store, schedules of dependence trees leave one final value in a register, operation pairs of the form (L, A) or (NOP, NOP) do not change the number of values in registers, and each operation pair of the form (NOP, A) reduces the number of values in registers by one. Any empty slots that follow the first empty arithmetic slot can be deleted without violating precedence. Furthermore the evaluation can be made to begin with R operation pairs of the form (L, NOP), followed by only (L, A) and (NOP, NOP) operation pairs up to the first store operation by simply pushing the leading A operations to the right until they are scheduled consecutively up to the first store operation (or consecutive slots up to the last (L, A) operation pair if there are no stores), and deleting any empty slots that precede the first arithmetic operation by more than one cycle.

7. Optimal parallel evaluations for latency = 1 or latency = 2. We describe an algorithm that solves the parallel scheduling problem given a computation F and R available registers. We first construct a k-spill, g-empty slot sequential evaluation P using an optimal sequential scheduling algorithm, such as the two described in section 3.1. Using the parallel transformation of section 3.3, we construct the parallel evaluation PQ_1. Using the load-contiguous transformation of section 4, we construct the evaluation PQ_2. Using the store-contiguous transformation of section 5, we construct the evaluation PQ_3. If $latency = 1$, we show that using the $latency = 1$ sequential scheduling algorithm to produce P in the first step gives an evaluation PQ_3 that is a solution to the parallel scheduling problem. Similarly, if $latency = 2$ we show that using the $latency = 2$ sequential scheduling algorithm to produce P in the first step gives an evaluation PQ_3 that is a solution to the parallel scheduling problem.

Note that the sequential evaluations produced by the two sequential scheduling algorithms can be quite different since they make different assumptions about the underlying processor. We begin by describing two properties that are independent of the optimal sequential scheduling algorithm used.

LEMMA 7.1. *Given a computation F with arbitrary load latencies and R available registers, there exists a solution to the parallel scheduling problem that is contiguous.*

Proof. By Theorem 4.1 and Theorem 5.1, given any parallel evaluation PQ of F that uses R registers, it is possible to construct another contiguous evaluation that uses R registers, contains no additional spills, and costs no more than PQ. □

As a result of Lemma 7.1, we consider only contiguous evaluations of F.

LEMMA 7.2. *Given a computation F with latency ≤ 2 and R available registers, evaluations P and PQ_3 produced by the parallel scheduling algorithm have the same number of spill operations plus empty slots, and PQ_3 has no fewer empty slots than P.*

Proof. By Lemma 3.2, no parallel evaluation of F that uses R registers can contain fewer spill operations plus empty slots than an optimal sequential evaluation. Since P is optimal, the number of spill operations plus empty slots in the parallel evaluations PQ_3 is not less than $2k + g$. But the transformations used to produce PQ_3 never increase the number of spill operations plus empty slots in the evaluation, as shown in Lemma 4.2 and Theorem 5.1. Therefore the number of spill operations plus empty slots in the parallel evaluation PQ_3 is exactly $2k+g$. Similarly, the number of empty slots in evaluation PQ_3 is not less than g. ∎

We now show that the parallel scheduling algorithm for *latency* $= 1$ gives an optimal evaluation.

THEOREM 7.3. *Given a computation F with latency $= 1$ and R available registers, the parallel scheduling algorithm for latency $= 1$ gives an evaluation, PQ_3, that is a solution to the parallel scheduling problem.*

Proof. By Lemma 7.2, the number of spill operations plus empty slots in parallel evaluation PQ_3 is $2k + g$. Since load latencies equal one we can assume that all evaluations contain no empty slots. Therefore, PQ_3 contains exactly k spills. We first show that only k-spill contiguous evaluations need to be considered. We then show that PQ_3 is an optimal k-spill contiguous evaluation of F.

Consider two contiguous evaluations of F, PQ and PQ', that contain k and k' spills, respectively, such that both use R registers and $k \neq k'$. We show that $c(PQ) \leq c(PQ')$. By Lemma 3.2 and since $g = 0$, no parallel evaluation of F that uses R registers can contain fewer than k spills, so $k < k'$. We first consider the case where $k > 0$. Since PQ is contiguous, and since it contains at least one spill, $\rho(PQ) = R$. Since $k < k'$, PQ' also contains at least one spill. Therefore $\rho(PQ) = \rho(PQ')$. Since both PQ and PQ' are contiguous, $c(PQ) = \rho(PQ) + 2k + |A(F)|$, and $c(PQ') = \rho(PQ') + 2k' + |A(F)|$. Since $k < k'$, $c(PQ) < c(PQ')$. Therefore if $k \neq 0$, no contiguous evaluation with more than k spills is optimal.

We now consider the case where $k = 0$. Since PQ uses R registers, $\rho(PQ) \leq R$ and $c(PQ) = \rho(PQ) + |A(F)|$. Since $k < k'$, PQ' contains at least one spill, so $\rho(PQ') = R$ and $c(PQ') = R + 2k' + |A(F)|$. Therefore, $c(PQ) < c(PQ')$. We have shown that given an arbitrary contiguous evaluation PQ' that uses R registers, if PQ' does not contain k spills, then PQ' cannot be an optimal evaluation of F. We will therefore only consider k-spill contiguous evaluations of F.

By Theorem 6.5, every k-spill contiguous evaluation PQ of F that uses R registers has cost $c(PQ) = \rho(PQ) + 2k + |A(F)|$. If $k > 0$, $c(PQ) = R + 2k + |A(F)|$, which is a constant. That is, all k-spill contiguous evaluations of F have the same cost and every one of them is optimal. In particular, PQ_3 is optimal.

If $k = 0$, $\rho(PQ)$ must be minimized in order to minimize $c(PQ) = \rho(PQ)+|A(F)|$. In [36] it is shown that the sequential scheduling algorithm minimizes the number of registers used. By Lemma 3.1, any parallel evaluation of a computation F can be transformed into a serial evaluation of F without increasing the maximum number of values in registers. Therefore, no parallel evaluation of F uses fewer than $\rho(P)$ registers. The evaluation P is transformed by our algorithm into PQ_2 by applying the parallel transformation followed by the load-contiguous transformation. Since $k = 0$ by assumption, the load-contiguous evaluation is also store-contiguous, and therefore contiguous. As described in section 3.3, the parallel transformation does

not change the maximum number of values in registers. By Theorem 4.1, the load-contiguous transformation also does not increase the maximum number of values in registers. Therefore, $\rho(PQ) = \rho(P)$ and $\rho(PQ)$ is minimized. We conclude therefore that PQ_3 is an optimal no-spill contiguous evaluation of F. ∎

The following theorem shows that the parallel scheduling algorithm for *latency* = 2 gives an optimal evaluation. The theorem relies on results regarding the optimal sequential scheduling algorithm for *latency* = 2 [28]. In particular we use the fact that if the number of available registers is large enough, the algorithm produces an evaluation containing no empty slots, and otherwise the evaluation produced must contain at least one empty slot. While the proof of Theorem 7.3 considered cases based on the number of spills, the proof of Theorem 7.4 considers cases based on the relative sizes of R and the minimum number of registers needed to avoid the use of spill code. With *latency* = 2, it is the number of available registers that affects the existence of empty slots in an optimal parallel evaluation.

THEOREM 7.4. *Given a computation F with latency = 2 and R available registers, the parallel scheduling algorithm for latency = 2 gives an evaluation, PQ_3, that is a solution to the parallel scheduling problem.*

Proof. We prove that no contiguous evaluation of F costs less than PQ_3. Let PQ' be an arbitrary k'-spill, g'-empty slot contiguous evaluation of F that uses R registers, and let $\rho' = \rho(PQ')$. We further let *minreg* equal the minimum number of registers needed to evaluate F without spill code on one processor with load latencies = 1. We first consider the case where $R \geq minreg + 1$. Since R is larger than *minreg*, evaluation P contains no spills and therefore PQ_3 contains no spills. Furthermore, when R is larger than *minreg* the sequential scheduling algorithm produces an evaluation containing no empty slots [28]. Since by Lemma 3.2 the transformations do not change $2k + g$, $c(PQ_3) = minreg + 1 + |A(F)|$. We now compare this cost to the possible costs of PQ'. If $\rho' \geq minreg + 1$, then by Theorem 6.5, $c(PQ_3) \leq c(PQ')$. If $\rho' = minreg$, then the sequential scheduling algorithm produces an evaluation containing at least one empty slot [28]. Since the transformations do not decrease the number of empty slots, $g \geq 1$, and again $c(PQ_3) \leq c(PQ')$. Finally if $\rho' < minreg$, then by assumption $\rho' < R$ and therefore k' must equal zero since PQ' is contiguous. This is a contradiction by Lemma 3.3 because all parallel evaluations that use fewer than *minreg* registers must contain at least one spill.

We next consider the case where $R = minreg$. The cost of evaluation PQ_3 is $R+2k+g+|A(F)|$. If $k' > 0$, then $\rho' = R$ since PQ' is contiguous. Therefore the cost of PQ' is $R+2k'+g'+|A(F)|$ which is not less than $c(PQ_3)$ because $2k+g \leq 2k'+g'$ by Lemma 3.2. If $k' = 0$, then it must be the case that $\rho' = R$, because if $\rho' < minreg$ then PQ' must contain at least one spill by Lemma 3.3. Therefore $c(PQ_3) \leq c(PQ')$ because $2k + g \leq 2k' + g'$.

Finally, we consider the case where $R < minreg$. The cost of evaluation PQ_3 is again $R + 2k + g + |A(F)|$. If $k' > 0$, then $\rho' = R$ and $c(PQ_3) \leq c(PQ')$ as before. If $k = 0$, then this contradicts Lemma 3.3 because $R < minreg$. Therefore in each case $c(PQ_3) \leq c(PQ')$, and we conclude that PQ_3 is an optimal evaluation of F. ∎

8. Computational complexity. We show in this section that the worst-case computational complexity of the parallel scheduling algorithms is $O(nk)$, where $n = |A| + |L|$ is the number of nodes in F and k is the number of spills in the evaluation.

The labeling routine of the sequential scheduling algorithms performs a depth-first traversal of the dependence graph and does a constant amount of work at each vertex. The worst-case complexity of a depth-first traversal of a binary tree is $O(n)$

[16]. Similarly, the worst-case complexity of the scheduling routine with load latencies $= 2$ is $O(n)$.

The parallel transformation of section 3.3 visits every time period in the sequential evaluation once and does a constant amount of work per visit. A sequential evaluation containing k spills is of length $n + 2k$, so the transformation's worst-case complexity is $O(n + k)$.

The load-contiguous transformation in section 4 can be implemented with two pointers. The first pointer points to each load operation in turn, starting from the beginning of the evaluation, and the second pointer always points to the latest empty load/store slot that is earlier than the first pointer. In the worst case, each pointer scans the $n + 2k$ time periods in the parallel evaluation once and is bounded by some constant time per time period. Thus, the transformation's complexity is $O(n + k)$.

The store-contiguous transformation in section 5 can be implemented by considering each store operation in turn, starting from the end of the evaluation. The transformation is repeatedly applied to the same store, moving it one time period later each time, until the transformation can no longer be applied. Applying the transformation once takes constant time. No store is moved more than $n + 2k$ time periods, i.e., from the beginning of the evaluation to the end. Since there are k stores, the transformation will take time $nk+2k^2$ in the worst case. Each value can be spilled at most once, so $k \leq n$. Thus, the complexity of the store-contiguous transformation is $O(nk)$. Since k is the minimum number of spills in any parallel evaluation of F, no stores will be deleted by the transformation and the load-contiguous transformation will not need to be reapplied. Unnecessary Empty slots can be deleted from the evaluation in $O(n + k)$ time. Thus, the worst-case complexity of the parallel scheduling algorithms is $O(nk)$.

9. Summary. We have presented an $O(nk)$ algorithm that solves the parallel scheduling problem for $latency = 1$ or $latency = 2$ by applying a series of transformations to an optimal sequential evaluation. We have shown that only contiguous evaluations need to be considered in searching for optimal parallel evaluations, and that optimal serial and optimal parallel evaluations have the same number of spill operations plus empty slots. We have fully described the structure of contiguous parallel evaluations and shown that the cost of the k-spill parallel evaluation PQ found by the algorithm is $\rho(PQ) + 2k + g + |A(F)|$.

These results may encourage further research on other, related problems. For example, extensions of our results may apply to trees with arbitrary arity, and to processors that can issue more operations simultaneously. The new transformations we describe may also form the basis for worst-case results for more general problems that cannot be efficiently solved.

Acknowledgments. We thank the anonymous referees for their detailed suggestions which have greatly improved this paper.

A POLYNOMIAL TIME APPROXIMATION SCHEME FOR INFERRING EVOLUTIONARY TREES FROM QUARTET TOPOLOGIES AND ITS APPLICATION*

TAO JIANG†, PAUL KEARNEY‡, AND MING LI‡

Abstract. Inferring evolutionary trees has long been a challenging problem for both biologists and computer scientists. In recent years research has concentrated on the *quartet method* paradigm for inferring evolutionary trees. Quartet methods proceed by first inferring the evolutionary history for every set of four species (resulting in a set Q of inferred quartet topologies) and then recombining these inferred quartet topologies to form an evolutionary tree. This paper presents two results on the quartet method paradigm. The first is a polynomial time approximation scheme (PTAS) for recombining the inferred quartet topologies optimally. This is an important result since, to date, there have been no polynomial time algorithms with performance guarantees for quartet methods. To achieve this result the natural *denseness* of the set Q is exploited. The second result is a new technique, called *quartet cleaning*, that detects and corrects errors in the set Q with performance guarantees. This result has particular significance since quartet methods are usually very sensitive to errors in the data. It is shown how quartet cleaning can dramatically increase the accuracy of quartet methods.

Key words. dense instance, evolutionary tree, approximation algorithm, quartet method, smooth polynomial

1. Introduction.

A fundamental problem in computational biology is inferring an evolutionary tree from biological data. Virtually all formulations of this problem (maximum likelihood, maximum parsimony, minimum distance, etc. [10, 15]) are NP-hard, and so, methods tend to be either heuristic (and seldom with performance guarantees) or prohibitively exhaustive. This is a real conundrum for evolutionary biologists as datasets can be very large forcing them to use heuristic methods that can lead to erroneous results.[1] The difficulties of inferring evolutionary trees that hamper biologists have also catalyzed a surge of algorithmic research in the computer science community. Despite this attention, efficient algorithms with performance guarantees have been slow in coming.

In recent years the computational biology community has focused on the *quartet method* paradigm for inferring evolutionary trees [3, 5, 8, 11, 14]. Quartet methods utilize topological information on sets of four labels[2] to infer an evolutionary tree. To illustrate, consider the four possible trees labeled by $\{a, b, c, d\}$ as depicted in Figure

[1] As exemplified by the *Out of Africa* fiasco [16, 17].

[2] A label may represent a species or, more generally, a DNA or protein sequence.

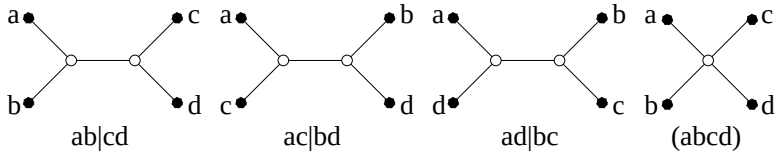

FIG. 1.1. *The four possible trees labeled by* $\{a, b, c, d\}$.

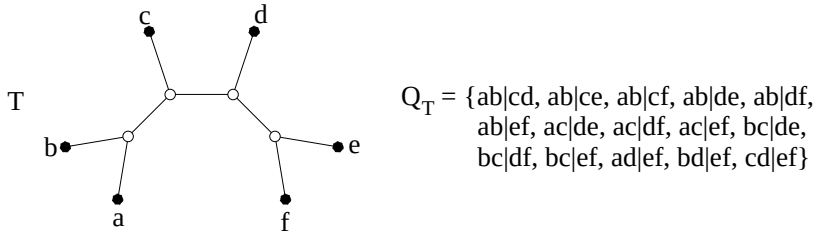

FIG. 1.2. *A tree* T *labeled by* $\{a, b, c, d, e, f\}$ *and* Q_T.

FIG. 1.3. *The quartet method paradigm.*

1.1. These labeled trees are denoted $ab|cd$, $ac|bd$, $ad|bc$, and $(abcd)$, respectively. The topology induced by the quartet $\{a, b, c, d\} \subseteq S$ in a tree T labeled by S is $ab|cd$ if a, b and c, d reside in disjoint subtrees of T. Q_T is defined to be the set of all topologies induced in T by quartets taken from S. For example, Figure 1.2 depicts a labeled degree-3 (i.e., fully resolved) tree T and its set of induced quartet topologies Q_T. We note that an evolutionary tree is usually represented by a labeled degree-3 tree with weighted edges. However, often the edge weights are determined after the shape of the tree is determined, as is the case for quartet methods. For the duration of the paper let evolutionary tree be synonymous with degree-3 labeled tree. Note that the set Q_T does not contain topologies of the form $(abcd)$ if T is a degree-3 tree.

Quartet methods are motivated by the following theorem that reveals the strong relationship between Q_T and T [7].

THEOREM 1.1. *Let* T *be an evolutionary tree.* Q_T *is unique to* T*, and furthermore,* T *can be recovered from* Q_T *in polynomial time.*

In other words, induced quartet topology provides much information about an evolutionary tree. This motivates the quartet method paradigm which is the following two step approach to inferring evolutionary trees (see Figure 1.3). Let T denote the evolutionary tree being estimated whose leaves are labeled by the elements of S:

1. A *quartet topology inference method* is used to infer the topology of each quartet in S from the data (typically DNA or protein sequence data). This results in a set Q of inferred quartet topologies.
2. A *quartet recombination method* is used to recombine the quartet topologies in Q to form an estimate T' of T.

There are several quartet topology inference methods including neighbor joining [12], the ordinal quartet method [11], maximum likelihood [9], and maximum

parsimony [15]. Quartet recombination methods attempt to solve variations of the following optimization problem.

MAXIMUM QUARTET CONSISTENCY (MQC).
Instance: A set Q of quartet topologies over label set S.
Goal: Find an evolutionary tree T labeled by S that maximizes $|Q_T \cap Q|$.

At this point we make an important distinction between two versions of MQC: *complete* MQC and *incomplete* MQC. A set Q of quartet topologies is *complete* if Q contains a quartet topology for each quartet over label set S. Incomplete MQC permits the input Q to be incomplete whereas the input to complete MQC is complete. Incomplete MQC is NP-hard [13]. In section 4 a proof of the NP-completeness of complete MQC is presented. Due to these results, most quartet recombination methods are heuristic or solve weaker optimization requirements. Examples are the Q^* method [5], the short quartet method [8], a semidefinite programming method [3], and quartet puzzling [14]. None of these methods give a performance guarantee. Despite the popularity of quartet methods, the absence of performance guarantees has been a legitimate criticism of the quartet method approach.

The distinction between complete and incomplete MQC is important for two reasons. First, in practice one almost always can obtain complete Q. Second, in this paper we present a polynomial time approximation scheme (PTAS) for complete MQC. In fact, this is the first PTAS for inferring an evolutionary tree under the quartet method paradigm and thus is a significant advancement in the development of algorithms for inferring evolutionary trees. A PTAS is desirable since it allows the approximation of an optimal solution with arbitrary precision (at the cost of efficiency). In contrast, Steel's proof that incomplete MQC is NP-hard can be adapted to show that incomplete MQC is MAX-SNP–hard; hence there is no PTAS for incomplete MQC unless NP=P, by the results of [2]. It should be pointed out that one may wish to weight quartets in practice. However, the weighted version of MQC is MAX-SNP–hard, as it generalizes the incomplete MQC, and thus has no PTAS.

Instances of complete MQC are *dense* relative to instances of incomplete MQC. Recently, the examination of dense versions of such MAX-SNP problems as Max–Cut, Betweenness, and Max–k–Sat has yielded PTASs for these problems [1, 2]. Dense instances of problems such as Max–Cut are graphs with $\Omega(n^2)$ edges whereas dense instances of Max–k–Sat are boolean k–Sat formulae with $\Omega(n^k)$ clauses. MQC is an example of an applied problem that motivates the examination of dense problems. How the natural denseness of an instance of MQC can be exploited to obtain a PTAS is explored further in section 2. In section 5 it is shown that the MQC PTAS can be extended to an important weighted variation of the problem and that this weighted version of the PTAS can be utilized to solve a consensus problem. For the duration of the paper MQC can be assumed to mean complete MQC.

Our second result is a new technique, called *quartet cleaning*, that can detect and correct quartet errors in the set Q of inferred quartet topologies. The quartet topology $ab|cd \in Q$ is called a quartet error if $ab|cd \notin Q_T$, where T is the evolutionary tree being estimated.

The practical motivation for quartet cleaning is that the accuracy of most quartet recombination methods depends critically upon the quality of the set Q. To illustrate, consider the sensitivity of the Q^* method and the short quartet method to quartet errors in Q. In particular, if e is an edge of T then $\{a, b, c, d\}$ is a quartet *across* e if a and b are in a separate component of $T - \{e\}$ than c and d (see Figure 1.4(i)). Both the Q^* method and the short quartet method have the property that a single

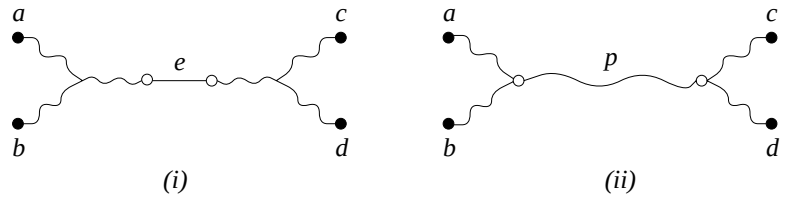

FIG. 1.4. (i) *ab|cd is a quartet across edge e.* (ii) *ab|cd is a quartet across path p.*

quartet error in Q involving a quartet across e can result in the edge e of T not being recovered. (These methods return a contraction of T at e.)

If there are m quartets across e in T and Q contains no more than $\alpha\sqrt{m}$ quartet errors involving quartets across e, where α is a constant, then quartet cleaning applied to Q returns a set Q' of quartet topologies where all of these quartet errors across e have been corrected. This results in a dramatic decrease in the sensitivity of quartet recombination methods such as Q^* method and the short quartet method to quartet errors; they can now tolerate up to $\alpha\sqrt{m}$ quartet errors across edge e, where before they could tolerate none. The bound $\alpha\sqrt{m}$ is shown to be asymptotically optimal in that no algorithm can correct more than $\alpha\sqrt{m}$ quartet errors across an edge.

A polynomial algorithm for quartet cleaning is presented in section 3. It makes nontrivial use of the PTAS for the MQC problem described above and thus serves as another motivation for this PTAS. This suggests that the ideas and techniques developed here are powerful and may find wider use for inferring evolutionary trees.

2. A PTAS for MQC. Let Q be an instance of MQC with label set S. Our discussion begins with the observation that $|Q_{T_{OPT}} \cap Q| \geq \binom{n}{4}/3$ where T_{OPT} is an optimal solution [3, 4]. This follows since a randomly selected tree has a 1/3 chance of inducing $ab|cd \in Q$, for each quartet $\{a, b, c, d\}$. Hence, for some constant c, $|Q_{T_{OPT}} \cap Q| \geq cn^4$. Our goal is then to find an approximation algorithm such that

$$|Q_{T_{APX}} \cap Q| \geq |Q_{T_{OPT}} \cap Q| - \epsilon n^4,$$

where T_{APX} is the result of the approximation algorithm.

The approximation algorithm is founded upon two concepts: a k–bin decomposition of T_{OPT} and smooth integer polynomial programs.

DEFINITION 2.1. *T_k is a k-bin decomposition of T_{OPT} if there is a partition of S into* bins *S_1, S_2, ..., S_k such that the following hold.*

- *For each S_i, $|S_i| \leq 6n/k$. Furthermore, there is a vertex v_i of degree $|S_i| + 1$, called the* bin root*, that is adjacent to each vertex in S_i.*
- *For all quartets $\{a, b, c, d\}$ where a, b, c, and d are in different bins of T_k, $ab|cd \in Q_{T_{OPT}}$ if and only if $ab|cd \in Q_{T_k}$.*

An example of a k-bin decomposition appears in Figure 2.1.

Section 2.1 will discuss k-bin decompositions in detail. In particular, it is shown that there is a k-bin decomposition T_k of T_{OPT} that is a good approximation of T_{OPT}, i.e., $|Q_{T_k} \cap Q| \geq |Q_{T_{OPT}} \cap Q| - (c'/k)n^4$, for some constant c'. Our approach is to approximate T_{OPT} indirectly by approximating T_k.

Consider a fixed k. Let K be T_k with all leaves removed (and thus the leaves of K are the bin roots of T_k). K is called the *kernel* of T_k and T_k is called a *completion* of K. K is completed to T_k by providing a label-to-bin assignment.

If the kernel K of T_k is known, then, to approximate T_k, it suffices to determine an approximately optimal label-to-bin assignment for K. This problem is formalized as follows.

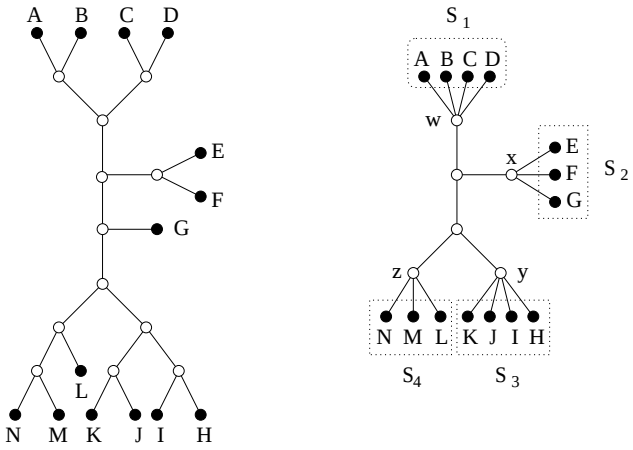

FIG. 2.1. *A tree (left) and a 4-bin decomposition of the tree (right) with bin roots w, x, y, and z.*

LABEL-TO-BIN ASSIGNMENT (LBA).
Instance: Set Q of quartet topologies and (degree-3) kernel K with k leaves.
Goal: Find a completion T' of K that maximizes $|Q_{T'} \cap Q|$.

It follows from the result in [6] that LBA is NP-hard. In section 2.2, LBA is formulated as a smooth integer polynomial problem and a PTAS for LBA is presented. In particular, it is shown that, for any $\epsilon > 0$, $|Q_{T'} \cap Q| \geq |Q_{\hat{T}} \cap Q| - \epsilon n^4$, where Q and K denote the instance of LBA, T' is the completion of K produced by our PTAS and $\hat{T}$ is an optimal completion of K.

The approximation algorithm solves (approximately) an instance of LBA for every tree with k leaves. Since k is a constant, this can be done in polynomial time using the PTAS for LBA. Let T_{APX} be the completed tree obtained that maximizes $|Q_{T_{APX}} \cap Q|$. Since the kernel K of T_k is one of the trees completed, it follows that $|Q_{T_{APX}} \cap Q| \geq |Q_{T'} \cap Q|$ where T' is the completion of K.

2.1. Decomposing the optimal tree. First we demonstrate that there is a k-bin decompositions that is a good approximation of the optimal evolutionary tree.

THEOREM 2.2. *There is a k-bin decomposition T_k of T_{OPT} such that $|Q_{T_k} \cap Q| \geq |Q_{T_{OPT}} \cap Q| - (c'/k)n^4$ for some constant c'.*

Theorem 2.2 is proven algorithmically. For convenience, let $T = T_{OPT}$ and assume that T is degree-3, without loss of generality. Let T_k denote the result of the following algorithm.

ALGORITHM k-BIN DECOMPOSITION(T).

1. Root T at an arbitrary internal vertex. Let $T(v)$ denote the subtree of T rooted at v.
2. Traverse T, beginning at the root, such that for each vertex v visited:
   If $|T(v)| \leq 6n/k$ then
   - contract all internal edges of $T(v)$,
   - label v as a bin root if v is not a leaf, and
   - continue traversal at v's parent.

   Otherwise, continue traversal at an unvisited child of v.
3. For each bin root v with parent v' and sibling u':
   If $|T(v)| \leq 3n/k$ and u' has a child u with $|T(u)| \leq 3n/k$ then
   - contract $\{u', v'\}$,

- transfer the leaves in $T(u)$ to the bin of v, and delete u.

4. For each leaf u of T not assigned to a bin, bisect the edge between u and its parent with a new vertex v, and mark v as a bin root.

Note that the last step of the algorithm is necessary since a leaf cannot be a bin root. Call a bin of T_k *small* if it has size less than $3n/k$. A bin root is *small* if its bin is small. Call a bin of T_k *large* if it has size between $3n/k$ and $6n/k$, inclusive. A bin root is *large* if its bin is large. Let s denote the number of small bins in T_k and l the number of large bins in T_k.

LEMMA 2.3. $s < 2l$.

Proof. We prove the following by induction: For every h, if u is a vertex of height h and is not a bin root then the lemma holds for the subtree $T(u)$.

For the base case, assume that u has children p and q. It cannot be that both p and q are small otherwise $|T(u)| < 6n/k$ and the algorithm would not have visited p and q. Hence, the lemma is true for $T(u)$.

In general, assume that u has children p and q. If both p and q are bin roots then the argument for the base case applies. If neither p nor q are bin roots then the inductive hypothesis applies to $T(p)$ and $T(q)$, and hence the lemma holds for $T(u)$. Otherwise, suppose that p is not a bin root but q is.

If q is large then the induction can be applied to $T(p)$ and the claim follows. Otherwise, suppose that q is small. Let p_1 and p_2 be the children of p. Neither p_1 nor p_2 are small, since otherwise the algorithm would have merged one of $T(p_1)$ and $T(p_2)$ with $T(q)$ in step 3. By the inductive hypothesis, $s_1 < 2l_1$ and $s_2 < 2l_2$ where s_1, l_1, s_2, and l_2 are the numbers of small and large bins in $T(p_1)$ and $T(p_1)$, respectively. It follows that $s_1 + s_2 + 1 < 2(l_1 + l_2)$, and hence the claim holds for $T(u)$. ∎

Since each large bin of T_k has size at least $3n/k$, $l \leq k/3$. T_k has $l + s$ bins, and so, $l + s < l + 2l = 3l \leq k$. We conclude that T_k has less than k bins each with size bounded by $6n/k$. Furthermore, since T_k was obtained from T by contracting edges and transferring leaves to neighboring bins, it follows that, for all quartets $\{a, b, c, d\}$ where a, b, c, and d are in different bins of T_k, $ab|cd \in Q_T$ if and only if $ab|cd \in Q_{T_k}$. The following lemma completes the proof of Theorem 2.2.

LEMMA 2.4. $|Q_{T_k} \cap Q| \geq |Q_{T_{OPT}} \cap Q| - (c'/k)n^4$ *for some constant* c'.

Proof. Observe that $|Q_{T_k} \cap Q| \geq |Q_{T_{OPT}} \cap Q| - |Q'|$ where Q' is the set of all quartets with an induced topology in T_{OPT} that is not induced in T_k. Let $\{a, b, c, d\} \in Q'$. It follows that at least two of these labels are in the same bin of T_k.

There are at most $k(6n/k)^2 n^2 = 36n^4/k$ quartets with two labels in the same bin. Similarly, there are at most $36n^4/k^2$ and $36n^4/k^3$ quartets with three and four labels in the same bin, respectively. It follows that

$$\begin{aligned} |Q_{T_k} \cap Q| &\geq |Q_{T_{OPT}} \cap Q| - 3(36n^4/k) \\ &\geq |Q_{T_{OPT}} \cap Q| - (108/k)n^4. \end{aligned}$$ ∎

2.2. A PTAS for LBA. Let Q and K be an instance of the LBA problem where K has k leaves. $\hat{T}$ is an optimal completion of K if $\hat{T}$ maximizes $|Q_{\hat{T}} \cap Q|$ over all completions of K. To formalize this optimization problem *smooth polynomials* are used. A degree d polynomial $p(x)$ is *t-smooth*, where t is a constant, if the coefficient of each degree i term is in the interval $[-tn^{d-i}, tn^{d-i}]$ for $0 \leq i \leq d$.

Define the 0-1 label-to-bin assignment $x = (x_{sb})$ as follows: $x_{sb} = 1$ if label s is assigned to bin b; otherwise x_{sb} is 0. For each quartet $\{a, b, c, d\} \in Q$, create a degree

4 polynomial

$$p_{ab|cd}(x) = \sum_{ij|kl \in Q_K} x_{ai}x_{bj}x_{ck}x_{dl},$$

and define

$$p(x) = \sum_{ab|cd \in Q} p_{ab|cd}(x).$$

Observe that $p(x)$ is 1-smooth. To ensure that each label is assigned to exactly one bin, the following constraints are added: for each label s, $\sum_{b=1}^{k} x_{sb} = 1$. We also require that none of the bins are too large: for each bin b, $\sum_{s=1}^{n} x_{sb} \leq 6n/k$.

Clearly, if x satisfies these constraints then $p_{ab|cd}(x) = 1$ if $ab|cd \in Q_{T'}$, and $p_{ab|cd}(x) = 0$ if $ab|cd \notin Q_{T'}$, where T' is the completion of K specified by the label-to-bin assignment x. Hence, our optimization problem is to find a 0-1 label-to-bin assignment $x = (x_{sb})$ so that

$$\begin{aligned} &p(x) \text{ is maximized,} \\ &\sum_{b=1}^{k} x_{sb} = 1 \text{ for each label } s, \\ &\sum_{s=1}^{n} x_{sb} \leq 6n/k \text{ for each bin } b. \end{aligned}$$

Arora, Frieze, and Kaplan [1] present a PTAS for solving t-smooth integer polynomial programs.

THEOREM 2.5. *For each $\epsilon > 0$ there is a polynomial time algorithm that produces a 0-1 assignment x such that $p(x) \geq m - \epsilon n^d$ where $p(x)$ is a t-smooth polynomial of degree d with maximum value m.*

The PTAS of Theorem 2.5 first solves the fractional version of the problem to obtain a solution $(\hat{x}_{sb})$. Randomized rounding is then used to obtain a 0-1 solution (x_{sb}). However, the rounding procedure used rounds each $\hat{x}_{sb}$ individually. This does not quite work here because of the additional constraints $\sum_{b=1}^{k} x_{sb} = 1$ for each label s. Hence, the following randomized rounding procedure is used instead: with probability $\hat{x}_{sb}$, $x_{sb} = 1$ and $x_{sj} = 0$ for all $j \neq b$. This ensures that exactly one of $x_{s1}, \ldots, x_{sk}$ is assigned 1 and the rest are assigned 0. This modification can be easily incorporated so that Theorem 2.5 holds. Following from the above discussion and Theorem 2.5, we have the following theorem.

THEOREM 2.6. *For each $\epsilon > 0$, there is a polynomial time algorithm that, for each instance Q and K of LBA, produces a completion T' of K such that $|Q_{T'} \cap Q| \geq |Q_{\hat{T}} \cap Q| - \epsilon n^4$ where $\hat{T}$ is an optimal completion of K.*

Combining the above results we can establish the following approximation result.

THEOREM 2.7. *For each $\epsilon > 0$, there is a polynomial time algorithm that, for each instance Q of* MQC*, produces a tree T_{APX} such that $|Q_{T_{APX}} \cap Q| \geq (1-\epsilon)|Q_{T_{OPT}} \cap Q|$.*

Proof. Let T_{OPT} and T_{APX} be defined as before and T_k be a k-bin decomposition of T_{OPT} that satisfies Theorem 2.2 for some constant k to be determined. Combining Theorems 2.6 and 2.2, we have that

$$\begin{aligned} |Q_{T_{APX}} \cap Q| &\geq |Q_{T_{OPT}} \cap Q| - (c'/k + \epsilon_1)n^4 \\ &\geq (1 - c'/(ck) - \epsilon_1/c)|Q_{T_{OPT}} \cap Q| \end{aligned}$$

for any constant $\epsilon_1 > 0$, since $|Q_{T_{OPT}} \cap Q| \geq cn^4$. The theorem result follows by choosing ϵ_1 sufficiently small and k sufficiently large. □

3. Quartet cleaning. Let T be an evolutionary tree and Q an estimate of Q_T. In order to correct quartet errors in Q we assume the following quartet error model: For each edge e of T there are at most $\alpha\sqrt{|Q_T(e)|}$ quartet errors in Q involving quartets across e where α is a constant to be determined and $Q_T(e)$ denotes the set of quartet topologies across the edge e of T (see Figure 1.4(i)). In this section we present a polynomial algorithm for correcting all quartet errors in Q under this error model. It is also shown that the above upper bound on quartet errors is asymptotically tight by proving a matching lower bound. More precisely, we prove that no algorithm can correctly infer the tree T when the set Q contains more than $\sqrt{|Q_T(e)|}$ errors across some edge e. Therefore, our algorithm is (asymptotically) optimal in terms of its power to correct quartet errors across an edge of T.

The section is organized as follows. We first define a variant of MQC, called the *minimum inconsistent balanced bipartition* (MIBB) problem, and devise a polynomial time approximation algorithm for MIBB with an additive error of ϵn^4 for any constant $\epsilon > 0$, using the same technique utilized by the PTAS for MQC. This approximation algorithm is then used recursively to clean quartets. The lower bound on quartet errors is given in section 3.3.

3.1. MIBB and its approximation. Let $S = \{1, \ldots, n\}$ denote the set of leaf labels. Each edge e of the evolutionary tree T induces a bipartition $X|Y$ of the labels. The quartets across the edge e are also referred to as the quartets induced by the bipartition $X|Y$. The bipartition $X|Y$ is called a *balanced bipartition* if $|X| \leq 2n/3$ and $|Y| \leq 2n/3$. An *edge separator* of the tree T is any edge that induces a bipartition $X|Y$ with the property that $|X| \leq 8n/9$ and $|Y| \leq 8n/9$. It is easy to see that T has at least one edge separator. We consider the following variant of MQC.

Minimum Inconsistent Balanced Bipartition (MIBB).
Instance: Set Q containing a quartet topology for each quartet of labels in S.
Goal: Find a balanced bipartition $A|B$ that induces the minimum number of quartet topologies inconsistent with the set Q. That is, we want to minimize the number of quartets $\{a, b, c, d\} \subseteq S$ such that $a, b \in A$, $c, d \in B$, and $ac|bd \in Q$.

MIBB is known to be NP-hard [6]. By formulating MIBB as a 2-bin variant of LBA, an approximation algorithm for MIBB with additive error ϵn^4 can be derived for any constant $\epsilon > 0$. This results in the following theorem.

Theorem 3.1. *For each $\epsilon > 0$, there is a polynomial time algorithm that produces a balanced bipartition $A|B$ that induces at most ϵn^4 more quartet topologies inconsistent with the set Q than an optimal balanced bipartition.*

3.2. A recursive algorithm for cleaning quartets. In this section we prove the following.

Theorem 3.2. *For some $\alpha > 0$, there is a polynomial time algorithm that produces the correct evolutionary tree T given a (complete) set Q of quartet topologies which contains at most $\alpha\sqrt{|Q_T(e)|}$ errors across any edge e of T.*

Before describing the algorithm in detail, we sketch its basic idea. First, we observe that the bipartition $A|B$ obtained by the approximation algorithm for MIBB on input Q is also a good approximation of a minimum inconsistent balanced bipartition for the set Q_T, since Q contains at most a total of $\alpha n^3 = o(n^4)$ erroneous quartet topologies. Moreover, we show that the bipartition $A|B$ in fact comes very close to the bipartition $X|Y$ induced by some edge separator of T, i.e., the symmetric differences

$A \oplus X$ and $B \oplus Y$ are very small. We *bootstrap* the bipartition $A|B$ by repeatedly swapping and joining incorrectly placed pairs of labels until it actually becomes the correct bipartition $X|Y$. Then we recursively bipartition sets X and Y independently, taking into account the labels in the set Y and X, respectively. Consider the case of bipartitioning X with the presence of Y. Let T_X denote the subtree of T induced by X. Observe that we can still approximately bipartition the set X as long as the errors in Q across an edge separator of T_X is significantly smaller than $|X|^4$. That is, we should have $|X|^4 \gg \alpha\sqrt{n^2|X|^2} = \alpha n|X|$, i.e., $|X| \gg n^{1/3}$. Hence, we stop the recursion at $|X| = \sqrt{n}$ and switch to a different algorithm which attempts to reconstruct the subtree T_X by directly taking advantage of the existence of a large "reference set" $Y = S - X$.[3] The details of the three main parts of the quartet cleaning algorithm are given below.

• **Inferring the first bipartition of *T*.** Fix a sufficiently small constant $\epsilon > 0$ so that all the inequalities below involving ϵ will hold. We run the approximation algorithm for MIBB on set Q to get a balanced bipartition $A|B$ of S. By Theorem 3.1, $A|B$ induces at most ϵn^4 quartet topologies inconsistent with Q and thus at most $\epsilon n^4 + O(n^3)$ quartet topologies inconsistent with Q_T. The following lemma shows that $A|B$ is "almost correct" in the sense that it is actually very close to the bipartition induced by some edge separator of T.

LEMMA 3.3. *Let e_0 be an edge separator of T inducing a bipartition $X|Y$ such that* (i) $|A \cap X| \geq |A|/3 \geq n/9$, (ii) $|B \cap Y| \geq |B|/3 \geq n/9$, *and* (iii) $\max\{|A \cap Y|, |B \cap X|\}$ *is minimized. (It is easy to see that such an edge e_0 exists.) Then* $\max\{|A \cap Y|, |B \cap X|\} \leq 11\epsilon^{1/3}n$.

Proof. Without loss of generality, assume that $|A \cap Y| \geq |B \cap X|$. Let $\epsilon_1 = |B \cap X|/n$ and $\epsilon_2 = |A \cap Y|/n$. Then

$$|Y| \geq |B \cap Y| = |B| - |B \cap X| \geq (1 - \epsilon_1)|B|.$$

Since each quartet $\{a, b, c, d\}$, where $a \in A \cap X$, $b \in A \cap Y$, $c \in B \cap X$, and $d \in B \cap Y$, yields a topology $ac|bd$ in T which is inconsistent with the bipartition $A|B$, we have

$$(n/9) \cdot (\epsilon_1 n) \cdot (\epsilon_1 n) \cdot (n/9) \leq \epsilon n^4 + O(n^3),$$

which implies that

$$\epsilon_1 \leq 9\sqrt{\epsilon}. \tag{3.1}$$

Suppose that the set Y is further partitioned into subsets Y_1 and Y_2, as illustrated in Figure 3.1. Without loss of generality, assume that $|B \cap Y_1| \leq |B \cap Y_2|$. Suppose that the constant ϵ (and thus the constant ϵ_1) is so small that

$$|B \cap Y_2| \geq (1 - \epsilon_1)|B| - |B \cap Y_1| \geq (1 - \epsilon_1)|B| - |B|/2 \geq |B|/3.$$

Thus, the edge e_1 inducing the partition $X \cup Y_1|Y_2$, as illustrated in Figure 3.1, is also an edge separator satisfying the conditions (i) and (ii) of the lemma. Then, we must have

$$|B \cap X| + |B \cap Y_1| \geq |A \cap Y|,$$

[3] There is certain analogy between this algorithm and the idea of using an *out-group* to root an evolutionary tree in biology.

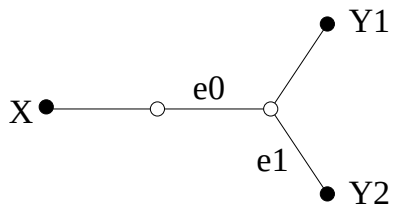

FIG. 3.1. *The edge separator e_0 and its induced bipartition.*

because otherwise the edge e_1 would have been a better choice than the edge e_0, violating the condition (iii) of the lemma. Since $|B \cap X| \leq \epsilon_1 n$,

$$|B \cap Y_1| \geq |A \cap Y| - \epsilon_1 n.$$

Since each quartet $\{a, b, c, d\}$, where $a \in A \cap X$, $b \in A \cap Y_1$, $c \in B \cap Y_1$, and $d \in B \cap Y_2$, yields a topology $ad|bc$ in T which is inconsistent with the bipartition $A|B$, we have

$$(n/9) \cdot |A \cap Y_1| \cdot (|A \cap Y| - \epsilon_1 n) \cdot (|A \cap Y| - \epsilon_1 n) \leq \epsilon n^4 + O(n^3).$$

Similarly, since each quartet $\{a, b, c, d\}$, where $a \in A \cap X$, $b \in A \cap Y_2$, $c \in B \cap Y_1$, and $d \in B \cap Y_2$, yields a topology $ac|bd$ in T which is inconsistent with the bipartition $A|B$,

$$(n/9) \cdot |A \cap Y_2| \cdot (|A \cap Y| - \epsilon_1 n) \cdot (|A \cap Y| - \epsilon_1 n) \leq \epsilon n^4 + O(n^3).$$

Summing up the above two inequalities, we have

$$(n/9) \cdot |A \cap Y| \cdot (|A \cap Y| - \epsilon_1 n)^2 \leq 2\epsilon n^4 + O(n^3).$$

Therefore,

$$\epsilon_2(\epsilon_2 - \epsilon_1)^2 \leq 18\epsilon.$$

It follows from (3.1) and the fact $\epsilon < 1$ that

$$\epsilon_2 < 11\epsilon^{1/3}. \qquad \square \tag{3.2}$$

Since the bipartition $A|B$ may still be incorrect (i.e., it may not be the bipartition induced by any edge of T), we try to revise it so it becomes eventually correct. From now on, let $\epsilon' = 11\epsilon^{1/3}$. We first try to detect the small number of pairs of labels that are "reversed" in the bipartition $A|B$. For any pair (a, b) of leaves, where $a \in A$ and $b \in B$, let us analyze how many quartet topologies $ax|by$ in the set Q, where $x \in A - \{a\}$ and $y \in B - \{b\}$, would "support" (i.e., be consistent with) the placement that the label a is in the set A and the label b is in the set B if (i) $a \in X$ and $b \in Y$ or (ii) $a \in Y$ and $b \in X$.

LEMMA 3.4. *Q has at least $((1-3\epsilon')^2 - \alpha/2)|X| \cdot |Y|$ quartet topologies supporting the placement $a \in A$ and $b \in B$ in case* (i) *(correctly), and at most $(12\epsilon' + \alpha/2)|X| \cdot |Y|$ quartet topologies supporting the placement $a \in A$ and $b \in B$ in case* (ii) *(incorrectly).*

Proof. Suppose that $a \in X$ and $b \in Y$. Let us first analyze how many quartet topologies $ax|by$ in the set Q_T, where $x \in A - \{a\}$ and $y \in B - \{b\}$, across the edge e_0 support the placement $a \in A$ and $b \in B$. Clearly, for any $x \in A \cap X - \{a\}$ and

$y \in B \cap Y - \{b\}$, the quartet topology $ax|by \in Q_T$ supports the placement. Hence the number of such supportive quartet topologies in Q_T across the edge e_0 is at least (roughly, omitting minor terms)

$$|A \cap X| \cdot |B \cap Y| \geq (1 - 3\epsilon')^2 |X| \cdot |Y|.$$

Since the set Q contains at most $\alpha|X| \cdot |Y|/2$ erroneous quartet topologies across the edge e_0, Q has at least

$$((1 - 3\epsilon')^2 - \alpha/2)|X| \cdot |Y|$$

quartet topologies supporting the placement $a \in A$ and $b \in B$.

The quartet topologies in Q supporting the placement $a \in A$ and $b \in B$ in case (ii) is at most

$$\begin{aligned} &|A| \cdot |B| - ((1 - 3\epsilon')^2 - \alpha/2)|X| \cdot |Y| \\ &\leq ((1 + 3\epsilon')^2 - (1 - 3\epsilon')^2 + \alpha/2)|X| \cdot |Y| \\ &= (12\epsilon' + \alpha/2)|X| \cdot |Y| \qquad \square \end{aligned}$$

Supposing that α is small enough and choosing ϵ sufficiently small, we can guarantee that the following inequality

$$\frac{12\epsilon' + \alpha/2}{(1 - 3\epsilon')^2 - \alpha/2} \leq \beta \tag{3.3}$$

holds for some small (but not too small) threshold β (exact value to be determined). Thus, from the set Q, we can decide if we should keep placing a in set A and b in set B, or switch them by checking the ratio between the supportive quartet topologies for each case.

We repeat the above test and correction until we cannot find any pair of labels to swap. Note that, in this process we may also swap pairs (a, b) with the property that $a \in A$, $b \in B$, and $a, b \in Y$ (or $a, b \in X$). That is, for such pairs we should (correctly) join them in the set Y (or X, respectively), but the quartet topologies in Q_T (and thus Q) tell us that they are reversed and we should swap them according to the above separation ratio. When this (e.g., $a, b \in Y$) happens, it must be the case that Y is bipartitioned into subsets Y_1 and Y_2 in the tree T, $a \in Y_1$, $b \in Y_2$, and $|Y_2| < \beta'|Y_1|$ for some constant β' depending on β, ϵ, and α. So, if we make sure that β is so small that $\beta' < 1/2$, then we won't switch such a pair (a, b) back and forth. Hence the process will converge in $O(n)$ swaps.

When the above process terminates, the bipartition $A|B$ may still not be consistent with any edge (separator) of T. But we must now have the property that either $X \subseteq A$ or $Y \subseteq B$, although we do not know which situation holds. So, in the following we try to further improve the bipartition $A|B$ assuming each situation separately.

Consider the case $X \subseteq A$ (the other case is symmetric). Let e be the edge of T whose induced bipartition, denoted $X'|Y'$, has the largest set X' that is completely contained in A. It is easy to see that $(1-3\epsilon')|Y'| \leq (1-3\epsilon')|Y| \leq |B \cap Y| \leq |B| \leq |Y'|$. Observe that e is in fact an edge separator. We will try to modify $A|B$ so it becomes the bipartition $X'|Y'$. Suppose that Y' is further bipartitioned into subsets Y_1' and Y_2' in the tree T, where $|Y_1'| \leq |Y_2'|$. By the choice of the edge e, $Y_1' \not\subseteq A$ and $Y_2' \not\subseteq A$. Moreover, from the above discussion on convergence, we know that if $|Y_1'| < \beta'|Y_2'|$ then $Y_2' \subseteq B$. Again, we take pairs of labels (a, b), where $a \in A$ and $b \in B$, and

analyze the support from Q for joining a and b in the set B if (i) $a \in X'$, or (ii) $a \in Y_i'$ and $b \in Y_i'$, for some i.

LEMMA 3.5. *Q contains at least* $(\min\{1/2 - 3\epsilon', \beta'/(1+\beta')\} - \alpha/2)|X'| \cdot |Y'|$ *supportive quartet topologies in case* (i) *and at most* $(6\epsilon' + \alpha/2)|X'| \cdot |Y'|$ *supportive quartet topologies in case* (ii).

Proof. Suppose that $a \in X'$. Q_T may contain a supportive quartet topology $ab|xy$, where $x \in A$ and $y \in B$, only if $x \in A \cap Y'$. Thus, the number of supportive quartet topologies in this case is at most

$$|Y' - Y' \cap B| \cdot |B| \leq 3\epsilon'|Y'|^2 \leq 6\epsilon'|X'| \cdot |Y'|.$$

Observe that, out of the $|X'|^2 \cdot |Y'|^2/4$ quartet topologies in Q_T across the edge e, only $\alpha|X'| \cdot |Y'|/2$ of them can go wrong in Q and become supportive; we claim Q contains at most

$$(6\epsilon' + \alpha/2)|X'| \cdot |Y'|$$

supportive quartet topologies.

Now suppose that $a \in Y_i'$ and $b \in Y_i'$ for some i. We consider two subcases. If $a \in Y_1'$ and $b \in Y_1'$, then all quartet topologies $ab|xy$ in Q_T, where $x \in A \cap X'$ and $y \in B \cap Y_2'$, would certainly be supportive. Hence, the number of supportive quartet topologies (across the edge connecting the sets $X \cup Y_2'$ and Y_1' in T) is at least

$$|X'| \cdot |Y_2'| \geq |X'| \cdot |Y'| \cdot (1/2 - 3\epsilon')$$

If $a \in Y_2'$ and $b \in Y_2'$, then $Y_2' \not\subseteq B$ and thus $|Y_1'| \geq \beta'|Y_2'|$. Since all quartet topologies $ab|xy$ in Q_T, where $x \in A \cap X'$ and $y \in B \cap Y_1'$, are supportive in this case, we have at least

$$|X'| \cdot |Y_1'| \geq |X'| \cdot \beta'|Y'|/(1+\beta')$$

supportive quartet topologies across the edge connecting the sets $X \cup Y_1'$ and Y_2' in T. Hence, Q contains at least

$$(\min\{1/2 - 3\epsilon', \beta'/(1+\beta')\} - \alpha/2)|X'| \cdot |Y'|$$

supportive quartet topologies in either subcase. ∎

Therefore, if we assume that α is sufficiently small, choose ϵ small enough and keep β' sufficiently large relative to α, then we can ensure that the inequality

$$\frac{6\epsilon' + \alpha/2}{\min\{1/2 - 3\epsilon', \beta'/(1+\beta')\} - \alpha/2} < \gamma \tag{3.4}$$

for some small threshold $\gamma < 1$. In other words, the set Q would contain sufficient information for us to tell if we should move a from the set A to the set B or not.

So we repeat the above step until (i) we cannot find any label to move or (ii) the size of A is getting below $|X| \geq n/9$. Observe that if we do not move anything at all in the whole process, then $A|B = X'|Y'$. In case (ii), we know that we have been moving in the wrong direction (i.e., $Y \subseteq B$ before the process started). In case (i), we could either get a correct bipartition $A|B = X'|Y'$ if $X \subseteq A$, or possibly an incorrect bipartition if $Y \subseteq B$. To check if the resulting bipartition is indeed one induced by some edge separator of T, all we need is to check if any pair (a, b), where $a \in A$ and

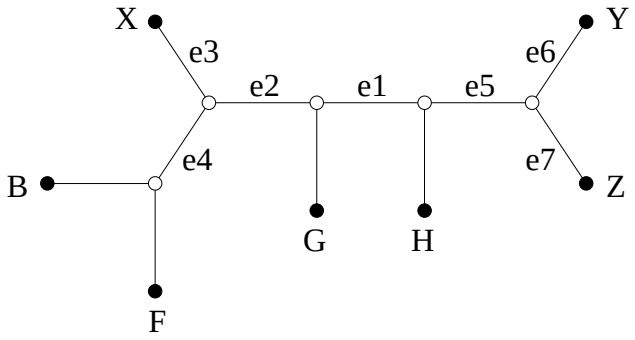

FIG. 3.2. *The placement of the labels $b \in B, x \in X, y \in Y$, and $z \in Z$ in T.*

$b \in B$, should be reversed under the criterion in inequality (3.3). Therefore, we can obtain at least one correct bipartition induced by some edge separator e' (which may or may not be e) of T, and clean up the erroneous quartets in Q across the edge e' safely.

• **The recursive step.** To continue cleaning up all errors in Q (or, equivalently, constructing the full T), we proceed in two stages. In the first stage, we recursively bipartition sets of sizes larger than $\sqrt{n}$. The general form of the problem is, given a correct bipartition $A|B$ of S, where $\sqrt{n} \leq |A| \leq 2n/3$, we try to find a bipartition of the set A consistent with T. The basic idea is the same as before, but we have to take into account the set B. Observe that since in the subtree of T induced by A, denoted as T_A, there can be at most $\alpha\sqrt{|A|^2 \cdot |B|^2} = \alpha|A| \cdot |B| = o(|A|^4)$ erroneous quartets across any edge of T_A, the approximation algorithm for MIBB will work on input Q_A (i.e., Q restricted to A), and will give us a good approximation of the bipartition induced by some edge separator of T_A as claimed in Lemma 3.3.

Let this approximate bipartition be $A_1|A_2$. We "hypothesize" if B should be placed in A_1 or A_2 by considering two bipartitions $A_1 \cup B|A_2$ and $A_1|A_2 \cup B$. For the bipartition $A_1 \cup B|A_2$, we swap and join pairs (a, b), where $a \in A_1$ and $b \in A_2$, as before, but by considering quartets $\{a, b, x, y\}$ of the special form $x \in B$ and $y \in A_2$. Similarly, for the bipartition $A_1|A_2 \cup B$, we swap and join pairs (a, b), where $a \in A_1$ and $b \in A_2$, by considering quartets $\{a, b, x, y\}$ of the form $x \in A_1$ and $y \in B$. It is straightforward to show that Lemmas 3.4 and 3.5 can be easily extended to work for these bipartitions. At the end we can again check which of the bipartitions yields a correct bipartition consistent with some edge separator of T_A as before.

• **Terminating the recursion.** We use the above recursive step to produce correct bipartitions $A|B$, where $|A| \leq \sqrt{n}$. Now we cannot continue the recursion since the errors in Q may jeopardize the performance of the approximation algorithm for MIBB when $|A|$ gets below $n^{1/3}$. So, we turn to a more direct cleaning approach which makes essential use of the large size of the set B.

Consider a quartet $\{b, x, y, z\}$, where $x, y, z \in A$ and $b \in B$. Suppose that the labels are placed in the tree T as illustrated in Figure 3.2.

Let's consider all quartets consisting of a label $b' \in B$, two of the labels x, y, z, and a label $a \in A - \{x, y, z\}$, and analyze the supports from the sets Q_T and Q for each of the three possible topologies $bx|yz$, $by|xz$, and $bz|xy$. For each edge e, let $f_Q(e)$ denote the number of errors in Q across edge e.

LEMMA 3.6. *The set Q contains at least*

$$\begin{aligned}&(1-6\alpha/2)|B|\cdot(|H|+|G|+|Y|+|Z|)-f_Q(e_3)-f_Q(e_4)\\&\leq(1-7\alpha/2)|B|\cdot(|H|+|G|+|Y|+|Z|)-\alpha|B|\cdot|X|\end{aligned}$$

more supportive quartet topologies for $bx|yz$ than for $by|xz$ or for $bz|xy$.

Proof. We first calculate the number of such quartet topologies in Q_T across an (arbitrarily chosen) edge e_1 as illustrated in the figure that support the correct topology $bx|yz$. A quartet $\{b', x, y, a\}$ would yield a supportive topology across e_1 if $a \in H \cup Z \cup Y - \{y\}$. So Q_T has $|B|\cdot(|H|+|Y|+|Z|-1)$ such supportive quartet topologies. Similarly, we know that Q_T has $|B|\cdot(|H|+|Y|+|Z|-1)$ supportive quartet topologies across e_1 of the form $b'x|az$ and $|B|\cdot(|F|+|G|+|X|)$ supportive quartet topologies across e_1 of the form $b'a|yz$. Hence, Q_T has a total of

$$|B|\cdot(2|H|+2|Y|+2|Z|+|F|+|G|+|X|-2)$$

supportive quartet topologies across the edge e_1. This implies that Q has at least

$$\begin{aligned}&|B|\cdot(2|H|+2|Y|+2|Z|+|F|+|G|+|X|-2)\\&-(\alpha/4)(|B|+|X|+|F|+|G|)\cdot(|Y|+|Z|+|H|)\\&\geq\ |B|\cdot(2|H|+2|Y|+2|Z|+|F|+|G|+|X|-\alpha(|Y|+|Z|+|H|)/4)\end{aligned}$$

supportive quartet topologies.

Let's calculate the number of quartet topologies in Q_T supporting the topology $by|xz$. A quartet $\{b', x, y, a\}$ would yield a supportive topology only if $a \in X - \{x\}$, and thus Q_T has $|B|\cdot(|X|-1)$ such supportive quartet topologies. Similarly, Q_T has $|B|\cdot|F|$ supportive quartet topologies of the form $b'a|xz$ and $|B|\cdot(|Z|-1)$ supportive quartet topologies of the form $b'y|az$. Hence, Q_T has a total of

$$|B|\cdot(|X|+|Z|+|F|-2)$$

supportive quartet topologies. This implies that Q has at most

$$|B|\cdot(|X|+|Z|+|F|-2)+\sum_{i=1}^{7}f_Q(e_i)$$

supportive quartet topologies, where $f_Q(e_i) \leq \alpha\sqrt{|Q_T(e_i)|}$ denotes the number of errors across the edge e_i in the current set Q.

Using the same idea, we claim that the set Q has at most

$$|B|\cdot(|X|+|Y|+|F|-2)+\sum_{i=1}^{7}f_Q(e_i)$$

members supporting the topology $bz|xy$.

So the difference between the support for the correct topology $bx|yz$ and that for incorrect ones $by|xz$ or $bz|xy$ is at least

$$\begin{aligned}&(1-\alpha/4)|B|\cdot(2|H|+|G|+|Y|+|Z|)-\sum_{i=1}^{7}f_Q(e_i)\\&\leq(1-\alpha/4)|B|\cdot(|H|+|G|+|Y|+|Z|)\end{aligned}$$

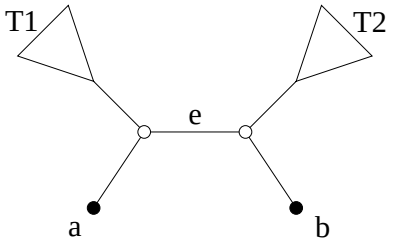

FIG. 3.3. *A hard case for quartet cleaning.*

$$\begin{aligned}
&- 5 \cdot (\alpha/4)|B| \cdot (|H| + |G| + |Y| + |Z|) - f_Q(e_3) - f_Q(e_4) \\
&\leq (1 - 6\alpha/4)|B| \cdot (|H| + |G| + |Y| + |Z|) - f_Q(e_3) - f_Q(e_4) \\
&\leq (1 - 6\alpha/4)|B| \cdot (|H| + |G| + |Y| + |Z|) \\
&\quad - \alpha|B| \cdot |X|/4 - \alpha|B| \cdot (|X| + |H| + |G| + |Y| + |Z|)/4 \\
&\leq (1 - 7\alpha/4)|B| \cdot (|H| + |G| + |Y| + |Z|) - \alpha|B| \cdot |X|/2. \qquad \square
\end{aligned}$$

The above difference between the supports is at least $-\alpha|B| \cdot |X|/2$ and would in fact be at least $(1 - 9\alpha/2)|B| \cdot (|H| + |G| + |Y| + |Z|)$ if (i) $|X| \leq |H| + |G| + |Y| + |Z|$ or (ii) the erroneous quartet topologies in Q across the edges e_3 and e_4 have already been fixed. This suggests that we should first work on the quartet $\{b, x, y, z\}$ which yields the largest difference.

More precisely, our algorithm finds the quartet $\{b, x, y, z\}$, where $x, y, z \in A$ and $b \in B$, with the largest margin in the supports from Q for each of its three possible topologies, and correct Q according to the topology with the highest support. We then consider the remaining quartets $\{b, x, y, z\}$ of the form $x, y, z \in A$ and $b \in B$, and repeat the same operation until correct topologies for all such quartets have been found.

3.3. An upper bound for quartet cleaning. The following theorem establishes an upper bound on the number of quartet errors across an edge that can be corrected.

THEOREM 3.7. *No algorithm can correctly reconstruct the evolutionary tree T if Q contains $\sqrt{|Q_T(e)|}$ or more erroneous quartet topologies across some edge e of T.*

Proof. Consider the tree in Figure 3.3 and quartets of the form $\{a, b, x, y\}$ where $x \in T_1$ and $y \in T_2$. If half of these quartets have topology $ax|by$ in Q whereas the other half have topology $ay|bx$ in Q then it cannot be decided which of these quartet topologies are erroneous. It follows that there must be no more that $|T_1||T_2|/2$ quartet errors across e. The theorem follows from

$$|T_1||T_2|/2 \leq \sqrt{|Q_T(e)|}. \qquad \square$$

4. Complete MQC is NP-complete. In this section we demonstrate that the following problem is NP-complete.

MAXIMUM QUARTET CONSISTENCY (DECISION) (MQCD).
Instance: A complete set Q of quartet topologies over label set S and nonnegative integer k.
Question: Is there an evolutionary tree T labeled by S such that $|Q_T \cap Q| \geq k$?

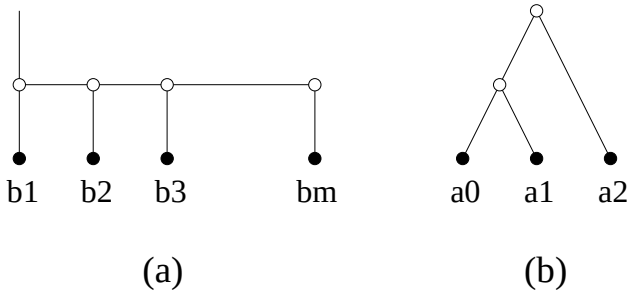

FIG. 4.1. (a) *The caterpillar tree M with $m \gg n^5$ feet (leaves).* (b) *Each label $a \in S$ is replaced by three $a_0, a_1, a_2 \in S'$.*

It is clear that MQC is in NP. To complete the proof we reduce Quartet Compatibility to MQC.

QUARTET COMPATIBILITY.
Instance: A (possibly incomplete) set Q of quartet topologies on label set S.
Question: Is Q compatible, i.e., does there exist an evolutionary tree T labelled by S such that $Q \subseteq Q_T$?

This problem is known to be NP-hard [13]. Given an instance of **Quartet Compatibility** with a quartet topology set Q defined on a label set S, where $n = |S|$, we will construct an instance of MQC with a *complete* quartet topology set Q' defined on a new label set S' such that there is a evolutionary tree T realizing Q with no error if and only if there is a evolutionary tree T' realizing Q' with at most $g(n)m + f(n)$ errors, where $f(n) = O(n^4)$, $g(n) = O(n^3)$ and $m \gg n^5$ will be specified later.

The basic idea behind this proof is to add topologies to Q for quartets that are not specified in Q to create a complete set Q' such that with respect to any optimal evolutionary tree T' for Q', precisely one third of the added quartet topologies are correct. In order to do this, we will need a large evolutionary tree M on m leaves with a fixed (e.g., caterpillar) structure (see Figure 4.1 (a)), where m is a number that is both divisible by three and much larger than the number of missing quartet topologies in Q, e.g., $m \gg n^5$. M will be embedded as a subtree in the optimal evolutionary tree T' and will be used to enforce certain useful structures in T'.

We construct the sets S' and Q' as follows. Add the m leaf-labels $b_1, \ldots, b_m$ in M to S', and for each $a \in S$, create three new labels a_0, a_1, a_2 and add them to S'. Note that we do not add the original labels in S to S'. We want to specify Q' such that (i) each triplet of labels a_0, a_1, a_2 appear together in a subtree of T' as in Figure 4.1(b) and (ii) the optimal evolutionary tree T' for Q' is formed by attaching M to some branch of a evolutionary tree $\hat{T}$ that is obtained from an optimal evolutionary tree T for Q by replacing every leaf of T with a subtree containing three leaves as shown in Figure 4.1(b).

Intuitively, Q' must be constructed to enforce the following conditions:

- M appears intact in T' as in Figure 4.1(a).
- Each created triplet of labels a_0, a_1, a_2 appear together in a subtree of T' as in Figure 4.1(b), with nothing else inserted between them.
- The quartet topologies in Q extend naturally to Q'. That is, if $ab|cd \in Q$, then $a_i b_j | c_k d_l$ is included in Q' for all $0 \le i, j, k, l \le 2$.
- For each quartet involving one label from M and three labels corresponding to three distinct elements of S, its topology is related to the (unknown) structure

of T (or $\hat{T}$) and the branch of $\hat{T}$ where M is attached. Hence, we should make sure that the number of erroneous topologies induced from such quartets is independent of the structure of T and the location where M is attached.

- For all quartets on S' that correspond to labels of Q with missing topologies in Q, we add quartet topologies in Q' such that precisely one third of these new quartet topologies are satisfied in T'. This is the difficult part since we do not know the structure of T'.

Here are the details of the construction. Let $w, x, y, z \in S'$ be four distinct labels.

1. If the labels are all in M, specify the quartet topology according to the structure of M as shown in Figure 4.1(a).
2. If $w = a_i$ for some $a \in S$, $x = b_j, y = b_k$, and $z = b_l$ with $j < k < l$, specify the topology as $wx|yz$.
3. If $w, x \in M$ and $y, z \notin M$, specify the topology as $wx|yz$.
4. If $w = b_i \in M$ and $x, y, z \notin M$, we consider two subcases.
   (a) If at least two of x, y, z correspond to the same label in S, then the quartet topology can be specified according to the required structure of T' described above.
   (b) If x, y, z correspond to distinct labels in S, then specify the topology as $b_i x|yz$ if $i \leq m/3$, or as $b_i y|xz$ if $m/3 < i \leq 2m/3$, or as $b_i z|xy$ if $i > 2m/3$. Intuitively, here we are partitioning M into three subsets $\{b_1, \ldots, b_{m/3}\}$, $\{b_{m/3+1}, \ldots, b_{2m/3}\}$, and $\{b_{2m/3+1}, \ldots, b_m\}$ so that quartets of the above form will introduce the same number of errors no matter how T looks and where M is attached in $\hat{T}$.
5. Finally, if none of the labels are from M, we consider three subcases.
   (a) If at least two of them correspond to the same label in S, then this quartet topology can be specified as before.
   (b) If they correspond to a quartet on S that has a resolved topology in Q, then specify the same topology in Q'.
   (c) If they correspond to a quartet on S whose topology is missing in Q, we take care of all such quartets collectively. Recall that each such quartet of labels $w, x, y, z \in S$ corresponds to $3^4 = 81$ different quartets on S'. We divide them into $81/3 = 27$ disjoint *groups*. Each group contains three quartets:

$$\begin{gathered} w_0, x_i, y_j, z_k, \\ w_1, x_{i+1 \bmod 3}, y_{j+1 \bmod 3}, z_{k+1 \bmod 3}, \\ w_2, x_{i+2 \bmod 3}, y_{j+2 \bmod 3}, z_{k+2 \bmod 3}. \end{gathered}$$

   For each group, we specify quartet topologies as follows:

$$\begin{gathered} w_0 x_i | y_j z_k, \\ w_1 y_{j+1 \bmod 3} | x_{i+1 \bmod 3} z_{k+1 \bmod 3}, \\ w_2 z_{k+2 \bmod 3} | x_{i+2 \bmod 3} y_{j+2 \bmod 3}. \end{gathered}$$

Obviously, the quartet topologies defined in items 1, 2, 3, 4(a), 5(a), and 5(b) do not introduce any errors in T' if M stays as shown in Figure 4.1(a) and for each label $a \in S$, its associated triplet of labels $a_0, a_1, a_2 \in S'$ appear together in a subtree of T' as shown in Figure 4.1(b). The following lemmas give exact error bounds for quartet topologies defined in items 4(b) and 5(c).

LEMMA 4.1. *If M does not split, item* 4(b) *introduces precisely $g(n)m$ quartet errors, where $g(n) = 18\binom{n}{3}$.*

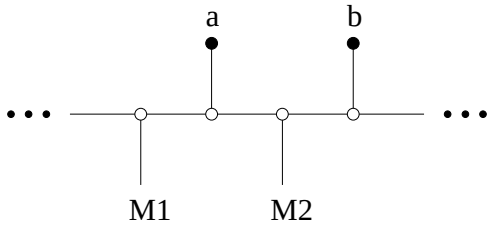

FIG. 4.2. *M is split by label a.*

Proof. The number of quartets considered in item 4(b) is $\binom{n}{3} \cdot 3^3 \cdot \frac{2m}{3} = 18\binom{n}{3}m = g(n)m$. ∎

LEMMA 4.2. *Let $q(n) = \binom{n}{4} - |Q|$ be the number of missing quartet topologies in Q. If M does not split, then for each $a \in S$, its associated triplet of labels $a_0, a_1, a_2 \in S'$ appear together in a subtree of T' as shown in Figure* 4.1(b) *and item* 5(c) *introduces precisely $f(n) = 54q(n)$ quartet errors.*

Proof. Suppose that for some $a \in S$, the triplet $a_0, a_1, a_2 \in S'$ do not appear together in a subtree as shown in Figure 4.1(b). Assume for the worst case that there is a single leaf x separating these three elements in T' as shown below: Then, for any label $y \in M$, the quartet topology $a_0x|a_1y$ in Q' would be an error. As there are at least m such y, this gives rise to at least m quartet errors. Since $m \gg n^5$, we can improve T' by moving x away from the triplet a_0, a_1, a_2, which contradicts to the fact that T' is optimal for Q'.

Given that each triplet of labels corresponding to a label in L appear together in a subtree in T' as shown in Figure 4.1(b), precisely one third of the 81 quartet topologies specified in item 5(c) for each missing quartet in Q are correct. Hence, item 5(c) introduces precisely $81 \cdot \frac{2}{3}q(n) = 54q(n) = f(n)$ quartet errors. ∎

Finally, we have to show that M does not split in the optimal evolutionary tree T'.

LEMMA 4.3. *In the optimal evolutionary tree T' realizing Q', M stays intact as the caterpillar shown in Figure* 4.1(a).

Proof. Splitting M may reduce the error terms in Lemma 4.1 and Lemma 4.2. We argue that such splittings are not worthwhile because they introduce more quartet errors to T' than they can save.

To illustrate the idea of the argument, suppose that some labels $a, b \notin M$ split M into two subsets M_1 and M_2, as shown in Figure 4.2.

In this case, we may (or may not) save at most $g(n) \cdot \min\{|M_1|, |M_2|\}$ errors from item 4 that. But this splitting creates at least $\Omega(|M_1| \cdot |M_2|)$ new errors because all quartet topologies of the form

$$m_1a|m_2b,$$

where $m_1 \in M_1, m_2 \in M_2$, are erroneous. Since $m \gg n^5$ and $g(n) = O(n^3)$, it is easy to see that $|M_1| \cdot |M_2| \gg g(n) \cdot \min\{|M_1|, |M_2|\}$. Hence, the splitting in fact creates more errors than it can save.

Therefore, in the optimal evolutionary tree T', M stays in one piece as a caterpillar subtree. ∎

From the above lemmas, we conclude that Q is compatible if and only if there exists an evolutionary tree T' that is inconsistent with Q' on at most (in fact, exactly) $g(n)m + f(n)$ quartets.

5. Discussion. In practice, the inference of quartet topology is not reliable, and so, confidence levels are assigned to quartet topologies. For example, for quartet $\{a, b, c, d\}$ the quartet topologies $ab|cd$, $ac|bd$, and $ad|bc$ may be assigned confidence levels 80%, 15%, and 5% indicating that we have the most confidence in the inference $ab|cd$ but that this confidence is not 100%. Given this information, the weighted MQC problem is to obtain an evolutionary tree T that maximizes

$$\sum_{ab|cd \in Q_T} w(ab|cd),$$

where $w(ab|cd)$ denotes the confidence level of quartet topology $ab|cd$. The MQC PTAS can be extended to solve this weighted variation on MQC as long as the weights are drawn from some interval of positive integers of constant range to preserve the smoothness of the polynomial integer programs. On the other hand, when the weights are allowed to be 0-1, weighted MQC becomes the incomplete MQC problem which is MAX-SNP–hard.

The PTAS for weighted MQC can also be used to solve the quartet consensus problem [6]. In the quartet consensus problem, several evolutionary trees T_1, T_2, ..., T_k compete as alternate hypotheses for the evolutionary history of a label set S. The goal is to produce an evolutionary tree T that maximizes the sum

$$\sum_{i=1}^{k} |Q_T \cap Q_{T_i}|.$$

When k is a constant this can be solved by defining $w(ab|cd)$ to be the number of evolutionary trees T_i in which $ab|cd$ is induced, for each quartet topology $ab|cd$, and then applying the weighted MQC PTAS.

In an error model that restricts the number of quartet errors across an edge, each quartet error may be "charged" to many edges. For example, in Figure 1.4(ii), a quartet error involving the labels a, b, c, and d would be charged to all edges on the path p connecting a, b with c, d. Hence, it is also natural to associate quartet errors with *paths* instead of edges. If p is a path in T then $\{a, b, c, d\}$ is a quartet across p if p contains all the edges crossed by the quartet $\{a, b, c, d\}$, as illustrated in Figure 1.4(ii). Error models that restrict the number of quartet errors across paths and those that restrict the number of quartet errors across edges are incomparable. In general, the former are good at capturing uniformly distributed errors while the latter are better suited for describing localized errors. Let $Q_T(p)$ denote the set of quartets across a path p of T. It is not hard to extend our bipartition-based quartet cleaning algorithm to work under the assumption that Q contains at most $\alpha\sqrt{|Q_T(p)|}$ quartet errors across any path p of T, for some constant $\alpha > 0$.

Several open problems present themselves. In particular, the quartet cleaning technique presented here is based upon an error model that bounds the number of quartet errors across every edge of the evolutionary tree. A method that could clean quartet errors across edges independently would be an improvement. It is hopeless to obtain a PTAS for the sparse MQC problem since it is MAX-SNP–hard. Can we obtain a better than 1/3 approximation for the sparse MQC problem?

Acknowledgment. We would like to thank the anonymous referees for their detailed comments.

AN EXTENSION OF PATH COUPLING AND ITS APPLICATION TO THE GLAUBER DYNAMICS FOR GRAPH COLORINGS*

MARTIN DYER†, LESLIE ANN GOLDBERG‡, CATHERINE GREENHILL§, MARK JERRUM¶, AND MICHAEL MITZENMACHER‖

Abstract. A new method for analyzing the mixing time of Markov chains is described. This method is an extension of path coupling and involves analyzing the coupling over multiple steps. The expected behavior of the coupling at a certain stopping time is used to bound the expected behavior of the coupling after a fixed number of steps. The new method is applied to analyze the mixing time of the Glauber dynamics for graph colorings. We show that the Glauber dynamics has $O(n \log(n))$ mixing time for triangle-free Δ-regular graphs if k colors are used, where $k \geq (2 - \eta)\Delta$, for some small positive constant η. This is the first proof of an optimal upper bound for the mixing time of the Glauber dynamics for some values of k in the range $k \leq 2\Delta$.

Key words. Markov chains, coupling, stopping times, graph coloring, Glauber dynamics

1. Introduction.

In this paper, a new method for analyzing the mixing time of Markov chains is described. This method is a nontrivial extension of path coupling, and applies in situations where path coupling is not enough to prove rapid mixing. We run the path coupling for multiple steps and use the expected behavior of the coupling at a certain *stopping time* to bound the expected behavior of the coupling after a fixed number of steps. Standard path coupling is a worst-case analysis in that it considers the expected change in the distance between the worst possible pair of states over a single step. However, in a multiple-step analysis, the choice of the initial pair of states is mitigated by the random choices made by the coupling over several steps. Hence, with some constant probability, we are not in the worst case. This is how a multiple-step analysis can improve upon one-step path coupling.

The approach of analyzing the behavior of a Markov chain over several steps has proved worthwhile in other settings. For example, it has been used to prove the stability of randomized bin-packing algorithms [7, 16, 1] and contention resolution protocols [14, 13]. Hence this approach appears to be a natural direction for coupling arguments as well.

Czumaj et al. [8] introduced a framework for multiple-step couplings based on path coupling, which they call *delayed path coupling*. Their "delayed path coupling lemma" [8, Lemma 4.2] (reproduced below as Lemma 2.2) shows how the mixing time of a Markov chain can be bounded above in terms of the behavior of a coupling over a fixed number of steps. However, the way in which the coupling is analyzed over the fixed time interval is not specified, and Czumaj et al. give a few different applications. In some applications, they explicitly construct a non-Markovian coupling over the full time interval. The construction and analysis of such a coupling can be very complicated. However, we use straightforward path coupling to drive our multiple-step coupling, performing most of our analysis at a specially defined stopping time. The next section contains a description of this new method.

We then apply our method to the problem of analyzing the mixing time of the Glauber dynamics for graph colorings. A proper k-coloring of a graph $G = (V, E)$ is a labelling of the vertices from a set of colors $C = \{1, \ldots, k\}$ such that no two neighboring vertices have the same color. We consider the problem of sampling nearly uniformly from the set of all proper k-colorings of a graph of maximum degree Δ. Note that efficiently sampling k-colorings nearly uniformly allows one to approximately count such colorings [15]. This problem is interesting as a fundamental combinatorial problem, and it also relates to several problems in statistical physics; see [15, 23] for more details.

A standard approach to the sampling problem is to design a Markov chain whose stationary distribution is uniform over all proper k-colorings. We can then sample nearly uniformly from all proper k-colorings by running the Markov chain until the distribution of the state is sufficiently near the stationary distribution. For this approach to be efficient, the number of steps for which we must run the Markov chain must be sufficiently small. The number of steps for which we must run the Markov chain is generally called the *mixing time*, and a Markov chain for sampling proper k-colorings is *rapidly mixing* if the mixing time is bounded above by some polynomial in $|V| = n$.

Jerrum [15] (and independently Salas and Sokal [21], using different methods) showed that when $k \geq 2\Delta$, a simple Markov chain is rapidly mixing. This Markov chain is easily described as follows: choose a vertex v uniformly at random and a color c uniformly at random; recolor v to color c if doing so yields a proper coloring. This Markov chain is generally referred to as the Glauber dynamics in the statistical physics literature. Jerrum proved that the Glauber dynamics has $O(n \log(n))$ mixing time for $k > 2\Delta$, while for $k = 2\Delta$ the best known upper bound was $O(n^3)$. We use our new method to show that, for $\Delta \geq 14$, the Glauber dynamics chain has $O(n \log(n))$ mixing time for $k \geq (2-\eta)\Delta$ whenever the graph is triangle-free and Δ-regular, where η is some small, positive constant. It seems to be widely believed that $\Omega(n \log n)$ is a lower bound on the mixing time of the Glauber dynamics; however, we do not know of an existing proof. We present a simple proof of this fact in Theorem 3.1, for the special case of graphs with no edges. Therefore our $O(n \log n)$ bound on the mixing time is optimal. Our main result is the first proof of an optimal upper bound for the mixing time of the Glauber dynamics for some values of k in the range $k \leq 2\Delta$.

The 2Δ barrier has been broken using more complicated chains, but as far as we know this is the first proof that involves direct analysis of the simple Glauber dynamics chain. In [5], a rapidly mixing Markov chain was presented for the case $\Delta = 3$, $k = 5$ (and for $\Delta = 4$, $k = 7$ when the graph is triangle-free and 4-regular). The proof involves the analysis of several (in the hundreds for the $\Delta = 3$ case)

linear programming problems related to the chain. Using a comparison technique such as [6, 9, 10, 11, 20] one can conclude that the Glauber dynamics is also rapidly mixing for these values of k, Δ. However, applying a comparison technique generally increases the upper bound on the mixing time by several factors of n.

In recent work, Vigoda [23] has proven that $k \geq 11\Delta/6$ is sufficient for rapid mixing, using an entirely different Markov chain (similar to the well-known Swendsen–Wang algorithm [22]). Again, his result implies rapid mixing of the Glauber dynamics for $k \geq 11\Delta/6$, but with an $O(n^2 \log n)$ bound on the mixing time. His result clearly dominates ours in terms of the range of k for which rapid mixing is established. However, because our analysis is based directly on the Glauber dynamics chain and achieves an optimal bound, and because we use a new technique based on analyzing this chain over multiple steps, our result is of independent interest.

2. Path coupling using stopping times. Before describing the new method we present some standard definitions and notation. Let Ω be a finite set and let $\mathcal{M}$ be a Markov chain with state space Ω, transition matrix P, and unique stationary distribution π. If the initial state of the Markov chain is x then the distribution of the chain at time t is given by $P_x^t(y) = P^t(x, y)$. The *total variation distance* of the Markov chain from π at time t, with initial state x, is defined by

$$\mathrm{d_{TV}}(P_x^t, \pi) = \frac{1}{2} \sum_{y \in \Omega} |P^t(x, y) - \pi(y)|.$$

Following Aldous [3], let $\tau_x(\varepsilon)$ denote the least value T such that $\mathrm{d_{TV}}(P_x^t, \pi) \leq \varepsilon$ for all $t \geq T$. The *mixing time* of $\mathcal{M}$, denoted by $\tau(\varepsilon)$, is defined by $\tau(\varepsilon) = \max\{\tau_x(\varepsilon) : x \in \Omega\}$. A Markov chain is said to be *rapidly mixing* if the mixing time is bounded above by some polynomial in n and $\log(\varepsilon^{-1})$, where n is a measure of the size of the elements of Ω. Throughout this paper all logarithms are to base e.

There are relatively few methods available to prove that a Markov chain is rapidly mixing. One such method is *coupling*. A coupling for $\mathcal{M}$ is a stochastic process (X_t, Y_t) on $\Omega \times \Omega$ such that each of (X_t), (Y_t), considered marginally, is a faithful copy of $\mathcal{M}$. The moves of the coupling are correlated to encourage the two copies of the Markov chain to *couple*: i.e., to achieve $X_t = Y_t$. This gives a bound on the total variation distance using the *coupling lemma* (see for example, Aldous [3]), which states that

$$\mathrm{d_{TV}}(P_x^t, \pi) \leq \mathrm{Prob}[X_t \neq Y_t],$$

where $X_0 = x$ and Y_0 is drawn from the stationary distribution π. The following standard result is used to obtain an upper bound on this probability and hence an upper bound for the mixing time (the proof is omitted).

THEOREM 2.1. *Let (X_t, Y_t) be a coupling for the Markov chain $\mathcal{M}$ and let ρ be any integer valued metric defined on $\Omega \times \Omega$. Suppose that there exists $\beta \leq 1$ such that $\mathbf{E}[\rho(X_{t+1}, Y_{t+1})] \leq \beta\, \rho(X_t, Y_t)$ for all t, and all $(X_t, Y_t) \in \Omega \times \Omega$. Let D be the maximum value that ρ achieves on $\Omega \times \Omega$. If $\beta < 1$ then the mixing time $\tau(\varepsilon)$ of $\mathcal{M}$ satisfies $\tau(\varepsilon) \leq \log(D\varepsilon^{-1})/(1 - \beta)$. If $\beta = 1$ and there exists $\alpha > 0$ such that*

$$\mathrm{Prob}[\rho(X_{t+1}, Y_{t+1}) \neq \rho(X_t, Y_t)] \geq \alpha$$

for all t, and all $(X_t, Y_t) \in \Omega \times \Omega$, then $\tau(\varepsilon) \leq \lceil eD^2/\alpha \rceil \lceil \log(\varepsilon^{-1}) \rceil$.

From now on, assume that all couplings are Markovian unless explicitly stated. The path coupling method, introduced in [4], is a variation of traditional coupling

which allows us to restrict our attention to a certain subset S of $\Omega \times \Omega$, where Ω is the state space of a given Markov chain. If we view S as a relation, the transitive closure of S must equal Ω. The rate of convergence of the chain is measured with respect to a (quasi)metric ρ on $\Omega \times \Omega$, which can be defined by lifting a proximity function on S to the whole of $\Omega \times \Omega$ (see [12] for details).

In this section we present a modification of path coupling which involves stopping times. Let (X, Y) be any element of $\Omega \times \Omega$. As for ordinary path coupling, we define a path, or sequence

$$X = Z_0,\ Z_1, \ldots, Z_r = Y$$

between X and Y, where $(Z_\ell, Z_{\ell+1}) \in S$ for $0 \le \ell < r$, and

$$\sum_{\ell=0}^{r-1} \rho(Z_\ell, Z_{\ell+1}) = \rho(X, Y).$$

In ordinary path coupling we allow the coupling to evolve for *one* step, giving a new path

$$Z_0',\ Z_1', \ldots, Z_r'$$

(for a precise definition of the probability distribution of this new path, see [12]). We then define $(X', Y') = \left(Z_0', Z_r'\right)$. The path coupling lemma says the following. Let $(X, Y) \mapsto (X', Y')$ be a coupling defined on all pairs in S. Suppose there exists a constant β such that $0 < \beta \le 1$ and for all $(X, Y) \in S$ we have

$$\mathbf{E}\left[\rho(X', Y')\right] \le \beta\, \rho(X, Y). \tag{2.1}$$

Then we can conclude that (2.1) holds for all $(X, Y) \in \Omega \times \Omega$, and apply Theorem 2.1. Suppose, however, that the smallest value of β for which (2.1) holds for all $(X, Y) \in S$ satisfies $\beta > 1$. Then path coupling is not good enough to allow us to apply Theorem 2.1. However, if β is not much larger than 1, and there are some "good" initial pairs $(X, Y) \in S$ where the distance *decreases* after one step (in expected value), then we can try the following approach.

The following lemma is the "delayed path coupling lemma" [8, Lemma 4.2] of Czumaj et al., which shows how the mixing time of a Markov chain may be related to the behavior of a t-step path coupling (which may be non-Markovian). For completeness, we present a proof.

LEMMA 2.2. *Let $S \subseteq \Omega \times \Omega$ be such that the transitive closure of S is the whole of $\Omega \times \Omega$. Let ρ be an integer-valued metric on $\Omega \times \Omega$ which takes values in $\{0, \ldots, D\}$. Given $(X_0, Y_0) \in S$, let $(X_0, Y_0), (X_1, Y_1), \ldots, (X_t, Y_t)$ be the t-step evolution of a (possibly non-Markovian) coupling starting from (X_0, Y_0). Suppose that there exists a constant γ such that $0 < \gamma < 1$ and*

$$\mathbf{E}\left[\rho(X_t, Y_t)\right] \le \gamma \rho(X_0, Y_0) \tag{2.2}$$

for all $(X_0, Y_0) \in S$. Then the mixing time $\tau(\varepsilon)$ of $\mathcal{M}$ satisfies

$$\tau(\varepsilon) \le \frac{\log(D\varepsilon^{-1})}{1 - \gamma} \cdot t.$$

Proof. Using the same argument as the path coupling lemma, we know that (2.2) holds for all $(X_0, Y_0) \in \Omega \times \Omega$. Run the coupling in epochs of length t. After r epochs, we have

$$\mathbf{E}\left[\rho(X_{rt}, Y_{rt})\right] \leq \gamma^r \, \rho(X_0, Y_0) \leq \gamma^r \, D.$$

If $r \geq \log(D\varepsilon^{-1})/(1-\gamma)$ then $\mathbf{E}\left[\rho(X_{rt}, Y_{rt})\right] \leq \varepsilon$. This gives an upper bound for the number of epochs required to ensure that the distribution of the chain is at most ε away from stationarity, in terms of total variation distance. Multiplying this number by t, the number of steps per epoch, gives the mixing time of the chain. □

Therefore it suffices to show that $\mathbf{E}\left[\rho(X_t, Y_t)\right] \leq \gamma \, \rho(X_0, Y_0)$ for all $(X_0, Y_0) \in S$, where γ is some positive constant less than 1. The main contribution of this paper is to provide a new approach to bounding $\mathbf{E}\left[\rho(X_t, Y_t)\right]$, which we now describe. Let $(X, Y) \mapsto (X', Y')$ be a (one-step, Markovian) coupling for $\mathcal{M}$ defined on all initial pairs in S; that is, $(X, Y) \in S$ and $(X', Y') \in \Omega \times \Omega$. We will apply this coupling for t steps, using the path coupling machinery to drive the coupling if the trajectory of the coupling leaves the set S. This gives a multiple-step coupling $\{(X_s, Y_s)\}_{s \geq 0}$. Let T be a stopping time for this coupling, defined in such a way that

$$\rho(X_s, Y_s) = \rho(X_0, Y_0) \text{ for } 0 \leq s < T.$$

Then T is a random variable which depends only on the history of the coupling up to the present time. For example, we could define T to be the first time at which the value of ρ changes.

If $T > t$ then we know that $\rho(X_t, Y_t) = \rho(X_0, Y_0)$. Otherwise, we consider (X_T, Y_T), the state of the coupling at the stopping time T. (The pair (X_T, Y_T) need no longer belong to the set S, but the path coupling machinery drives the coupling for all pairs in $\Omega \times \Omega$.) The analysis gives an upper bound for the quantity

$$\mathbf{E}\left[\rho(X_T, Y_T) \mid T \leq t\right].$$

We hope that this quantity will be smaller than $\mathbf{E}\left[\rho(X_1, Y_1)\right]$, with the following heuristic justification. The analysis of one-step coupling is a worst-case analysis. However, after running the Markov chain for T steps, the effect of the chosen starting state is mitigated to some extent by the random choices made during the running of the coupling. In other words, with some positive probability we are not in the worst case. It is here that we can improve on one-step coupling.

We now show how to relate $\mathbf{E}\left[\rho(X_T, Y_T) \mid T \leq t\right]$ and $\mathbf{E}\left[\rho(X_t, Y_t)\right]$.

THEOREM 2.3. *Let $\mathcal{M}$ be a Markov chain with state space Ω. Let ρ be a metric on $\Omega \times \Omega$ and let S be some subset of $\Omega \times \Omega$ such that the transitive closure of S is $\Omega \times \Omega$. Suppose that we have a (one-step, Markovian) coupling $(X, Y) \mapsto (X', Y')$, defined on pairs in S such that*

$$\mathbf{E}\left[\rho(X', Y')\right] \leq \beta \, \rho(X, Y)$$

for some constant β such that $\beta \geq 1$. Let $t > 0$ be a fixed integer. Apply the coupling for t steps from initial state $(X_0, Y_0) \in S$, using the path coupling lemma. Let T be some stopping time for $\{(X_s, Y_s)\}_{s \geq 0}$ such that

$$\rho(X_s, Y_s) = \rho(X_0, Y_0)$$

whenever $0 \leq s < T$. Then

$$\mathbf{E}\left[\rho(X_t, Y_t)\right] \leq \text{Prob}\left[T > t\right] \cdot \rho(X_0, Y_0) + \text{Prob}\left[T \leq t\right] \cdot \beta^t \cdot \mathbf{E}\left[\rho(X_T, Y_T) \mid T \leq t\right]$$

for all $(X_0, Y_0) \in S$.

Proof. The coupling defined on the set S gives rise to a coupling $(X, Y) \mapsto (X', Y')$ on the entire set $\Omega \times \Omega$ such that $\mathbf{E}[\rho(X', Y')] \leq \beta\, \rho(X, Y)$ for all $(X, Y) \in \Omega \times \Omega$, by the path coupling lemma [4]. Let (X_0, Y_0), $(X_1, Y_1), \ldots, (X_t, Y_t)$ be the t-step evolution of this coupling from the starting state $(X_0, Y_0) \in S$.

If $T > t$ then $\rho(X_t, Y_t) = \rho(X_0, Y_0)$. Next suppose that $T \leq t$. Then

$$\begin{aligned}\mathbf{E}[\rho(X_t, Y_t) \mid T \leq t] &\leq \beta\, \mathbf{E}[\rho(X_{t-1}, Y_{t-1}) \mid T \leq t] \\ &\leq \mathbf{E}\left[\beta^{t-T}\, \rho(X_T, Y_T) \mid T \leq t\right] \\ &\leq \beta^t\, \mathbf{E}[\rho(X_T, Y_T) \mid T \leq t]\,.\end{aligned}$$

(By replacing $t - T$ by t we are, in effect, assuming that the stopping time occurs at the very beginning of the interval.) This proves the theorem. □

Suppose that S is the set of all pairs (X, Y) with $\rho(X, Y) = 1$. In this case, Theorem 2.3 can be rewritten to assert that

$$\mathbf{E}[\rho(X_t, Y_t) - 1] \leq \mathrm{Prob}[T \leq t]\left(\beta^t \cdot \mathbf{E}[\rho(X_T, Y_T) \mid T \leq t] - 1\right).$$

Combining Lemma 2.2 and Theorem 2.3, we see that γ can be defined to be the maximum of the values

$$1 - \mathrm{Prob}[T \leq t]\left(1 - \beta^t \cdot \mathbf{E}[\rho(X_T, Y_T) \mid T \leq t]\right) \tag{2.3}$$

over all $(X_0, Y_0) \in S$. In order to obtain a good bound on the mixing time of the chain, we aim to show that $\gamma < 1$. Clearly $\gamma < 1$ if

$$\beta^t\, \mathbf{E}[\rho(X_T, Y_T) \mid T \leq t] < 1$$

for all $(X_0, Y_0) \in S$.

3. Applying the new method to the Glauber dynamics for graph colorings. In this section we illustrate the new method by using it to analyze the mixing time of the Glauber dynamics for graph colorings.

Let $G = (V, E)$ be a given graph and let $\Omega_k(G)$ be the set of all proper k-colorings of G, where C is the set of colors. The Glauber dynamics is a Markov chain on $\Omega_k(G)$ with transitions from the current state according to the following procedure:

- choose $(v, i) \in V \times C$ uniformly at random,
- recolor v with i if this results in v being properly recolored.

This chain was analyzed by Jerrum [15] and independently by Salas and Sokal [21]. They proved that the chain is rapidly mixing for graphs with maximum degree Δ when $k > 2\Delta$. The fact that the chain is also rapidly mixing for $k = 2\Delta$ can be found in [4]. Jerrum showed that the Glauber dynamics has $O(n \log(n))$ mixing time for $k > 2\Delta$, and the best known upper bound when $k = 2\Delta$ was $O(n^3)$.

In section 3.1 we describe the standard path coupling for this chain. Section 3.2 contains the definition of the stopping time for this coupling, and gives a necessary condition for the success of the new method. In section 3.3 we perform the calculations needed to establish the necessary condition. All calculations are combined in section 3.4 to provide an $O(n \log(n))$ upper bound for the mixing time of the Glauber dynamics for Δ-regular, triangle-free graphs, when $(2 - \eta)\Delta \leq k \leq 2\Delta$, where η is a small positive constant.

Before we proceed, we present a proof of the "folklore" result that the mixing time of the Glauber dynamics is bounded below by $\Omega(n \log n)$. Our proof concerns graphs with no edges.

THEOREM 3.1. *Let G be the empty graph with n vertices, and let $k \geq 2$. Then*

$$\tau((2e)^{-1}) = \Omega(n \log n).$$

Proof. A *stopping rule* Γ (see [17]) is a map that associates every initial sequence w of Markov chain states with a number $\Gamma[w] \in [0,1]$, which is taken to be the probability that the sequence should continue. We can also think of Γ as a random variable taking values in $\{0,1,2,\ldots\}$, whose distribution depends only on $w_0,\ldots,w_\Gamma$ (and w_Γ is the state where we stop). If w_0 is drawn from the distribution σ and $\mathbf{E}[\Gamma]$ is finite and the distribution of final states is τ, then the rule is called a stopping rule from σ to τ. It is said to be *optimal* for σ and τ if $\mathbf{E}[\Gamma]$ is minimal. For each $x \in \Omega_k(G)$ let σ_x be the distribution concentrated on the state x. Define τ_2 to be the maximum, over all initial states x, of the expected length of an optimal stopping rule from σ_x to π. Since the Glauber dynamics is time-reversible, a result of Aldous [2, Lemma 12] applies, showing that

$$\tau((2e)^{-1}) \geq c\tau_2,$$

where $c = (1-e^{-1})^2/2$. Now let Γ be the stopping rule which says, "stop when you have visited every vertex of G at least once." (It may not be immediately apparent that this rule satisfies the definition of a stopping rule given in [17], since it uses information not encoded in the states of the chain. However, it is routine to formulate an equivalent randomized stopping rule which does fit the definition; see [18, p. 89].) Since G has no edges and every vertex has been randomly recolored, the coloring obtained at time Γ is distributed according to π. Hence Γ is a stopping rule from σ_x to π for all $x \in \Omega_k(G)$. Let $y \in \Omega_k(G)$ be any coloring of G such that $y(v) \neq x(v)$ for all $v \in V$. Then y is a halting state for this stopping rule (that is, the probability that the process will halt if it reaches y is 1). Since Γ has a halting state it is an optimal stopping rule, using [17, Theorem 5.1]. This shows that $\tau_2 = \mathbf{E}[\Gamma]$. Therefore $\tau((2e)^{-1})$ is bounded below by a constant times the expected number of steps required to visit every vertex at least once, and the latter is $\Theta(n \log n)$ by the well-known coupon collector's lemma (see, for example, [19, section 3.6]). ∎

3.1. Path coupling for the Glauber dynamics. We now give the standard path coupling analysis of the Glauber dynamics. The proximity function is given by Hamming distance, and we let $\mathcal{S}$ be the set of all pairs with Hamming distance 1. The state space of the Markov chain must be extended to the set of all colorings (including nonproper colorings) in order to be able to form a path of length $H(X,Y)$ between any two colorings $(X,Y) \in \Omega_k(G)$. (This approach is standard and does not cause any problems, since the nonproper colorings are transient states. The stationary distribution is uniform over all proper colorings, and zero elsewhere. Although the extended chain is no longer reversible, the path coupling lemma still applies. Moreover, the mixing time of the chain on the original state space is bounded above by the mixing time of the chain on the extended state space.)

Consider $(X,Y) \in \mathcal{S}$, so X and Y differ just at a single vertex v. Let $N(v)$ denote the set of neighbors of v in G. We can couple at (X,Y) as follows: choose (u,i) uniformly at random from $V \times C$. If $u = v$ then attempt to recolor v with i in both X and Y. This will either succeed in both or fail in both. If it succeeds then the Hamming distance decreases by 1. The only other moves which can affect the Hamming distance are when $u = w$ where $w \in N(v)$. In this case, if $i \notin \{X(v), Y(v)\}$ then attempt to recolor w with i in both X and Y. This will either succeed in both

or fail in both, and the Hamming distance is unaffected. If $i = X(v)$ then attempt to recolor w with $X(v)$ in X and attempt to recolor w with $Y(v)$ in Y. This will fail in both X and Y, so the Hamming distance is unaffected. Finally, if $i = Y(v)$ then attempt to recolor w with $Y(v)$ in X, and attempt to recolor w with $X(v)$ in Y. This may succeed or fail in either, so the Hamming distance could increase by 1 here. Thus the expected change in the Hamming distance is at most

$$-\frac{(k - |\{X(w) : w \in N(v)\}|)}{kn} + \frac{\Delta}{kn}.$$

In general, we have $|\{X(w) : w \in N(v)\}| \leq \Delta$, so that the expected change in the Hamming distance is at most $-(k - 2\Delta)/(kn)$. This gives nonincreasing Hamming distance for $k \geq 2\Delta$. The aim of the new approach is to show that, with constant positive probability, there are fewer than Δ distinct colors around v, just before the stopping time. This gives nonincreasing Hamming distance for a wider range of k.

3.2. A stopping time for the Glauber dynamics on colorings. For simplicity, assume that the given graph G is Δ-regular and triangle-free. Let η be a small positive constant which we fix later, and suppose that $(2-\eta)\Delta \leq k \leq 2\Delta$. We analyze the mixing time of the Glauber dynamics using our new method, to show that the Glauber dynamics has $O(n \log(n))$ mixing time for this range of k.

Let $(X_0, Y_0) \in S$ be given, so that X_0, Y_0 differ just at a single vertex $v \in V$. Perform the coupling described in section 3.1 with starting point (X_0, Y_0). Let $Q(X_0, Y_0)$ be the set of all moves which involve v or increase the Hamming distance; that is,

$$Q(X_0, Y_0) = \{(v, i) : i \in C\} \cup \{(w, Y_0(v)) : w \in N(v)\}.$$

Then $Q(X_0, Y_0)$ contains all the choices which may affect the Hamming distance, but also some which will not. Define the random variable T to be the first step at which a pair in $Q(X_0, Y_0)$ is chosen by the coupling. Then T is a stopping time since it depends only on the coupling up to the present time. Now (X_T, Y_T) is the state of the coupling after the Tth step, which we refer to as the state of the coupling at the stopping time. Note that $H(X_s, Y_s) = H(X_0, Y_0) = 1$ for $0 \leq s < T$ by the analysis of section 3.1. Clearly $|Q(X_0, Y_0)| = k + \Delta$ for all pairs $(X_0, Y_0) \in \mathcal{S}$. Let δ be a positive constant, and assume that δn is an integer. (Since n can grow arbitrarily large, there is not much harm in making this assumption.) An (approximately) optimal value of δ will be fixed later, which will satisfy $\delta < (2 - \eta)/3$. We run the coupling for t steps, where $t = \delta n$.

Let $\mathcal{C}$ be a random variable which denotes the number of colors which occur more than once around v *just before* the stopping time T (that is, after step $T - 1$). In the next section we prove that, when n and Δ are "big enough" and η is "small enough," we have

$$\mathbf{E}[\mathcal{C} \mid T \leq \delta n] \geq \xi\Delta$$

for some constant ξ such that $\xi \geq 2\eta$. We now show why this is sufficient.

The arguments of section 3.1 show that the expected value of the Hamming distance after one step of normal path coupling from $(X, Y) \in S$ is at most

$$1 - \frac{k - 2\Delta}{kn} \leq 1 + \frac{\eta\Delta}{kn}$$

since $(2-\eta)\Delta \le k \le 2\Delta$. Next, notice that

$$\begin{aligned}\mathbf{E}\left[H(X_T,Y_T)-1 \mid T \le \delta n\right] &\le -\frac{k-(\Delta-\mathbf{E}\left[\mathcal{C} \mid T \le \delta n\right])}{k+\Delta}+\frac{\Delta}{k+\Delta}\\ &\le -\frac{k-(1-2\eta)\Delta}{k+\Delta}+\frac{\Delta}{k+\Delta}\\ &\le -\frac{\eta}{3}.\end{aligned}$$

Therefore, using Theorem 2.3 (and in particular the remarks following the theorem),

$$\begin{aligned}\mathbf{E}\left[H(X_{\delta n},Y_{\delta n})-1\right] &\le \mathrm{Prob}\left[T \le \delta n\right]\left(\beta^{\delta n}\cdot \mathbf{E}\left[H(X_T,Y_T) \mid T \le \delta n\right]-1\right)\\ &\le \mathrm{Prob}\left[T \le \delta n\right]\left(\left(1+\frac{\eta\Delta}{kn}\right)^{\delta n}\left(1-\frac{\eta}{3}\right)-1\right)\\ &\le \mathrm{Prob}\left[T \le \delta n\right]\left(e^{\eta\delta/(2-\eta)}e^{-\eta/3}-1\right). \qquad (3.1)\end{aligned}$$

This quantity is nonpositive whenever

$$\frac{\eta\delta}{2-\eta}-\frac{\eta}{3} \le 0,$$

and this holds for $\delta \le (2-\eta)/3$.

We now calculate a lower bound for $\mathbf{E}\left[T \mid T \le \delta n\right]$, which is needed in section 3.3.

LEMMA 3.2. *Suppose that $n \ge \delta^{-1}$ and $(2-\eta)\Delta \le k \le 2\Delta$, where $0<\eta<2$. Let $\theta = 3/(2-\eta)$. Then*

$$\mathbf{E}\left[T \mid T \le \delta n\right] \ge \frac{\delta n}{2}(1-\theta\delta).$$

Proof. Let $q = 1-(k+\Delta)/(kn)$, and let p_s denote the probability that $T=s$. Then $p_s = \mathrm{Prob}\left[T=s\right] = (1-q)q^{s-1}$ and $\mathrm{Prob}\left[T \le \delta n\right] = 1-q^{\delta n}$. Now $q^{\delta n} \ge 1-(k+\Delta)\delta/k$ since $n \ge \delta^{-1}$. Therefore

$$\begin{aligned}\mathbf{E}\left[T \mid T \le \delta n\right] &= \left(1-q^{\delta n}\right)^{-1}\sum_{s=0}^{\delta n} s p_s\\ &\ge \frac{p_{\delta n}\,\delta^2\,n^2}{2\left(1-q^{\delta n}\right)}\\ &> \frac{(1-q)\,q^{\delta n}\,\delta^2\,n^2}{2\left(1-q^{\delta n}\right)}\\ &\ge \frac{(1-q)\left(1-\frac{k+\Delta}{k}\delta\right)}{2\frac{k+\Delta}{k}\delta}\,\delta^2\,n^2\\ &\ge (1-\theta\delta)\,\frac{\delta n}{2},\end{aligned}$$

as claimed. ∎

3.3. The expected number of repeated colors just before the stopping time. Let (X_0,Y_0) be a given pair in $\mathcal{S}$ and let v be the vertex which is colored differently in X and Y. Let T be the stopping time for the coupling when started at

(X_0, Y_0). Denote by $\mathcal{C}$ the number of colors which occur at least twice around v just before the stopping time T. That is,

$$\mathcal{C} = |\{i \in C : |\{w \in N(v) : X_{T-1}(w) = i\}| \geq 2\}|.$$

In this section we obtain a lower bound for $\mathbf{E}[\mathcal{C} \mid T \leq \delta n]$ which holds when Δ and n are both "large enough" and η is "small enough." Specifically, take $\Delta \geq 14$, $n \geq 120$, and $\eta < 1/210$.

Let A_w be defined by

$$A_w = C \setminus (\{X_0(u) : \{u, w\} \in E\} \cup \{Y_0(v)\})$$

for $w \in N(v)$. Then A_w is the set of colors which are acceptable at w in both X_0 and Y_0. Note that $|A_w| \geq k - \Delta - 1$ for all $w \in N(v)$. Next, let

$$B_i = \{w \in N(v) : i \in A_w\}$$

and let $b_i = |B_i|$ for each $i \in C$. So B_i is the set of vertices $w \in N(v)$ at which i is acceptable in both X_0 and Y_0.

LEMMA 3.3. *Assume that $\eta < 1/210$ and $\Delta \geq 14$. Let k satisfy $(2-\eta)\Delta \leq k \leq 2\Delta$. Then there are at least $\lceil k/5 \rceil$ colors i such that $b_i \geq \Delta/3$.*

Proof. Let $Z = |\{(i, w) : i \in A_w\}|$. Now $Z \geq \Delta(k - \Delta - 1)$. For a contradiction, suppose that fewer than $\lceil k/5 \rceil$ colors i have $b_i \geq \Delta/3$. If k is a multiple of 5 then

$$\begin{aligned} Z &\leq \left(\frac{k}{5} - 1\right)\Delta + \left(\frac{4k}{5} + 1\right)\frac{\Delta}{3} \\ &\leq \left(1 - \left(\frac{1}{15} - \frac{1}{3\Delta}\right)\right)\Delta^2 - \Delta \\ &< \Delta(k - \Delta - 1), \end{aligned}$$

giving the desired contradiction. Next, suppose that $k = 5\ell + r$, where $r \in \{1, 2, 3, 4\}$. Then

$$\begin{aligned} Z &\leq \ell\Delta + (k - \ell)\frac{\Delta}{3} \\ &\leq \left(1 - \left(\frac{1}{15} - \frac{15 - 2r}{15\Delta}\right)\right)\Delta^2 - \Delta \\ &< \Delta(k - \Delta - 1) \end{aligned}$$

since $\eta < 1/210$ and $\Delta \geq 14$. Again, this is a contradiction. □

Using this information we can prove a lower bound for the expected number of repeated colors around v just before the stopping time, given that the stopping time occurs in the first δn steps.

THEOREM 3.4. *Suppose that $n \geq 120$, $\Delta \geq 14$, $\eta < 1/210$, and $\delta < (2-\eta)/3$. Also assume that $(2-\eta)\Delta \leq k \leq 2\Delta$. Then*

$$\mathbf{E}[\mathcal{C} \mid T \leq \delta n] \geq \frac{1}{3840} \cdot \delta^2 (1 - \theta\delta)^2 \cdot e^{-4\delta} \cdot \Delta,$$

where $\theta = 3/(2-\eta)$.

Proof. By Lemma 3.3, there are at least $\lceil k/5 \rceil$ colors i such that $b_i \geq \Delta/3$. Consider ways in which such a color i can occur at least twice around v just before

the stopping time T. One way in which this can occur is as follows. Suppose that there are exactly two distinct elements u, $w \in B_i$ which were chosen with the color i during the coupling. That is, (u,i) and (w,i) were both chosen but (q,i) was not chosen for any $q \in B_i \setminus \{u,w\}$. Also suppose that u and w are never chosen at any other time, with any color, and that no neighbor of u or w is ever chosen with color i. In this situation, both u and w end up colored i. We now analyze the probability that this event occurs for a given value of T.

We know that T is the first stopping time, so there are $T-1$ steps before the stopping time step. We do not have kn possible choices at each of these $T-1$ steps, but rather $kn-(k+\Delta)$ possibilities. With this in mind, the probability that, say, w is chosen with color i is given by $1/(kn-(k+\Delta)) \geq 1/(kn)$. There are at least $\Delta^2/24$ choices for the unordered pair $\{u,w\} \subseteq B_i$ since $b_i \geq \Delta/3$ and $\Delta \geq 14$. The probability that both (u,i) and (w,i) are chosen at two distinct times in the first $T-1$ steps is at least $\binom{T-1}{2} \cdot 1/(k^2n^2)$. There are also choices which we have ruled out for all other steps, corresponding to the vertex-color pairs from the set

$$\{(q,i) : q \in (N(u) \cup N(w) \setminus \{v\}) \cup (B_i \setminus \{u,w\})\} \bigcup \{(u,j),\,(w,j) : j \in C \setminus \{Y(v)\}\}.$$

(Note that the selection of $j = Y(v)$ is ruled out because s is not a stopping time for $0 \leq s < T$.) We have ruled out at most $3\Delta + 2k - 6$ choices at each of $T-3$ steps. Thus we see that

$$\text{Prob}\left[i \text{ is repeated} \mid T,\, b_i \geq \frac{\Delta}{3}\right] \geq \frac{\Delta^2}{24} \cdot \binom{T-1}{2} \cdot \frac{1}{k^2n^2} \cdot \left(1 - \frac{3\Delta + 2k - 6}{kn - (k+\Delta)}\right)^{T-3}.$$

Let $x = 3\Delta + 2k - 6$ and $y = kn - (k+\Delta)$. Then

$$\begin{aligned}
\left(1 - \frac{x}{y}\right)^{T-3} &= \exp\left(-(T-3)\sum_{i=1}^{\infty} \frac{1}{i}\left(\frac{x}{y}\right)^i\right) \\
&= \exp\left(-\frac{Tx}{y} + \sum_{i=1}^{\infty}\left(\frac{3}{i} - \frac{Tx}{(i+1)y}\right)\left(\frac{x}{y}\right)^i\right) \\
&\geq e^{-Tx/y} \\
&\geq e^{-4\delta}.
\end{aligned}$$

The first inequality follows since $3/i \geq Tx/((i+1)y)$ for all $i \geq 1$, and the second inequality follows since $4y \geq nx$ (using the definition of x, y and the assumptions of the theorem). Plugging this back into our calculations, we obtain

$$\text{Prob}\left[i \text{ is repeated} \mid T,\, b_i \geq \frac{\Delta}{3}\right] \geq \frac{\Delta^2}{24} \cdot \binom{T-1}{2} \cdot \frac{1}{k^2n^2} \cdot e^{-4\delta}.$$

Now we shall take expectation with respect to T, conditional on $T \leq \delta n$. Using Lemma 3.2 and the fact that $n \geq 120$, we find that

$$\binom{\mathbf{E}\left[T \mid T \leq \delta n\right] - 1}{2} \geq \frac{\delta^2\, n^2\, (1-\theta\delta)^2}{16}.$$

Applying Jensen's inequality, we obtain

$$\begin{aligned}
\text{Prob}\left[i \text{ is repeated} \mid T \leq \delta n,\, b_i \geq \frac{\Delta}{3}\right] &\geq \frac{\Delta^2}{384} \cdot \delta^2\, n^2\, (1-\theta\delta)^2 \cdot \frac{1}{k^2n^2} \cdot e^{-4\delta} \\
&\geq \frac{1}{768} \cdot \delta^2\, (1-\theta\delta)^2 \cdot e^{-4\delta} \cdot \frac{\Delta}{k}. \qquad (3.2)
\end{aligned}$$

By summing (3.2) over the $\lceil k/5 \rceil$ most popular colors, the theorem is proved. □

3.4. The mixing time of the Glauber dynamics. We now calculate an upper bound for the mixing time of the Glauber dynamics, using Lemma 2.2 and Theorem 2.3. Let ξ be defined by

$$\begin{aligned}\xi(\delta,\eta) &= \frac{1}{3840}\cdot\delta^2\,(1-\theta\delta)^2\,\cdot e^{-4\delta}\\ &= \frac{1}{3840}\cdot\delta^2\left(1-\frac{3\delta}{2-\eta}\right)^2\cdot e^{-4\delta}.\end{aligned}$$

Theorem 3.4 shows that $\mathbf{E}\,[\mathcal{C} \mid T \le \delta n] \ge \xi\Delta$. Note that ξ is a decreasing function of η. Take $\delta = 1/8$ and $\eta = 8\times 10^{-7}$. Then $\xi(\delta,\eta) \ge 2\eta$. (These values of δ, η are approximately optimal.) The discussion of section 3.2 suggested that this condition was sufficient to ensure rapid mixing of the Glauber dynamics. We now give the details.

THEOREM 3.5. *Let $n \ge 120$ and $\Delta \ge 14$. Suppose that $(2-\eta)\Delta \le k \le 2\Delta$, where $\eta = 8\times 10^{-7}$. The mixing time of the Glauber dynamics for graph colorings of Δ-regular, triangle-free graphs is bounded above by*

$$\tau(\varepsilon) \le 4\times 10^6\, n\log(n\varepsilon^{-1}).$$

Proof. Let $\delta = 1/8$, as in the previous section. We bound the mixing time by finding an upper bound on the quantity γ such that

$$H(X_{\delta n}, Y_{\delta n}) \le \gamma$$

over all initial pairs $(X_0, Y_0) \in S$. Using the remark following Theorem 2.3, we can define γ by (2.3). Let $q = 1-(k+\Delta)/(kn)$, as in Lemma 3.2. Then

$$\begin{aligned}\text{Prob}\,[T \le \delta n] &= 1-q^{\delta n}\\ &\ge 1-\exp\left(-\frac{k+\Delta}{k}\delta\right) \ge 1-e^{-4\delta/3}.\end{aligned}$$

Using this, with the calculations of (3.1), we obtain

$$\begin{aligned}\gamma &\le 1-\left(1-e^{-4\delta/3}\right)\left(1-\exp\left(\frac{\eta\delta}{2-\eta}-\frac{\eta}{3}\right)\right)\\ &\le 1-3.3\times 10^{-8},\end{aligned}$$

substituting $\delta = 1/8$ and $\eta = 8\times 10^{-7}$. Now applying Lemma 2.2 we find that the mixing time of the Glauber dynamics is bounded above by

$$\begin{aligned}\tau(\varepsilon) &\le \delta n\cdot\frac{\log(n\varepsilon^{-1})}{1-\gamma}\\ &\le \frac{10^8}{26.4}\,n\log(n\varepsilon^{-1})\\ &< 4\times 10^6\, n\log(n\varepsilon^{-1}).\end{aligned}$$

This bound holds for $(2-\eta)\Delta \le k \le 2\Delta$, where $\eta = 8\times 10^{-7}$, assuming that $\Delta \ge 14$ and $n \ge 120$. □

Vigoda [23] described a new Markov chain for graph colorings which alters the coloring of up to six vertices at each transition. He showed using path coupling that this chain is rapidly mixing for $k \geq 11\Delta/6$. The mixing time of this chain is bounded above by

$$\frac{k}{k - \frac{11}{6}\Delta}\, n \log(n\varepsilon^{-1})$$

for $k > 11\Delta/6$. Vigoda also applies the comparison technique of Diaconis and Saloff-Coste [9] to show that the mixing time of the Glauber dynamics is at most

$$O\left(k \log(k)\, n^2 \log(n)\right)$$

when $k > 11\Delta/6$. In particular, this gives an upper bound of $O(n^2 \log n)$ when $k = 2\Delta$. It seems unlikely that any comparison technique could yield the optimal bound of $O(n \log n)$.

OPTIMAL SIMULATIONS BETWEEN UNARY AUTOMATA*

CARLO MEREGHETTI† AND GIOVANNI PIGHIZZINI‡

Abstract. We consider the problem of computing the costs—*in terms of states*—of optimal simulations between different kinds of finite automata recognizing *unary* languages. Our main result is a tight simulation of unary n-state two-way nondeterministic automata by $O(\mathrm{e}^{\sqrt{n \ln n}})$-state one-way deterministic automata. In addition, we show that, given a unary n-state two-way nondeterministic automaton, one can construct an equivalent $O(n^2)$-state two-way nondeterministic automaton performing *both* input head reversals and nondeterministic choices only at the ends of the input tape. Further results on simulating unary one-way alternating finite automata are also discussed.

Key words. formal languages; deterministic, nondeterministic, and alternating finite state automata; unary languages

1. Introduction.

Finite automata are probably one of the simplest and most extensively studied models of computation. First of all, their computational power is well established: they exactly define the class of regular languages. Furthermore, it is also well known that several added features, such as nondeterminism, alternation, and two-way motion of the input head, do not increase their computing ability. Equivalences are clearly obtained by simulating different kinds of automata by the original device, the one-way deterministic finite automaton (1dfa) [22]. Here, we are particularly interested in the cost—*in terms of states*—of simulations between automata.

The following are the well-known costs of simulating different automata by 1dfa's (number of states of the best 1dfa simulating any n-state automaton in the class): one-way nondeterministic finite automata (1nfa): $O(2^n)$ [22], one-way alternating finite automata (1afa): $O(2^{2^n})$ [7], two-way deterministic finite automata (2dfa): $O(n^n)$ [22, 24], two-way nondeterministic finite automata (2nfa): $O(2^{n^2})$ [22, 24]. All these bounds are tight. We refer the reader to [3] which is a valuable source for results and references.

There are several open questions concerning automata simulation, the most important being probably the one posed by Sakoda and Sipser in [23]: how many states are necessary and sufficient to simulate 2nfa's (or 1nfa's) by 2dfa's? They conjecture such a cost to be exponential, and Sipser [25] proves that this is exactly the case when 2dfa's are required to be *sweeping*, i.e., to have head reversals only at the ends of the input tape. Berman and Lingas [2] state a lower bound of $\Omega(n^2/\log n)$ for the general problem and provide an interesting connection with the celebrated open problem DLOGSPACE $\stackrel{?}{=}$ NLOGSPACE. More precisely, they show that

if DLOGSPACE = NLOGSPACE then for some polynomial p and for all integers m and k-state 2nfa A, there is a $p(mk)$-state 2dfa accepting a subset of $\mathcal{L}(A)$, the language accepted by A. The subset consists of all strings of length no more than m in $\mathcal{L}(A)$. As a consequence of this result, Sipser [25] relates the DLOGSPACE $\stackrel{?}{=}$ NLOGSPACE question also to the existence of sweeping automata with a polynomial number of states for a certain family of regular languages. This might give added evidence that the problem of evaluating how the number of states changes when turning one automaton into another is not only motivated by the investigation on the succinctness of representing regular languages but is also related to fundamental questions in complexity.

It is important to stress that the optimality of such simulations has been established by witness languages built over alphabets of two or more symbols. As a matter of fact, the situation turns out to be quite different whenever we restrict the problems to *unary* automata, i.e., automata with a single letter input alphabet. The problem of evaluating the costs of unary automata simulations was raised in [25] and has led to emphasize some relevant differences with the general case. For instance, we know that $O(\mathrm{e}^{\sqrt{n \ln n}})$ states suffice in order to simulate a unary n-state 1nfa or 2dfa by a 1dfa. Furthermore, a unary n-state 1nfa can be simulated by a 2dfa having $O(n^2)$ many states. All these results and their optimality have been proved in 1986 by Chrobak [8].

In this paper, we further deepen the study of optimal simulations between unary automata. To this aim, we find it useful to consider some techniques from the *sublogarithmic space world* (see, e.g., [11, 12, 27]).

The first part of the paper is devoted to study unary 2nfa's. We closely analyze the structure of their computation paths. In particular, using graph theoretical and number theoretical arguments, we show that, for sufficiently large inputs, it is possible to consider only computation paths in which states are repeated in a very regular way. This allows us to state our main result concerning the optimal simulation of unary 2nfa's by 1dfa's: each unary n-state 2nfa can be optimally simulated by a 1dfa with $O(\mathrm{e}^{\sqrt{n \ln n}})$ states. Note that such a complexity is the same as the above mentioned optimal simulations of unary 1nfa's and 2dfa's by 1dfa's. Thus, we can conclude that the simultaneous elimination of both two-way motion and nondeterminism on unary automata has the same cost as the elimination of either of them.

As another consequence of our analysis of unary 2nfa's, we are able to prove that each unary n-state 2nfa can be simulated by a 2nfa with $O(n^2)$ states which reverses the input head direction and makes nondeterministic decisions *only* when the input head visits the left or the right end of the input. This result can be regarded as a further step toward the solution of the Sakoda–Sipser open problem recalled above, at least for unary inputs.

In the second part of the paper, we study the relationships between unary 1afa's, dfa's and nfa's. This problem was proposed in [8] and partly solved in [3], where it is proved that 2^n states are necessary for 2nfa's to simulate unary n-state 1afa's. Here, we point out an optimal simulation of unary n-state 2nfa's by $O(\sqrt{n \ln n})$-state 1afa's.

By combining our results with those in the literature, we are able to draw an almost complete description of the costs of optimal simulations between the different types of unary automata here considered. We do not explicitly list all the resulting optimal bounds, which can be better understood by observing Figure 1.1.

2. Preliminary notions and results. In this section, we begin by recalling basic notions on finite state automata (subsection 2.1). Then, for the reader's ease of

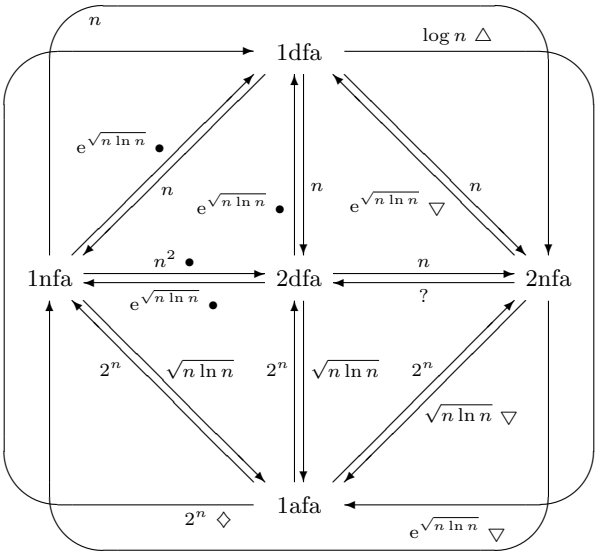

FIG. 1.1. *Costs of the optimal simulations between different kinds of unary automata. An arc labeled $f(n)$ from a vertex x to a vertex y means that a unary n-state automaton of type x can be simulated by a $O(f(n))$-state automaton of type y. Costs marked by "•" are proved in* [8]*, by "◇" in* [7]*, by "△" in* [17]*, by "▽" in this paper. The unmarked costs can be trivially obtained. The arc labeled "?" represents the open question of Sakoda and Sipser* [23].

mind, a brief outline of the main result of this paper—the $O(\mathrm{e}^{\sqrt{n \ln n}})$ simulation of 2nfa's by 1dfa's—is provided (subsection 2.2). In the following two subsections, we set up some mathematical tools to study the costs of our simulations. More precisely, we prove some new facts concerning *linear Diophantine equations* (subsection 2.3) and *directed graphs* (subsection 2.4).

2.1. Finite state automata. Given a set S, $\sharp S$ denotes its cardinality, and 2^S the family of all its subsets. Given an alphabet Σ, Σ^* denotes the set of strings on Σ, with the empty string ϵ. Given a string $x \in \Sigma^*$, $|x|$ denotes its length. A language $\mathcal{L}$ is said to be *unary* (or *tally*) whenever it can be built over a *single letter* alphabet. In this case, we let $\mathcal{L} \subseteq 1^*$.

Let us take a brief look on the computational model of finite automata. For a detailed exposition, we refer the reader to [14]. A *one-way nondeterministic finite automaton* is a 5-tuple $A = (Q, \Sigma, \delta, q_0, F)$, where Q is the finite set of states, Σ is the finite input alphabet, $\delta : Q \times \Sigma \to 2^Q$ is the transition function, $q_0 \in Q$ is the initial state, $F \subseteq Q$ is the set of final states. The transition function δ can be extended to strings in a standard way. The language accepted by A is the set $\mathcal{L}(A) = \{x \in \Sigma^* \mid \delta(q_0, x) \cap F \neq \emptyset\}$. The one-way automaton A is *deterministic* if and only if $\sharp\delta(q, \sigma) = 1$, for any $q \in Q$, and $\sigma \in \Sigma$. (This implies that deterministic automata are assumed to be *complete*.)

It is well known that a one-way automaton can be viewed as a control unit that reads, by an input head, a tape containing input strings stored one symbol per square. At each move, the input head is shifted one square right. This model can be extended to encompass *stationary* and *left* moves of the input head. More precisely, we can define a 2nfa as a 5-tuple $A = (Q, \Sigma, \delta, q_0, F)$ in which Q, Σ, q_0, and F are defined as for 1nfa's, while $\delta : Q \times (\Sigma \cup \{\vdash, \dashv\}) \to 2^{Q \times \{-1, 0, +1\}}$ is the transition function, where

$\vdash, \dashv$ are two special symbols—the left and the right endmarker, respectively—not in Σ. Input strings are stored onto the input tape surrounded by the two endmarkers, the left endmarker being at the 0th square. The computation begins with the input head scanning the 0th square. In a move, A reads an input symbol, changes its state, and moves the input head one position forward or backward or keeps it stationary, depending on whether δ returns $+1$, -1, or 0, respectively. Left and right moves on the left and right endmarker, respectively, are forbidden. A is *deterministic* if and only if $\sharp\delta(q, \sigma) = 1$, for any $q \in Q$, and $\sigma \in \Sigma \cup \{\vdash, \dashv\}$.

Alternating finite automata[1] provide a natural generalization of nondeterministic automata. We now briefly recall their formal definition and refer the reader to [7, 10] for more details. A *one-way alternating finite automaton* is a 5-tuple $A = (Q, \Sigma, g, q_1, F)$, where $Q = \{q_1, \ldots, q_k\}$ is the set of states, Σ is the input alphabet, $F \subseteq Q$ is the set of final states, q_1 is the initial state, and $g : Q \to (\Sigma \times \mathbf{B}^k \to \mathbf{B})$ is a mapping of Q into the set of all mappings of $\Sigma \times \mathbf{B}^k$ into $\mathbf{B} = \{0, 1\}$. To explain the behavior of A, consider, for $i = 1, \ldots, k$, the function $g_i : \Sigma \times \mathbf{B}^k \to \mathbf{B}$ representing the image by g of the state q_i, i.e., $g_i = g(q_i)$. Such functions can be inductively extended to strings to obtain $G_i : \Sigma^* \times \mathbf{B}^k \to \mathbf{B}$ as: $G_i(\epsilon, \mathbf{u}) = u_i$, and $G_i(\sigma x, \mathbf{u}) = g_i(\sigma,\ G_1(x, \mathbf{u}), \ldots, G_k(x, \mathbf{u}))$, for $\sigma \in \Sigma$, $x \in \Sigma^*$, and $\mathbf{u} = (u_1, \ldots, u_k) \in \mathbf{B}^k$. The language accepted by A is the set $\mathcal{L}(A) = \{x \in \Sigma^* \mid G_1(x, \mathbf{f}) = 1\}$, where $\mathbf{f} \in \mathbf{B}^k$ denotes the characteristic vector of the set of final states. Notice that $G_i(\epsilon, \mathbf{f}) = 1$ if and only if q_i is a final state. Moreover, $G_i(\sigma x, \mathbf{f})$ can be computed as follows: a process in the state q_i reads σ from the input tape, and splits into k independent processes computing $G_j(x, \mathbf{f})$, for $j = 1, \ldots, k$. Then, by applying $g_i(\sigma, \_)$ to all these results, we get $G_i(\sigma x, \mathbf{f})$.

It is easy to see that 1nfa's are just special cases of 1afa's up to setting

$$g_i(\sigma, \mathbf{u}) = \bigvee_{q_j \in \delta(q_i, \sigma)} u_j,$$

for $i = 1, \ldots, k$, $\sigma \in \Sigma$, and $\mathbf{u} \in \mathbf{B}^k$.

We call *unary* any automaton that works with a single letter input alphabet.

2.2. Outline of the main result. The proof of the optimal $O(\mathrm{e}^{\sqrt{n \ln n}})$ simulation of 2nfs's by 1dfa's, which is the main result of this paper, is rather long and complex. To help the reader, we emphasize the main ideas here.

Let $\mathcal{C}$ be an accepting computation path of an n-state 2nfa A on input 1^m. Along $\mathcal{C}$, consider the sequence $r_0, r_1, \ldots, r_p$ of states in which the input head scans either of the endmarkers. For $j = 1, \ldots, p$, the following two possibilities arise:

(i) *U-Turn*: in both r_{j-1} and r_j, the input head scans the same endmarker.

(ii) *Left-to-right (right-to-left) traversal:* in r_{j-1} the input head scans the left (right) endmarker, while in r_j it scans the other one.

For sufficiently large inputs, U-Turns can be nondeterministically guessed without moving the input head (by Lemma 3.1). As a consequence, the computation $\mathcal{C}$ can be reduced to a sequence of left-to-right and right-to-left traversals.

Now, the key point is that in each traversal the automaton A can only measure the length of the input 1^m modulo some integer $\ell_i \leq n$. Hence, it can be argued that if there exists a traversal from r_{j-1} to r_j on 1^m, then there also exists a traversal with the same endpoints on $1^{m+\mu\ell_i}$, for every (possibly negative) integer μ exceeding

[1] Automata hereafter defined are sometimes, and perhaps more appropriately, called *boolean automata* (see, e.g., [6, 17]).

a certain value. This enables us to prove that *the language accepted by A forms an ultimately periodic set of period $\ell = \mathrm{lcm}(\ell_1, \ldots, \ell_r)$,* where the ℓ_i's depend on the cycle structure of the transition graph of A and their sum does not exceed n (Theorem 3.5).

By using a number theoretical result that will be recalled in Lemma 2.1, we get that $\ell = O(\mathrm{e}^{\sqrt{n \ln n}})$. So, the number of states in the cycle of a 1dfa A' simulating A is $O(\mathrm{e}^{\sqrt{n \ln n}})$, and this actually turns out to be an upper bound on the number of all states of A'.

As the reader will notice when we get into proof details, the study of path structure in certain weighted digraphs representing automata transitions will be crucial. Such graph theoretical problems are tackled in subsection 2.4 by using some number theoretical tools presented in the next subsection.

2.3. Number theory and Diophantine equations. As usual, we let $\mathbf{Z}^+$ ($\mathbf{Z}^-$) be the set of positive (negative) integers, and $\mathbf{Z}$ be the set of whole integers. Natural numbers are the elements of the set $\mathbf{N} = \mathbf{Z}^+ \cup \{0\}$. The absolute value of z is denoted by $|z|$. For any $z > 0$, $\ln z$ denotes the natural logarithm of z, while $\log z$ is the logarithm of z taken to the base 2. The *greatest common divisor* of integers $a_1, \ldots, a_s$ is denoted by $\gcd(a_1, \ldots, a_s)$. Their *least common multiple* is denoted by $\mathrm{lcm}(a_1, \ldots, a_s)$. Both gcd and lcm are, actually, meant to be taken on $|a_1|, \ldots, |a_s|$. We sometimes write $\gcd(A)$ to denote the greatest common divisor of the integers in the set A.

In estimating the simulation costs of unary automata, a crucial role is played by the function

$$F(n) = \max\{\mathrm{lcm}(x_1, \ldots, x_s) \mid x_1, \ldots, x_s \in \mathbf{Z}^+ \text{ and } x_1 + \cdots + x_s = n\}.$$

Evaluating the growth rate of $F(n)$ is known as Landau's problem [15, 16]. Such a problem is related to the study of the maximal order in the symmetric group S_n [26, 28]. Several approximations for $F(n)$ are given in the literature. The best one is contained in [26, Theorem I] from which we can derive the following upper bound that suffices to our purposes.

LEMMA 2.1. $F(n) = O(\mathrm{e}^{\sqrt{n \ln n}})$.

The other arithmetical tool we shall make use of is the theory of linear Diophantine equations, whose principles can be found, for instance, in [21]. We consider equations in the form

$$a_1 x_1 + \cdots + a_s x_s = z, \tag{2.1}$$

where $a_1, \ldots, a_s, z$ are given integers, and $x_1, \ldots, x_s$ are integer variables. It is a very well-known fact that (2.1) has (infinitely many) solutions in integers if and only if $\gcd(a_1, \ldots, a_s)$ divides z.

THEOREM 2.2. *For any given integers $a_1, \ldots, a_s$, the set of integers*

$$\{a_1 x_1 + \cdots + a_s x_s \mid x_1, \ldots, x_s \in \mathbf{Z}\}$$

is exactly the set of all integral multiples of $\gcd(a_1, \ldots, a_s)$.

We are sometimes interested in solving Diophantine equations in *natural numbers*. To this regard, an interesting question, first raised by Frobenius (see [4, 5]), can be stated as follows: given positive integers $a_1, \ldots, a_s$ satisfying $\gcd(a_1, \ldots, a_s) = 1$, what is the greatest number b such that the Diophantine equation $a_1 x_1 + \cdots + a_s x_s = b$ has no solution in natural numbers? For $s = 2$, such b is known to be $(a_1 - 1)(a_2 - 1) - 1$

[4, 5]. For $s \geq 3$, the problem is still open, even though several upper bounds are proved. We will refer to the following one.

THEOREM 2.3 (see [4, 5, 19]). *Let $a_1 < a_2 < \cdots < a_s$ be positive integers with $\gcd(a_1, \ldots, a_s) = 1$. Then, the greatest number b such that the Diophantine equation $a_1x_1 + \cdots + a_sx_s = b$ has no solution in natural numbers does not exceed $(a_1 - 1)(a_s - 1)$.*

More accurate estimations can be found in [9]. However, the bound in Theorem 2.3 will suffice for our purposes. By combining Theorem 2.2 and Theorem 2.3, one easily obtains the following corollary.

COROLLARY 2.4. *Let $a_1, \ldots, a_s$ be positive integers less than or equal to n, and let*

$$\mathcal{X} = \{a_1x_1 + \cdots + a_sx_s \mid x_1, \ldots, x_s \in \mathbf{N}\}.$$

Then, the set $\mathcal{X} \cap \{z \in \mathbf{Z}^+ \mid z > n^2\}$ is exactly the set of all integral multiples of $\gcd(a_1, \ldots, a_s)$ greater than n^2.

In order to consider sets defined not only by positive coefficients, but even by *both* positive and negative coefficients, we generalize Corollary 2.4 as follows.

LEMMA 2.5. *Let $A = \{a_1, \ldots, a_p\}$ and $B = \{b_1, \ldots, b_q\}$ be sets of positive integers less than or equal to n, with $\gcd(A) = \alpha$ and $\gcd(B) = \beta$. Moreover, let*

$$\mathcal{X} = \{a_1x_1 + \cdots + a_px_p \ - \ (b_1y_1 + \cdots + b_qy_q) \mid x_1, \ldots, x_p\,,\, y_1, \ldots, y_q \in \mathbf{N}\},$$

with $\gcd(A \cup B) = \gcd(\alpha, \beta) = \gamma$.

(a) *If $A = \emptyset$ ($B = \emptyset$), then $\mathcal{X} \cap \{z \in \mathbf{Z}^- \mid z < -n^2\}$ ($\mathcal{X} \cap \{z \in \mathbf{Z}^+ \mid z > n^2\}$) is exactly the set of negative (positive) integral multiples of β (α) smaller than $-n^2$ (greater than n^2).*

(b) *If $A \neq \emptyset$ and $B \neq \emptyset$, then $\mathcal{X}$ is exactly the set of integral multiples of γ.*

Proof. (a) follows trivially from Corollary 2.4. For (b) let us denote by $\mathcal{T}$ the set of integral multiple of γ. It is easy to see that $\mathcal{X} \subseteq \mathcal{T}$. In fact, each number in $\mathcal{X}$ is obtained from the Diophantine equation defining $\mathcal{X}$ itself, and hence it must be a multiple of γ.

Conversely, to show $\mathcal{T} \subseteq \mathcal{X}$, let us first define the sets

$$\mathcal{A} = \{a_1x_1 + \cdots + a_px_p \mid x_1, \ldots, x_p \in \mathbf{N}\},$$
$$\mathcal{B} = \{b_1y_1 + \cdots + b_qy_q \mid y_1, \ldots, y_q \in \mathbf{N}\}.$$

Corollary 2.4 says that $\mathcal{A} \cap \{z \in \mathbf{Z}^+ \mid z > n^2\}$ ($\mathcal{B} \cap \{z \in \mathbf{Z}^+ \mid z > n^2\}$) is exactly the set of positive integral multiples of α (β) greater than n^2. Moreover, it is easy to see that

$$\mathcal{X} = \{h - k \mid h \in \mathcal{A} \text{ and } k \in \mathcal{B}\}. \tag{2.2}$$

So, consider $\xi \in \mathcal{T}$. Since ξ is an integral multiple of $\gamma = \gcd(\alpha, \beta)$, there exist two integers $\overline{x}$ and $\overline{y}$ such that $\xi = \alpha\overline{x} - \beta\overline{y}$. Moreover, it is well known that there are infinitely many solutions of the equation $\xi = \alpha x - \beta y$ that can be obtained from the particular solution $(\overline{x}, \overline{y})$ as follows:

$$\begin{aligned} x &= \overline{x} - \tfrac{\beta}{\gamma}\, t, \\ y &= \overline{y} - \tfrac{\alpha}{\gamma}\, t, \qquad t \in \mathbf{Z}. \end{aligned}$$

At this point, it is easy to find $\hat{t} \in \mathbf{Z}$, giving the solution $(\hat{x}, \hat{y})$, such that both $\alpha\hat{x}$ and $\beta\hat{y}$ are greater than n^2, and hence belong to $\mathcal{A}$ and $\mathcal{B}$, respectively. In other words, we have found two integers $h = \alpha\hat{x} \in \mathcal{A}$ and $k = \beta\hat{y} \in \mathcal{B}$ such that $\xi = h - k$. This together with (2.2) shows that $\xi \in \mathcal{X}$ and completes the proof. □

We end this subsection by showing a further property of solutions of Diophantine equations in natural numbers.

LEMMA 2.6. *Let $a_1, \ldots, a_s$ be positive integers less than or equal to n, and let the integer $z \geq 0$. If the equation $a_1x_1 + a_2x_2 + \cdots + a_sx_s = z$ has a solution in natural numbers, then it also has a solution in natural numbers satisfying*

$$a_2x_2 + \cdots + a_sx_s \leq n^2.$$

Proof. We prove a stronger result, namely, that there exists a solution $x_1, \ldots, x_s$ satisfying $x_2 + \cdots + x_s \leq a_1$. Suppose that $(\overline{x}_1, \overline{x}_2, \ldots, \overline{x}_s)$ is a solution in natural numbers, with $\mu = \overline{x}_2 + \cdots + \overline{x}_s > a_1$. Let us form the sequence

$$\underbrace{a_2, a_2, \ldots, a_2}_{\overline{x}_2-\text{times}}, \underbrace{a_3, a_3, \ldots, a_3}_{\overline{x}_3-\text{times}}, \ \ldots\ , \underbrace{a_s, a_s, \ldots, a_s}_{\overline{x}_s-\text{times}}. \tag{2.3}$$

Now, for $i = 1, \ldots, \mu$, let S_i be the sum of the first i members in (2.3). Since the length of the sequence $S_1, \ldots, S_\mu$ exceeds a_1, there must exists a pair of indices $1 \leq i < j \leq \mu$ satisfying $S_i \equiv S_j \pmod{a_1}$, or equivalently, such that $S_j - S_i$ is a multiple of a_1. This enables us to remove from (2.3) the elements forming $S_j - S_i$, consequently augmenting the value of $\overline{x}_1$ by $(S_j - S_i)/a_1$. By iterating this process, we get the claimed result. □

2.4. Paths in directed graphs. Here, we recall some basic notions and prove—by the mathematics above developed—some results on directed graphs. Our interest in this topic is due to the fact that, as we will see in the next section, computation paths of unary automata can be represented as paths in suitable directed graphs. Few elementary notions of graph theory are required and summarized below. For more details, we refer the reader to any of the standard text on graph theory such as, e.g., [1].

Let $G = (V, E)$ be a directed graph or *digraph*, with V the set of vertices, and $E \subseteq V \times V$ the set of arcs. An *oriented path* $\mathcal{P}$ in G is a sequence of vertices $\mathcal{P} = v_0, v_1, \ldots, v_n$ where, for $i = 1, \ldots, n$, $(v_{i-1}, v_i) \in E$. Since we will be dealing with digraphs only, the attribute "oriented" will always be intended. The *length* of $\mathcal{P}$ is the number of arcs $\mathcal{P}$ consists of, and is denoted by $|\mathcal{P}|$. The path $\mathcal{P}$ is a *cycle (*or *closed path)* if $v_0 = v_n$. We call *elementary* (or, sometimes, *simple*) any cycle in which no vertex is encountered more than once (except, of course, the initial vertex which is also the terminal vertex).

A *subgraph* of G is any digraph $G' = (V', E')$ satisfying $V' \subseteq V$ and $E' \subseteq E \cap (V' \times V')$. The subgraph G' is said to be *induced by* V', whenever $E' = E \cap (V' \times V')$. The digraph G is *strongly connected* if there exists a path between any two vertices. A *strongly connected component* of G is a subgraph which is strongly connected and not contained in any other strongly connected subgraph.

The following two results concern length and structure of paths in digraphs.

LEMMA 2.7. *Let G be a digraph with n vertices, and let $\mathcal{P}$ be a path of length x which*

(a) *starts from vertex v_1 and ends in vertex v_2,*
(b) *visits* all *vertices in G.*

Then, there also exists a path $\mathcal{P}_0$ of length x_0 which satisfies (a) *and* (b) *and such that*

(c) $x_0 \leq n^2$,

(d) *there exist integers $x_1, x_2, \ldots, x_s \geq 0$ such that $x = x_0 + a_1x_1 + a_2x_2 + \cdots + a_sx_s$, where $a_1, a_2, \ldots, a_s$ are the lengths of the elementary cycles in G.*

Proof. We can factorize the sequence of the $x+1$ vertices visited along $\mathcal{P}$ as a concatenation of n subsequences of vertices $\sigma_1, \sigma_2, \ldots, \sigma_n$, each one starting from a *different* vertex of G. This can be done since $\mathcal{P}$ visits *all* vertices, as required in (b).

Suppose that $x > n^2$. Then, there exists $1 \leq j \leq n$ such that σ_j contains more than n vertices, i.e., $\sigma_j = v_{j_1} v_{j_2} \ldots v_{j_m}$ with $m > n$. A simple pigeonhole argument shows that there must exist $1 \leq h < k \leq m$ such that $v_{j_h} = v_{j_k}$. This clearly means that, when passing through σ_j, our path $\mathcal{P}$ presents a cycle beginning and ending in $v_{j_h} = v_{j_k}$. Call σ'_j the sequence obtained from σ_j after the elimination of the part corresponding to such a cycle, namely, $\sigma'_j = v_{j_1} v_{j_2} \ldots v_{j_h} v_{j_{k+1}} \ldots v_{j_m}$. The sequence $\sigma_1 \cdots \sigma_{j-1}\, \sigma'_j\, \sigma_{j+1} \cdots \sigma_n$ defines a new path which satisfies (a) and (b) and whose length is strictly less than the length of $\mathcal{P}$. By iterating such a path-compression, we eventually obtain a path $\mathcal{P}_0$ of length x_0 satisfying (a), (b), and (c).

In conclusion, it is not hard to see that the whole process can be carried on by eliminating *elementary cycles*. Thus, one can easily express the length x of $\mathcal{P}$ as in (d), where, for $i = 1, \ldots, s$, x_i denotes the number of times elementary cycles of length a_i have been deleted. □

THEOREM 2.8. *Let G be a digraph with n vertices, and let $\mathcal{P}$ be a path from vertex v_1 to vertex v_2. Then, there also exists a path $\mathcal{P}'$ from v_1 to v_2 with the same length as $\mathcal{P}$ which consists of*

(a) *an initial path $\mathcal{P}_1$,*

(b) *an elementary cycle $\mathcal{P}_2$, with $1 \leq |\mathcal{P}_2| \leq n$, which is repeated λ times,*

(c) *a final path $\mathcal{P}_3$,*

satisfying $|\mathcal{P}_1| + |\mathcal{P}_3| \leq 2n^2$. (Hence, notice that $|\mathcal{P}'| = |\mathcal{P}| = |\mathcal{P}_1| + \lambda\,|\mathcal{P}_2| + |\mathcal{P}_3|$.)

Proof. Without loss of generality, we suppose that $\mathcal{P}$ visits all vertices of G. Otherwise, we consider the subgraph of G induced by the set of vertices visited along $\mathcal{P}$. The new path $\mathcal{P}'$ can be obtained by suitably "reorganizing"—in the light of our result on Diophantine equations in Lemma 2.6—the way of $\mathcal{P}$ through its elementary cycles.

The first step amounts to eliminate some of the elementary cycles in $\mathcal{P}$ to obtain the path $\mathcal{P}_0$, as explained in Lemma 2.7. The total number of arcs eliminated in this step can be expressed as

$$|\mathcal{P}| - |\mathcal{P}_0| = a_1x_1 + a_2x_2 + \cdots + a_sx_s \tag{2.4}$$

for some integers $x_1, x_2, \ldots, x_s \geq 0$, as one may easily check from Lemma 2.7(d). Now, notice that the a_i's in (2.4) are positive integers not exceeding n, being lengths of elementary cycles in a digraph of n vertices. Hence, from Lemma 2.6, we know that there exist integers $\overline{x}_1, \overline{x}_2, \ldots, \overline{x}_s \geq 0$ which are solutions for (2.4), and such that

$$a_2\overline{x}_2 + \cdots + a_s\overline{x}_s \leq n^2. \tag{2.5}$$

All this leads us to construct the path $\mathcal{P}'$ by "padding" $\mathcal{P}_0$ with $\overline{x}_i$ consecutive repetitions of an elementary cycle of length a_i for $i = 1, \ldots, s$. Let $\mathcal{P}_2$ be an elementary cycle of length a_1, and let $\mathcal{P}_1$ ($\mathcal{P}_3$) be the part of $\mathcal{P}'$ which precedes (follows) the $\overline{x}_1$ consecutive repetitions of $\mathcal{P}_2$. Then, we have

- $1 \leq |\mathcal{P}_2| = a_1 \leq n$,

- $\lambda = \overline{x}_1$,
- $|\mathcal{P}_1| + |\mathcal{P}_3| = x_0 + a_2\overline{x}_2 + \cdots + a_s\overline{x}_s \leq 2n^2$, since $x_0 \leq n^2$, from Lemma 2.7(c), and by considering inequality (2.5). □

Let us now turn to *weighted digraphs*. In particular, we are interested in digraphs whose arcs have weights from the set $\{-1, 0, +1\}$. As usual, the *weight of a path* is the sum of weights of the arcs in the path. The following theorem states a periodicity property on cycle weights in strongly connected weighted digraphs.

THEOREM 2.9. *Let $G = (V, E)$ be a strongly connected weighted digraph with n vertices, and let $\{a_1, \ldots, a_s\}$ be the set of weights of all the elementary cycles in G, with $\alpha = \gcd(a_1, \ldots, a_s)$. For each $v \in V$, let $\mathcal{X}_v$ be the set of weights of all the cycles containing v. If there exists at least one $a_i > 0$ ($a_i < 0$), then the set $\mathcal{X}_v$ and the set of positive (negative) integral multiples of α coincide on the elements greater than $2n^2$ (less than $-2n^2$).*

Proof. Since each cycle in G is the sum of elementary cycles, $x \in \mathcal{X}_v$ implies that

$$x = a_1x_1 + \cdots + a_sx_s, \tag{2.6}$$

where, for $i = 1, \ldots, s$, the value $x_i \geq 0$ is the number of times an elementary cycle of weight a_i is passed through to form our cycle of weight x. For what we have recalled in subsection 2.3, this means that x must be an integral multiple of α.

Conversely, if x is an integral multiple of α, with $|x| > n^2$, then, by Lemma 2.5, it can be expressed as in (2.6) for some $x_1, \ldots, x_s \geq 0$. However, such a solution does not necessarily describe a cycle in G. To see this, consider the following example: Suppose we have a digraph with three elementary cycles of weights a_1, a_2, a_3, in which the first and the last cycle are connected *only by the cycle of weight a_2*. Any solution with $x_1, x_2, x_3 > 0$ certainly defines (at least) one cycle in such a digraph, where the ith elementary cycle is passed through x_i times, $i = 1, 2, 3$. On the other hand, a solution with $x_1, x_3 > 0$ *and* $x_2 = 0$ does not define any cycle at all, since we cannot traverse both the first and the third elementary cycle without entering (since, $x_2 = 0$) the second one.

To deal with such kind of connectivity problems, we consider a cycle $\mathcal{C}_0$ of weight x_0 which visits *all* vertices of G. From Lemma 2.7(c), $\mathcal{C}_0$ consists of at most n^2 arcs, and this clearly implies that $|x_0| \leq n^2$. Now, notice that x_0 can be expressed as in (2.6) for some $x_1, \ldots, x_s \geq 0$. Hence, $x_0 = k_0\alpha$ for some $k_0 \in \mathbf{Z}$.

Assume $x = k\alpha$ with $|x| > 2n^2$ for $k \in \mathbf{Z}$, and set $z = x - x_0 = (k - k_0)\alpha$. We have that $|z| = |x - x_0| \geq |x| - |x_0| > n^2$. Since $|a_i| \leq n$ for $i = 1, \ldots, s$, from Lemma 2.5 we get $z = a_1z_1 + \cdots + a_sz_s$, for some $z_1, \ldots, z_s \geq 0$. This enables us to "pad" the cycle $\mathcal{C}_0$ with an amount of z_i elementary cycles of weight a_i for $i = 1, \ldots, s$, in order to obtain a cycle of weight x in G. □

3. Computation paths of 2nfa's and simulation by 1dfa's. In this section, we focus on unary 2nfa's. By using results in subsection 2.4, we show that any unary language $\mathcal{L}$ accepted by a 2nfa with n states *forms an ultimately periodic set of period* $\ell = O(\mathrm{e}^{\sqrt{n \ln n}})$. More precisely, we prove that, for any integer $m > 5n^2$, *the string* 1^m *belongs to* $\mathcal{L}$ *if and only if* $1^{m+\ell}$ *belongs to* $\mathcal{L}$. This immediately leads to a $O(\mathrm{e}^{\sqrt{n \ln n}})$ simulation of unary n-state 2nfa's by 1dfa's. The optimality of such a simulation is a direct consequence of a result in [8].

To state our results, we need some tools to examine computations on unary inputs. Specifically, we refer to three properties that Geffert proved in [11] for two-way nondeterministic Turing machines accepting unary languages in sublogarithmic space. We

are now going to reformulate such properties within the realm of unary 2nfa's. Their validity in this new form comes straightforwardly by observing that finite automata can be clearly seen as Turing machines working in sublogarithmic space. Moreover, we improve the last of these three results. Such an improvement will be particularly useful in the next section where we show that, by just squaring the number of states, it is possible to consider 2nfa's with a very particular structure.

From now on, we will always refer to a *unary 2nfa A with n states*.

The first lemma [11, Lemma 3] says that each computation path of A beginning and ending at the same input square and visiting neither of the endmarkers (*U-Turn*) can be replaced by an equivalent computation path not moving the input head "too far," precisely, no more than n^2 positions to the right (or left).

LEMMA 3.1 (U-Turn). *Suppose there exists a computation path of A on input 1^m where*

(a) *the first state is q_1 with the input head at a position i,*
(b) *the last state is q_2 with the input head at the same position,*
(c) *the input head never moves to the left (right) of the ith position, nor does it visit the right (left) endmarker.*

Then, there also exists a computation path on input 1^m satisfying (a), (b), (c) *and where the input head never moves farther than n^2 positions to the right (left) of the ith position.*

The second lemma [11, Lemma 4] states that we can freely "shift" any computation path that never visits the endmarkers to any position of the input tape, provided that we are sufficiently far from the endmarkers. To our purposes, we give this lemma in a slightly different form. (Recall that the left and right endmarker occupy positions 0 and $m+1$, respectively, on the input tape.)

LEMMA 3.2 (position independence). *Suppose there exists a computation path Π of A on input 1^m beginning in the state q_1 with the input head at a position i, ending in the state q_2 with the input head at a position j, and such that*

(a) $1 \le i < j \le m+1$,
(b) *the left endmarker is never visited along Π,*
(c) *the jth position is reached at the last move only.*

Then, there also exists a computation path beginning in the state q_1 with the input head at a position $i+h$, with $h \in \mathbf{Z}$, ending in the state q_2 with the input head at the position $j+h$ which is reached at the last move only, and satisfying (b), *provided that*

$$n^2 \le i+h < j+h \le m+1.$$

A similar result can be stated for computation paths moving toward left, i.e., with the initial (final) position i (j) satisfying $0 \le j < i \le m$.

Proof. Without loss of generality, from Lemma 3.1, we can assume that Π never visits more than n^2 positions to the left of the ith position. Since the input is unary, we can shift Π within the position bounds stated in the theorem. Notice that the right endmarker can possibly be reached only at the end of the path. □

The third lemma [11, Theorem 1] defines the structure of the computation paths that traverse the entire input, from one endmarker to the other. We provide a new proof of this lemma for unary 2nfa's which is different from the one given in [11]. Our proof makes use of the results on the structure of paths in digraphs in subsection 2.4. As a consequence, we obtain a quadratic estimation of the parameters s_1 and s_2 involved in the lemma; this is to be compared with the $O(n^4)$ upper bound in

[11].[2] Though not essential in the unary 2nfa's by 1dfa's simulation, this improvement will be crucial in the quadratic simulation of unary 2nfa's by 2nfa's having both head reversals and nondeterminism at the endmarkers only (Theorem 4.1).

In what follows, by *loop of length* ℓ, we mean a computation path of the automaton A beginning in a state p with the input head at a position i, and ending in the same state with the input head at the position $i+\ell$.

LEMMA 3.3 (dominant loop). *Suppose the input* 1^m *is traversed from left to right by a computation path* Π *of* A *beginning at the left endmarker in the state* q_1*, ending at the right endmarker in the state* q_2*, and such that the endmarkers are visited only in states* q_1 *and* q_2*. Then,* 1^m *can also be traversed by a computation path beginning in the state* q_1*, ending in the state* q_2*, and in which* A

(a) *having traversed the left endmarker and* s_1 *positions,*
(b) *gets into a loop (called* dominant loop*) of length* ℓ*, which starts from a state* p *and is repeated* λ *times,*
(c) *then traverses the remaining* s_2 *input squares, and finally gets the right endmarker,*

for some s_1*,* s_2*,* ℓ *satisfying*

$$1 \le \ell \le n,$$
$$s_1 + s_2 \le 3n^2.$$

Notice that $m = s_1 + \lambda\ell + s_2$*. The same result holds for computation paths traversing inputs from right to left.*

Proof. If $m \le 3n^2$, the result follows trivially. Hence, suppose $m > 3n^2$. Define the digraph $G = (Q, E)$, where Q is the set of states of A, and $(p, q) \in E$ if and only if there exists a computation path of A which starts from p with the input head at a position $n^2 \le i \le m$, reaches q with the input head at the position $i+1$, and never visits either the endmarkers or the $(i+1)$th input square in the intermediate steps.

Since we are sufficiently (namely, more than n^2 positions) far from the left endmarker, and since computations take place on unary inputs, Lemma 3.2 implies that the digraph G does not depend on the input length. For the same reasons, it is also easy to see that for any path in G of length d starting from the state q' and ending in the state q'', there exists a computation path of A on input 1^m beginning in q' with the input head at a position i, ending in q'' with the input head at the position $i+d$, provided that $n^2 \le i < i+d \le m+1$.

Conversely, for any computation path of A on input 1^m beginning in the state q' with the input head at a position i, ending in q'' with the input head at the position j, and satisfying conditions (a), (b), and (c) in Lemma 3.2, one can easily find a path in G of length $j-i$ joining q' to q''.

Let us subdivide the computation path Π into

- Π_{in} which is the part of Π ending when the (n^2+1)th input square is reached for the first time,
- Π_{fin} which is the remaining part of Π.

For the correspondence between paths in G and computations in A above described, we can associate with Π_{fin} a path $\mathcal{P}$ in G. As shown in Theorem 2.8, $\mathcal{P}$ can be rearranged into a path $\mathcal{P}'$ of the same length as $\mathcal{P}$ made of

[2] At the time the conference version of this paper [20] was completed, the authors learned from Viliam Geffert [13] that he too had obtained, by different arguments, a quadratic upper bound on s_1 and s_2.

- an initial path $\mathcal{P}_1$,
- an elementary cycle $\mathcal{P}_2$, with $1 \leq |\mathcal{P}_2| \leq n$, which is repeated λ times,
- a final path $\mathcal{P}_3$,

satisfying $|\mathcal{P}_1| + |\mathcal{P}_3| \leq 2n^2$. Now, again for the correspondence paths-computations, we can associate with $\mathcal{P}_1$, $\mathcal{P}_2$, and $\mathcal{P}_3$, three computation paths Π_1, Π_2, and Π_3, respectively; in particular, Π_2 is a loop—the *dominant loop*—of length $1 \leq \ell \leq n$.

In conclusion, the input 1^m can be traversed by a computation path of A which starts with Π_{in}, continues with Π_1 which is followed by λ consecutive repetitions of the loop Π_2, and ends with Π_3. Let s be the total amount of cells visited outside the dominant loop (without counting the endmarkers), i.e., during Π_{in}, Π_1, and Π_3. It is easy to see that

$$s \leq n^2 + |\mathcal{P}_1| + |\mathcal{P}_3| \leq 3n^2. \qquad \square$$

From the previous lemma, we learn that loops play an important role in the structure of computations of unary 2nfa's. By using Theorem 2.9, we can show that possible loop lengths follow a very regular pattern which is directly predictable from the structure of unary 2nfa's themselves.

To this purpose, let us consider the weighted digraph $\mathcal{A}$ consisting of the digraph representing the transition diagram of our automaton A after removing transitions on the endmarkers, and in which we set weights $+1$, -1, or 0 to arcs depending on whether they represent transitions where the input head is moved right, left, or kept stationary, respectively. It is straightforward that *any cycle of weight ℓ in $\mathcal{A}$ represents a computation loop of length ℓ in the automaton A.* Hence, by taking into account Theorem 2.9, we get the following lemma.

LEMMA 3.4. *Let p be any given state of A, and let α be the greatest common divisor of weights of the elementary cycles in the strongly connected component of $\mathcal{A}$ containing p. Let $\mathcal{X}_p^+$ ($\mathcal{X}_p^-$) be the set of integers $x > 2n^2$ ($x < -2n^2$) such that the automaton A, starting from the state p with the input head at the ith input square, reaches the $(i+x)$th input square in the same state p, without visiting the endmarkers. If $\mathcal{X}_p^+ \neq \emptyset$ ($\mathcal{X}_p^- \neq \emptyset$), then it is exactly the set of all integral multiples of α greater than $2n^2$ (less than $-2n^2$).*

The following result is crucial in order to obtain our simulations.

THEOREM 3.5. *There exists a set of positive integers $\{\ell_1, \ldots, \ell_r\} \subseteq \{1, \ldots, n\}$ satisfying $\ell_1 + \cdots + \ell_r \leq n$, such that, for any $m \geq n$, if the input 1^m can be traversed from left to right by a computation path of A beginning in the state q_1, ending in the state q_2, and where the endmarkers are visited on the first and last move only, then there exists an index $i \in \{1, \ldots, r\}$ such that, for any $\mu > \frac{5n^2 - m}{\ell_i}$, there is also a computation path from q_1 to q_2 which traverses from left to right the input*

$$1^{m+\mu\ell_i}.$$

The same result holds for computation paths traversing inputs from right to left.

Proof. Again, consider the weighted digraph $\mathcal{A}$ associated with the automaton A. Suppose $\mathcal{A}$ has r strongly connected components and, for $i = 1, \ldots, r$, denote by ℓ_i the greatest common divisor of weights of the elementary cycles in the ith strongly connected component. Clearly, ℓ_i cannot exceed n, and since strongly connected components partition the set of vertices of $\mathcal{A}$, we get $\ell_1 + \cdots + \ell_r \leq n$.

Given the left-to-right traversing of input 1^m, let s_1, s_2, ℓ, λ, p, be as in Lemma 3.3, so to have the "decomposition" $m = s_1 + \lambda\ell + s_2$, and p being the state the dominant

loop starts from. Let us suppose that p is contained in the ith strongly connected component of $\mathcal{A}$. By Lemma 3.4, the set of integers $x > 2n^2$, for which there exists a path from p to itself visiting neither of the endmarkers and moving the input head x positions right, is exactly the set of the multiples of ℓ_i greater than $2n^2$. This leads us to conclude that, for integers $\eta > \frac{2n^2}{\ell_i}$, there exists a computation from the state q_1 to the state q_2 that completely traverses inputs $1^{s_1+\eta\ell_i+s_2}$, and visits the endmarkers on the first and last move only. It is enough, in fact, to use the original traverse of 1^m, and substitute the λ repetitions of the dominant loop with a single loop of length $\eta\ell_i$.

Now, by choosing $\mu > \frac{5n^2-m}{\ell_i}$ and suitably setting $\eta = \mu + \frac{\lambda\ell}{\ell_i}$, we get

$$\eta > \frac{5n^2-m}{\ell_i} + \frac{\lambda\ell}{\ell_i} = \frac{5n^2-(s_1+\lambda\ell+s_2)+\lambda\ell}{\ell_i} = \frac{5n^2-(s_1+s_2)}{\ell_i} \geq \frac{2n^2}{\ell_i},$$

where the last inequality is obtained by recalling that $s_1 + s_2 \leq 3n^2$, as stated in Lemma 3.3. Thus, for such η's, we obtain a complete traversing of inputs

$$1^{s_1+\eta\ell_i+s_2} = 1^{s_1+\left(\mu+\frac{\lambda\ell}{\ell_i}\right)\ell_i+s_2} = 1^{m+\mu\ell_i},$$

provided that $\mu > \frac{5n^2-m}{\ell_i}$. □

The technique used in the proof of the following theorem can be regarded as a refinement of the well-known $n \to n + n!$ pumping technique [18]. The result in Theorem 3.5 enables us to suitably pump and compress unary strings in order to show that unary languages accepted by n-state 2nfa's form ultimately periodic sets of period $O(\mathrm{e}^{\sqrt{n \ln n}})$.

THEOREM 3.6. *Let $\mathcal{L}$ be a unary language accepted by a n-state 2nfa. Then, there exists a constant $\ell = O(\mathrm{e}^{\sqrt{n \ln n}})$ such that, for any integer $m > 5n^2$,*

$$1^m \in \mathcal{L} \text{ if and only if } 1^{m+\ell} \in \mathcal{L}.$$

Proof. Given our 2nfa A, we let $\{\ell_1, \ldots, \ell_r\}$ be the set defined in Theorem 3.5 and let $\ell = \mathrm{lcm}(\ell_1, \ldots, \ell_r)$. Since we have observed that $\ell_1 + \cdots + \ell_r \leq n$, as a consequence of Lemma 2.1 we have that $\ell = O(\mathrm{e}^{\sqrt{n \ln n}})$.

Compression. Suppose $1^{m+\ell} \in \mathcal{L}$, and let $\mathcal{C}$ be an accepting computation path of A on such an input. Along $\mathcal{C}$, consider $r_0, r_1, \ldots, r_p$, the sequence of all states in which the input head scans either of the endmarkers. For $j = 1, \ldots, p$, the following two possibilities arise:

(i) In both r_{j-1} and r_j, the input head scans the same endmarker. By Lemma 3.1 (U-Turn), we can suppose that this part of the computation can be accomplished by moving no more than n^2 positions away from the endmarker, and hence it can take place on the input 1^m as well, m being greater than $5n^2$.

(i) In r_{j-1} the input head scans one of the two endmarkers, while in r_j it scans the other. By Theorem 3.5, for some $\ell_i \in \{\ell_1, \ldots, \ell_r\}$, we can replace the computation path from r_{j-1} to r_j on input $1^{m+\ell}$ with a computation path from r_{j-1} to r_j on input $1^{m+\ell+\mu\ell_i}$, provided that $\mu > \frac{5n^2-(m+\ell)}{\ell_i}$. Choose $\mu = \mu_i = -\frac{\ell}{\ell_i}$. Since $m > 5n^2$, it is easy to verify that $\mu_i > \frac{5n^2-(m+\ell)}{\ell_i}$. Thus, we get a computation path on the input $1^{m+\ell+\mu_i\ell_i} = 1^m$ which begins and ends in the states r_{j-1} and r_j, respectively, and visits the endmarkers on the first and last move only.

From (i) and (ii), it is easy to conclude that A accepts the input 1^m as well.

Pumping. The proof of the converse is similar: choose $\mu = \mu_i = \frac{\ell}{\ell_i}$ at point (ii). □

As an immediate consequence of Theorem 3.6 we are able to state our main result of this section.

COROLLARY 3.7. *Each unary n-state 2nfa can be simulated by a $O(e^{\sqrt{n \ln n}})$-state 1dfa.*

Proof. Given a unary n-state 2nfa accepting the language $\mathcal{L}$, the state diagram of an equivalent 1dfa consists of a path of no more than $5n^2$ states joined to a single elementary cycle involving $\ell = O(e^{\sqrt{n \ln n}})$ states. The path takes care of the nonperiodic part of $\mathcal{L}$ (i.e., strings of length not exceeding $5n^2$), while the cycle accounts for the periodic part (i.e., strings of length greater than $5n^2$). Final states are placed onto the path by inspecting membership of all strings of length not exceeding $5n^2$. Moreover, the property "$1^m \in \mathcal{L}$ if and only if $1^{m+\ell} \in \mathcal{L}$" stated in Theorem 3.6 allows us to set final states onto the cycle by just testing membership for strings $1^{5n^2+1}, 1^{5n^2+2}, \ldots, 1^{5n^2+\ell}$. □

It is possible to show that this simulation cost cannot be improved. Actually, a stronger result can be stated, which proves the optimality of all $O(e^{\sqrt{n \ln n}})$ bounds in Figure 1.1.

THEOREM 3.8 (see [8, Theorem 6.1]). *For any integer n, there exists a unary 2dfa with n states such that any equivalent 1nfa requires $\Omega(e^{\sqrt{n \ln n}})$ states.*

The trivial simulations of cost n in Figure 1.1 are optimal. In fact, for fixed $n > 0$, consider the single word language $\mathcal{L}_n = \{1^{n-1}\}$. Such a language is clearly accepted by a (minimum) 1dfa with n states. On the other hand, any 2nfa for $\mathcal{L}_n$ cannot have less than n states [3].

For the optimality of the quadratic simulation of unary 1nfa's by 2dfa's we refer the reader to [8, Theorem 6.2]. Thus, to complete Figure 1.1, we are left to examine unary one-way alternation versus determinism and nondeterminism. This is precisely the subject matter of section 5. Before that, we briefly show how to use the results so far proved to confine *both reversals and nondeterminism* to the endmarkers on unary 2nfa's by just paying a quadratic increase of the number of states.

4. Bringing reversals and nondeterminism at the endmarkers.

THEOREM 4.1. *Each unary n-state 2nfa A can be simulated by a $O(n^2)$-state 2nfa A' which performs both input head reversals and nondeterministic choices only when the input head scans the endmarkers.*

Proof. Without loss of generality, and by adding one more state, we can assume that A accepts with the input head parked on the left endmarker. We informally describe how A' simulates the computation of A on a given input 1^m.

In a first scan, A' deterministically checks whether $m \leq 5n^2$ and, if so, accepts if and only if $1^m \in \mathcal{L}(A)$. We can assume that at the end of this phase, which clearly requires $O(n^2)$ states, the input head is still positioned on the left endmarker.

Otherwise, if $m > 5n^2$, the second part of the simulation starts from the initial state of A. We briefly explain what happens when A' simulates the behavior of A from a given state q_1 and with the input head scanning the left endmarker. (A symmetrical simulation for computations of A from the right endmarker can be trivially stated.) A' nondeterministically chooses one of the following operations:

(a) simulation of a "U-Turn,"
(b) simulation of a left-to-right traversal of the input.

Since $m > 5n^2$, by Lemma 3.1 the simulation (a) can take place in one step, regardless the length of the input. Hence, each U-Turn from the left endmarker can be "embedded" in the transition function of A'. More precisely, it can be replaced by one stationary move. This part of the simulation does not require new states.

Now, we describe how to perform simulation (b). (In the following, a mod b denotes the remainder of the integer division of a by b.) Let $\{\ell_1, \ldots, \ell_r\}$ be the set introduced in Theorem 3.5 with respect to the automaton A. Given a ℓ_i, with $i \in \{1, \ldots, r\}$, two integers m', m'' satisfying

- $5n^2 < m' < m''$, and
- $m' \bmod \ell_i = \varrho = m'' \bmod \ell_i$,

and two states q_1, q_2 of A, it is not hard to prove that

> there exists a computation path of A from q_1 to q_2, scanning the input $1^{m'}$ from left to right, and touching the endmarkers on the first and last moves only if and only if there exists an analogous computation path on $1^{m''}$.

In fact, write $m' = h'\ell_i + \varrho$, $m'' = h''\ell_i + \varrho$ for some $0 < h' \leq h''$ and $0 \leq \varrho < \ell_i$. This yields $m' = m'' + \mu\ell_i$, where $\mu = h' - h'' = \frac{m' - \varrho - m'' + \varrho}{\ell_i} > \frac{5n^2 - m''}{\ell_i}$, by recalling that $m' > 5n^2$. Hence, by Theorem 3.5, from the left-to-right scan of $1^{m''}$, we can obtain a similar computation path for $1^{m'}$. The proof of the converse is similar. As a consequence of this observation, we get that, given the starting state q_1 of A and the input length $m > 5n^2$, the set of states reachable by A after traversing from left to right the input 1^m depends only on q_1 and on the set of pairs

$$\{(\ell_i\,,\ m \bmod \ell_i) \mid i = 1, \ldots, r\}.$$

Thus, in simulating a left-to-right traversal of A on 1^m starting from the state q_1 with the input head on the left endmarker, A' performs the following steps:

(i) nondeterministically selects an ℓ_i, with $i \in \{1, \ldots, r\}$,
(ii) scans the input tape, counting the input length m modulo ℓ_i,
(iii) when the input head reaches the right endmarker, nondeterministically selects one of the states associated with the starting state q_1 and the pair $(\ell_i\,,\ m \bmod \ell_i)$.

A' is easily seen to have both input head reversals and nondeterministic choices at the endmarkers only. Furthermore, during such a simulation from q_1, A' must remember the chosen ℓ_i, and the value m mod ℓ_i; this information can be clearly maintained in $\ell_1 + \cdots + \ell_s$ many states. Globally, $\ell_1 + \cdots + \ell_s$ more states are needed for each possible (starting) state, and since $\ell_1 + \cdots + \ell_s \leq n$, as observed in Theorem 3.5, we conclude that this part of the simulation requires $O(n^2)$ states. This completes the proof. □

5. Some remarks on 1afa's versus other models. We end the paper by briefly discussing the cost of simulating unary 1afa's with deterministic and nondeterministic automata, and the cost of the converse simulations. We begin with the simulations between 1afa's and 1dfa's:

- In [7, section 5.1], it is shown that for any n-state 1afa accepting a language $\mathcal{L}$ on an arbitrary alphabet there exists a 2^n-state 1dfa accepting $\mathcal{L}^R = \{x^R \mid x \in \mathcal{L}\}$, where x^R denotes the reversal of the string x. Such a result is easily seen to directly define the cost of simulating unary 1afa's with 1dfa's, since $x = x^R$ for unary strings.
- Conversely, in [17, Theorem 1] it is shown that for any n-state 1dfa accepting $\mathcal{L}$ there exists a $\lceil \log n \rceil$-state 1afa for $\mathcal{L}^R$.

This leads to the following equivalence which is basically contained in Corollary 1 and Corollary 2 of [17].

THEOREM 5.1. *The class of unary languages accepted by n-state 1afa's is exactly the class of unary languages accepted by 2^n-state 1dfa's.*

As an immediate consequence, one also gets the following corollary.

COROLLARY 5.2. *Let $\mathcal{L}$ be a unary language for which the minimum 1dfa has n states. Then, every 1afa accepting $\mathcal{L}$ requires at least $\lceil \log n \rceil$ states.*

The simulation costs between unary 1afa's and 1dfa's above stated are optimal, as pointed out in the following theorem.

THEOREM 5.3. *For any integer n, there exists a unary n-state 1afa (1dfa) such that each equivalent 1dfa (1afa) requires not less than 2^n ($\lceil \log n \rceil$) states.*

Proof.

1afa by 1dfa. We again refer to the single word language $\mathcal{L}_{2^n} = \{1^{2^n-1}\}$ considered at the end of section 3. Such a language can be accepted by a 1dfa with 2^n states and hence, according to Corollary 5.2, by a 1afa with n states. On the other hand, any 2nfa for $\mathcal{L}_{2^n}$ requires not less than 2^n states [3].

1dfa by 1afa. The minimum 1dfa for $\mathcal{L}_n = \{1^{n-1}\}$ has n state. Thus, the results follows from Corollary 5.2. □

Yet, we have the following theorem.

THEOREM 5.4. *Each unary n-state 1afa can be simulated by a 2^n-state 1nfa, 2dfa, or 2nfa. Such a simulation cost is tight in all the three cases.*

Proof. It is enough to recall that simulating unary 1afa's with 1dfa's costs 2^n states, and that 1afa's are exponentially more succinct than 2nfa's (Theorem 5.3 [*1afa by 1dfa*]). □

Thus, as already pointed out in [3], Theorem 5.4 says that 1afa's and 2dfa's are not polynomially equivalent regarding their state complexity, as conjectured in [8].

Our results in section 3 allow us to show that simulating 2nfa's (and hence 1nfa's and 2dfa's) by 1afa's takes a sublinear amount of states.

THEOREM 5.5. *Each unary 2nfa, 1nfa, and 2dfa with n states can be simulated by a $O(\sqrt{n \ln n})$-state 1afa.*

Proof. Clearly, it suffices to show the bound for 2nfa's. By Corollary 3.7, a unary n-state 2nfa can be simulated by a $O(e^{\sqrt{n \ln n}})$-state 1dfa which in turn, by Theorem 5.1, can be simulated by a 1afa with $O(\sqrt{n \ln n})$ states. □

The simulations by 1afa's in Theorem 5.5 are optimal.

THEOREM 5.6. *For any integer n, there exists a unary 1nfa and a unary 2dfa with n states such that each equivalent 1afa requires $\Omega(\sqrt{n \ln n})$ states.*

Proof. By [8, Theorem 4.5], for any n there exists a unary n-state 1nfa A such that each 1dfa recognizing $\mathcal{L}(A)$ requires $\Omega(e^{\sqrt{n \ln n}})$ states. By Corollary 5.2, this implies that each 1afa for $\mathcal{L}(A)$ must have $\Omega(\sqrt{n \ln n})$ states. Furthermore, the language $\mathcal{L}(A)$ is accepted even by a unary n-state 2dfa [8, Theorem 5.2]. □

With these results, we complete proving the results summarized in Figure 1.1, section 1.

AN APPROXIMATION ALGORITHM FOR FEEDBACK VERTEX SETS IN TOURNAMENTS*

MAO-CHENG CAI†, XIAOTIE DENG‡, AND WENAN ZANG§

Abstract. We obtain a necessary and sufficient condition in terms of forbidden structures for tournaments to possess the min-max relation on packing and covering directed cycles, together with strongly polynomial time algorithms for the feedback vertex set problem and the cycle packing problem in this class of tournaments. Applying the local ratio technique of Bar-Yehuda and Even to the forbidden structures, we find a 2.5-approximation polynomial time algorithm for the feedback vertex set problem in any tournament.

Key words. feedback vertex set, tournament, min-max relation, approximation algorithm

1. Introduction.

Given a digraph with weights on the vertices, a subset of vertices is called a *feedback vertex set* if it intersects every directed cycle in the digraph. The problem of finding a feedback vertex set with the minimum total weight is called the *feedback vertex set problem*, which arises in a variety of applications. In the area of operating systems, the problem of breaking deadlocks can be formulated as a feedback vertex set problem. Other applications can be found in VLSI, manufacturing systems, and so on. As is well known, the feedback vertex set problem is NP-hard. Furthermore, this problem admits no fully polynomial approximation scheme unless $P = NP$ [11]. For general digraphs, this problem is approximable within $O(\log n \log\log n)$ [7, 17], where n is the number of vertices in the input; for planar digraphs, it is approximable within 9/4 [8] by a primal-dual method.

The feedback vertex set problem remains NP-hard even in tournaments [18], where a tournament is an orientation of a complete graph; Speckenmeyer established this NP-hardness using the vertex cover problem as the source problem. It can be shown that Speckenmeyer's reduction is an L-reduction (a concept introduced by Papadimitriou and Yannakakis [14]). Moreover, with this reduction, an instance of the vertex cover problem has a solution of size $\leq k$ if and only if the instance of the corresponding feedback vertex set problem has a solution of size $\leq k$. Thus the feedback vertex set problem in tournaments is a generalization of the vertex cover problem, and any inapproximability result of the vertex cover problem [9] is also valid for the feedback vertex set problem in tournaments.

It is well known that the vertex cover problem is approximable within a factor of 2, which can be achieved by several methods [10], such as the local ratio technique [3],

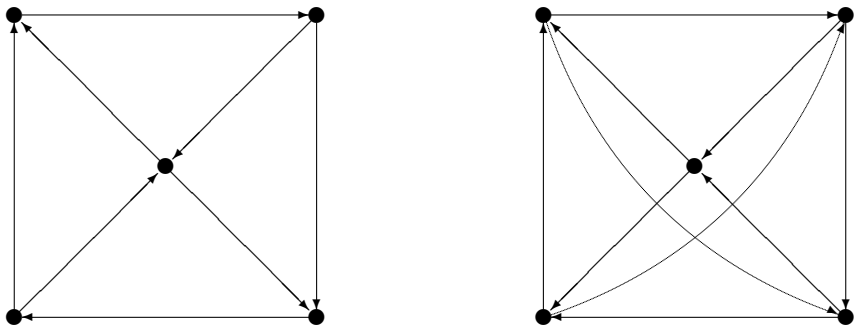
the LP-relaxation method, and the primal-dual method. Despite much recent research effort and progress that have been made in the area of approximation algorithms, the best known approximation ratio of the vertex cover problem is $2-\frac{\log\log n}{2\log n}$ [3, 13], and no approximation algorithm with performance guarantee of $2-\epsilon$ has been discovered so far, no matter how small the positive constant ϵ is. It is thus conjectured in [10] that 2 is the best possible constant. Let us point out that each of those methods mentioned above leads to a 3-approximation algorithm for the feedback vertex set problem in tournaments, which is in the same spirit as the corresponding 2-approximation algorithm for the vertex cover problem. One such algorithm for the unweighted case was first given in [18]. In this work, we improve the approximation ratio to 2.5 for the feedback vertex set problem in tournaments; our approach relies on the local ratio technique of Bar-Yehuda and Even [3] and a characterization of tournaments that possess a min-max relation on packing and covering cycles.

Clearly, a set of vertices in a tournament is a feedback vertex set if and only if it intersects every triangle (a directed cycle of length three, denoted by Δ); thus the feedback vertex set problem is actually the triangle covering problem, which is closely related to the triangle packing problem. Let us now introduce some notions for convenience of presentation.

Given a digraph $T=(V,A)$ such that each vertex $v\in V$ is associated with a nonnegative integer $w(v)$, a *$\triangle$-packing* in T is a family of triangles (repetition is allowed) in T such that each vertex is contained in at most $w(v)$ triangles in this family. A *maximum* $\triangle$-packing in T is a $\triangle$-packing in T with largest size. The *$\triangle$-packing number* of T is the size of a maximum $\triangle$-packing in T. A *$\triangle$-covering* in T is a vertex set $S\subseteq V$ that intersects each triangle in T. The *size* of S, denoted by $w(S)$, is $\sum_{v\in S} w(v)$. A *minimum* $\triangle$-covering in T is a $\triangle$-covering with smallest size; the *$\triangle$-covering number* of T is the size of a minimum $\triangle$-covering in T. The case in which $w(v)=1$ for each $v\in V$ is called *unweighted*; clearly in this case any $\triangle$-packing in T is a family of vertex disjoint triangles of T and the size of any $\triangle$-covering S in T is the number of vertices in S.

Let $\triangle_1,\triangle_2,\ldots,\triangle_m$ be all the triangles in T, let $v_1,v_2,\ldots,v_n$ be all the vertices in V, and let $H_{m\times n}$ be the triangle-vertex incidence matrix, that is, $h_{i,j}=1$ if $\triangle_i$ contains v_j and $h_{i,j}=0$ otherwise. Then the *$\triangle$-covering number* of T equals $\min\{w^Tx \mid Hx\geq e_m,\ x\geq 0,\ \text{integer}\}$, and the *$\triangle$-packing number* of T is $\max\{y^Te_m \mid y^TH\leq w^T,\ y\geq 0,\ \text{integer}\}$, where e_m is the all-one column of size m. It follows from the duality theory of linear programming [16] that the $\triangle$-covering number of T is always greater than or equal to the $\triangle$-packing number of T. The situation in which the packing and covering numbers are equal is particularly interesting. We point out that equality does not necessarily hold in general tournaments: in the unweighted case, both F_1 and F_2 have $\triangle$-packing number of 1 and $\triangle$-covering number of 2. We shall demonstrate that actually F_1 and F_2 are the only obstructions in our problem: if a tournament $T=(V,A)$ contains no F_1 nor F_2, then the $\triangle$-packing number of T always equals the $\triangle$-covering number of T.

The remainder of this paper is organized as follows. In section 2, we give a structural description of tournaments with no F_1 nor F_2. We start with a vertex w with the maximum out-degree, and partition the vertices of T according to their distance from w, that is, $V=\cup_{i=1}^{k}V_i$, where a vertex $v\in V_i$ if and only if the distance from w to v is $i-1$. The subtournament induced by V_i is shown to be acyclic if T contains no F_1 nor F_2. This property leads to a natural order for vertices in V_i. For each $v\in V_{i+1}$, let $V_-(v)$ be the set of vertices in V_i that point to v and let $V_+(v)$ be



$\mathbf{F}_1$ $\mathbf{F}_2$

FIG. 1. *Two Forbidden Subtournaments, where the two arcs not shown in F_1 may take any directions.*

the set of vertices in V_i that are pointed from v. Then every vertex in $V_-(v)$ points to every vertex in $V_+(v)$. Moreover, if $u, v \in V_{i+1}$ with u pointing to v, then every vertex in V_i that points to u also points to v. These properties turn out to be very useful in establishing the fact that, for every triangle in the tournament, its three vertices are in three consecutive subsets of the partition, i.e., V_i, V_{i+1}, V_{i+2} for some i. Then the triangle packing problem becomes the P_3 (a directed path of length 2) packing problem in the digraph D obtained from T by only keeping all the arcs between two consecutive subsets (i.e., V_i and V_{i+1}) of the partition.

In section 3, using the combinatorial structure obtained in section 2, we show that in the unweighted case the P_3-packing number and the P_3-covering number of D are equal if the tournament T is free of subdigraphs F_1 and F_2. To establish the min-max relation, we first show that a particular greedy algorithm for packing P_3 in D results in an optimal solution to the P_3 packing problem. Informally, we prove that the P_3 with the smallest lexicographical (according to the order in section 2) index from V_3 to V_2 to V_1 is in an optimal solution. Then, we show that there is a vertex in this P_3 whose removal reduces the P_3-packing number by one. This implies that both the linear program relaxation $\min\{e_n^t x \mid Hx \geq e_m,\ x \geq 0\}$ and the dual program $\max\{e_n^t y \mid y^t H \leq e_n^t,\ y \geq 0\}$ have integral optimal solutions for every tournament with no F_1 nor F_2 as subdigraph. We further generalize the min-max result to the weighted case.[1]

In section 4, we present a 2.5-approximation polynomial time algorithm for the feedback vertex set problem in any tournament. Applying the local ratio technique to F_1 and F_2, we obtain a 2.5-approximation algorithm for the minimum feedback set problem in any tournament by the local ratio theorem of Bar-Yehuda and Even [3]. We conclude this paper with discussion and remarks in section 5.

2. A structural description. The purpose of this section is to present a structural description of the tournaments with no F_1 nor F_2, which will be used repeatedly in the remaining sections. In our proof, we shall say that u points to v in a digraph, write $u \to v$ if (u, v) is an arc, and we let $N_-(u)$ (resp., $N_+(u)$) stand for the set of all the vertices v with $v \to u$ (resp., $u \to v$).

[1] In the preliminary version [4], this was done by applying a sophisticated TDI technique due to Edmonds and Giles [5, 6, 15]. The present simple proof is suggested by one of the referees.

LEMMA 2.1. *Let $T = (V, A)$ be a strongly connected tournament with no subtournament isomorphic to F_1 nor F_2. Then V can be partitioned into $V_1, V_2, \ldots, V_k$ for some $3 \le k \le |V|$, which have the following properties:*

(a) *For each $i = 1, 2, \ldots, k$, V_i is acyclic and thus V_i admits a linear order $\prec$ such that $x \prec y$ whenever (x, y) is an arc in V_i.*

(b) *For each $i = 1, 2, \ldots, k-1$, there is a map $f : V_{i+1} \to V_i$ such that*
- *for any $v \in V_{i+1}$,*
  (x, v) is an arc for each x in V_i with $x \prec f(v)$ and
  (v, x) is an arc for each x in V_i with $f(v) \preceq x$ and that
- *for any $u, v \in V_{i+1}$ with $u \prec v$, there holds $f(u) \preceq f(v)$.*

(c) *For any i, j with $1 \le i \le j-2 \le k-2$, each arc between V_i and V_j is directed from V_i to V_j.*

Proof. We reserve the symbol w for a vertex in T with *maximum outdegree* throughout the proof. Now let us apply the *breadth-first search* to T and partition the vertices of T as follows.

$V_1 = \{w\}$;
$k = 1$;
while $V - (\cup_{i=1}^{k} V_i) \neq \emptyset$
do $V_{k+1} = \{v \in V - (\cup_{i=1}^{k} V_i) :$ there exists $x \in V_k$ such that $v \to x\}$;
k=k+1;
end

As soon as this algorithm constructs $V_1, V_2, \ldots, V_i$, it proceeds to construct a V_{i+1} if $V - (\cup_{p=1}^{i} V_p) \neq \emptyset$. Since T is strongly connected, $V_{i+1} \neq \emptyset$ for otherwise all the arcs between $\cup_{p=1}^{i} V_p$ and $V - (\cup_{p=1}^{i} V_p)$ are directed to $V - (\cup_{p=1}^{i} V_p)$, a contradiction. Since $V_1, V_2, \ldots$ are pairwise disjoint subsets of V, the algorithm terminates in finite number of steps. It follows that

(2.1) $V_1, V_2, \ldots, V_k$ form a partition of V.

We aim to show that $V_1, V_2, \ldots, V_k$ are as desired. For this purpose, note that (it follows immediately from the algorithm)

(2.2) for each $i = 1, 2, \ldots, k-1$ and each $x \in V_i$, $N_-(x) \cap (V - \cup_{p=1}^{i+1} V_p) = \emptyset$.

Thus property (c) follows. Since T is strongly connected, $N_-(w) \neq \emptyset$ and $N_+(w) \neq \emptyset$, so $V_2 \neq \emptyset$ and $V - (V_1 \cup V_2) \neq \emptyset$. In view of (2.1), we have $k \ge 3$. To prove that $V_1, V_2, \ldots, V_k$ enjoy properties (a) and (b), we apply induction on the subscripts of V_i's.

(2.3) For each $x \in V_2$, we have $N_-(x) \cap V_3 \neq \emptyset$.

To justify it, note that otherwise $d_+(x) > d_+(w)$, contradicting the definition of w.

(2.4) For any $x, y \in V_2$, either $(N_-(x) \cap V_3) \subseteq (N_-(y) \cap V_3)$ or $(N_-(y) \cap V_3) \subseteq (N_-(x) \cap V_3)$.

Assume the contrary: (2.3) guarantees the existence of a vertex u in $(N_-(x) - N_-(y)) \cap V_3$ and a vertex v in $(N_-(y) - N_-(x)) \cap V_3$. Since $uxvyu$ is a cycle of length 4, w points to both u and v (recall (2.2)), and both x and y point to w, $\{u, v, w, x, y\}$ induces an F_1 in T, a contradiction.

Similarly, we can prove that

(2.5) for any $u, v \in V_3$, either $(N_+(u) \cap V_2) \subseteq (N_+(v) \cap V_2)$ or $(N_+(v) \cap V_2) \subseteq (N_+(u) \cap V_2)$.

It follows from (2.3), (2.4), (2.5), and the definition of V_3 that

(2.6) there exists $x \in V_2$ such that $V_3 \subseteq N_-(x)$; there exists $u \in V_3$ such that $V_2 \subseteq N_+(u)$.

The following statement will be used repeatedly in our proof.

(2.7) Let U_1, U_2, and U_3 be three disjoint vertex-subsets of T such that all the arcs between U_i and U_{i+1} are directed to U_{i+1} for each $i = 1, 2, 3$, where the subscript is taken modulo 3. Then each of U_1, U_2, and U_3 is acyclic.

To justify it, assume the contrary: some U_i, say, U_1, contains a triangle $x_1x_2x_3x_1$. Let x_4 be a vertex in U_2 and let x_5 be a vertex in U_3. Then, by hypothesis, x_4 points to x_5; each of x_1, x_2, and x_3 points to x_4; and x_5 points to each of x_1, x_2, and x_3. Thus $x_1x_2x_4x_5x_1$ is a cycle of length 4, x_3 points to both x_1 and x_4, and both x_2 and x_5 point to x_3. Hence $\{x_1, x_2, x_3, x_4, x_5\}$ induces an F_1 in T, a contradiction.

(2.8) Each of V_2 and V_3 is acyclic.

Let $x \in V_2$ and $u \in V_3$ be two vertices as specified in (2.6). By (2.7) with $U_1 = \{w\}$, $U_2 = \{u\}$, and $U_3 = V_2$, we conclude that V_2 is acyclic; by (2.7) with $U_1 = \{w\}$, $U_2 = V_3$, and $U_3 = \{x\}$, we conclude that V_3 is acyclic.

(2.9) Let x, y be two vertices in V_2 and let u, v be two vertices in V_3. Suppose that u points to both x and y, x points to v, and v points to y. Then x points to y and u points to v.

Suppose the contrary, let us distinguish among three cases.

If $y \to x$ and $v \to u$, then $uyxvu$ is a cycle of length 4, both $wvyw$ and $wuxw$ are triangles. Hence $\{u, v, w, x, y\}$ induces an F_2 in T, a contradiction.

If $y \to x$ and $u \to v$, then $uvywu$ is a cycle of length 4, x points to both v and w, and both u and y point to x. Hence $\{u, v, w, x, y\}$ induces an F_1 in T, a contradiction.

If $x \to y$ and $v \to u$, then $uxywu$ is a cycle of length 4, v points to both u and y, and both w and x point to v. Hence $\{u, v, w, x, y\}$ induces an F_1 in T, a contradiction.

(2.10) Let x, y be two vertices in V_2 with $|N_-(x) \cap V_3| < |N_-(y) \cap V_3|$. Then x points to y.

By hypothesis, we have $v \in V_3$ such that x points to v and v points to y. Moreover, (2.6) guarantees the existence of $u \in V_3$ such that u points to both x and y. It follows from (2.9) that x points to y.

(2.11) Let u, v be two vertices in V_3 with $|N_+(v) \cap V_2| < |N_+(u) \cap V_2|$. Then u points to v.

By hypothesis, we have $x \in V_2$ such that u points to x and x points to v. Moreover, (2.6) guarantees the existence of $y \in V_2$ such that both u and v point to y. It follows from (2.9) that u points to v.

It can be seen from (2.8) that V_i admits a linear order $\prec$ such that $x \prec y$ whenever (x, y) is an arc in V_i for each $i = 2, 3$.

(2.12) Let (u, x) be an arbitrary arc from V_3 to V_2. Then $u \to y$ for any y in V_2 with $x \prec y$.

Assume the contrary: $y \to u$ for some y in V_2 with $x \prec y$. By virtue of (2.6), we have $v \in V_3$ such that $v \to x$ and $v \to y$. It follows from (2.9) that $y \to x$, contradicting the hypothesis $x \prec y$.

Since V_1 consists of a single vertex w, property (b) holds trivially for V_1 and V_2.

(2.13) Let $f : V_3 \to V_2$ be the map defined as follows: for any $v \in V_3$, $f(v)$ is the smallest vertex in V_2 such that $v \to f(v)$. Then

- for any $v \in V_3$,
  - (x, v) is an arc for each x in V_2 with $x \prec f(v)$ and
  - (v, y) is an arc for each y in V_2 with $f(v) \preceq y$ and
- for any $u, v \in V_3$ with $u \prec v$, there holds $f(u) \preceq f(v)$.

The first statement follows instantly from (2.12). To justify the second statement, assume the contrary: $f(v) \prec f(u)$ for some u, v in V_3 with $u \prec v$. It follows from

(2.12) that $|N_+(u) \cap V_2| < |N_+(v) \cap V_2|$. By (2.11), we have $v \to u$, contradicting the hypothesis $u \prec v$.

Suppose we have proved that $V_1, V_2, \ldots, V_i$ enjoy properties (a) and (b) for $3 \leq i \leq k-1$; let us proceed to the induction step and consider V_{i+1}. Let $\prec$ be a linear order on V_p as specified in property (a) for $p = 1, 2, \ldots, i$. For convenience, we reserve the symbol s for the largest vertex in V_{i-1} and the symbol t for the largest vertex in V_{i-2}.

(2.14) The following statements hold.

- s points to each vertex in $\{t\} \cup V_{i+1}$;
- t points to each vertex in $V_i \cup V_{i+1}$.

Indeed, by the induction hypothesis of property (b), s points to t and each vertex in V_i points to s; the remaining statements follow from property (c).

(2.15) Let (u, x) be an arbitrary arc from V_{i+1} to V_i. Then $u \to y$ for any y in V_i with $x \prec y$.

Assume the contrary: $y \to u$ for some y in V_i with $x \prec y$. Then $uxstu$ is a cycle of length 4 (recall (2.14)), both t and x point to y, and y points to both s and u. Thus $\{s, t, u, x, y\}$ induces an F_1 in T, a contradiction.

(2.16) V_{i+1} is acyclic.

Let r be the largest vertex in V_i. Then, in view of (2.15) and the definition of V_{i+1}, each vertex in V_{i+1} points to r. By (2.7) with $U_1 = \{r\}$, $U_2 = \{s\}$, and $U_3 = V_{i+1}$, we conclude that V_{i+1} is acyclic.

(2.17) Let u, v be two vertices in V_{i+1} with $|N_+(v) \cap V_i| < |N_+(u) \cap V_i|$. Then u points to v.

Assume the contrary: v points to u. The hypothesis guarantees the existence of $x \in V_i$ such that $u \to x$ and $x \to v$. Let y be the largest vertex in V_i. Then, by (2.15) and the definition of V_{i+1}, we have $u \to y$ and $v \to y$, which implies that $x \neq y$ and hence $x \to y$. Note that $xysux$ is a cycle of length 4, v points to both u and y, and both s and x point to v. Hence $\{s, u, v, x, y\}$ induces an F_1 in T, a contradiction.

According to (2.16), V_{i+1} admits a linear order $\prec$ such that $x \prec y$ whenever (x, y) is an arc in V_{i+1}.

(2.18) Let $f : V_{i+1} \to V_i$ be the map defined as follows: for any $v \in V_{i+1}$, $f(v)$ is the smallest vertex in V_i such that $v \to f(v)$. Then

- for any $v \in V_{i+1}$,
  - (x, v) is an arc for each x in V_i with $x \prec f(v)$ and
  - (v, x) is an arc for each x in V_i with $f(v) \preceq x$ and
- for any $u, v \in V_{i+1}$ with $u \prec v$, there holds $f(u) \preceq f(v)$.

The first statement follows instantly from (2.15). To justify the second statement, assume the contrary: $f(v) \prec f(u)$ for some u, v in V_{i+1} with $u \prec v$. It follows from (2.15) that $|N_+(u) \cap V_2| < |N_+(v) \cap V_2|$. By (2.17), we have $v \to u$, contradicting the hypothesis $u \prec v$. This completes the proof. □

COROLLARY 2.1. *For each $i = 1, 2, \ldots, k-1$, if (v, x) is an arc from V_{i+1} to V_i in T, then (u, x) is an arc for any u in V_{i+1} with $u \prec v$.*

Proof. Since $u \prec v$, by property (b) of the lemma we have $f(u) \preceq f(v) \preceq x$, thus (u, x) is an arc. □

COROLLARY 2.2. *Let $xyzx$ be a triangle in T and let $\{V_1, V_2, \ldots, V_k\}$ be a partition of V as specified in the lemma. Then there exists an i with $1 \leq i \leq k-2$ such that $z \in V_i$, $y \in V_{i+1}$, and $x \in V_{i+2}$ (renaming x, y, and z if necessary).*

Proof. By property (a) of Lemma 2.1, V_i is acyclic for each $i = 1, 2, \ldots, k$. Hence each V_i contains at most two of x, y, and z; let us now verify that V_i cannot contain

two of them. Assume the contrary: both x and y are in V_i. (Rename the vertices if necessary.) By property (c) of the lemma, $z \in V_{i-1}$ or $z \in V_{i+1}$, for otherwise z would have two outgoing or two incoming arcs in the triangle $xyzx$, a contradiction. If $z \in V_{i-1}$, then (since $y \to z$ and $z \to x$) by Corollary 1 we have $y \prec x$, contradicting the fact that $x \to y$; if $z \in V_{i+1}$, then (since $y \to z$ and $z \to x$) by property (b) of the lemma, $y \prec f(z) \preceq x$, contradicting the fact that $x \to y$.

It follows that there exist three subscripts r, s, t with $1 \le r < s < t \le k$ such that $|\{x, y, z\} \cap V_p| = 1$ for each $p = r, s, t$. We claim that $t - r = 2$, for otherwise $t \ge r + 3$, thus either $t \ge s + 2$ (by property (c) of the lemma, the vertex in $\{x, y, z\} \cap V_t$ has two incoming arcs in the triangle $xyzx$) or $s \ge r + 2$ (the vertex in $\{x, y, z\} \cap V_r$ has two outgoing arcs in the triangle), we reach a contradiction in either case, completing the proof. □

LEMMA 2.2. *Let $T = (V, A)$ be a strongly connected tournament. Then* either *one of F_1 and F_2 in T* or *a partition $\{V_1, V_2, \ldots, V_k\}$ of V as described in Lemma* 2.1 *can be found in time $O(|V|^2)$.*

Proof. Let us apply the same algorithm as described in the proof of Lemma 2.1 to T first. This algorithm is essentially a breadth-first search, so it can be implemented in time $O(|V|^2)$. We then need to check if each of (2.4), (2.5), (2.8), (2.10)–(2.12), (2.15)–(2.17) holds. (Recall the proof of Lemma 2.1. The other statements need not be checked; for example, (2.6) follows from (2.4) and (2.5) and (2.9) is proved for (2.10) and (2.11).) If yes, $\{V_1, V_2, \ldots, V_k\}$ is a partition as desired; else, we can exhibit an F_1 or F_2.

Note that (2.4) can be checked in time $O((|V_2| + |V_3|)^2)$. To see it, we first find $N_-(x) \cap V_3$ for each $x \in V_2$; this step takes $O(|V_2||V_3|)$ time. Then sort the vertices in V_2 in nondecreasing order according to $|N_-(x) \cap V_3|$; this step takes $O(|V_2| \log |V_2|)$ time. Suppose $x_1, x_2, \ldots, x_t$ is the resulting order, where $t = |V_2|$. Then we check if $(N_-(x_i) \cap V_3) \subseteq (N_-(x_{i+1}) \cap V_3)$ for $i = 1, 2, \ldots, t-1$. If not, let i be the smallest subscript that violates this condition; then we can exhibit an F_1. (Recall the proof of (2.4).) Otherwise, (2.4) is satisfied; this step takes $O(|V_2||V_3|)$ time. So our statement follows.

Similarly, (2.5) can be checked in time $O((|V_2| + |V_3|)^2)$.

As for (2.8), we can find a triangle in V_2 or declare V_2 is acyclic in time $O(|V_2|^2)$. To see it, let us apply the depth-first search to output the strongly connected components of V_2. If there is no component that contains at least three vertices, then V_2 is acyclic; otherwise, apply the depth-first search on such a component to output a directed cycle C. If C has three vertices, then C is as desired; else, take an arbitrary chord e of C, $\{e\} \cup C$ contains a directed cycle C_1 shorter than C; replace C by C_1; repeat the process.

Similarly, it can be shown that the time complexity for checking each of (2.10)–(2.12), (2.15)–(2.17) is no more than $O((|V_i| + |V_{i+1}|)^2)$ when we proceed to the structure between V_i and V_{i+1} for $i = 1, 2, \ldots, k-1$. Hence, the total complexity is $\sum_{i=1}^{k-1} O((|V_i| + |V_{i+1}|)^2) + O(|V|^2) = O(|V|^2)$.

3. Min-max theorems. The present section is devoted to min-max theorems on packing and covering directed cycles in tournaments. Recall that in the unweighted case every $\triangle$-packing in T is a family of vertex disjoint triangles and the size of a $\triangle$-covering S in T is the number of vertices in S.

THEOREM 3.1. *Let $T = (V, A)$ be a tournament with no subtournament isomorphic to F_1 nor F_2. Then the $\triangle$-packing number of T equals the $\triangle$-covering number of T.*

Proof. Without loss of generality, we may assume that T is strongly connected.

We shall let P_3 stand for an induced directed path with three vertices. Recall the definitions of a $\triangle$-packing and a $\triangle$-covering in section 1; with P_3 in place of $\triangle$ over there, we can define a P_3-packing and a P_3-covering.

Since T contains no F_1 nor F_2, V admits a partition $\{V_1, V_2, \ldots, V_k\}$ as described in Lemma 2.1. Let D be the digraph obtained from T by deleting all arcs in V_i for each i and deleting all the arcs from V_i to V_j for any $i < j$. Then we have

(3.1.1) the $\triangle$-packing number of T equals the P_3-packing number of D; the $\triangle$-covering number of T equals the P_3-covering number of D.

To see it, let $xyzx$ be an arbitrary triangle in T. Then Corollary 2.2 guarantees the existence of some i such that $z \in V_i$, $y \in V_{i+1}$, and $x \in V_{i+2}$. Hence xyz is a P_3 in D. Conversely, if xyz is a P_3 in D, then we have some i (recall the construction of D) such that $z \in V_i$, $y \in V_{i+1}$, and $x \in V_{i+2}$. By property (c) of Lemma 2.1, z points to x in T. Hence $xyzx$ is a triangle in T. So there is a one to one correspondence between triangles in T and $P_3's$ in D; (3.1.1) follows.

In view of (3.1.1), the present theorem is equivalent to the following statement.

(3.1.2) The P_3-packing number of D equals the P_3-covering number of D.

We shall turn to prove (3.1.2). For this purpose, note the following:

(3.1.3) Let $\prec$ be the linear order as defined in Lemma 2.1. Then the following statements hold:

(i) For each $i = 1, 2, \ldots, k-1$, if (v, x) is an arc from V_{i+1} to V_i in D, then (u, x) is an arc in D for any u in V_{i+1} with $u \prec v$.

(ii) For each $i = 1, 2, \ldots, k-1$, there is a map $f : V_{i+1} \to V_i$ such that for each $v \in V_{i+1}$, (v, x) is an arc for each x in V_i with $f(v) \preceq x$ and that there is no arc between v and any x in V_i with $x \prec f(v)$.

From the construction of D, it can be seen that (i) follows instantly from Corollary 2.1 and (ii) follows from property (b) of Lemma 2.1.

Let i^* be the smallest vertex in V_i with respect to the linear order $\prec$ as defined in (3.1.3) for $i = 1, 2, \ldots, k$.

(3.1.4) Without loss of generality, we may assume that $f((i+1)^*) = i^*$ for $i = 1$ and 2.

Suppose the contrary: $f((i+1)^*) \neq i^*$ for $i = 1$ or 2. Then there is no P_3 in D passing through i^*, for otherwise $i \leq 2$ and the construction of D imply that such a P_3 would contain an arc (v, i^*) for some $v \in V_{i+1}$. From (i) of (3.1.3), we conclude that $((i+1)^*, i^*)$ would be an arc in D, so $f((i+1)^*) = i^*$, a contradiction. Hence we may consider $D - \{i^*\}$ instead of D. □

(3.1.5) There exists a maximum P_3-packing in D which contains $3^*2^*1^*$.

To justify (3.1.5), note that, by (3.1.4), $3^*2^*1^*$ is a P_3 in D. Now let $\mathcal{P}$ be a maximum P_3-packing in D such that $|\theta(\mathcal{P}) \cap F^*|$ is as large as possible, where $\theta(\mathcal{P})$ is the set of all the vertices and all the arcs appeared in P_3's in $\mathcal{P}$ and $F^* = \{1^*, 2^*, 3^*, (3^*, 2^*), (2^*, 1^*)\}$. We aim to show that this $\mathcal{P}$ contains $3^*2^*1^*$. To this end, observe that

(i) $\{1^*, 2^*, 3^*\} \cap \theta(\mathcal{P}) \neq \emptyset$. For otherwise, we may add $3^*2^*1^*$ to $\mathcal{P}$ to obtain a larger P_3-packing in D, a contradiction.

(ii) $1^* \in \theta(\mathcal{P})$. For otherwise, in case $2^* \in \theta(\mathcal{P})$, let Q be the P_3 containing 2^* in $\mathcal{P}$ and let Q' be the P_3 obtained from Q by replacing one arc with $(2^*, 1^*)$; in case $2^* \notin \theta(\mathcal{P})$, let Q be the P_3 containing 3^* in $\mathcal{P}$ (recall (i)) and let $Q' = 3^*2^*1^*$. Next, let $\mathcal{P}'$ be the P_3-packing obtained from $\mathcal{P}$ by replacing Q with Q'. Then we have $|\theta(\mathcal{P}') \cap F^*| > |\theta(\mathcal{P}) \cap F^*|$ in each case, a contradiction.

(iii) $2^* \in \theta(\mathcal{P})$. Assume the contrary, let Q be the P_3 containing 1^* in $\mathcal{P}$; we distinguish between two cases: in case 3^* is contained in no $R \in \mathcal{P}$ with $R \neq Q$, let $\mathcal{P}'$ be the P_3-packing obtained from $\mathcal{P}$ by replacing Q with $3^*2^*1^*$. In case 3^* is contained in an $R \in \mathcal{P}$ with $R \neq Q$, we consider two subcases: if 3^* is not a source of R, then let R' be the P_3 obtained from R by replacing one arc with $(3^*, 2^*)$; if 3^* is a source of R, say, $R = 3^*yx$, then set $R' = 3^*2^*x$ (note that $(2^*, x)$ is an arc in D by (3.1.3)); next, let $\mathcal{P}'$ be the P_3-packing obtained from $\mathcal{P}$ by replacing R with R'. It can be seen that $|\theta(\mathcal{P}') \cap F^*| > |\theta(\mathcal{P}) \cap F^*|$ in either case, a contradiction.

(iv) $3^* \in \theta(\mathcal{P})$. For otherwise, let $Q = xy1^*$ be the P_3 containing 1 in $\mathcal{P}$ (recall (ii)). Then $(3^*, y)$ is an arc in D by (i) of (3.1.3) as $3^* \prec x$. Now let $\mathcal{P}'$ be the P_3-packing obtained from $\mathcal{P}$ by replacing Q with 3^*y1^*. Then $|\theta(\mathcal{P}') \cap F^*| > |\theta(\mathcal{P}) \cap F^*|$, a contradiction.

(v) $(3^*, 2^*) \in \theta(\mathcal{P})$. Suppose the contrary: let Q (resp., R) be the P_3 containing 2^* (resp., 3^*) in $\mathcal{P}$ (recall (iii) and (iv)). Then $Q \neq R$. We distinguish between two cases according to the position of 2^* in Q.

Case 1. $Q = x2^*y$. In case $R = 3^*uv$, (x, u) is an arc in D by (ii) of (3.1.3) as $2^* \prec u$, let $Q' = 3^*2^*y$ and $R' = xuv$; in case $R = u3^*v$, both (u, x) and (x, v) are arcs in D according to (3.1.3), let $Q' = 3^*2^*y$ and $R' = uxv$; in case $R = uv3^*$, (v, x) is an arc in D by (3.1.3), let $Q' = 3^*2^*y$ and $R' = uvx$.

Case 2. $Q = xy2^*$. In case $R = 3^*uv$, both $(2^*, v)$ and (y, u) are arcs in D by (3.1.3), let $Q' = 3^*2^*v$ and $R' = xyu$; in case $R = u3^*v$, (y, v) is an arc in D according to (3.1.3), let $Q' = u3^*2^*$ and $R' = xyv$; in case $R = uv3^*$, we consider two subcases: If $v \prec x$, then (u, x) is an arc in D by (3.1.3), let $Q' = v3^*2^*$ and $R' = uxy$; if $x \prec v$, then both $(x, 3^*)$ and (v, y) are arcs in D by (3.1.3), let $Q' = x3^*2^*$ and $R' = uvy$.

Next, in each case let $\mathcal{P}'$ be the P_3-packing obtained from $\mathcal{P}$ by replacing Q with Q' and by replacing R with R'. Then $|\theta(\mathcal{P}') \cap F^*| > |\theta(\mathcal{P}) \cap F^*|$, a contradiction.

(vi) $(2^*, 1^*) \in \theta(\mathcal{P})$. Suppose the contrary: Let Q (resp., $R = yz1^*$) be the P_3 containing $(3^*, 2^*)$ (resp., 1^*) in $\mathcal{P}$ (recall (v) and (ii)). Then $Q \neq R$. In case $Q = 3^*2^*x$, (z, x) is an arc in D by (3.1.3), let $Q' = 3^*2^*1^*$ and $R' = yzx$; in case $Q = x3^*2^*$, (x, y) is an arc in D by (3.1.3), let $Q' = 3^*2^*1^*$ and $R' = xyz$. Next, in each case let $\mathcal{P}'$ be the P_3-packing obtained from $\mathcal{P}$ by replacing Q with Q' and by replacing R with R'. Then $|\theta(\mathcal{P}') \cap F^*| > |\theta(\mathcal{P}) \cap F^*|$, a contradiction.

Since P_3's in $\mathcal{P}$ are vertex disjoint, it follows from (v) and (vi) that $3^*2^*1^*$ is a P_3 in $\mathcal{P}$, completing the proof of (3.1.5).

In view of (3.1.4) and (3.1.5), we have the following *greedy algorithm* for a maximum P_3-packing in D.

(3.1.6) DESCRIPTION. *If $f((i+1)^*) \neq i^*$ for $i = 1$ or 2, then any maximum P_3-packing in $D - \{i^*\}$ is a maximum P_3-packing in D, replace D by $D - \{i^*\}$; else, the union of any maximum P_3-packing in $D - \{1^*, 2^*, 3^*\}$ and $3^*2^*1^*$ gives a maximum P_3-packing in D, replace D by $D - \{1^*, 2^*, 3^*\}$; repeat the process.*

Since (3.1.3) is closed under taking connected induced subdigraphs of D, both (3.1.4) and (3.1.5) are valid with respect to each connected component of new D's. Hence the algorithm will eventually return a maximum P_3-packing in the original D.

Recall (3.1.3): $\prec$ is a linear order defined on each V_i; however, there is no order between any two vertices in two distinct V_i's. Now let us fix this gap and extend $\prec$ to the whole vertex-set V of D.

(3.1.7) Define $u \prec v$ whenever $u \in V_i$ and $v \in V_j$ for any $i < j$.

We point out that if xyz is a P_3 in D, then, according to (3.1.7), there holds $z \prec y \prec x$. Now let us proceed to the order of P_3's in D.

(3.1.8) Let $Q_1 = x_1y_1z_1$ and $Q_2 = x_2y_2z_2$ be two P_3's in D. Define $Q_1 \prec Q_2$ if one of the following three conditions is satisfied: (i) $x_1 \prec x_2$; (ii) $x_1 = x_2$ and $y_1 \prec y_2$; (iii) $x_1 = x_2$, $y_1 = y_2$, and $z_1 \prec z_2$.

Based on (3.1.8), we can further define the order of two P_3-packings with the same size.

(3.1.9) Let $\mathcal{Q} = \{Q_i : i = 1, 2, \ldots, m\}$ and $\mathcal{Q}' = \{Q'_i : j = 1, 2, \ldots, m\}$ be two P_3-packings in D sorted in *increasing* order: $Q_i \prec Q_{i+1}$ and $Q'_i \prec Q'_{i+1}$ for $i = 1, 2, \ldots, m-1$. Define $\mathcal{Q} \prec \mathcal{Q}'$ if there is some i with $1 \leq i \leq m$ such that $Q_i \prec Q'_i$ and $Q_j = Q'_j$ for each $j > i$.

(3.1.10) Let $Q_1 = x_1y_1z_1$ and $Q_2 = x_2y_2z_2$ be two P_3's in D. Define $Q_1 \prec_{strict} Q_2$ if the following two conditions are satisfies simultaneously: (i) $x_1 \prec x_2$, $y_1 \prec y_2$, and $z_1 \prec z_2$; (ii) for each $1 \leq j \leq k$, if $u_1 \in V_j \cap \{x_1, y_1, z_1\}$ and $u_2 \in V_j \cap \{x_2, y_2, z_2\}$, then $u_1 \prec u_2$.

(3.1.11) A maximum P_3-packing $\mathcal{Q} = \{Q_i : i = 1, 2, \ldots, m\}$ in D is called *good* if $Q_1 \prec_{strict} Q_2 \prec_{strict} \ldots \prec_{strict} Q_m$ (renaming Q_i's if necessary).

The algorithm described in (3.1.6) asserts that

(3.1.12) there exists a *good* maximum P_3-packing in D.

Recall that our target is to prove (3.1.2). To achieve it, we still need some preparations.

(3.1.13) Let $\mathcal{Q} = \{Q_i : i = 1, 2, \ldots, m\}$ be a good maximum P_3-packing in D (recall (3.1.11)) with the largest possible order with respect to (3.1.9) and let w be an arbitrary vertex in $\{1^*, 2^*, 3^*\}$. Assume that D and $D - \{w\}$ have the same P_3-packing number. Then there exists a good maximum P_3-packing $\mathcal{Q}' = \{Q'_i : i = 1, 2, \ldots, m\}$ in $D - \{w\}$ such that $Q'_1 \prec Q_1$ and $Q'_i = Q_i$ for $i = 2, 3, \ldots, m$.

To justify (3.1.13), let $\mathcal{Q}' = \{Q'_i : i = 1, 2, \ldots, m\}$ be a good maximum P_3-packing in $D - \{w\}$ with the largest possible order with respect to (3.1.9), the existence of $\mathcal{Q}'$ is guaranteed by (3.1.12) (with $D - \{w\}$ in place of D over there). Let us show that $\mathcal{Q}'$ is as desired. Assume the contrary: let i be the largest index with $Q'_i \prec Q_i$. Then $i \geq 2$. Suppose $Q_i = x_iy_iz_i$ and $Q'_i = x'_iy'_iz'_i$, we distinguish among three cases.

Case 1. $x'_i = x_i$ and $y'_i = y_i$ and $z'_i \prec z_i$. In this case $Q'_i \prec_{strict} Q_i$. Let $\tilde{\mathcal{Q}} = (\mathcal{Q}' - \{Q'_i\}) \cup \{Q_i\}$. Then $\tilde{\mathcal{Q}}$ is a good maximum P_3-packing in $D - \{w\}$. To see it, note that $Q'_j = Q_j$ for each $j > i$. By definition (3.1.11), $Q'_j \prec_{strict} Q'_i$ for each $j < i$, thus no Q'_j with $j < i$ in $\mathcal{Q}'$ passes through any of x_i, y_i, z_i. The statement follows. Since $\mathcal{Q}' \prec \tilde{\mathcal{Q}}$, the existence of $\tilde{\mathcal{Q}}$ contradicts the selection of $\mathcal{Q}'$.

Case 2. $x'_i = x_i$ and $y'_i \prec y_i$. In case $z'_i \preceq z_i$, our proof is exactly the same as that in Case 1; in case $z_i \prec z'_i$, (y_i, z'_i) is an arc in D by (3.1.3). Let $\tilde{\mathcal{Q}} = (\mathcal{Q} - \{Q_i\}) \cup \{x_iy_iz'_i\}$. Then $\tilde{\mathcal{Q}}$ is a good maximum P_3-packing in D with $\mathcal{Q}' \prec \tilde{\mathcal{Q}}$, a contradiction.

Case 3. $x'_i \prec x_i$. Let us consider three subcases.

Subcase 3.1. x'_i and x_i belong to the same V_j for some $1 \leq j \leq k$. In case $y'_i \preceq y_i$, our proof is exactly the same as that in Case 2. So we suppose $y_i \prec y'_i$. Thus (x_i, y'_i) is an arc in D by (3.1.3). Let $\tilde{\mathcal{Q}}$ be the P_3-packing obtained from $\mathcal{Q}'$ by replacing Q'_i with $x_iy'_iz'_i$. Then $\tilde{\mathcal{Q}}$ is a good maximum P_3-packing in $D - \{w\}$ with $\mathcal{Q}' \prec \tilde{\mathcal{Q}}$, contradicting the definition of $\mathcal{Q}'$.

Subcase 3.2. x'_i and y_i belong to the same V_j for some $1 \leq j \leq k$.

Consider the case $x'_i \preceq y_i$. If $y'_i \preceq z_i$ (resp., $z_i \prec y'_i$), let $\tilde{\mathcal{Q}}$ be the P_3-packing obtained from $\mathcal{Q}'$ by replacing Q'_i with Q_i (resp., with $x_iy_iy'_i$, recall (3.1.3)), then $\tilde{\mathcal{Q}}$ is a good maximum P_3-packing in $D - \{w\}$ with $\mathcal{Q}' \prec \tilde{\mathcal{Q}}$, a contradiction.

Next, consider the case $y_i \prec x'_i$. Note that (x_i, x'_i) is an arc in D by (3.1.3). Let

$\tilde{\mathcal{Q}}$ be the P_3-packing obtained from $\mathcal{Q}'$ by replacing Q'_i with $x_i x'_i y'_i$, then $\tilde{\mathcal{Q}}$ is a good maximum P_3-packing in $D - \{w\}$ with $\mathcal{Q}' \prec \tilde{\mathcal{Q}}$, a contradiction.

Subcase 3.3. x'_i and z_i belong to the same V_j for some $1 \leq j \leq k$. Let u be the smaller vertex in $\{x'_i, z_i\}$. Then (y_i, u) is an arc in $D - \{w\}$ by (3.1.3). Let $\tilde{\mathcal{Q}}$ be the P_3-packing obtained from $\mathcal{Q}'$ by replacing Q'_i with $x_i y_i u$, then $\tilde{\mathcal{Q}}$ is a good maximum P_3-packing in $D - \{w\}$ with $\mathcal{Q}' \prec \tilde{\mathcal{Q}}$, a contradiction.

This completes the proof of (3.1.13).

(3.1.14) There exists a $w \in \{1^*, 2^*, 3^*\}$ such that $D - \{w\}$ has less P_3-packing number than D.

To verify (3.1.14), let $\mathcal{Q} = \{Q_i : i = 1, 2, \ldots, m\}$ be a good maximum P_3-packing in D with the largest possible order with respect to (3.1.9). It follows from (3.1.11) that at least one of $1^*, 2^*$, and 3^* is on Q_1, for otherwise we may add $3^*2^*1^*$ to $\mathcal{Q}$ to get a larger good P_3-packing of D, a contradiction. Now let us exhibit w in each of the following cases.

Case 1. 1^* is on Q_1. In this case we may set 1^* as w. To see it, suppose the contrary: (3.1.13) guarantees the existence of a good maximum P_3-packing $\mathcal{Q}' = \{Q'_i : i = 1, 2, \ldots, m\}$ in $D - \{1^*\}$ such that $Q'_1 \prec Q_1$ and $Q'_i = Q_i$ for $i = 2, 3, \ldots, m$. Let $Q_1 = xy1^*$ and let z be the vertex of Q'_1 in V_1. Then (y, z) is an arc in D by (3.1.3). Let $\mathcal{T}$ be the P_3-packing obtained from $\mathcal{Q}$ by replacing Q_1 with xyz, then $\mathcal{T}$ is a good maximum P_3-packing in D with $\mathcal{Q} \prec \mathcal{T}$, a contradiction.

Case 2. 2^* is on Q_1 but neither of 1^* and 3^* is. In this case we may set 2^* as w. To see it, suppose the contrary: (3.1.13) guarantees the existence of a good maximum P_3-packing $\mathcal{Q}' = \{Q'_i : i = 1, 2, \ldots, m\}$ in $D - \{2^*\}$ such that $Q'_1 \prec Q_1$ and $Q'_i = Q_i$ for $i = 2, 3, \ldots, m$. If $Q_1 = x2^*y$, then $Q'_1 \prec Q_1$ implies that $Q'_1 = abc$ for some $a \prec x$ and $2^* \prec b$ with $a \in V_3$. By virtue of (3.1.3), (x, b) is an arc in D; set $R = xbc$. If $Q_1 = xy2^*$, then $Q'_1 \prec Q_1$ implies that Q'_1 contains a vertex z in V_2 with $2^* \prec z$. By (3.1.3), (y, z) is an arc in D; set $R = xyz$. In each case, let $\mathcal{T}$ be the P_3-packing obtained from $\mathcal{Q}$ by replacing Q_1 with R, then $\mathcal{T}$ is a good maximum P_3-packing in D with $\mathcal{Q} \prec \mathcal{T}$, a contradiction.

Case 3. 3^* is on Q_1. In this case we may set 3^* as w. To see it, suppose the contrary: (3.1.13) guarantees the existence of a good maximum P_3-packing $\mathcal{Q}' = \{Q'_i : i = 1, 2, \ldots, m\}$ in $D - \{3^*\}$ such that $Q'_1 \prec Q_1$ and $Q'_i = Q_i$ for $i = 2, 3, \ldots, m$. It follows that 3^* is not the source of Q_1 for otherwise $Q_1 \prec Q'_1$, a contradiction. In case $Q_1 = y3^*z$, let $Q'_1 = abc$. Then $a \in V_3$ or $a \in V_4$ in order for $Q'_1 \prec Q_1$. Set $R = yab$ in the former case (note that (y, a) is an arc in D by (3.1.3)), and set $R = ybc$ in the latter case (note that (y, b) is an arc in D by (3.1.3)). In case $Q_1 = yz3^*$, Q'_1 must contain a vertex a in V_3 in order for $Q'_1 \prec Q_1$, set $R = yza$ (note that (z, a) is an arc in D by (3.1.3)). Now let $\mathcal{T}$ be the P_3-packing obtained from $\mathcal{Q}$ by replacing Q_1 with R. Then $\mathcal{T}$ is a good maximum P_3-packing in D with $\mathcal{Q} \prec \mathcal{T}$ in each case, a contradiction.

This completes the proof of (3.1.14).

Now we are ready to prove (3.1.2).

We apply induction on the number of vertices in D. If D has at most three vertices, the statement is trivial. Let us proceed to the induction step. If $f((i+1)^*) \neq i^*$ for $i = 1$ or 2, then any P_3 in $D - \{i^*\}$ is a P_3 in D (recall (3.1.4)). Thus the desired statement follows from the induction hypothesis on $D - \{i^*\}$. So we suppose $f((i+1)^*) = i^*$ for $i = 1$ and 2. By (3.1.5), $3^*2^*1^*$ is in a maximum P_3-packing in D, so the P_3-packing number of D = the P_3-packing number of $D - \{1^*, 2^*, 3^*\}+1$; by (3.1.14) there exists a vertex w on $3^*2^*1^*$ such that the P_3-covering number of D

= the P_3-covering number of $D-\{w\}+1$, which implies that the P_3-covering number of $D \geq$ the P_3-covering number of $D-\{1^*,2^*,3^*\}+1$. Since by induction hypothesis $D-\{1^*,2^*,3^*\}$ has the same P_3-packing and P_3-covering numbers, the P_3-packing number of $D \geq$ the P_3-covering number of D, so equality must hold and (3.1.2) follows.

This completes the proof of Theorem 3.1.

We further generalize Theorem 3.1 to the weighted case. In the next section we show that it allows us to obtain a 2.5-approximation polynomial time algorithm for the feedback vertex set problem in any tournament.

THEOREM 3.2. *Let $T=(V,A)$ be a tournament with a weight $w(v)$ on each vertex $v \in V$. Then the $\triangle$-packing number of T equals the $\triangle$-covering number for any nonnegative integral w if and only if T contains no F_1 nor F_2.*

Proof. To see the necessity, suppose the contrary: T contains some F_i, $i=1$ or 2. Let w be such that $w(v)=1$ if v is a vertex of F_i and 0 otherwise. Then the $\triangle$-packing (resp., $\triangle$-covering) number of T with respect to w equals the packing (resp., covering) number of F_i in the unweighted case, which is 1 (resp., 2). Hence the min-max relation is violated.

Now let us justify the sufficiency. Suppose T contains no F_1 nor F_2; we aim to establish the min-max result. Without loss of generality, we assume that T is strongly connected and that $w(v)>0$ for each $v \in V$ (for otherwise we may delete it from T).

Let us now construct a new tournament $\tilde{T}$ from T by replacing each vertex v in T with an acyclic subtournament on vertex set $S(v)$ such that $|S(v)|=w(v)$ and that for each $i \in S(u)$ and each j in $S(v)$, (i,j) is an arc in $\tilde{T}$ if and only if (u,v) is an arc in T. It is easy to see that $|S(v) \cap \{i,j,k\}| \leq 1$ for each $S(v)$ and each triangle $ijki$ in $\tilde{T}$. Observe that

(3.2.1) $\tilde{T}$ contains no F_1 nor F_2.

Assume the contrary: $\tilde{T}$ contains some F_k, where $k=1$ or 2. Suppose the vertex set of F_k is $\{i_1,i_2,\ldots,i_5\}$. Since F_k is not a subgraph of T, we may assume the existence of a vertex v in T with $\{i_1,i_2,\ldots,i_5\} \cap S(v) = \{i_1,\ldots,i_j\}$ and $j \geq 2$. From the construction of $\tilde{T}$, it follows that $j=2$ for otherwise $F_k-\{i_{j+1}\}$ contains no triangle, a contradiction; next, there exist two vertices in $\{i_3,i_4,i_5\}$, say, i_3 and i_4, such that the arcs between $\{i_1,i_2\}$ and $\{i_3,i_4\}$ are all directed to $\{i_1,i_2\}$ or all directed to $\{i_3,i_4\}$. Thus $F_k-\{i_5\}$ is acyclic, a contradiction.

By virtue of (3.2.1), we deduce the following statement from Theorem 3.1.

(3.2.2) The $\triangle$-packing number of $\tilde{T}$ equals the $\triangle$-covering number of $\tilde{T}$.

Now let $\tilde{\mathcal{Q}}$ be a maximum $\triangle$-packing in $\tilde{T}$ and let $\tilde{C}$ be a minimum $\triangle$-covering in $\tilde{T}$. We construct a $\triangle$-packing $\mathcal{Q}$ of T from $\tilde{\mathcal{Q}}$ as follows: for each triangle $ijki$ in $\tilde{\mathcal{Q}}$ with $i \in S(a)$, $j \in S(b)$ and $k \in S(c)$, create a triangle $abca$ in $\mathcal{Q}$ (note that a triangle in T may appear multiple times); that is, $\mathcal{Q}$ consist of all the created triangles in T. Then $\mathcal{Q}$ is a $\triangle$-packing of T for each vertex v of T is contained in at most $w(v)$ triangles of $\mathcal{Q}$.

In order to construct a $\triangle$-covering C of T from $\tilde{C}$, observe that $S(v) \subseteq \tilde{C}$ whenever $S(v) \cap \tilde{C} \neq \emptyset$. To see it, assume the contrary: $i \in \tilde{C}$ but $i' \notin \tilde{C}$ for some i and i' in $S(v)$. By the minimality of $\tilde{C}$, there exists a triangle $ijki$ in $\tilde{Q}$ which is covered by a unique vertex, i, in $\tilde{C}$. Thus the triangle $i'jki'$ is not covered by $\tilde{C}$, a contradiction. Now define $C=\{v \in V \mid S(v) \subseteq \tilde{C}\}$. Then it follows from the above observation that C is a $\triangle$-covering of T.

According to (3.2.2), $\sum_{v \in C} w(v) = \sum_{v \in C} |S(v)| = |\tilde{C}| = |\tilde{Q}| = |Q|$. Thus Q is a maximum $\triangle$-packing of T and C is a minimum $\triangle$-covering of T; we therefore get the desired min-max relation.

4. Algorithms. Now we are ready to present an $O(|V|^2)$ algorithm for the maximum $\triangle$-packing problem and an $O(|V|^3)$ algorithm for the minimum $\triangle$-covering problem in any tournament with no F_1 nor F_2.

To find a maximum $\triangle$-packing in T, let us apply the following algorithm, where $\triangle(P(T))$ stands for a maximum $\triangle$-packing in T and $P_3(P(D))$ stands for a maximum P_3-packing in D.

MAXIMUM $\triangle$-PACKING ALGORITHM.

DESCRIPTION. Find all the strongly connected components $T_1, T_2, \ldots, T_s$ of T. If $s \geq 2$, then apply the algorithm on each of $T_1, T_2, \ldots, T_s$, $\triangle(P(T)) = \cup_{i=1}^{s} \triangle(P(T_i))$. Otherwise, let $\{V_1, V_2, \ldots, V_k\}$ be a partition of T as described in Lemma 2.1 and let D be the digraph as constructed in the proof of Theorem 3.1. Find $P_3(P(D))$ as follows: If $f((i+1)^*) \neq i^*$ for $i = 1$ or 2, then $P_3(P(D)) = P_3(P(D - \{i^*\}))$. Replace D by $D - \{i^*\}$; else, set $w(x) = w(x) - \delta$ for each $x \in \{1^*, 2^*, 3^*\}$, where $\delta = \min\{w(1^*), w(2^*), w(3^*)\}$, and set $W = \{v \in V : w(v) = 0\}$. Then $P_3(P(D)) = P_3(P(D - W)) \cup \{3^*2^*1^*, \ldots, 3^*2^*1^*\}$, where the multiplicity of $3^*2^*1^*$ is δ. Replace D by $D - W$; repeat the process. Return $\triangle(P(T)) = P_3(P(D))$.

To show the validity of the algorithm, we need only consider the case $f((i+1)^*) = i^*$ for $i = 1$ and 2. Let $\tilde{D}$ be the digraph obtained from D as follows: each vertex v in D is replaced by a set $S(v)$ of $w(v)$ vertices; for each $i \in S(u)$ and each j in $S(v)$, (i, j) is an arc in $\tilde{D}$ if and only if (u, v) is an arc in D. Clearly, there is a one to one correspondence between maximum *weighted* P_3-packings in D and maximum *unweighted* P_3-packings in $\tilde{D}$. With $\tilde{D}$ in place of D, repeated applications of (3.1.5) guarantee the existence of a maximum P_3-packing in $\tilde{D}$ which contains δ copies of $3^*2^*1^*$. (After getting the first copy, we remove the three vertices on this copy from $\tilde{D}$; then applying (3.1.5) in the resulting digraph, we get the second copy, etc.) Thus the validity of the algorithm follows instantly from the above-mentioned correspondence.

The strongly connected components can be found in time $O(|V|^2)$ by the depth-first search; in case T is strongly connected, the partition $\{V_1, V_2, \ldots, V_k\}$ can be constructed in time $O(|V|^2)$ by the breadth-first search; D can be obtained from the partition in time $O(|V|^2)$; $P_3(P(D))$ can be obtained in time $O(|V|)$. Hence, the total time complexity of the algorithm is $O(|V|^2)$.

To find a minimum covering set, let us apply the following algorithm, where $\triangle(C(T))$ stands for a minimum $\triangle$-covering in T.

MINIMUM $\triangle$-COVERING ALGORITHM.

DESCRIPTION. Find all the strongly connected components $T_1, T_2, \ldots, T_s$ of T. If $s \geq 2$, then apply the algorithm on each of $T_1, T_2, \ldots, T_s$, $\triangle(C(T)) = \cup_{i=1}^{s} \triangle(C(T_i))$. Otherwise, let $\{V_1, V_2, \ldots, V_k\}$ be the partition as described in Lemma 2.1 and let D be the digraph as constructed in the proof of Theorem 3.1. If $f((i+1)^*) \neq i^*$ for $i = 1$ or 2, then $\triangle(C(T)) = \triangle(C(T - \{i^*\}))$. Replace T by $T - \{i^*\}$ and replace D by $D - \{i^*\}$; else, find an x in $\{1^*, 2^*, 3^*\}$ by the maximum $\triangle$-packing algorithm such that $|\triangle(P(T))| = |\triangle(P(T - \{x\}))| + w(x)$. Set $\triangle(C(T)) = \triangle(C(T - \{x\})) \cup \{x\}$. Replace T by $T - \{x\}$ and replace D by $D - \{x\}$; repeat the process.

To justify the validity of the algorithm, we need to show the existence of an x in $\{1^*, 2^*, 3^*\}$ such that $|\triangle(P(T))| = |\triangle(P(T - \{x\}))| + w(x)$. Let S be a minimum $\triangle$-covering of T. Then S must contain at least one $x \in \{1^*, 2^*, 3^*\}$ as $3^*2^*1^*$ is a P_3 in D, which corresponds to a triangle in T. For this x, $S - \{x\}$ is clearly a minimum $\triangle$-covering of $T - \{x\}$. Thus $w(\triangle(C(T))) = w(\triangle(C(T - \{x\}))) + w(x)$. It follows from the min-max result that $|\triangle(P(T))| = |\triangle(P(T - \{x\}))| + w(x)$ since both T and $T - \{x\}$ have the same $\triangle$-packing and $\triangle$-covering numbers. In addition, we need to

show that if $|\triangle(P(T))| = |\triangle(P(T-\{x\}))|+w(x)$, then x is in a minimum $\triangle$-covering of $T-\{x\}$. This implication is trivial as $w(\triangle(C(T))) = w(\triangle(C(T-\{x\}))) + w(x)$.

Since the time complexity of the maximum $\triangle$-packing algorithm is $O(|V|^2)$, it takes $O(|V|^2)$ to find the desired x. Note that T has $|V|$ vertices, the total complexity of the algorithm is $O(|V|^3)$. The proof is complete. □

Given an arbitrary tournament $T = (V, A)$ with a positive integer $w(v)$ on each vertex $v \in V$, let us now present a 2.5-approximation algorithm for the minimum $\triangle$-covering problem in T, which relies on "eliminating" the problematic subdigraphs, F_1 and F_2, from T.

Approximation $\triangle$-Covering Algorithm.

Step 0. Set $\tilde{w} = w$.

Step 1. While T contains a subtournament H isomorphic to F_1 or F_2 such that $\tilde{w}(v) > 0$ for each vertex v in H, do: set $\tilde{w}(v) = \tilde{w}(v) - \delta$ for each vertex v in H, where $\delta = \min\{\tilde{w}(v) : v \in V(H)\}$.

Step 2. Set $\triangle(C_0) = \{v \in V : \tilde{w}(v) = 0\}$ and $V_1 = V - \triangle(C_0)$.

Step 3. Let $\triangle(C_1)$ be returned by applying the minimum $\triangle$-covering algorithm on $T(V_1)$ with respect to the weight $\tilde{w}$. Return $\triangle(C) = \triangle(C_0) \cup \triangle(C_1)$.

Since it takes $O(|V|^2)$ time to output an H in Step 1 according to Lemma 2.2, the total complexity for Step 1 is $O(|V|^3)$; as justified in section 4, Step 3 takes $O(|V|^3)$. So the total complexity of our algorithm is $O(|V|^3)$.

Based on the local ratio theorem of Bar-Yehuda and Even [3], we get the following statement.

Theorem 4.1. *The performance guarantee of the above algorithm is* 2.5*; that is, if* $\triangle(C^*)$ *is a minimum* $\triangle$*-covering in* T*, then* $w(\triangle(C)) \leq 2.5\ w(\triangle(C^*))$.

5. Concluding remarks. The feedback vertex problem in tournaments is a generalization of the vertex cover problem. In this work, we have pointed out that each existing method that leads to a 2-approximation algorithm for the latter problem yields a 3-approximation algorithm for the former problem and that the corresponding algorithms are in the same spirit. Although it is hard to improve the approximation ratio of 2 for the vertex cover problem, by characterizing the class of tournaments with the min-max relation on packing and covering directed cycles, we have succeeded in improving the approximation ratio for the feedback vertex set problem from 3 to 2.5, using the local ratio technique.

Recent applications of the local ratio technique are made by Bar-Yehuda to some other problems [1, 2]. It would be interesting to see if the local ratio technique can be applied in a more sophisticated way to improve the approximation ratio for the feedback set problem in tournaments, for example, by combining the methods developed for the triangle packing and covering problems in graphs by Krivelevich [12].

Acknowledgments. The authors are grateful to Dr. Xiaoyun Lu for his stimulating suggestions and helpful discussions. They also wish to thank anonymous referees for their critical comments that have greatly improved the presentation of this paper. One referee was very kind to suggest that the authors adopt the current simple proof of Theorem 4.1 of his/hers.

THE SHORTEST VECTOR IN A LATTICE IS HARD TO APPROXIMATE TO WITHIN SOME CONSTANT*

DANIELE MICCIANCIO†

Abstract. We show that approximating the *shortest vector problem* (in any ℓ_p norm) to within any constant factor less than $\sqrt[p]{2}$ is hard for NP under *reverse unfaithful random* reductions with inverse polynomial error probability. In particular, approximating the *shortest vector problem* is not in RP (random polynomial time), unless NP equals RP. We also prove a proper NP-hardness result (i.e., hardness under deterministic many-one reductions) under a reasonable number theoretic conjecture on the distribution of square-free smooth numbers. As part of our proof, we give an alternative construction of Ajtai's constructive variant of Sauer's lemma that greatly simplifies Ajtai's original proof.

Key words. NP-hardness, shortest vector problem, point lattices, geometry of numbers, sphere packing

1. Introduction.

Lattices are geometric objects that can be pictorially described as the set of intersection points of an infinite, regular (but not necessarily orthogonal) n-dimensional grid. The rich combinatorial structure of lattices makes them very powerful tools to attack many important problems in mathematics and computer science. In particular, lattices have been used to solve integer programming with finitely many variables [25, 24, 20], factorization of polynomials over the integers [24, 31], low density subset-sum problems [23, 12, 8], and many cryptanalytic problems [32, 17, 13, 7, 6].

Despite the many successful applications of lattice techniques, the most fundamental problems on lattices resisted any attempt to devise polynomial time algorithm to solve them. These are the *shortest vector problem* (SVP) and the *closest vector problem* (CVP). In SVP, given a lattice, one must find the shortest nonzero vector in the lattice (i.e., the intersection point in the grid closest to the origin). CVP is the inhomogeneous counterpart of SVP: given a lattice and a target point (not necessarily in the lattice), find the lattice point closest to the target. Both problems can be defined with respect to any norm, but the Euclidean norm ℓ_2 is the most commonly used.

The first intractability results for lattice problems date back to 1981 when van Emde Boas [34] proved that CVP[1] is NP-hard and conjectured the same for SVP. Since then, the hardness result for CVP was considerably strengthened, proving that even finding approximate solutions to CVP is hard (see section 2 for more information). Despite the similarities between the two problems, progress in proving the hardness of

[1]In this van Emde Boas paper, this problem is called "Nearest Vector," and the name "Closest Vector" is used for SVP in the ℓ_∞ norm.

SVP was much slower. Even for the exact version of this problem, proving the conjectured NP-hardness remained an open problem for almost two decades. Recently, Ajtai [2] proved that the SVP is hard for NP under *reverse unfaithful random* reductions (RUR-reductions for short, see [18]). These are probabilistic reductions that map NO instances to NO instances with probability 1 and YES instances to YES instances with non-negligible probability.[2] Although not a proper NP-hardness result (i.e., hardness for NP under many-one reductions, which would imply that SVP is not in P unless NP = P), hardness under RUR-reductions also gives evidence of the intractability of a problem. In particular, it implies that SVP is not in RP unless NP = RP. (Here RP is the class of decision problems with random polynomial decision algorithms that are always correct on NO instances and "usually" correct on YES instances.) So, Ajtai's result gives the first theoretical evidence that SVP is indeed intractable, resolving (in a probabilistic sense) van Emde Boas' conjecture. In the same paper, Ajtai also remarks that his NP-hardness proof can be adapted to show the hardness of approximating the length of the shortest vector within some very small factor $1 + o(1)$ that rapidly approaches 1 as the dimension of the lattice grows.

In this paper we prove the first nonapproximability result for the shortest vector problem to within some factor bounded away from 1. Namely, we show that (for any ℓ_p norm) approximating SVP within any constant factor less than $\sqrt[p]{2}$ is hard for NP under RUR-reductions. In particular, approximating SVP in the Euclidean norm within any factor less then $\sqrt{2}$ is hard for NP. The error probability of the reduction is polynomially small, i.e., the reduction correctly maps YES instances to YES instances with probability $1 - 1/\operatorname{poly}(n)$ for some polynomial function $\operatorname{poly}(n)$. Moreover, randomness itself is used in a very restricted way and it can be removed under standard computational or number theoretic assumptions. In particular we show that

(i) SVP has no polynomial time approximation algorithm unless the polynomial hierarchy [26, 33] collapses to the second level.

(ii) Approximating SVP is NP-hard (under deterministic many-one reductions) if the following conjecture on the distribution of square-free smooth numbers holds true: for any $\epsilon > 0$ and for all sufficiently large n there exists a square-free polylog-smooth integer in the interval $[n, n + n^{\epsilon}]$, i.e., an integer whose prime factors are all less than $(\lg n)^c$ (for some constant c independent of n) and have exponent one.

The rest of the paper is organized as follows. In section 2 we give an overview of related work. In section 3 we formally define the approximation problems associated to SVP, CVP, and a variant of the latter. In section 4 we prove that SVP is NP-hard to approximate by reduction from the modified CVP using a geometric lemma which is proved in section 5. In section 6 we present deterministic reductions under various computational or number theoretic assumptions. Section 7 concludes with remarks and open problems.

In section 5 we use a combinatorial theorem (Theorem 5.9) similar to a result originally proved by Ajtai in [2]. In the appendix we present a proof of this combinatorial theorem that greatly simplifies Ajtai's original construction.

2. Related work. The complexity of lattice problems has been widely investigated since the early 1980s because of the many connections between these problems and other areas of computer science. Results are usually presented for the Euclidean

[2] In Ajtai's proof, as well in our result, the success probability is in fact $1 - 1/p(n)$ for some polynomial function $p(n)$.

(ℓ_2) norm but can be easily adapted to any ℓ_p norm, or in some cases any norm. Unless otherwise stated, the following results refer to the ℓ_2 norm.

The first polynomial time approximation algorithms for SVP was the celebrated Lenstra–Lenstra–Lovász (LLL) basis reduction algorithm [24] that achieves an approximation factor $2^{O(n)}$ exponential in the dimension n. In [4] Babai showed how to achieve a similar approximation factor for CVP combining LLL with a lattice rounding technique. To date, the best approximation factor for SVP achievable in polynomial time is $2^{O(n(\log\log n)^2/\log n)}$ using Schnorr's block reduction algorithm [29]. In fact, Schnorr gives a hierarchy of basis reduction algorithms that go from polynomial time to exponential time achieving better and better approximation factors. Unfortunately, Schnorr's result is almost ubiquitously cited as a polynomial time algorithm for approximating SVP within a factor $2^{\epsilon n}$ for any fixed $\epsilon > 0$. It turns out, as recently observed by Goldreich and Håstad [14], that one can set ϵ to a slowly decreasing function of n while maintaining the running time polynomial and achieving a slightly subexponential approximation factor $2^{O(n(\log\log n)^2/\log n)}$. A similar approximation factor can be achieved for CVP combining Schnorr's block reduction algorithm with Kannan's reduction [19] from approximate CVP to approximate SVP.

On the complexity side, CVP was proved NP-hard to solve exactly by van Emde Boas in [34]. The first inapproximability results for CVP are due to Arora et al. [3] who proved that CVP is NP-hard to approximate within any constant factor, and quasi NP-hard to approximate within factor $2^{\log^{1-\epsilon} n}$. The latter result is improved to a proper NP-hardness result by Dinur, Kindler, and Sufra in [10], but the proof is much more complicated. Interestingly, CVP remains hard to solve exactly even if the lattice is known in advance and can be arbitrarily preprocessed before the target point is revealed [28].

The NP-hardness of SVP (in the ℓ_2 norm) was conjectured in [34] but remained an open problem for a long time. The first result is due to Ajtai [2] who proved that solving the problem exactly is NP-hard for randomized reductions. Ajtai's result can also be adapted to show the inapproximability of SVP within certain factors $1 + o(1)$ that rapidly approach 1 as the dimension of the lattice grows. In this paper we prove the first NP-hardness result for approximating SVP within factors bounded away from one.

Interestingly, SVP in the ℓ_∞ norm seems to bear much more similarities to CVP than SVP in the ℓ_2 norm. In fact, the NP-hardness of SVP in the ℓ_∞ norm was already proved in [34]. The quasi NP-hardness of approximating SVP within $2^{\log^{0.5-\epsilon} n}$ appeared in [3], and a proper NP-hardness result is proved in [9] using techniques similar to [10].

The unlikelihood of the NP-hardness of approximating SVP and CVP within polynomial factors has also been investigated. In [22], Lagarias, Lenstra, and Schnorr showed that approximating SVP and CVP within factors $O(n)$ and $O(n^{1.5})$ is in coNP. This result is improved by Banaszczyk [5] where both problems are shown in coNP for $O(n)$ approximation factors. These results imply that approximating SVP and CVP within $\Omega(n)$ polynomial factors cannot be NP-hard, unless NP=coNP. Under the stronger assumption that NP is not contained in coAM, Goldreich and Goldwasser [15] show that approximating SVP and CVP within $\Omega(\sqrt{n}/\log n)$ cannot be NP-hard.

Our results are achieved by reducing the approximate SVP from a variant of CVP which was shown NP-hard to approximate in [3]. The techniques we use to reduce CVP to SVP are related to those used in [30, 1] and [2]. In particular all these works use variants of the "prime number lattice" originally defined by Schnorr in [30] to

(empirically) reduce factoring to lattice reduction. The intent in [30] was to find new factoring algorithms and the method is not formally analyzed. In [1] Adleman attempts to give a formal reduction from factoring to the shortest vector problem. Although based on relatively complicated number theoretic conjectures, Adleman's work marks an important step in the study of the hardness of the shortest vector problem because the reduction from factoring to SVP is presented for the first time as theoretical evidence that SVP is hard. Trying to remove the number theoretic conjectures from Adleman's proof, Ajtai had the fundamental intuition that variants of the prime number lattice could be used to reduce any NP problem (not necessarily related to factoring) to SVP. In the breakthrough paper [2] Ajtai uses an enhanced version of the prime number lattice to reduce an NP-complete problem (a variant of subset sum) to SVP.

In this paper we use a variant of the prime number lattice which is much closer to the original lattice introduced by Schnorr. However, it should be noted that the enhanced lattice defined by Ajtai was the starting point of our investigation, and we rediscovered Schnorr's prime number lattice while trying to understand and simplify Ajtai's construction.

In our proof the prime number lattice is for the first time explicitly connected to sphere packing, giving a simpler and more geometric interpretation of the combinatorics underlying the lattice. The simpler and more geometric approach used in this paper allows us to translate some of the techniques to other settings. In fact, similar techniques have been recently used by Dumer, Micciancio, and Sudan [11] to prove similar results for the minimum distance problem for linear codes.

3. Definitions. Let $\mathbb{R}$ and $\mathbb{Z}$ be the sets of the reals and the integers, respectively. The m-dimensional Euclidean space is denoted $\mathbb{R}^m$. A *lattice* in $\mathbb{R}^m$ is the set of all integer combinations $\mathcal{L} = \{\sum_{i=1}^{n} x_i \mathbf{b}_i : x_i \in \mathbb{Z}\}$ of n linearly independent vectors $\mathbf{b}_1, \ldots, \mathbf{b}_n$ in $\mathbb{R}^m$ $(m \geq n)$. The set of vectors $\mathbf{b}_1, \ldots, \mathbf{b}_n$ is said to form a *basis* of the lattice, and the integer n is called the *rank* of the lattice. A basis can be compactly represented by the matrix $\mathbf{B} = [\mathbf{b}_1 | \ldots | \mathbf{b}_n] \in \mathbb{R}^{m \times n}$ having the basis vectors as columns. The lattice generated by $\mathbf{B}$ is denoted $\mathcal{L}(\mathbf{B})$. Notice that $\mathcal{L}(\mathbf{B}) = \{\mathbf{Bx} : \mathbf{x} \in \mathbb{Z}^n\}$, where $\mathbf{Bx}$ is the usual matrix-vector multiplication.

For any $p \geq 1$, the ℓ_p norm of a vector $\mathbf{x} \in \mathbb{R}^n$ is defined as $\|\mathbf{x}\|_p = \sqrt[p]{\sum x_i^p}$. The following definitions can be given with respect to any norm. Since in the rest of this paper the norm being used will always be clear from the context, we omit explicit references to a norm in order to keep notation simple, but it should be noted that the definitions are norm dependent. The *minimum distance* of a lattice, $\lambda(\mathcal{L})$, is the minimum distance between any two distinct lattice points and equals the length of the shortest nonzero lattice vector:

$$\lambda(\mathcal{L}) = \min\{\|\mathbf{x} - \mathbf{y}\| : \mathbf{x} \neq \mathbf{y} \in \mathcal{L}\} = \min\{\|\mathbf{x}\| : \mathbf{x} \in \mathcal{L}, \mathbf{x} \neq \mathbf{0}\}.$$

For vector $\mathbf{x} \in \mathbb{R}^n$ and set $S \subseteq \mathbb{R}^n$, let $\operatorname{dist}(\mathbf{v}, S) = \min_{\mathbf{w} \in S} \|\mathbf{v} - \mathbf{w}\|$ be the distance between $\mathbf{v}$ and S. For vector $\mathbf{x} \in \mathbb{R}^n$ and real r, let $\mathcal{B}(\mathbf{v}, r) = \{\mathbf{w} \in \mathbb{R}^n : \|\mathbf{v} - \mathbf{w}\| \leq r\}$ be the ball of radius r centered in $\mathbf{v}$.

When discussing computational issues related to lattices, it is customary to assume that the lattices are represented by a basis matrix $\mathbf{B}$ and that $\mathbf{B}$ has integer entries. In order to study the computational complexity of lattice problems, we formulate them in terms of promise problems. A *promise* problem is a generalization of the familiar notion of decision problem. The difference is that in a promise problem not every string is required to be either a YES or a NO instance. Given a string with

the promise that it is either a YES or NO instance, one has to decide which of the two sets it belongs to.

Following [15], we formulate the approximation problems associated with the shortest vector problem and the closest vector problem in terms of the following promise problems.

DEFINITION 3.1 (approximate SVP). *The promise problem* GAPSVP_γ *(where* $\gamma \geq 1$ *is a function of the dimension) is defined as follows. Instances are pairs* $(\mathbf{B}, d)$*, where* $\mathbf{B} \in \mathbb{Z}^{n \times k}$ *is a lattice basis and* d *a positive number such that*

(i) $(\mathbf{B}, d)$ *is a* YES *instance if* $\lambda(\mathbf{B}) \leq d$*, i.e.,* $\|\mathbf{Bz}\| \leq d$ *for some* $\mathbf{z} \in \mathbb{Z}^n \setminus \{\mathbf{0}\}$*;*

(ii) $(\mathbf{B}, d)$ *is a* NO *instance if* $\lambda(\mathbf{B}) > \gamma \cdot d$*, i.e.,* $\|\mathbf{Bz}\| > \gamma \cdot d$ *for all* $\mathbf{z} \in \mathbb{Z}^n \setminus \{\mathbf{0}\}$*.*

DEFINITION 3.2 (approximate CVP). *The promise problem* GAPCVP_γ *(where* $\gamma \geq 1$ *is a function of the dimension) is defined as follows. Instances are triples* $(\mathbf{B}, \mathbf{y}, d)$*, where* $\mathbf{B} \in \mathbb{Z}^{n \times k}$ *is a lattice basis,* $\mathbf{y} \in \mathbb{Z}^n$ *a vector, and* d *a positive number such that*

(i) $(\mathbf{B}, \mathbf{y}, d)$ *is a* YES *instance if dist*$(\mathbf{y}, \mathcal{L}(\mathbf{B})) \leq d$*, i.e.,* $\|\mathbf{Bz} - \mathbf{y}\| \leq d$ *for some* $\mathbf{z} \in \mathbb{Z}^n$*;*

(ii) $(\mathbf{B}, \mathbf{y}, d)$ *is a* NO *instance if dist*$(\mathbf{y}, \mathcal{L}(\mathbf{B})) > \gamma \cdot d$*, i.e.,* $\|\mathbf{Bz} - \mathbf{y}\| > \gamma \cdot d$ *for all* $\mathbf{z} \in \mathbb{Z}^n$*.*

The relation between the promise problems above and the corresponding lattice optimization problems is easily explained. On one hand, if one can compute a γ-approximation $d' \in [\lambda(\mathbf{B}), \gamma \cdot \lambda(\mathbf{B})]$ to the length of the shortest nonzero lattice vector, then one can solve GAPSVP_γ by checking whether $d' \leq \gamma \cdot d$ or $d' > \gamma \cdot d$. On the other hand, assume one has a decision oracle O that solves GAPSVP_γ. (By definition, when the input does not satisfy the promise, the oracle can return any answer.) Let $u \in \mathbb{Z}$ be an upper bound to $\lambda(\mathbf{B})$ (for example, let u be the length of any of the basis vectors). Notice that $O(\mathbf{B}, u)$ always returns YES, while $O(\mathbf{B}, 0)$ always returns NO. Using binary search find an integer $d \in \{0, \ldots, u^2\}$ such that $O(\mathbf{B}, \sqrt{d}) = \text{YES}$ and $O(\mathbf{B}, \sqrt{d-1}) = \text{NO}$. Then, $\lambda(\mathbf{B})$ must lie in the interval $[\sqrt{d}, \gamma \cdot \sqrt{d}]$. A similar argument holds for the closest vector problem.

Reductions between promise problems are defined in the obvious way. A function $f\colon \{0,1\}^* \to \{0,1\}^*$ is a reduction from $(\Pi_{\text{YES}}, \Pi_{\text{NO}})$ to $(\Sigma_{\text{YES}}, \Sigma_{\text{NO}})$ if it maps YES instances to YES instances and NO instances to NO instances, i.e., $f(\Pi_{\text{YES}}) \subseteq \Sigma_{\text{YES}}$ and $f(\Pi_{\text{NO}}) \subseteq \Sigma_{\text{NO}}$. Clearly any algorithm A to solve $(\Sigma_{\text{YES}}, \Sigma_{\text{NO}})$ can be used to solve $(\Pi_{\text{YES}}, \Pi_{\text{NO}})$ as follows: on input $I \in \Pi_{\text{YES}} \cup \Pi_{\text{NO}}$, run A on $f(I)$ and output the result. Notice that $f(I)$ always satisfies the promise $f(I) \in \Sigma_{\text{YES}} \cup \Sigma_{\text{NO}}$, and $f(I)$ is a YES instance iff I is a YES instance.

We define one last promise problem that will be useful in the sequel. The problem is a modification of GAPCVP in which YES instances are required to have a boolean solution, and in the NO instances the target vector can be multiplied by any nonzero integer.

DEFINITION 3.3 (modified CVP). *The promise problem* GAPCVP'_γ *(where* $\gamma \geq 1$ *is a function of the dimension) is defined as follows. Instances are triples* $(\mathbf{B}, \mathbf{y}, d)$ *where* $\mathbf{B} \in \mathbb{Z}^{n \times k}$ *is a full rank matrix,* $\mathbf{y} \in \mathbb{Z}^n$ *a vector, and* d *a positive number such that*

(i) $(\mathbf{B}, \mathbf{y}, d)$ *is a* YES *instance if* $\|\mathbf{Bz} - \mathbf{y}\| \leq d$ *for some* $\mathbf{z} \in \{0,1\}^n$*;*

(ii) $(\mathbf{B}, \mathbf{y}, d)$ *is a* NO *instance if* $\|\mathbf{Bz} - w\mathbf{y}\| > \gamma \cdot d$ *for all* $\mathbf{z} \in \mathbb{Z}^n$ *and all* $w \in \mathbb{Z} \setminus \{\mathbf{0}\}$*.*

In [3] it is proved that GAPCVP_γ and its variant GAPCVP'_γ are NP-hard for any constant factor $\gamma \geq 1$.

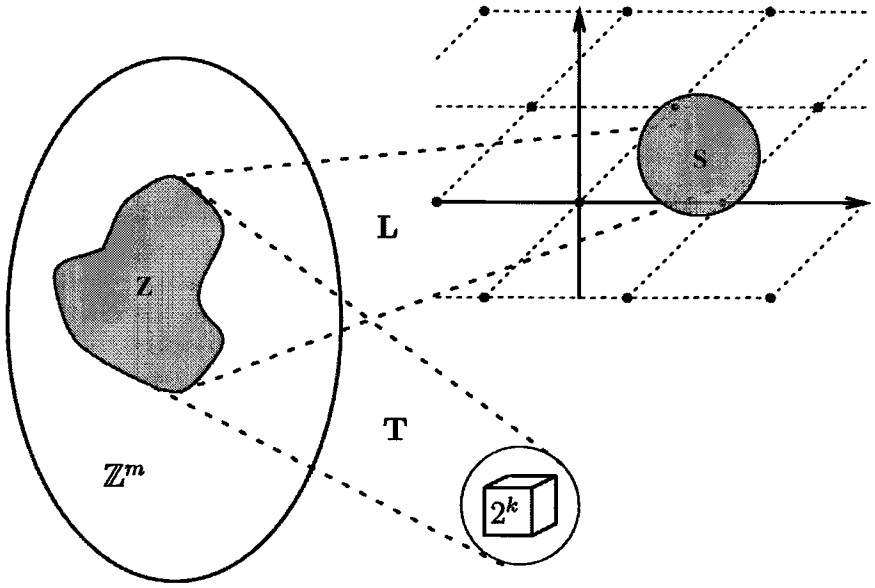

FIG. 4.1. *Lattice $\mathcal{L}(\mathbf{L})$ has minimum distance $\widetilde{\gamma} \approx \sqrt[p]{2}$ times the radius of sphere $\mathcal{B}(\mathbf{s}, r)$ and all boolean vectors of length k can be expressed as $\mathbf{Tz}$ for some lattice vector $\mathbf{Lz}$ inside the sphere.*

4. Hardness of approximating SVP. In this section we present the main result of this paper: for any ℓ_p norm ($p \geq 1$), and for any constant $\gamma \in [1, \sqrt[p]{2})$, the promise problem GAPSVP$_\gamma$ is hard for NP (under RUR-reductions). The proof is by reduction from a variant of the closest vector problem (GAPCVP$'$) and is based on the following simple idea: Assume one wants to find the point in a lattice $\mathcal{L}(\mathbf{B})$ (approximately) closest to some vector $\mathbf{y}$. One may look for the shortest nonzero vector in the lattice generated by the matrix $[\mathbf{B}|\mathbf{y}]$, i.e., the Minkowski sum of the original lattice $\mathcal{L}(\mathbf{B})$ and the lattice $\mathcal{L}(\mathbf{y}) = \mathbb{Z} \cdot \mathbf{y}$ of all integer multiples of the target vector. If the shortest vector in $\mathcal{L}([\mathbf{B}|\mathbf{y}])$ is of the form $\mathbf{Bx} - \mathbf{y}$ then $\mathbf{Bx}$ necessarily is the lattice vector in $\mathcal{L}(\mathbf{B})$ closest to $\mathbf{y}$. However, if the original lattice $\mathcal{L}(\mathbf{B})$ contains vectors as short as the distance of $\mathbf{y}$ from $\mathcal{L}(\mathbf{B})$, then solving the shortest vector problem in the lattice $\mathcal{L}([\mathbf{B}|\mathbf{y}])$ might find a vector of the form $\mathbf{Bx}$, unrelated to the target $\mathbf{y}$. (Notice that the shortest vector in $\mathcal{L}([\mathbf{B}|\mathbf{y}])$ might also correspond to a vector in $\mathcal{L}(\mathbf{B})$ close to a multiple of $\mathbf{y}$, but this is not a problem if we are reducing from GAPCVP$'$.)

We solve this problem by embedding the lattice $\mathcal{L}([\mathbf{B}|\mathbf{y}])$ in a higher dimensional space; i.e., we introduce new coordinates and extend the basis vectors in $[\mathbf{B}|\mathbf{y}]$ with appropriate values. The embedding is based on the construction of a lattice $\mathcal{L}(\mathbf{L})$ and a sphere $\mathcal{B}(\mathbf{s}, r)$ with the property that the minimum distance between lattice points in $\mathcal{L}(\mathbf{L})$ is bigger than the radius r of the sphere (by a constant factor $\widetilde{\gamma} > \gamma$) and at the same time the sphere contains exponentially many lattice vectors from $\mathcal{L}(\mathbf{L})$. We use the lattice points in the sphere to represent all potential solutions to the GAPCVP$'$ problem. In particular, we also build a linear integer transformation $\mathbf{T}$ such that any boolean vector $\mathbf{x} \in \{0,1\}^k$ (i.e., any potential solution to the GAPCVP$'$ problem) can be expressed as $\mathbf{Tz}$ ($\mathbf{z}$ an integer vector) for some lattice point $\mathbf{Lz}$ in the ball $\mathcal{B}(\mathbf{s}, r)$. These requirements are summarized in the following lemma (see Figure 4.1).

LEMMA 4.1. *For any ℓ_p norm ($p \geq 1$) and any constant $\widetilde{\gamma} \in [1, \sqrt[p]{2})$ there exists a (probabilistic) algorithm that on input $k \in \mathbb{Z}^+$ outputs, in* $\mathrm{poly}(k)$ *time, two positive integers $m, r \in \mathbb{Z}^+$, a lattice basis $\mathbf{L} \in \mathbb{Z}^{(m+1)\times m}$, a vector $\mathbf{s} \in \mathbb{Z}^{m+1}$, and a linear integer transformation $\mathbf{T} \in \mathbb{Z}^{k\times m}$ such that*

(i) $\lambda(\mathbf{L}) > \widetilde{\gamma} \cdot r$,

(ii) *with probability at least* $1 - 1/\mathrm{poly}(k)$ *for all $\mathbf{x} \in \{0,1\}^k$ there exists a $\mathbf{z} \in \mathbb{Z}^m$ such that $\mathbf{Tz} = \mathbf{x}$ and $\mathbf{Lz} \in \mathcal{B}(\mathbf{s}, r)$.*

Remark. From the proof of Lemma 4.1 in section 5 it appears that the lemma can be stated in a stronger form asserting the existence of a single algorithm that takes p and $\widetilde{\gamma}$ as additional parameters. However, it should be noted that for every ℓ_p norm, the algorithm can be used only for factors $\widetilde{\gamma} < \sqrt[p]{2}$, and the complexity of the algorithm (e.g., running time or output size) grows to infinity as $\widetilde{\gamma}$ gets closer to $\sqrt[p]{2}$. Stating the result as a single algorithm would require to determine the dependency of the running time on how close $\widetilde{\gamma}$ is to $\sqrt[p]{2}$. In order to keep the notation simple, we will state all the results in this paper for fixed norms ℓ_p and factors γ, but a generalization of the results to variable ℓ_p and γ (subject to the constraint $\gamma < \sqrt[p]{2}$) is indeed possible and the dependency of the running time on p and γ can (in principle) be extracted from the proofs presented in this paper. It should also be noted that as p gets larger and larger, the maximum constant for which we can prove hardness of SVP in the ℓ_p norm approaches 1. This is quite counterintuitive, as we know that SVP in the ℓ_∞ norm is hard to approximate within any constant [3, 9]. So, it is natural to expect that SVP in the ℓ_p norm is harder when p is large.

We defer the proof of the above lemma to section 5 and move straight to the main theorem.

THEOREM 4.2. *For any ℓ_p norm ($p \geq 1$) and for any constant $\gamma \in [1, \sqrt[p]{2})$, the promise problem* GAPSVP_γ *is hard for* NP *under RUR-reductions with inverse polynomial error probability.*

Proof. Fix an ℓ_p norm and a constant $\gamma \in [1, \sqrt[p]{2})$. Let $\widetilde{\gamma}$ be a real between γ and $\sqrt[p]{2}$ and let γ' be a real greater than $(\gamma^{-p} - \widetilde{\gamma}^{-p})^{-1/p}$, and assume without loss of generality that γ'/γ and $\widetilde{\gamma}/\gamma$ are rational numbers. We prove that GAPSVP_γ is hard for NP by reduction from the promise problem $\mathrm{GAPCVP}'_{\gamma'}$ which is known to be NP-hard (see [3]).

Let $(\mathbf{B}, \mathbf{y}, d)$ be an instance of $\mathrm{GAPCVP}'_{\gamma'}$ with $\mathbf{B} \in \mathbb{Z}^{n\times k}$, $\mathbf{y} \in \mathbb{Z}^n$, and $d \in \mathbb{Z}$. We define an instance $(\mathbf{V}, t)$ of GAPSVP_γ such that if $(\mathbf{B}, \mathbf{y}, d)$ is a NO instance of $\mathrm{GAPCVP}'_{\gamma'}$ then $(\mathbf{V}, t)$ is a NO instance of GAPSVP_γ, and if $(\mathbf{B}, \mathbf{y}, d)$ is a YES instance of $\mathrm{GAPCVP}'_{\gamma'}$ then $(\mathbf{V}, t)$ is a YES instance of GAPSVP_γ with high probability.

Run the (randomized) algorithm from Lemma 4.1 on input k to obtain a lattice basis $\mathbf{L} \in \mathbb{Z}^{(m+1)\times m}$, a vector $\mathbf{s} \in \mathbb{Z}^{m+1}$, a linear integer transformation $\mathbf{T} \in \mathbb{Z}^{k\times m}$ and a integer $r \in \mathbb{Z}$ such that

(i) $\|\mathbf{Lz}\|_p > \widetilde{\gamma} \cdot r$ for all $\mathbf{z} \in \mathbb{Z}^m \setminus \{\mathbf{0}\}$,

(ii) with probability at least $1 - 1/\mathrm{poly}(k)$, for all vectors $\mathbf{x} \in \{0,1\}^k$ there exists a $\mathbf{z} \in \mathbb{Z}^m$ such that $\mathbf{Tz} = \mathbf{x}$ and $\|\mathbf{Lz} - \mathbf{s}\|_p \leq r$.

Define the lattice

$$\mathbf{V} = \left[\begin{array}{c|c} a \cdot \mathbf{BT} & a \cdot \mathbf{y} \\ b \cdot \mathbf{L} & b \cdot \mathbf{s} \end{array}\right],$$

where a and b are two integer scaling factors such that $\frac{a}{b} = \frac{r\widetilde{\gamma}}{d\gamma'}$ and $t = a \cdot d\gamma'/\gamma = b \cdot r\widetilde{\gamma}/\gamma$ is integer. We want to prove that if $(\mathbf{B}, \mathbf{y}, d)$ is a NO instance of $\mathrm{GAPCVP}'_{\gamma'}$

then $(\mathbf{V}, t)$ is a NO instance of GAPSVP$_\gamma$, and (provided the construction in the lemma succeeds) if $(\mathbf{B}, \mathbf{y}, d)$ is a YES instance of GAPCVP$'_{\gamma'}$ then $(\mathbf{V}, t)$ is a YES instance of GAPSVP$_\gamma$.

First assume $(\mathbf{B}, \mathbf{y}, d)$ is a NO instance and consider a generic nonzero integer vector

$$\mathbf{w} = \begin{bmatrix} \mathbf{z} \\ w \end{bmatrix}.$$

We want to prove that $\|\mathbf{V}\mathbf{w}\|_p^p > (\gamma t)^p$. Notice that

$$\|\mathbf{V}\mathbf{w}\|_p^p = (a \cdot \|\mathbf{B}\mathbf{x} + w\mathbf{y}\|_p)^p + (b \cdot \|\mathbf{L}\mathbf{z} + w\mathbf{s}\|_p)^p,$$

where $\mathbf{x} = C\mathbf{z}$. We prove that

$$a \cdot \|\mathbf{B}\mathbf{x} + w\mathbf{y}\|_p > \gamma t, \qquad \text{or} \qquad b \cdot \|\mathbf{L}\mathbf{z} + w\mathbf{s}\|_p > \gamma t.$$

We distinguish two cases:

1. If $w \neq 0$, then by definition of GAPCVP$'_{\gamma'}$,
$$a \cdot \|\mathbf{B}\mathbf{x} + w\mathbf{y}\|_p > a \cdot \gamma' d = \gamma t;$$
2. if $w = 0$, then $\mathbf{z} \neq 0$ and by construction
$$b \cdot \|\mathbf{L}\mathbf{z} + w\mathbf{s}\|_p = b \cdot \|\mathbf{L}\mathbf{z}\|_p > b \cdot \widetilde{\gamma} r = \gamma t.$$

Now assume that $(\mathbf{B}, \mathbf{y}, d)$ is a YES instance, i.e., there exists a boolean vector $\mathbf{x} \in \{0,1\}^k$ such that $\|\mathbf{B}\mathbf{x} - \mathbf{y}\|_p \leq d$. By construction, there exists a vector $\mathbf{z} \in \mathbb{Z}^m$ such that $\mathbf{T}\mathbf{z} = \mathbf{x}$ and $\|\mathbf{L}\mathbf{z} - \mathbf{s}\|_p \leq r$. Define

$$\mathbf{w} = \begin{bmatrix} \mathbf{z} \\ -1 \end{bmatrix}$$

and compute the norm of the corresponding lattice vector:

$$\begin{aligned} \|\mathbf{V}\mathbf{w}\|_p^p &= (a \cdot \|\mathbf{B}\mathbf{x} - \mathbf{y}\|_p)^p + (b \cdot \|\mathbf{L}\mathbf{z} - \mathbf{s}\|_p)^p \\ &\leq (ad)^p + (br)^p \\ &= \left(\frac{\gamma t}{\gamma'}\right)^p + \left(\frac{\gamma t}{\widetilde{\gamma}}\right)^p \\ &\leq t^p \gamma^p \left(\left(\frac{1}{\gamma^p} - \frac{1}{\widetilde{\gamma}^p}\right) + \frac{1}{\widetilde{\gamma}^p}\right) \\ &= t^p, \end{aligned}$$

proving that $(\mathbf{V}, t)$ is a YES instance of GAPSVP$_\gamma$. ∎

5. Proof of the geometric lemma. In this section we prove Lemma 4.1. As explained in section 4, this lemma asserts the existence of an integer lattice $\mathcal{L}(\mathbf{L})$ with large minimum distance, a sphere $\mathcal{B}(\mathbf{s}, r)$ of radius less than $\lambda(\mathbf{L})$ (by a constant factor $\widetilde{\gamma}$) containing a large number of lattice points, and a linear integer transformation that maps the coordinates (with respect to $\mathbf{L}$) of the lattice points in the sphere onto the set of all binary strings of some shorter length. Moreover, $\mathbf{L}, \mathbf{s}$, and $\mathbf{T}$ can be computed in (random) polynomial time.

The lattice and the sphere are more easily defined using arbitrary real numbers. So, we first drop the requirement that $\mathbf{L}$ and $\mathbf{s}$ have integer entries and define a real matrix $\widetilde{\mathbf{L}}$ and a real vector $\widetilde{\mathbf{s}}$ with the desired properties. Then, we show how to approximate $\widetilde{\mathbf{L}}$ and $\widetilde{\mathbf{s}}$ with integer matrices. Finally, we prove Lemma 4.1 combining the integer lattice construction with a combinatorial theorem on low-degree hypergraphs.

5.1. The real lattice. In the next lemma we define a real lattice $\mathcal{L}(\widetilde{\mathbf{L}})$ and prove a lower bound on the length of its nonzero vectors. The definition of $\widetilde{\mathbf{L}}$ is parametric with respect to an ℓ_p norm ($p \geq 1$), a real number $\alpha > 0$, and a set of positive integers $A = \{a_1, \ldots, a_m\}$. The idea is to map the multiplicative structure of the integers $a_1, \ldots, a_m$ to the additive structure of the lattice $\mathcal{L}(\widetilde{\mathbf{L}})$, defining a basis vector for each a_i and expressing its entries in terms of the logarithm of a_i. This way the problem of finding a sphere containing many lattice points is reduced to the problem of finding a small interval containing many products of the a_i's. At the end we will set α to some large number (exponential in m), and A to a set of small primes. The existence of a sphere containing many lattice points will follow from the density of the primes and a simple averaging argument.

LEMMA 5.1. *Let $A = \{a_1, \ldots, a_m\}$ be a set of relatively prime odd positive integers. Then for any ℓ_p norm ($p \geq 1$), and any real $\alpha > 0$, all nonzero vectors in the lattice generated by the (columns of the) matrix*

$$\widetilde{\mathbf{L}} = \begin{bmatrix} \sqrt[p]{\ln a_1} & 0 & 0 \\ 0 & \ddots & 0 \\ 0 & 0 & \sqrt[p]{\ln a_m} \\ \alpha \ln a_1 & \cdots & \alpha \ln a_m \end{bmatrix} \in \mathbb{R}^{(m+1)\times m} \tag{5.1}$$

have ℓ_p norm bigger than $\sqrt[p]{2 \ln \alpha}$.

Proof. We want to prove that for all nonzero integer vectors $\mathbf{z} \in \mathbb{Z}^m$,

$$\|\widetilde{\mathbf{L}}\mathbf{z}\|_p^p \geq 2 \ln \alpha.$$

We first introduce some notation. Let $\mathbf{R} \in \mathbb{R}^m$ be the row vector

$$\mathbf{R} = [\ln a_1, \ln a_2, \ldots, \ln a_m] \tag{5.2}$$

and $\mathbf{D} \in \mathbb{R}^{m\times m}$ be the diagonal matrix

$$\mathbf{D} = \begin{bmatrix} \sqrt[p]{\ln a_1} & 0 & \cdots & 0 \\ 0 & \sqrt[p]{\ln a_2} & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & \cdots & 0 & \sqrt[p]{\ln a_m} \end{bmatrix}. \tag{5.3}$$

Notice that

$$\widetilde{\mathbf{L}} = \begin{bmatrix} \mathbf{D} \\ \alpha \mathbf{R} \end{bmatrix}$$

and $\|\widetilde{\mathbf{L}}\mathbf{z}\|_p^p = \|\mathbf{D}\mathbf{z}\|_p^p + \alpha^p |\mathbf{R}\mathbf{z}|^p$. We bound the two terms separately. Define the integers

$$\hat{g} = \prod\{a_i^{z_i} : z_i > 0\}, \qquad \check{g} = \prod\{a_i^{-z_i} : z_i < 0\}, \qquad g = \hat{g}\check{g} = \prod_{i=1}^{m} a_i^{|z_i|}.$$

Using this notation, the first term satisfies

$$\begin{aligned}\|\mathbf{Dz}\|_p^p &= \sum_i |z_i|^p \ln a_i \\ &\geq \sum_i |z_i| \ln a_i \\ &= \ln g\end{aligned}$$

because $p \geq 1$ and the z_i's are integers. Bounding the second term is slightly more complex:

$$\begin{aligned}|\mathbf{Rz}| &= \left| \sum_i z_i \ln a_i \right| \\ &= |\ln \hat{g} - \ln \check{g}| \\ &= \ln \left(1 + \frac{|\hat{g} - \check{g}|}{\min\{\hat{g}, \check{g}\}} \right).\end{aligned}$$

Now notice that since $\mathbf{z}$ is nonzero, $\hat{g}$ and $\check{g}$ are distinct odd integers and therefore $|\hat{g} - \check{g}| \geq 2$. Moreover, $\min\{\hat{g}, \check{g}\} < \sqrt{\hat{g}\check{g}} = \sqrt{g}$. By monotonicity and concavity of function $\ln(1 + x)$ over the interval $[0, 2]$, one gets

$$\ln \left(1 + \frac{|\hat{g} - \check{g}|}{\min\{\hat{g}, \check{g}\}} \right) > \ln \left(1 + \frac{2}{\sqrt{g}} \right) > \frac{2}{\sqrt{g}} \cdot \frac{\ln 3}{2} > \frac{1}{\sqrt{g}}.$$

Combining the two bounds one gets

$$\|\widetilde{\mathbf{L}}\mathbf{z}\|_p^p = \|\mathbf{Dz}\|_p^p + \alpha^p (\mathbf{Rz})^p > \ln g + \frac{\alpha^p}{g^{p/2}}$$

which is a continuous function of g with derivative

$$\frac{1}{g} \left(1 - \frac{p}{2} \cdot \frac{\alpha^p}{g^{p/2}} \right).$$

The function is minimized (over the reals) when $g = \alpha^2 \left(\frac{p}{2}\right)^{2/p}$ with minimum

$$2 \ln \alpha + \left(\frac{2}{p} \right) \ln \left(\frac{p}{2} \right) + \left(\frac{2}{p} \right) > 2 \ln \alpha + \left(\frac{2}{p} \right) \ln p > 2 \ln \alpha.$$

Therefore, for all nonzero integer vectors $\mathbf{z}$, $\|\widetilde{\mathbf{L}}\mathbf{z}\|_p^p > 2 \ln \alpha$. □

Consider now a sphere centered in

$$\widetilde{\mathbf{s}} = \begin{bmatrix} 0 \\ \vdots \\ 0 \\ \alpha \ln \beta \end{bmatrix}, \tag{5.4}$$

where β is a positive real to be specified. We now show that there is a close relationship between finding lattice vectors close to $\widetilde{\mathbf{s}}$ and approximating β as a product of the a_i's.

LEMMA 5.2. *Let* $\widetilde{\mathbf{L}}$ *and* $\widetilde{\mathbf{s}}$ *be defined as in* (5.1) *and* (5.4). *For any* ℓ_p *norm* ($p \geq 1$), *reals* $\alpha, \beta \geq 1$, *positive integers* $a_1, \ldots, a_m$, *and boolean vector* $\mathbf{z} \in \{0,1\}^m$, *if the integer* $g = \prod_i a_i^{z_i}$ *belongs to the interval* $[\beta, \beta(1+1/\alpha)]$, *then*

$$\|\widetilde{\mathbf{L}}\mathbf{z} - \widetilde{\mathbf{s}}\|_p \leq \sqrt[p]{\ln \beta + 2}.$$

Proof. Let $\mathbf{D}$ and $\mathbf{R}$ be as defined in (5.3) and (5.2). Notice that since $\mathbf{z}$ is a 0-1 vector,

$$\|\mathbf{D}\mathbf{z}\|_p^p = \mathbf{R}\mathbf{z} = \ln g,$$

and therefore

$$\begin{aligned}\|\widetilde{\mathbf{L}}\mathbf{z} - \widetilde{\mathbf{s}}\|_p^p &= \|\mathbf{D}\mathbf{z}\|_p^p + \alpha^p |\mathbf{R}\mathbf{z} - \ln \beta|^p \\ &= \ln g + \alpha^p |\ln g - \ln \beta|^p \\ &= \ln \beta + \ln \frac{g}{\beta} + \left|\alpha \ln \frac{g}{\beta}\right|^p.\end{aligned}$$

From the assumption $g \in [\beta, \beta(1+1/\alpha)]$ and using the inequality $\ln(1+x) < x$ (true for all $x \neq 0$) one gets

$$0 \leq \ln \frac{g}{\beta} \leq \ln\left(1 + \frac{1}{\alpha}\right) < \frac{1}{\alpha}$$

which, substituted in the above expression, gives

$$\|\widetilde{\mathbf{L}}\mathbf{z} - \widetilde{\mathbf{s}}\|_p^p < \ln \beta + \frac{1}{\alpha} + 1 \leq \ln \beta + 2 \qquad \square$$

Now let ϵ be a small positive real constant and set $\alpha = \beta^{(1-\epsilon)}$. From Lemma 5.1, the minimum distance between lattice points is bigger than $\lambda = \sqrt[p]{2(1-\epsilon)\ln \beta}$, and there are many lattice points within distance $\sqrt[p]{\ln \beta + 2} \approx \lambda / \sqrt[p]{2}$ from $\widetilde{\mathbf{s}}$, provided that the interval $[\beta, \beta + \beta^\epsilon]$ contains many products of the form $\prod_{i \in S} a_i$ ($S \subseteq \{1, \ldots, m\}$). If $a_1, \ldots, a_m$ are the first m odd prime numbers, this is the same as saying that $[\beta, \beta + \beta^\epsilon]$ contains many square-free odd (a_m)-smooth numbers. We now informally estimate for which values of m and β one should expect $[\beta, \beta + \beta^\epsilon]$ to contain a large number of such products. A rigorous probabilistic analysis will follow right after.

Fix some integer $c > 1/\epsilon$, let h be a sufficiently large integer and set $m = h^c$. Let $a_1, \ldots, a_m$ be the first m odd primes, and consider the set of products

$$M = \left\{ \prod_{i \in S} a_i : S \subset \{1, \ldots, m\}, |S| = h \right\}.$$

Notice that

$$|M| = \binom{m}{h} = \prod_{i=0}^{h-1} \frac{m-i}{h-i} \geq \prod_{i=0}^{h-1} \frac{m}{h} = h^{(c-1)h} \tag{5.5}$$

and all elements of M belong to the interval $[1, (a_m)^h]$. If we choose β uniformly at random in this interval, the expected size of $[\beta, \beta + \beta^\epsilon]$ is $\Omega((a_m)^{\epsilon h})$ and we can estimate the number of elements of M contained in $[\beta, \beta + \beta^\epsilon]$ to be

$$\Omega((a_m)^{\epsilon h}) \cdot \frac{|M|}{(a_m)^h} \geq \Omega\left(\frac{h^{c-1}}{(a_m)^{1-\epsilon}}\right)^h.$$

By the prime number theorem, $a_m = O(m \ln m) = O(h^c \ln h)$ and therefore our estimate is $\Omega(h^{\epsilon c - 1}/\ln h)^h > 2^h$ for all sufficiently large h.

Making the above argument more formal, one can prove that there exists an interval $[\beta, \beta + \beta^\epsilon]$ containing exponentially (in h) many products from M. Still, it is not clear how to find the right β. If square-free smooth numbers are distributed uniformly enough, any choice of β is good. Unfortunately, we do not know enough about the distribution of smooth numbers to prove such a statement about small intervals $[\beta, \beta + \beta^\epsilon]$. (It can be proved that for all β the interval $[\beta, 2\beta]$ contains square-free smooth numbers, but not much is known about interval of sublinear size.)

So, we exploit the smooth number distribution (whatever it is) to bias the choice of the interval toward those containing many smooth numbers. The idea is to set β to the product of a random (size h) subset of the a_i's. This way, the interval $[\beta, \beta + \beta^\epsilon]$ is selected with a probability roughly proportional to the number of square-free (a_m)-smooth numbers contained in it. So, for example, intervals containing no smooth numbers are never selected, and intervals containing few smooth numbers are selected with very small probability. The probability of choosing an interval containing few products is bounded in the next lemma. In fact the lemma is quite general and applies to any set M of real numbers bigger than 1.

LEMMA 5.3. *For every positive real numbers $\epsilon \in [0, 1)$, $\mu > 1$, integer $H \geq 1$, and any finite subset $M \subset [1, \mu)$, if β is chosen uniformly at random from M, then the probability that $[\beta, \beta + \beta^\epsilon)$ contains less than H elements from M is at most*

$$\Pr_{\beta \in M}\{|[\beta, \beta + \beta^\epsilon) \cap M| < H\} \leq \frac{\mu^{1-\epsilon} \cdot H}{\kappa(\epsilon) \cdot |M|},$$

where $\kappa(\epsilon) = 1 - 2^{1-\epsilon}$.

Proof. Let B be the set of all $\beta \in M$ such that $|[\beta, \beta + \beta^\epsilon) \cap M| < H$. We show that $|B|$ can be partitioned into at most $K = \mu^{1-\epsilon}/\kappa(\epsilon)$ subsets, each containing less than H elements. It follows that

$$\Pr_{\beta \in M}\{\beta \in B\} = \frac{|B|}{|M|} \leq \frac{K(H-1)}{|M|} = \frac{\mu^{1-\epsilon} \cdot H}{\kappa(\epsilon) \cdot |M|}.$$

Divide $[1, \mu)$ into $\lceil \log_2 \mu \rceil$ intervals $[2^k, 2^{k+1})$ for $k = 0, \ldots, \lceil \log_2 \mu \rceil - 1$. Then divide each interval $[2^k, 2^{k+1})$ into $2^k/2^{\epsilon k} = 2^{(1-\epsilon)k}$ subintervals of size $2^{\epsilon k}$. Notice that each subinterval is of the form $[x, x + y)$ for some $y \leq x^\epsilon$, therefore it contains at most $H - 1$ points from B. It remains to count the total number of subintervals. Adding up the number of subintervals for each interval $[2^k, 2^{k+1})$ we get

$$\begin{aligned} K &= \sum_{k=0}^{\lceil \log_2 \mu \rceil - 1} 2^{(1-\epsilon)k} \\ &= \frac{2^{(1-\epsilon)\lceil \log_2 \mu \rceil} - 1}{2^{1-\epsilon} - 1} \\ &< \frac{(2\mu)^{1-\epsilon}}{2^{1-\epsilon} - 1} = \frac{\mu^{1-\epsilon}}{\kappa(\epsilon)}. \end{aligned}$$

□

Applying this lemma to the set of square free smooth numbers we get the following proposition.

PROPOSITION 5.4. *For all reals $\epsilon, \delta > 0$, there exists an integer c such that for all sufficiently large integer h, the following holds. Let $m = h^c$, $a_1, \ldots, a_m$ be the*

first m odd primes, and M the set of all products $\prod_{i\in S} a_i$, where S is a size h subset of $\{1,\ldots,m\}$. If β is chosen uniformly at random from M then the probability that $[\beta,\beta+\beta^\epsilon)$ contains less than $h^{\delta h}$ elements of M is at most 2^{-h}.

Proof. Fix some $\epsilon,\delta>0$ and let c be an integer bigger than $(1+\delta)/\epsilon$. Let $\mu=a_m^h$. Notice that M is contained in $[1,\mu)$ and $|M|\geq h^{(c-1)h}$ (see (5.5)). Applying Lemma 5.3 to set M with $H=h^{\delta h}$, we get

$$\begin{aligned}\Pr\{|[\beta,\beta+\beta^\epsilon)\cap M|<H\} &< \frac{h^{\delta h}\cdot\mu^{1-\epsilon}}{\kappa(\epsilon)|M|}\\ &< \frac{h^{\delta h}a_m^{(1-\epsilon)h}}{\kappa(\epsilon)h^{(c-1)h}}.\end{aligned}$$

By the prime number theorem, $a_m=O(m\ln m)=O(h^c\ln h)$, which substituted in the above expression gives

$$\begin{aligned}\Pr\{|[\beta,\beta+\beta^\epsilon]\cap M|\leq H\} &< \frac{h^{\delta h}\,O(h^c\ln h)^{(1-\epsilon)h}}{\kappa(\epsilon)h^{(c-1)h}}\\ &= \left(\frac{O(\ln h)^{(1-\epsilon)}}{h^{\epsilon c-(1+\delta)}}\right)^h\\ &< \left(\frac{O(\ln h)}{h^{\epsilon c-(1+\delta)}}\right)^h\\ &< 2^{-h}\end{aligned}$$

for all sufficiently large h because $\epsilon c-(1+\delta)>0$. □

Combining Lemma 5.1, Lemma 5.2, and Proposition 5.4, we immediately get the following theorem.

THEOREM 5.5. *For all reals $\epsilon,\delta>0$, there exists an integer c such that the following holds. Let h be a positive integer, $m=h^c$, and $a_1,\ldots,a_m$ be the first m odd primes. Let β be the product of a random subset of $\{a_1,\ldots,a_m\}$ of size h and set $\alpha=\beta^{1-\epsilon}$. Define $\widetilde{\mathbf{L}}$ and $\widetilde{\mathbf{s}}$ as in (5.1) and (5.4), and let $\widetilde{r}=\sqrt[p]{(1+\epsilon)\ln\beta}>1$. Then*

(i) *all nonzero vectors in $\mathcal{L}(\widetilde{\mathbf{L}})$ have ℓ_p norm greater than $\sqrt[p]{2\left((1-\epsilon)/(1+\epsilon)\right)}r$.*

(ii) *For all sufficiently large h, with probability at least $1-2^{-h}$, the ball $\mathcal{B}(\widetilde{\mathbf{s}},r)$ contains more than $h^{\delta h}$ lattice points of the form $\mathbf{Lz}$ where $\mathbf{z}$ is a 0-1 vector with exactly h ones.*

5.2. Working over the integers. In the previous subsection we proved that as far as real entries are allowed one can easily define a basis $\widetilde{\mathbf{L}}$ and probabilistically find a vector $\widetilde{\mathbf{s}}$ with the property that a sphere of radius slightly more then $\lambda(\widetilde{\mathbf{L}})/\sqrt[p]{2}$ contains many lattice points. We now prove that the same result can be achieved using a suitable integer approximation of $\widetilde{\mathbf{L}}$ and $\widetilde{\mathbf{s}}$. The error incurred by approximating a multiple of $\widetilde{\mathbf{L}}$ and $\widetilde{\mathbf{s}}$ with integers is bounded in the following two lemmas.

LEMMA 5.6. *For all $\eta\geq 1$ and all integer vectors $\mathbf{z}\in\mathbb{Z}^m$,*

$$\|\mathbf{Lz}\|_p\geq(\eta-1)m\|\widetilde{\mathbf{L}}\mathbf{z}\|_p,$$

where $\mathbf{L}=\lfloor(m\eta)\widetilde{\mathbf{L}}\rceil$ is the matrix obtained multiplying $\widetilde{\mathbf{L}}$ by $m\eta$ and rounding each entry to the closest integer.

Proof. By triangular inequality

$$\|\mathbf{Lz}\|_p=\|(m\eta)\widetilde{\mathbf{L}}\mathbf{z}+(\mathbf{L}-(m\eta)\widetilde{\mathbf{L}})\mathbf{z}\|_p$$

$$\begin{aligned}&\geq \|(m\eta)\widetilde{\mathbf{L}}\mathbf{z}\|_p - \|(\mathbf{L}-(m\eta)\widetilde{\mathbf{L}})\mathbf{z}\|_p\\&= \eta m\|\widetilde{\mathbf{L}}\mathbf{z}\|_p - \|(\mathbf{L}-(m\eta)\widetilde{\mathbf{L}})\mathbf{z}\|_p.\end{aligned}$$

It remains to prove that $\|(\mathbf{L}-(m\eta)\widetilde{\mathbf{L}})\mathbf{z}\|_p \leq m\|\widetilde{\mathbf{L}}\mathbf{z}\|_p$. Notice that all entries in $(\mathbf{L}-(m\eta)\widetilde{\mathbf{L}})$ are at most $1/2$ in absolute value. Therefore

$$\begin{aligned}\|(\mathbf{L}-(m\eta)\widetilde{\mathbf{L}})\mathbf{z}\|_p &\leq \frac{1}{2}\sqrt[p]{\|\mathbf{z}\|_p^p + \left(\sum|z_i|\right)^p}\\&\leq \frac{1}{2}\sqrt[p]{\|\mathbf{z}\|_p^p + m^p\|\mathbf{z}\|_p^p}\\&\leq m\|\mathbf{z}\|_p.\end{aligned}$$

Furthermore,

$$\begin{aligned}\|\widetilde{\mathbf{L}}\mathbf{z}\|_p^p &= \|\mathbf{D}\mathbf{z}\|_p^p + \alpha^p|\mathbf{R}\mathbf{z}|^p\\&\geq \|\mathbf{D}\mathbf{z}\|_p^p\\&\geq \|\mathbf{z}\|_p^p\end{aligned}$$

because $\mathbf{D}$ is diagonal with all entries greater than 1. This proves that $\|(\mathbf{L}-(m\eta)\widetilde{\mathbf{L}})\mathbf{z}\|_p \leq m\|\widetilde{\mathbf{L}}\mathbf{z}\|_p$ and therefore $\|\mathbf{L}\mathbf{z}\|_p \geq (\eta-1)m\|\widetilde{\mathbf{L}}\mathbf{z}\|_p$. □

LEMMA 5.7. *For all $\eta > 0$ and all integer vectors $\mathbf{z} \in \mathbb{Z}^m$*

$$\|\mathbf{L}\mathbf{z}-\mathbf{s}\|_p \leq (\eta+1)m\|\widetilde{\mathbf{L}}\mathbf{z}-\widetilde{\mathbf{s}}\|_p,$$

where $\mathbf{L} = \lfloor(m\eta)L\rceil$ and $\mathbf{s} = \lfloor(m\eta)\mathbf{s}\rceil$ are the matrices obtained multiplying $\widetilde{\mathbf{L}}$ and $\widetilde{\mathbf{s}}$ by $m\eta$ and rounding each entry to the closest integer.

Proof. By triangular inequality

$$\begin{aligned}\|\mathbf{L}\mathbf{z}-\mathbf{s}\|_p &= \|((m\eta)\widetilde{\mathbf{L}}\mathbf{z}-(m\eta)\widetilde{\mathbf{s}}) + (\mathbf{L}-(m\eta)\widetilde{\mathbf{L}})\mathbf{z} - (\mathbf{s}-(m\eta)\widetilde{\mathbf{s}})\|_p\\&\leq \|((m\eta)\widetilde{\mathbf{L}}\mathbf{z}-(m\eta)\widetilde{\mathbf{s}})\|_p + \|(\mathbf{L}-(m\eta)\widetilde{\mathbf{L}})\mathbf{z} - (\mathbf{s}-(m\eta)\widetilde{\mathbf{s}})\|_p\\&= \eta m\|\widetilde{\mathbf{L}}\mathbf{z}-(m\eta)\widetilde{\mathbf{s}}\|_p + \|(\mathbf{L}-(m\eta)\widetilde{\mathbf{L}})\mathbf{z} - (\mathbf{s}-(m\eta)\widetilde{\mathbf{s}})\|_p.\end{aligned}$$

Notice that all entries in $(\mathbf{L}-(m\eta)\widetilde{\mathbf{L}})$ and $(\mathbf{s}-(m\eta)\widetilde{\mathbf{s}})$ are at most $1/2$ in absolute value. Therefore

$$\|(\mathbf{L}-(m\eta)\widetilde{\mathbf{L}})\mathbf{z} - (\mathbf{s}-(m\eta)\widetilde{\mathbf{s}})\|_p^p \leq \left(\frac{1}{2}\right)^p\left(\|\mathbf{z}\|_p^p + \left(\sum|z_i|+1\right)^p\right) < m^p\|\mathbf{z}\|_p^p.$$

Furthermore,

$$\|\widetilde{\mathbf{L}}\mathbf{z}-\widetilde{\mathbf{s}}\|_p \geq \|\mathbf{D}\mathbf{z}\|_p \geq \|\mathbf{z}\|_p$$

because $\mathbf{D}$ is diagonal with all entries greater than 1. This proves that

$$\|(\mathbf{L}-(m\eta)\widetilde{\mathbf{L}})\mathbf{z} - (\mathbf{s}-(m\eta)\widetilde{\mathbf{s}})\|_p \leq m\|\widetilde{\mathbf{L}}\mathbf{z}-\widetilde{\mathbf{s}}\|_p,$$

and therefore

$$\|\mathbf{L}\mathbf{z}-\mathbf{s}\|_p \leq (\eta+1)\|\mathbf{L}\mathbf{z}-\mathbf{s}\|_p \qquad \square$$

We can now prove a variant of Theorem 5.5 where all the numbers are integers.

THEOREM 5.8. *For every $p \geq 1$, $\gamma \in [1, \sqrt[p]{2})$ and $\delta > 0$ there exists a probabilistic algorithm that on input an integer h outputs (in $\mathrm{poly}(h)$ time) integers m, r, a matrix $\mathbf{L} \in \mathbb{Z}^{(m+1)\times m}$, and an integer vector $\mathbf{s} \in \mathbb{Z}^{m+1}$ such that*

(i) *all vectors in* $\mathcal{L}(\mathbf{L})$ *have* ℓ_p *norm bigger than* γr*;*
(ii) *for all sufficiently large* h*, with probability at least* $1-2^{-h}$ *the sphere* $\mathcal{B}(\mathbf{s},r)$ *contains at least* $h^{\delta h}$ *lattice points of the form* $\mathbf{Lz}$ *where* $\mathbf{z}$ *is a* 0-1 *vector with exactly* h *ones.*

Proof. We show that for all $p \geq 1, \delta > 0$ and $\epsilon > 0$ the theorem is satisfied with

$$\gamma = \left(\frac{(1-\epsilon)^{1+1/p}}{(1+\epsilon)^{2+1/p}}\right) \cdot \sqrt[p]{2}.$$

Let c be as in Theorem 5.5. On input h, algorithm A computes $m = h^c$, and the first m odd primes $a_1, a_2, \ldots, a_m$. Let $\widetilde{\mathbf{L}}$, $\widetilde{\mathbf{s}}$, and $\widetilde{r}$ be as defined in Theorem 5.5, and compute the approximations

$$\mathbf{L} = \lfloor (m/\epsilon)\widetilde{\mathbf{L}} \rceil, \qquad \mathbf{s} = \lfloor (m/\epsilon)\widetilde{\mathbf{s}} \rceil, \qquad r = \lceil (1+1/\epsilon) m\widetilde{r} \rceil.$$

Let $\mathbf{z} \in \mathbb{Z}^m$ be a nonzero integer vector. We want to bound $\|\mathbf{Lz}\|_p$. We know from Theorem 5.5 that

$$\|\widetilde{\mathbf{L}}\mathbf{z}\|_p > \sqrt[p]{2\frac{1-\epsilon}{1+\epsilon}}\widetilde{r}. \tag{5.6}$$

Using Lemma 5.6 (with $\eta = 1/\epsilon$) and (5.6) we get

$$\begin{aligned} \|\mathbf{Lz}\|_p &\geq \left(\frac{1}{\epsilon} - 1\right) m \|\widetilde{\mathbf{L}}\mathbf{z}\|_p \\ &> \left(\frac{(1-\epsilon)^{1+1/p}}{\epsilon(1+\epsilon)^{1/p}}\right) m \sqrt[p]{2} \cdot \widetilde{r}. \end{aligned} \tag{5.7}$$

Notice that r satisfies the bounds $r < (1+1/\epsilon)m\widetilde{r} + 1$ and $r > (1+1/\epsilon)$ because $\widetilde{r} > 1$. Thus, we can bound $\widetilde{r}$ as follows:

$$\begin{aligned} \widetilde{r} &> \frac{r-1}{(1+1/\epsilon)m} \\ &= \frac{1-1/r}{(1+1/\epsilon)m} \cdot r \\ &> \frac{1-1/(1+1/\epsilon)}{(1+1/\epsilon)m} \cdot r \\ &= \frac{\epsilon}{(\epsilon+1)^2 m} \cdot r. \end{aligned} \tag{5.8}$$

Combining (5.7) and (5.8) we get

$$\|\mathbf{Lz}\|_p > \left(\frac{(1-\epsilon)^{1+1/p}}{\epsilon(1+\epsilon)^{1/p}}\right) \sqrt[p]{2} \frac{\epsilon}{(\epsilon+1)^2} r = \gamma r.$$

Now consider the sphere $\mathcal{B}(\mathbf{s}, r)$. By Theorem 5.5, for all sufficiently large h, with probability at least $1-2^{-h}$, the ball $\mathcal{B}(\widetilde{\mathbf{s}}, \widetilde{r})$ contains at least $h^{\delta h}$ lattice points of the form $\widetilde{\mathbf{L}}\mathbf{z}$ where $\mathbf{z}$ is a 0-1 vector with exactly h ones. For each such point $\widetilde{\mathbf{L}}\mathbf{z}$, we can use Lemma 5.7 (with $\eta = 1/\epsilon$) to bound the distance of $\mathbf{Lz}$ from $\mathbf{s}$ as follows:

$$\begin{aligned} \|\mathbf{Lz} - \mathbf{s}\|_p &\leq (1+1/\epsilon) m \|\widetilde{\mathbf{L}}\mathbf{z} - \widetilde{\mathbf{s}}\|_p \\ &\leq (1+1/\epsilon) m\widetilde{r} \leq r. \end{aligned}$$

Therefore $\mathbf{Lz}$ belongs to the sphere $\mathcal{B}(\mathbf{s}, r)$. This proves that $\mathcal{B}(\mathbf{s}, r)$ also contains at least $h^{\delta h}$ lattice points of the desired form. ∎

5.3. Projecting lattice points to binary strings. In order to complete the proof of Lemma 4.1 we need the following combinatorial theorem from [27]. (See the proof in the appendix.)

THEOREM 5.9. *Let $\mathcal{Z} \subseteq \{0,1\}^m$ be a set of vectors containing exactly h ones. If $|\mathcal{Z}| \geq h! m^{\frac{4\sqrt{h}k}{\epsilon}}$, and $\mathbf{T} \in \{0,1\}^{k \times m}$ is chosen setting each entry to 1 independently at random with probability $p = \frac{1}{4hk}$, then the probability that all binary vectors $\{0,1\}^k$ are contained in $\mathbf{T}(\mathcal{Z}) = \{\mathbf{Tz} : \mathbf{z} \in \mathcal{Z}\}$ is at least $1 - 6\epsilon$.*

We remark that a similar theorem was already proved in [2], and we could have used that result instead of Theorem 5.9. However, our construction and analysis are much simpler than those in [2] and are probably more efficient.

We can now prove Lemma 4.1. Fix an ℓ_p norm ($p \geq 1$) and a constant $\gamma \in [1, \sqrt[p]{2})$. Let k be a sufficiently large integer. We want to build in $\text{poly}(k)$ time an integer lattice $\mathbf{L}$, an integer vector $\mathbf{s}$, an integer transformation matrix $\mathbf{T}$, and an integer radius r such that

(i) all nonzero vectors in $\mathcal{L}(\mathbf{L})$ have ℓ_p norm greater than γr;

(ii) with probability at least $1 - 1/\text{poly}(k)$, for all $\mathbf{x} \in \{0,1\}^k$ there exists a $\mathbf{z} \in \mathbb{Z}^m$ such that $\mathbf{Tz} = \mathbf{x}$ and $\|\mathbf{Lz} - \mathbf{s}\|_p \leq r$.

Let $\delta = 2$ and run the algorithm from Theorem 5.8 on input $h = k^4$. This algorithm outputs an integer matrix $\mathbf{L} \in \mathbb{Z}^{(m+1) \times m}$ and a vector $\mathbf{s} \in \mathbb{Z}^m$ and $r \in \mathbb{Z}$. Notice that since $\mathbf{s}$ is computed in polynomial time, m must be polynomial in h, i.e., $m < h^c$ for some constant c independent of h. Let $\mathcal{Z}$ be the set of all vectors $\mathbf{z} \in \{0,1\}^m$ with exactly h ones, such that $\mathbf{Lz} \in \mathcal{B}(\mathbf{s}, r)$. We know from Theorem 5.8 that all nonzero vectors in $\mathcal{L}(\mathbf{L})$ have ℓ_p norm greater than γr, and with probability at least $1 - 2^{-h}$ the set $\mathcal{Z}$ contains at least h^{2h} elements.

Now, choose matrix $\mathbf{T} \in \{0,1\}^{k \times m}$ by setting each entry to one independently with probability $1/(4hk)$. Notice that

$$|\mathcal{Z}| \geq h^{2h} > h! m^{h/c} = h! m^{\frac{4\sqrt{h}k}{\epsilon}},$$

where $\epsilon = 4c/k$. So, by Theorem 5.9, the probability that for each $\mathbf{x}$ there exists a vector $\mathbf{z}$ such that $\mathbf{x} = \mathbf{Tz}$ and $\mathbf{Lz} \in \mathcal{B}(\mathbf{s}, r)$ is at least $1 - 1/O(k)$. This concludes the proof of Lemma 4.1.

6. Deterministic reductions. In section 4 we proved that approximating SVP is hard for NP under RUR-reductions. In particular, this proves that approximating SVP is not in RP unless NP = RP. In this section we address the question whether SVP is hard under deterministic reductions.

A quick inspection of the proof of Theorem 4.2 immediately shows that the only place in the reduction where randomness is used is Lemma 4.1. A deterministic polynomial time algorithm satisfying the conditions in Lemma 4.1 would immediately give a proper NP-hardness result (under deterministic many-one reductions) for GAPSVP.

To date, we do not know if such a deterministic polynomial time algorithm exists. However, one can show that such an algorithm exists if one assumes a reasonable number theoretic conjecture, or allows for nonuniform reductions.

6.1. Nonuniform reductions. The reduction presented in the proof of Theorem 4.2 always maps NO instances to NO instances and YES instances to YES instances provided that the probabilistic algorithm in the lemma succeeds. Notice that the construction in the lemma depends only on the dimension k of the GAPCVP$'$ instance we are reducing. Moreover, the success of the algorithm does not depend on the particular instance we are reducing.

Therefore, if we allow for nonuniform reductions in the proof of Theorem 4.2, we can encode the objects $\mathbf{L}, \mathbf{T}, \mathbf{s}, r$ satisfying Lemma 4.1 directly in the reduction as polynomial size nonuniform hints. Notice that the existence of $\mathbf{L}, \mathbf{T}, \mathbf{s}, r$ is guaranteed by the (probabilistic) proof of Lemma 4.1.

This gives the following variant of Theorem 4.2.

THEOREM 6.1. *For any ℓ_p norm ($p \geq 1$) and for any constant $\gamma \in [1, \sqrt[p]{2})$, the promise problem* GAPSVP$_\gamma$ *is hard for* NP *under deterministic nonuniform polynomial reductions. In particular,* GAPSVP$_\gamma$ *is not in* P/poly *unless* NP $\subseteq$ P/poly.

Using standard results on nonuniform complexity [21], this also implies the following corollary.

COROLLARY 6.2. *For any ℓ_p norm ($p \geq 1$) and for any constant $\gamma \in [1, \sqrt[p]{2})$, the promise problem* GAPSVP$_\gamma$ *is not in* P *unless the polynomial hierarchy* [26, 33] *collapses to the second level.*

6.2. NP-hardness under a number theoretic conjecture. In this section we show how the proof of the geometric lemma can be made deterministic using a number theoretic conjecture. This results in a proper NP-hardness result for GAPSVP (i.e. NP-hardness under deterministic many-one reductions) but relies on an unproven assumption on the distribution of square-free smooth numbers. The conjecture is the following.

CONJECTURE 1. *For any $\epsilon > 0$ there exists a d such that for all large enough n, there exists an (odd) integer in $[n, n + n^\epsilon]$ which is square-free and $(\log^d n)$-smooth; i.e., all of its prime factors have exponent 1 and are less than $\log^d n$.*

We remark that although the above conjecture is very plausible, proving it seems to be beyond current mathematical techniques. We now show that if the above conjecture is true, then there exists a deterministic (uniform) polynomial time algorithm satisfying the requirements of Lemma 4.1. For simplicity, we show how to build real matrices $\mathbf{L}, \mathbf{s}, r$ satisfying the condition in the lemma. $\mathbf{L}, \mathbf{s}, r$ can be easily transformed into integer matrices as explained in subsection 5.2 using Lemma 5.6 and Lemma 5.7 to bound the errors incurred in the approximation process.

Let ϵ be a positive real between 0 and 1. Let d be an integer (whose existence is guaranteed by the conjecture) such that for all large enough n there exists a $(\log^d n)$-smooth square-free (odd) integer in the interval $[n, n+n^{\epsilon/2}]$. Let $\mathbf{L}$ and $\mathbf{s}$ be as defined in (5.1) and (5.4) with $m = k^{d+1} + k$, $a_1, \ldots, a_m$ the first m (odd) prime numbers, $\beta = a_m^{\frac{2k}{\epsilon}}$ and $\alpha = \beta^{1-\epsilon}$. Finally, let $\mathbf{T} \in \{0,1\}^{k \times m}$ be the matrix $\mathbf{T} = [\mathbf{0}_{k \times k^{d+1}} | \mathbf{I_k}]$.

From Lemma 5.1 we know that for all nonzero vectors $\mathbf{z} \in \mathbb{Z}^m$,

$$\|L\mathbf{z}\|_p \geq \sqrt[p]{2(1-\epsilon)\ln\beta}.$$

We now show that for all $\mathbf{x} \in \{0,1\}^k$ there exists a $\mathbf{y} \in \mathbb{Z}^{k^{d+1}}$ such that

$$\left\| \mathbf{L} \begin{bmatrix} \mathbf{y} \\ \mathbf{x} \end{bmatrix} - \mathbf{s} \right\|_p < \sqrt[p]{\ln\beta + 2} = r. \tag{6.1}$$

Since the equality

$$\mathbf{T} \begin{bmatrix} \mathbf{y} \\ \mathbf{x} \end{bmatrix} = \mathbf{x}$$

follows directly from the definition to $\mathbf{T}$, (6.1) proves the second condition in Lemma 4.1. By Lemma 5.2 it is sufficient to show that for every integer $g_{\mathbf{x}} = \prod_{i=1}^k a_{k^{d+1}+i}^{x_i}$

(with $x_i \in \{0,1\}$) there exists an integer $g_{\mathbf{y}} = \prod_{i=1}^{k^{d+1}} a_i^{y_i}$ (with $y_i \in \{0,1\}$) such that $g = g_{\mathbf{x}} g_{\mathbf{y}} \in [\beta, \beta + \beta^{\epsilon}]$. Fix some $g_{\mathbf{x}} = \prod_{i=1}^{k} a_{k^{d+1}+i}^{x_i}$. Notice that

$$\frac{\beta}{g_{\mathbf{x}}} > \frac{\beta}{a_m^k} = a_m^{(\frac{2}{\epsilon}-1)k} > 2^k$$

so for all sufficiently large k, there exists a $\log^d(\beta/g_{\mathbf{x}})$-smooth square-free (odd) integer in the interval

$$[\beta/g_{\mathbf{x}}, (\beta/g_{\mathbf{x}}) + (\beta/g_{\mathbf{x}})^{\epsilon/2}].$$

But

$$\log^d(\beta/g_{\mathbf{x}}) \leq \log^d(\beta) = O(k \log k)^d < k^{d+1}.$$

So, this smooth number can be expressed as $g_{\mathbf{y}} = \prod_{i=1}^{k^{d+1}} a_i^{y_i}$ with $y_i \in \{0,1\}$. Therefore,

$$g_{\mathbf{x}} g_{\mathbf{y}} \in [\beta, \beta + g_{\mathbf{x}}(\beta/g_{\mathbf{x}})^{\epsilon/2}].$$

Finally, notice that $g_{\mathbf{x}} \leq a_m^k = \beta^{\epsilon/2}$. So, if we define

$$\mathbf{z} = \begin{bmatrix} \mathbf{y} \\ \mathbf{x} \end{bmatrix}$$

then

$$\prod a_i^{z_i} = g_{\mathbf{x}} g_{\mathbf{y}} \in [\beta, \beta + \beta^{\epsilon}]$$

and by Lemma 5.2 the lattice vector $\mathbf{Lz}$ belongs to the sphere $\mathcal{B}(\mathbf{s}, r)$.

This completes the proof that if Conjecture 1 is true, then $\mathbf{L}, \mathbf{T}, \mathbf{s}, r$ satisfy the conditions of Lemma 4.1. Then, the reduction in the proof of Theorem 4.2 gives the following corollary.

COROLLARY 6.3. *If Conjecture* 1 *holds true, then for any ℓ_p norm and any constant $\gamma < \sqrt[p]{2}$,* GAPSVP$_\gamma$ *is* NP*-hard (under deterministic many-one reductions).*

7. Discussion. We proved that approximating the shortest vector problem in any ℓ_p within factors less than $\sqrt[p]{2}$ is not in polynomial time under any of the following assumptions:

1. NP $\neq$ RP,
2. NP $\not\subseteq$ P/poly,
3. Conjecture 1 is true and NP $\neq$ P.

Although all of these results give theoretical evidence that SVP cannot be approximated in polynomial time, the problem whether solving SVP (even exactly) is NP-hard under deterministic many-one reductions remains open. We notice that the only place where randomness (or nonuniform hints, or the number theoretic conjecture) is used in our reduction is the proof of Lemma 4.1. A deterministic polynomial time solution to Lemma 4.1 would immediately give an NP-hardness result for SVP under deterministic many-one reductions. We leave finding a deterministic algorithm satisfying Lemma 4.1 as an open problem.

Our NP-hardness proof is by reduction from approximate CVP. In particular we reduced instances of CVP of size n to instances of SVP of size $m = n^c$, where $c > 2$

is a constant independent of n. Although this gives a polynomial relation between n and m it should be noted that m can be much bigger than n. Therefore, in order to assert that an instance of SVP is hard to solve in practice, the dimension m must be rather large. Finding a more efficient reduction, where, for example, $m = O(n)$, is left as an open problem. Interestingly, a dimension and approximation preserving reduction is possible in the other direction from SVP to CVP [16].

The geometric lemma used in our reduction is in a certain sense optimal (in the ℓ_2 norm): it can be formally proved that any lattice $\mathbf{L}$ satisfying the lemma must have vectors of length less than $r/\sqrt{2}$ (see [27]). Proving that SVP is NP-hard to approximate within factors larger than $\sqrt{2}$ cannot be done by simply improving the geometric lemma. We leave as an open problem to prove that SVP is NP-hard to approximate within any constant factor.

Appendix. A combinatorial theorem on low-degree hyper-graphs.

In this appendix we prove Theorem 5.9. We want to prove that if $\mathcal{Z} \subset \{0,1\}^m$ is a set of vectors of weight h, and $|\mathcal{Z}| \geq h! m^{\frac{4\sqrt{h}k}{\epsilon}}$, then the probability that $\{0,1\}^k \subseteq \mathbf{T}(\mathcal{Z})$ (where $\mathbf{T} \in \{0,1\}^{k\times m}$ is a linear transformation chosen at random setting each entry to 1 independently with probability $p = \epsilon/(4hk)$) is at least $1 - 6\epsilon$.

The theorem can be reformulated in terms of hyper-graphs as follows. Let $(N, \mathcal{Z})$ be an h-regular hyper-graph, i.e., a hyper-graph all of whose hyper-edges have size h. Let $\mathbf{T} = (T_1, \ldots, T_k)$ be a collection of subsets of N chosen at random including each element of N in T_i independently with probability $p = \epsilon/(4hk)$. For any subset $U \subseteq N$, let

$$\mathbf{T}(U) = (|T_1 \cap U|, |T_2 \cap U|, \ldots, |T_k \cap U|)$$

and define $\mathbf{T}(\mathcal{Z}) = \{\mathbf{T}(U) : U \in \mathcal{Z}\}$. We want to prove that if $|\mathcal{Z}| > h!|N|^{4\sqrt{h}k/\epsilon}$, then $\{0,1\}^k \subseteq \mathbf{T}(\mathcal{Z})$ with probability at least $1 - 6\epsilon$.

The correspondence between the matrix and hyper-graph formulation is immediate: identify the hyper-edges with the corresponding characteristic vectors in $\{0,1\}^{|N|}$ and the collection $\mathbf{T}$ with a matrix whose rows are the characteristic vectors of the sets T_i. Then $\mathbf{T}(U) = \mathbf{Tu}$ where $\mathbf{u}$ is the characteristic vector of set U.

We first prove a weaker result: we show for every vector $\mathbf{x} \in \{0,1\}^k$, $\mathbf{x} \in \mathbf{T}(\mathcal{Z})$ with high probability. Consider the target vector $\mathbf{x}$ as fixed. We want to bound the probability that $\mathbf{T}(U) \neq \mathbf{x}$ for all $U \in \mathcal{Z}$. Since the set $\mathcal{Z}$ is very big, the expected number of $U \in \mathcal{Z}$ such that $\mathbf{T}(U) = \mathbf{x}$ is also very high. Unfortunately, this is not sufficient to conclude that with high probability there exists a $U \in \mathcal{Z}$ such that $\mathbf{T}(U) = \mathbf{x}$, because the events $\mathbf{T}(U) = \mathbf{x}$ (indexed by the hyper-edges $U \in \mathcal{Z}$) might be strongly correlated. Notice that if U and V are disjoint (i.e., $U \cap V = \emptyset$), then the corresponding events are independent. In fact the size of the intersection $|U \cap V|$ is a good measure of the correlation between the events $\mathbf{T}(U) = \mathbf{x}$ and $\mathbf{T}(V) = \mathbf{x}$. Notice that if $|\mathcal{Z}|$ is big, then many hyper-edges in $\mathcal{Z}$ will intersect because there cannot be more than m/h mutually disjoint hyper-edges. However, one can still hope that for most of the pairs $U, V \in \mathcal{Z}$, the intersection $U \cap V$ is very small. This is not necessarily true for any hyper-graph $\mathcal{Z}$, but one can show that if $\mathcal{Z}$ is sufficiently large, then it must contain a large hyper-graph with this small intersection property.

The proof of the theorem is divided in four major steps:

1. We first show that the probability that $\mathbf{x} \notin \mathbf{T}(\mathcal{Z})$ can be bounded by the expectation

$$\operatorname*{Exp}_R[e^{\gamma R} - 1], \tag{A.1}$$

where γ is a small positive real, and $R = |U \cap V|$ is the random variable defined as the size of the intersection of two randomly chosen hyper-edges $U, V \in \mathcal{Z}$.

2. We show that $\mathcal{Z}$ "contains" a hyper-graph such that the intersection of two randomly selected hyper-edges is very small with high probability.

3. Then, we prove the weak version of the theorem applying the bound (A.1) to this hyper-graph contained in $\mathcal{Z}$.

4. Finally, we derive the strong version of our theorem from the weak one.

Each of the above steps is described in the following subsections.

A.1. The exponential bound. We start by computing the probability that $\mathbf{T}(U) = \mathbf{x}$ for some fixed set U. In the next lemma we prove a more general statement concerning the probability that two events $\mathbf{T}(U) = \mathbf{x}$ and $\mathbf{T}(V) = \mathbf{x}$ are simultaneously satisfied and relate it to the size of the intersection $r = |U \cap V|$ of the two sets U, V.

LEMMA A.1. *Let $\mathbf{x} \in \{0,1\}^k$ be any boolean vector, $U, V \subset N$ be two sets of size d and let $\mathbf{T} \in \{0,1\}^{k \times |N|}$ be chosen at random by setting each entry to 1 independently with probability p. Then, the probability (over the choice of $\mathbf{T}$) that both $\mathbf{T}(U)$ and $\mathbf{T}(V)$ equal $\mathbf{x}$ is*

$$\Phi(r) = (1-p)^{(2d-r)k} \left[\frac{pr}{1-p} + \left(\frac{p(d-r)}{1-p} \right)^2 \right]^{\|\mathbf{x}\|_1},$$

where $r = |U \cap V|$.

Proof. Since the rows of matrix $\mathbf{T}$ are chosen independently,

$$\Pr_{\mathbf{T}}\{\mathbf{T}(U) = \mathbf{T}(V) = \mathbf{x}\} = \prod_{i=1}^{k} \Pr_{T_i}\{|T_i \cap U| = |T_i \cap V| = x_i\}.$$

We prove that for all $i = 1, \ldots, k$,

$$\Pr_{T_i}\{|T_i \cap U| = |T_i \cap V| = x_i\} = (1-p)^{(2d-r)} \left[\frac{pr}{1-p} + \left(\frac{p(d-r)}{1-p} \right)^2 \right]^{x_i}.$$

First consider the case $x_i = 0$ and compute the probability (over the choice of T_i) that $|T_i \cap U| = |T_i \cap V| = 0$. This is true iff none of the elements of $U \cup V$ belongs to T_i, so the probability is

$$\Pr_{T_i}\{|T_i \cap U| = |T_i \cap V| = 0\} = (1-p)^{|U \cup V|} = (1-p)^{2d-r}.$$

Now consider the case $x_i = 1$ and compute the probability (over the choice of T_i) that $|T_i \cap U| = |T_i \cap V| = 1$. This is true iff either (1) T_i contains one element of $U \cap V$ and no other element of $U \cup V$, or (2) T_i contains one element of $U \setminus V$, one element of $V \setminus U$, and no other element of $U \cup V$. Event (1) has probability

$$|U \cap V| \cdot p(1-p)^{|U \cup V|-1} = (1-p)^{2d-r} \left(\frac{pr}{1-p} \right)$$

while event (2) has probability

$$|U \setminus V| \cdot |V \setminus U| \cdot p^2 (1-p)^{|U \cup V|-2} = (1-p)^{2d-r} \left(\frac{p(d-r)}{1-p} \right)^2.$$

Adding up the two probabilities, we get

$$\Pr_{T_i}\{|T_i \cap U| = |T_i \cap V| = 1\} = (1-p)^{(2d-r)}\left(\frac{pr}{1-p} + \left(\frac{p(d-r)}{1-p}\right)^2\right). \qquad \square$$

By choosing $U = V$ in the previous lemma one gets the following corollary.

COROLLARY A.2. *Let $\mathbf{x} \in \{0,1\}^k$ be a boolean vector, $U \subseteq N$ a subset of size d, and $\mathbf{T} \in \{0,1\}^{k \times |N|}$ a random matrix chosen by setting each entry to 1 independently with probability p. Then,*

$$\Pr_{\mathbf{T}}\{\mathbf{T}(U) = \mathbf{x}\} = \Phi(d) = (1-p)^{dk}\left(\frac{pd}{1-p}\right)^{\|\mathbf{x}\|_1}.$$

Notice that when $U \cap V = \emptyset$,

$$\Pr\{\mathbf{T}(U) = \mathbf{T}(V) = \mathbf{x}\} = \Phi(0) = \Phi(d)^2 = \Pr\{\mathbf{T}(U) = \mathbf{x}\}\Pr\{\mathbf{T}(V) = \mathbf{x}\},$$

i.e., the events $\mathbf{T}(U) = \mathbf{x}$ and $\mathbf{T}(V) = \mathbf{x}$ are independent. We can now prove the following proposition.

PROPOSITION A.3. *Let $(N, \mathcal{Z})$ be a d-regular hyper-graph and let $\mathbf{T} \in \{0,1\}^{k \times |N|}$ be chosen at random by setting each entry to 1 independently with probability p. Then, for each $\mathbf{x} \in \{0,1\}^k$ the probability (over the choice of $\mathbf{T}$) that $\mathbf{x} \notin \mathbf{T}(\mathcal{Z})$ is at most $\mathrm{Exp}_R[e^{\gamma R}] - 1$, where $\gamma = \frac{kp}{1-p} + \frac{k}{pd^2}$ and $R = |U \cap V|$ is the random variable defined as the size of the intersection of two randomly chosen elements of $\mathcal{Z}$.*

Proof. Fix some vector $\mathbf{x} \in \{0,1\}^k$ and choose $\mathbf{T}$ at random as specified in the proposition. For all $U \in \mathcal{Z}$, let X_U be the indicator random variable

$$X_U = \begin{cases} 1 & \text{if } \mathbf{T}(U) = \mathbf{x}, \\ 0 & \text{otherwise.} \end{cases}$$

Define the random variable $X = \sum_{U \in \mathcal{Z}} X_U$. Notice that $X = 0$ iff $\mathbf{x} \notin \mathbf{T}(\mathcal{Z})$. Moreover, if $X = 0$ then $|X - \mathrm{Exp}[X]| \geq \mathrm{Exp}[X]$. Using Chebyshev's inequality we get the following bound:

$$\begin{aligned} \Pr\{\mathbf{x} \notin \mathbf{T}(\mathcal{Z})\} &= \Pr\{X = 0\} \\ &\leq \Pr\{|X - \mathrm{Exp}[X]| \geq \mathrm{Exp}[X]\} \\ &\leq \frac{\mathrm{Var}[X]}{\mathrm{Exp}[X]^2} = \frac{\mathrm{Exp}[X^2]}{\mathrm{Exp}[X]^2} - 1. \end{aligned}$$

So, let us compute the moments $\mathrm{Exp}[X]$ and $\mathrm{Exp}[X^2]$. For the first moment we have

$$\mathop{\mathrm{Exp}}_{\mathbf{T}}[X] = \sum_{U \in \mathcal{Z}} \Pr_{\mathbf{T}}\{\mathbf{T}(U) = \mathbf{x}\} = |\mathcal{Z}| \cdot \Phi(d),$$

and for the second one

$$\begin{aligned} \mathop{\mathrm{Exp}}_{\mathbf{T}}[X^2] &= \mathop{\mathrm{Exp}}_{\mathbf{T}}\left[\left(\sum_{U \in \mathcal{Z}} X_U\right)^2\right] \\ &= \mathop{\mathrm{Exp}}_{\mathbf{T}}\left[\sum_{U,V \in \mathcal{Z}} X_U \cdot X_V\right] \\ &= \sum_{U,V \in \mathcal{Z}} \Pr_{\mathbf{T}}\{\mathbf{T}(U) = \mathbf{T}(V) = \mathbf{x}\} \\ &= |\mathcal{Z}|^2 \cdot \mathop{\mathrm{Exp}}_{R}[\Phi(R)], \end{aligned}$$

where $R = |U \cap V|$ is the size of two randomly chosen $U, V \in \mathcal{Z}$. Therefore,

$$\begin{aligned}
\Pr_{\mathbf{T}}\{\mathbf{x} \notin \mathbf{T}(\mathcal{Z})\} &= \frac{\operatorname{Exp}_R[\Phi(R)]}{\Phi(d)^2} - 1 \\
&= \operatorname*{Exp}_R\left[(1-p)^{-kR}\left(\frac{(1-p)R}{pd^2} + \left(1 - \frac{R}{d}\right)^2\right)^{\|\mathbf{x}\|_1}\right] - 1 \\
&< \operatorname*{Exp}_R\left[\left(1 + \frac{p}{1-p}\right)^{kR}\left(\frac{R}{pd^2} + 1\right)^k\right] - 1 \\
&< \operatorname*{Exp}_R\left[e^{\frac{pkR}{1-p}} e^{\frac{kR}{pd^2}}\right] - 1 \\
&= \operatorname*{Exp}_R[e^{\gamma R} - 1],
\end{aligned}$$

where $\gamma = \frac{kp}{1-p} + \frac{k}{pd^2}$. ∎

A.2. Well spread hyper-graphs. In the previous section we showed that the probability that $\mathbf{x} \notin \mathbf{T}(\mathcal{Z})$ is at most $\operatorname{Exp}_R[e^{\gamma R}] - 1$. Obviously, the bound is interesting only when $\operatorname{Exp}_R[e^{\gamma R}] < 2$. Notice that this can be true only if

$$\Pr_R\{R = r\} < e^{-\gamma r}$$

for all but a single value of r. Therefore the probability $\Pr_R\{R = r\}$ must decrease exponentially fast in r. This is not necessarily true for any low degree regular hyper-graph $\mathcal{Z}$. In this section we show that if $\mathcal{Z}$ is sufficiently large, then $\mathcal{Z}$ must "contain" a hyper-graph such that

$$\Pr_R\{R = r\} \le 1/r!.$$

More precisely we show that $\mathcal{Z}$ contains a hyper-graph satisfying the following property.

DEFINITION A.4. *Let $(N, \mathcal{Z})$ be a d-regular hyper-graph. $\mathcal{Z}$ is* well spread *if for all $W \subseteq N$ of size at most d, the fraction of hyper-edges containing W is at most*

$$\frac{|\{U \in \mathcal{Z} : W \subseteq U\}|}{|\mathcal{Z}|} \le \frac{1}{d(d-1)\cdots(d-|W|+1)} = \frac{(d-|W|)!}{d!}.$$

Well spread hyper-graphs have the important property that the size of the intersection of two randomly selected hyper-edges is small with very high probability, as shown in the next lemma.

LEMMA A.5. *Let $(N, \mathcal{Z})$ a regular well spread hyper-graph. Choose $U, V \in \mathcal{Z}$ independently and uniformly at random and let $R = |U \cap V|$. For all $r > 0$,*

$$\Pr_R\{R \ge r\} < \frac{1}{r!}.$$

Proof. Let d be the degree of the hyper-graph. We prove that for any fixed set U of size d, the probability that $|U \cap V| \ge r$ when V is chosen at random from $\mathcal{Z}$ is at most $\frac{1}{r!}$. If $|U \cap V| \ge r$ then V contains a subset of U of size r. Therefore, by union bound,

$$\Pr_{V \in \mathcal{Z}}\{|U \cap V| \ge r\} \le \sum_{W \in \binom{U}{r}} \Pr_{V \in \mathcal{Z}}\{W \subseteq V\} = \sum_{W \in \binom{U}{r}} \frac{|\{V \in \mathcal{Z} : W \subseteq V\}|}{|\mathcal{Z}|},$$

where $\binom{U}{r}$ denotes the set of all the size r subsets of U. Since $\mathcal{Z}$ is well spread, the fraction $|\{V \in \mathcal{Z} : W \subseteq V\}|/|\mathcal{Z}|$ is at most $\frac{(d-r)!}{d!}$, which substituted in the previous expression, gives

$$\Pr_{V \in \mathcal{Z}}\{|U \cap V| \geq r\} \leq \binom{d}{r}\frac{(d-r)!}{d!} = \frac{1}{r!}. \qquad \square$$

We now show how to find well spread hyper-graphs "inside" any sufficiently big regular hyper-graph. For any subset $W \subseteq N$, define the induced hyper-graph

$$\mathcal{Z}_W = \{A \subseteq N \setminus W : A \cup W \in \mathcal{Z}\}.$$

In other words, $\mathcal{Z}_W$ is the set of hyper-edges containing W, with the nodes in W removed. Notice the following basic facts:

1. Hyper-graph $\mathcal{Z}$ is well spread if for every set W of size at most d, $|\mathcal{Z}_W| \leq \frac{(d-|W|)!}{d!}|\mathcal{Z}|$.
2. $\mathcal{Z}_W$ is d'-regular with $d' = d - |W|$.
3. If $W = \emptyset$ then $\mathcal{Z}_W = \mathcal{Z}$.
4. $(\mathcal{Z}_W)_V = \mathcal{Z}_{W \cup V}$ if $U \cap V = \emptyset$, and $(\mathcal{Z}_W)_V = \emptyset$ otherwise.
5. If $|W| > d$ then $\mathcal{Z}_W = \emptyset$.

In the following lemma we prove that for any regular hyper-graph $\mathcal{Z}$, there exists a set W such that $\mathcal{Z}_W$ is well spread.

LEMMA A.6. *Let $(N, \mathcal{Z})$ be an h-regular hyper-graph. Then there exists a set $W \subset N$ such that $(N, \mathcal{Z}_W)$ is well spread and $|\mathcal{Z}_W| > |\mathcal{Z}|/h!$.*

Proof. If $(N, \mathcal{Z})$ is well spread, let $W = \emptyset$ and the statement is obviously true. Otherwise, there exists some set W of size at most h such that $|\mathcal{Z}_W| > \frac{(h-|W|)!}{h!} \cdot |\mathcal{Z}|$. Let W be maximal (with respect to the set inclusion ordering relation) among these sets. Obviously, $|\mathcal{Z}_W| > |\mathcal{Z}|/h!$. Notice that $\mathcal{Z}_W$ is d-regular, with $d = h - |W|$. We prove that $(N, \mathcal{Z}_W)$ is well spread. Let V be a subset of N of size at most d. There are three cases:

(i) If $V \cap W \neq \emptyset$ then $|(\mathcal{Z}_W)_V| = 0 \leq \frac{(d-|V|)!}{d!} \cdot |\mathcal{Z}_W|$.
(ii) If $V = \emptyset$, then $|(\mathcal{Z}_W)_V| = |\mathcal{Z}_W| = \frac{d!}{d!} \cdot |\mathcal{Z}_W|$.
(iii) Finally assume $V \neq \emptyset$ and $V \cap W = \emptyset$. By the maximality of W one gets

$$\begin{aligned} |(\mathcal{Z}_W)_V| &= |\mathcal{Z}_{V \cup W}| \\ &\leq \frac{(h-|V \cup W|)!}{h!}|\mathcal{Z}| \\ &= \frac{(d-|V|)!}{d!}\frac{(h-|W|)!}{h!}|\mathcal{Z}| \\ &< \frac{(d-|V|)!}{d!}|\mathcal{Z}_W|. \qquad \square \end{aligned}$$

A.3. Weak probabilistic construction. We now combine the tools developed in the previous sections to prove the following theorem.

THEOREM A.7. *For every sufficiently small constant $\epsilon > 0$, positive integer k and h-regular hyper-graph $(N, \mathcal{Z})$ of size $|\mathcal{Z}| > h!|N|^{\sqrt{h}k/\epsilon}$ the following holds. Define matrix $\mathbf{T} \in \{0,1\}^{k \times |N|}$ at random by setting each entry to 1 independently with probability $p = \frac{\epsilon}{hk}$. Then, for every $\mathbf{x} \in \{0,1\}^k$,*

$$\Pr\{\mathbf{x} \in \mathbf{T}(\mathcal{Z})\} > 1 - 5\epsilon.$$

From Lemma A.6, there exists a subset $W \subset N$ such that $(N, \mathcal{Z}_W)$ is well spread and $|\mathcal{Z}_W| \geq |\mathcal{Z}|/h! > |N|^{\sqrt{h}k/\epsilon}$. Choose $\mathbf{T} \in \{0,1\}^{k \times |N|}$ at random by setting each entry to one independently with probability $p = \frac{\epsilon}{hk}$. Let F be the event that all entries in $\mathbf{T}$ that belongs to the columns corresponding to elements in W are 0. Notice that $\Pr\{\neg F\} \leq |W|kp \leq hkp = \epsilon$. Notice also that

$$\Pr_{\mathbf{T}}\{\mathbf{x} \notin \mathbf{T}(\mathcal{Z}) \mid F\} \leq \Pr_{\mathbf{T}}\{\mathbf{x} \notin \mathbf{T}(\mathcal{Z}_W)\}$$

Let d be the degree of $\mathcal{Z}_W$. Since $|\mathcal{Z}_W| \leq \binom{|N|}{d} < |N|^d$ and $|\mathcal{Z}_W| > |N|^{\sqrt{h}k/\epsilon}$, hyper-graph $\mathcal{Z}_W$ has degree at least $d > \sqrt{h}k/\epsilon$.

Applying Proposition A.3 to d-regular hyper-graph $\mathcal{Z}_W$, the probability (over the choice of $\mathbf{T}$) that $\mathbf{x} \notin \mathbf{T}(\mathcal{Z}_W)$ is at most $\mathrm{Exp}_R[e^{\gamma R}] - 1$, where R is the size of the intersection of two random elements in $\mathcal{Z}_W$ and

$$\begin{aligned}\gamma &= \frac{kp}{1-p} + \frac{k}{pd^2} \\ &= \frac{\epsilon}{h - \epsilon/k} + \frac{hk^2}{\epsilon d^2} \\ &< \frac{\epsilon}{1-\epsilon} + \epsilon.\end{aligned}$$

But $\mathcal{Z}_W$ is well spread, so by lemma A.5, $\Pr_R\{R \geq r\} < 1/r!$ and the expectation $\mathrm{Exp}_R[e^{\gamma R}]$ can be bounded as follows:

$$\begin{aligned}\mathop{\mathrm{Exp}}_R[e^{\gamma R}] &= \sum_{r \geq 0} e^{\gamma r} \Pr_R\{R = r\} \\ &= \sum_{r \geq 0} e^{\gamma r} \left(\Pr_R\{R \geq r\} - \Pr_R\{R \geq r+1\}\right) \\ &= \sum_{r \geq 0} e^{\gamma r} \Pr_R\{R \geq r\} - \sum_{r \geq 1} e^{\gamma(r-1)} \Pr_R\{R \geq r\} \\ &= 1 + (1 - e^{-\gamma}) \sum_{r \geq 1} e^{\gamma r} \Pr_R\{R \geq r\} \\ &< 1 + \gamma \sum_{r \geq 1} \frac{e^{\gamma r}}{r!} \\ &= 1 + \gamma(e^{e^\gamma} - 1).\end{aligned}$$

So, the probability that $\mathbf{x} \notin \mathbf{T}(\mathcal{Z})$ given F is less than $\gamma(e^{e^\gamma} - 1)$ and

$$\begin{aligned}\Pr_{\mathbf{T}}\{\mathbf{x} \notin \mathbf{T}(\mathcal{Z})\} &\leq \Pr\{\neg F\} + \Pr\{\mathbf{x} \notin \mathbf{T}(\mathcal{Z}) \mid F\} \\ &\leq \epsilon + \gamma(e^{e^\gamma} - 1).\end{aligned}$$

Using the bound $\gamma < \epsilon(1 + 1/(1-\epsilon))$, we get that for all sufficiently small ϵ

$$\Pr_{\mathbf{T}}\{\mathbf{x} \notin \mathbf{T}(\mathcal{Z})\} \leq 5\epsilon.$$

A.4. Strong probabilistic construction. We proved that for every boolean vector $\mathbf{x}$, if $\mathbf{T}$ is chosen as described in Theorem A.7, then with high probability there

exists a $U \in \mathcal{Z}$ such that $\mathbf{T}(U) = \mathbf{x}$. It follows by an averaging argument that with high probability the size of $\mathbf{T}(\mathcal{Z}) \cap \{0,1\}^k$ (the set of all boolean vectors that can be represented as $\mathbf{T}(U)$ for some $U \in \mathcal{Z}$) is almost equal to the size of the whole $\{0,1\}^k$. We now show how to project $\mathbf{T}(\mathcal{Z}) \cap \{0,1\}^k$ onto the set of all binary strings of some shorter length.

For any vector $\mathbf{x} \in \{0,1\}^n$ and subset $G \subseteq \{1,\ldots,n\}$, define the projection $\mathbf{x}|_G \in \{0,1\}^{|G|}$ as the vector obtained taking the coordinates of $\mathbf{x}$ with index in G. The projection operation is extended to set of vectors in the obvious way: $\mathcal{W}|_G = \{\mathbf{x}|G : \mathbf{x} \in \mathcal{W}\}$. The next lemma shows that the probability that a random projection $\mathcal{W}|_G$ covers the whole set $\{0,1\}^G$ of binary strings is at least equal to the density of $|\mathcal{W}|$ in $\{0,1\}^n$.

LEMMA A.8. *Let $\mathcal{W}$ be a subset of $\{0,1\}^n$. If G is chosen uniformly at random among all subsets of $\{1,\ldots,n\}$, then*

$$\Pr_G\left\{\mathcal{W}|_G = \{0,1\}^G\right\} \geq \frac{|\mathcal{W}|}{2^n}.$$

Proof. By induction on n. The base case $n = 0$ is trivially true. (Notice that $\{0,1\}^G = \{0,1\}^n = \{\varepsilon\}$ and $\mathcal{W}|_G = \mathcal{W} = \{0,1\}^G$ iff $|\mathcal{W}| = 1$.) So, assume the statement holds for all $\mathcal{W} \subseteq \{0,1\}^n$ and let us prove it for $\mathcal{W} \subseteq \{0,1\}^{n+1}$. Choose G at random and let $G' = G \setminus \{n+1\}$. Notice that G' is a random subset of $\{1,\ldots,n\}$. Define the following sets:

$$\mathcal{W}_0 = \left\{\mathbf{x} : \begin{bmatrix}\mathbf{x}\\0\end{bmatrix} \in \mathcal{W}\right\}, \qquad \mathcal{W}_1 = \left\{\mathbf{x} : \begin{bmatrix}\mathbf{x}\\1\end{bmatrix} \in \mathcal{W}\right\}.$$

Notice that $|\mathcal{W}| = |\mathcal{W}_0| + |\mathcal{W}_1| = |\mathcal{W}_0 \cup \mathcal{W}_1| + |\mathcal{W}_0 \cap \mathcal{W}_1|$. Moreover, if

(i) either $(n+1) \in G$ and $(\mathcal{W}_0 \cap \mathcal{W}_1)|_{G'} = \{0,1\}^{G'}$
(ii) or $(n+1) \notin G$ and $(\mathcal{W}_0 \cup \mathcal{W}_1)|_{G'} = \{0,1\}^{G'}$,

then $\mathcal{W}|_G = \{0,1\}^G$. Therefore, using the inductive hypothesis, we get

$$\begin{aligned}
\Pr\{\mathcal{W}|_G = \{0,1\}^G\} &\geq \Pr\{(n+1) \in G\} \Pr\{(\mathcal{W}_0 \cup \mathcal{W}_1)|_{G'} = 2^{G'}\} \\
&\quad + \Pr\{(n+1) \notin G\} \Pr\{(\mathcal{W}_0 \cap \mathcal{W}_1)|_{G'} = 2^{G'}\} \\
&\geq \frac{1}{2}\left(\frac{|\mathcal{W}_0 \cup \mathcal{W}_1|}{2^n}\right) + \frac{1}{2}\left(\frac{|\mathcal{W}_0 \cap \mathcal{W}_1|}{2^n}\right) \\
&= \frac{|\mathcal{W}_0 \cup \mathcal{W}_1| + |\mathcal{W}_0 \cap \mathcal{W}_1|}{2^{n+1}} \\
&= \frac{|\mathcal{W}|}{2^{n+1}}. \qquad \square
\end{aligned}$$

Now, we can easily derive Theorem 5.9 from Lemma A.8 and Theorem A.7. Instead of choosing the matrix $\mathbf{T} \in \{0,1\}^{k \times m}$ as specified in Theorem 5.9, we do the following mental experiment. First choose a bigger matrix $\mathbf{T}' \in \{0,1\}^{4k \times n}$ at random by setting each entry to 1 independently with probability $p = \frac{4\epsilon}{dk}$. Then choose a random subset $G \subseteq 1,\ldots,4k$ of its rows. If G has size at least k, set $\mathbf{T}$ to the submatrix of $\mathbf{T}'$ with rows corresponding to the first k elements of G. (If G has less than k elements, the experiment fails.)

Let $\mathcal{W} = \mathbf{T}'(\mathcal{Z}) \cap \{0,1\}^{4k}$. Notice that the probability distribution of matrix $\mathbf{T}$ (conditioned on the event $|G| \geq k$) is the same as in Theorem 5.9. Moreover, if $|G| \geq k$ and $\{0,1\}^G \subseteq \mathcal{W}|_G$ then $\{0,1\}^k \subseteq \mathbf{T}(\mathcal{Z})$. So, we can bound the probability

that matrix $\mathbf{T}$ does not satisfy Theorem 5.9 as the sum of the probabilities that $|G| < k$ and $\{0,1\}^k \not\subseteq \mathbf{T}(\mathcal{Z})$.

Notice that $\mathrm{Exp}[|G|] = 2k$ and $\mathrm{Var}[|G|] = k$. So, by Chebychev's inequality

$$\begin{aligned}\Pr\{|G| < k\} &< \Pr\{||G| - \mathrm{Exp}[|G|]| < k\} \\ &< \frac{\mathrm{Var}[|G|]}{k^2} \\ &= \frac{1}{k} < \epsilon\end{aligned}$$

for all sufficiently large k. Now, let us bound the probability that $\{0,1\}^G \subseteq \mathcal{W}|_G$ when G and $\mathbf{T}'$ are chosen at random. Using Lemma A.8 and the independence of G and $\mathbf{T}'$, one gets

$$\begin{aligned}\Pr_{G,\mathbf{T}'}\{\{0,1\}^G \subseteq \mathcal{W}|_G\} &= \mathop{\mathrm{Exp}}_{\mathbf{T}'}[\Pr_G\{\{0,1\}^G \subseteq \mathcal{W}|_G\}] \\ &\geq \mathop{\mathrm{Exp}}_{\mathbf{T}'}\left[\frac{|\mathcal{W}|}{2^{4k}}\right] \\ &= \mathop{\mathrm{Exp}}_{\mathbf{T}'}\left[\Pr_{\mathbf{x}\in\{0,1\}^{4k}}[\mathbf{x} \in \mathcal{W}]\right] \\ &= \mathop{\mathrm{Exp}}_{\mathbf{x}\in\{0,1\}^{4k}}\left[\Pr_{\mathbf{T}'}[\mathbf{x} \in \mathbf{T}'(\mathcal{Z})]\right] \\ &\geq \min_{\mathbf{x}\in\{0,1\}^{4k}} \Pr_{\mathbf{T}'}\{\mathbf{x} \in \mathbf{T}'(\mathcal{Z})\} \\ &\geq 1 - 5\epsilon.\end{aligned}$$

Therefore the probability that $\{0,1\}^k \not\subseteq \mathbf{T}(\mathcal{Z})$ is at most 5ϵ. By union bound, with probability at least $1 - 6\epsilon$ matrix $\mathbf{T}$ satisfies Theorem 5.9.

Acknowledgments. Many people contributed to this work with useful discussions and comments. I wish to thank all of them. I will not attempt to list them all here, but some of them deserve a special mention. Special thanks to Shafi Goldwasser who convinced me that SVP was NP-hard to approximate and encouraged me to work on this problem, Oded Goldreich who patiently listened to my proofs when I had not even started writing this paper and actively contributed to the proof of Theorem 5.9, and Muli Safra who suggested an important simplification in Lemma 5.2. Thanks also to Miklós Ajtai, whose work has largely inspired the results presented in this paper.

DUAL-BOUNDED GENERATING PROBLEMS: PARTIAL AND MULTIPLE TRANSVERSALS OF A HYPERGRAPH*

ENDRE BOROS†, VLADIMIR GURVICH†, LEONID KHACHIYAN‡, AND KAZUHISA MAKINO§

Abstract. We consider two generalizations of the notion of transversal to a finite hypergraph, the so-called *multiple* and *partial* transversals. Multiple transversals naturally arise in 0-1 programming, while partial transversals are related to data mining and machine learning. We show that for an arbitrary hypergraph the families of multiple and partial transversals are both dual-bounded in the sense that the size of the corresponding dual hypergraph is bounded by a polynomial in the cardinality and the length of description of the input hypergraph. Our bounds are based on new inequalities of extremal set theory and threshold Boolean logic, which may be of independent interest. We also show that the problems of generating all multiple and all partial transversals for a given hypergraph are polynomial-time reducible to the generation of all ordinary transversals for another hypergraph, i.e., to the well-known dualization problem for hypergraphs. As a corollary, we obtain incremental quasi-polynomial-time algorithms for both of the above problems, as well as for the generation of all the minimal binary solutions for an arbitrary monotone system of linear inequalities.

Key words. transversal, independent set, hypergraph, dualization, monotone Boolean function, incremental polynomial time, threshold function, data mining, maximal frequent set, minimal infrequent set

1. Introduction.

In this paper we consider problems involving the generation of all sets of some implicitly given set families. The most well-known problem of this type, the generation of all minimal *transversals* of a given hypergraph, has applications in combinatorics [32], graph theory [21, 23, 33, 35], artificial intelligence [13], game theory [16, 17, 31], reliability theory [10, 31], database theory [1, 27, 36], and learning theory [2, 12].

Given a finite set V of $n = |V|$ points and a hypergraph (set family) $\mathcal{A} \subseteq 2^V$, a subset $B \subseteq V$ is called a *transversal* of the family $\mathcal{A}$ if $A \cap B \neq \emptyset$ for all sets $A \in \mathcal{A}$; it is called a *minimal transversal* if no proper subset of B is a transversal of $\mathcal{A}$. The hypergraph $\mathcal{A}^d$ consisting of all minimal transversals of $\mathcal{A}$ is called the *dual* (or *transversal*) hypergraph of $\mathcal{A}$. It is easy to see that if $A \in \mathcal{A}$ is not minimal in $\mathcal{A}$, that is, if $A' \subset A$ for some $A' \in \mathcal{A}$, then $(\mathcal{A} \setminus \{A\})^d = \mathcal{A}^d$. We can therefore assume that all sets in $\mathcal{A}$ are minimal; in other words, the hypergraph $\mathcal{A}$ is Sperner. (The dual hypergraph $\mathcal{A}^d$ is Sperner by definition.) It is then easy to verify that $(\mathcal{A}^d)^d = \mathcal{A}$ and $\bigcup_{A\in\mathcal{A}} A = \bigcup_{B\in\mathcal{A}^d} B$.

For a subset $X \subseteq V$, let $X^c = V \setminus X$ denote the complement of X and let $\mathcal{A}^c = \{A^c | A \in \mathcal{A}\}$ be the *complementary* hypergraph of $\mathcal{A}$. Then, for instance, $\mathcal{A}^{dc}$ consists of all maximal subsets containing no hyperedge of $\mathcal{A}$, while the hypergraph $\mathcal{A}^{cd}$ consists of all minimal subsets of V which are not contained in any hyperedge of $\mathcal{A}$.

1.1. Dualization. Given a Sperner hypergraph $\mathcal{A}$, a frequently arising task is the generation of the transversal hypergraph $\mathcal{A}^d$. This problem, known as *dualization*, can be stated as follows: *Given a complete list of all hyperedges of $\mathcal{A}$ and a set of minimal transversals $\mathcal{B} \subseteq \mathcal{A}^d$, either prove that $\mathcal{B} = \mathcal{A}^d$, or find a new transversal $X \in \mathcal{A}^d \setminus \mathcal{B}$.*

Clearly, we can generate all of the hyperedges of $\mathcal{A}^d$ by initializing $\mathcal{B} = \emptyset$ and iteratively solving the above problem $|\mathcal{A}^d| + 1$ times. Also note that in general, $|\mathcal{A}^d|$ can be exponentially large in both $|\mathcal{A}|$ and $|V|$. For this reason, the complexity of generating $\mathcal{A}^d$ is customarily measured in the input and output sizes. In particular, we say that $\mathcal{A}^d$ can be generated in *incremental polynomial time* if the dualization problem can be solved in time, polynomial in $|V|, |\mathcal{A}|$, and $|\mathcal{B}|$.

The dualization problem can be efficiently solved for many classes of hypergraphs. For example, if the sizes of all the hyperedges of $\mathcal{A}$ are limited by a constant r, then dualization can be executed in incremental polynomial time (see, e.g., [6, 12, 13]), and it can also be done efficiently in parallel (see [8]). In the quadratic case, i.e., when $r = 2$, there are dualization algorithms that run with *polynomial delay*, i.e., in $poly(|V|, |\mathcal{A}|)$ time, where $\mathcal{B}$ is systematically enlarged from $\mathcal{B} = \emptyset$ during the generation process of $\mathcal{A}^d$ (see, e.g., [21, 23, 35]). Efficient algorithms also exist for the dualization of 2-monotonic, threshold, matroid, read-bounded, acyclic, and some other classes of hypergraphs (see, e.g., [4, 9, 11, 26, 29, 30]).

Even though no incremental polynomial-time algorithm for the dualization of arbitrary hypergraphs is known, an incremental *quasi-polynomial-time* algorithm exists (see [14]). This algorithm solves the dualization problem in $O(nm) + m^{o(\log m)}$ time, where $n = |V|$ and $m = |\mathcal{A}| + |\mathcal{B}|$ (see also [19] for more detail).

In this paper, we consider two natural generalizations of minimal transversals, so-called *multiple transversals* and *partial transversals.* See section 5 for related hypergraphs in the data mining and machine learning literature.

1.2. Multiple transversals. Given a hypergraph $\mathcal{A} \subseteq 2^V$ and a nonnegative weight b_A associated with every hyperedge $A \in \mathcal{A}$, a subset X is called a *multiple transversal* (or *b-transversal*) if $|X \cap A| \geq b_A$ holds for all $A \in \mathcal{A}$. The family of all minimal b-transversals can then also be viewed as the family of support sets of minimal feasible binary solutions to the system of inequalities

$$Ax \geq b, \tag{1.1}$$

where the rows of $A = A_{\mathcal{A}}$ are exactly the characteristic vectors of the hyperedges $A \in \mathcal{A}$ and the corresponding component of b is equal to b_A. Clearly, $b = (1, 1, \ldots, 1)$ corresponds to the case of (ordinary) transversals in which case (1.1) is also known as a *set covering* problem.

Generalizing further and giving up the binary nature of A as well, we shall consider the family $\mathcal{F} = \mathcal{F}_{A,b}$ of (support sets of) all minimal feasible binary vectors to (1.1) for a given $m \times n$-matrix A and a given m-vector b. We assume that (1.1) is a *monotone* system of inequalities: if $x \in \{0,1\}^n$ satisfies (1.1), then any vector $y \in \{0,1\}^n$ such that $y \geq x$ is also feasible. For instance, (1.1) is monotone if A is

nonnegative. Note that for a monotone system (1.1) the dual hypergraph $\mathcal{F}^d = \mathcal{F}^d_{A,b}$ is (the complementarity hypergraph of) the collection of (supports of) all maximal infeasible vectors for (1.1). In what follows, we assume that the hypergraph $\mathcal{F}_{A,b}$ is represented by the system (1.1) and not given explicitly, i.e., by a list of all its hyperedges. In particular, this means that the generation of $\mathcal{F}_{A,b}$ and its dual $\mathcal{F}^d_{A,b}$ are both nontrivial.

Let us consider in general a Sperner hypergraph $\mathcal{F} \subseteq 2^V$ on a finite set V represented in some implicit way and let GEN($\mathcal{F}$) denote the problem of generating all the hyperedges of $\mathcal{F}$: *Given $\mathcal{F}$ and a list of hyperedges $\mathcal{H} \subseteq \mathcal{F}$, either prove that $\mathcal{H} = \mathcal{F}$ or find a new hyperedge in $\mathcal{F} \setminus \mathcal{H}$.*

It is known that problem GEN($\mathcal{F}^d_{A,b}$) is NP-hard even for binary matrices A (see [24]). In contrast, we show that the tasks of generating multiple and ordinary transversals are polynomially related.

THEOREM 1.1. *Problem GEN($\mathcal{F}_{A,b}$) is polytime reducible to dualization.*

In particular, for any monotone system of linear inequalities (1.1), all minimal binary solutions of (1.1) can be generated in quasi-polynomial incremental time. It is also easy to see that if the number of nonzero coefficients in each inequality of $Ax \geq b$ is bounded, then problem GEN($\mathcal{F}_{A,b}$) can be solved in incremental polynomial time.

REMARK 1. *Even though generating all maximal infeasible binary points for* (1.1) *is hard, there is a polynomial randomized scheme for nearly uniform sampling from the set of all binary infeasible points for arbitrary, not necessarily monotone, system* (1.1). *Such a scheme can be obtained by combining the algorithm* [22] *for approximating the size of set-unions with the rapidly mixing random walk* [28] *on the binary cube truncated by a single linear inequality. On the other hand, a similar randomized scheme for nearly uniform sampling from within the set of all binary (or all minimal binary) solutions to a given monotone system* (1.1) *would imply that any NP-complete problem can be solved in polynomial time by a randomized algorithm with arbitrarily small one-sided failure probability. By using the amplification technique of* [20]*, this can already be shown for systems* (1.1) *with two nonzero coefficients per inequality; see* [18] *for more detail.*

1.3. Partial transversals. Given a hypergraph $\mathcal{A} \subseteq 2^V$ and a nonnegative threshold $k < |\mathcal{A}|$, a subset $X \subseteq V$ is said to be a *partial transversal*, or more precisely, a *k-transversal*, to the family $\mathcal{A}$ if it intersects all but at most k of the subsets of $\mathcal{A}$, i.e., if $|\{A \in \mathcal{A} | A \cap X = \emptyset\}| \leq k$.

Denote by $\mathcal{A}^{d_k}$ the family of all minimal k-transversals of $\mathcal{A}$. Clearly, 0-transversals are exactly the standard transversals defined above, i.e., $\mathcal{A}^{d_0} = \mathcal{A}^d$. In what follows, we assume that the hypergraph $\mathcal{A}^{d_k}$ is represented by a list of all the edges of $\mathcal{A}$ along with the value of $k \in \{0, 1, \ldots, |\mathcal{A}| - 1\}$.

Define a *k-union* from $\mathcal{A}$ as the union of some k subsets of $\mathcal{A}$ and let $\mathcal{A}^{u_k}$ denote the family of all minimal k-unions of $\mathcal{A}$. In other words, $\mathcal{A}^{u_k}$ is the family of all the minimal subsets of V which contain at least k hyperedges of $\mathcal{A}$. By the above definitions, k-union and k-transversal families are both Sperner (even if the input hypergraph $\mathcal{A}$ is not). It is also easy to see that the families of all minimal k-transversals and $(k+1)$-unions are in fact dual:

$$\mathcal{A}^{d_k} = (\mathcal{A}^{u_{k+1}})^d, \quad k = 0, 1, \ldots, |\mathcal{A}| - 1.$$

The tasks of generating partial and ordinary transversals also turn out to be polynomially equivalent.

THEOREM 1.2. *Problem GEN($\mathcal{A}^{d_k}$) is polytime reducible to dualization.*

It should be mentioned that the dual problem $\mathrm{GEN}(\mathcal{A}^{u_{k+1}})$ is NP-hard (see [25]).

1.4. Bounding dual hypergraphs. Our proofs of Theorems 1.1 and 1.2 make use of the fact that the Sperner hypergraphs $\mathcal{F}_{A,b}$ and $\mathcal{A}^{d_k}$ are *dual-bounded* in the sense that in both cases, the size of the dual hypergraph can be bounded by a polynomial in the size and the length of description of the primal hypergraph.

THEOREM 1.3. *For any monotone system* (1.1) *of m linear inequalities in n binary variables,*

$$|\mathcal{F}^d_{A,b}| \le mn|\mathcal{F}_{A,b}|.$$

Moreover,

$$|\mathcal{H}^d \cap \mathcal{F}^d_{A,b}| \le mn|\mathcal{H}| \quad \text{for any } \mathcal{H} \subseteq \mathcal{F}_{A,b}. \tag{1.2}$$

THEOREM 1.4. *For any hypergraph $\mathcal{A} \subseteq 2^V$ of $m = |\mathcal{A}|$ hyperedges and any threshold $k = 0, \dots, m-1$, we have*

$$|\mathcal{A}^{u_{k+1}}| \le (m-k)|\mathcal{A}^{d_k}|.$$

Moreover, for any hypergraph $\mathcal{H} \subseteq \mathcal{A}^{d_k}$,

$$|\mathcal{H}^d \cap \mathcal{A}^{u_{k+1}}| \le (m-k)|\mathcal{H}|. \tag{1.3}$$

We derive Theorem 1.3 from the following lemma.

LEMMA 1.5. *Let $h : \{0,1\}^n \to \{0,1\}$ be a monotone Boolean function such that*

$$h(x) = 1 \text{ and } x \in \{0,1\}^n \Rightarrow wx \stackrel{\text{def}}{=} \sum_{i=1}^n w_i x_i \ge t,$$

where $w = (w_1, \dots, w_n)$ is a given weight vector and t is a threshold. If $h \not\equiv 0$, then

$$|\max F(h) \cap \{x \mid wx < t\}| \le \sum_{x \in \min T(h)} ex,$$

where $\max F(h) \subset \{0,1\}^n$ is the set of all maximal false points of h, $\min T(h) \subseteq \{0,1\}^n$ is the set of all minimal true points of h, and e is the vector of all ones. In particular,

$$|\max F(h) \cap \{x \mid wx < t\}| \le n|\min T(h)|.$$

If the function h is threshold ($h(x) = 1 \Leftrightarrow wx \ge t$), then $|\max F(h)| \le n|\min T(h)|$ and, by symmetry, $|\min T(h)| \le n|\max F(h)|$ hold, which are well-known inequalities (see [4, 11, 29, 30]). Lemma 1.5 thus extends the above threshold inequalities to arbitrary monotone functions h.

As we shall see, Theorem 1.4 can be derived from the following combinatorial inequality.

LEMMA 1.6. *Given a base set U of size $|U| = m$ and a threshold $k \in \{0, \dots, m-1\}$, let $\mathcal{S} = \{S_1, \dots, S_\alpha\}$ and $\mathcal{T} = \{T_1, \dots, T_\beta\}$ be two families of subsets of U for which*

$$\begin{aligned} |S| &\ge k+1 \quad \text{for all } S \in \mathcal{S}, \\ |T| &\le k \quad \text{for all } T \in \mathcal{T}, \end{aligned} \tag{1.4}$$

and such that for each of the $\alpha(\alpha-1)/2$ *pairs* $S', S'' \in \mathcal{S}$ *there exists a* $T \in \mathcal{T}$ *with* $S' \cap S'' \subseteq T$. *Then*

$$\alpha \leq (m-k)\beta \tag{1.5}$$

whenever $\alpha \geq 2$.

Let us first remark that if $\alpha = 1$, then the family $\mathcal{T}$ might be empty, which would violate the inequality (1.5); otherwise $\beta \geq 1$ must hold whenever $\alpha \geq 2$, since at least one set is needed to cover the intersections of the $\binom{\alpha}{2} \geq 1$ pairs of sets from $\mathcal{S}$. In addition, the assumptions of the lemma imply that the family $\mathcal{S}$ must be Sperner, since $S_i \subseteq S_j$ for some $i \neq j$ would give $S_i = S_i \cap S_j \subseteq T_l$ for some $T_l \in \mathcal{T}$, contradicting (1.4). We can further assume the family $\mathcal{T}$ to be Sperner, without any loss of generality, for otherwise we could replace $\mathcal{T}$ by the family of all maximal sets of $\mathcal{T}$.

Let us mention next the special case of Lemma 1.6 for $\mathcal{T} = \mathcal{S}^{\cap}$, where $\mathcal{S}^{\cap}$ is the family of all the maximal subsets of U which can be obtained as the intersection of two distinct hyperedges of $\mathcal{S}$. For a Sperner hypergraph $\mathcal{S}$ on m vertices such that each hyperedge of $\mathcal{S}$ contains at least $k+1$ vertices and $|S' \cap S''| \leq k$ for any two distinct hyperedges S', S'' of $\mathcal{S}$, Lemma 1.6 yields the inequality (cf. [7])

$$|\mathcal{S}| \leq (m-k)|\mathcal{S}^{\cap}|. \tag{1.6}$$

We discuss some generalizations of this inequality in section 4.4. (Several other inequalities on hypergraphs with restricted intersections can be found in Chapter 4 of [3].)

Let us remark finally that the thresholdness condition (1.4) is essential for the validity of Lemma 1.6—without (1.4) the size of $\mathcal{S}$ can be exponentially larger than that of $\mathcal{S}^{\cap}$. In section 4.2 we give examples of Sperner hypergraphs $\mathcal{S}$ on m vertices for which $|\mathcal{S}^{\cap}| = m/5$ and $|\mathcal{S}| = 3^{m/5} + 2m/5$ or $|\mathcal{S}^{\cap}| = (m-2)^2/9$ and $|\mathcal{S}| = 3^{(m-2)/3} + 2(m-2)/3$.

The remainder of the paper is organized as follows. In section 2 we discuss the complexity of jointly generating a pair of dual hypergraphs defined via a superset oracle. For a polynomial-time superset oracle the above problem reduces to dualization. This reduction, along with the bounds stated in Theorems 1.3 and 1.4, yield Theorems 1.1 and 1.2. In section 3 we consider minimal 0-1 solutions to systems of monotone linear inequalities and prove Lemma 1.5 and Theorem 1.3. Section 4 deals with partial transversals and proves Lemma 1.6 and Theorem 1.4. Finally, section 5 discusses some of the related set families and results, and section 6 contains our concluding remarks.

2. Joint and separate generation of dual hypergraphs.

2.1. Superset oracles. Let $\mathcal{G} \subseteq 2^V$ be a Sperner hypergraph on n vertices. In many applications, $\mathcal{G}$ is represented by a *superset oracle* and not given explicitly. Such an oracle can be viewed as an algorithm which, given an input description $\mathfrak{D}$ of $\mathcal{G}$ and a vertex set $X \subseteq V$, can decide whether or not X contains a hyperedge of $\mathcal{G}$. We assume that the length $|\mathfrak{D}|$ of the input description of $\mathcal{G}$ is at least n and denote by $T_s = T_s(|\mathfrak{D}|)$ the worst-case running time of the oracle on any superset query "Does X contain a hyperedge of $\mathcal{G}$?" In particular, $\mathfrak{D}$ is polynomial-time if $T_s \leq poly(|\mathfrak{D}|)$. In what follows, we do not distinguish the superset oracle and the input description $\mathfrak{D}$ of $\mathcal{G}$. Note that a vertex set X contains a hyperedge of $\mathcal{A}^d$ if and only if the complement

of X contains no hyperedge of $\mathcal{A}$. For this reason, $\mathfrak{O}$ also specifies (a superset oracle for) the dual hypergraph $\mathcal{G}^d$. We list below several simple examples.

(1) *Multiple transversals.* Let (1.1) be a monotone system of linear inequalities and let $\mathcal{G} = \mathcal{F}_{A,b}$ be the hypergraph introduced in section 1.2. Then the input description $\mathfrak{O}$ is (A, b). Clearly, for any input set $X \subseteq V$, we can decide whether X contains a hyperedge of $\mathcal{F}_{A,b}$ by checking the feasibility of (the characteristic vector of) X for (1.1).

(2) *Partial transversals.* Let $\mathcal{G} = \mathcal{A}^{d_k}$ be the hypergraph of the minimal k-transversals of a family $\mathcal{A}$ (see section 1.2). Then $\mathcal{G}$ is given by the threshold value k and a complete list of all hyperedges of $\mathcal{A}$, i.e., $\mathfrak{O} \sim (k, \mathcal{A})$. For a subset $X \subseteq V$, determining whether X contains a hyperedge in $\mathcal{A}^{d_k}$ is equivalent to checking if X is intersecting at least $|\mathcal{A}| - k$ hyperedges of $\mathcal{A}$.

(3) *Monotone Boolean formulae.* Let f be a $(\vee, \wedge)$-formula with n variables and let $\mathcal{G} = \mathcal{A}_f$ be the supporting sets of all the minimal true vectors for f. Then $\mathfrak{O} \sim f$ and the superset oracle checks if (the characteristic vector of) $X \subseteq V$ satisfies f. The dual hypergraph $\mathcal{G}^d$ is the set of all the (complements to the support sets of) maximal false vectors of f.

(4) *Two-terminal connectivity.* Consider a digraph Γ with a source s and a sink t, each arc of which is assigned a *relay* $r \in V$ (two or more distinct edges may be assigned identical relays). Let $\mathcal{G}$ be the set of *relay s-t paths*, i.e., minimal subsets of relays that connect s and t. Then $\mathfrak{O} \sim \Gamma$, and for a given relay set $X \subseteq V$, the superset oracle can use breadth-first search to check the reachability of t from s via a path consisting of relays in X. Note that the dual hypergraph $\mathcal{G}^d$ is the set of all relay *s-t cuts*, i.e., minimal subsets of relays that disconnect s and t.

(5) *Helly's systems of polyhedra.* Consider a family of n convex polyhedra $P_i \subseteq \mathbb{R}^r$, $i \in V$, and let $\mathcal{G}$ denote the minimal subfamilies with no point in common. Then $\mathcal{G}^{dc}$ is the family of all maximal subfamilies with a nonempty intersection. (In particular, if $P_1, \ldots, P_n$ are the facets of a convex polytope Q, then $\mathcal{G}^{dc}$ corresponds to the set of vertices of Q.) We have $\mathfrak{O} \sim (P_1, \ldots, P_n)$ and, given subsets of polytopes $X \subseteq V$, the superset oracle can use linear programming to check whether $\cap_{i \in X} P_i \neq \emptyset$.

2.2. Joint generation of dual pairs of hypergraphs. In all of the above examples, we have pairs of dual Sperner hypergraphs given by polynomial-time superset oracles. Let $\mathcal{G}, \mathcal{G}^d \subseteq 2^V$ be a pair of dual Sperner hypergraphs given by a superset oracle $\mathfrak{O}$. Consider the problem GEN$(\mathcal{G}, \mathcal{G}^d)$ of *generating jointly* all the hyperedges of $\mathcal{G}$ and $\mathcal{G}^d$: *Given two explicitly listed set families $\mathcal{A} \subseteq \mathcal{G}$ and $\mathcal{B} \subseteq \mathcal{G}^d$, either prove that these families are complete, $(\mathcal{A}, \mathcal{B}) = (\mathcal{G}, \mathcal{G}^d)$, or find a new set in $(\mathcal{G} \setminus \mathcal{A}) \cup (\mathcal{G}^d \setminus \mathcal{B})$.*

For the special case when $\mathcal{A} = \mathcal{G}$ and $\mathfrak{O}$ is a list of all the sets in $\mathcal{G}$, we obtain the dualization problem as stated in section 1.1. In fact, as observed in [5, 18], for any polynomial-time superset oracle $\mathfrak{O}$, problem GEN$(\mathcal{G}, \mathcal{G}^d)$ can be reduced in polynomial time to dualization. This can be done via the following Algorithm $\mathcal{J}$.

Step 1. Check whether each element of $\mathcal{B}$ is a minimal transversal to $\mathcal{A}$, i.e., $\mathcal{B} \subseteq \mathcal{A}^d$. (Recall that $\mathcal{A}$ and $\mathcal{B}$ are given explicitly.) Note that each set $X \in \mathcal{B}$ is a transversal to $\mathcal{A}$ because $\mathcal{A} \subseteq \mathcal{G}$ and $\mathcal{B} \subseteq \mathcal{G}^d$. If some transversal $X \in \mathcal{B}$ is not *minimal* for $\mathcal{A}$, then we can easily find a proper subset Y of X such that Y is also a transversal to $\mathcal{A}$. Since Y is a proper subset of X, and X is a minimal transversal to $\mathcal{G}$, Y must miss some hyperedges of $\mathcal{G}$. Hence Y^c, the complement of Y, contains a hyperedge of $\mathcal{G}$. By querying the superset oracle $\mathfrak{O}$ at most $|Y^c|$ times we can find such a hyperedge $Z \in \mathcal{G}$. Note that $Z \cap Y = \emptyset$, whereas $A \cap Y \neq \emptyset$ for all hyperedges $A \in \mathcal{A}$. This means that

Z is a new hyperedge of $\mathcal{G}$. Thus, if the inclusion $\mathcal{B} \subseteq \mathcal{A}^d$ is not satisfied, we can obtain an element in $\mathcal{G} \setminus \mathcal{A}$ and halt.

Step 2. Step 2 is similar to Step 1. Check whether $\mathcal{A} \subseteq \mathcal{B}^d$. If $\mathcal{A}$ contains a nonminimal transversal to $\mathcal{B}$, find a new element in $\mathcal{G}^d \setminus \mathcal{B}$ and halt.

Step 3. Suppose that $\mathcal{B} \subseteq \mathcal{A}^d$ and $\mathcal{A} \subseteq \mathcal{B}^d$. Then $\mathcal{B} = \mathcal{A}^d \Rightarrow (\mathcal{A}, \mathcal{B}) = (\mathcal{G}, \mathcal{G}^d)$. (This is because any hyperedge $X \in \mathcal{G} \setminus \mathcal{A}$ would be a transversal for $\mathcal{B}$, which would then imply that X contains some hyperedge of $\mathcal{A} = \mathcal{B}^d$, a contradiction. By symmetry, the duality of $\mathcal{A}$ and $\mathcal{B}$ also implies the emptiness of $\mathcal{G}^d \setminus \mathcal{B}$.) Hence $(\mathcal{A}, \mathcal{B}) = (\mathcal{G}, \mathcal{G}^d) \Leftrightarrow \mathcal{B} = \mathcal{A}^d$. The condition $\mathcal{B} = \mathcal{A}^d$ can be checked by solving the dualization problem for $\mathcal{A}$ and $\mathcal{B}$. If $\mathcal{B} \neq \mathcal{A}^d$, we obtain a new minimal transversal $X \in \mathcal{A}^d \setminus \mathcal{B}$; see section 1.1. By definition, X contains no hyperedge in $\mathcal{B}$ and X^c contains no hyperedge in $\mathcal{A}$. Due to the duality of $\mathcal{G}$ and $\mathcal{G}^d$, either (i) X^c contains a hyperedge of $\mathcal{G}$ or (ii) X contains a hyperedge of $\mathcal{G}^d$ but not both. We can call the superset oracle to decide which of the two cases holds. In case (i) we obtain a new hyperedge in $\mathcal{G} \setminus \mathcal{A}$ by querying the superset oracle at most $|X^c|$ times. Similarly, in case (ii) we get a new hyperedge in $\mathcal{G}^d \setminus \mathcal{B}$ in at most $|X|$ calls to the oracle.

Algorithm $\mathcal{J}$ readily implies the following result.

PROPOSITION 2.1 (see [5, 18]). *Problem GEN$(\mathcal{G}, \mathcal{G}^d)$ can be solved in $n\,(poly(|\mathcal{A}|, |\mathcal{B}|) + T_s(|\mathfrak{D}|)) + T_{dual}$ time, where T_{dual} denotes the time required for solving the dualization problem with $\mathcal{A}$ and $\mathcal{B}$.*

In particular, for any (quasi-)polynomial-time oracle $\mathfrak{D}$, problem GEN$(\mathcal{G}, \mathcal{G}^d)$ can be solved in quasi-polynomial time. Thus, for each of the five examples above we can jointly generate all the hyperedges of $(\mathcal{G}, \mathcal{G}^d)$ in incremental quasi-polynomial time. Note, however, that separately generating all the hyperedges of $\mathcal{G}$ or all the hyperedges of $\mathcal{G}^d$ may be substantially harder. For instance, as shown in [18], both problems GEN$(\mathcal{G})$ and GEN$(\mathcal{G}^d)$ are NP-hard for examples 3–5 above. In fact, in example 3 these problems are already NP-hard for $\vee, \wedge$-formulae of depth 3; if the depth is 2, then the formula is either a CNF or a DNF, and we get exactly dualization.

2.3. Dual-bounded hypergraphs. Algorithm $\mathcal{J}$ may not be efficient for solving either of the problems GEN$(\mathcal{G})$ or GEN$(\mathcal{G}^d)$ separately for the simple reason that we do not control which of the families $\mathcal{G} \setminus \mathcal{A}$ and $\mathcal{G}^d \setminus \mathcal{B}$ contains each new hyperedge produced by the algorithm. Suppose we want to generate $\mathcal{G}$ and the family $\mathcal{G}^d$ is exponentially larger than $\mathcal{G}$. Then, if we are unlucky, we can get hyperedges of $\mathcal{G}$ with exponential delay while getting large subfamilies of $\mathcal{G}^d$ (which are not needed at all) in between.

Such a problem will not arise and simultaneous generation of $(\mathcal{G}, \mathcal{G}^d)$ can be used to produce $\mathcal{G}$ efficiently, in some sense, if the size of $\mathcal{G}^d$ is polynomially limited in the size of $\mathcal{G}$ and in the input size $|\mathfrak{D}|$, or more precisely, when there exists a polynomial p such that

$$|\mathcal{G}^d| \leq p(|V|, |\mathfrak{D}|, |\mathcal{G}|). \tag{2.1}$$

We call such Sperner hypergraphs $\mathcal{G}$ *dual-bounded*.

If $\mathcal{G}$ is dual-bounded, we can generate both $\mathcal{G}$ and $\mathcal{G}^d$ in $|\mathcal{G}^d| + |\mathcal{G}| \leq poly(|V|, |\mathfrak{D}|, |\mathcal{G}|)$ rounds of Algorithm $\mathcal{J}$, and hence obtain all the hyperedges of $\mathcal{G}$ in *total quasi-polynomial* time.

This approach, however, may still be inefficient incrementally, i.e., for obtaining a single hyperedge of $\mathcal{G}$ as required in problem GEN$(\mathcal{G})$. It is easy to see that the decision problem "given a family $\mathcal{A} \subseteq \mathcal{G}$, determine whether $\mathcal{A} = \mathcal{G}$" is polynomially reducible

to dualization for any dual-bounded hypergraphs represented by a polynomial-time superset oracle. If $\mathcal{A}$ is much smaller than $\mathcal{G}$, however, getting a new hyperedge in $\mathcal{G} \setminus \mathcal{A}$ may require exponentially many (in $|\mathcal{A}|$) rounds of $\mathcal{J}$.

2.4. Uniformly dual-bounded hypergraphs. Let us call a Sperner hypergraph $\mathcal{G}$ *uniformly dual-bounded* if

$$|\mathcal{H}^d \cap \mathcal{G}^d| \leq p(|V|, |\mathfrak{D}|, |\mathcal{H}|) \text{ for any hypergraph } \mathcal{H} \subseteq \mathcal{G}.$$

Note that for $\mathcal{H} = \mathcal{G}$ the above condition gives (2.1).

PROPOSITION 2.2. *Problem GEN($\mathcal{G}$) is polytime reducible to dualization for any uniformly dual-bounded hypergraph $\mathcal{G}$ defined by a polynomial-time superset oracle.*

Proof. Given a proper subfamily $\mathcal{A}$ of $\mathcal{G}$, we wish to find a new hyperedge $\mathcal{G} \setminus \mathcal{A}$. Start with the given $\mathcal{A}$ and $\mathcal{B} = \emptyset$ and run Algorithm $\mathcal{J}$ repeatedly until it outputs a required hyperedge. Suppose this takes t rounds of $\mathcal{J}$; then $\mathcal{J}$ produces $t-1$ hyperedges of $\mathcal{G}^d$, each of which is also a hyperedge of $\mathcal{A}^d$; see Step 1 of the algorithm. Since $\mathcal{G}$ is uniformly dual-bounded, we have $t-1 \leq |\mathcal{A}^d \cap \mathcal{G}^d| \leq p(|V|, |\mathfrak{D}|, |\mathcal{A}|)$. ∎

Theorems 1.3 and 1.4 state that the hypergraphs $\mathcal{F}_{A,b}$ and $\mathcal{A}^{d_k}$ are both uniformly dual-bounded. In view of Proposition 2.2, this means that Theorems 1.3 and 1.4 imply Theorems 1.1 and 1.2, respectively.

3. Minimal solutions of monotone 0-1 inequalities. In this section, we prove Lemma 1.5 and Theorem 1.3.

3.1. Proof of Lemma 1.5. Suppose that some of the coefficients $w_1, \ldots, w_n$ are negative, say, $w_1 < 0, \ldots, w_r < 0$ and $w_{r+1} \geq 0, \ldots, w_n \geq 0$. Since $wx = w_1x_1 + \ldots + w_nx_n \geq t$ for any true point of $h(x)$ and $h(x)$ is monotone, each true point of $h(x)$ satisfies $w'x \geq t'$, where $w' = (0, \ldots, 0, w_{r+1}, \ldots, w_n) \geq 0$ and $t' = t - (w_1 + \cdots + w_r)$. Since $wx < t \Rightarrow w'x < t'$ for any binary x, it suffices to prove the lemma for w' and t'. Hence we may assume without loss of generality that all the n components of w are nonnegative. Now we prove the lemma by induction on n with the trivial base $n = 1$.

For $i \in \{1, 2, \ldots, n\}$, let $h_i = h|_{x_i=0}$ denote the restriction of h on the hyperplane $\{x \mid x_i = 0\}$. We split the proof into two cases.

Case 1. Suppose that for some variable, say, x_1, we have $h_1(x_2, x_3, \ldots, x_n) \equiv 0$, i.e., $h = x_1 q(y)$, where $y = (x_2, x_3, \ldots, x_n)$ and $q(y)$ is some monotone Boolean function. Then $\min T(h) = \{(1, y) \mid y \in \min T(q)\}$; consequently, $|\min T(h)| = |\min T(q)|$ and

$$\sum_{x \in \min T(h)} ex = |\min T(q)| + \sum_{y \in \min T(q)} ey. \tag{3.1}$$

Similarly, we have

$$\max F(h) = \{(1, y) \mid y \in \max F(q)\} \cup \{(0, e)\},$$

which implies

$$|\max F(h) \cap \{x \mid wx < t\}| \leq 1 + |\max F(q) \cap \{y \mid w'y < t - w_1\}|,$$

where $w' = (w_2, \ldots, w_n)$. Since $q \not\equiv 0$, we have

$$|\max F(q) \cap \{y \mid w'y < t - w_1\}| \leq \sum_{y \in \min T(q)} ey$$

by the induction hypothesis. Hence

$$|\max F(h) \cap \{x \mid wx < t\}| \leq 1 + \sum_{y \in \min T(q)} ey.$$

Therefore,

$$1 + \sum_{y \in \min T(q)} ey \leq |\min T(q)| + \sum_{y \in \min T(q)} ey,$$

which in view of (3.1) completes the inductive proof for Case 1.

Case 2. Let us now assume that $h_i \not\equiv 0$ for all $i = 1, \ldots, n$. It is easy to see that

$$\min T(h) \cap \{x \mid x_i = 0\} = \{(0, y) \mid y \in \min T(h_i)\}, \tag{3.2}$$

$$\max F(h) \cap \{x \mid x_i = 0\} \subseteq \{(0, y) \mid y \in \max F(h_i)\}. \tag{3.3}$$

Since $h_i \not\equiv 0$, we can apply the inductive hypothesis to each h_i to obtain the inequalities

$$|\{(0, y) \mid y \in \max F(h_i)\} \cap \{x \mid wx < t\}| \leq \sum_{x \in \min T(h_i)} ex,$$

from which by (3.3) we get

$$|\max F(h) \cap \{x \mid x_i = 0, wx < t\}| \leq \sum_{x \in \min T(h_i)} ex$$

for $i = 1, \ldots, n$. By multiplying the above inequalities by the nonnegative weights w_i and summing up the resulting bounds for all i, we obtain

$$\sum_{\substack{x \in \max F(h) \\ x_i = 0, wx < t}} w_i \leq \sum_{i=1}^{n} w_i \sum_{x \in \min T(h_i)} ex. \tag{3.4}$$

We can rewrite the left-hand side as

$$\sum_{\substack{x \in \max F(h) \\ x_i = 0, wx < t}} w_i = \sum_{\substack{x \in \max F(h) \\ wx < t}} \sum_{i : x_i = 0} w_i = \sum_{x \in \max F(h) \cap \{x \mid wx < t\}} w\bar{x},$$

where $\bar{x}$ is the complement of x, i.e., $\bar{x}_i = 1 - x_i$ for all i. Similarly, by using (3.2) on the right-hand side of (3.4) we can get

$$\sum_{i=1}^{n} w_i \sum_{x \in \min T(h_i)} ex = \sum_{x \in \min T(h)} ex \sum_{i : x_i = 0} w_i = \sum_{x \in \min T(h)} w\bar{x} \cdot ex.$$

Thus, (3.4) can be written equivalently as

$$\sum_{x \in \max F(h) \cap \{x \mid wx < t\}} w\bar{x} \leq \sum_{x \in \min T(h)} w\bar{x} \cdot ex.$$

Let $\omega = w_1 + \cdots + w_n$; then $w\bar{x} = \omega - wx \leq \omega - t$ for all $x \in \min T(h)$. In addition, we have $\omega - t < w\bar{x}$ for any point in the open half-space $\{x \mid wx < t\}$. Hence

$$(\omega - t)|\max F(h) \cap \{x \mid wx < t\}| \leq (\omega - t) \sum_{x \in \min T(h)} ex.$$

If $\omega - t \leq 0$, then $\omega = t$ (since $h \neq 0$) and thus $\min T(h)$ contains exactly one point from which the lemma follows. Otherwise we can cancel out the multiplicative factor $\omega - t$ and complete the proof. □

3.2. Proof of Theorem 1.3. To show (1.2) for a hypergraph $\mathcal{H} \subseteq \mathcal{F}_{A,b}$, define the monotone Boolean function $h(x)$ by the condition

$$h(x) = 1 \quad \Leftrightarrow \quad x \geq char(H) \text{ for some } \ H \in \mathcal{H},$$

where $char(H)$ is the characteristic vector of H. Note that since $\mathcal{H} \subseteq \mathcal{F}_{A,b}$ and the characteristic vector of any hyperedge of $\mathcal{F}_{A,b}$ satisfies the monotone system (1.1), each true point of $h(x)$ satisfies (1.1), i.e.,

$$h(x) = 1 \ \text{ and } \ x \in \{0,1\}^n \quad \Rightarrow \quad Ax \geq b. \tag{3.5}$$

Also note that since $\mathcal{H} \subseteq \mathcal{F}_{A,b}$ is Sperner, we have

$$|\min T(h)| = |\mathcal{H}|. \tag{3.6}$$

In addition, if $X \in \mathcal{H}^d$, then X^c contains no hyperedge of $\mathcal{H}$ and hence $char(X^c)$ is a false point of h. It is easily seen that $char(X^c)$ is a *maximal* false point of h, for otherwise X would not be a minimal transversal for $\mathcal{H}$. Thus,

$$char(X^c) \in \max F(h) \text{ for any } \ X \in \mathcal{H}^d. \tag{3.7}$$

By the definition of $\mathcal{F}^d_{A,b}$, the inclusion $X \in \mathcal{F}^d_{Ab}$ implies that $char(X^c)$ is infeasible for (1.1). In view of (3.7), this gives

$$|\mathcal{H}^d \cap \mathcal{F}^d_{A,b}| \leq \sum_{i=1}^{m} |\max F(h) \cap \{x \mid a_i x < b_i\}|,$$

where $a_i x \geq b_i$ is the ith inequality of (1.1). By (3.5) we can apply Lemma 1.5 to the monotone Boolean function h to obtain

$$|\max F(h) \cap \{x \mid a_i x < b_i\}| \leq n |\min T(h)|.$$

Now (1.2) follows from (3.6). □

4. Partial transversals. In this section, we prove Lemma 1.6 and Theorem 1.4.

4.1. Proof of Lemma 1.6. We shall prove the lemma by induction on k. If $k = 0$, then $\mathcal{T} = \{\emptyset\}$ by condition (1.4), thus implying that $\beta = 1$ and that the sets of $\mathcal{S}$ are pairwise disjoint. Hence $\alpha \leq m = (m-k)\beta$ follows.

In a general step, let us define subfamilies $\mathcal{S}_v = \{S \setminus \{v\} \mid S \in \mathcal{S},\ v \in S\}$ and $\mathcal{T}_v = \{T \setminus \{v\} \mid T \in \mathcal{T},\ v \in T\}$ for each $v \in U$. Let us further introduce the notations $\alpha_v = |\mathcal{S}_v|$, and $\beta_v = |\mathcal{T}_v|$.

For vertices $v \in U$ for which $\alpha_v \geq 2$ (and thus $\beta_v \geq 1$) the families $\mathcal{S}_v$ and $\mathcal{T}_v$ satisfy all the assumptions of the lemma with $m' = m - 1$ and $k' = k - 1$, and hence

$$\alpha_v \leq (m' - k')\beta_v = (m-k)\beta_v \tag{4.1}$$

follows by the inductive hypothesis. Then let us consider the partition $U = U_1 \cup U_2$, where $U_1 = \{v \in U \mid \alpha_v \leq 1\}$ and $U_2 = \{v \in U \mid \alpha_v \geq 2\}$. Summing up the inequalities (4.1) for all $v \in U_2$, we obtain

$$\sum_{v \in U_2} \alpha_v \leq (m-k) \sum_{v \in U_2} \beta_v. \tag{4.2}$$

On the left-hand side, using the thresholdness conditions (1.4) and the definition of α_v we obtain

$$\begin{aligned}\alpha(k+1)-|U_1| &\le \sum_{S\in\mathcal{S}} |S|-|U_1| \\ &\le \sum_{S\in\mathcal{S}} (|S|-|S\cap U_1|) \\ &= \sum_{S\in\mathcal{S}} |S\cap U_2| \\ &= \sum_{v\in U_2} \alpha_v,\end{aligned} \tag{4.3}$$

where the first inequality follows by $|S|\ge k+1$ for $S\in\mathcal{S}$, the second one is implied by $|U_1|\ge\sum_{S\in\mathcal{S}}|S\cap U_1|$ following from the definition of U_1, while the equations follow from the definitions of α_v, U_1, and U_2.

On the right-hand side of (4.1) we can write

$$\begin{aligned}\sum_{v\in U_2}\beta_v &= \sum_{T\in\mathcal{T}} |T\cap U_2| \\ &\le \sum_{T\in\mathcal{T}} |T| \\ &\le \beta k,\end{aligned} \tag{4.4}$$

where the first equality follows by the definition of β_v and $\mathcal{T}_v$ and the last inequality follows by the conditions $|T|\le k$ for $T\in\mathcal{T}$.

Putting together (4.2), (4.3), and (4.4) we obtain $(k+1)\alpha-|U_1|\le(m-k)k\beta$, or equivalently that

$$\alpha \le \frac{|U_1|}{k+1}+\frac{k}{k+1}(m-k)\beta. \tag{4.5}$$

If $|U_1|\le m-k$, then

$$\frac{|U_1|}{k+1}+\frac{k}{k+1}(m-k)\beta \le (m-k)\beta,$$

and hence $\alpha\le(m-k)\beta$ by (4.5). On the other hand, if $|U_1|>m-k$, then for each set $S\in\mathcal{S}$ we have $|S\cap U_1|\ge|S|-|U_2|\ge(k+1)-|U_2|>1$. Now by the definition of the set U_1 we obtain $\alpha\le|U_1|/(k+1-|U_2|)=(m-|U_2|)/(k+1-|U_2|)\le m-k\le(m-k)\beta$. ∎

4.2. Exponentially large Sperner families with few maximal intersections. Let s be a positive integer, and let U be a finite set of $m=2+3s$ elements, consisting of two special vertices a,b and s disjoint sets $U_1,\dots,U_s$ of size 3 each. Let us consider the hypergraph $\mathcal{S}$ with $\alpha=2s+3^s$ hyperedges of the following three types:

(a) $U\setminus(\{a\}\cup U_i)$, $i=1,\dots,s$,
(b) $U\setminus(\{b\}\cup U_i)$, $i=1,\dots,s$,.
(c) 3^s hyperedges obtained by selecting exactly one vertex from each U_i.

It is easy to see that $\mathcal{S}^\cap$ consists of exactly $s+2\binom{s}{2}=s^2$ maximal intersections, namely, the sets $U\setminus(\{a\}\cup\{b\}\cup U_i)$, for $i=1,\dots,s$, and $U\setminus(\{a\}\cup U_i\cup U_j)$ and $U\setminus(\{b\}\cup U_i\cup V_j)$ for $1\le i<j\le s$.

As another example, let $m = 5s$ and let U contain two additional vertices a_i, b_i for every 3-element set U_i. Consider the hypergraph $\mathcal{S}'$ defined by the 3^s hyperedges of the form as in (c) above and by $2s$ additional edges of the form $\{a_i\} \cup (W \setminus U_i)$ and $\{b_i\} \cup (W \setminus U_i)$, where $W = \cup_{j=1}^{s} U_j$ and $i = 1, \dots, s$. Then $\mathcal{S}'$ has exactly s maximal intersections, namely, the sets $W \setminus U_i$ for $i = 1, 2, \dots, s$.

4.3. Proof of Theorem 1.4. Given a hypergraph $\mathcal{A} \subseteq 2^V$ of m hyperedges on an n-element vertex set V, let $\phi : 2^V \to 2^{\{1,\dots,m\}}$ be the monotone mapping which assigns to a vertex set $X \subseteq V$ the subset $\phi(X) \subseteq U \doteq \{1, 2, \dots, m\}$ of indices of all those hyperedges of $\mathcal{A}$ which are contained in X, i.e., $\phi(X) = \{i \mid A_i \subseteq X,\ 1 \le i \le m\}$. Note that for any two sets $X, Y \subseteq V$ we have the identity

$$\phi(X) \cap \phi(Y) \equiv \phi(X \cap Y). \tag{4.6}$$

Let $\mathcal{H} = \{H_1, \dots, H_\beta\} \subseteq 2^V$ be an arbitrary nonempty collection of k-transversals for $\mathcal{A}$. To show that $\mathcal{H}$ satisfies inequality (1.3), consider the (multi-)hypergraph $\mathcal{T} = \{\phi(H_1^c), \dots, \phi(H_\beta^c)\}$. Since each $H_l \in \mathcal{H}$ is a k-transversal to $\mathcal{A}$, the complement of H_l contains at most k hyperedges of $\mathcal{A}$. Hence $|\phi(H_l^c)| \le k$, i.e., the size of each hyperedge of $\mathcal{T}$ is at most k.

Let the hypergraph $\mathcal{H}^d \cap \mathcal{A}^{u_{k+1}}$ consist of α hyperedges, say, $\mathcal{H}^d \cap \mathcal{A}^{u_{k+1}} = \{X_1, \dots, X_\alpha\} \subseteq 2^V$. Consider the (multi-)hypergraph $\mathcal{S} = \{\phi(X_1), \dots, \phi(X_\alpha)\}$. Since $X_1, \dots, X_\alpha$ are $(k+1)$-unions, each hyperedge of $\mathcal{S}$ has size at least $k+1$.

Now let us show that for any two distinct indices $1 \le i < j \le \alpha$, the intersection of the hyperedges $\phi(X_i)$ and $\phi(X_j)$ is contained in a hyperedge of $\mathcal{T}$. In view of (4.6) we have to show that $\phi(X_i \cap X_j)$ is contained in some hyperedge of $\mathcal{T}$. To this end, observe that $\mathcal{H}^d \cap \mathcal{A}^{u_{k+1}}$ is a Sperner hypergraph, and hence $X_i \cap X_j$ is a proper subset of X_i. However, $X_i \in \mathcal{H}^d \cap \mathcal{A}^{u_{k+1}}$ is a minimal transversal to $\mathcal{H}$. For this reason, $X_i \cap X_j$ misses a hyperedge of $\mathcal{H}$, say, H_l. Equivalently, $X_i \cap X_j \subseteq H_l^c$ which implies $\phi(X_i \cap X_j) \subseteq \phi(H_l^c) \in \mathcal{T}$. Now inequality (1.3) and Theorem 1.4 readily follow from Lemma 1.6. □

4.4. Generalized intersection inequalities. In this section we list some generalizations of the intersection inequality (1.6).

A hypergraph $\mathcal{S}$ on a base set V of size $m = |U|$ is called *l-covering* if every l points of U belong to at least two hyperedges of $\mathcal{S}$ or, in other words, to a maximal intersection in $\mathcal{S}^\cap$. Let $\mathcal{S}$ be an l-covering hypergraph satisfying the following thresholdness conditions: $|S| \ge k+1$ for all $S \in \mathcal{S}$ and $|S' \cap S''| \le k$ for any pair of distinct hyperedges $S', S'' \in \mathcal{S}$. Then the following inequality can be shown to hold for any $l \le k$:

$$|\mathcal{S}| \le |\mathcal{S}^\cap|(m-k)[1 - l/(k+1)].$$

Since every hypergraph is 0-covering, this is always at least as strong as (1.6).

Next let us assume that $|S| \ge k+1$ for all $S \in \mathcal{S}$, while $|T| \le k'$ for all $T \in \mathcal{S}^\cap$ for some integers $0 \le k' \le k < m$. Then

$$|\mathcal{S}| \le |\mathcal{S}^\cap|(m-k')/(k-k'+1).$$

In the case $k = k'$ we get the inequality (1.6) back again.

Finally, instead of pairwise intersections, let us consider r-wise intersections. Let $\mathcal{S}_r^\cap$ denote the hypergraph of all maximal intersections of r distinct edges of a (multi-) hypergraph $\mathcal{S}$. Then for $r \ge 2$ we can show that

$$|\mathcal{S}| \le |\mathcal{S}_r^\cap|(m-k)(r-1),$$

assuming, as before, that each hyperedge of $\mathcal{S}$ contains at least $k+1$ vertices and that every r-wise intersection has size at most k. Again for $r = 2$ this gives (1.6).

5. Related set-families. The notion of frequent sets appears in the data mining literature (see [1, 27]) and can be related naturally to the families considered above. More precisely, following a definition of [34], given a $(0,1)$-matrix and a threshold k, a subset of the columns is called *frequent* if there are at least k rows having a 1 entry in each of the corresponding positions. The problems of generating all *maximal frequent* sets and their duals, the so-called *minimal infrequent* sets (for a given binary matrix), were proposed and the complexity of the corresponding decision problems were asked in [34]. Results of [25] imply that it is NP-hard to determine whether a family of maximal frequent sets is incomplete, while our results prove that generating all minimal infrequent sets polynomially reduces to dualization.

Since the family $\mathcal{A}^{d_k}$ consists of all the minimal k-transversals to $\mathcal{A}$, that is, subsets of V which are disjoint from at most k hyperedges of $\mathcal{A}$, the family $\mathcal{A}^{cd_k}$ consists of all the minimal subsets of V which are contained in at most k hyperedges of $\mathcal{A}$. It is easy to recognize that these are the *minimal infrequent sets* in a matrix, the rows of which are the characteristic vectors of the hyperedges of $\mathcal{A}$. Furthermore, the family $\mathcal{A}^{d_k c}$ consists of all the maximal subsets of V, which are supersets of at most k hyperedges of $\mathcal{A}$.

Due to our results above, all these families can be generated in incremental quasi-polynomial time.

In the special case, if $\mathcal{A}$ is a quadratic set-family, i.e., if all hyperedges of $\mathcal{A}$ are of size 2, the family $\mathcal{A}$ can also be interpreted as the edge set of a graph G on vertex set V. Then, $\mathcal{A}^{d_k c}$ is also known as the family of the so-called *fairly independent sets* of the graph G consisting of all the vertex subsets which induce at most k edges (see [34].)

As it was defined above, the family $\mathcal{A}^{u_k}$ consists of all the minimal k-unions of $\mathcal{A}$, i.e., all minimal subsets of V which contain at least k hyperedges of $\mathcal{A}$, and hence the family $\mathcal{A}^{cu_k}$ consists of all the minimal subsets which contain at least k hyperedges of $\mathcal{A}^c$. Thus, the family $\mathcal{A}^{cu_k c}$ consists of all the maximal k-intersections, that is, maximal subsets of V which are subsets of at least k hyperedges of $\mathcal{A}$. These sets can be recognized as the *maximal frequent sets* in a matrix, the rows of which are the characteristic vectors of the hyperedges of $\mathcal{A}$. Finally, the family $\mathcal{A}^{u_k c}$ consists of all the maximal subsets of V which are disjoint from at least k hyperedges of $\mathcal{A}$.

As it follows from the mentioned results (see, e.g., [25]), generating all hyperedges for each of these families is NP-hard unless k (or $|\mathcal{A}| - k$) is bounded by a constant.

Let us add finally that since $|\mathcal{A}^c| = |\mathcal{A}|$, $|\mathcal{A}^{cu_{k+1}c}| = |\mathcal{A}^{u_{k+1}}|$, and $|\mathcal{A}^{d_k c}| = |\mathcal{A}^{d_k}|$ hold, Theorem 1.4 implies that for any binary matrix A with m rows and for any threshold value k $(0 \le k < m)$, the number of maximal frequent column sets of A is at most $(m-k)$ times the number of minimal infrequent column sets of A.

6. General closing remarks. In this paper we considered the problems of generating all partial and all multiple transversals. Both problems are formally more general than dualization, but in fact both are polynomially equivalent to it because the corresponding pairs of hypergraphs are uniformly dual-bounded. We close with the following negative result: *Generating all the minimal partial binary solutions to a system of inequalities $Ax \ge b$ is NP-hard even if A is binary and $b = (2, 2, \dots, 2)$.* To show this we can use arguments analogous to those of [24, 25]. Consider the well-known NP-hard problem of determining whether a given graph $G = (V, E)$ contains an independent vertex set of size t, where $t \ge 2$ is a given threshold; see [15]. Introduce

$|V|+1$ binary variables x_0 and $x_v,\ v \in V$, and write t inequalities $x_u + x_v \geq 2$ for each edge $e = (u, v) \in E$ followed by the inequalities $x_0 + x_v \geq 2,\ v \in V$. It is easily seen that the characteristic vector of any edge $e = (u, v)$ is a minimal binary solution satisfying at least t inequalities of the resulting system. Deciding whether there are other minimal binary solutions satisfying at least t inequalities of the system is equivalent to determining whether G has an independent set of size t.

Acknowledgment. The authors are thankful to József Beck for helpful discussions.

A CONSTANT-FACTOR APPROXIMATION ALGORITHM FOR PACKET ROUTING AND BALANCING LOCAL VS. GLOBAL CRITERIA*

ARAVIND SRINIVASAN† AND CHUNG-PIAW TEO‡

Abstract. We present the first constant-factor approximation algorithm for a fundamental problem: the *store-and-forward packet routing problem on arbitrary networks*. Furthermore, the queue sizes required at the edges are bounded by an absolute constant. Thus, this algorithm balances a *global* criterion (routing time) with a *local* criterion (maximum queue size) and shows how to get simultaneous good bounds for both. For this particular problem, approximating the routing time well, even without considering the queue sizes, was open. We then consider a class of such local vs. global problems in the context of covering integer programs and show how to improve the local criterion by a logarithmic factor by losing a constant factor in the global criterion.

Key words. packet routing, approximation algorithms, linear programming, multicommodity flow, rounding theorems, randomized algorithms, covering integer programs, randomized rounding, discrete ham-sandwich theorems

1. Introduction.

Recent research on approximation algorithms has focused a fair amount on *bicriteria* (or even multicriteria) minimization problems, attempting to simultaneously keep the values of two or more parameters "low" (see, e.g., [11, 21, 22, 29, 30, 32]). One motivation for this is that real-world problems often require such balancing. In this work, we consider a family of bicriteria problems that involve balancing a *local capacity* constraint (e.g., the maximum queue size at the links of a packet routing network, the maximum number of facilities per site in facility location) with a global criterion (resp., routing time, total cost of constructing the facilities). Since these global criteria are NP-hard to minimize even with no constraint on the local criterion, we shall seek good approximation algorithms.

1.1. Packet routing.

Our main result is a constant-factor approximation algorithm for store-and-forward packet routing, a fundamental routing problem in interconnection networks (see Leighton's book and survey [14, 15]); furthermore, the queue sizes will all be bounded by a constant. This packet routing problem has received considerable attention for more than 15 years and is as follows.

DEFINITION 1.1 (store-and-forward packet routing). *We are given an arbitrary N-node routing network (directed or undirected graph) G and a set $\{1, 2, \ldots, K\}$ of packets which are initially resident (respectively) at the (multi-)set of nodes $\{s_k : 1 \leq$*

$k \leq K\}$ of G. Each packet k is a message that needs to be routed to some given destination node t_k in G. We have to route each packet k from s_k to t_k, subject to the following: (i) *each packet k must follow some path in G;* (ii) *each edge traversal takes one unit of time;* (iii) *no two packets can traverse the same edge at the same unit of time; and* (iv) *packets are only allowed to queue along the edges of G during the routing stage. There are no other constraints on the paths taken by the packets: these can be arbitrary paths in G. The NP-hard objective is to select a path for each packet and to coordinate the routing so that the elapsed time by which all packets have reached their destinations is minimized; i.e., we wish to keep this routing time as small as possible.*

Extensive research has been conducted on this problem: see [14, 15] and the references therein. The most desirable type of algorithm here would, in addition to keeping the routing time and queue sizes low, also be *distributed*: given a set of incoming packets and their (source, destination) values, any switch (node of G) decides what to do with them next, without any other knowledge of the (multi-)set $\{(s_k, t_k) : 1 \leq k \leq K\}$. This would be ideal for parallel computing. (Distributed algorithms in this context are also termed *on-line* algorithms in the literature.) Several such ingenious results are known for specific networks such as the mesh, butterfly, or hypercube. For instance, given any routing problem with N packets on an N-node butterfly, there is a randomized on-line routing algorithm that, with high probability, routes the packets in $O(\log N)$ time using $O(1)$-sized queues [28]. (We let e denote the base of the natural logarithm, and, for $x > 0$, $\lg x$, $\ln x$, and $\ln^+ x$, respectively, denote $\log_2 x$, $\log_e x$, and $\max\{\log_e x, 1\}$. Also, Z_+ will denote the set of nonnegative integers.)

Good on-line algorithms here, however, are not always feasible or required for the following reasons:

- A large body of research in routing is concerned with *fault-tolerance*: the possibility of G being a reasonable routing network when its nodes are subject to (e.g., random or worst-case) faults. See, e.g., Kaklamanis et al. [12], Leighton, Maggs, and Sitaraman [18], and Cole, Maggs, and Sitaraman [6]. In this case, we do not expect good on-line algorithms, since the fault-free subgraph $\hat{G}$ of G has an unpredictable structure. Indeed, a fair amount of research in this area, e.g., [6, 18], focuses on showing that $\hat{G}$ is still a reasonably good routing network under certain fault models, assuming global information about $\{(s_k, t_k)\}$ and the fault structure.
- Ingenious on-line algorithms for specific networks such as the butterfly in the fault-free case [28] are only *existentially* (near-)optimal. For instance, the $O(\lg N)$ routing time of [28] is existentially optimal to within a constant factor, since there are families of routing instances that require $\Theta(\lg N)$ time. However, the worst-case approximation ratio can be $\Theta(\lg N)$. It seems very hard (potentially impossible) to devise on-line algorithms that are near-optimal on *each instance*.
- The routing problem can be considered as a variant of unit-demand multicommodity flow, where all arc capacities are the same, queuing is allowed, and where delivery time is also a crucial criterion. (Algorithms for this problem that require just $O(1)$ queue sizes, such as ours, will also scale with network size.) For such flow problems, the routing problems often have to be run repeatedly. It is therefore reasonable to study *off-line* approximation algorithms, i.e., efficient algorithms that use the knowledge of the network and of

$\{(s_k, t_k)\}$ and have a good approximation ratio.

Furthermore, it seems like a difficult problem to construct on-line routing algorithms for *arbitrary* networks, even with, say, a polylogarithmic approximation guarantee. See Ostrovsky and Rabani [26] for good on-line packet scheduling algorithms, *given the path to be traversed for each packet.*

By combining some new ideas with certain powerful results of Leighton, Maggs, and Rao [16], Leighton, Maggs, and Richa [17], Karp et al. [13], and Lin and Vitter [20], we present the first polynomial-time off-line *constant-factor* approximation algorithm for the store-and-forward packet routing problem. Furthermore, the queue sizes of the edges are bounded by $O(1)$. No approximation algorithms with a sublogarithmic approximation guarantee were known for this problem, to the best of our knowledge. For instance, a result from the seminal work of Leighton and Rao [19] leads to routing algorithms that are *existentially* good. Their network embedding of G ensures that there is some routing instance on G for which their routing time is to within an $O(\lg N)$ factor of optimal, but no good worst-case performance guarantee is known. We may attempt randomized rounding on some suitable linear programming (LP) relaxation of the problem; however, apart from difficulties like controlling path lengths, it seems hard to get a constant-factor approximation using this approach for families of instances where the LP optimal value grows as $o(\lg(N+K))$. Our approach uses the rounding theorem of [13] to select the set of paths that will be used in the routing algorithm of [17]. The analysis involves an interesting trade-off between the "dilation" criterion (maximum path length) and the "congestion" criterion (maximum number of paths using any edge).

1.2. Covering integer programs. Let v^T denote the transpose of a (column) vector v. In the second part of the paper, we continue to address the problem of simultaneously obtaining good bounds on two criteria of a problem. We focus on the NP-hard family of *covering integer programs* (CIPs), which includes the well-known set cover problem. This class of problems exhibits features similar to our packet routing problem: the latter can be formulated as a covering problem with side packing constraints. In CIPs, the packing constraints are upper bound constraints on the variables.

DEFINITION 1.2 (CIPs). *Given $A \in [0,1]^{m\times n}$, $b \in [0,\infty)^m$, and $c \in [0,1]^n$, a CIP seeks to minimize $c^T \cdot x$ subject to $Ax \geq b$, $x \in Z_+^n$, and $0 \leq x_j \leq d_j$ for each j (the $d_j \in Z_+$ are given integers). If $A \in \{0,1\}^{m\times n}$, then we assume without loss of generality (w.l.o.g.) that each b_i is a positive integer. Define $B = \min_i b_i$; w.l.o.g., we may assume $B \geq 1$. A CIP is* uncapacitated *if for all j, $d_j = \infty$.*

It is well known that the two assumptions above are w.l.o.g. (i) If $A \in \{0,1\}^{m\times n}$, then we can clearly replace each b_i by $\lceil b_i \rceil$. (ii) Given a CIP with some $A_{i,j} > b_i$, we can *normalize* it by first setting $A_{i,j} := b_i$ for each such (i,j) and then scaling A and b uniformly so that for all k, ($b_k \geq 1$ and $\max_\ell A_{k,\ell} \leq 1$). This is easily seen to result in an equivalent CIP.

To motivate the model, we consider a concrete CIP example: a facility location problem that generalizes the set cover problem. Here, given a digraph G, we want to place facilities on the nodes suitably so that every node has at least B facilities in its out-neighborhood. Given a cost-per-facility c_j of placing facilities at node j, we desire to place the facilities in a way that will minimize the total cost. It is easy to see that this NP-hard problem is a CIP, with the matrix A having only zeroes and ones. This problem illustrates one main reason for the constraints $\{x_j \leq d_j\}$: for reasons of capacity, security, or fault-tolerance (not many facilities will be damaged if, for

instance, there is an accident/failure at a node), we may wish to upper bound the number of facilities that can be placed at individual sites. The more general problem of "file sharing" in a network has been studied by Naor and Roth [24], where again, the maximum load (number of facilities) per node is balanced with the global criterion of total construction cost. For similar reasons, CIPs typically include the constraints $\{x_j \leq d_j : 1 \leq j \leq n\}$. In fact, the case where $d_j = 1$ for all j is quite common.

Dobson [7] and Fisher and Wolsey [8] study a natural greedy algorithm $\mathcal{GA}$ for CIPs. For a given CIP, let OPT denote the value of its optimal *integral* solution. We define $\gamma_1 \doteq \min_{i,j}\{A_{i,j}/c_j : A_{i,j} \neq 0\}$ and $\gamma_2 \doteq \max_j(\sum_{i=1}^m A_{i,j}/c_j)$. Then, it is shown in [8] that $\mathcal{GA}$ produces a solution of value at most $OPT(1 + \ln(\gamma_2/\gamma_1))$. If each row of the linear system $Ax \geq b$ is scaled so that the minimum nonzero entry in the row is at least 1, it is shown in [7] that $\mathcal{GA}$'s output is at most $OPT(1 + \ln(\max_j \sum_{i=1}^n A_{i,j}))$.

Another well-known approach to CIPs is to start with their LP relaxation, wherein each x_j is allowed to be a *real* in the range $[0, d_j]$. Throughout, we shall let y^* denote the LP optimum of a given CIP. Clearly, y^* is a lower bound on OPT. Bertsimas and Vohra [5] conduct a detailed study of approximating CIPs and present an approximation algorithm which finds a feasible solution whose value is $O(y^* \lg m)$ [5]. Previous work of this paper's first author [31] presents an algorithm that computes an $x \in Z_+^n$ such that $Ax \geq b$ and

$$c^T \cdot x \leq a_0 y^* \cdot \max\{\ln^+(mB/y^*)/B, \sqrt{\ln^+(mB/y^*)/B}\} \tag{1.1}$$

for some absolute constant $a_0 > 0$.[1] The bound "$x_j \leq d_j$" may not hold for all j, but we will have for all j that

$$x_j \leq d_j \cdot \left(1 + a_1 \max\left\{\ln^+(mB/y^*)/B, \sqrt{\ln^+(mB/y^*)/B}\right\}\right) \tag{1.2}$$

for a certain absolute constant $a_1 > 0$. A related result is presented in [24] for file-sharing.

If B is "large" (greater than a certain threshold), then these results significantly improve previous results in the "global" criterion of keeping $c^T \cdot x$ small while compromising somewhat on the "local" capacity constraints $\{x_j \leq d_j\}$. This is a common approach in bicriteria approximation: losing a small amount in each criterion to keep the maximum such loss "low." In particular, if y^* grows at least as fast as $me^{-O(B)}$, then the output value here is $O(y^*)$, while maintaining $x_j = O(d_j)$ for all j. (Also, if the CIP is uncapacitated, then the above is a significant improvement if B is large.)

We see from (1.2) that in the case where $\ln^+(mB/y^*) \leq B$, both $(c^T \cdot x)/y^*$ and the maximum "violation" $\max_j\ x_j/d_j$ are bounded by constants, which is reasonable. Thus, we consider the case where $\ln^+(mB/y^*) > B$. Here, however, the violation $\max_j\ x_j/d_j$ can be as high as $1 + a_1 \ln^+(mB/y^*)/B$, which is unsatisfactory. If it is not feasible (e.g., for capacity/fault-tolerance reasons) to deviate from the local constraints by this much, then even the gain in the global criterion (caused by the large value of B) will not help justify such a result. Therefore, a natural question is: is it possible to lose a small amount in the global criterion, while losing much less in the local criterion (i.e., in $\max_j\ x_j/d_j$), in the case where $\ln^+(mB/y^*) > B$? We answer this in the affirmative.

[1] Recall that $\ln^+(x)$ denotes $\max\{\ln(x), 1\}$. To parse the term "$\ln^+(mB/y^*)/B$", note that it is $\ln(mB/y^*)/B$ if $y^* \leq me^{-B}$ and is $O(1)$ otherwise.

(a) For the important special case of *unweighted* CIPs (for all j, $c_j = 1$), consider the case $\ln^+(mB/y^*) > B$. Then, for any parameter ϵ, $0 < \epsilon < 1$, we present an algorithm that outputs an x with

(i) $x_j \leq \lceil d_j/(1-\epsilon) \rceil$ for all j, where
(ii) the objective function value is at most $a_2 y^*(1/(1-\epsilon)+(1/\epsilon^2)\ln^+(mB/y^*)/B)$ for an absolute constant $a_2 > 0$.

Note the significant improvement over (1.1) and (1.2), particularly if ϵ is a constant: by losing just a constant factor in the output value of the objective function, we have ensured that each x_j/d_j is bounded by a *constant* (at most $1/(1-\epsilon)+1/d_j$). This is an improvement over the bound stated in (1.2). In our view, ensuring little loss in the local criterion here is quite important as it involves *all* the variables x_j (e.g., all the nodes of a graph in facility location) and since $\max_j x_j/d_j$ may be *required* to be low due to physical and other constraints.

(b) For the case where the coefficient matrix A has only zeroes and ones and where a feasible solution (i.e., for all j, $x_j \leq d_j$) to a (possibly weighted) CIP is really required, we present an approximation algorithm with output value at most $O(y^* \ln^+(m/y^*))$. This works whether $\ln^+(mB/y^*) > B$ or not. While incomparable with the results of [7, 8], this is better if y^* is bigger than a certain threshold. This is also seen to be an improvement over the $O(y^* \lg m)$ bound of [5] if $y^* \geq m^a$, where $a \in (0, 1)$ is an absolute constant.

Thus, this work presents improved local vs. global balancing for a family of problems: the basic packet routing problem (the first constant-factor approximation) and CIPs (gaining more than a constant factor in the local criterion while losing a constant factor in the global criterion). The structure of the rest of the paper is as follows. In section 2, we discuss the algorithm for the packet routing problem, which consists mainly of three steps: (1) constructing and solving an LP relaxation (section 2.1); (2) obtaining a set of routes via suitable rounding (section 2.2); and (3) scheduling the packets (section 2.3) using the algorithm of [17]. The nature of our LP relaxation also provides an interesting re-interpretation of our result, as shown by Theorem 2.4 in section 2.3. We discuss in section 2.4 an extension of our idea to a more general setting, where the routing problem is replaced by a canonical covering problem. In section 3, we discuss our results for the general CIPs. We present our improved local vs. global balancing for unweighted CIPs in section 3.1; the case where $x_j \leq d_j$ is really required for all j is handled in section 3.2 for the case where the coefficient matrix has only zeroes and ones. (Note, for instance, that the coefficient matrix has only zeroes and ones for the facility location problem discussed in section 1.2.)

2. Approximating the routing time to within a constant factor. We refer the reader to the introduction for the definition and motivation for packet routing. Leighton, Maggs, and Rao, in a seminal paper, studied the issue of scheduling the movement of the packets *given the path to be traversed by each packet* [16]. They showed that the packets can be routed in time proportional to the sum of the *congestion* and *dilation* of the paths selected for each packet (see the sentence preceding section 1.2 for the definition of these two parameters). However, they did not address the issue of path selection; one motivation for their work is that paths can plausibly be selected using, e.g., the well-known "random intermediate destinations" idea [33, 34]. However, no general results on path selection, and hence on the time needed for packet routing, were known for *arbitrary* networks G. We address this issue here by studying the path selection problem.

THEOREM 2.1. *There are constants $c', c'' > 0$ such that the following holds. For any packet routing problem on any network, there is a set of paths and a corresponding schedule that can be constructed in polynomial time such that the routing time is at most c' times the optimal. Furthermore, the maximum queue size at each edge is bounded by c''.*

We shall denote any path from s_k to t_k as an (s_k, t_k)-path. Given a (directed) path P, $E(P)$ will denote its set of (directed) edges.

2.1. A linear programming relaxation. Consider any given packet routing problem. Let us consider any feasible solution for it, where packet k is routed on path P_k. Let D denote the *dilation* of the paths selected, i.e., D is the length of a longest path among the P_k. Clearly, the time to route all the packets is bounded below by D. Similarly, let C denote the congestion of the paths selected, i.e., the maximum number of packets that must traverse any single edge during the entire course of the routing. Clearly, C is also a lower bound on the time needed to route the packets.

Let N denote the number of nodes in the network and K the number of packets in the problem. We now present an LP relaxation for the problem; some of the notation used in this relaxation is explained in the following paragraph.

$$\text{(ROUTING)}\ \min(C+D)/2 \text{ subject to}$$

$$\sum_{k=1}^{K} x_f^k \leq C \quad \forall f \in E(G), \tag{2.1}$$

$$\sum_{f \in E(G)} x_f^k \leq D \quad \forall k \in \{1, 2, \ldots, K\}, \tag{2.2}$$

$$\mathcal{N}^k x^k = b^k \quad \forall k \in \{1, 2, \ldots, K\}, \tag{2.3}$$

$$0 \leq x_f^k \leq 1 \quad \forall k \in \{1, 2, \ldots, K\}\ \forall f \in E(G).$$

The vector x above is basically a "fractional flow" in G, where x_f^k denotes the amount of "flow" of packet k on edge $f \in E(G)$. The superscript k merely indexes a packet and *does not* mean a kth power. The constraints "$\mathcal{N}^k x^k = b^k$" model the requirement that for packet k, (i) a total of one unit of flow leaves s_k and reaches t_k, and (ii) at all other nodes, the net inflow of the flow corresponding to packet k, equals the net outflow of the flow corresponding to packet k. For conciseness, we have avoided explicitly writing out this (obvious) set of constraints above. Constraints (2.1) say that the "fractional congestion" on any edge f is at most C. Constraints (2.2) say that the "fractional dilation" $\sum_f x_f^k$ is at most D. This is a somewhat novel way of relaxing path lengths to their fractional counterparts.

It is easy to see that any path-selection scheme for the packets, i.e., any *integral* flow (where all the x_f^k are either 0 or 1) with congestion C and dilation D, satisfies the above system of inequalities. Thus, since C and D are both lower bounds on the length of the routing time for such a path-selection strategy, so is $(C+D)/2$. Hence, the optimum value of the LP is indeed a lower bound on the routing time for a given routing problem: it is indeed a relaxation. Note that the LP has polynomial size since it has "only" $O(Km)$ variables and $O(Km)$ constraints, where m denotes the number of edges in the network. Thus, it can be solved in polynomial time. Let $\{\overline{x}, \overline{C}, \overline{D}\}$ denote an optimal solution to the program. In section 2.2, we will conduct a certain type of "filtering" on $\overline{x}$. Section 2.3 will then construct a path for each packet and then invoke the algorithm of [17] for packet scheduling.

2.2. Path filtering. The main ideas now are to decompose $\overline{x}$ into a set of "flow paths" via the "flow decomposition" approach and then to adapt the ideas in Lin-Vitter [20] to "filter" the flow paths by effectively eliminating all flow paths of length more than $2\overline{D}$.

The reader is referred to section 3.5 of [1] for the well-known flow decomposition approach. This approach efficiently transforms $\overline{x}$ into a set of flow paths that satisfy the following conditions. For each packet k, we get a collection $\mathcal{Q}^k$ of flows along (s_k, t_k)-paths; each $\mathcal{Q}^k$ has at most m paths. Let $P_{k,i}$ denote the ith path in $\mathcal{Q}^k$. $P_{k,i}$ has an associated flow value $z_{k,i} \geq 0$ such that for each k, $\sum_i z_{k,i} = 1$. (In other words, the unit flow from s_k to t_k has been decomposed into a convex combination of (s_k, t_k)-paths.) The total flow on any edge f will be at most $\overline{C}$:

$$\sum_{(k,i):f \in E(P_{k,i})} z_{k,i} = \sum_{k=1}^{K} \overline{x}_f^k \leq \overline{C}; \tag{2.4}$$

the inequality in (2.4) follows from (2.1). Also, let $|P|$ denote the length of (i.e., the number of edges in) a path P. Importantly, the following bound will hold for each k:

$$\sum_i z_{k,i} |P_{k,i}| = \sum_{f \in E(G)} \overline{x}_f^k \leq \overline{D} \tag{2.5}$$

with the inequality following from (2.2).

The main idea now is to "filter" the flow paths so that only paths of length at most $2\overline{D}$ remain. For each k, define

$$g_k = \sum_{i:|P_{k,i}| > 2\overline{D}} z_{k,i}.$$

It is to easy to check via (2.5) that $g_k \leq 1/2$ for each k. Thus, suppose we define new flow values $\{y_{k,i}\}$ as follows for each k: $y_{k,i} = 0$ if $|P_{k,i}| > 2\overline{D}$, and $y_{k,i} = z_{k,i}/(1 - g_k)$ if $|P_{k,i}| \leq 2\overline{D}$. We still have the property that we have a convex combination of flow values: $\sum_i y_{k,i} = 1$. Also, since $g_k \leq 1/2$ for all k, we have $y_{k,i} \leq 2z_{k,i}$ for all k, i. Therefore, (2.4) implies that the total flow on any edge f is at most $2\overline{C}$:

$$\sum_{(k,i):f \in E(P_{k,i})} y_{k,i} \leq 2\overline{C}. \tag{2.6}$$

Most importantly, by setting $y_{k,i} = 0$ for all the "long" paths $P_{k,i}$ (those of length more than $2\overline{D}$), we have ensured that all the flow paths under consideration are of length at most $O(\overline{D})$. We denote the collection of flow paths for packet k by $\mathcal{P}^k$. For ease of exposition, we will also let y_P denote the flow value of any general flow path P.

Remarks. We now point out two other LP relaxations which can be analyzed similarly and which yield slightly better constants in the approximation guarantee.

- It is possible to directly bound path-lengths in the LP relaxation so that filtering need not be applied; one can show that this improves the approximation guarantee somewhat. On the other hand, such an approach leads to a somewhat more complicated relaxation, and furthermore, binary search has to be applied to get the "optimal" path-length. This, in turn, entails potentially $O(\lg N)$ calls to an LP solver, which increases the running time. Thus, there is a trade-off involved between the running time and the quality of approximation.

- In our LP formulation, we could have used a variable W to stand for $\max\{C, D\}$ in place of C and D; the problem would have been to minimize W subject to the fractional congestion and dilation being at most W. Since W is a lower bound on the optimal routing time, this is indeed a relaxation; using our approach with this formulation leads to a slightly better constant in the quality of our approximation. Nevertheless, we have used our approach to make the relationship between C and D explicit.

2.3. Path selection and routing. Note that $\{y_P : P \in \bigcup_{k=1}^{K} \mathcal{P}^k\}$ is a fractional feasible solution to the following set of inequalities:

$$\sum_k \sum_{P \in \mathcal{P}^k, (i,j) \in E(P)} y_P \leq 2\overline{C} \quad \forall f \in E(G),$$
$$\sum_{P \in \mathcal{P}^k} y_P = 1 \quad \forall k.$$

To select one path from $\mathcal{P}^k$ for each packet k, we need to modify the above fractional solution to an integral 0-1 solution. To ensure that the congestion does not increase by much, we shall use the following rounding algorithm of [13].

THEOREM 2.2 (see [13]). *Let A be a real valued $r \times s$ matrix and y be a real-valued s-vector. Let b be a real-valued vector such that $Ay = b$ and t be a positive real number such that, in* every column *of A,* (i) *the sum of all the positive entries is at most t* and (ii) *the sum of all the negative entries is at least $-t$. Then we can compute an integral vector $\overline{y}$ such that for every i, either $\overline{y}_i = \lfloor y_i \rfloor$ or $\overline{y}_i = \lceil y_i \rceil$ and $A\overline{y} = \overline{b}$ where $\overline{b}_i - b_i < t$ for all i. Furthermore, if y contains d nonzero components, the integral approximation can be obtained in time $O(r^3 \lg(1 + s/r) + r^3 + d^2 r + sr)$.*

To use Theorem 2.2, we first transform our linear system above to an equivalent system

$$\sum_k \sum_{P \in \mathcal{P}^k, (i,j) \in E(P)} y_P \leq 2\overline{C} \quad \forall\ (i,j) \in E(G),$$
$$\sum_{P \in \mathcal{P}^k} (-2\overline{D}) y_P = -2\overline{D} \quad \forall\ k.$$

The set of variables above is $\{y_P : P \in \bigcup_{k=1}^{K} \mathcal{P}^k\}$. Note that $y_P \in [0,1]$ for all these variables. Furthermore, in this linear system, the positive column sum is bounded by the maximum length of the paths in $\mathcal{P}^1 \cup \mathcal{P}^2 \cup \cdots \cup \mathcal{P}^K$. Since each path in any $\mathcal{P}^k$ is of length at most $2\overline{D}$ due to our filtering, each positive column sum is at most $2\overline{D}$. Each negative column sum is clearly $-2\overline{D}$. Thus, the parameter t for this linear system, in the notation of Theorem 2.2, can be taken to be $2\overline{D}$. Hence by Theorem 2.2, we can obtain in polynomial time an *integral* solution $\overline{y}$ satisfying

$$\sum_k \sum_{P \in \mathcal{P}^k, f \in E(P)} \overline{y}_P \leq 2\overline{C} + 2\overline{D} \quad \forall\ f \in E(G), \tag{2.7}$$

$$\sum_{P \in \mathcal{P}^k} (-2\overline{D}) \overline{y}_P < 0 \quad \forall\ k, \tag{2.8}$$

$$\overline{y}_P \in \{0,1\} \quad \forall\ P \in \bigcup_{k=1}^{K} \mathcal{P}^k. \tag{2.9}$$

For each packet k, by conditions (2.8) and (2.9), we have $\sum_{P \in \mathcal{P}^k} \overline{y}_P \geq 1$. (Note the crucial role of the *strict* inequality in (2.8).) Thus, for each packet k, we have selected at least one path from s_k to t_k with length at most $2\overline{D}$; furthermore, the congestion is bounded by $2\overline{C}+2\overline{D}$ (from (2.7)). If there are two or more such (s_k, t_k)-paths, we can arbitrarily choose one among them, which of course cannot increase the congestion. The next step is to schedule the packets, given the set of paths selected for each packet. To this end, we use the following result of [17], which provides an algorithm for the existential result of [16].

THEOREM 2.3 (see [17]). *For any set of packets with edge-simple paths having congestion c and dilation d, a routing schedule having length $O(c+d)$ and constant maximum queue size can be found in random polynomial time.*

Applying this theorem to the paths selected from the previous stage, which have congestion $c \leq 2\overline{C} + 2\overline{D}$ and dilation $d \leq 2\overline{D}$, we can route the packets in time $O(\overline{C} + \overline{D})$. Recall that $(\overline{C} + \overline{D})/2$ is a lower bound on the length of the optimal schedule. Thus, we have presented a constant-factor approximation algorithm for the off-line packet routing problem; furthermore, the queue sizes are also bounded by an absolute constant in the routing schedule produced. An interesting related point is that our LP relaxation is reasonable: its integrality gap (worst-case ratio between the optima of the integral and fractional versions) is bounded above by $O(1)$.

An alternative view. There is an equivalent interesting interpretation of Theorem 2.1.

THEOREM 2.4. *Suppose we have an arbitrary routing problem on an arbitrary graph $G = (V, E)$; let L be any nonnegative parameter (e.g., $O(1)$, $O(\lg n)$, $O(\sqrt{n})$). Let $\{(s_k, t_k) : 1 \leq k \leq K\}$ be the set of source-destination pairs for the packets. Suppose we can construct a probability distribution D_k on the (s_k, t_k)-paths for each k such that if we sample, for each packet k, an (s_k, t_k)-path from D_k independently of the other packets, then we have (a) for any edge $e \in E(G)$, the expected congestion on e is at most L, and (b) for each k, the expected length of the (s_k, t_k)-path chosen is at most L. Then, there is a choice of paths for each packet such that the congestion and dilation are $O(L)$. Thus, the routing can be accomplished in $O(L)$ time using constant-sized queues; such a routing can also be constructed off-line in time polynomial in $|V|$ and K.*

We remark that the converse of Theorem 2.4 is trivially true: if an $O(L)$ time routing can be accomplished, we simply let D_k place all the probability on the (s_k, t_k)-path used in such a routing.

Proof of Theorem 2.4. Let π_P^k denote the probability measure of any (s_k, t_k)-path P under the distribution D_k. Let $supp(D_k)$ denote the *support* of D_k, i.e., the set of (s_k, t_k)-paths on which D_k places nonzero probability. The proof follows from the fact that for any $(i, j) \in E(G)$,

$$x_{i,j}^k \equiv \sum_{P:(i,j)\in E(P),\ P\in supp(D_k)} \pi_P^k$$

is a feasible solution to (ROUTING), with C, D replaced by L. Hence, by our filter-round approach, we can construct one path for each packet k such that the congestion and dilation are $O(L)$. As seen above, the path selection and routing strategies can be found in polynomial time. □

We consider the above interesting because many fault-tolerance algorithms use very involved ideas to construct a suitable (s_k, t_k)-path for (most) packets [6]. These paths will need to simultaneously have small lengths and lead to small edge congestion.

Theorem 2.4 shows that much more relaxed approaches could work: a distribution that is "good" in expectation on individual elements (edges, paths) is sufficient. Recall that in many "discrete ham-sandwich theorems" (Beck and Spencer [4], Raghavan and Thompson [27]), it is easy to ensure good expectation on individual entities (e.g., the constraints of an integer program), but it is much more difficult to construct one solution that is simultaneously good on all these entities. Our result shows one natural situation where there is just a constant-factor loss in the process.

2.4. Extensions. The result above showing a constant integrality gap for packet routing can be extended to a general family of combinatorial packing problems as follows. Let S_k be the family of all the subsets of vertices S such that $s_k \in S$ and $t_k \notin S$. Recall that the (s_k, t_k)-shortest path problem can be solved as an LP via the following covering formulation:

$$\min \sum_{i,j} c_{i,j} x^k_{i,j} \text{ subject to}$$

$$\begin{aligned} \sum_{(i,j)\in E:\ i\in S, j\notin S} x^k_{i,j} &\geq 1 \quad \forall S \in S_k, \\ x^k_{i,j} &\geq 0 \quad \forall\ (i,j) \in E(G). \end{aligned} \tag{2.10}$$

Constraint (2.10) expresses the idea that "flow" crossing each s-t cut is at least 1. The following is an alternative relaxation for the packet routing problem:

$$\text{(ROUTING-II)} \quad \min(C+D)/2 \text{ subject to}$$

$$\begin{aligned} \sum_{k=1}^{K} x^k_{i,j} &\leq C \quad \forall\ (i,j) \in E(G), \\ \sum_{i,j} x^k_{i,j} &\leq D \quad \forall\ k, \\ \sum_{(i,j)\in E:\ i\in S, j\notin S} x^k_{i,j} &\geq 1 \quad \forall S \in S_k, \\ x^k_{i,j} &\in [0,1] \quad \forall\ k,i,j. \end{aligned} \tag{2.11}$$

We can use the method outlined in sections 2.1, 2.2, and 2.3 to show that the optimal solution of (ROUTING-II) is within a constant factor of the optimal routing time. A natural question that arises is whether the above conclusion holds for more general combinatorial packing problems. To address this question, we need to present an alternative (polyhedral) perspective of our (path) selection routine. First we recall some standard definitions from polyhedral combinatorics. The reader is referred to [10] for related concepts.

Suppose we are given a finite set $\mathcal{N} = \{1, 2, \ldots, n\}$ and a family $\mathcal{F}$ of subsets of $\mathcal{N}$. For any $S \subseteq \mathcal{N}$, let $\chi_S \in \{0,1\}^n$ denote the incidence vector of S. We shall consider the problem

$$(OPT) \quad \min\{c^T \chi_F : F \in \mathcal{F}\},$$

where $c \in \Re^n_+$ is a weight function on the elements of $\mathcal{N}$.

DEFINITION 2.5 (see [25]). *The blocking clutter of $\mathcal{F}$ is the family $B(\mathcal{F})$, whose members are precisely those $H \subseteq \mathcal{N}$ that satisfy the following:*

P1. *Intersection: $H \cap F \neq \emptyset$ for all $F \in \mathcal{F}$.*

P2. *Minimality: If H' is any proper subset of H, then H' violates property* P1.

A natural LP relaxation for (OPT) is

$$\min\{c^T x : x \in Q\}, \text{ where } Q = \{x^T \chi_H \geq 1 \text{ for all } H \in B(\mathcal{F}),\ x_i \geq 0 \text{ for all } i\}.$$

Q is known as the blocking polyhedron of $\mathcal{F}$. The following result is well known and easy to check:

$$Q \cap Z^n = \{x \in Z^n :\ \exists F \in \mathcal{F} \text{ such that } \ \forall i \in F,\ x_i \geq 1\}.$$

For several classes of clutters (set-systems), it is known that the extreme points of Q are the integral vectors that correspond to incidence vectors of elements in $\mathcal{F}$. By Minkowski's theorem [25], every element in Q can be expressed as a convex combination of the extreme points and extreme rays in Q. For blocking polyhedra, the set of rays is

$$\{x \in \Re^n :\ \forall i,\ x_i \geq 0\}.$$

Suppose we have a generic integer programming problem that is similar to (ROUTING-II), except for the fact that for each k, (2.11) is replaced by the constraint

$$\sum_{i \in H} x_i^k \geq 1 \ \ \forall\ H \in B(\mathcal{F}^k);$$

$\mathcal{F}^k$ can be any clutter that is well-characterized by its blocking polyhedron Q^k (i.e., the extreme points of the blocking polyhedron Q^k are incidence vectors of the elements of the clutter $\mathcal{F}^k$). Thus, we have a generalization of (ROUTING-II):

$$\text{(BLOCK)} \quad \min(C + D)/2 \text{ subject to}$$

$$\sum_{k=1}^{K} x_i^k \quad \leq \quad C \ \ \forall\ i \in \mathcal{N},$$

$$\sum_{i} x_i^k \quad \leq \quad D \ \ \forall\ k, \tag{2.12}$$

$$\sum_{i \in H} x_i^k \quad \geq \quad 1 \ \ \forall\ k \text{ and } \forall\ H \in B(\mathcal{F}^k),$$

$$x_i^k \quad \in \quad \{0, 1\} \ \ \forall\ k \text{ and } \forall i \in \mathcal{N}. \tag{2.13}$$

Note that the variables x are now indexed by elements of the set $\mathcal{N}$. In the previously discussed special cases, the elements of $\mathcal{N}$ are edges or pairs of nodes.

The LP relaxation of (BLOCK) replaces the constraint (2.13) by

$$0 \leq x_i^k \leq 1 \ \ \forall\ k = 1, \ldots, K\ \forall i \in \mathcal{N}.$$

THEOREM 2.6. *The optimal integral solution value of (BLOCK) is at most a constant factor times the optimal value of the LP relaxation.*

Proof. Let $(\overline{x}_i^k : k = 1, \ldots, K; i \in \mathcal{N})$ denote an optimal solution to the LP relaxation. By Caratheodory's theorem [25], for each fixed k, $(\overline{x}_i^k : i \in \mathcal{N})$ can be expressed as a convex combination of extreme points and extreme rays of the blocking polyhedron Q^k. However, note that the objective function can improve only by decreasing the value of $(\overline{x}_i^k)$ coordinatewise, as long as the solution remains

feasible. Furthermore, the extreme rays of the blocking polyhedron correspond to vectors v with each v_i nonnegative. Thus, w.l.o.g., we may assume that the LP optimum is *lexicographically minimal*. This ensures that the optimal solution $(\overline{x}_i^k)$ can be expressed as a convex combination of the extreme points of the polyhedron alone. As seen above, the extreme points in this case are incidence vectors of elements of the kth clutter (we use polyhedral language to let "kth clutter" denote the set-system $\mathcal{F}^k$).

Let $\overline{C}$ and $\overline{D}$ denote the fractional congestion and fractional dilation of the optimal solution obtained by the LP relaxation of (BLOCK). Let $A_1^k, A_2^k, \ldots$ denote incidence vectors of the elements in the kth clutter, and let $A_j^k(i)$ be the ith coordinate of A_j^k. Then we have a convex combination for each k:

$$\forall i,\ \overline{x}_i^k = \sum_j \alpha_j^k \cdot A_j^k(i),\ \text{where}$$

$$\alpha_j^k \geq 0\ \forall j,\ \text{and}\ \sum_j \alpha_j^k = 1.$$

Thus, by constraints (2.12), $\sum_{j:|A_j^k| \leq 2\overline{D}} \alpha_j^k \geq 1/2$, since $\sum_j \alpha_j^k |A_j^k| \leq \overline{D}$.

By filtering out those A_j^k with size greater than $2\overline{D}$, we obtain a set of canonical objects for each k, whose sizes are at most $2\overline{D}$. By scaling the α_j^k by a suitable factor, we also obtain a new set of $\overline{\alpha}_j^k$ such that

$$\sum_{j:|A_j^k| \leq 2\overline{D}} \overline{\alpha}_j^k = 1,\quad \overline{\alpha}_j^k \leq 2\alpha_j^k.$$

Using these canonical objects and $\{\overline{\alpha}_j^k\}$ as the input to Theorem 2.2, we obtain a set of objects (one from each clutter) such that the dilation is not more than $2\overline{D}$ and the congestion not more than $2(\overline{C} + \overline{D})$. Hence the solution obtained is at most $O(1)$ times the LP optimum. □

Remark. As pointed out by one of the referees, it is not clear whether the lexicographically minimal optimal solution can be constructed in polynomial time. The above result is thus only about the quality of the LP relaxation. It would be nice to find the most general conditions under which the above can be turned into a polynomial-time approximation algorithm.

3. Improved local vs. global balancing for covering. Coupled with the results of [16, 17], our approximation algorithm for the routing time (a *global* criterion) also simultaneously kept the maximum queue size (a *local capacity* constraint) constant; our approach there implicitly uses the special structure of the cut covering formulation. We now continue the study of such balancing in the context of CIPs. The reader is referred to section 1.2 for the relevant definitions and history of CIPs. In section 3.1, we will show how to approximate the global criterion well without losing much in the "local" constraints $\{x_j \leq d_j\}$. In section 3.2, we present approximation algorithms for a subfamily of CIPs where $x_j \leq d_j$ is *required* for all j. One of the key tools used in sections 3.1 and 3.2 is Theorem 3.3, which builds on an earlier rounding approach (Theorem 3.2) of [31].

3.1. Balancing local with global. The main result of section 3.1 is Corollary 3.5. This result is concerned with unweighted CIPs and the case where $\ln^+(mB/y^*) > B$. In this setting, Corollary 3.5 shows how the local capacity constraints can be violated much less in comparison with the results of [31], while keeping the objective function value within a constant factor of that of [31].

Let $\exp(x)$ denote e^x; given any nonnegative integer k, let $[k]$ denote the set $\{1, 2, \ldots, k\}$. We start by reviewing the Chernoff–Hoeffding bounds in Theorem 3.1. Let $G(\mu, \delta) \doteq (\exp(\delta)/(1+\delta)^{(1+\delta)})^{\mu}$, $H(\mu, \delta) \doteq \exp(-\mu\delta^2/2)$.

THEOREM 3.1 (see [23]). *Let $X_1, X_2, \ldots, X_\ell$ be* independent *random variables, each taking values in $[0,1]$, $R = \sum_{i=1}^{\ell} X_i$, and $E[R] = \mu$. Then, for any $\delta \geq 0$, $\Pr(R \geq \mu(1+\delta)) \leq G(\mu, \delta)$. Also, if $0 \leq \delta \leq 1$, $\Pr(R \leq \mu(1-\delta)) \leq H(\mu, \delta)$.*

We shall use the following easy fact:

$$\forall \mu \geq 0 \ \forall \delta \in [0,1], \ G(\mu, \delta) \leq \exp(-\mu\delta^2/3). \tag{3.1}$$

From now on, we will let $\{x_j^* : j \in [n]\}$ be the set of values for the variables in an arbitrary feasible solution to the LP relaxation of the CIP; thus, $0 \leq x_j^* \leq d_j$. (In particular, x^* could be an optimal LP solution.) Let $y^* = c^T \cdot x^*$. Recall that the case where $\ln^+(mB/y^*) \leq B$ is handled well in [31]; thus we shall assume $\ln^+(mB/y^*) > B$. We now summarize the main result of [31] for CIPs as a theorem. A key ingredient of Theorem 3.2 is the FKG inequality [9].

THEOREM 3.2 (see [31]). *For any given CIP, suppose we are given any $1 \leq \beta < \alpha < \kappa$ such that*

$$(1 - H(B\alpha, 1 - \beta/\alpha))^m > G(y^*\alpha, \kappa/\alpha - 1) \tag{3.2}$$

holds. Then we can find in deterministic polynomial time a vector $z = (z_1, z_2, \ldots, z_n)$ of nonnegative integers *such that* (a) $(Az)_i \geq b_i\beta$ *for each $i \in [m]$,* (b) $\sum_j c_j z_j \leq y^*\kappa$, *and* (c) $z_j \leq \lceil \alpha x_j^* \rceil \leq \lceil \alpha d_j \rceil$ *for each $j \in [n]$.*

The next theorem presents a rounding algorithm by building on Theorem 3.2.

THEOREM 3.3. *There are positive constants a_3 and a_4 such that the following holds. Given any parameter ϵ, $0 < \epsilon < 1$, let α be any value such that $\alpha \geq (a_3/\epsilon^2)\max\{\ln^+(mB/y^*)/B, 1\}$. Then we can find in deterministic polynomial time a vector $z = (z_1, z_2, \ldots, z_n)$ of nonnegative integers such that* (a) $(Az)_i \geq b_i\alpha(1-\epsilon)$ *for each $i \in [m]$,* (b) $c^T \cdot z \leq a_4 y^* \alpha$, *and* (c) $z_j \leq \lceil \alpha x_j^* \rceil \leq \lceil \alpha d_j \rceil$ *for each $j \in [n]$.*

Remark. It will be shown in the proof of Theorem 3.3 that we can choose, for instance, $a_3 = 3$ and $a_4 = 2$. Since there is a trade-off between a_3 and a_4 that can be fine-tuned for particular applications, we have avoided using specific values for a_3 and a_4 in the statement of Theorem 3.3.

The following simple proposition will also be useful.

PROPOSITION 3.4. *If $0 < x < 1/e$, then $1 - x > \exp(-1.25x)$.*

Proof of Theorem 3.3. We choose $a_3 = 3$ and $a_4 = 2$. In the notation of Theorem 3.2, we take $\beta = \alpha(1-\epsilon)$ and $\kappa = a_4\alpha$. Our goal is to validate (3.2); by (3.1), it suffices to show that

$$\exp(-y^*\alpha/3) < (1 - \exp(-B\alpha\epsilon^2/2))^m. \tag{3.3}$$

Note that the left- and right-hand sides of (3.3), respectively, decrease and increase with increasing α; thus, since $\alpha \geq \alpha_0 \doteq (3/\epsilon^2)\max\{\ln^+(mB/y^*)/B, 1\}$ it is enough to prove (3.3) for $\alpha = \alpha_0$. We consider two cases.

Case I. $\ln^+(mB/y^*) \leq B$.

Thus, $\alpha_0 = 3/\epsilon^2$ here. Since $B \geq 1$, we have $\exp(-B\alpha_0\epsilon^2/2) < 1/e$. Therefore, Proposition 3.4 implies that in order to prove (3.3), it suffices to show that

$$y^*\alpha_0/3 \geq 1.25m\exp(-B\alpha_0\epsilon^2/2),$$

i.e., that $y^*/\epsilon^2 \geq 1.25m\exp(-1.5B)$. This is true from the facts that (i) $m/y^* \leq \exp(B)$ (which follows from the fact that $\ln(m/y^*) \leq \ln^+(mB/y^*) \leq B$), and (ii) $\exp(1.5B) \geq \sqrt{e}\exp(B) \geq 1.25\epsilon^2\exp(B)$.

Case II. $\ln^+(mB/y^*) > B$.

Here, it suffices to show that

$$\exp(-y^*\ln^+(mB/y^*)/(B\epsilon^2)) < (1-\exp(-1.5\cdot\ln^+(mB/y^*)))^m. \tag{3.4}$$

Recall that $\ln^+(mB/y^*) > B \geq 1$. Therefore, we have $mB/y^* > e$, i.e., $y^*/(mB) < 1/e$. Thus,

$$(1-\exp(-1.5\cdot\ln^+(mB/y^*)))^m = \left(1-\left(\frac{y^*}{mB}\right)^{1.5}\right)^m > \exp(-1.25m(y^*/(mB))^{1.5}).$$

The inequality follows from Proposition 3.4. Therefore, to establish (3.4), we just need show that

$$y^*\ln^+(mB/y^*)/(B\epsilon^2) \geq 1.25\cdot\sqrt{\frac{y^*}{mB}}\cdot\frac{y^*}{B},$$

i.e., that $\ln^+(mB/y^*)/\epsilon^2 \geq 1.25/\sqrt{e}$, which in turn follows from the facts that $\ln^+(mB/y^*) \geq 1$ and $1/\epsilon^2 \geq 1$. This completes the proof. □

Our required result is as follows.

COROLLARY 3.5. *Given any* unweighted *CIP with* $\ln^+(mB/y^*) > B$ *and any parameter* ϵ, $0 < \epsilon < 1$, *we can find in deterministic polynomial time a vector* $v = (v_1, v_2, \ldots, v_n)$ *of nonnegative integers such that* (a) $Av \geq b$, (b) $\sum_j v_j \leq a_2 y^*(1/(1-\epsilon) + (1/\epsilon^2)\ln^+(mB/y^*)/B)$, *where* $a_2 > 0$ *is an absolute constant, and* (c) $v_j \leq \lceil d_j/(1-\epsilon)\rceil$ *for all* j.

Proof. Let $\alpha = \lceil (a_3/\epsilon^2)\ln^+(mB/y^*)/B\rceil$ and z be as in the statement of Theorem 3.3. Define $v_j = \lceil z_j/(\alpha(1-\epsilon))\rceil$ for each j. Conditions (a) and (c) are easy to check, given Theorem 3.3. Since the z_j's are all nonnegative integers and since the CIP is unweighted ($c_j = 1$ for all j), condition (b) of Theorem 3.3 shows that at most $a_4 y^*\alpha$ of them can be nonzero. Thus, condition (b) follows since $v_j \leq z_j/(\alpha(1-\epsilon))+1$ if $z_j > 0$ and since $v_j = 0$ if $z_j = 0$. □

As mentioned in section 1, this improves the value of $\max_j x_j/d_j$ from $O(\ln^+(mB/y^*)/B)$ [31] to $O(1/(1-\epsilon))$, while keeping $(c^T\cdot x)/y^*$ relatively small at $O((1/\epsilon^2)\cdot\ln^+(mB/y^*)/B)$ (as long as ϵ is a constant bounded away from 1).

3.2. Handling stringent constraints. We now handle the case where the constraints $x_j \leq d_j$ have to be satisfied and where the coefficient matrix A has only zeroes and ones. Recall from section 1 that there is a family of facility location problems where the coefficient matrix has only zeroes and ones; this is an example of the CIPs to which the following results apply.

We start with a technical lemma.

LEMMA 3.6. *For any* $0 = u_0 < u_1 \leq u_2 \leq \cdots \leq u_i$ *and any* $\ell > 0$, *the sum* $s_i = \sum_{j=1}^{i}(u_j - u_{j-1})\ln^+(\ell/u_j)$ *is at most* $u_i\ln^+(\ell/u_i) + u_i$.

Proof. If $u_1 \geq \ell/e$, then $s_i = \sum_{j=1}^{i}(u_j - u_{j-1}) = u_i$. Otherwise, let $r \geq 1$ be the highest index such that $u_r < \ell/e$. Thus, $s_i = t_r + u_i - u_r$, where $t_r = \sum_{j=1}^{r}(u_j - u_{j-1})\ln(\ell/u_j)$. Since

$$\sum_{j=1\ldots r}(u_j - u_{j-1})\ln(l/u_j) \leq \int_0^{u_r} \ln(l/x)dx = (x\ln(l/x) + x)|_0^{u_r},$$

it follows that $t_r \leq u_r \ln(\ell/u_r) + u_r$. Hence,

$$s_i = t_r + u_i - u_r \leq u_r \ln(\ell/u_r) + u_i \leq u_i \ln^+(\ell/u_i) + u_i;$$

the last inequality follows from the fact that for any $x \leq y$ such that $x < \ell/e$, $x\ln(\ell/x) \leq y\ln^+(\ell/y)$. □

The following simple proposition will also help.

PROPOSITION 3.7. *For any $\ell > 0$ and $\ell' \geq 1$, $\ln^+(\ell) \geq (\ln^+(\ell\ell'))/\ell'$.*

Proof. The proposition is immediate if $\ell\ell' \leq e$. Next note that for any $a \geq e$, the function $g_a(x) = \ln(ax)/x$ decreases as x increases from 1 to infinity. Therefore, if $\ell \leq e$ and $\ell\ell' > e$, then

$$(\ln^+(\ell\ell'))/\ell' = (\ln(\ell\ell'))/\ell' = g_\ell(\ell') \leq g_e(\ell') \leq g_e(1) = 1 = \ln^+(\ell).$$

Finally, if $\ell > e$ and $\ell\ell' > e$, then $(\ln^+(\ell\ell'))/\ell' = g_\ell(\ell') \leq g_\ell(1) = \ln^+(\ell)$. □

THEOREM 3.8. *Suppose we are given a CIP with the matrix A having only zeroes and ones. In deterministic polynomial time, we can construct a feasible solution z to the CIP with $z_j \leq d_j$ for each j, and such that the objective function value $c^T \cdot z$ is $O(y^* \ln^+(m/y^*))$.*

Proof. Let a_3 and a_4 be as in the proof of Theorem 3.3. Define $a_5 = \max\{2, 4a_3\}$ and, for any $S \subseteq [n]$, $y^*_S = \sum_{j\in S} c_j x^*_j$. Starting with $S_0 = [n]$, we construct a sequence of sets $S_0 \supset S_1 \supset \cdots$ as follows. Suppose we have constructed $S_0, S_1, \ldots, S_i$ so far. Let $h_i = y^*_{S_i}$. If $S_i = \emptyset$, we stop; or else, if all $j \in S_i$ satisfy $a_5 \ln^+(m/h_i)x^*_j \leq d_j$, we stop. If not, define the proper subset S_{i+1} of S_i to be $\{j \in S_i : a_5 \ln^+(m/h_i)x^*_j > d_j\}$. For all $j \in (S_i - S_{i+1})$, we fix z_j to be $d_j \geq x^*_j$: note that for all such j, $z_j \leq a_5 \ln^+(m/h_i)x^*_j$.

Let S_t be the final set we construct. If $S_t = \emptyset$, we do nothing more; since $z_j \geq x^*_j$ for all j, we will have $Az \geq b$ as required. Also, it is easy to check that $z_j \leq d_j$ for all j. Therefore suppose $S_t \neq \emptyset$. Let $\alpha = a_5 \ln^+(m/h_t)$. Since we stopped at the nonempty set S_t, we see that $\alpha x^*_j \leq d_j$ for all $j \in S_t$. Recall that for all $j \notin S_t$, we have fixed the value of z_j to be $d_j \geq x^*_j$. Let w denote the vector of the remaining variables, i.e., the restriction of x^* to S_t. Let A' be the submatrix of A induced by the columns corresponding to S_t. We will now focus on rounding each x^*_j ($j \in S_t$) to a suitable nonnegative integer $z_j \leq d_j$.

Define, for each $i \in [m]$,

$$b'_i = b_i - \sum_{j\notin S_t} A_{i,j} z_j;$$

since $z_j \geq x^*_j$ for all $j \notin S_t$, we get

$$(A'w)_i = \sum_{j\in S_t} A_{i,j} x^*_j \geq b'_i \ \forall i \in [m].$$

Since each b_i and $A_{i,j}$ is an integer, so is each b'_i. Suppose $b'_i \leq 0$ for some i. Then, whatever nonnegative integers z_j we round the $j \in S_t$ to, we will satisfy the constraint $(Az)_i \geq b_i$. Therefore, we can ignore such indices i and assume w.l.o.g. that $B' \doteq \min_i b'_i \geq 1$. (The constraints corresponding to indices i with $b'_i \leq 0$ can be retained as "dummy constraints.") Define $\epsilon = 1/2$; recall that $\alpha = a_5 \ln^+(m/h_t)$. Therefore Proposition 3.7 shows that

$$\alpha \geq 4a_3 \max\{\ln^+(mB'/h_t)/B', 1\},$$

i.e., that $\alpha \geq (a_3/\epsilon^2) \max\{\ln^+(mB'/h_t)/B', 1\}$. Thus, by Theorem 3.3, we can round each x^*_j ($j \in S_t$) to some nonnegative integer $z_j \leq \lceil \alpha x^*_j \rceil \leq d_j$ in such a manner that

$$\sum_{j \in S_t} c_j z_j = O(h_t \alpha), \text{ and } \forall i \in [m], (A'z)_i \geq b_i \alpha(1-\epsilon) \geq b_i; \tag{3.5}$$

the last inequality (i.e., that $\alpha(1-\epsilon) \geq 1/2$) follows from the fact that $\alpha \geq a_5 \geq 2$. Therefore we can check that the final solution is indeed feasible. We need only to bound the objective function value, which we proceed to do now.

We first bound

$$\sum_{j \notin S_t} c_j z_j = \sum_{i=0}^{t-1} \sum_{j \in (S_i - S_{i+1})} c_j z_j. \tag{3.6}$$

Fix any i, $0 \leq i \leq t-1$. Recall that for each $j \in (S_i - S_{i+1})$, we set $z_j = d_j \leq a_5 \ln^+(m/h_i) x^*_j$. Thus,

$$\sum_{j \in (S_i - S_{i+1})} c_j z_j \leq O(\ln^+(m/h_i) \sum_{j \in (S_i - S_{i+1})} c_j x^*_j) = O(\ln^+(m/h_i) \cdot (h_i - h_{i+1})). \tag{3.7}$$

Setting $u_i = h_{t+1-i}$ and substituting (3.7) into (3.6),

$$\sum_{j \notin S_t} c_j z_j = O\left(\sum_{i=2}^{t+1} (u_i - u_{i-1}) \ln^+(m/u_i)\right), \tag{3.8}$$

where $u_{t+1} = y^*$. Now, if $S_t = \emptyset$, (3.8) gives the final objective function value. Otherwise, if $S_t \neq \emptyset$, (3.5) shows that

$$\sum_{j \in S_t} c_j z_j = O(h_t \alpha) = O(u_1 \ln^+(m/u_1)).$$

This, in combination with (3.8) and Lemma 3.6, shows that $\sum_j c_j z_j = O(y^* \ln^+(m/y^*))$.

This completes the proof. □

4. Conclusion. In this paper, we analyze various classes of problems in the context of balancing global vs. local criteria.

Our main result is the first constant-factor approximation algorithm for the off-line packet routing problem on arbitrary networks: for certain positive constants c' and c'', we show that given any packet routing problem, the routing time can efficiently be approximated to within a factor of c', while ensuring that all edge-queues are of size at most c''. Our result builds on the work of [16, 17], while exploiting an interesting trade-off between a (hard) congestion criterion and an (easy) dilation

criterion. Furthermore, we show that the result can be applied to a more general setting, by providing a polyhedral perspective of our technique. Our approach of appropriately using the rounding theorem of [13] has subsequently been applied by Bar-Noy et al. [3] to develop approximation algorithms for a family of multicasting problems. It has also been applied for a family of routing problems by Andrews and Zhang [2].

The second major result in the paper improves upon a class of results in multicriteria CIPs. We show that the local criterion of unweighted CIPs can be improved from an approximately logarithmic factor to a constant factor with the global criterion not deteriorating by more than a constant factor (i.e., we maintain a logarithmic factor approximation).

The third main result improves upon a well-known bound for CIPs, in the case where the coefficient matrix A has only zeroes and ones. We show that the approximation ratio can be improved from $O(y^* \lg m)$ to $O(y^* \ln^+(m/y^*))$.

Some open questions are as follows. It would be interesting to study our packet routing algorithm empirically and to fine-tune the algorithm based on experimental observation. It would also be useful to determine the best (constant) approximation possible in approximating the routing time. An intriguing open question is whether there is a *distributed* packet routing algorithm with a constant-factor approximation guarantee. Finally, in the context of covering integer programs, can we approximate the objective function to within bounds such as ours, with (essentially) no violation of the local capacity constraints?

Acknowledgments. We thank Bruce Maggs, the STOC 1997 program committee member(s) and referee(s), and the journal referees for their helpful comments. These have helped improve the quality of this paper a great deal. In particular, one of the journal referees simplified our original proof of Lemma 3.6.

VARIABLE-SIZED BIN PACKING: TIGHT ABSOLUTE WORST-CASE PERFORMANCE RATIOS FOR FOUR APPROXIMATION ALGORITHMS*

CHENGBIN CHU† AND RÉMY LA†

Abstract. In this paper we consider a one-dimensional bin packing problem where the bins do not have identical sizes, or a variable-sized bin packing problem, to minimize the bin consumption, i.e., the total size of the opened bins. The identical size problem has been extensively studied in the literature both for static and dynamic settings. The worst-case or average-case performance has been analyzed. Our problem setting particularly arises in metal cutting industries. Therefore, it presents a great practical relevance. Four greedy approximation algorithms based on a construction approach called largest object first with least absolute waste (LFLAW), largest object first with least relative waste (LFLRW), least absolute waste (LAW), and least relative waste (LRW) are examined. Their absolute worst-case performances are analyzed. The worst case bounds are 2 for LFLAW and LFLRW, 3 for LAW, and $2 + \ln 2$ for LRW. We also show that these worst-case bounds are tight.

Key words. variable-sized bin packing, absolute worst-case performance ratios, approximation algorithms

1. Introduction.

This paper addresses the worst-case performance of four approximation algorithms to solve a one-dimensional bin packing problem. The performance of an approximation algorithm can be measured by worst-case performance bounds. Two types of bounds can be distinguished: asymptotic worst-case performance bounds and absolute worst-case performance bounds. If, for a given instance I, $C_{\mathrm{H}}(I)$ and $C^*(I)$ are the criterion value given by approximation algorithm H and the optimal criterion value, respectively, an *asymptotic worst-case analysis* consists of finding a relation of the form

$$C_{\mathrm{H}}(I) \leq R \times C^*(I) + A \qquad \text{for any } I,$$

where A and R are nonnegative constants independent of I. An *absolute worst-case analysis* establishes a relation of the form

$$C_{\mathrm{H}}(I) \leq \Omega \times C^*(I) \qquad \text{for any } I.$$

The smallest values of R and Ω satisfying the relations above are called *asymptotic worst-case performance ratio* and *absolute worst-case performance ratio* and denoted as R_{H} and Ω_{H}, respectively. Sometimes, R_{H} and Ω_{H} are also said to be *tight asymptotic worst-case bound* and *tight absolute worst-case bound*, respectively. Therefore, we have

$$R_{\mathrm{H}} = \lim_{k \to +\infty} \sup_I \left\{ \frac{C_{\mathrm{H}}(I)}{C^*(I)} \middle| C^*(I) \geq k \right\},$$

$$\Omega_{\mathrm{H}} = \sup_I \left\{ \frac{C_{\mathrm{H}}(I)}{C^*(I)} \right\} = \inf \left\{ \rho \middle| \frac{C_{\mathrm{H}}(I)}{C^*(I)} \leq \rho \quad \forall I \right\}.$$

Note that there may be no instance I such that $\frac{C_{\mathrm{H}}(I)}{C^*(I)} = \Omega_{\mathrm{H}}$. In this case, Ω_{H} can only be asymptotically reached; i.e., for any $\varepsilon > 0$, there is an instance I such that $0 \leq \Omega_{\mathrm{H}} - \frac{C_{\mathrm{H}}(I)}{C^*(I)} \leq \varepsilon$. By definition, the following relation is true:

$$R_{\mathrm{H}} \leq \Omega_{\mathrm{H}}.$$

The problem considered in this paper is a one-dimensional bin packing problem. The classical one-dimensional bin packing problem, called unit-capacity bin packing in the literature, can be described as follows: Given a list of m objects $\mathcal{L} = \{1, 2, \ldots, m\}$ with sizes $s_i \leq 1$ $(i = 1, 2, \ldots, m)$, pack all the objects into a minimum number of bins of size 1. Because of the NP-hardness of the problem and the limitation on computation time due to specific application environments (telecommunications and computer systems, for instance), low complexity methods are needed. Many approximation algorithms, sometimes even with linear complexity, have been proposed with evaluated performance. These methods can be classified into on-line algorithms, such as first fit (FF) and best fit (BF), and off-line algorithms, such as first fit decreasing (FFD) and best fit decreasing (BFD). The performance is evaluated either in average-case [7], [5] or in worst-case [4], [6]. An excellent survey of the research on this problem was given by Coffman, Garey, and Johnson, [4]. This survey was again updated in 1996 [6]. Johnson [12] examined the asymptotic worst-case performance of four approximation algorithms: FF, BF, FFD, and BFD. Tighter bounds on the performance of FF and BF are given in [10] and those of FFD and BFD by Baker [2], respectively. Ivanyi [11] studied the absolute worst-case performances of these four approximation algorithms. Simchi–Levi [17] proved that the absolute worst-case performance ratio is 1.5 for FFD and BFD and it is at least 1.7, but no more than 1.75, for FF and BF. The asymptotic worst-case ratios for best-k-fit and next-k-fit are given in [14], [15], respectively. That for HARMONIC$_M$ is given in [13].

In this paper, we study a slightly different problem, a so-called variable-sized bin packing problem: Given a set $\mathcal{L}$ of m objects $\{1, 2, \ldots, m\}$ with sizes s_i $(i = 1, 2, \ldots, m)$ and given M types of bins of sizes S_j $(i = 1, 2, \ldots, M)$, pack all the objects so that the sum of the sizes of the bins used (called *bin consumption* hereafter) is minimum. It is generally assumed that any object of $\mathcal{L}$ can be packed into at least one type of bin and there is an inexhaustible supply of bins of each type. Compared with the unit-capacity bin packing problem, variable-sized bin packing received less attention, because it is more general and therefore more difficult, but is receiving more and more interest from researchers [9], [16], [8], [18] due to its variety of interpretations from computer storage allocation to stock cutting. As for unit-capacity bin packing, both on-line [8], [18] and off-line [9], [16] settings are studied. However, only asymptotic worst-case performance ratios are given for proposed algorithms. In this paper, we propose four greedy approximation algorithms and we analyze their absolute worst-case performance. This work is motivated by a real life cutting stock problem for which we developed effective approximation algorithms to fulfill industrial requirements [1], [3]. The real life problem has a more complex model and the proposed algorithms are more sophisticated than those analyzed in this paper. To some extent, the results of this paper can be seen as a preliminary step for the worst-case analysis of algorithms proposed in [1] and [3].

Section 2 describes the four approximation algorithms. In section 3, their absolute worst-case performance is analyzed.

2. Description of the approximation algorithms. Let M be the number of bin types. Let S_j be the size of bins of type j $(j = 1, 2, \ldots, M)$. The number of bins

in each type is assumed to be infinite. Without loss of generality, we assume that the objects of $\mathcal{L}$ are arranged into nonincreasing size order ($s_1 \geq s_2 \geq \cdots \geq s_m$). Before properly describing the approximation algorithms, we introduce a subproblem.

2.1. A subproblem. For any approximation algorithm considered in this paper, there is a subproblem to be solved: Pack a subset of objects from a given set E into a given type j of bin. This subproblem, which is a knapsack problem, can be approximately solved by the FFD method: At each step, the lowest indexed (i.e., the longest) remaining object is packed among those fitting the remaining capacity of the bin. This process is repeated until either there is no more unpacked object or no object fits the remaining size of the bin.

Another way to describe this procedure is the following. The objects are arranged in a list in increasing order of their indexes. The first object in the list fitting the remaining capacity of the bin is packed and then removed from the list. This process is repeated until either no more object in the list fits the remaining capacity of the bin or the list becomes empty.

Note that if an object does not fit the remaining capacity of the bin at a step, it does not fit the remaining capacity of the bin at a subsequent step, since the remaining capacity decreases along with the procedure. As a consequence, the object packed at a step is necessarily larger indexed than those packed at previous steps.

Throughout the paper, $\sigma(j, E)$, $\delta(j, E)$, and $\omega(j, E)$ denote the set of packed objects, the total size of these objects, and the resulting waste (unused capacity of the bin), respectively. By notation, we have

$$\delta(j, E) = \sum_{i \in \sigma(j,E)} s_i,$$
$$\omega(j, E) = S_j - \delta(j, E).$$

An important property of the solution is the following.

PROPERTY 2.1. *For any unpacked object $i \in E - \sigma(j, E)$, we have*

$$s_i > S_j - \sum_{i' \in \sigma(j,E), i' < i} s_{i'} = \omega(j, E) + \sum_{i' \in \sigma(j,E), i' > i} s_{i'}.$$

Proof. Assume that there is an object $i^* \in E - \sigma(j, E)$ such that $s_{i^*} \leq S_j - \sum_{i' \in \sigma(j,E), i' < i^*} s_{i'}$. Let $A = \{i | i \in \sigma(j, E), i < i^*\}$. After the objects in A are packed, the remaining capacity is $S_j - \sum_{i \in A} s_i$. By assumption, object i^* fits the remaining capacity of the bin. Therefore, the index of the next object to be packed must be less than or equal to i^*, which is in contradiction with the fact that the next object actually packed belongs to $\sigma(j, E) - A = \{i | i \in \sigma(j, E), i > i^*\}$. □

The consequence of this property is the following corollaries.

COROLLARY 2.2. *For any unpacked object $i \in E - \sigma(j, E)$, if $i < \inf \sigma(j, E)$, and in particular if $s_i > \delta(j, E)$, then $s_i > S_j$.*

This corollary holds, since if $i < \inf \sigma(j, E)$, then $\sum_{i' \in \sigma(j,E), i' < i} s_{i'} = 0$.

COROLLARY 2.3. *For any unpacked object $i \in E - \sigma(j, E)$, we have $s_i > \omega(j, E)$.*

This corollary holds since $\sum_{i' \in \sigma(j,E), i' > i} s_{i'} \geq 0$.

PROPERTY 2.4. *Let E' be a set of objects such that $E \subseteq E'$ and $\inf(E' - E) > \sup \sigma(j, E)$. Then $\sigma(j, E) \subseteq \sigma(j, E')$.*

Proof. In the list corresponding to E', the objects are arranged so that objects in E are at the head of the list and the remaining ones are arranged at the tail. According

to the procedure, an object in $E' - E$ can be packed only if no more object in E can fit the remaining capacity of the bin. Before this stage, the procedure proceeds as if there were only objects in E; i.e., all objects in $\sigma(j, E)$ are packed. □

2.2. Approximation algorithms. The proposed approximation algorithms are iterative procedures. At each step, a subset of objects is packed into one chosen bin. Let $\mathcal{L}_k$ be the set of unpacked objects at the *beginning* of the kth step ($\mathcal{L}_1 = \mathcal{L}$). At step k, the set of appropriate bin types T_k is identified and for each appropriate bin type $j \in T_k$, the subproblem corresponding to the bin type j and the set of unpacked objects $\mathcal{L}_k$ is solved and the corresponding waste $\omega(j, \mathcal{L}_k)$ is computed.

One bin is actually chosen according to a given indicator specific to each approximation algorithm. Let t_k be the type of the bin chosen at step k. The subset $\sigma(t_k, \mathcal{L}_k)$ of objects which are packed into one bin of type t_k is removed from $\mathcal{L}_k$. This gives the set of unpacked objects at the beginning of the $k + 1$st step; namely, $\mathcal{L}_{k+1} = \mathcal{L}_k - \sigma(t_k, \mathcal{L}_k)$.

Let largest object first with least absolute waste (LFLAW), largest object first with least relative waste (LFLRW), least absolute waste (LAW), and least relative waste (LRW) be the names of the four approximation algorithms, respectively.

In LFLAW and LFLRW, only those bin types at least as large as the longest unpacked object are considered to be appropriate (i.e., $T_k = \{j | S_j \geq s_i \ \forall\, i \in \mathcal{L}_k\}$) while in LAW and LRW, all bin types are appropriate at each step (i.e., $T_k = \{1, 2, \ldots, M\}$ for any k).

In LFLAW and LAW, the bin type t_k is the one that generates the lowest absolute waste $\omega(j, \mathcal{L}_k)$:

$$t_k = \arg\min_{j \in T_k} \omega(j, \mathcal{L}_k) = \arg\min_{j \in T_k} \{S_j - \delta(j, \mathcal{L}_k)\}.$$

In LFLRW and LRW, the bin type t_k is the one that generates the lowest relative waste:

$$t_k = \arg\min_{j \in T_k} \frac{\omega(j, \mathcal{L}_k)}{S_j},$$

or equivalently

$$t_k = \arg\max_{j \in T_k} \frac{\delta(j, \mathcal{L}_k)}{S_j} = \arg\min_{j \in T_k} \frac{\omega(j, \mathcal{L}_k)}{\delta(j, \mathcal{L}_k)}.$$

It can be shown that the four approximation algorithms have the same complexity, which is $O(m^2 M)$.

3. Worst-case performance analysis. Throughout the paper, we assume, without loss of generality, that $\sum_{i=a}^{b} x_i = 0$ whenever $b < a$. The following notation is also used in this paper.

NOTATION 3.1.

N: number of bins used to pack all objects of $\mathcal{L}$ according to the considered approximation algorithm, which is also equal to the number of steps needed for the approximation algorithm to pack all of the objects;

P_k: set of objects packed at step k: $P_k = \sigma(t_k, \mathcal{L}_k)$;

l_k: total size of the objects packed at step k: $l_k = \delta(t_k, \mathcal{L}_k) = \sum_{i \in P_k} s_i$;

L_k: size of the bin chosen at step k: $L_k = S_{t_k}$;

w_k: waste generated at step k: $w_k = L_k - l_k = \omega(t_k, \mathcal{L}_k)$;

u_k: *the largest indexed (i.e., the shortest) unpacked object at the* beginning *of step* k: $u_k = \sup \mathcal{L}_k$;

v_k: *the smallest indexed (i.e., the longest) unpacked object at the* beginning *of step* k: $v_k = \inf \mathcal{L}_k$;

Λ: *total size of all objects in* $\mathcal{L}$;

C_{H}: *total size of the bins used to pack the objects of* $\mathcal{L}$ *according to approximation algorithm* H;

C^*: *total size of the bins used to pack the objects of* $\mathcal{L}$ *in an optimal solution;*

α: *the smallest* k *such that* L_k *is the longest.*

By notation, we have the following properties.

PROPERTY 3.2. *In the solution given by LFLAW or LFLRW, we have* $v_k \in P_k$ *for any* $1 \le k \le N$.

PROPERTY 3.3. *In a solution given by any one of the approximation algorithms proposed, we have* $L_k < L_\alpha$ *for any* k *such that* $1 \le k < \alpha$ *and* $L_k \le L_\alpha$ *for any* k *such that* $\alpha \le k \le N$.

PROPERTY 3.4. *For any* k $(k = 1, 2, \ldots, N-1)$ *and for any* $i \in \mathcal{L}_{k+1}$ *we have* $w_k < s_i$.

Proof. This relation is straightforward after Corollary 2.3 by taking into account the fact that $\mathcal{L}_{k+1} = \mathcal{L}_k - \sigma(t_k, \mathcal{L}_k)$. □

The following corollary is one of the consequences of this property.

COROLLARY 3.5. *For any* k $(k = 1, 2, \ldots, N-1)$, *and for any* k' $(k' = k+1, k+2, \ldots, N)$, *we have* $w_k < l_{k'}$.

Proof. For any object $i \in P_{k'}$, we have $i \in \mathcal{L}_{k+1}$. Therefore $l_{k'} \ge s_i > w_k$, according to Property 3.4. □

PROPERTY 3.6. *For any approximation algorithm considered in this paper, we have* $L_N = \min\{S_j | S_j \ge l_N, j = 1, 2, \ldots, M\}$. *In other words, the last bin is the shortest one among those being capable of containing all objects of* $\mathcal{L}_N$.

Proof. Assume that there is a bin type j such that $S_j \ge l_N$ and $L_N > S_j$. This implies that $\delta(j, \mathcal{L}_N) = \delta(t_N, \mathcal{L}_N) = l_N$ and $\omega(j, \mathcal{L}_N) < \omega(t_N, \mathcal{L}_N)$. This is in contradiction with the fact that $\omega(t_N, \mathcal{L}_N) \le \omega(j, \mathcal{L}_N)$ for LFLAW and LAW and with the fact that $\frac{\omega(t_N, \mathcal{L}_N)}{\delta(t_N, \mathcal{L}_N)} \le \frac{\omega(j, \mathcal{L}_N)}{\delta(j, \mathcal{L}_N)}$ for LFLRW and LRW. □

The following corollary is a consequence of this property.

COROLLARY 3.7. *For any bin type* j *such that* $S_j < L_N$, *we have* $S_j < l_N$.

LEMMA 3.8. *For any* $\tau \in \{1, 2, \ldots, M\}$, *if* $S_\tau \ge s_{v_N}$ *and* $S_\tau < L_N$, *then* $S_\tau < 2\delta(\tau, \mathcal{L}_N)$.

Proof. The fact that $S_\tau \ge s_{v_N}$ implies $v_N \in \sigma(\tau, \mathcal{L}_N)$ and consequently

$$s_{v_N} \le \delta(\tau, \mathcal{L}_N). \tag{3.1}$$

Due to Corollary 3.7, the assumptions of Lemma 3.8 imply

$$S_\tau < l_N. \tag{3.2}$$

Let $G = \mathcal{L}_N - \sigma(\tau, \mathcal{L}_N)$. As S_τ is shorter than l_N (see 3.2), all objects of $\mathcal{L}_N$ cannot be packed into one bin of type τ; G is then nonempty. Furthermore, from Corollary 2.3, we obtain

$$s_i > S_\tau - \delta(\tau, \mathcal{L}_N) \qquad \forall i \in G, \tag{3.3}$$

By notation of v_N, we also have

$$s_i \le s_{v_N} \qquad \forall i \in G. \tag{3.4}$$

From (3.1), (3.3), and (3.4), we derive

$$S_\tau - \delta(\tau, \mathcal{L}_N) < s_{v_N} \le \delta(\tau, \mathcal{L}_N).$$

Therefore,

$$S_\tau < 2\delta(\tau, \mathcal{L}_N). \qquad \square$$

3.1. Worst-case analysis of algorithms LFLAW and LFLRW. An interesting property of the solution yielded by LFLAW or LFLRW is that all bins are used more than half, except perhaps the last one. This is shown in the following lemma.

LEMMA 3.9. *In the solution given by LFLAW or LFLRW, for any k such that $1 \le k < N$, we have $L_k < 2l_k$.*

Proof. According to LFLAW and LFLRW, for any k such that $1 \le k < N$, we have $v_k \in P_k$ and consequently $s_{v_k} \le l_k$. According to Corollary 3.4, $w_k < s_{u_{k+1}}$ for any k such that $1 \le k < N$. If there is some k such that $1 \le k < N$ and $l_k \le w_k$, we would have $s_{v_{k+1}} \le s_{v_k} \le l_k \le w_k < s_{u_{k+1}}$, which is in contradiction with the fact that $u_{k+1} \ge v_{k+1}$. $\square$

LEMMA 3.10. *In the solution given by LFLAW or LFLRW, if $\alpha \ne N$, then the bin consumption $C < 2C^*$.*

Proof. The bin consumption C can be upper bounded as follows:

$$C = \sum_{k=1}^{N} L_k \le \sum_{k=1, k\ne\alpha}^{N-1} L_k + 2L_\alpha = \sum_{k=1, k\ne\alpha}^{N-1} L_k + 2(l_\alpha + w_\alpha).$$

Using Lemma 3.9, this relation leads to

$$C < 2 \sum_{k=1, k\ne\alpha}^{N-1} l_k + 2(l_\alpha + w_\alpha).$$

Furthermore, from Corollary 3.5, $w_\alpha < l_N$. Therefore,

$$C < 2 \sum_{k=1, k\ne\alpha}^{N-1} l_k + 2(l_\alpha + l_N) = 2\Lambda \le 2C^*. \qquad \square$$

LEMMA 3.11. *In the solution given by LFLAW or LFLRW, if $\alpha = N$, then $C < 2C^*$.*

Proof. We first prove that

$$L_N < 2l_N. \tag{3.5}$$

By notation, we have $s_{v_N} \le s_{v_{N-1}}$. Since $v_{N-1} \in P_{N-1}$ (see Property 3.2), we should have $s_{v_{N-1}} \le L_{N-1}$. Therefore,

$$s_{v_N} \le L_{N-1}. \tag{3.6}$$

In other words, v_N can be packed into a bin of type t_{N-1}; i.e., $v_N \in \sigma(t_{N-1}, \mathcal{L}_N)$. The fact that $\alpha = N$ implies

$$L_{N-1} < L_N \tag{3.7}$$

according to Property 3.3. According to Lemma 3.8, relations (3.6) and (3.7) imply

$$L_{N-1} < 2\delta(t_{N-1}, \mathcal{L}_N). \tag{3.8}$$

For LFLAW, this relation implies

$$\begin{aligned} w_N &= \omega(t_N, \mathcal{L}_N) \le \omega(t_{N-1}, \mathcal{L}_N) \\ &= L_{N-1} - \delta(t_{N-1}, \mathcal{L}_N) \\ &< \delta(t_{N-1}, \mathcal{L}_N) \le l_N \end{aligned}$$

which is equivalent to (3.5).

For LFLRW, (3.8) implies that

$$L_N/l_N \le L_{N-1}/\delta(t_{N-1}, \mathcal{L}_N) < 2$$

which is equivalent to (3.5).

As a consequence, if $\alpha = N$, (3.5) holds for both the solutions given by LFLAW and LFLRW.

Considering Lemma 3.9 and relation (3.5), we obtain

$$C = \sum_{k=1}^{N} L_k < 2 \sum_{k=1}^{N} l_k = 2\Lambda \le 2C^* \qquad \square$$

The following theorem is straightforward from Lemmas 3.10 and 3.11.

THEOREM 3.12. *For any instance, we have* $C_{\mathrm{LFLAW}}/C^* < 2$ *and* $C_{\mathrm{LFLRW}}/C^* < 2$.

THEOREM 3.13. *The upper bound* 2 *is tight for* C_{LFLAW}/C^* *and* C_{LFLRW}/C^*; *i.e.,* $\Omega_{\mathrm{LFLAW}} = \Omega_{\mathrm{LFLRW}} = 2$.

Proof. For LFLAW, consider the following instance composed of two types of bins with sizes $S_1 = n + 1$ and $S_2 = 2 - 1/n$ (n being a positive integer) and n objects of same sizes $l_1 = l_2 = \cdots = l_n = 1$ have to be packed. In the solution given by LFLAW, each object is packed into one bin of type 2, whereas the optimal solution consists of packing all objects into one bin of type 1. Therefore $C_{\mathrm{LFLAW}} = n(2 - 1/n) = 2n - 1$ and $C^* = n + 1$. When n tends towards $+\infty$, the ratio C_{LFLAW}/C^* tends towards 2.

For LFLRW, consider the following instance composed of three types of bins with sizes $S_1 = 2n$, $S_2 = 2$, and $S_3 = 1$ (n being a positive integer). The $n + 1$ objects to be packed are of sizes $s_1 = 1 + 1/n$, $s_2 = s_3 = \cdots = s_{n+1} = 1$. According to LFLRW, all objects are packed into one bin of type 1, whereas the optimal solution consists of packing object 1 into one bin of type 2 and each object i ($i > 1$) into one bin of type 3. Therefore $C_{\mathrm{LFLRW}} = 2n$ and $C^* = n + 2$. When n tends towards $+\infty$, the ratio C_{LFLRW}/C^* tends towards 2. $\square$

3.2. Worst-case performance of LAW. This subsection is devoted to the worst-case performance of LAW. As for LFLAW and LFLRW, we first prove some lemmas used in the proof of the worst-case bound.

LEMMA 3.14. *In the solution given by LAW,* $L_N \le \max(C^*, 2l_N)$.

Proof. Assume that $L_N > \max(C^*, 2l_N)$; i.e., $L_N > C^*$ and $L_N > 2l_N$, from which we can derive

$$l_N < L_N - l_N. \tag{3.9}$$

Let τ be the type of the bin into which object v_N is packed in an optimal packing. By notation,

$$s_{v_N} \leq S_\tau \leq C^*. \tag{3.10}$$

Together with the assumption that $L_N > C^*$, we obtain

$$S_\tau < L_N. \tag{3.11}$$

From Corollary 3.7, we obtain

$$S_\tau - \delta(\tau, \mathcal{L}_N) < S_\tau < l_N.$$

Considering (3.9), we obtain

$$S_\tau - \delta(\tau, \mathcal{L}_N) < l_N < L_N - l_N$$

which is in contradiction with the principle of LAW. □

THEOREM 3.15. *For any instance,* $C_{\mathrm{LAW}}/C^* < 3$.

Proof. The bin consumption C_{LAW} is given by

$$C_{\mathrm{LAW}} = \sum_{k=1}^{N} L_k = \sum_{k=1}^{N-1} (l_k + w_k) + L_N.$$

According to Corollary 3.5, we have

$$\sum_{k=1}^{N-1} w_k < \sum_{k=2}^{N} l_k.$$

Consequently

$$\begin{aligned} C_{\mathrm{LAW}} &< \sum_{k=1}^{N-1} l_k + \sum_{k=2}^{N} l_k + L_N \\ &< 2\Lambda - l_N + L_N. \end{aligned}$$

According to Lemma 3.14, we obtain

$$C_{\mathrm{LAW}} < 2\Lambda + \max(C^* - l_N, l_N).$$

Further considering the fact that $\Lambda \leq C^*$, $C^* - l_N \leq C^*$, and $l_N \leq C^*$, the relation above allows us to prove the lemma. □

THEOREM 3.16. *The upper bound* 3 *is tight for* C_{LAW}/C^*, *i.e.,* $\Omega_{\mathrm{LAW}} = 3$.

Proof. Consider the following instance: Given two types of bins with sizes $S_1 = n + 3$ and $S_2 = 2 - 1/n$ (n being a positive integer), the $n + 1$ objects to be packed are with sizes $s_1 = 2$, $s_2 = s_3 = \cdots = s_{n+1} = 1$.

The packing provided by LAW is as follows: Each of the objects $2, 3, \ldots, n+1$ is packed into one bin of type 2 and object 1 is packed into one bin of type 1. For this instance, $C_{\mathrm{LAW}} = n(2 - 1/n) + n + 3 = 3n + 2$. In the optimal packing all objects are packed into one bin of type 1. Therefore, $C^* = n + 3$. The ratio between C_{LAW} and C^* tends towards 3 when n tends towards $+\infty$. □

3.3. Worst-case performance bound of LRW. In this subsection, we use the following notation.

NOTATION 3.17.

Q_k: the total size of objects packed from step k to step N; i.e., $Q_k = \sum_{j=k}^{N} l_j$;

p: index such that $Q_p \le L_N$ and $Q_{p-1} > L_N$; without loss of generality, p is set to 1 if $L_N \ge Q_1 = \Lambda$;

q: index such that $Q_q \le L_N/2$ and $Q_{q-1} > L_N/2$; without loss of generality, q is set to 1 if $L_N \ge 2Q_1 = 2\Lambda$;

r: the smallest k such that $L_k \ge 2l_k$; if $L_k < 2l_k$ $\forall$ k such that $1 \le k \le N$, then r is set to $N+1$, without loss of generality.

By notation, we have

$$\Lambda = Q_1 > Q_2 > \cdots > Q_N,$$
$$p \le q. \tag{3.12}$$

The last relation can be justified as follows. If $p > q$, we would have $p - 1 \ge q$ and therefore $Q_{p-1} \le Q_q$ from which it follows $L_N < Q_{p-1} \le Q_q \le L_N/2$ which implies $L_N < 0$. This latter relation, however, is impossible.

For any k such that $k \ge p$, we have $Q_k \le L_N$; i.e., all objects in $\mathcal{L}_k$ can be packed into one bin of type t_N. Therefore, $\delta(t_N, \mathcal{L}_k) = Q_k$. On the other hand, $\delta(t_k, \mathcal{L}_k) = l_k$. According to LRW, we must have

$$\frac{l_k}{L_k} = \frac{\delta(t_k, \mathcal{L}_k)}{S_{t_k}} \ge \frac{\delta(t_N, \mathcal{L}_k)}{S_{t_N}} = \frac{Q_k}{L_N}, \quad k = p, p+1, \ldots, N. \tag{3.13}$$

In LRW, if one bin is packed at less than the half of its size, the subsequent bins (in the packing order) are also packed at less than the half of their size. That is the purpose of the following lemma.

LEMMA 3.18. *In the solution given by LRW, if $r < N$, then for any k such that $r \le k < N$, we have $L_k \ge 2l_k$ and $l_{k+1} > L_k$.*

Proof. It is sufficient to prove that for any k such that $1 \le k < N$, if $L_k \ge 2l_k$, then $L_{k+1} \ge 2l_{k+1}$, $l_{k+1} > L_k$.

From the assumption that $L_k \ge 2l_k$, we can derive $w_k = L_k - l_k \ge l_k$. According to Corollary 2.3, we have

$$s_i > w_k \ge l_k \qquad \forall i \in \mathcal{L}_{k+1} \tag{3.14}$$

which means that $\sup \mathcal{L}_{k+1} < \inf P_k = \inf(\mathcal{L}_k - \mathcal{L}_{k+1})$.

From Property 2.4, it follows that $P_{k+1} = \sigma(t_{k+1}, \mathcal{L}_{k+1}) \subseteq \sigma(t_{k+1}, \mathcal{L}_k)$. This implies that

$$w_{k+1} = \omega(t_{k+1}, \mathcal{L}_{k+1}) \ge \omega(t_{k+1}, \mathcal{L}_k). \tag{3.15}$$

On the other hand, according to LRW, we have $\omega(t_{k+1}, \mathcal{L}_k)/L_{k+1} \ge w_k/L_k \ge 1/2$ which implies

$$\omega(t_{k+1}, \mathcal{L}_k) \ge \frac{1}{2} L_{k+1}. \tag{3.16}$$

The two last relations (3.15) and (3.16) give $w_{k+1} \ge \frac{1}{2} L_{k+1}$; namely, $L_{k+1} \ge 2l_{k+1}$.

Relation (3.14) also implies $s_{u_{k+1}} > L_k$, according to Corollary 2.2. Considering the fact that $l_{k+1} \ge s_{u_{k+1}}$, we can conclude that $l_{k+1} > L_k$. ∎

From Lemma 3.18, we can deduce $r \geq q$. This relation is obviously true if $r = N+1$. If $r \leq N$, we have $L_N \geq 2l_N > l_N + L_{N-1} = l_N + 2l_{N-1} > \cdots > l_N + l_{N-1} + \cdots + 2l_r > Q_r$. Therefore $r \geq p$. Considering (3.13), this implies $2 \leq L_r/l_r \leq L_N/Q_r$; i.e., $Q_r \leq L_N/2$. As a consequence $r \geq q$. Together with the relation $p \leq q$, we obtain

$$1 \leq p \leq q \leq r \leq N+1.$$

The following corollary is a consequence of Lemma (3.18).

COROLLARY 3.19. *If $L_\alpha \geq 2l_\alpha$, then $r \leq N$ and $\alpha = N$ ($L_k < L_N$ for any k such that $1 \leq k < N$).*

LEMMA 3.20. *In the solution given by LRW, if $L_\alpha < 2l_\alpha$, then $C_{\mathrm{LRW}} < 2C^*$.*

Proof. The bin consumption is given by

$$\begin{aligned} C_{\mathrm{LRW}} &= \sum_{k=1}^{\alpha-1} L_k + \sum_{k=\alpha}^{N-1} L_k + L_N \\ &\leq \sum_{k=1}^{\alpha-1} L_k + \sum_{k=\alpha}^{N-1} l_k + \sum_{k=\alpha}^{N-1} w_k + l_\alpha + w_\alpha. \end{aligned} \tag{3.17}$$

This relation is true whether or not $\alpha = N$. According to Lemma 3.18, the fact that $L_\alpha < 2l_\alpha$ implies that

$$L_k < 2l_k, \qquad k = 1, 2, \ldots, \alpha. \tag{3.18}$$

From Corollary 3.5, we obtain

$$\sum_{k=\alpha}^{N-1} w_k < \sum_{k=\alpha+1}^{N} l_k \tag{3.19}$$

and

$$w_\alpha < l_N. \tag{3.20}$$

The last relation holds whether or not $\alpha = N$, since $L_\alpha < 2l_\alpha$, or equivalently $w_\alpha < l_\alpha$. Relations (3.17), (3.18), (3.19) and (3.20) give

$$\begin{aligned} C_{\mathrm{LRW}} &< 2\sum_{k=1}^{\alpha-1} l_k + \sum_{k=\alpha}^{N-1} l_k + \sum_{k=\alpha+1}^{N} l_k + l_\alpha + l_N \\ &= 2\Lambda \leq 2C^*. \end{aligned}$$

∎

LEMMA 3.21. *In the solution given by LRW, if $L_N \geq 2l_N$, then $C^* \geq L_N$.*

Proof. Assume that $L_N > C^*$. We would have

$$L_N > C^* \geq \Lambda.$$

Let τ be the type of bin into which object v_N is packed in an optimal solution. This gives $S_\tau \geq s_{v_N}$ and $S_\tau \leq C^*$ by definition. Considering the assumption that $C^* < L_N$, we have $S_\tau < L_N$. According to Lemma 3.8, we have

$$S_\tau < 2\delta(\tau, \mathcal{L}_N). \tag{3.21}$$

On the other hand, from the assumption that $L_N \geq 2l_N$ and the principle of LRW, we must have

$$2 \leq L_N/l_N \leq S_\tau/\delta(\tau, \mathcal{L}_N)$$

which is in contradiction with (3.21). □

From now on, we derive the upper bounds of subsets of bins.

LEMMA 3.22. *In the solution given by LRW, if $r \leq N$, we have $\sum_{k=r}^{N-1} L_k < Q_r$.*

Proof. The lemma is obviously true if $r = N$. If $r < N$, for any k such that $r \leq k < N$, according to Lemma 3.18, we have $L_k < l_{k+1}$. Therefore, $\sum_{k=r}^{N-1} L_k < \sum_{k=r+1}^{N} l_k = Q_{r+1} < Q_r$. □

LEMMA 3.23. *In the solution given by LRW, we have $\sum_{k=q}^{r-1} L_k \leq 2(Q_q - Q_r)$.*

Proof. If $q = r$, we must have $\sum_{k=q}^{r-1} L_k = 0 = 2(Q_q - Q_r)$. The lemma thus is true when $q = r$.

If $q < r$, for any k such that $q \leq k < r$, we have $L_k < 2l_k$, according to the definition of r. Therefore $\sum_{k=q}^{r-1} L_k < 2\sum_{k=q}^{r-1} l_k = 2(\sum_{k=q}^{N} l_k - \sum_{k=r}^{N} l_k) = 2(Q_q - Q_r)$. The lemma also is true when $q < r$. □

LEMMA 3.24. *For any $a > 0$ and $x > 0$, we have $\ln(ax) - x/2 \leq \ln(2a) - 1$.*

Proof. Consider a function $f(x) = \ln(ax) - x/2$. For this function, we have $f'(x) = 1/x - 1/2$ and $f''(x) = -1/x^2 < 0$. Therefore, $f(x)$ is a concave function over $(0, +\infty)$. The maximum is obtained at $f'(x) = 0$, i.e., at $x = 2$. Therefore, $\ln(ax) - x/2 \leq \ln(2a) - 1$. □

LEMMA 3.25. *For any $a \in (0, 1]$ and for any $x > 0$, we have $(1 - a^x)/x \leq -\ln a$.*

Proof. Consider a function $g(x) = 1 - a^x + x \ln a$ defined over $[0, +\infty)$. For this function, we have $g'(x) = (1 - a^x) \ln a$. Due to the fact that $0 < a \leq 1$ and $x \geq 0$, we have $a^x \leq 1$ and $\ln a \leq 0$; namely, $g'(x) \leq 0$. Thus, $g(x)$ is a nonincreasing function. As a consequence, $g(x) \leq g(0) = 0$. As a result, $1 - a^x + x \ln a \leq 0$, or equivalently $(1 - a^x)/x \leq -\ln a$ for any $x > 0$. □

LEMMA 3.26. *In the solution given by LRW, if $L_\alpha \geq 2l_\alpha$, we have*

$$\sum_{k=p}^{q-1} L_k \leq (1 + \ln 2)L_N - 2Q_q. \tag{3.22}$$

Proof. The lemma is obviously true if $q = p$, since $(1+\ln 2)L_N - 2Q_q \geq L_N - 2Q_q \geq 0 = \sum_{k=p}^{q-1} L_k$. To prove the lemma when $q > p$, it is sufficient to show that

$$\sum_{k=p}^{q-1} L_k \leq \left(\ln \frac{Q_p}{Q_{q-1}} + 2 - \frac{L_N}{2Q_{q-1}}\right) L_N - 2Q_q. \tag{3.23}$$

In fact, from Lemma 3.24, $\ln(ax) - x/2 \leq \ln(2a) - 1$ for any $x > 0$ and $a > 0$. By substituting a and x with Q_p/L_N and L_N/Q_{q-1}, respectively, all the conditions are fulfilled and relation (3.23) implies (3.22). What follows shows the correctness of (3.23).

From the fact that $l_{q-1} = Q_{q-1} - Q_q$, we obtain

$$L_{q-1} = \frac{L_{q-1}(L_N/2 - Q_q)}{l_{q-1}} + \frac{L_{q-1}(Q_{q-1} - L_N/2)}{l_{q-1}}.$$

From (3.13) and notation of q, we obtain

$$L_{q-1}/l_{q-1} \leq L_N/Q_{q-1} < 2.$$

The last two relations give

$$\begin{aligned} L_{q-1} &< 2(L_N/2 - Q_q) + L_N/Q_{q-1}(Q_{q-1} - L_N/2) \\ &= \left(2 - \frac{L_N}{2Q_{q-1}}\right) L_N - 2Q_q. \end{aligned} \tag{3.24}$$

Therefore, if $p = q-1$, then $\sum_{k=p}^{q-1} L_k = L_{q-1} < (2 - \frac{L_N}{2Q_{q-1}})L_N - 2Q_q = (\ln \frac{Q_p}{Q_{q-1}} + 2 - \frac{L_N}{2Q_{q-1}})L_N - 2Q_q$; in other words, (3.23) holds when $p = q-1$.

Now consider the case where $p < q-1$. From (3.13), we have

$$l_k/L_k \geq Q_k/L_N, \quad k = p, p+1, \ldots, q-2,$$

or equivalently

$$(Q_k - Q_{k+1})/L_k \geq Q_k/L_N, \quad k = p, p+1, \ldots, q-2,$$

which implies

$$Q_{k+1} \leq (1 - L_k/L_N)Q_k, \quad k = p, p+1, \ldots, q-2.$$

As a matter of results,

$$Q_{q-1} \leq Q_p \prod_{k=p}^{q-2} (1 - L_k/L_N). \tag{3.25}$$

Since $L_\alpha \geq 2l_\alpha$, from Corollary 3.19, we obtain $1 - L_k/L_N > 0$ for any $k = p, \ldots, q-2$. We have, using (3.25) and the property that the geometric mean of positive numbers is less than or equal to the arithmetic mean of the same numbers,

$$\begin{aligned} Q_{q-1} &\leq Q_p \left[\frac{1}{q-1-p} \sum_{k=p}^{q-2} (1 - L_k/L_N)\right]^{q-1-p} \\ &= Q_p \left[1 - \frac{1}{(q-1-p)L_N} \sum_{k=p}^{q-2} L_k\right]^{q-1-p}, \end{aligned}$$

or equivalently

$$\sum_{k=p}^{q-2} L_k \leq (q-1-p)L_N \left[1 - \left(\frac{Q_{q-1}}{Q_p}\right)^{\frac{1}{q-1-p}}\right]. \tag{3.26}$$

From Lemma 3.25, we have $(1 - a^x)/x \leq -\ln a$ for any $a \in (0, 1]$ and for any $x > 0$. By substituting a and x with $\frac{Q_{q-1}}{Q_p}$ and $1/(q-1-p)$, respectively, all the conditions are fulfilled and (3.26) implies

$$\sum_{k=p}^{q-2} L_k \leq L_N \ln \frac{Q_p}{Q_{q-1}}. \tag{3.27}$$

Relation (3.23) is straightforward from (3.24) and (3.27). ∎

LEMMA 3.27. *In the solution given by LRW, if* $L_\alpha \geq 2l_\alpha$, *then*

$$\sum_{k=1}^{p-1} L_k < 2\max(0, \Lambda - L_N) + Q_r. \tag{3.28}$$

Proof. The lemma is obviously true if $p = 1$. When $p > 1$, we first show that

$$L_{p-1} < Q_r. \tag{3.29}$$

In fact, if $L_{p-1} \geq Q_r$, we would have $L_{p-1} \geq Q_r \geq Q_N = l_N$ since $L_\alpha \geq 2l_\alpha$ which implies $r \leq N$ (see Corollary 3.19). This relation would lead to $L_{p-1} \geq L_N$, according to Property 3.6, which would be in contradiction with the fact that $L_\alpha \geq 2l_\alpha$ which implies $L_{p-1} < L_N$ (see Corollary 3.19).

Therefore, if $p = 2$, we would have $\sum_{k=1}^{p-1} L_k = L_{p-1} < Q_r \leq 2\max(0, \Lambda - L_N) + Q_r$, As a matter of result, (3.28) holds if $p = 2$.

If $p > 2$, due to the fact that $p - 1 < r$, we have $L_k < 2l_k$ for any k such that $1 \leq k \leq p - 2$. Therefore,

$$\begin{aligned}\sum_{k=1}^{p-2} L_k < 2\sum_{k=1}^{p-2} l_k &= 2\left(\sum_{k=1}^{N} l_k - \sum_{k=p-1}^{N} l_k\right) \\ &= 2\left(\Lambda - Q_{p-1}\right) < 2(\Lambda - L_N) \\ &\leq 2\max(0, \Lambda - L_N). \end{aligned} \tag{3.30}$$

Relations (3.30) and (3.29) show that (3.28) is also true when $p > 2$. □

LEMMA 3.28. *In the solution given by LRW, if* $L_\alpha \geq 2l_\alpha$ *then* $C_{\mathrm{LRW}} < (2 + \ln 2)C^*$.

Proof. According to Corollary 3.19, we have $\alpha = N$, $L_N \geq 2l_N$ and $r \leq N$. According to Lemma 3.21, we have

$$L_N \leq C^*. \tag{3.31}$$

From Lemmas 3.22–3.27, the bin consumption C_{LRW} can be upper bounded as

$$\begin{aligned} C_{\mathrm{LRW}} &= \sum_{k=1}^{p-1} L_k + \sum_{k=p}^{q-1} L_k + \sum_{k=q}^{r-1} L_k + \sum_{k=r}^{N-1} L_k + L_N \\ &< 2\max(0, \Lambda - L_N) + (1 + \ln 2)L_N + L_N \\ &= \max\left\{(2 + \ln 2)L_N, 2\Lambda + L_N \ln 2\right\}. \end{aligned}$$

By definition, $C^* \geq \Lambda$. From this relation and (3.31), we can deduce

$$\begin{aligned} C_{\mathrm{LRW}} &< \max\left\{(2 + \ln 2)L_N, 2\Lambda + L_N \ln 2\right\} \\ &\leq (2 + \ln 2)C^*. \end{aligned}$$ □

The following theorem is straightforward from Lemmas 3.20 and 3.28.

THEOREM 3.29. *For any instance,* $C_{\mathrm{LRW}}/C^* < 2 + \ln 2$.

THEOREM 3.30. *The bound* $(2+\ln 2)$ *is tight for* C_{LRW}/C^*; *i.e.,* $\Omega_{\mathrm{LRW}} = 2+\ln 2$.

Proof. Consider the following instance composed of two types of bins with sizes $S_1 = 2n + 2$ and $S_2 = 2$, n being a positive integer strictly greater than 2. Let

$y(n) = \frac{\ln 2}{\ln(n^2+n+1)-\ln n^2}$ and $z = \lfloor y(n) \rfloor$. The objects to be packed are as follows: $s_1 = 2\frac{n+1}{n}$, $s_2 = (\frac{n^2+n+1}{n^2})^z$, $s_3 = (\frac{n^2+n+1}{n^2})^{z-1}$, ..., $s_{z+1} = \frac{n^2+n+1}{n^2}$, $s_{z+2} = s_{z+3} = \cdots = s_{n+z-1} = \frac{n+1}{n}$.

All objects except object 1 are strictly longer than 1 and strictly less than 2. Object 1 is strictly longer than 2. In the solution resulting from algorithm LRW, $n + z - 2$ bins of type 2 are used to pack objects 2 to $n + z - 1$, each containing exactly one object. Object 1 is packed into one bin of type 1. This gives rise to a bin consumption $C_{\mathrm{LRW}} = 2(n + z - 2) + (2n + 2) = 2z + 4n - 2$. The optimal packing consists of packing all objects into one bin of type 1. Then $C^* = 2n + 2$. Therefore,

$$\frac{C_{\mathrm{LRW}}}{C^*} = \frac{2n-1}{n+1} + \frac{z}{n+1}.$$

According to the definition of z,

$$y(n) - 1 < z \leq y(n).$$

Then,

$$\frac{2n-2}{n+1} + \frac{y(n)}{n+1} < \frac{C_{\mathrm{LRW}}}{C^*} \leq \frac{2n-1}{n+1} + \frac{y(n)}{n+1}.$$

When n tends towards $+\infty$, both $\frac{2n-2}{n+1}$ and $\frac{2n-1}{n+1}$ tend towards 2, and $\frac{y(n)}{n+1}$ tends towards $\ln 2$. Therefore, the ratio $\frac{C_{\mathrm{LRW}}}{C^*}$ tends towards $2 + \ln 2$. □

3.4. Additional topic. Let LW be the name of the algorithm which consists of selecting the best one among the solutions found by the four algorithms described and analyzed previously. By definition, it is obvious that

$$\Omega_{\mathrm{LW}} \leq 2.$$

On the other hand, there is an instance such that C_{LW}/C^* tends towards $1 + \ln 2$. Therefore, we can claim that

$$1 + \ln 2 \leq \Omega_{\mathrm{LW}} \leq 2.$$

This instance is quite similar to the one in the previous section. Two types of bins are available, respectively, with sizes $S_1 = 2n$ and $S_2 = 2$, n being a positive integer strictly greater than 2. The objects to be packed are as follows: $s_1 = (\frac{n^2+n+1}{n^2})^z$, $s_2 = (\frac{n^2+n+1}{n^2})^{z-1}$, ..., $s_z = \frac{n^2+n+1}{n^2}$, $s_{z+1} = s_{z+2} = \cdots = s_{n+z-2} = \frac{n+1}{n}$.

Proof. All objects are strictly longer than 1 and strictly less than 2. In the solution resulting from algorithm LW (all four algorithms yield the same solution), $n + z - 2$ bins of type 2 are used to pack objects 1 to $n + z - 2$, each containing exactly one object. This gives rise to a bin consumption $C_{\mathrm{LW}} = 2(n + z - 2)$. The optimal packing consists of packing all objects into one bin of type 1. Then $C^* = 2n$. Therefore,

$$\frac{C_{\mathrm{LW}}}{C^*} = \frac{n-2}{n} + \frac{z}{n}.$$

Then,

$$\frac{n-3}{n} + \frac{y(n)}{n} < \frac{C_{\mathrm{LW}}}{C^*} \leq \frac{n-2}{n} + \frac{y(n)}{n}.$$

When n tends towards $+\infty$, both $\frac{n-3}{n}$ and $\frac{n-2}{n}$ tend towards 1, and $\frac{y(n)}{n}$ tends towards $\ln 2$. Therefore, the ratio $\frac{C_{\mathrm{LW}}}{C^*}$ tends towards $1 + \ln 2$. □

4. Conclusion. Four greedy approximation algorithms based on a construction approach have been proposed to pack a given set of objects into bins of different sizes. The worst-case performance has been determined for each approximation algorithm. Current investigations aim at finding worst-case performance bounds for LW and for more sophisticated approximation algorithms developed for a real life cutting stock problem.

FIRST-ORDER SPECIFICATIONS OF PROGRAMMABLE DATA TYPES*

GRAŻYNA MIRKOWSKA†, ANDRZEJ SALWICKI†, MARIAN SREBRNY‡, AND ANDRZEJ TARLECKI§

Abstract. We consider first-order specifications together with the restriction to accept only programmable algebras as models. We provide a criterion which links this approach with the "generation principle": all programmable models of any specification SP that meets this criterion are reachable. We also show an example of a specification which does not satisfy the criterion and admits a programmable yet nonreachable model. Moreover, a general method of showing the existence of programmable but nonreachable models for a class of first-order specifications is given.

Key words. algebraic specification, reachable algebra, data types

1. Introduction. The problem of characterizing intended algebras is important in various areas of computer science. In the areas of specification, development, and validation of software systems one needs to describe the intended models—typically "no junk" algebras—modelling (representing) possible or actual implementations of software systems being specified.

In this paper we make use of intrinsic conceptual parallelism between software engineering and metamathematics. Some software modules—classes, libraries, packets, etc.—can be conveniently viewed as algebraic structures. The goal of specifying software modules then finds its formal counterpart: specification of algebraic structures. In the terminology of computer scientists one sometimes also says specification of data types. A formal specification may (and should) serve as the only source of information on a data structure $\mathcal{A}$ when one constructs and/or analyzes a program P which uses the data structure $\mathcal{A}$. Suppose that such a data structure $\mathcal{A}$ is described by a specification SP. Is the specification SP sufficiently rich in order to ensure that any proof of a valid semantical property of the program P (such as correctness, termination, etc.) can rely only on the axioms listed in SP? Or should one add some extra constraints—or further information—on data structure $\mathcal{A}$ beyond those contained in the specification SP?

Typically, the answer to the latter question is affirmative: first-order logic is not strong enough to exclude all nonintended models of a specification, and hence nonintended implementations of the specified module. Similar problems arise also with specifications intended to be loose though not "too loose."

Various authors introduce some special strong additional requirements to cope with this problem. For instance, the category-theoretic initial (also, terminal) alge-

bra semantics approach has attracted a lot of attention. In these approaches, one selects as the semantics of a specification only initial (respectively, terminal) objects in the category of all algebras that satisfy given specification axioms; see, e.g., [4], [2], [18]. Another option is to require the algebras to be reachable (generated by the empty set, or standard—see the "generation principle" of [1]). Reachable algebras cannot be characterized by any set of first-order axioms, since every reachable algebra has an elementary extension that is not reachable, by direct application of the Skolem–Löwenheim theorem. None of these extra requirements (initiality, terminality, reachability) is expressible in first-order logic or its fragments (e.g., equational logic) often used in algebraic specifications. They can, however, be expressed in some stronger logics, for instance, in various versions of algorithmic logic (see [12]) or infinitary logics with proof systems involving infinitary proof rules (e.g., a version of the ω-rule) or in the second-order logic with the semantics where second-order variables range either over all subsets of the universe or only over finite subsets (weak second-order logic). Nevertheless, the classical first-order logic is of special interest here, at least because of its familiarity and since most of the contemporary mathematics has been done in it.

There are two possible ways to proceed: either we can restrict the class of models considered to some special structures only, characterized by some extralogical means, or we can work with a stronger logic. In this paper we promote and advocate the first possibility. However, we propose a "new" natural requirement of programmability (computability) of the models as the extralogical selection criterion. This seems more natural and friendly to programmers and to programming environment than other approaches proposed so far. By the Church thesis all possible implementations of any specification are programmable. Therefore, selecting programmable algebras as the only models considered is kind of a "minimal" requirement. It is perhaps surprising that this natural possibility has not been properly exploited in the theory and practice of algebraic specifications. The surprise is even more evident in light of a whole line of interesting results by Bergstra and Tucker [2] on the interplay between computability and equational specifications and on the expressive power of the initial algebra specifications.

To reiterate, we propose the classical first-order logic with the programmable (recursive) algebra semantics to be used for algebraic specifications.

It should be emphasized here with no need of any further details that the programmability requirement is natural and comprehensible to potential software developers, specifiers, and validators, as perhaps opposed to the abstract category-theoretic initiality or terminality criteria. A serious demand for detailed study of this kind of requirements follows, for instance, from a work of Sannella and Tarlecki [14] on a "gap" between the usual viewpoint of algebraic specification based on arbitrary models and that of programming frameworks (such as Extended ML [8]) more realistically based on programmable models. Traditionally in the area, abstract many-sorted algebras are used to model programs: the representation of data is arbitrary and operations are modelled as functions. Formal development of software systems from specifications calls for restriction of these general concepts to the kind of models that underlie semantics of programming languages. For example, the semantics of Standard ML [10] uses rather concrete models, where data values are represented as closed constructor terms and operations are represented as "closures."

We believe that the programmable reachable algebras provide an interesting general framework for algebraic specifications. In this note we present some technical

results to justify this belief and to start a proper investigation of such a framework.

2. Terminology and notation. In this paper we consider specifications as classical first-order (or *elementary*) theories. Unlike in the classical model-theory, we work with many-sorted algebras; a many-sorted algebra consists of a carrier set split into a family of nonempty carriers named by sorts with (a finite number of) operations on them. The carriers and operations of an algebra are named in the algebra's signature. Zero-ary operations are just the distinguished elements, interpreting constants of the language according to the algebra's signature. In general, the operations may be partial functions on their sorts. Throughout the paper we work with first-order logic with equality, i.e., formulas include equalities between terms of the same sort (for each sort) interpreted as the identity of the denotations of the terms. Occasionally we simplify the exposition by leaving the reader with many details of rigorous "sorting" of the formal expressions whose content is sketched only informally.

DEFINITION 2.1. *An algebra (in general, a relational structure) is called* programmable *(or* recursive*, or* computable*) whenever all of its carriers are computable sets and all of its operations (in the general case, relations) are computable functions defined on computable domains.*

We will be talking only about countable algebras. Therefore we can always consider beforehand an isomorphic copy of a given algebra built on the natural numbers and then define the algebra to be recursive whenever this copy is recursive. For example, the natural numbers with the usual arithmetic operations form a programmable algebra $(N; 0, suc, +, \times)$. Given a nonrecursive function f, the algebra $(N; 0, suc, +, \times, f)$ is not programmable.

We illustrate the ideas and results of this paper with various data types of stacks and their first-order specifications. We focus on the stacks because of their relevance for implementing recursive computations and modelling recursively defined collections of data, and because they provide a convenient example that we hope should be familiar to the reader. Stack theory can be formalized in various forms, essentially different in many ways from the metamathematical viewpoint. All of them share in their signature two sorts (one for elements and another for stacks) and the usual stack operations.

Given a finite or infinite set E, by *the true stack theory on* E we mean the first-order theory of the model with two-sorted carrier set E, E^*, where E^* is the set of all finite sequences of the members of E, and the usual operations *top*, *pop*, *push*, the distinguished *empty* sequence, and with all the elements of E as constants in the signature. In this paper we typically consider at most countably infinite E. The operations *top* and *pop* are undefined on *empty*. Here are the usual definitions for each $e \in E$ and $s = (e_0, \ldots, e_n) \in E^*$:

$$\begin{aligned} push(e, s) &= (e_0, \ldots, e_n, e), \\ top(s) &= e_n \quad \text{for nonempty } s, \\ pop(s) &= (e_0, \ldots, e_{n-1}) \quad \text{for nonempty } s. \end{aligned}$$

This yields a family of different true stack theories, one for each E. Modulo the names of the constants used, we in fact consider here one such theory for each (finite or infinite) cardinality of E. Each of them is formally a theory over a different signature (following the usual terminology in mathematical logic, we will say a *language* of a theory, rather than its signature).

In the countably infinite case, one can think of E as of the set of natural numbers. However, the members of E need not be the natural numbers, since the signature of the model does not contain any arithmetic operations.

By *the axiomatic theory of stacks on* E we mean the (classical first-order) consequences of the universal closure of the following axioms in the (first-order) language corresponding to the above model:

$$\begin{array}{ll} \text{(Ax1)} & push(x,s) \neq empty, \\ \text{(Ax2)} & top(push(x,s)) = x, \\ \text{(Ax3)} & pop(push(x,s)) = s, \\ \text{(Ax4)} & s \neq empty \rightarrow push(top(s), pop(s)) = s. \end{array}$$

This theory is a proper subtheory of the true stack theory on E. In particular, the true stack theory, but not the axiomatic stack theory, admits the following *scheme of structural induction* for every first-order formula φ:

$$[\varphi(empty) \wedge \forall x \, \forall s \, (\varphi(s) \rightarrow \varphi(push(x,s)))] \rightarrow \forall s \, \varphi(s).$$

By *the true theory of stacks on the natural numbers* we mean the first-order theory of the model $(N, N^*; 0, suc, +, \times, top, pop, push, empty)$ with the usual meaning of the arithmetic operations on the set N of natural numbers. The Peano axioms for the sort of elements and axioms (Ax1–Ax4) for stacks form yet another formalization, which we will call the *axiomatic stack theory on the natural numbers*.

Let us point out that here we mean the Peano axioms with the scheme of elementary induction

$$[\varphi(0) \wedge \forall x \, (\varphi(x) \rightarrow \varphi(x+1))] \rightarrow \forall x \, \varphi(x)$$

for every first-order formula φ. By Peano Arithmetic we mean the (classical) first-order consequences of the usual axioms for $0, suc, +, \times$ with the scheme of elementary induction.

3. Reachable algebras.

DEFINITION 3.1. *An algebra is called* reachable *if it is generated from it's underlying constants by finitely many successive applications of the algebra's operations.*

An algebra $\mathcal{A}$ is generated by a subset X of the carrier of $\mathcal{A}$ (a set of generators) if all the elements of $\mathcal{A}$ are the values of Σ-terms under some valuation of variables into X. Σ is the signature of $\mathcal{A}$. Now $\mathcal{A}$ is reachable iff it is generated by the empty set of generators.

Equivalently, an algebra is reachable if each element of its universe (carrier sets) is the denotation of a closed (ground) term in the (first-order) signature of the algebra (cf. the notion of a Herbrand model in model-theory). The reachable algebra of natural numbers, the only reachable model of Peano Arithmetic, is usually called the *standard model*. One says the reachable algebras have "no junk" property: they contain all data you can talk about in the algebra's formal language and nothing more. This does not imply, of course, another useful property of "no confusion" (or "unambiguity," or "the unique name") that different terms denote distinct data items, unless those terms are forced to be identified by the specification axioms.

Of course, reachable algebras need not be programmable in general. For instance, the nonprogrammable algebra $(N, 0, suc, f)$ with nonrecursive f mentioned above is reachable. In this paper we show that for a sufficiently rich theory its reachable

models can be distinguished in the class of programmable models by a single first-order axiom. This is based on a deep result of Tennenbaum [17] that *every recursive model of Peano Arithmetic (with the first-order induction scheme) is standard.*

Roughly, a first-order theory T is sufficiently rich in this context if Peano Arithmetic can be recursively interpreted in T and T has the finite sequence coding property. Let us recall the necessary notions of mathematical logic.

For the concept of an interpretation we refer, for instance, to Shoenfield [15]. We say that Peano Arithmetic can be interpreted in T whenever there are formulas $I_N(\cdot)$, $I_0(\cdot)$, $I_S(\cdot,\cdot)$, $I_{Add}(\cdot,\cdot,\cdot)$, and $I_{Mult}(\cdot,\cdot,\cdot)$ in the language of T such that T proves all the Peano axioms relativized to the interpretation I. An interpretation defines a model of Peano Arithmetic within every model of T: I_N defines its carrier, while the other formulas define the operations (or their graphs) of arithmetic, respectively. An interpretation is recursive if it defines a recursive model of Peano Arithmetic within every recursive model of T.

Given a theory with an interpretation of (enough of) arithmetic, one can think of sequences indexed by the natural numbers of the interpretation, i.e., by the elements of the carrier of the interpretation. Then one can talk about possible coding of initial segments of such sequences by single elements. In the following definition, intuitively, *BETA* is a uniform projection (decoding) function: for a sequence $a_0, a_1, \ldots, a_l$, there is a code u such that $BETA(u, j) = a_j$ for each $j \leq l$. Let us stress once more though that the "length" of the sequence and the "indexing subscripts" are numbers only in the sense of the interpretation of arithmetic.

DEFINITION 3.2. *We say that a theory T with an interpretation of arithmetic has* the finite sequence coding property *if there is a binary function BETA definable in T such that*

for every formula $A(x, y, parameters)$ in the language of T, if T proves
"for each x of the arithmetic interpretation universe I_N, there exists exactly one y such that $A(x, y, parameters)$,"
then T also proves the following:
"for each l of I_N, there exists a u such that for each $j \leq l$, $A(j, BETA(u, j), parameters)$."

Models of a theory with the finite sequence coding property should be compared with the concept of arithmetical universes of Harel [6]. Harel's arithmetical universes are equipped with a copy of the standard model of arithmetic, whereas we consider algebras equipped with a copy of just a model of Peano Arithmetic. The latter turns out to be standard under the assumptions of the following theorem.

THEOREM 3.3. *Let T be a first-order theory over a finite language such that*

1. *Peano Arithmetic can be recursively interpreted in T and*
2. *T has the finite sequence coding property.*

Then there is a single sentence σ_{reach} in the language of T such that every recursive model of T satisfying σ_{reach} is reachable.

Proof. To prove the above theorem we take the following sentence as σ_{reach}:

$$\forall x\, \exists u\, (u \text{ codes a path of reaching } x \text{ from the generators}).$$

More precisely, though still informally, the formula under the two quantifiers says the following: u codes a sequence of values in a given model M such that x is the last element of the sequence and each element in the sequence is either a denotation of a constant in M or can be obtained from earlier values in the sequence by application of one of the operations of M. Then consider a recursive model M of T. M contains a

recursive model of Peano Arithmetic. The latter has to be standard by Tennenbaum's result [17]. Therefore, if σ_{reach} holds in M, then M is reachable. □

Since the above sentence σ_{reach} holds in the standard model of the theory of stacks on the natural numbers (which contains Peano Arithmetic and clearly has the sequence coding property) the above theorem gives us the following corollary.

COROLLARY 3.4. *Every recursive model of the true theory of stacks on natural numbers is reachable.*

It now follows easily that every programmable model of the true stack theory on natural numbers is isomorphic to $(N, N^*; 0, suc, +, \times; top, pop, push, empty)$. Can anyone supply a better, while so friendly, specification of this data type?

The message can now be put forward as follows. For any sufficiently rich specification, if one restricts its semantics to programmable models only, then in order to ensure reachability, which in many cases means uniqueness, one simply needs to throw *implicitly* or *explicitly* the appropriate σ_{reach} into the specification. Given a sufficiently rich specification, in order to verify that all its programmable models are reachable it is necessary and sufficient to check whether the appropriate σ_{reach} is derivable from this specification. We have just applied this result to the true stack theory on natural numbers.

4. Nonreachable programmable algebras. Theorem 3.3 indicates that computability of a model of a sufficiently rich specification implies its reachability. In this section we provide examples of specifications (theories) that are not rich enough and admit recursive nonreachable models.

As an easy warm-up example consider the usual specification axioms for successor:

$$succ(x) \neq 0,$$
$$succ(x) = succ(y) \rightarrow x = y.$$

Any linear order of type $\omega + (\omega^* + \omega)$ provides a model of these axioms in the obvious way (with no claim of induction). Clearly, this model is recursive but nonreachable.

There are several ways of constructing a recursive nonreachable model of the true stack theory (as well as of its axiomatic mutations) on a finite set of elements. The present research has evolved from a definition of such a model written as a program in [11].

Here we give details of one possible construction of a recursive nonreachable model of the axiomatic stack theory on a finite E.

Let us first recall the Gödel's recursive function β such that for any natural numbers $a_1, \ldots, a_n$, there exists an $a \in N$ with $\beta(a, i) = a_i$, for each $i = 1, \ldots, n$, and with $\beta(a, 0) = n$. Moreover, $\beta(a, i) \leq a \dot{-} 1$. One can introduce the following sequence coding function:

$$SC(a_1, \ldots, a_n) \quad \stackrel{df}{=} \quad \mu x\, (\beta(x, 0) = n \wedge \beta(x, 1) = a_1 \wedge \cdots \wedge \beta(x, n) = a_n).$$

Define also the length function $lh(a) = \beta(a, 0)$, and the projection functions $(a)_i = \beta(a, i)$, for $i = 1, \ldots, lh(a)$. For $n = 0$, $\beta(0, i) = 0$, and so for the empty sequence ε we have $SC(\varepsilon) = 0$. We also need

$$Seq(a) \quad \stackrel{df}{\equiv} \quad a \textit{ is a code of a sequence of length } lh(a).$$

The reader is referred to [15] for further details.

Now we define the model. Let $\{0,1\}$ be its carrier set of the element sort. The reader can easily modify this construction to any finite set of elements. Let its stack carrier be the union $S \cup S_0 \cup S_1$ of the following three sets of 0–1 sequences (finite or infinite):

- S is the set of all the finite 0–1 sequences;
- S_0 is the set of all the infinite 0–1 sequences stabilizing on 0;
- S_1 is the set of all the infinite 0–1 sequences stabilizing on 1.

Their union is recursive since they can be viewed as copies of the following sets of finite 0–1 sequences preceded by one of the markers 0, 1, or 2 and by their lengths. We use 0 as a marker for S_0, 1 for S_1, and 2 for S. Look at S_0 as the set of all finite sequences with 1 at the end, followed by infinitely many 0's. Allow the empty sequence there too—although it has no 1 at the end, it is needed to cover the case of the infinite sequence consisting only of 0's. Such infinite sequences can be coded up by pairs $\langle 0, a\rangle$ with sequence numbers a. The length $lh(a)$ indicates the position of the last 1. $lh(a) = 0$ indicates that there is no 1 at all. Similarly, deal with S_1 by indicating the position of the last 0 or indicating there is no 0 at all. Formally:

$$S \cup S_0 \cup S_1 = \{\langle \delta, a\rangle \mid \delta = 0,1,2 \wedge Seq(a) \wedge \forall 1 \le i \le lh(a)\,((a)_i = 0 \vee (a)_i = 1) \\ \wedge\ (lh(a) > 0 \to (a)_{lh(a)} \neq \delta)\}.$$

Define $empty = \langle 2, SC(\varepsilon)\rangle$, and for each $\delta = 0,1,2$ and each sequence code a of $(a_1, a_2, \ldots, a_{lh(a)})$ define the operations

- $top(\langle \delta, a\rangle) = \begin{cases} a_1 & \text{if } lh(a) > 0, \\ 0 & \text{if } lh(a) = 0 \text{ and } \delta = 0, \\ 1 & \text{if } lh(a) = 0 \text{ and } \delta = 1, \\ \text{undefined} & \text{otherwise.} \end{cases}$

- $pop(\langle \delta, a\rangle) = \begin{cases} \langle \delta, SC(a_2, \ldots, a_{lh(a)})\rangle & \text{if } lh(a) > 0, \\ \langle \delta, a\rangle & \text{if } lh(a) = 0 \text{ and } \delta \neq 2, \\ \text{undefined} & \text{otherwise.} \end{cases}$

- $push(e, \langle \delta, a\rangle) = \begin{cases} \langle \delta, SC(e, a_1, \ldots, a_{lh(a)})\rangle & \text{if } lh(a) > 0 \text{ or } \delta \neq e, \\ \langle \delta, a\rangle & \text{if } lh(a) = 0 \text{ and } \delta = e. \end{cases}$

LEMMA 4.1. *$(\{0,1\}, S \cup S_0 \cup S_1; top, pop, push, empty, 0, 1)$ is a recursive nonreachable model of the axiomatic stack theory.*

Proof. The proof has an easy verification. □

5. Nonreachable programmable models of decidable theories. In this section we show that there exists a nonreachable recursive model of the true stack theory on any given finite set E. We get it as an application of a general method (Corollary 5.4). The argument below relies heavily on the following theorem (known in the folklore of the field).

THEOREM 5.1 (the computable model existence theorem). *Every consistent decidable theory has a recursive model.*

Proof. One can "effectivize" Henkin's proof of the completeness theorem for the classical first-order logic. Some details are given in [7] and related results in [9]—for the reader's convenience we sketch a full proof in the appendix. The key step is an effective version of the celebrated Lindenbaum–Tarski theorem: every decidable consistent theory has a decidable complete extension in the same language. □

DEFINITION 5.2. *A theory is* reachably unambiguous *if all its reachable models are elementarily equivalent.*

It is easy to see that many interesting and useful theories are reachably unambiguous, e.g., Peano Arithmetic and Presburger Arithmetic. This is also the case for the stack theory in any of the above formalizations. In all these cases the theory has just one reachable model up to an isomorphism.

COROLLARY 5.3. *If T is a reachably unambiguous, incomplete, and decidable theory, then T has a recursive nonreachable model.*

Proof. In the algorithm of completion of T following Tarski [16], one can keep control on which of either σ or its negation $\neg\sigma$ gets into the completion, for a sentence σ such that neither $T \vdash \sigma$ nor $T \vdash \neg\sigma$. Since T is incomplete and reachably unambiguous, there is a sentence σ_0 such that neither $T \vdash \sigma_0$ nor $T \vdash \neg\sigma_0$, although σ_0 holds in every reachable model of T. Thus, a recursive model of the completion of T with $\neg\sigma_0$, built as in the proof of Theorem 5.1 above, cannot be reachable. □

COROLLARY 5.4. *Suppose T is a first-order theory. Let $c_0, c_1, c_2, \ldots$ be all the closed terms of the language of T, and let c be a new individual constant. If $T \cup \{\, c \neq c_n \mid n \text{ natural}\}$ is a consistent decidable theory, then T has a recursive nonreachable model.*

Proof. The proof is obvious by Theorem 5.1. □

We establish some results concerning decidability of the true stack theory in order to apply Corollary 5.4.

THEOREM 5.5. *Given a finite set E, the true stack theory on E is decidable.*

Proof. We show an interpretation of the true stack theory on E in Presburger Arithmetic (the first-order theory of $(N, suc, +, 0)$) which is well known to be decidable; see [13]. In fact, we show a somewhat stronger result by defining in $(N, suc, +, 0)$ an isomorphic copy of the model $(E, E^*; top, pop, push, empty, \{e\}_{e\in E})$.

Let k be the cardinality of E. We define the two-sorted carrier of our interpretation and its operations as follows with the usual notation for operations and relations definable in Presburger Arithmetic. ($\underline{k}$ denotes the kth numeral, i.e., $\underline{k}$ abbreviates $\underbrace{suc(\ldots suc(}_{k \text{ times}}\underline{0})\ldots)$).

- $U_E^I(e) \stackrel{df}{\equiv} e = \underline{0} \vee e = suc(\underline{0}) \vee \cdots \vee e = \underline{k-1}$;
- $U_S^I(s) \stackrel{df}{\equiv} s \geq \underline{k}$;
- $empty^I \stackrel{df}{=} \underline{k}$;
- $push^I(e, s) \stackrel{df}{=} \underline{k} \times (s - \underline{k}) + e + \underline{k} + 1$;
- $top^I(s) \stackrel{df}{=} (s - \underline{k} - 1) \bmod \underline{k}$, for $s > \underline{k}$;
- $pop^I(s) \stackrel{df}{=} [(s - \underline{k} - 1) \operatorname{div} \underline{k}] + \underline{k}$, for $s > \underline{k}$.

The idea behind this construction is that the stacks are coded up by numbers in their k-adic expansions, shifted up by adding $k + 1$ to make disjoint room for the elements and for the empty stack. The top^I operation returns the last digit of the expansion which is just the remainder of dividing by k. Similarly, pop^I cuts off the last digit. This is legal here since division by a given numeral is expressible in Presburger Arithmetic. Consequently, the decidability procedure for Presburger Arithmetic does the job for the true stack theory on E. □

The above proof gives immediately the following complexity results inherited from Presburger Arithmetic. The double exponential upper bound is due to Ferrante and Rackoff [3]. There exists a decision procedure and a constant c such that it takes

at most $2^{2^{cn}}$ deterministic single-tape Turing machine space to decide a sentence of length n. This gives deterministic time upper bound $2^{2^{2^{dn}}}$; see also Fischer and Rabin [5]. Precise complexity bounds for the true theory of stacks, which we have established recently beyond the scope of the present paper, will appear elsewhere.

LEMMA 5.6. *Let TST denote the true stack theory on a given finite set E. Then the theory $TST \cup \{c \neq c_n \mid n \text{ natural}\}$ is decidable, where $c_0, c_1, c_2, \ldots$ are all the closed terms of the stack sort of the language of TST, and c is a new individual constant of the stack sort.*

Proof. We reduce the decidability problem for this theory to the decidability of Presburger Arithmetic (denoted by PrA below). Let T denote the extended theory $TST \cup \{c \neq c_n \mid n \text{ natural}\}$. By a reduction we mean an effective mapping f associating to each sentence σ of the language $L(T)$ a sentence $f(\sigma)$ of the language $L(PrA)$ such that $T \vdash \sigma$ iff $PrA \vdash f(\sigma)$. Thus a decision procedure whether σ is a theorem of T will be reduced to whether $f(\sigma)$ is a theorem of Presburger Arithmetic. This will imply the decidability of T since Presburger Arithmetic is decidable.

For each σ of $L(T)$, we define $f(\sigma) = \exists y \forall x[x > y \longrightarrow I\sigma(x/c)]$, where $I\sigma$ is the interpretation of σ in Presburger Arithmetic as introduced in the proof of Theorem 5.5, separately for each E, and $I\sigma(x/c)$ is the substitution of x for c in $I\sigma$. We show that f is a reduction, i.e., $T \vdash \sigma$ iff $PrA \vdash f(\sigma)$.

($\Longrightarrow$) Suppose $T \vdash \sigma$. At most finitely many axioms of the form $c \neq c_n$ may appear in a proof of σ in T. Let l be the greatest number (subscript) of a constant c_n appearing in this proof. Then $TST \cup \{c \neq c_0, c \neq c_1, c \neq c_2, \ldots, c \neq c_l\} \vdash \sigma$. Thus

$$TST \vdash [c \neq c_0 \wedge c \neq c_1 \wedge c \neq c_2 \wedge \cdots \wedge c \neq c_l \rightarrow \sigma].$$

Since c is a new constant, there are no axioms concerning c in TST. Therefore

$$TST \vdash \forall x\,[x \neq c_0 \wedge x \neq c_1 \wedge x \neq c_2 \wedge \cdots \wedge x \neq c_l \rightarrow \sigma(x/c)],$$

and so

$$PrA \vdash \forall x\,[x \neq Ic_0 \wedge x \neq Ic_1 \wedge x \neq Ic_2 \wedge \cdots \wedge x \neq Ic_l \rightarrow I\sigma(x/c)].$$

In the standard model of Presburger Arithmetic the latter implies $\forall x[x > c_m \longrightarrow I\sigma(x/c)]$, where c_m is the greatest of Ic_0, Ic_1, Ic_2,..., Ic_l. Here by Ic_i we denote the interpretation of the constant term c_i. Hence $\exists y \forall x\,[x > y \rightarrow I\sigma(x/c)]$ holds in the standard model of Presburger Arithmetic. By completeness of Presburger Arithmetic we get $PrA \vdash \exists y \forall x\,[x > y \rightarrow I\sigma(x/c)]$.

($\Longleftarrow$) Suppose $PrA \vdash \exists y \forall x\,[x > y \rightarrow I\sigma(x/c)]$. Let m be such a number that $\forall x\,[x > m \rightarrow I\sigma(x/c)]$ holds in the standard model of PrA. Hence,

$$PrA \vdash \forall x\,[x \geq \underline{k} \wedge x \neq Ic_0 \wedge x \neq Ic_1 \wedge x \neq Ic_2 \wedge \cdots \wedge x \neq Ic_l \rightarrow I\sigma(x/c)],$$

where k is the cardinality of E and l is large enough for all the numerals from $\underline{k}$ to $\underline{m}$ to occur among Ic_0, Ic_1, Ic_2,..., Ic_l. Therefore

$$PrA \vdash [c \geq \underline{k} \wedge c \neq Ic_0 \wedge c \neq Ic_1 \wedge c \neq Ic_2 \wedge \cdots \wedge c \neq Ic_l \rightarrow I\sigma(c)],$$

where c is a new constant. Hence

$$TST \ \cup \ \{c \neq c_0 \wedge c \neq c_1 \wedge c \neq c_2 \wedge \cdots \wedge c \neq c_l\} \vdash \sigma(c)$$

for a new constant c of the stack sort. We get $T \vdash \sigma(c)$, since T contains

$$TST \cup \{c \neq c_0 \wedge c \neq c_1 \wedge c \neq c_2 \wedge \cdots \wedge c \neq c_l\}. \qquad \square$$

COROLLARY 5.7. *The true stack theory on a given finite set E has a recursive nonreachable model.*

Proof. The proof follows from Lemma 5.6 and Corollary 5.4. $\square$

COROLLARY 5.8. *The axiomatic stack theory on any finite E with the (first-order) scheme of structural induction has a recursive nonreachable model.*

Proof. It follows immediately from the above, since this theory is contained in the true stack theory on E. $\square$

REMARK 5.9. *Presburger Arithmetic has a recursive nonreachable model.*

Proof. It follows from Corollary 5.4 by a similar argument as in the proof of Lemma 5.6. This has been known to the experts although never published. $\square$

6. Conclusion. In general a first-order specification (axiomatization) has too many models. There have been several approaches in order to restrict the semantics of specifications to intended models only. The initial algebra approach proposed by [4] in the mid 1970s has particularly attracted a lot of attention. In this paper we propose and advocate the programmable algebra approach, i.e., to consider the programmable algebras as the only models. That is, by a specification we mean a pair (Σ, T), where Σ is a signature and T is a list of axioms in the classical first-order logic (with equality) of signature Σ, and the models of such a specification under the proposed semantics are all computable Σ-algebras that satisfy the axioms T. Furthermore,

- we give a criterion assuring that any specification which satisfies the criterion has only reachable models. Often this means just one model up to isomorphism. This is the case of the axiomatic theory of stacks on natural numbers.
- We give some examples of specifications that do not satisfy the criterion and admit programmable models which are not reachable. This is the case of both axiomatic and true stack theory on any given finite set E.
- We give a rather powerful method of constructing programmable nonreachable models.

These results can be easily generalized to provide a criterion that ensures that computable models of a theory are generated by a set of generators whenever this set is definable by a first-order formula. For instance, we may always indicate a subset of sorts and consider the carriers of these sorts as such a definable set of generators. This slightly more general version would be needed, for instance, to deal with stack theories on infinite sets of elements, which then can be considered over a finite signature, without constants for elements.

We also show decidability of the true stack theory on a finite set of elements, a result of interest on its own. One can use it, for instance, to conclude that Peano Arithmetic is not interpretable in the theory of stacks on a finite set of elements.

We do not know if the axiomatic stack theory is decidable. It remains as an intriguing open question. We conjecture that given a set E, the true stack theory on E is contained in the axiomatic stack theory on E with the scheme of structural induction. (Since the other inclusion is obvious, this would mean that the true and axiomatic theories are equivalent in this case.)

7. Appendix. In this appendix we provide a proof of Theorem 5.1: every decidable consistent theory has a recursive (computable) model. In view of this paper, it

seems to be of considerable revitalized interest for use in the area of algebraic specification of software systems, their semantics, validation, and systematic development. It provides a source of supply of programmable algebras to various purposes. The result has been in the folklore for many years. Some variant of it was stated in [9] without proof and another one (a bit stronger than our formulation) in [7] with a sketch of the proof idea.

As throughout this paper, we assume the reader is familiar with the usual formalization of classical first-order logic and its semantics; see, for example, [15]. All the theories considered will be formalized in classical first-order logic with countably many symbols. For simplicity we give the result and our proof here for the single-sorted case.

Recall that a theory T is called *decidable* if T is a recursive set (of Gödel numbers) of sentences, i.e., if there is an effective procedure deciding in a finite number of steps whether a given sentence is a theorem of T or not. Let us recall also that a theory T is *complete* if for every sentence σ exactly one of the following holds: either $\sigma \in T$ or $\neg\sigma \in T$. For two theories T and T', we say that T' is an extension of T if T' contains T. By $L(T)$ we denote the language of T.

To prove the theorem we follow Henkin's proof of the completeness theorem for classical first-order logic with appropriate modifications. Let T be a consistent decidable theory. We extend T to another theory T' such that T' is decidable, complete, and Skolemized. The latter means it has a term witness for each existential statement derivable in this theory. The *canonical structure* will be constructed on the terms of the language of T'. Its interpretations of relation and function symbols will be defined according to what T' knows about them. We then prove the canonical structure is a model of T'. Thus it is a model of T too, since T is a subtheory of T'. The model turns out recursive because T' is a decidable theory. That is, the construction of the model is described recursively by the story of T'. To this end we need the following two lemmas. The first of them can be thought of as an effectivized Lindenbaum theorem.

LEMMA 7.1. *Every decidable consistent theory has a complete decidable and consistent extension in the same language.*

Sketch of proof (Lindenbaum–Tarski). Let T be a decidable consistent theory. Let $\varphi_0, \varphi_1, \varphi_2, \ldots$ be a recursive enumeration of all sentences of the language of T. Let T_0 be T itself. Given decidable theory T_n, define k_n as the least k such that $\neg\varphi_k$ is not a theorem of T_n. Then let T_{n+1} be the theory that results from adding φ_{k_n} to T_n as a new axiom. T_{n+1} is decidable, since T_{n+1} proves σ iff T_n proves $\varphi_{k_n} \to \sigma$. Now let T' be the theory which has as its axioms all of the axioms of these theories T_n, $n \geq 0$. One can show that T' is consistent, complete, and decidable. □

LEMMA 7.2 (Skolemization). *If T is a consistent decidable theory, then there is a consistent decidable extension T' of T with the language $L(T')$ containing $L(T)$ and such that if a sentence $\exists x\varphi(x)$ is a theorem of T, then there is a term t in $L(T')$ with $\varphi(t)$ belonging to T'.*

Proof. Let T be a consistent decidable theory. We construct by recursion a sequence of languages L_0, L_1, L_2, ... and a sequence of theories T_0, T_1, T_2, ... At each step we extend the language with a new constant and adjoin one new axiom to the theory. First, let us enumerate recursively all the existential sentences of $L(T)$: $\exists x\varphi_n(x)$, n natural. We take off with $L_0 = L(T)$ and $T_0 = T$. Now suppose we are given a consistent decidable theory T_n in $L(T_n)$. If $\exists x\varphi_n(x)$ is derivable in T_n, then we take L_{n+1} to be L_n plus a new constant c_n, and T_{n+1} to result from T_n by adding $\varphi_n(c_n)$ as an axiom. Otherwise, we take $L_{n+1} = L_n$ and $T_{n+1} = T_n$. Clearly, new

theory T_{n+1} is consistent.

To show that in the nontrivial case T_{n+1} is decidable we reduce the decidability problem for this theory to decidability of T_n. As in the proof of Lemma 5.6, here by a reduction we mean an effective mapping f associating with each sentence σ of the language $L(T_{n+1})$ a sentence $f(\sigma)$ of the language $L(T_n)$ such that $T_{n+1} \vdash \sigma$ iff $T_n \vdash f(\sigma)$. Thus a decision procedure whether σ is a theorem of T_{n+1} will be reduced to that of whether $f(\sigma)$ is a theorem of T_n. This will mean decidability of T_{n+1}, since T_n is decidable, by the inductive hypothesis. We take $f(\sigma) \stackrel{df}{=} \exists x[\varphi_n(x)\&\sigma(x/c_n)]$. Given a sentence σ in $L(T_{n+1})$ and a proof d of σ in T_{n+1}, we notice that the axiom $\varphi_n(c_n)$ can occur at most finitely many times in d. We can obtain a proof d' of $\exists x[\varphi_n(x)\&\sigma(x/c_n)]$ in T_n out of d as follows. Replace each occurrence of the axiom $\varphi_n(c_n)$ in d by $\exists x\varphi_n(x)$. Then introduce the prefix $\exists x[\varphi_n(x)\&\ldots]$ to each member (step) of d containing c_n, possibly renaming the other variables. Finally, substitute each occurrence of c_n with x. The other way around is proved similarly. Thus f is a reduction.

To complete the proof, let T' be the union of all the theories T_n, $n \geq 0$. Clearly, T' is consistent. It is decidable as a recursive union of recursive sets. □

Proof of Theorem 5.1. Let T be a consistent decidable theory. As the first step we construct a consistent, decidable, complete, and Skolemized extension T^* of T. To this end we construct recursively a sequence L_0, L_1, L_2, ... of languages and a sequence T_0, T_0', T_1, T_1', T_2, T_2', ... of theories as follows. We start off with $L_0 = L(T)$ and $T_0 = T$ and set T_0' to be an extension of T provided by Lemma 7.1. Suppose we are given a consistent and decidable theory T_n in language $L_n = L(T_n)$. We take $L_{n+1} = L(T')$ and $T_{n+1} = T'$ where T' is an extension of T_n provided by Lemma 7.2. Clearly, T_{n+1} is consistent and decidable. Now we take the union of all of them:

$$L^* = \bigcup_{n \geq 0} L_n$$

and

$$T^* = \bigcup_{n \geq 0} T_n = \bigcup_{n \geq 0} T_n'.$$

T^* is decidable, consistent, complete, and Skolemized.

As for the rest of the proof we only use a standard construction of the canonical model for T^* (see, e.g., [15], pp. 44–46). We represent the resulting equivalence relations on the natural numbers. Equivalence classes can be identified with their least (number) representatives. The resulting model is computable since T^* is decidable. □

Acknowledgments. The third author would like to thank Richard Kaye for a number of inspiring conversations. Thanks to an anonymous referee who suggested to improve the paper by including a proof of Theorem 5.1 as an appendix.
