Each process performs only $O(1)$ steps, so wait-free termination is guaranteed. The protocol satisfies the validity condition, since the winning team's value is written into the team's register before any process from that team can access the object X. The protocol also satisfies the consistency condition: all processes agree on the winning team and return the value of that team's register (which never changes after it is first written, since all processes on the same team have the same input value). □

The following theorems follow immediately from Lemma 7 and Propositions 5 and 6.

THEOREM 8. *The RMW objects $X_2, \ldots, X_n$ can be used, with $2(n-1)$ registers,*

to solve n-consensus if the type of X_i is i-discerning for each i.

THEOREM 9. *If T is an n-discerning RMW type, then there is a protocol for n-consensus that uses $n-1$ objects of type T and $2(n-1)$ registers.*

Theorems 3 and 9 show that an RMW type can be used with registers to solve n-consensus if and only if it is n-discerning. The remainder of this section discusses some consequences of this characterization.

The constructive proof of Theorem 9 provides upper bounds on the complexity of solving the consensus problem using RMW objects and registers. If objects of an RMW type T and registers can be used to solve n-consensus at all, then T is n-discerning by Theorem 3, and the tournament-style algorithm in the proof of Proposition 5 can solve n-process consensus in $O(n)$ steps per process, using $n-1$ objects of type T and $2(n-1)$ registers.

COROLLARY 10. *RMW objects of type T can be used, with registers, to implement any type of object in a system of n processes if and only if T is n-discerning.*

Proof. This follows from Theorems 3 and 9 and the fact that n-consensus objects can be used to obtain an implementation of any shared object in a system of n processes [10]. □

COROLLARY 11. *For RMW types with finite state sets, the following question is decidable: "Given an integer n and an RMW type T, can n-consensus be solved using registers and RMW objects of type T?"*

Proof. The conditions of Definition 1 can be checked for each of the finite number of possible choices of $v_0, A, B, f_1, \ldots, f_n$ in a finite amount of time. □

For every value of n, there is an RMW object type with consensus number exactly n. This can be shown by considering an RMW object that behaves like a sticky bit [20] that gets reset after n accesses.

PROPOSITION 12. *Let $n \geq 2$. Let $V = \{\perp\} \cup (\{A, B\} \times \{1, \ldots, n-1\})$. Let T be the RMW type with state set V whose operations can apply the functions f_A and f_B, where*

$$f_{team}(x) = \begin{cases} (team, 1) & \text{if } x = \perp, \\ \perp & \text{if } x = (team', n-1), \\ (team', z+1) & \text{if } x = (team', z) \text{ and } z < n-1. \end{cases}$$

Then T is n-discerning but not $(n+1)$-discerning.

Proof. First, it is shown that T is n-discerning. Let $v_0 = \perp$, $A = \{P_1\}$, $B = \{P_2, \ldots, P_n\}$, $f_1 = f_A$, and $f_2 = \cdots = f_n = f_B$. Then, each value in $V_{\text{team},j}$ is an ordered pair whose first component is team. The conditions of Definition 1 are therefore clearly satisfied.

Next, it is shown that T is not $(n+1)$-discerning. Consider any choice of $v_0, A, B, f_1, \ldots, f_{n+1}$.

If v_0 is an ordered pair, let z be the second component of v_0. Let P_j be any process. Both $V_{A,j}$ and $V_{B,j}$ contain the element $\perp$, since any sequence of $n-z$ functions applied to v_0 will result in the value $\perp$. This violates condition I in the definition of $(n+1)$-discerning.

If $v_0 = \perp$, let P_j be a process in team B. The set $V_{A,j}$ contains v_0, since any sequence of n functions when applied to $\perp$ results in the value $\perp$. This violates condition II of the definition of $(n+1)$-discerning. □

4. Solving consensus with readable objects. Let T be a readable object type with state set $Q = \bigtimes_{k \in \Gamma} Q_k$. Consider a distributed system with $n \geq 2$ processes, called $P_1, \ldots, P_n$, which communicate via shared objects of type T and

registers. The ability of such a system to solve the consensus problem will be studied in this section.

A readable type T is defined to be *n-discerning* if the set $\{P_1, \ldots, P_n\}$ can be partitioned into two nonempty teams and a single operation can be assigned to each process so that if processes from some subset of $\{P_1, \ldots, P_n\}$ each perform their own operation on an appropriately initialized object X of type T, then each one could determine which team accessed X first, provided that it could see the final state of X. The operation assigned to each process cannot be a *read* operation: it must be possible for the operation to update the state of the readable object. This is formalized as follows.

DEFINITION 13. *The readable type T is called n-discerning if there exist*

- *a state $q_0 \in Q$,*
- *a partition of the set of processes $\{P_1, \ldots, P_n\}$ into two nonempty teams A and B, and*
- *an update operation op_i for $1 \leq i \leq n$*

such that $R_{A,j} \cap R_{B,j} = \emptyset$, for all $j \in \{1, \ldots, n\}$, where $R_{A,j}$ is the set of pairs (r, q) for which there exist distinct process indices $i_1, \ldots, i_\alpha$ including j with $P_{i_1} \in A$ such that if $P_{i_1}, \ldots, P_{i_\alpha}$ each perform their operations (in that order) on an object of type T that is initially in state q_0, P_j gets the result r, and the object ends in state q. The set $R_{B,j}$ is defined similarly as the set of pairs (r, q) for which there exist distinct process indices $i_1, \ldots, i_\alpha$ including j with $P_{i_1} \in B$ such that if $P_{i_1}, \ldots, P_{i_\alpha}$ each perform their operations (in that order) on an object of type T that is initially in state q_0, P_j gets the result r, and the object ends in state q.

It will be shown in Theorems 15 and 18 that readable objects of type T can be used, along with registers, to solve the consensus problem for n processes if and only if T is n-discerning. First, the conditions are shown to be necessary.

LEMMA 14. *If S_0 is a critical configuration of an n-process consensus protocol and the next step by every process is an operation on a readable object X of type T, then T is n-discerning.*

Proof. This proof is similar to the proof of Lemma 2. Let q_0 be the state of X in S_0, and let op_i be the operation performed by P_i in its first step after S_0. Partition the processes into two teams A and B according to their critical values.

To derive a contradiction, suppose these choices for $q_0, A, B, op_1, \ldots, op_n$ do not satisfy Definition 13. Then, there is a pair $(r, q) \in R_{A,j} \cap R_{B,j}$ for some j. There is some sequence $i_1, \ldots, i_\alpha$ of distinct process indices, including j, such that $P_{i_1} \in A$ and if processes $P_{i_1}, \ldots, P_{i_\alpha}$ each perform their next operation, in that order, starting from S_0, process P_j will receive the result r, and the system will end in a configuration S_A where X is in state q. There is some other sequence $k_1, \ldots, k_\beta$ of distinct process indices, including j, such that $P_{k_1} \in B$ and if processes $P_{k_1}, \ldots, P_{k_\beta}$ each perform their next operation, in that order, starting from S_0, process P_j will again receive the result r, and the system will end in a configuration S_B where X is in state q. The configurations S_A and S_B are indistinguishable to P_j, so a solo execution by P_j from either of these two configurations would lead to the same decision value. This contradicts the fact that S_A and S_B are univalent configurations that lead to different decision values.

The operation performed by each process must be an update operation; otherwise the configuration obtained from S_0 by allowing the process to perform its operation could not be distinguished from S_0 by any process on the opposite team. □

Combining this lemma with a bivalency argument yields the following theorem.

THEOREM 15. *If n-process consensus can be solved using registers and objects of a readable type T, then T is n-discerning.*

Proof. A bivalency argument, as in the proof of Theorem 3, shows that any n-consensus protocol that uses registers and objects of type T must have a critical configuration S_0, and that the next operation by each process will be applied to the same object of type T. The theorem then follows from Lemma 14. □

Theorem 15 may be used to establish an upper bound on the consensus number of any (deterministic) type T, whether it is readable or not. If, for some n, the update operations that are permitted for type T do not satisfy Definition 13, then type T cannot be used with registers to solve n-consensus. This is because the addition of a *read* operation to the specification of type T would create a readable type T' that is at least as powerful as type T but has consensus number less than n, by Theorem 15.

The team-restricted n-consensus problem will now be used to provide a converse to Theorem 13.

LEMMA 16. *Let T be an n-discerning readable object type. An object of type T and two registers can be used to solve team-restricted n-consensus.*

Proof. Choose $q_0, A, B, op_1, \ldots, op_n$ to satisfy Definition 13. A protocol will be developed for team-restricted n-consensus that uses one register for each team and one shared object X of type T, initialized to the state q_0. Each process P_j writes its team's common input value into its team's register. It then applies the operation op_j to X and attempts to read the state of X to determine which team accessed X first.

The state set of T has the form $Q = \bigtimes_{k\in\Gamma} Q_k$. Since Γ may be an infinite set, it will first be shown that process P_j can determine the winning team from the values of a finite number of the components. Let $R_{A,j}$ and $R_{B,j}$ be the disjoint sets defined in Definition 13. These sets are finite, since the number of ways to choose $\alpha, i_1, \ldots, i_\alpha$ in the definitions of $R_{A,j}$ and $R_{B,j}$ is bounded by $n \cdot n!$. For $(r, q) \in R_{A,j}$ and $(r', q') \in R_{B,j}$, let $k(q, q')$ be an element of Γ that indexes some state component where q and q' differ, if such a component exists. Let Δ_j be the set of such indices $k(q, q')$ for all possible choices of (r, q) and (r', q'). The number of such choices is finite, so Δ_j is a finite set. Let π_j be the projection function from Q to the set $\bigtimes_{k\in\Delta_j} Q_k$. This projection function discards all components of the state, except for the finite number of components indexed by the elements of Δ_j.

Suppose the sets $\{(r, \pi_j(q)) : (r, q) \in R_{A,j}\}$ and $\{(r', \pi_j(q')) : (r', q') \in R_{B,j}\}$ have an element in common. Then there are two distinct pairs $(r, q) \in R_{A,j}$ and $(r, q') \in R_{B,j}$ such that $q \neq q'$ and $\pi_j(q) = \pi_j(q')$. This is impossible, since $k(q, q') \in \Delta_j$. Thus, process P_j can discern executions in which team A performed the first update from executions in which team B performed the first update, using only the response to its own update operation and the projection $\pi_j(q)$ of the state q of X at any time after P_j's update has been performed.

After performing its update operation, the process P_j reads, one by one, the components of the state that are indexed by Δ_j. The state of X may be updated by other processes while process P_j is performing this scan of the components. Each scan produces a view of the image of the state of X under the projection π_j. Such a view is called *accurate* if it correctly reflects the state of X at some moment during the execution of the scan. If another process performs an update operation during a scan, the resulting view may not be accurate, but any scan that is not interrupted by an update will produce an accurate view.

To ensure that P_j can correctly determine which team accessed X first, the scan of the components of X is repeated $2n - 1$ times. An update of X can occur during

at most $n-1$ of these scans, so at least n of the scans will return an accurate view of the state of X. By Definition 13, P_j can correctly determine which team accessed X first using the information from any accurate scan and the result of its operation op_j. Since a majority of the scans are accurate, P_j can correctly determine which team accessed X first. Process P_j then decides on the value stored in the register belonging to the team that accessed X first.

The validity condition for the consensus problem is satisfied, since every process must agree on the team that accessed X first. The consistency condition is also satisfied, since a process from the winning team must have written its value to its team's register before accessing X. The protocol is wait-free, since each of the $2n-1$ scans reads only a finite number of components of X. □

The following theorems follow immediately from Lemma 16 and Propositions 5 and 6.

THEOREM 17. *Let T_i be an i-discerning readable object type for $2 \leq i \leq n$. Then the n-consensus problem can be solved using one object O_i of each type T_i, together with $2(n-1)$ registers.*

THEOREM 18. *If T is an n-discerning readable object type, then there is a protocol for n-consensus that uses $n-1$ objects of type T and $2(n-1)$ registers.*

This completes the proof that a readable type T can be used with registers to solve n-consensus if and only if T is n-discerning. This characterization has the following consequences.

COROLLARY 19. *Readable objects of type T can be used, along with registers, to implement every other type of object in a system with n processes if and only if T is n-discerning.*

Proof. This follows from Theorems 15 and 18 and the fact that n-consensus objects can be used to obtain an implementation of any shared object in a system of n processes [10]. □

COROLLARY 20. *If the state set of object type T and the set of possible operations on object type T are both finite, then the following question is decidable: "Given a positive integer n and a readable type T, can n-consensus be solved using only objects of type T and registers?"*

Proof. The conditions of Definition 13 can be checked for each of the finite number of choices of $q_0, A, B, op_1, \ldots, op_n$ in a finite amount of time. □

It will now be shown that the addition of a *scan* operation, which reads the entire state atomically, to any readable type T does not increase its power to solve consensus.

COROLLARY 21. *Let T be a readable type. Let T' be a type that is the same as T, except that it allows an additional scan operation that reads the entire state of T. Then T and T' have the same consensus number.*

Proof. Let n be the consensus number of T'. Clearly, the consensus number of T is at most n. By Theorem 15, T' is an n-discerning readable type. Let $q_0, op_1, \ldots, op_n, A$ and B be chosen to satisfy Definition 13 for T'. None of the operations can be a *scan*, since *scan* operations never update the state of an object. Therefore, the choice of $q_0, op_1, \ldots, op_n, A$ and B will also satisfy Definition 13 for type T. By Theorem 18, it is possible to solve n-consensus using objects of type T and registers. □

It can be shown that, for each $n > 1$, there is a readable object type, analogous to the RMW object defined in Proposition 12, that has consensus number n. (See [23] for a detailed description of this object.)

5. Robustness for RMW and readable objects. Jayanti [14] formalized Herlihy's notion of a hierarchy [10] of shared object types and defined a number

of desirable properties for hierarchies, including robustness. A *wait-free hierarchy* classifies object types according to their power to implement one another. Formally, it is a mapping h of object types to the set of levels $\mathbb{N} \cup \{\infty\}$, where a type T is in level n only if objects of type T, together with registers, can be used to implement any other type of object in a system of n processes. If $h(T) = \infty$, then objects of type T and registers can be used to implement any other type of object in a system of n processes for all n. A wait-free hierarchy is *tight* if every object type is mapped to the highest level possible. Thus, if type T is mapped to level n of a tight wait-free hierarchy, there is some type that cannot be implemented using objects of type T and registers in a system of $n + 1$ processes. A wait-free hierarchy is *robust* if no object in any level of the hierarchy can be implemented using a finite number of types of objects from lower levels. In the consensus hierarchy, h^r_m, the level of a type T is the consensus number of T. Jayanti showed that h^r_m is the (unique) tight wait-free hierarchy [14].

Chandra et al. [6] showed that the consensus hierarchy is not robust, if nondeterministic, nonoblivious objects are allowed. Schenk [24] proved that the consensus hierarchy is not robust, even for oblivious objects, if objects with unbounded nondeterminism are allowed. Lo and Hadzilacos [17] improved this, showing that the hierarchy h^r_m restricted to oblivious objects is not robust even when nondeterminism is bounded. Moran and Rappoport [19] showed that the consensus hierarchy is not robust for deterministic nonoblivious objects using the restricted hard-wired binding model. (See Jayanti's survey [13] for a description of binding models, which restrict the ways that processes can access nonoblivious objects.)

Borowsky, Gafni, and Afek [5] claimed that the consensus hierarchy is robust for deterministic objects using a less restrictive binding model. Their paper is quite complex. Here, the characterizations of RMW and readable objects that can solve n-process consensus will be used to provide a concise proof of the robustness of the hierarchy when restricted to deterministic RMW and readable objects.

THEOREM 22. *Let T be a readable or RMW object type. Let $\mathcal{S}$ be a finite set of readable and RMW object types such that $h^r_m(T') < h^r_m(T)$ for each $T' \in \mathcal{S}$. Then an object of type T cannot be implemented using objects whose types are from the set $\mathcal{S}$.*

Proof. Let $n = \max\{h^r_m(T') \mid T' \in \mathcal{S}\} + 1$. This quantity is finite, since $h^r_m(T')$ is less than $h^r_m(T)$ and therefore finite for each $T' \in \mathcal{S}$, and $\mathcal{S}$ is a finite set.

To derive a contradiction, suppose the claim is false. Then, since $h^r_m(T) \geq n$, there is a protocol using objects whose types are from the set $\mathcal{S}$ that solves consensus among n processes. A bivalency argument [10] shows that this protocol has a critical configuration, S_0, and that the next operation taken by any process when the system is in this configuration must be an operation on the same object, X. Let T_X be the type of object X.

First, suppose that T_X is an RMW type. Then T_X is n-discerning, by Lemma 2. It follows from Theorem 9 that $h^r_m(T_X) \geq n$, contradicting the definition of n.

Now suppose that T_X is a readable type. The type T_X is n-discerning, by Lemma 14. By Theorem 18, $h^r_m(T_X) \geq n$, which again contradicts the definition of n. □

This theorem allows the decidability results of Corollaries 11 and 20 to be extended to finite sets of object types. If $\mathcal{S}$ is any finite set of finitely-specified RMW and readable object types, then one can decide whether objects whose types are in $\mathcal{S} \cup \{\text{register}\}$ can be used to solve n-process consensus, by checking whether any of the types in $\mathcal{S}$ are n-discerning.

Acknowledgments. This research forms part of my Ph.D. thesis [23] which was done at the University of Toronto. I am grateful for the guidance of my adviser, Faith Fich. I thank the anonymous PODC referees for their suggestions, and Vassos Hadzilacos, Maurice Herlihy, Wai-Kau Lo, Michael Merritt, and Eric Schenk for helpful discussions.

EARLY DETECTION OF MESSAGE FORWARDING FAULTS*

AMIR HERZBERG† AND SHAY KUTTEN‡

Abstract. In most communication networks, pairs of processors communicate by sending messages over a path connecting them. We present communication-efficient protocols that quickly detect and locate any failure along the path. Whenever there is excessive delay in forwarding messages along the path, the protocols detect a failure (even when the delay is caused by maliciously programmed processors). The protocols ensure optimal time for either message delivery or failure detection.

We observe that the actual delivery time δ of a message over a link is usually much smaller than the a priori known upper bound D on that delivery time. The main contribution of this paper is the way to model and take advantage of this observation. We introduce the notion of asynchronously early-terminating protocols, as well as protocols that are asynchronously early-terminating, i.e., time optimal in both worst case and typical cases. More precisely, we present a time complexity measure according to which one evaluates protocols both in terms of D and δ. We observe that asynchronously early termination is a form of competitiveness.

The protocols presented here are asynchronously early terminating since they are time optimal both in terms of D and of δ. Previous communication-efficient solutions were slow in the case where $\delta \ll D$. We observe that this is the most typical case.

It is suggested that the time complexity measure introduced, as well as the notion of asynchronously early-terminating, can be useful when evaluating protocols for other tasks in communication networks. The model introduced can be a useful step towards a formal analysis of real-time systems.

Our protocols have $O(n \log n)$ worst-case communication complexity. We show that this is the best possible for protocols that send immediately any acknowledgment they ever send. Then we show an early-terminating protocol which uses timing and delay to reduce the communication complexity in the typical executions where the number of failures is small and $\delta \ll D$. In such executions, its message complexity is linear, as is the complexity of nonfault tolerant protocols.

1. Introduction.

In this paper, we introduce a complexity measure of time complexity for asynchronous networks for which there exists an upper bound on the delivery time of a message over a link. It is suggested that this can be a useful step toward improving the analysis of actual communication networks, as well as a step toward the formal analysis of real-time systems. Using this complexity measure, we develop optimal protocols for dealing with the task of managing end-to-end communication sessions.

The end-to-end delivery of information from *source to destination* is a basic communication task. The most communication-complexity-efficient method for delivering

information is to send it along a fixed (short) path between two processors. There are also some other reasons that make this method the most common (e.g., as used in [Tan81, BGJ+85, MRR80]). For example, "first-in first-out" (FIFO) service for messages is then guaranteed, without the need for expensive hardware or for software intervention to restore the order of the messages.

Of course, this requires that all the links and the processors along the path are operational. When a link or a processor fails (which does not happen very often, compared to the rate of message traffic), a different fixed path is established instead of the disconnected one. For that, additional mechanisms are used to detect and locate failures. These mechanisms are based on acknowledgments and use a time-out value D, which is a bound on the transmission delay over one link. Often fail-stop failures are detected by *hop-by-hop acknowledgments*, which are control messages sent by a processor to its neighbor upon receiving a data message from that neighbor. If processor u does not receive an acknowledgment from neighbor v within D since u sent a data message to v, then either v or link (u, v) failed.

There are some failures which are not detected by the hop-by-hop acknowledgments mechanism. A simple example is a malicious failure, where v "intentionally" sends an acknowledgment without forwarding the data message toward the destination. A similar outcome may result without malicious intent, i.e., when a processor breaks down after sending the acknowledgment but before succeeding in forwarding the data message. (A more likely case is that a processor did forward the message before it failed, but the message got lost over the link; the failed processor cannot now retransmit the message.) This kind of failure is usually dealt with by an *end-to-end acknowledgment* mechanism. This is an acknowledgment message which is sent from the destination to the source when the destination receives a data message. If the source does not receive an acknowledgment within $2(n-1)D$ since it sent the data message, where n is the number of processors along the path, then a failure has occurred.

For a given execution of the protocol, and for any f, let δ_f denote the maximal transmission delay over a link in this execution, when not counting the worst f links. Moreover, $\delta_f \leq D$ is not any bound (even unknown) but rather the actual maximal delay as could be observed had there been some outside observer. Intuitively, when f is the number of faults in an execution, δ_f is the maximum delay over nonfaulty links (and between two nonfaulty neighboring processors). However, this definition makes sense also when there are no "real faults" (or at least no faults can be detected, since the delay on all links is still smaller than D); some links just happened to be slower than others. For simplicity, we prefer to use δ_f rather than the actual delay (in the execution) over each link separately. In addition, since our protocols can deal even with malicious faults of processors, most of the paper uses this meaning of f. Thus, f is clear from the context, and we shall use the notation δ instead of δ_f. In section 7, we analyze briefly the meaning of the results in the case where no faults occur.

Network designers usually choose a bound D which is much larger than the typical transmission delay. This is due to the unpredictability of the actual delay, and to the huge overhead of disconnecting a link (see, e.g., [GSK87]). Therefore, in typical executions, $\delta \ll D$ holds. This motivates an analysis of the time complexity which considers both D and δ; intuitively, one would like to derive a bound on the time complexity that will depend, as much as possible, on the (usually small) value of δ, rather than on the value of D.

We call a protocol *asynchronously early-terminating* if its time complexity is op-

TABLE 1
Parameters.

Parameter	Meaning	Typical value	Initially known?
n	Number of processors	< 20	Yes
f	Number of faulty processors and links	0 or 1	No
D	Bound on the delay on a nonfaulty link	1 sec.	Yes
δ	Actual delay on a nonfaulty link	10 msec.	No

timal for any selection of the number of faults f, of D, and, of δ. (We shorten it to *early-terminating*, when there is no ambiguity with the "early-stopping" synchronous Byzantine agreement protocols discussed in many papers [DRS86].) We present early-terminating detection protocols, with time complexity $O(fD + n\delta)$, where f is the number of faults. This improves substantially over the common end-to-end mechanism, which requires $2(n-1)D$, for typical executions where $f \ll n$ and $\delta \ll D$. Typical values of the parameters n, f, D, and δ are shown in Table 1.

Another way to see the improvement is when considering the competitiveness of the protocols. Consider the time complexity $T_C(P)$ of a protocol P for a given configuration C, that is, given the set F of faulty processors (where $|F| = f$) and the values of D and δ. Define the competitive ratio of a protocol P_1 with respect to protocol P_2 and the given configuration as $\frac{T_C(P_1)}{T_C(P_2)}$. The competitive ratio of P_1 with respect to P_2 is $\max_C \frac{T_C(P_1)}{T_C(P_2)}$. Clearly, the competitive ratio of the common end-to-end mechanism with respect to our protocols is $\Omega(n)$, where the maximum ratio is achieved when δ approaches zero.

To compute the distributed competitiveness of a protocol P_1, one needs to compare it to the "best" distributed algorithm, rather than to any other. To rephrase the recent definition of [AADW94], for a given configuration C, one divides $T_C(P_1)$ by the complexity (for configuration C) of a distributed protocol OPT_C that achieves the best time complexity for configuration C. It is required that OPT_C will perform correctly in any case. The distributed competitiveness of P_1 is the maximum (over all the configurations) of such ratio. It can be shown that early-terminating protocols for our problem are distributively competitive (i.e., have constant competitive ratios). Thus, our protocols are also distributively competitive.

The protocols presented in this paper allow early-terminating and communication-efficient detection of arbitrary faults, while forwarding information from the source to the destination. Our protocols also provide fault *location*, i.e., when a failure occurs, the source learns of a specific link such that either the link or one of its endpoints is faulty. This is useful for most recovery actions. Both detection and location are done in optimal time for any value of D and δ. (Recall that we analyze the time complexity as a function of D and δ.)

Table 2 summarizes our results and previous results. Note that all of our protocols provide fault location, which was achieved previously only with $O(n^2)$ communication complexity.

Our main contribution is the measure of time complexity as depending on D and δ, with the concept that one should strive to obtain time complexity bounds that depend as much as possible on δ rather than on D. Other contributions are communication-efficient early-terminating protocols. The *immediate-Acks protocol*,

TABLE 2
Protocols.

Protocol	Time	Communication	Remarks
ISO 8072/3, CCITT x.224	$O(nD)$	$O(n)$	Not locating
[Per88, section 3.5]	$O(nD)$	$O(n^2)$	Locating
End-to-end (section 4.1)	$O(nD)$	$O(n)$	Locating
Hop-by-hop (section 4.2)	$O(fD + n\delta)$	$O(n^2)$	Locating
Immediate-Acks (section 6.1)	$O(fD + n\delta)$	$O(n \log(n))$	Locating
Adaptive (section 6)	$O(fD + n\delta)$	$O(n \log(f + \frac{n\delta}{D}))$	Locating

presented in section 6.1, has $O(n \log n)$ communication complexity. We present in sections 6.3 and 6.4 an early terminating protocol which is adaptive, in the sense that the number of acknowledgment messages sent depends on the delays and the behavior of the adversary in the particular execution. Its communication complexity is $O(n \log(2 + f + \frac{n\delta}{D}))$. We argue that in typical applications of this type of protocol, the number of failures f is zero or very small; otherwise the network designer will avoid transmission of messages over a fixed path. The term $\frac{n\delta}{D}$ is also usually small. Hence, in practice, this communication complexity is close to the optimal communication complexity ($O(n)$).

We show that for other kinds of protocols (i.e., those that are message-driven, except for the decision to disconnect a link that may be time-driven), a lower bound of $\Omega(n \log n)$ exists. The proof of the lower bound shows collections of paths of total length $\Omega(n \log n)$ that any protocol must use for sending message (acknowledgments). Our adaptive protocol mentioned economizes on message-sending by avoiding using some of these paths when the delays and number of faults are small. However, there are some executions in which this protocol must utilize all the paths in its collections. It is an open problem whether there exists an optimal time, early terminating protocol whose worst-case message complexity is better (in order of magnitude). An interesting corollary from the proof of the lower bound is that such a protocol (if it exists) will not have an execution that sends messages over every path that is used in some execution.

Related works. The asynchronous model with bounded delay was previously studied in [AE86, CCGZ88, DHSS84] without considering early termination.

Communication via a fixed path was studied in [SJ86]. Detection of failures was addressed in accepted and in proposed standards [Sta87]. Recovery from (detected) errors during such communication was studied in [Gro82]. Detection, location, and recovery from arbitrary transmission failures were studied by Perlman [Per88], who introduced the notions of communication failure detection in the environment of malicious processors, and that of failure location in this context.

Many works presented end-to-end communication protocols which do not depend on a single path [CR87, Fin79, Per88, AG88, AAGMRS97, AGH90]. The goal of these works is to increase reliability. In the extreme, these works achieve communication even if there is no moment when there is a nonfaulty path from the source to the destination [AE86, AG88, AAGMRS97]. These methods are useful for source-to-destination communication only in applications where the increased reliability compensates for the much higher communication complexity, storage requirements, and local processing.

We permitted the processors to fail in an arbitrary manner. However, we assumed that the links are "well-behaved"; namely, the links either work correctly or their failure is detected. The justification for this assumption is the known link protocols [BS88, GHM89, Zim80].

Our adaptive protocol (section 6) is based on the idea that a processor i can "piggyback" its acknowledgment on an acknowledgment of another processor j. This raises the question: How long should processor i wait for the acknowledgment of processor j before it gives up the idea of piggybacking (and sends its acknowledgment)? A similar problem was studied in [AAPS87, AS87, BYKWZ87, K88].

Our protocols can be viewed as being competitive (especially in the time complexity measure). Competitive distributed algorithms were studied further in later papers, e.g., [AKP92, AADW94].

Finally, this work should be viewed in the context of the important work published later dealing with formal approach and modeling of distributed real-time systems. A paper with a strong impact is [ADLS91], which suggests a more detailed model, and gives an algorithm for agreement whose time depends mostly on δ, and only minimally on D. This work was extended by [Pon91] to handle omission and Byzantine faults. In [AL89], formal analysis of timing uncertainties and time bounds is done with respect to another task.

Organization. In the next two sections, we define the communication model and the problem. In section 4, we present two natural, simple protocols that solve the problem. The two protocols are presented mainly in order to demonstrate the problem and the model. One (which is similar to the x.244 protocol [Sta87]) is communication-optimal, but is not early-terminating. (The difference between this protocol and that of x.244 is that our protocol also locates the faults.) The other is early-terminating, but has high communication complexity. This protocol is similar to that of [Per88]. In section 5, we present a high level design of a fault isolator. This design is implemented by all the protocols in this paper and the protocols previously published. In section 6.1, we give an implementation which is early-terminating and with message complexity which is $O(n \log n)$. This message complexity is achieved by optimizing a certain combinatorial cover problem introduced in that section. We also show that every early-terminating protocol sends messages over paths that are included in such a cover. In sections 6.3–6.5, we present an early-stopping protocol that economizes on messages by avoiding sending messages over some of these paths in favorable executions. We conclude and discuss open problems in section 7.

2. The model. Our model is a modification of the standard model of dynamic networks [AE86, AAG87]. Since we are interested in detecting failures, we do not include recoveries. We assume some synchronization, namely, a known bound D on the transmission time over a nonfaulty link. We also introduce some new notations and assumptions, since we discuss communication only along a fixed path.

Denote the path as processors $1, \ldots, n$. Even though the task of our protocols is to deal with a message from processor 1 to processor n, our protocols send additional messages from intermediate nodes and to intermediate nodes. Consider a message ϕ (e.g., an acknowledgment) that was sent by processor $1 \leq j \leq n$ (the *sender* of ϕ) to another processor $1 \leq k \leq j$ (the *recipient* of ϕ). If k is not a neighbor of j, then message Φ needs to be received and resent by processors on the path between j and k. We use the following (somewhat "visual") notation to emphasize that in this case $k \leq j$: The protocol in processor i for $(k \leq i \leq j)$ interacts with the links by the

events $\texttt{Send}_i^{k\leftarrow j}[\phi]$, and $\texttt{Receive}_i^{k\leftarrow j}[\phi]$. Similarly, in the case that k is larger than j: $\texttt{Send}_i^{j\rightarrow k}[\phi]$, $\texttt{Receive}_i^{j\rightarrow k}[\phi]$. The events have their natural meanings.

In actual networks, following a message sent by i to $i+1$, the lower layer link level protocol will deliver a $\texttt{fail}_{i+1}$ event to i (i.e., the failure of the link from i to $i+1$) when more than $2D$ time passed without an acknowledgment whose sender is processor $i+1$, being received at i. For simplicity, we do not use such an event. Our protocol will detect a fault in such a case anyhow. We do not distinguish here between faults of links and those of processors except that when i detects a fault in the communication with $i+1$, we call it a failure of link $(i, i+1)$ (although it may be just the fault of processor $i+1$), and similarly in the case when $i+2$ detects a fault in its communication with processor $i+1$, we speak of a failure of link $(i+1, i+2)$. Since we do not allow recoveries, we assume that each link fails at most once.

We assume that whenever processor i receives a message, the message was indeed issued by the sender and later forwarded by every processor between the sender and i, and moreover that processor i is between the sender and the recipient. This assumption holds if the failures are nonmalicious, and otherwise can be enforced by cryptographic techniques.

AXIOM 1. *If* $\texttt{Receive}_i^{j\rightarrow k}[\phi]$ *occurs, then* $j < i \leq k$ *and for every* p *between* j *and* i, *previously* $\texttt{Receive}_p^{j\rightarrow k}[\phi]$ *and* $\texttt{Send}_p^{j\rightarrow k}$ *(as well as* $\texttt{Send}_j^{j\rightarrow k}$*) occurred. Similarly, if* $\texttt{Receive}_i^{j\leftarrow k}[\phi]$ *occurs, previously* $\texttt{Receive}_q^{j\leftarrow k}[\phi]$ *and* $\texttt{Send}_p^{j\leftarrow k}$ *(and* $\texttt{Send}_k^{j\leftarrow k}$*) occurred.*

The major deviation of our model from the standard dynamic network model is the addition of *synchronization* assumptions. Intuitively, these assumptions imply that the lower layer guarantees that it takes at most D time units from a $\texttt{Send}_i^{j\rightarrow k}[\phi]$ (respectively, $\texttt{Send}_i^{j\leftarrow k}[\phi]$) event till the corresponding $\texttt{Receive}_{i+1}^{j\rightarrow k}[\phi]$ (respectively, $\texttt{Receive}_{i-1}^{j\leftarrow k}[\phi]$) event occurs, unless the link (or one of the processors) failed. For simplicity of exposition, we use global time terminology and assume that all of the clocks have the same rate. We model the clocks by an "alarm clock" that generates an event every D time units. Namely, a "ticker" that sends interrupts every D time actually suffices for our protocols. We express this a little more formally in the following axiom.

AXIOM 2. *For every processor* i, *a TICK event occurs exactly once every* D *time units.*

Faulty processors whose number, f, is unknown are chosen by the adversary. In section 7, we discuss other meanings of f (and of the time complexity) in the cases in which there are no faults. A faulty link is one that is adjacent to a faulty processor. (This is a simplification. As mentioned above, in reality, it is possible that a processor will continue to function, and its other links will thus not be faulty.) The time for message delivery over faulty links is bounded by D, after which we say that a fault has occurred. Note that the adversary can choose to deliver messages over faulty links very quickly (e.g., in less than δ) or very slowly (e.g., even more than D). However, if a message is sent over a link at a time t and no acknowledgment arrives at time $t+2D$, a fault has occurred, and an algorithm is permitted to announce a detected fault. Axiom 3 bounds the message delivery time to δ over nonfaulty links.

AXIOM 3. *Assume that at time* t, *a* $\texttt{Send}_i^{j\rightarrow k}[\phi]$ *(*$\texttt{Send}_i^{j\leftarrow k}[\phi]$*) event occurs. Then, before* $t+\delta \leq t+D$, *if the link* $(i, i+1)$ *(respectively,* $(i-1, i)$ *is nonfaulty, then a* $\texttt{Receive}_{i+1}^{j\rightarrow k}[\phi]$ *(respectively,* $\texttt{Receive}_{i-1}^{j\leftarrow k}[\phi]$*) event occurs.*

3. The task. Intuitively, we want to deliver a message from a source processor to a destination processor. The protocol should detect any failure of links or processors which may delay (or disable) the transmission along the path. Both the transmission and the detection should be done in minimal time.

In our model, processor 1 is the *source* and processor n is the *destination*. The path consists of processors $1, \ldots, n$ and the links connecting them. We discuss only the transmission of a single message. There are standard methods to extend the results when many messages are transmitted, e.g., appending counters.

The operation of the protocol is based on transmitting the message and additional (control) information between the processors. Therefore, the protocol *accepts* a message from the higher layer in the source, and *delivers* a message to the higher layer in the destination; and for this purpose, it sends and receives (other) messages between processors along the path. Whenever confusion arises, we use the term *data message* (recall that in this paper we discuss only the case of a single data message, though, of course, multiple data messages can be handled by the same protocols) to refer to the message accepted from and delivered to the higher layer, and the term *control messages* to refer to the messages transmitted over the links (by the protocol). Note that some of the "control messages" that we use contain the "data message." (Some papers instead make the distinction between "messages" that arrive at the sender from a higher layer and delivered to a higher layer at the receiver, and "packets" that are sent in the network.)

In the protocols, we use two kinds of control messages (in addition to those that carry the data to be delivered): acknowledgments and disconnection notifications $Disc_i$. A disconnection notification $Disc_i$ means that processor i detected a failure in processor $i+1$ or in the link $(i, i+1)$. Such messages are normally flooded in the network, and therefore we assume that the protocol terminates when a nonfaulty processor sends $Disc_i$.

Loosely speaking, the protocols are resilient to a strong "adversary," which "knows" the state of every processor and every link, and "controls" the transmission delays of every link (up to D), the actual failures of the faulty links (delay larger than D), and the entire behavior of the faulty processors. However, the nonfaulty links never fail (always deliver messages in less than D) and the nonfaulty processors always operate according to the protocol. This resilience is formally stated in the following definition.

DEFINITION 1. *A protocol* $(P_1, \ldots, P_n)$ *is a* resilient forwarding faults detector *if for every selection of faulty processors and links, in every execution where every nonfaulty processor* i *executes* P_i*, the following conditions are kept.*

Detection: If the source and the destination are nonfaulty, then within a bounded time from the time the source accepts the message, either the message is delivered or a $Disc_i$ message is sent by some nonfaulty processor.

Location: If a $Disc_i$ message is sent by a nonfaulty processor, the link $(i, i+1)$ is faulty (that is, either processor i or processor $i+1$ is faulty).

Note that in the detection condition we do not require that the $Disc_i$ message be issued by a nonfaulty processor i.

In fact, a correct protocol should also guarantee the following.

Safety: If the source and the destination are nonfaulty, then the destination delivers a message only if this message was the one accepted at the source.

However, from Axiom 1 we assume that when a message is delivered to a processor it indeed knows who was its initiator.

Complexity measures. The complexity measure given here is the main difference between the model in the paper and the ones in previous works.

We consider time and communication complexities. Both measures are stated as functions of n, f, D, and δ, where the parameters are defined in Table 1. The complexities are the worst-case values for any execution over paths of length n with the actual (unknown) number f of faulty processors, bound D on the delay, and actual delay δ over nonfaulty links whose endpoints are also nonfaulty.

The time complexity is the maximum over all executions of the time since the source accepts the (data) message and until either the destination delivers that message or a failure is detected. To compute the time complexity, we consider only executions where the source and the destination processors are nonfaulty, since otherwise it is impossible to guarantee termination.

The communication complexity is the maximum number of transmissions of messages by nonfaulty processors. Messages transmitted by faulty processors are not counted.

4. Simple solutions. To demonstrate the problem, this section contains two simple protocols. The first, presented in section 4.1, is communication-optimal but has high time complexity. We point out the cause of the high time complexity. This weakness is removed in the protocol presented in section 4.2. The protocol of section 4.2 is early-terminating but has high communication complexity.

4.1. End-to-end fault detector. This protocol resembles the time-out mechanism of the data link. The data message ϕ is forwarded towards the destination (by $\texttt{Send}_i^{1\to n}[\phi]$ events). When the destination accepts the data message ($\texttt{Receive}_n^{1\to n}[\phi]$), it sends an acknowledgment backward ($\texttt{Send}_n^{1\leftarrow n}[Ack]$). Every processor $i < n$ checks whether $i+1$ is faulty. Namely, processor i expects to receive the acknowledgment ($\texttt{Receive}_i^{1\leftarrow n}[Ack]$) after $3(n-i)$ or less $TICK_i$ events since $\texttt{Send}_i^{1\to n}[\phi]$. If neither the acknowledgment nor the disconnection message is accepted, then i disconnects link $(i, i+1)$. Processor i forwards ϕ at most one $TICK_{i-1}$ event after $i-1$ forwarded it (assuming i, $i-1$, and $(i-1, i)$ are nonfaulty). Hence, and from the synchronization axioms, processor $i-1$ will accept either the acknowledgment or the disconnection from i at most $3(n-(i-1))$ $TICK_{i-1}$ events since forwarding ϕ. This means that nonfaulty processors will not be accidentally disconnected.

The communication complexity of the end-to-end detector is optimal ($3(n-1)$). The time complexity is $3(n-1)\cdot D$. (This is the complexity in the case that processor 2 is faulty.) When $\delta \ll D$, this time complexity is much inferior to the early-terminating time complexity $O(fD + n\delta)$, achieved by the protocols presented later.

4.2. Hop-by-hop detector. The end-to-end detector suffers from $O(nD)$ time complexity. We now describe a detector with time complexity $O(n\delta + fD)$, which is later shown to be optimal. We do this by extending the use of the acknowledgments. In the end-to-end detector, we use only one acknowledgment message, which signals the completion of the transmission. The idea is to use additional acknowledgments, which signal that the transmission is progressing properly.

In the hop-by-hop fault detector, we carry this idea to the extreme, thereby obtaining optimal time complexity. Namely, each processor sends an acknowledgment towards the source immediately upon receiving the message ϕ en route to the destination.

The improvement in time complexity is obtained by a tighter time-out check in the processors. Consider an arbitrary processor i. In the end-to-end detector, processor i

Constants of processor i:
  A_i (*integer*)): array of integer; (different for each protocol)
  (If $A_i(t) \neq \perp$, then after tD since processor i accepts ϕ, it sends Ack to processor $A_i(t)$.)

Variables of processor i:
{
  $done_i$: logical (init: *FALSE*); (*True* after i terminated (ϕ delivered or failure detected))
  $time_i$: integer; (The current time, i.e., number of $TICK_i$ events since start)
  $AckSet_i$: set of intervals (init: $\emptyset$); (Intervals of Ack which i received or sent)
}

FIG. 1 *Design of forwarding faults detector: declarations.*

disconnects from $i+1$ if it does not receive the acknowledgment from the destination n after more than $3(n-i)$ $TICK_i$ events since i forwarded ϕ toward the destination. (In fact, for this specific protocol we could have written $2(n-i)$, but $3(n-i)$ is used for compatibility with protocols presented later.) In essence, i waits the time needed in the worst case for the data message to reach its final destination n and for an acknowledgment to arrive from n to i. Consider the case that $i+1$ never forwards the message to $i+2$. Intuitively, this can be detected by i (using another protocol in which $i+2$ sends an acknowledgment to i) with $O(D)$ time. However, the end-to-end protocol detects the disconnection only in $\Omega((n-i)D)$ time.

In the hop-by-hop detector, processor i disconnects from $i+1$ if it does not receive any of the acknowledgments from $k = i+2, i+3, \ldots, n$ after more than $3(k-i)$ $TICK_i$ events. Intuitively, this mechanism guarantees that every $3D$ time unit the message processes toward the destination over an additional link (if this link is faulty; otherwise traversing the link costs δ time).

5. A design of resilient detectors. Both simple detectors presented in section 4 are extremely inefficient in one measure (either time or communication) and optimal in the other measure. In the rest of the paper, we present detectors which are efficient in both measures by providing reasonable trade-offs between them. In particular, the detectors are time-optimal up to a constant factor. It is also easy to present implementations of the design which are communication-optimal but with suboptimal time complexity.

Instead of presenting each detector "from scratch," we regard them all as implementations of a common "design." The end-to-end and the hop-by-hop detectors may also be regarded as implementations of this design. We prove that every implementation of this design, which satisfies a simple condition, is a resilient forwarding faults detector. Furthermore, we give a simple yet useful bound on the time complexity of implementations. In particular, these general results are used to prove that the detectors of section 4 are resilient and that the hop-by-hop detector is time-optimal.

The design is presented in Figures 1 and 2, and the explanations are given below.

Different implementations are defined by different selections of values for the array $A_{node}(time)$. Basically, if $A_{node}(time) \neq \perp$, then processor *node* will send an acknowledgment to processor $A_{node}(time)$ after *time* events of type D_{node} (i.e., additional D time units elapsed) occurred since *node* entered the protocol. The detectors of section 4 are implemented by using $A_i(t) = \perp$, except for the following.

For the end-to-end detector: use $A_n(0) = 1$.

For the hop-by-hop detector: for every $1 < i \leq n$, use $A_i(0) = 1$.

That is, in the end-to-end detector, only processor n initiates an acknowledgment

Algorithm for the source $i = 1$:

⟨B1⟩ On accepting ϕ:
⟨B2⟩ { $\texttt{Send}_1^{1\rightarrow n}[\phi]$;
⟨B3⟩ repeat WORKLOOP() until $done_i$;}

Algorithm for the destination $i = n$;

⟨C1⟩ On $\texttt{Receive}_n^{1\rightarrow n}[\phi]$: { deliver ϕ; $\texttt{Send}_n^{1\leftarrow n}[Ack]$; $done_n \leftarrow TRUE$;}

Algorithm for intermediate processors $1 < i < n$:

⟨D1⟩ On $\texttt{Receive}_i^{1\rightarrow n}[\phi]$:
⟨D2⟩ { $\texttt{Send}_i^{1\rightarrow n}[\phi]$; (forward message)
⟨D3⟩ if $A_i(0) \neq \perp$ then
⟨D4⟩ { $\texttt{Send}_i^{A_i(0)\leftarrow i}[Ack]$;
⟨D5⟩ $AckSet_i \leftarrow \{[A_i(0), i]\}$; }
⟨D6⟩ repeat WORKLOOP() until $done_i$; }

Procedure WORKLOOP():{
⟨E1⟩ On $\texttt{Receive}_i^{j\leftarrow l}[Ack]$ such that
$((\exists t)A_l(t) = j) \wedge ((\forall [j', l'] \in AckSet_i)(j < j') \vee (l' < l))$:
⟨E2⟩ { if $j = 1$ and $l = n$ then $done_i \leftarrow TRUE$;
⟨E3⟩ if $j < i$ then $\texttt{Send}_i^{j\leftarrow l}[Ack]$; (Forward Ack if i is not its destination)
⟨E4⟩ $AckSet_i \leftarrow AckSet_i \cup \{[j, l]\}$; }

⟨F1⟩ On $TICK_i$:
⟨F2⟩ { increment $time_i$;
⟨F3⟩ if $(A_i\ (time_i) \neq \perp) \wedge ((\forall [j', l'] \in AckSet_i)A_i\ (time_i) < j')$ then
⟨F4⟩ { $\texttt{Send}_i^{A_i(time_i)\leftarrow i}[Ack]$; $AckSet_i \leftarrow AckSet_i \cup \{[A_i(time_i), i]\}$ }
⟨F5⟩ if $\exists l > i$ and $(\exists t) t < time_i - 3(l - i)$ such that $i \geq A_l(t) \neq \perp$ and
$(\forall [j', l'] \in AckSet_i)(A_l(t) < j' \vee l' < l)$ then DISCONNECT() ;}

⟨G1⟩ On $\texttt{fail}_i$: DISCONNECT() ;

⟨H1⟩ On $\texttt{Receive}_i^{1\leftarrow j}[Disc_j]$:
⟨H2⟩ { $done_i \leftarrow TRUE$; $\texttt{Send}_i^{1\leftarrow j}[Disc_j]$; }
}

Procedure DISCONNECT() ; (Disconnect processor i from $i + 1$)
⟨I1⟩ { $\texttt{Send}_i^{1\leftarrow i}[Disc_i]$;
⟨I2⟩ $done_i \leftarrow TRUE$; }

FIG. 2 *Design of a forwarding faults detector for processor i.*

(thus $A_i(0) = \perp$ for every $i \neq n$). Moreover, processor n sends the acknowledgment to processor 1, and after 0 time, i.e., immediately on receiving the message. In the hop-by-hop detector, every processor sends an acknowledgment to processor 1 immediately upon receiving the message. For now, it will be easier to think of the more intuitive case that $A_i(t) = \perp$ for every $t > 0$. The usefulness of the case that $A_i(t) \neq \perp$ for $t > 0$ is demonstrated in subsection 6.3.

The operation begins when the source (processor 1) accepts the message ϕ from the higher layer. Each processor $i > 1$ begins operating when receiving ϕ from $i - 1$. When the message is received, every processor i (except for the destination) forwards it to the next processor $i + 1$. If $i = n$, the message is delivered to the higher layer, an Ack is sent to the source, and the protocol terminates. In the other processors ($i < n$), an Ack is sent to $A_i(0)$ (provided that $A_i(0) \neq \perp$) and i starts executing its

WORK_LOOP procedure. The WORK_LOOP is executed repeatedly, terminating only if a failure is detected or the *Ack* from n is accepted.

Processor i may also issue *Ack* later, sometime after it started operating. This is done according to the protocol-dependent $A_i(t)$ array. The value of $A_i(t)$ is the identity of the processor to which i should send an *Ack* at $t \cdot D$ after i began executing. We say that processor $A_i(t)$ is the *recipient* of this *Ack* message.

Some economizing is done at that point. (This economizing does not occur in the hop-by-hop and the end-to-end implementation; however, it proves very useful in the implementations of section 6.) Assume that $t_1 D$ time units after i started operating, it forwarded some *Ack* whose destination is some node k, and later, after $t_2 D$ time units, it is supposed to send an *Ack* to some $j > k$. (That is, $A_i(t_2) = j$.) Intuitively, this later *Ack* is no longer necessary, since the earlier *Ack* (that of time $t_1 D$) was already supposed to tell j (as well as k) that processor i received the message.

Thus, the *Ack* is sent only if its recipient $A_i(t)$ is farther from i than the most distant recipient of some previous *Ack* which i already forwarded. The set $AckSet_i$ holds all the intervals of *Ack* which i already forwarded. Processor i checks every $TICK_i$ event while in WORK_LOOP, if it should issue an *Ack*. The time since i began executing is approximated (in the variable $time_i$) by counting the number of $TICK_i$ events since i began executing.

The *Ack* messages are forwarded to their recipients by the nodes along the path. Namely, when processor i receives an *Ack* (from $i+1$) then i sends this *Ack* to processor $i-1$. There are three exceptions. First, if i is the recipient, then, of course, it does not forward the *Ack* any further. Second, processor i checks that this *Ack* is not "bogus," namely, that for some t and some $l > i$ the value of $A_l(t)$ is j. This prevents *Ack* messages from "maliciously" increasing message complexity.

The third exception is that the *Ack* is forwarded only if it may give some processor new information about the progress of the protocol. When a processor i receives an *Ack* which cannot give new information about the progress of the protocol, we say that the *Ack* is *redundant* and i does not forward it toward the recipient. Formally, an *Ack* from l to j is *redundant* when received by i if i already sent an *Ack* from some $l' \geq l$ to some $j' \leq j$.

Let us comment about nonredundant *Acks*. Note that for i to forward l's *Ack* it is unnecessary for i to learn anything new from that *Ack*. For example, it may be the case that i already received an *Ack* from $l+1$, and thus i already "knows" that l received the messages. Still, it may be the case that this *Ack* of $l+1$ was not forwarded to j, and that j does not "know" that the message arrived at $l+1$, or even at l. Thus, this *Ack* may be nonredundant.

In every $TICK_i$ event, processor i checks for time-out of any expected *Ack*. A time-out is a failure of $i+1$ to deliver the acknowledgment in time or to disconnect from $i+2$. Note that if i does not receive an *Ack* on time from any processor $l > i+1$ that is supposed to send an *Ack* to i, then $i+1$ has the opportunity to discover that before i does. In this case, if $i+1$ is not faulty, it must detect a disconnection of its link to $i+2$ and tell it to i. If this did not happen, then i concludes that $i+1$ is faulty.

Let us now elaborate on instruction ⟨F5⟩, where the mentioned check is done. Processor i checks if there exists some processor $l > i$ that was supposed to send an *Ack* to be received by i. That is $A_l()$ equals some j that is either i or smaller than i. As mentioned above, such an *Ack* message should pass i. If such an *Ack* was supposed to be sent, it may have not been sent yet, since the original message did not have time

to reach l yet. Alternatively, the *Ack* may have already been sent by l, but did not have enough time to reach i. That is why in instruction $\langle$F5$\rangle$ i also checks that there was enough time for the *Ack* to reach it if there were no disconnections. This is the meaning of the check on t in instruction $\langle$F5$\rangle$. Finally, it could be the case that the *Ack* was redundant, and thus was never sent or was omitted. Processor i verifies that this did not happen, by checking that other *Ack* messages it received or forwarded were not sent over intervals that contained l and j.

The check is done using the values of $A_i()$ of the different processor $j > i$, and the fact that $time_{i+1} \geq time_i - 2$. This fact follows from the synchronization axioms and the fact that ϕ is forwarded immediately. If the check fails, procedure DISCONNECT() is used to disconnect processor i from $i+1$ (since processor $i+1$ or the link to it, or both, are faulty).

5.1. Resilience of the design. In this subsection, we prove that every implementation of the design, which satisfies a simple condition, is a resilient forwarding faults detector. Most of the effort is required to prove the location property, which shows that a nonfaulty link $(i, i+1)$ between nonfaulty processors i, $i+1$ will not be disconnected. We begin with several simpler observations regarding such a link. First, we show that if $i+1$ finishes operating, then i will also finish operating after at most δ.

LEMMA 1. *Consider an execution in which link* $(i, i+1)$ *and processors* i *and* $i+1$ *are nonfaulty. Processor* i *sets* $done_i \leftarrow TRUE$ *at most* δ *after processor* $i+1$ *sets* $done_{i+1} \leftarrow TRUE$.

Proof. Processor $i+1$ sets $done_{i+1} \leftarrow TRUE$ only after $\texttt{Send}_{i+1}^{1 \leftarrow n}[Ack]$ or $\texttt{Send}_{i+1}^{1 \leftarrow j}[Disc_j]$. In any case, the corresponding `Receive` will occur at most after δ, by Axiom 3. Either message will cause $done_i \leftarrow TRUE$ unless it is already $TRUE$. □

We now prove that until processors i and $i+1$ finish, they are "nearly synchronized" in the values of the variable *time*.

LEMMA 2. *Consider an execution in which link* $(i, i+1)$ *and processors* i *and* $i+1$ *are nonfaulty. Whenever* $done_{i+1} = FALSE$, *then* $time_i - 2 \leq time_{i+1}$.

Proof. Processor i performs $\texttt{Send}_i^{1 \rightarrow n}[\phi]$ immediately upon starting operation. From Axiom 3, processor $i+1$ accepts ϕ at most $\delta < D$ later. As long as $done_{i+1} = FALSE$, the value of $time_{i+1}$ is the number of $TICK_{i+1}$ events since $i+1$ began executing. Similarly, the value of $time_i$ is at most the number of $TICK_i$ events since i began executing. The claim follows from Axiom 2. □

We now prove that if $i+1$ sends an *Ack* to i, then this *Ack* will not be ignored by (statement $\langle$E1$\rangle$ of the design) processor i.

LEMMA 3. *Consider an execution in which link* $(i, i+1)$ *and processors* i *and* $i+1$ *are nonfaulty. Assume that a* $\texttt{Send}_{i+1}^{j \leftarrow l}[Ack]$ *occurs at time* τ *for* $j \leq i$, $l \geq i+1$, *while* $done_i = done_{i+1} = FALSE$. *Then, at time* $\tau + \delta$, *either* $done_i = TRUE$ *or* $(\exists [j', l'] \in AckSet_i)(j' \leq j < l \leq l')$.

Proof. From Axiom 3, event $\texttt{Receive}_i^{j \leftarrow l}[Ack]$ will occur before time $\tau + \delta$. Assume that at time $\tau + \delta$, the following holds: $done_i = FALSE$. Therefore, statement $\langle$E1$\rangle$ is executed in i upon $\texttt{Receive}_i^{j \leftarrow l}[Ack]$. However, since $i+1$ is nonfaulty, it also used statement $\langle$E1$\rangle$, $\langle$D3$\rangle$, or $\langle$F3$\rangle$ before $\texttt{Send}_{i+1}^{j \leftarrow l}[Ack]$. Hence $(\exists t) A_l(t) = j$. This proves the claim, since if the other check of statement $\langle$E1$\rangle$ fails, then the claim holds trivially; and if both checks succeed, then statement $\langle$E4$\rangle$ is executed and the claim follows. □

We now prove the core of the location property. This claim is still slightly weaker than the location property, since it deals only with the case that i sends the $Disc_i$ message.

LEMMA 4. *Consider an execution in which link* $(i, i+1)$ *and processors* i *and* $i+1$ *are nonfaulty. Then the execution does not contain a* $\texttt{Send}_i^{1 \leftarrow i}[Disc_i]$.

Proof. The proof is by contradiction. Assume that $\texttt{Send}_i^{1 \leftarrow i}[Disc_i]$ occurs at time τ. By definition, a $\texttt{fail}_i$ event does not occur. Therefore, statement $\langle$F5$\rangle$ in the design caused the $\texttt{Send}_i^{1 \leftarrow i}[Disc_i]$ event at τ. Namely, while $done_i = FALSE$, a $TICK_i$ event occurs where for some $l > i$ and $t < time_i - 3(l-i)$ holds $i \geq A_l(t) \neq \perp$ and $(\forall [j', l'] \in AckSet_i)(A_l(t) < j' \vee l' < l)$.

The proof is based on considering the state of $i+1$ at $\tau - D$. From Lemma 1, if $done_{i+1}$ is $TRUE$ at $\tau - D$, then $done_i$ is $TRUE$ at $\tau - D + \delta < \tau$. Assume, therefore, that $done_{i+1} = FALSE$ at $\tau - D$. From Axiom 2, a $TICK_i$ event occurred at $\tau - D$ with $time_i$ less by one than at τ; namely, at time $\tau - D$ the following holds: $time_i = t + 3(l-i)$. (Recall that t, l, i are integers.) From Lemma 2, the maximum value of $time_i - time_{i+1}$ until $\tau - D$ is 2 (since $done_{i+1}$ is $FALSE$). Hence, the $TICK_{i+1}$ event in which $time_{i+1} \leftarrow t + 1 + 3(l - (i+1))$ is before $\tau - D$. Denote the time of this $TICK_{i+1}$ event by τ'. We derive a contradiction from considering the state of $i+1$ at τ'. Consider the two cases: $l > i+1$ and $l = i+1$.

We first deal with the case $l > i+1$, i.e., processor $i+1$ failed to forward to i the Ack from l (to some $A_l(t) \leq i$) or to disconnect from $i+2$. At τ', since $done_{i+1}$ is $FALSE$, then $(\exists [j', l'] \in AckSet_{i+1})(j' \leq A_l(t) \leq i < l \leq l')$. (Otherwise, processor $i+1$ would have invoked statement $\langle$F5$\rangle$.) An interval $[j', l']$ is added to $AckSet_{i+1}$ only by one of statements $\langle$F4$\rangle$, $\langle$D5$\rangle$, or $\langle$E4$\rangle$. Since $j' < i+1$, exactly before any of these statements is executed, a $\texttt{Send}_{i+1}^{j' \leftarrow l'}[Ack]$ occurs (see Figure 2). Hence, at (or before) $\tau - D$ a $\texttt{Send}_{i+1}^{j' \leftarrow l'}[Ack]$ occurs with $j' \leq A_l(t) < l \leq l'$. From this follows, using Lemma 3, that at τ there must be some $[x', y'] \in AckSet_i$ such that $x' \leq j' < l' \leq y'$. This contradicts the assumption that statement $\langle$F5$\rangle$ was invoked at τ.

We now deal with the case $l = i+1$. First, assume $t = 0$. Namely, $\texttt{Send}_{i+1}^{j \leftarrow i+1}[Ack]$ occurs when $i+1$ starts operating, i.e., at most δ after i starts operating. Hence, from Lemma 3, there will be some $[j', l'] \in AckSet_i$ such that $j' \leq j$ and $i+1 \leq l'$, after at most an additional δ (i.e., 2δ since i started). From Axiom 2 and the design, the value of $time_i$ at 2δ since i started is at most 2. Hence, when $time_i > 3$ statement $\langle$F5$\rangle$ is not invoked by i with $l = i+1$ and $t = 0$.

Assume, therefore, that $t > 0$ and $l = i+1$. Recall that $done_{i+1} = FALSE$ at τ'. Processor $i+1$ checks, at τ', the condition of statement $\langle$F3$\rangle$. If the condition holds, then statement $\langle$F4$\rangle$ is executed, i.e., a $\texttt{Send}_{i+1}^{j \leftarrow i+1}[Ack]$ occurs at τ', and the contradiction again follows from Lemma 3.

Assume that the condition of $\langle$F3$\rangle$ does not hold, namely, $(\exists [j', l'] \in AckSet_{i+1})$ $j' \leq j$. Then, previously one of statements $\langle$F4$\rangle$, $\langle$D5$\rangle$, or $\langle$E4$\rangle$ was executed, adding $[j', l']$ to $AckSet_{i+1}$. Since $j' < i+1$, exactly before any of these statements is executed, a $\texttt{Send}_{i+1}^{j' \leftarrow l'}[Ack]$ occurred (see Figure 2). Hence, at or before τ', a $\texttt{Send}_{i+1}^{j' \leftarrow l'}[Ack]$ occurs with $j' \leq j$. The contradiction follows from Lemma 3. □

We now complete the proof that every implementation of the design, which satisfies a simple condition, is a resilient forwarding faults detector.

THEOREM 5. *Every implementation* $A()$ *of the design such that* $A_n(0) = 1$ *is a resilient forwarding faults detector.*

Proof. The safety property follows immediately from the design and Axiom 1. To prove the detection property, consider an execution where no message is delivered,

and the source and destination are nonfaulty. Since the destination is nonfaulty and no message is delivered, there will be no $\texttt{Send}_n^{1\leftarrow n}[Ack]$ event. From Axiom 1, there will be no $\texttt{Receive}_1^{1\leftarrow n}[Ack]$ event. We assumed that $A_n(0) = 1$. Hence, after $time_1 = 3(n-1)$, statement $\langle$F5$\rangle$ sets $done_1 \leftarrow TRUE$ (unless $done_1 = TRUE$ already). But since processor 1 did not accept Ack from n, when it sets $done_1 \leftarrow TRUE$ it also did $\texttt{Send}_1^{1\leftarrow 1}[Disc_j]$.

We now prove the location property. Consider an execution where $Disc_i$ is sent by a nonfaulty processor j, and i is nonfaulty. The only event in which j sends, according to the design, a $Disc_i$ message, is by a $\texttt{Send}_j^{1\leftarrow i}[Disc_i]$ event. From Figure 2, a nonfaulty processor $j \neq i$ sends $Disc_i$ only if a $\texttt{Receive}_j^{1\leftarrow i}[Disc_i]$ occurred. Since $j \neq i$, it follows from Axiom 1 that $j < i$ and that before the $\texttt{Send}_j^{1\leftarrow i}[Disc_i]$ event, a $\texttt{Send}_i^{1\leftarrow i}[Disc_i]$ event occurred. From Lemma 4, either $i+1$ or the link $(i, i+1)$ or both are faulty. □

Since both detectors of section 4 are implementations of the design with $A_n(0) = 1$, we conclude with the following corollary.

COROLLARY 6. *The end-to-end and the hop-by-hop detectors are both resilient forwarding faults detectors.*

5.2. A bound on time complexity. In this subsection, we show a bound on the time complexity of implementations of the design. This bound suffices to show that the implementations we present later, as well as the hop-by-hop detector, are early-terminating.

Let $T_A(n, f, \delta, D)$ (respectively, $T_{\text{opt}}(n, f, \delta, D)$) be the maximal time since an execution of implementation A starts (respectively, since an execution of a time-optimal implementation starts) and until the destination receives the message ϕ or an error is detected. We want a bound for the worst ratio $\frac{T_A(n,f,\delta,D)}{T_{\text{opt}}(n,f,\delta,D)}$ over every selection of n, f, δ, and D.

Obviously, we can bound T_A by the time required to reach from 1 to any processor i, plus the time required to reach from i to n. Likewise, we bound T_A by the sum of times required to reach from 1 to 2, from 2 to 3, and so on. Also, if some processor k between j and l is nonfaulty, then the time to reach from j to l is bounded by the time to reach from j to k plus the time to reach from k to l. Note that if every processor and link from j to l is nonfaulty, then it takes exactly $(l-j)\delta$ to reach from j to l. Therefore, we can bound the time complexity by regarding the worst ratio of the times required to reach from processor j to l when all of the processors between j and l are faulty.

The best time to reach from j to l is achieved if j expects l to acknowledge immediately; then the delay is $3D(l-j)$. The time of a specific implementation A is the minimal value of $3D(l'-j)+t$, where l' is a processor after l which sends at time t, according to A, an acknowledgment whose recipient is $j' \leq j$. We call this ratio the *covering factor* of the interval $[j, l]$.

DEFINITION 2. *Let j, l be processors such that $1 \leq j < l \leq n$. The covering factor of $[j, l]$ with respect to $A_i(t)$ is denoted $F_{[j,l]}(A())$ and defined as follows:*

$$F_{[j,l]}(A()) \stackrel{\text{def}}{=} \min_{t',j',l'} \left\{ \frac{(3(l'-j)+t') | (A_{l'}(t') = j') \wedge (j' \leq j < l \leq l')}{3(l-j)} \right\}. \tag{1}$$

Note that $A_i(t)$ is a set of intervals. The covering factor $F_{[j,l]}(C)$ for any set of intervals C (called a *cover*) is defined similarly.

We now define the covering factor of an implementation, which is the worst covering factor of any interval.

DEFINITION 3. *The covering factor with respect to $A_i(t)$ is denoted $F(A())$ and is defined as follows:*

$$F(A()) \stackrel{\text{def}}{=} \max_{1 \le j < l \le n} F_{[j,l]}(A()). \tag{2}$$

The covering factor $F(C)$ for a cover C is defined in a similar way.

The covering factor of an implementation gives an upper bound on the time complexity of this implementation, as follows.

THEOREM 7. *The time complexity of every implementation $A()$ of the design is $O(n\delta + f \cdot F(A()) \cdot D)$.*

Proof. For simplicity, we ignore link failures, which may be emulated by corresponding processor failures. Also, we assume that the source accepted the message from the higher layer at time 0. Finally, we assume that the source and the destination are nonfaulty, since the time complexity is defined under this assumption. We use the following notations.

Notations. Let f_i be the number of faulty processors before processor i. Also, let τ_i denote the time when processor i received the message and entered the protocol, i.e., the time of $\texttt{Receive}_i^{1 \to n}[\phi]$.

We prove the following claim for every processor i: if i is nonfaulty, then before time $i\delta + 8D \cdot F(A()) \cdot f_i$ one of the following happens: either some nonfaulty processor sent $Disc_j$ for some j, or processor i received the message and entered the protocol. The theorem follows by considering $i = n$.

The claim is trivial for $i = 1$. We now prove the claim for processor i assuming that it holds for every processor before i. If processor i is faulty, then the claim holds trivially. If both processors i and $i-1$ are nonfaulty, then the claim holds since processor $i-1$ forwards the message to processor i immediately.

Assume, therefore, that processor i is nonfaulty, but processor $i-1$ is faulty. Let i' be the last nonfaulty processor before i, i.e., $i' < i$ and every processor in $[i'+1, i-1]$ is faulty. By the induction hypothesis, before time $i' \cdot \delta + 8D \cdot F(A()) \cdot f_{i'}$, either some nonfaulty processor sent $Disc_j$, for some j, or processor i' received the message. In the first case, where some nonfaulty processor sent $Disc_j$, the claim for i holds trivially.

Assume, hence, that processor i' received the message before $i' \cdot \delta + 8D \cdot F(A()) \cdot f_{i'}$. Denote by τ the time when the $1 + 3 \cdot (i - i') \cdot F(A())^{th}$ event of the kind $TICK_{i'}$ occurs since i' received the message. From Axiom 2, time τ is not more than $3 \cdot (i - i') \cdot F(A()) \cdot D + 2D$ time units since processor i' received the message, namely,

$$\tau \le i' \cdot \delta + 8D \cdot F(A()) \cdot f_{i'} + 3(i - i') \cdot F(A()) \cdot D + 2D.$$

Since $f_i = f_{i'} + (i - i' - 1)$ and $i' + 1 < i$, then

$$\tau < i \cdot \delta + 8D \cdot F(A()) \cdot f_i.$$

Hence, it suffices to show that at time τ, either processor i received the message or processor i' sent $Disc_j$ for some j. We now consider two cases, depending on the state of processor i' at τ. The first case we consider is that at time τ holds $done_{i'} = TRUE$; later we deal with the other case.

Since at τ holds $done_{i'} = TRUE$, then previously either statement $\langle$H2$\rangle$ of procedure DISCONNECT() or statement $\langle$E2$\rangle$ was executed at processor i'. If procedure

DISCONNECT() was executed, then $\texttt{Send}_{i'}^{1 \leftarrow i'}[Disc_{i'}]$ occurred already, and the claim for i follows. Similarly, if statement $\langle$H2$\rangle$ was executed, then $\texttt{Send}_{i'}^{1 \leftarrow j}[Disc_j]$ occurred already for some j, and the claim for i follows.

If statement $\langle$E2$\rangle$ was executed, then statement $\langle$E3$\rangle$ was also executed, since $j = 1 < i'$. Hence, $\texttt{Send}_{i'}^{1 \leftarrow n}[Ack]$ occurred. This happens only if i previously received the message, and then the claim for i follows.

Consider now the second case, where at time τ it holds that $done_{i'} = FALSE$. Hence, at τ processor i' executes $\langle$F2$\rangle$, after which $time_{i'} = 1 + 3 \cdot (i - i') \cdot F(A())$.

By Definition 3, $F(A()) \geq F_{[i',i]}(A())$. By Definition 2, there are l, t such that $A_l(t) \leq i'$ and $i \leq l$ and

$$F_{[i',i]}(A()) = \frac{3(l - i') + t}{3(i - i')}.$$

Hence, when processor i' executes $\langle$F5$\rangle$ at time τ, then

$$\begin{aligned} time_{i'} &= 1 + 3 \cdot (i - i') \cdot F(A()) \\ &> 3 \cdot (i - i') \cdot F_{[i',i]}(A()) \\ &= 3 \cdot (i - i') \cdot \frac{3 \cdot (l - i') + t}{3(i - i')} \\ &= 3 \cdot (l - i') + t. \end{aligned}$$

Hence, $t < time_{i'} - 3 \cdot (l - i')$ at time τ. Namely, at time τ, either $\texttt{Send}_{i'}^{j' \leftarrow l'}[Ack]$, $\texttt{Receive}_{i'}^{j' \leftarrow l'}[Ack]$ occurred with $j' \leq A_l(t) \leq i' < l \leq l'$, or processor i' executes procedure DISCONNECT() due to $\langle$F5$\rangle$. If processor i' executes procedure DISCONNECT(), then $\texttt{Send}_{i'}^{1 \leftarrow i'}[Disc_{i'}]$ occurs and the claim follows. On the other hand, from Axiom 1, if $\texttt{Receive}_{i'}^{j' \leftarrow l'}[Ack]$ occurred, then $\texttt{Send}_{i}^{j' \leftarrow l'}[Ack]$ occurred before, and this happens only after i entered the algorithm. □

We now observe that the optimal time complexity is bounded by $(n - f)\delta + fD$.

LEMMA 8. *Every forwarding faults detector has a run with time complexity at least* $(n - f)\delta + fD$.

Proof. Consider the execution where processors $2, \ldots, 2 + f - 1$ are faulty. The fault merely causes the delay upon forwarding the message through these processors to be D instead of δ. □

We deduce the following.

COROLLARY 9. *A detector that implements the design such that* $F(A())$ *is bounded by a constant is early-terminating. In particular, the hop-by-hop detector is early-terminating.*

Proof. The general claim follows from Theorem 7 and Lemma 8. The hop-by-hop detector has $A_l(t) = 1$. By definition, for every j, l, $F_{[j,l]}(A()) = 1$; hence, $F(A()) = 1$. The claim follows. □

6. Optimal time and communication-efficient implementations. In this section we present three implementations of the design, which ensure early termination (time complexity $O(n\delta + fD)$) and efficient ($O(n \log n)$ in the worst case) communication. Each implementation is a refinement of the previous one.

Throughout this section, we make the simplifying assumption that $n - 1$ is an even power of 2. This at most quadruples the complexities of the solutions, when applied to paths were $n - 1$ is not an even power of 2. In these cases, the source

processor may "play the rule" of a sufficient number of processors to extend n so that $n-1$ will become an even power of 2.

6.1. The immediate acknowledgments implementation. We begin by considering implementations where every acknowledgment is sent immediately upon receiving the message. For such an implementation $A()$, the covering factor of an interval $[j,l]$, as defined in (1), has the following simplified form:

$$F_{[j,l]}(A()) = \min_{j',l'} \left\{ \frac{l'-j \mid (A_{l'}(0) = j') \wedge (j' \le j < l \le l')}{l-j} \right\}. \tag{3}$$

We are interested in implementations which are early-terminating. From Corollary 9, such are the implementations where $F(A())$ is bounded by a constant. Namely, for every $[j,l]$ where $j < l$ there is some interval $[j',l']$ such that $A_{l'}(0) = j'$ and $j' \le j < l \le l'$ and $\frac{l'-j}{l-j}$ is bounded by a constant.

A natural selection of $A()$ is to send acknowledgments over intervals of lengths which are powers of two, i.e., $1, 2, 4, \ldots, (n-1)$. Let us describe the set of intervals used (see also a definition below). For every length $2^k \le (n-1)$ there are two types of intervals. Intervals of the first type start at every processor in a position of the form $r \cdot 2^k + 1$ for every r for which such a processor exists. For example, if $2^k = \frac{n-1}{2}$ one such interval starts at processor $2^k + 1$ (for $r = 1$) and the other starts at n. All acknowledgment intervals of length 2^k that start at a processor, i, end at processor $i - 2^k$. For example, the interval that starts at processor $2^k + 1$ ends at processor 1. Note, for example, that a subpath (of the message path) of length L such that $\frac{n}{4} < L < \frac{n}{2}$ is covered with a covering factor of less than 2 if and only if it is contained in one of the two acknowledgment intervals (described above) of length $\frac{n}{2}$. However, if it partially intersects with both, then only the end-to-end acknowledgment interval covers it. This effect becomes more damaging to the covering factor when we consider a shorter subpath.

To alleviate this effect, we introduce the second type of acknowledgment interval used. A subpath not covered (with a covering factor of 2 or less) by an interval of the first type will be covered (with a covering factor of 4 or less) by an interval of the second type. The intervals of the second type (still of length 2^k) start at $(r+\frac{1}{2}) \cdot 2^k + 1$ for every $r > 0$ for which there is such a processor. For example, for $2^k = \frac{n-1}{2}$ there is only one interval of the second type, and it starts at $\frac{3}{4}(n-1)+1$. The acknowledgment intervals which are "shifted," and start at $(r+\frac{1}{2}) \cdot 2^k + 1$, are needed to cover intervals which span over the connection between the acknowledgment intervals of the first kind, e.g., intervals which include processor $\frac{n-1}{2}+1$. This selection of acknowledgment intervals ensures that every interval $[j,l]$ is covered by an acknowledgment interval which is not "much larger," as we now formalize.

We specify this implementation in (4). We now prove that $F(A())$ is bounded by a constant, and hence that it is early-terminating.

$$A_i^{(1)}(0) \stackrel{\text{def}}{=} i - \max_{k \ge 0} \left\{ 2^k \,\middle|\, (\exists r \in \mathbb{N}) \left((i = 2^k \cdot r + 1) \text{ or } \left(i = 2^k \cdot \left(r + \frac{1}{2} \right) + 1 \right) \right) \right\}. \tag{4}$$

(No acknowledgment interval is defined for the case that $t > 0$.)

LEMMA 10. *The implementation $A^{(1)}()$ is early-terminating.*

Proof. From Corollary 9, it suffices to show that $F(A^{(1)}())$ is bounded by a constant. The proof is by showing that every interval $[j,l]$ is "covered" by an interval in $A^{(1)}()$ whose length is at most four times $l - j + 1$.

Consider an interval $[j,l]$ such that $1 \leq j < l \leq n$. Without loss of generality, assume that $l - j < \frac{n-1}{4}$. Let k be the minimal such that $l - j < \frac{2^k}{4}$, i.e., $k \stackrel{\text{def}}{=} \lceil \log_2(4 \cdot (l - j + 1)) \rceil$. Let r be the minimal such that $l < 2^k \cdot r + 1$. Namely, $2^k \cdot (r-1) + 1 \leq l$.

If $2^k \cdot (r-1) + 1 < j$, then $[j,l]$ is covered by the acknowledgment interval $[A^{(1)}_{2^k \cdot r+1}(0),\ 2^k \cdot r + 1]$. From (3), $F_{[j,l]}(A^{(1)}()) \leq 4$.

Assume, therefore, that $j \leq 2^k \cdot (r-1) + 1$. In this case, $2^k \cdot (r - \frac{3}{2}) + 1 < j \leq l < 2^k \cdot (r - \frac{1}{2}) + 1$, since $l - j < 2^{k-2}$ and $2^k \cdot (r-1) + 1 \leq l$. Again, from (3), $[j,l]$ is covered by the acknowledgment interval whose last processor is $2^k \cdot (r - \frac{1}{2}) + 1$. Hence, again $F_{[j,l]}(A^{(1)}()) \leq 4$. □

To complete the analysis of this implementation, we note that the communication complexity is obviously the total length of the intervals, which is $O(n \log(n))$.

6.2. A tight lower bound for oblivious protocols. We consider protocols whose operations include forwarding the message, computing, using time-outs, and sending acknowledgments. It is natural to classify such protocols by the way they handle the acknowledgments. An important subset, termed *oblivious protocols*, sends any acknowledgments they wish to send immediately, without delaying it. Similarly, if they receive an acknowledgment to be forwarded, they forward it immediately. All the previously published protocols, as well as all the protocols up to this point in this paper, are oblivious. In the design, this family of protocols is captured by having $A_i(t) = 0$ for every $t \neq 0$.

THEOREM 11. *An oblivious protocol is time-optimal if and only if $F(A())$ is a constant in it.*

Proof. The "if" part follows from Corollary 9. For the "only if" part, consider an oblivious protocol for which $F(A())$ is some $f(n)$. (Notice that for an oblivious protocol $F(A())$ does not depend on t.) Let j, l be two processors such that $F_{[j,l]}(A()) = f(n)$ (see Definitions 2 and 3) and let l' be the one mentioned in Definition 2. Consider the case that all the processors in the closed interval $[j,l]$ are faulty, but no other processor is faulty. Consider the state of knowledge (see, e.g., [HM90]) of processor j' at any time before $(l' - j)D$. Clearly there is a run where it did not receive any message from a nonfaulty processor $p > l$. Thus, the state of knowledge of processor j at such a time is the same as in the case that all the processors in the interval $[j,l']$ are faulty. The theorem now follows from Lemma 8. □

We now prove that the set of intervals used by the previous implementation is optimal in the sum of the lengths of the intervals. Note that this sum determines the message complexity of the protocol. Let an *interval* $c = [i,j]$ for $1 \leq i < j \leq n$ be the set $\{i, i+1, \ldots, j\}$. The *length* of interval c, denoted $L(c)$, is $j - i$. An *interval cover* C of an interval $[1,n]$ is a set of intervals that includes interval $[1,n]$.

The claim is that for an interval cover C, if $F(C)$ is a constant, then $L(C) = \Theta(n \log n)$, where $L(C) = \sum_{c \in C} L(c)$.

Intuitively, to cover long intervals, the cover must contain some long intervals. In fact, a few long intervals in the cover suffices to cover every long interval. The main observation in the proof is that a long interval cannot cover too many short intervals. Thus, additional intervals must be introduced into the cover. These intervals may be short and thus, it may seem that the contribution of each of them to $L(C)$ is small. However, many short intervals are needed in the cover to cover all the short intervals. Thus, the total contribution of the short intervals to $L(C)$ is large.

THEOREM 12. *For every interval cover C such that $F(C)$ is a constant, the total*

length $L(C)$ is $\Omega(n \log n)$.

Proof. Without loss of generality, assume $(\exists k)n - 1 = 2(F(C))^k$. (Otherwise, prove for $n' > n$ for which there exists such k; this adds only a constant factor.)

Let I_x be the set of intervals of path $[n, 1]$ that contain (each) exactly x links. The key observation is that any single interval in C (even a very long one) can cover at most $(F(C)-1)x+1 \leq (F(C)-1)x+x \leq F(C)x$ intervals in I_x with covering factor of $F(C)$. Consider the sets $I_{x(i)}$, where $x(i) = \frac{n-1}{2F(C)^{i+1}}$ for $1 \leq i \leq -1 + \log_{F(C)}(\frac{n-1}{2})$. Clearly $|I_{x(i)}| \geq \frac{n-1}{2}$. Thus, the observation implies that C must contain at least $\frac{|I_{x(i)}|}{F(C)x(i)} \geq \frac{(n-1)2F(C)^{i+1}}{2(n-1)F(C)} \geq F(C)^i$ intervals, the length of each at least $\frac{n-1}{2F(C)^{i+1}}$.

We now partition C into sets of intervals and give a lower bound for the total sum of each set. The sum of these bounds will later give us a lower bound for the total sum of C. Let $C_0 \subset C$ include the interval $[n, 1]$. For $i = 1$ we have that $x(i) = \frac{n-1}{2F(C)^2}$. To cover $I_{x(1)}$ cover C must include $F(C)$ intervals, the length of each is at least $x(1) = \frac{n-1}{2F(C)^2}$. One of them can be the $[n, 1]$ interval, but additional $F(C) - 1$ intervals are needed. Let $C_1 \subset C$ be a set of such additional intervals. Note that $C_1 \cap C_0 = \emptyset$. The total sum of C_1 is at least $\frac{(F(C)-1)(n-1)}{2F(C)^2}$. We continue to construct the C_i's inductively. For intervals in $I_{x(i)}$, C must include at least $F(C)^i$, where the length of each is at least $\frac{n-1}{2F(C)^{i+1}}$. As before, $F(C)^{i-1}$ such intervals are already included in the sets $C_0, C_1, C_2, \ldots, C_{i-1}$. Thus, we can construct a set $C_i \subset C$ such that $\forall_{1 \leq j < i} C_i \cap C_j = \emptyset$ and the cardinality of C_i is $F(C)^i - F(C)^{i-1}$. Thus, the total sum of C_i is at least $\frac{F(C)^{i-1}(F(C)-1)(n-1)}{2F(C)^{i+1}} = \frac{(n-1)(F(C)-1)}{2F(C)^2}$. Since we can construct $r(\log_{F(C)} n)$ such disjointed sets, the total length of C is $\Omega(\frac{n}{F(C)} \log_{F(C)} n)$. Since $F(C)$ is a constant, the theorem follows. □

6.3. The ideas behind the adaptive implementations. The immediate-Ack implementation sends $r(n \log n)$ messages even in executions where there are no faults ($f = 0$) and δ is small. We next present implementations of the design which are early-terminating but use less messages when f and δ are small. The worst-case communication complexity remains $O(n \log n)$.

Recall that in the design (Figure 2), processor i does not forward an *Ack* from processor l to processor j if this *Ack* is redundant, namely, if i already forwarded an *Ack* from some $l' \geq l$ to some $j' \leq j$. However, in the immediate-Ack implementation, each processor sends its acknowledgments upon beginning execution. Therefore, the immediate-Ack implementation of the design sends all of its acknowledgments in every execution (without failures).

However, if some of the processors *delay* issuing their acknowledgments, then it is possible that a delayed acknowledgment will become "redundant." For example, suppose that each of the processors delay all their acknowledgments by D except for the destination. If *Ack* from the destination n reaches the source 1 before D since the source started the protocol, then all of the other acknowledgments become redundant.

Obviously, the delay until the acknowledgments are sent increases the maximal time until the protocol terminates. For example, if the processors i s.t. $1 < i < n$ delay their acknowledgments by $2Dn$, then the resulting implementation has the same time complexity, up to a constant, as the end-to-end fault detector.

The decrease in message complexity comes, therefore, at the cost of an increase in the time complexity. The implementations presented in this section are early-terminating, since the delay is bounded by twice the time required for the immediate-Ack implementation. In fact, the adaptive implementations, presented in the rest of

this section, are modifications of the immediate-Ack implementation.

The first adaptive implementation saves messages mainly if there are no faulty processors. The number of acknowledgments sent is a function of the time complexity, which is lowest when there are no faults. The second adaptive implementation saves messages when there are faulty processors. In the following subsections we explain each of these implementations and analyze their properties.

6.4. Send *Ack* only when really needed. The first idea is to wait, as long as possible, before sending intermediate acknowledgments (i.e., *Ack* from $l < n$ to $j \geq 1$). The longer the delay in sending an intermediate acknowledgment, the larger the hope that the acknowledgment from n to 1 will make the intermediate acknowledgment redundant. In this subsection, we study how much any specific processor can wait without increasing the time complexity "too much." By implementing the idea of this subsection, the communication complexity is reduced to $O(n \log(1 + \frac{n\delta}{D}))$ if $f = 0$. In the next subsection, we show how to keep the communication complexity low, even when $f > 0$.

To demonstrate the idea, let us first investigate the case that there is exactly one faulty processor i (although the algorithm must still be early-terminating for any number of faults). Early termination is assured in the immediate-Ack implementation since i is covered by the interval $[i-1,\ i+1]$ of length two in $A^{(1)}()$. Note that an *Ack* from $i+1$ to $i-1$ is allowed to take at least D times if i is faulty. (Recall also that time complexity in the presence of one fault is $\Omega(D)$.) Hence, if $i+1$ waits D times before sending the *Ack*, it at most doubles the protocol's time complexity in executions with one fault. In executions with no faults, no acknowledgment is needed (although acknowledgments must be sent, since the number of faults is not known). Thus, a delay in any acknowledgment does not increase the time complexity in such executions. Finally, in executions with more than one fault, the acknowledgments over intervals of length 2 do not help, so any delay in them cannot increase the time complexity.

The adaptive detector sends the acknowledgments of the intervals of length 2 of $A^{(1)}()$, but only after waiting $O(D)$ for *Ack* from n. Early termination is always obtained, as explained above. However, in executions with exactly one fault (and a small δ), this achieves both early termination and optimal message complexities. The optimal message complexity is achieved, in this case, since the acknowledgment from processor n arrives at every other processor before it sends any acknowledgment of its own. Thus, all the other acknowledgments become redundant and are not sent.

In general, if there are at most f faults, then the time complexity with f faulty processors is at least $O(f \cdot D)$. Hence, the adaptive implementation delays sending the acknowledgments of intervals of length f by $f \cdot D$.

We now formally present the implementation of this subsection. It is easy to see that the covering factor is bounded by a constant. Hence, by Corollary 9, the implementation is early-terminating; we later show this formally. For simplicity, we assume that $n-1$ is an even power of 2. For $1 < i \leq n$ and $0 \leq t < n-1$, define $A_i^{(2)}(t)$ as follows:

$$A_i^{(2)}(t) \stackrel{\text{def}}{=} \begin{cases} 1 & \text{if } i = n, \\ i - t & \text{if } (\exists k) t = 2^k \wedge (\exists r \in \mathbb{N})\ i = rt + 1, \\ i - t & \text{if } (\exists k) t = 2^k \wedge (\exists r \in \mathbb{N})\ i = (r + \frac{1}{2})t + 1, \\ \perp & \text{otherwise.} \end{cases} \tag{5}$$

The implementation of this subsection achieves communication complexity $O(n \log(\frac{n\delta}{D}))$ if $f = 0$. We do not prove this here, since it is a corollary of a theorem presented in what follows.

6.5. Saving acknowledgments. In this section, we improve the previous implementation to save messages in a particular bad scenario. This improves the worst-case message complexity for $f > 0$.

Recall that acknowledgments are sent (in the previous implementation) at times $2^k \cdot D$ for $k = 0, 1, 2, \ldots$. At first glance, this seems to imply that the communication complexity is $O(n)$ times the logarithm of the time complexity divided by D, i.e., $O(n \log(f + \frac{n\delta}{D}))$. However, there is a bad scenario in which the complexity is $\Omega(nf)$. Indeed, in this scenario, the number of acknowledgments sending (and forwarding) events until the message is delivered at processor n (at time that is $O(fD)$) is just $O(n \log f)$. However, additional acknowledgments are sent *after* the message is delivered.

Put differently, what we did prove (regarding time complexity) is that if there are f faults, then the message must be delivered at node n at time that is $O(fD)$ (if δ is small). However, we did not prove that the acknowledgment from n to 1 is delivered in such a time. In fact, for the implementation of the previous subsection, one can show a case where for $f = O(\log n)$ faults the time for delivering n's acknowledgment in that implementation is $\Omega(2^f D)$. The way the time complexity is defined (only until the delivery of the message, or the disconnection of a link), we do not care about the time it takes the acknowledgment to arrive after the message is delivered. Still, this increases the message complexity of the previous implementation, since its message complexity is, actually, in the order of n multiplied by the logarithm of the time until all protocol-related communication ceases. The improvement of the message complexity in this section is obtained by shortening that ceasing time.

Let us demonstrate a bad scenario. Assume that processor $n-1$ is faulty; more specifically, assume that a message over any link of processor $n-1$ is delivered exactly after D time (rather than after δ time). Processor $n-2$ expects (and receives) an Ack from n within $4D$ time after $n-2$ forwarded the message to $n-1$. By that time, processor $n-2$ already sent a length 2 interval acknowledgment to $n-4$. Thus, the next acknowledgment that $n-4$ is waiting for is a length 4 interval acknowledgment, expected to arrive after a time that is double that of the length 2 acknowledgment.

Carrying this argument further, when a length 2^i interval acknowledgment Ack_i arrives at its destination, j, the next acknowledgment expected by processor $j-1$ is a length 2^{i+1} interval acknowledgment Ack_{i+1}, that is expected in double the time. Even if both Ack_i and Ack_{i+1} arrive at j at the same time, processor j can delay Ack_{i+1} without $j-1$ noticing a fault and disconnecting the link. Let f_j be the number of faults in the interval $[j, n]$. The state of knowledge of $j-1$ at this point is the same as in the case that the number of faults is 2^{f_j}. Thus, the length $n-1$ interval acknowledgment from n to 1 (i.e., the end-to-end acknowledgment) can also be delayed 2^{f_j} without causing $j-1$ to detect the fault.

Let us now describe the improvement to the previous implementation. The idea is to send (a few) other acknowledgments for "long" intervals. Acknowledgments sent quickly over "long" intervals which do not contain faults will reach every processor in the interval quickly. Therefore, many "short" acknowledgments whose intervals are contained in the "long" interval will become redundant, and therefore, these "short" acknowledgments will not be sent.

A natural selection is the set of intervals whose length is $\sqrt{n-1}$. Let us comment that using *only* this set, without using the shorter acknowledgments, we could obtain $O(n\delta + f\sqrt{n}D)$ time with $O(n)$ communication, which is a communication optimal but time suboptimal solution. However, to achieve time-optimality, we do combine this set with the "short" intervals.

Furthermore, as we now explain, we need also to send "quickly" acknowledgments over "long" intervals, i.e., intervals whose length is *more* than $\sqrt{n-1}$. By sending acknowledgments over the intervals of length $\sqrt{n-1}$ immediately upon forwarding the message, we prevent scenarios as described above for intervals whose length is less than $\sqrt{n-1}$, except for the few intervals of length $\sqrt{n-1}$ which contain faulty processors. However, we still have to deal with the intervals whose length is more than $\sqrt{n-1}$.

Recall that the "short acks," as defined in (5), are sent in order of increasing length. Namely, the *Ack* of interval of length l is sent after lD. The "long acks" are acknowledgments sent in the *reverse order*, from the longest to the shortest. Namely, the "long ack" of interval of length $\frac{n-1}{l}$ is sent after lD. (The length of the intervals divide $n-1$.) The reason the "long" intervals are sent in this order is similar to the idea behind the intervals of length $\sqrt{n-1}$: a single successful longer interval may make many *relatively* shorter intervals redundant. Note that the intervals which we want to become redundant as a result of the "long" intervals are not really short; their lengths are *more* than $\sqrt{n-1}$.

Formally, the implementation of this subsection is presented in (6) below. For simplicity, we assume that $n-1$ is an even power of 2. For $1 < i \leq n$ and $0 \leq t < n-1$ define $A_i^{(3)}(t)$ as follows:

$$
(6) \qquad A_i^{(3)}(t) \stackrel{\text{def}}{=} \begin{cases} 1 & \text{if } i = n, \\ i - \sqrt{n-1} & \text{if } (\exists r \in \mathbb{N}) i = r\sqrt{n-1} + 1, \\ i - \sqrt{n-1} & \text{if } (\exists r \in \mathbb{N}) i = (r + \frac{1}{2})\sqrt{n-1} + 1, \\ i - \frac{n-1}{t} & \text{if } (\exists k) t = 2^k \wedge (\exists r \in \mathbb{N}) i = r\frac{n-1}{t} + 1, \\ i - \frac{n-1}{t} & \text{if } (\exists k) t = 2^k \wedge (\exists r \in \mathbb{N}) i = (r + \frac{1}{2})\frac{n-1}{t} + 1, \\ i - t & \text{if } (\exists k) t = 2^k \wedge (\exists r \in \mathbb{N}) i = rt + 1, \\ i - t & \text{if } (\exists k) t = 2^k \wedge (\exists r \in \mathbb{N}) i = (r + \frac{1}{2})t + 1, \\ \perp & \text{otherwise.} \end{cases}
$$

Note that the first, sixth, and seventh lines correspond to acknowledgments that are sent also by the previous implementation. We term the acknowledgments defined in the sixth and seventh lines "short" acknowledgments. The new acknowledgments defined in the fourth and fifth lines are termed "long" acknowledgments. The new acknowledgments defined in the second and third lines are termed "medium" acknowledgments.

Intuitively, this helps since "long" intervals which contain no faulty processors are "almost unaffected" by the faults "outside." For example, if all the processors from 1 till $(\sqrt{n-1}+1)$ are nonfaulty, they send only $O(n \log(\frac{n\delta}{D}))$ messages.

6.6. Complexities of the adaptive implementations. We begin by showing that the time complexity has not deteriorated significantly.

LEMMA 13. *The implementations $A^{(2)}()$ and $A^{(3)}()$ are early-terminating.*

Proof. We state the proof for $A^{(3)}()$, but all of our arguments hold for $A^{(2)}()$ as well. From Corollary 9, it is sufficient to bound $F(A^{(3)}())$ by a constant. We use the similarity between $A^{(3)}()$ and $A^{(1)}()$.

From Lemma 10 we know that $F(A^{(1)}())$ is bounded by a constant. For every j, l such that $1 \leq j < l \leq n$, we show that $F_{[j,l]}(A^{(3)}()) \leq \frac{1}{3} + F_{[j,l]}(A^{(1)}())$. Let j', l' be such that $j' \leq j < l \leq l'$ and $A^{(1)}_{l'}(0) = j'$ and $[j', l']$ is the "best cover" of $[j, l]$ in $A^{(3)}()$, namely,

$$F_{[j,l]}(A^{(1)}()) = \frac{l' - j}{l - j}.$$

By the definition of $A^{(3)}()$ there is some $t' \leq (l - j)$, such that $A^{(3)}_{l'}(t') = j'$. Hence,

$$\begin{aligned} F_{[j,l]}(A^{(3)}()) &\leq \frac{3(l' - j) + t'}{3(l - j)} \\ &\leq \frac{3(l' - j) + (l - j)}{3(l - j)} \\ &\leq \frac{1}{3} + \frac{3(l' - j)}{3(l - j)} \\ &\leq \frac{1}{3} + F_{[j,l]}(A^{(1)}()), \end{aligned}$$

which completes the proof. □

We now turn to the proof of the communication complexity. We begin by showing a simple necessary condition for sending a particular "short acknowledgment."

LEMMA 14. *Let j, i be processors such that $0 < i - j < \frac{\sqrt{n-1}}{2}$. If $\texttt{Send}_i^{j \leftarrow i}[Ack]$ occurs, then either there is a faulty processor in $[i, i + \sqrt{n-1}\,]$ or in $i - j \leq \sqrt{n-1} \cdot \frac{2\delta}{D}$.*

Proof. Since $i - j < \frac{\sqrt{n-1}}{2}$ and from (6), there is some processor l such that $A^{(3)}_l(0) \neq \perp$ and $l - A^{(3)}_l(0) = \sqrt{n-1}$ and $A^{(3)}_l(0) \leq j < i \leq l$. If there is a faulty processor in $[i, l]$, then the claim holds. Assume, therefore, that there is no faulty processor in $[i, l]$.

Since every nonfaulty processor forwards the message and the acknowledgments immediately, then $\texttt{Receive}_i^{A^{(3)}_l(0) \leftarrow l}[Ack]$ occurs not later than $2\sqrt{n-1} \cdot \delta$ after processor i entered the protocol. From the second condition of ⟨F3⟩, processor i does not issue the acknowledgment to j after $\texttt{Receive}_i^{A^{(3)}_l(0) \leftarrow l}[Ack]$. Hence, $\texttt{Send}_i^{j \leftarrow i}[Ack]$ may occur only before $\texttt{Receive}_i^{A^{(3)}_l(0) \leftarrow l}[Ack]$ occurs, i.e., before $2\sqrt{n-1} \cdot \delta$ since processor i started.

On the other hand, from (6) and since $i - j < \frac{\sqrt{n-1}}{2}$, then $\texttt{Send}_i^{j \leftarrow i}[Ack]$ occurs only when $time_i > i - j$. From ⟨F2⟩ and Axiom 2 holds $i - j < time_i$ only after at least $(i - j) \cdot D$ since processor i started. Hence, $\texttt{Send}_i^{j \leftarrow i}[Ack]$ occurs only if $(i - j) \cdot D \leq 2 \cdot \sqrt{n-1} \cdot \delta$. □

Lemma 14 shows that a "short acknowledgment" is issued only if it is one of the very short ones which are required since δ is not negligible, or if it is "close" to a faulty processor. We now bound the maximal number of "short" acknowledgments issued due to "close" faulty processors.

LEMMA 15. *For every k such that $\sqrt{n-1} \cdot \frac{2\delta}{D} < 2^k < \frac{\sqrt{n-1}}{2}$, there are at most $f \cdot 2 \cdot \frac{\sqrt{n-1}+1}{2^k}$ events of type $\texttt{Send}_i^{(i-2^k) \leftarrow i}[Ack]$.*

Proof. From Lemma 14, if $\texttt{Send}_i^{(i-2^k)\leftarrow i}[Ack]$ occurs as specified, then there is a faulty processor in $[i, i+\sqrt{n-1}\,]$. From (6), for some integer r either $i = r2^k + 1$ or $i = (r+\frac{1}{2})2^k + 1$ holds. Hence, for every faulty processor l, there are at most $2 \cdot \frac{\sqrt{n-1}+1}{2^k}$ intervals $[i-2^k, i]$ such that $l \in [i, i+\sqrt{n-1}\,]$. ∎

Lemma 15 bounds the communication due to acknowledgment intervals shorter than $\frac{\sqrt{n-1}}{2}$. In order to bound the entire communication complexity, we have to consider also longer acknowledgment intervals. We begin by bounding the maximal number of intervals either containing, or "near to," faulty processors.

LEMMA 16. *For every $k \in \mathbb{N}$, there are at most $5 \cdot f$ processors i such that for some t holds $A_i^{(3)}(t) = i - 2^k$ and the interval $[i-2^k, i+2^k]$ contains a faulty processor.*

Proof. From (6), and since we assumed that $\sqrt{n-1}$ is a power of 2, it follows that if $A_i^{(3)}(t) = i - 2^k$, then $(\exists r \in \mathbb{N})(i = r \cdot 2^k + 1) \vee (i = (r+\frac{1}{2}) \cdot 2^k + 1)$. Hence, for any faulty processor l, there are at most five processors i such that $A_i^{(3)}(t) = i - 2^k$ and $l \in [i-2^k,\, i+2^k]$. ∎

All that remains is to bound the communication in "long" intervals that do *not* contain, and are not near, a faulty processor.

LEMMA 17. *Consider k such that $\sqrt{n-1} < 2^k$. If $\texttt{Send}_i^{(i-2^k)\leftarrow i}[Ack]$ occurs, then either there is a faulty processor in $[i, i+2^k]$ or in $2^k > \sqrt{\frac{D\cdot(n-1)}{8\cdot\delta}}$.*

Proof. Assume that $\texttt{Send}_i^{(i-2^k)\leftarrow i}[Ack]$ occurs. Since $\sqrt{n-1} < 2^k$, from subsection 6.4 we know that processor $i+2^k$ is to send an acknowledgment over an interval of length 2^{k+1} (if $2^{k+1} \le n-1$). That is,

$$A_{i+2^k}^{(3)}\left(\frac{n-1}{2^{k+1}}\right) = (i+2^k) - 2^{k+1} = i - 2^k.$$

Assume that there is no faulty processor in $[i, i+2^k]$. Every nonfaulty processor forwards the message immediately. Hence, processor $i+2^k$ receives the message and starts executing at most $2^k \cdot \delta$ after processor i started executing. After at most $\frac{n-1}{2^{k+1}}\, TICK_{i+2^k}$ events, processor $i+2^k$ either sends its own length 2^{k+1} interval acknowledgment, or this acknowledgment is already redundant since it already performed some other $\texttt{Send}_{i+2^k}^{j\leftarrow l}[Ack]$ such that $j \le i-2^k < i < i+2^k \le l$. From Axiom 2, this occurs after at most $(\frac{n-1}{2^{k+1}}+1) \cdot D$ since processor $i+2^k$ started. Since every processor in $[i, i+2^k]$ is nonfaulty, it follows that $\texttt{Receive}_i^{j'\leftarrow l'}[Ack]$ occurs at most $2^k \cdot \delta$ after $\texttt{Send}_{i+2^k}^{j\leftarrow l}[Ack]$ with $j' \le j < l \le l'$. Namely, $\texttt{Receive}_i^{j'\leftarrow l'}[Ack]$ occurs after at most $2 \cdot 2^k \cdot \delta + (\frac{n-1}{2^{k+1}}+1) \cdot D$ since processor i started.

From (6) and since $\sqrt{n-1} < 2^k$, it follows that $\texttt{Send}_i^{(i-2^k)\leftarrow i}[Ack]$ occurs only after $time_i \ge \frac{n-1}{2^k}$. From Axiom 2, this occurs at least $\frac{n-1}{2^k} \cdot D$ since processor i starts executing. However, $\texttt{Send}_i^{(i-2^k)\leftarrow i}[Ack]$ does not happen after $\texttt{Receive}_i^{j'\leftarrow l'}[Ack]$ where $j' \le i-2^k < i < l'$. Since we assumed that $\texttt{Send}_i^{(i-2^k)\leftarrow i}[Ack]$ does occur, it follows that

$$\frac{n-1}{2^k} \cdot D < 2 \cdot 2^k \cdot \delta + \left(\frac{n-1}{2^{k+1}} + 1\right) \cdot D$$

from which the claim follows. ∎

We now use Lemmas 14–17 to compute the communication complexity.

THEOREM 18. *The communication complexity of implementation* $A^{(3)}()$ *is* $O(n\log(f+\frac{n\delta}{D}))$.

Proof. It is immediate that the communication complexity due to the data message and to the disconnection messages is $O(n)$. Therefore, we consider only acknowledgments.

Let n_k be the number of $\texttt{Send}_i^{(i-2^k)\leftarrow i}[Ack]$ events during the execution. The communication complexity due to acknowledgments is at most

$$C_{Ack} \leq \sum_{k=0}^{\log(n-1)} n_k \cdot 2^k \tag{7}$$

directly from (6) and since $\sqrt{n-1}$ is a power of 2, $n_k \leq \frac{n-1}{2^k}\cdot 2$.

By substituting this bound for n_k in (7), we obtain

$$C_{Ack} = O(n\log(n)). \tag{8}$$

The rest of the proof is needed to refine this bound. Let us first outline the proof. Lemma 15 gives tighter bounds of n_k for $\frac{\sqrt{n-1}\cdot 2\delta}{D} < 2^k < \frac{\sqrt{n-1}}{2}$. Lemmas 16 and 17 give tighter bounds of n_k for $\sqrt{n-1} < 2^k \leq \sqrt{\frac{D\cdot(n-1)}{8\cdot\delta}}$. We combine these tighter bounds with the simple bound of $\frac{(n-1)\cdot 2}{2^k}$ for other values of k and obtain the desired bound on the communication complexity.

Directly, since $n_k \leq \frac{n-1}{2^k}\cdot 2$, i.e., $n_k \cdot 2^k \leq (n-1)\cdot 2$, it follows that

$$\sum_{k=0}^{\lceil\log\frac{\sqrt{n-1}\cdot 2\delta}{D}\rceil} n_k\cdot 2^k \leq \sum_{k=0}^{\lceil\log\frac{\sqrt{n-1}\cdot 2\delta}{D}\rceil} 2(n-1) = O\left(n\log\frac{n\delta}{D}\right), \tag{9}$$

$$\sum_{k=(\log\sqrt{n-1})-1}^{\log\sqrt{n-1}} n_k\cdot 2^k \leq \sum_{k=(\log\sqrt{n-1})-1}^{\log\sqrt{n-1}} 2(n-1) = O(n), \tag{10}$$

$$\begin{aligned}\sum_{k=\lceil\log\sqrt{\frac{D(n-1)}{8\delta}}\rceil}^{\log(n-1)} n_k\cdot 2^k &\leq \sum_{k=\lceil\log\sqrt{\frac{D(n-1)}{8\delta}}\rceil}^{\log(n-1)} 2(n-1)\\ &\leq 2(n-1)\cdot\log\sqrt{\frac{8\delta(n-1)}{D}} = O\left(n\log\frac{n\delta}{D}\right),\end{aligned} \tag{11}$$

$$\begin{aligned}\sum_{k=\lceil\log\frac{2(n-1)}{5f}\rceil}^{\log(n-1)} n_k\cdot 2^k &\leq \sum_{k=\lceil\log\frac{2(n-1)}{5f}\rceil}^{\log(n-1)} 2(n-1)\\ &\leq 2(n-1)\cdot\log\frac{5f}{2} = O(n\log(f)).\end{aligned} \tag{12}$$

From Lemmas 16 and 17, if $\sqrt{n-1} < 2^k \leq \sqrt{\frac{D\cdot(n-1)}{8\cdot\delta}}$, then $n_k \leq 5\cdot f$. Therefore, the following holds:

$$\sum_{k=1+\log\sqrt{n-1}}^{\lceil\log\sqrt{\frac{D\cdot(n-1)}{8\delta}}\rceil-1} n_k\cdot 2^k \leq \sum_{k=1+\log\sqrt{n-1}}^{\lceil\log\frac{2(n-1)}{5f}\rceil} 5f\cdot 2^k + \sum_{k\lceil\log\frac{2(n-1)}{5f}\rceil}^{\log(n-1)} n_k\cdot 2^k. \tag{13}$$

Obviously,

$$\sum_{k=1+\log\sqrt{n-1}}^{\lceil \log \frac{2(n-1)}{5f} \rceil} 5f \cdot 2^k \leq 5f \cdot \frac{2(n-1)}{5f} \cdot 2 = O(n). \tag{14}$$

From inequalities (12), (13), and (14), we obtain

$$\sum_{k=1+\log\sqrt{n-1}}^{\lceil \log \sqrt{\frac{D\cdot(n-1)}{8\delta}} \rceil - 1} n_k \cdot 2^k \leq O(n) + O(n\log(f)) = O(n\log(f)). \tag{15}$$

From Lemma 15, it follows that if $\frac{\sqrt{n-1}\cdot 2\delta}{D} < 2^k < \frac{\sqrt{n-1}}{2}$, then $n_k \leq 2f \cdot \frac{\sqrt{n-1}+1}{2^k}$. Hence,

$$\begin{aligned} \sum_{k=1+\lceil \log \frac{\sqrt{n-1}\cdot 2\delta}{D} \rceil}^{(\log\sqrt{n-1})-2} n_k \cdot 2^k &\leq \sum_{k=1+\lceil \log \frac{\sqrt{n-1}\cdot 2\delta}{D} \rceil}^{(\log\sqrt{n-1})-2} 2f \cdot \frac{\sqrt{n-1}+1}{2^k} \cdot 2^k \\ &= O(\sqrt{n} \cdot f \cdot \log(n)). \end{aligned} \tag{16}$$

From inequalities (7), (9), (10), (11), (15), and (16), we obtain

$$C_{Ack} \leq \sum_{k=0}^{\log(n-1)} n_k \cdot 2^k = O\left(n \log \frac{n\delta}{D}\right) + O(n\log(f)) + O(\sqrt{n} \cdot f \cdot \log(n)). \tag{17}$$

For $f \geq n^{\frac{1}{4}}$ the claim follows from (8), since $C_{Ack} = O(n \log n)$, and in this case $O(n\log(f)) = O(n\log(n))$. For the case that $f < n^{\frac{1}{4}}$ the claim follows from (17) since then $O(\sqrt{n} \cdot f \cdot \log(n)) \leq O(n)$. □

7. Conclusions. We have observed that the actual delivery time in asynchronous bounded networks is much shorter than the known bound on the delivery time. We introduced a way to model and take advantage of that fact and the notion of early termination for protocols in the asynchronous bounded network. Following [AADW94], we observed that early termination is a form of distributed competitiveness.

The protocols presented ensure early-terminating detection of arbitrary failures in forwarding a message along a fixed route. The protocols are quite simple and need only finite memory. The penalty in message complexity is acceptable for most applications. The message complexity is at most $O(n \log n)$, where n is the length of the path, compared to $O(n)$ for the trivial protocol which cannot overcome faults other than those detectable by the link protocol. The message complexity of our adaptive detector is $O(n \log(f + \frac{n\delta}{D}))$, where $\frac{\delta}{D}$ is the ratio between the actual delay and the a priori bound on the delay, and f is the number of faults. Since usually $\frac{\delta}{D} \ll 1$ and $f = 0$ (or $f = O(1)$), the communication complexity is nearly optimal. Theorems 5 and 7 may be used to achieve other trade-offs by different implementations of the design, some of which may be better in practical applications. For example, it is easy to keep the communication complexity optimal (i.e., $O(n)$) while still improving the time complexity from the $O(nD)$ of the trivial protocol to $(O(n\delta + \sqrt{n} \cdot f \cdot D))$.

Further work is needed to find the best communication complexity for early-terminating protocols, possibly generalizing our lower bound to hold for a general

protocol. Let us list some additional open problems: generalizing our results to networks and rings (rather than a path), considering probabilistic protocols, dealing with clock drifts, and efficient handling of many messages. Additional further work is needed in order to understand the implications of the model for other tasks and, possibly, to generalize the model further. As mentioned in the introduction, some of this further research has meanwhile already taken place.

Acknowledgments. Special thanks to Oded Goldreich and Adrian Segall, who supervised the work of the first author, for their encouragement and help in obtaining the results and improving the exposition.

It is a pleasure to thank Hagit Attiya, Baruch Awerbuch, Gil Barzilai, Tsipi Barzilai, Inder Gopal, Madan Gopal, George Grover, Radia Perlman, Ken Perry, and Moti Yung for helpful discussions and motivations for this work.

THE DENSITY OF WEAKLY COMPLETE PROBLEMS UNDER ADAPTIVE REDUCTIONS*

JACK H. LUTZ† AND YONG ZHAO‡

Abstract. Given a real number $\alpha < 1$, every language that is weakly $\leq^{\mathrm{P}}_{n^{\alpha/2}-\mathrm{T}}$-hard for E or weakly $\leq^{\mathrm{P}}_{n^{\alpha}-\mathrm{T}}$-hard for E_2 is shown to be exponentially dense. This simultaneously strengthens the results of Lutz and Mayordomo (1994) and Fu (1995).

Key words. complexity classes, computational complexity, resource-bounded measure, polynomial reductions, weakly complete problems

AMS subject classification. 68Q15

1. Introduction.

In the mid-1970s, Meyer [16] proved that every $\leq^{\mathrm{P}}_{\mathrm{m}}$-complete language for exponential time—in fact, every $\leq^{\mathrm{P}}_{\mathrm{m}}$-hard language for exponential time—is dense. That is,

$$\mathrm{E} \not\subseteq \mathrm{P}_{\mathrm{m}}(\mathrm{DENSE}^c), \tag{1.1}$$

where $\mathrm{E} = \mathrm{DTIME}(2^{\mathrm{linear}})$, DENSE is the class of all dense languages, DENSE^c is the complement of DENSE, and $\mathrm{P}_{\mathrm{m}}(\mathrm{DENSE}^c)$ is the class of all languages that are $\leq^{\mathrm{P}}_{\mathrm{m}}$-reducible to nondense languages. (A language $A \in \{0,1\}^*$ is *dense* if there is a real number $\epsilon > 0$ such that $|A_{\leq n}| > 2^{n^{\epsilon}}$ for all sufficiently large n, where $A_{\leq n} = A \cap \{0,1\}^{\leq n}$.) Since that time, a major objective of computational complexity theory has been to extend Meyer's result from $\leq^{\mathrm{P}}_{\mathrm{m}}$-reductions to $\leq^{\mathrm{P}}_{\mathrm{T}}$-reductions, i.e., to prove that every $\leq^{\mathrm{P}}_{\mathrm{T}}$-hard language for E is dense. That is, the objective is to prove that

$$\mathrm{E} \not\subseteq \mathrm{P}_{\mathrm{T}}(\mathrm{DENSE}^c), \tag{1.2}$$

where $\mathrm{P}_{\mathrm{T}}(\mathrm{DENSE}^c)$ is the class of all languages that are $\leq^{\mathrm{P}}_{\mathrm{T}}$-reducible to nondense languages. The importance of this objective derives largely from the fact (noted by Meyer [16]) that the class $\mathrm{P}_{\mathrm{T}}(\mathrm{DENSE}^c)$ contains all languages that have subexponential circuit-size complexity. (A language $A \subseteq \{0,1\}^*$ has *subexponential circuit-size complexity* if, for every real number $\epsilon > 0$ and for every sufficiently large n, there is an n-input, 1-output Boolean circuit that decides that the set $A_{=n} = A \cap \{0,1\}^n$ and has fewer than $2^{n^{\epsilon}}$ gates. Otherwise, we say that A has *exponential circuit-size complexity*.) Thus a proof of (1.2) would tell us that E contains languages with exponential circuit-size complexity, thereby answering a major open question concerning the relationship between (uniform) time complexity and (nonuniform) circuit-size complexity. Of course (1.2) also implies the more modest, but more famous, conjecture that

$$\mathrm{E} \not\subseteq \mathrm{P}_{\mathrm{T}}(\mathrm{SPARSE}), \tag{1.3}$$

where SPARSE is the class of all sparse languages. (A language $A \subseteq \{0,1\}^*$ is *sparse* if there is a polynomial $q(n)$ such that $|A_{\leq n}| \leq q(n)$ for all $n \in \mathbb{N}$.) As noted by Meyer [16], the class $\mathrm{P_T}(\mathrm{SPARSE})$ consists precisely of all languages that have polynomial circuit-size complexity, so (1.3) asserts that E contains languages that do not have polynomial circuit-size complexity.

Knowing (1.1) and wanting to prove (1.2), the natural strategy has been to prove results of the form

$$\mathrm{E} \not\subseteq \mathrm{P}_r(\mathrm{DENSE}^c)$$

for successively larger classes $\mathrm{P}_r(\mathrm{DENSE}^c)$ in the range

$$\mathrm{P_m}(\mathrm{DENSE}^c) \subseteq \mathrm{P}_r(\mathrm{DENSE}^c) \subseteq \mathrm{P_T}(\mathrm{DENSE}^c).$$

The first major step beyond (1.1) in this program was the proof by Watanabe [18] that

$$\mathrm{E} \not\subseteq \mathrm{P}_{O(\log n)-\mathrm{tt}}(\mathrm{DENSE}^c), \tag{1.4}$$

i.e., that every language that is $\leq^{\mathrm{P}}_{O(\log n)-\mathrm{tt}}$-hard for E is dense. The next big step was the proof by Lutz and Mayordomo [11] that, for every real number $\alpha < 1$,

$$\mathrm{E} \not\subseteq \mathrm{P}_{n^\alpha-\mathrm{tt}}(\mathrm{DENSE}^c). \tag{1.5}$$

This improved Watanabe's result from $O(\log n)$ truth-table (i.e., nonadaptive) queries to n^α such queries for α arbitrarily close to 1 (e.g., to $n^{0.99}$ truth-table queries). Moreover, Lutz and Mayordomo [11] proved (1.5) by first proving the stronger result that for all $\alpha < 1$,

$$\mu_{\mathrm{p}}(\mathrm{P}_{n^\alpha-\mathrm{tt}}(\mathrm{DENSE}^c)) = 0, \tag{1.6}$$

which implies that every language that is weakly $\leq^{\mathrm{P}}_{n^\alpha-\mathrm{tt}}$-hard for E or for $\mathrm{E_2} = \mathrm{DTIME}(2^{\mathrm{poly}})$ is dense. (A language A is *weakly* $\leq^{\mathrm{P}}_r$*-hard* for a complexity class $\mathcal{C}$ if $\mu(\mathrm{P}_r(A) \mid \mathcal{C}) \neq 0$, i.e., if $\mathrm{P}_r(A) \cap \mathcal{C}$ is a nonnegligible subset of $\mathcal{C}$ in the sense of the resource-bounded measure developed by Lutz [10]. A language A is *weakly* $\leq^{\mathrm{P}}_r$*-complete* for $\mathcal{C}$ if $A \in \mathcal{C}$ and A is weakly $\leq^{\mathrm{P}}_r$-hard for $\mathcal{C}$. See [13] or [2] for a survey of resource-bounded measure and weak completeness.) It is now known that the set of $\leq^{\mathrm{P}}_{n^\alpha-\mathrm{tt}}$-hard languages for $\mathrm{E_2}$ has measure 0 in $\mathrm{E_2}$ [7], while the set of weakly $\leq^{\mathrm{P}}_{n^\alpha-\mathrm{tt}}$-hard languages for $\mathrm{E_2}$ has measure 1 in $\mathrm{E_2}$ [3]. Thus almost every language in $\mathrm{E_2}$ is weakly $\leq^{\mathrm{P}}_{n^\alpha-\mathrm{tt}}$-hard, but not $\leq^{\mathrm{P}}_{n^\alpha-\mathrm{tt}}$-hard, for $\mathrm{E_2}$, so the result of Lutz and Mayordomo [11] for $\mathrm{E_2}$ is provably much more general than the fact that every $\leq^{\mathrm{P}}_{n^\alpha-\mathrm{tt}}$-hard language for $\mathrm{E_2}$ is dense. We conjecture that this also holds for E.

A word on the relationship between hardness notions for E and $\mathrm{E_2}$ is in order here. It is well known that a language is $\leq^{\mathrm{P}}_{\mathrm{m}}$-hard for E if and only if it is $\leq^{\mathrm{P}}_{\mathrm{m}}$-hard for $\mathrm{E_2}$; this is because $\mathrm{E_2} = \mathrm{P_m}(\mathrm{E})$. The same equivalence holds for $\leq^{\mathrm{P}}_{\mathrm{T}}$-hardness. It is also clear that every language that is $\leq^{\mathrm{P}}_{n^\alpha-\mathrm{tt}}$-hard for $\mathrm{E_2}$ is $\leq^{\mathrm{P}}_{n^\alpha-\mathrm{tt}}$-hard for E. However, it is not generally the case that $\mathrm{P_m}(\mathrm{P}_{n^\alpha-\mathrm{tt}}(A)) = \mathrm{P}_{n^\alpha-\mathrm{tt}}(A)$, so it may well be the case that a language can be $\leq^{\mathrm{P}}_{n^\alpha-\mathrm{tt}}$-hard for E but not for $\mathrm{E_2}$. These same remarks apply to $\leq^{\mathrm{P}}_{n^\alpha-\mathrm{T}}$-hardness.

The relationship between weak hardness notions for E and $\mathrm{E_2}$ is somewhat different. Juedes and Lutz [9] have shown that weak $\leq^{\mathrm{P}}_{\mathrm{m}}$-hardness for E implies weak

$\leq^{\mathrm{P}}_{\mathrm{m}}$-hardness for E_2, and their proof of this fact also works for weak $\leq^{\mathrm{P}}_{\mathrm{T}}$-hardness. However, Juedes and Lutz [9] also showed that weak $\leq^{\mathrm{P}}_{\mathrm{m}}$-hardness for E_2 does not generally imply weak $\leq^{\mathrm{P}}_{\mathrm{m}}$-hardness for E, and it is reasonable to conjecture (but has not been proven) that the same holds for weak $\leq^{\mathrm{P}}_{\mathrm{T}}$-hardness. We further conjecture that the notions of weak $\leq^{\mathrm{P}}_{n^\alpha-\mathrm{tt}}$-hardness for E and weak $\leq^{\mathrm{P}}_{n^\alpha-\mathrm{tt}}$-hardness E_2 are incomparable, and similarly for weak $\leq^{\mathrm{P}}_{n^\alpha-\mathrm{T}}$-hardness. In any case, (1.6) implies that, for every $\alpha < 1$, every language that is weakly $\leq^{\mathrm{P}}_{n^\alpha-\mathrm{tt}}$-hard for either E or E_2 is dense.

Shortly after, but independently of [11], Fu [8] used very different techniques to prove that, for every $\alpha < 1$,

$$\mathrm{E} \not\subseteq \mathrm{P}_{n^{\alpha/2}-\mathrm{T}}(\mathrm{DENSE}^c) \tag{1.7}$$

and

$$\mathrm{E}_2 \not\subseteq \mathrm{P}_{n^\alpha-\mathrm{T}}(\mathrm{DENSE}^c). \tag{1.8}$$

That is, every language that is $\leq^{\mathrm{P}}_{n^{\alpha/2}-\mathrm{T}}$-hard for E or $\leq^{\mathrm{P}}_{n^\alpha-\mathrm{T}}$-hard for E_2 is dense. These results do not have the measure-theoretic strength of (1.6), but they are a major improvement over previous results on the densities of hard languages in that they hold for Turing reductions, which have *adaptive* queries.

In the present paper, we prove results which simultaneously strengthen results of Lutz and Mayordomo [11] and the results of Fu [8]. Specifically, we prove that, for every $\alpha < 1$,

$$\mu_{\mathrm{p}}(\mathrm{P}_{n^{\alpha/2}-\mathrm{T}}(\mathrm{DENSE}^c)) = 0 \tag{1.9}$$

and

$$\mu_{\mathrm{p}_2}(\mathrm{P}_{n^\alpha-\mathrm{T}}(\mathrm{DENSE}^c)) = 0. \tag{1.10}$$

These results imply that every language that is weakly $\leq^{\mathrm{P}}_{n^{\alpha/2}-\mathrm{T}}$-hard for E or weakly $\leq^{\mathrm{P}}_{n^\alpha-\mathrm{T}}$-hard for E_2 is dense. The proof of (1.9) and (1.10) is not a simple extension of the proof in [11] or the proof in [8], but rather combines ideas from both [11] and [8] with the martingale dilation technique introduced by Ambos-Spies, Terwijn, and Zheng [3].

Our results also show that the strong hypotheses $\mu_{\mathrm{p}}(\mathrm{NP}) \neq 0$ and $\mu_{\mathrm{p}_2}(\mathrm{NP}) \neq 0$ (surveyed in [13] and [2]) have consequences for the densities of adaptively hard languages for NP. Mahaney [14] proved that

$$\mathrm{P} \neq \mathrm{NP} \Rightarrow \mathrm{NP} \not\subseteq \mathrm{P}_{\mathrm{m}}(\mathrm{SPARSE}), \tag{1.11}$$

and Ogiwara and Watanabe [17] improved this to

$$\mathrm{P} \neq \mathrm{NP} \Rightarrow \mathrm{NP} \not\subseteq \mathrm{P}_{\mathrm{btt}}(\mathrm{SPARSE}). \tag{1.12}$$

That is, if $\mathrm{P} \neq \mathrm{NP}$, then no sparse language can be $\leq^{\mathrm{P}}_{\mathrm{btt}}$-hard for NP. Lutz and Mayordomo [11] used (1.6) to obtain a stronger conclusion from a stronger hypothesis; namely, for all $\alpha < 1$,

$$\mu_{\mathrm{p}}(\mathrm{NP}) \neq 0 \Rightarrow \mathrm{NP} \not\subseteq \mathrm{P}_{n^\alpha-\mathrm{tt}}(\mathrm{DENSE}^c). \tag{1.13}$$

By (1.10) and the known fact that $\mu_{\mathrm{p}}(\mathrm{NP}) \neq 0$ iff $\mu_{\mathrm{p}_2}(\mathrm{NP}) \neq 0$ [3], we now have, for all $\alpha < 1$,

$$\mu_{\mathrm{p}}(\mathrm{NP}) \neq 0 \Rightarrow \mathrm{NP} \not\subseteq \mathrm{P}_{n^\alpha-\mathrm{T}}(\mathrm{DENSE}^c). \tag{1.14}$$

Thus, if $\mu_{\mathrm{p}}(\mathrm{NP}) \neq 0$, then every language that is $\leq^{\mathrm{P}}_{n^{0.99}-\mathrm{T}}$-hard for NP is dense.

2. Preliminaries. The *Boolean value* of a condition ψ is

$$[\![\psi]\!] = \begin{cases} 1 & \text{if } \psi, \\ 0 & \text{if not } \psi. \end{cases}$$

The *standard enumeration* of $\{0,1\}^*$ is $s_0 = \lambda, s_1 = 0, s_2 = 1, s_3 = 00, \ldots$. This enumeration induces a total ordering of $\{0,1\}^*$ which we denote by $<$.

All *languages* here are subsets of $\{0,1\}^*$. The *Cantor space* is the set $\mathbf{C}$ of all languages. We identify each language $A \in \mathbf{C}$ with its characteristic sequence, which is the infinite binary sequence

$$[\![s_0 \in A]\!][\![s_1 \in A]\!][\![s_2 \in A]\!] \cdots,$$

where $s_0 = \lambda, s_1 = 0, s_2 = 1, s_3 = 00, \ldots$ is the standard enumeration of $\{0,1\}^*$. For $w \in \{0,1\}^*$ and $A \in \mathbf{C}$, we write $w \sqsubseteq A$ to indicate that w is a prefix of (the characteristic sequence of) A. The *symmetric difference* of the two languages A and B is $A \triangle B = (A - B) \cup (B - A)$.

The *cylinder generated* by a string $w \in \{0,1\}^*$ is the set

$$\mathbf{C}_w = \{A \in \mathbf{C} | w \sqsubseteq A\}.$$

Note that $\mathbf{C}_\lambda = \mathbf{C}$.

In this paper, a set $X \subseteq \mathbf{C}$ that appears in a probability $\Pr(X)$ or a conditional probability $\Pr(X|\mathbf{C}_w)$ is regarded as an event in the sample space $\mathbf{C}$ with the uniform probability measure. Thus, for example, $\Pr(X)$ is the probability that $A \in X$ when the language $A \subseteq \{0,1\}^*$ is chosen probabilistically by using an independent toss of a fair coin to decide membership of each string in A. In particular, $\Pr(\mathbf{C}_w) = 2^{-|w|}$. The *complement* of a set $X \subseteq \mathbf{C}$ is the set $X^c = \mathbf{C} - X$.

Let $d \in \mathbb{N}$ and $t : \mathbb{N} \to \mathbb{N}$. A function $f : \mathbb{N}^d \times \{0,1\}^* \to \mathbb{Q}$ is *exactly $t(n)$-time-computable* if there is an algorithm that, on input $(k_1, \ldots, k_d, w) \in \mathbb{N}^d \times \{0,1\}^*$, runs for at most $O(t(k_1, \ldots, k_d, |w|))$ steps and outputs an ordered pair $(a, b) \in \mathbb{Z} \times \mathbb{Z}$ such that $f(k_1, \ldots, k_d, w) = \frac{a}{b}$. A function $f : \mathbb{N}^d \times \{0,1\}^* \to \mathrm{R}$ is *$t(n)$-time-computable* if there is an exactly $t(n)$-time-computable function $\widehat{f} : \mathbb{N}^{d+1} \times \{0,1\}^* \to \mathbb{Q}$ such that, for all $r, k_1, \ldots, k_d \in \mathbb{N}$ and $w \in \{0,1\}^*$,

$$|\widehat{f}(r, k_1, \ldots, k_d, w) - f(k_1, \ldots, k_d, w)| \leq 2^{-r}.$$

We briefly review those aspects of martingales and resource-bounded measure that are needed for our main theorem. The reader is referred to [2], [10], [13], or [15] for more thorough discussion.

A *martingale* is a function $d : \{0,1\}^* \to [0, \infty)$ such that, for all $w \in \{0,1\}^*$,

$$d(w) = \frac{d(w0) + d(w1)}{2}.$$

If $t : \mathbb{N} \to \mathbb{N}$, then a *$t(n)$-martingale* is a martingale that is $t(n)$-time-computable, and an *exact $t(n)$-martingale* is a (rational-valued) martingale that is exactly $t(n)$-time-computable. A martingale d *succeeds* on a language $A \in \mathbf{C}$ if, for every $c \in \mathbb{N}$, there exists $w \sqsubseteq A$ such that $d(w) > c$. The *success set* of a martingale d is the set

$$S^\infty[d] = \{A \in \mathbf{C} | d \text{ succeeds on } A\}.$$

The *unitary success set* of d is

$$S^1[d] = \bigcup_{\substack{w \in \{0,1\}^* \\ d(w) \geq 1}} \mathbf{C}_w.$$

The following result was proved by Juedes and Lutz [9] and independently by Mayordomo [15].

LEMMA 2.1 (exact computation lemma). *Let $t : \mathbb{N} \to \mathbb{N}$ be nondecreasing with $t(n) \geq n^2$. Then, for every $t(n)$-martingale d, there is an exact $n \cdot t(2n+2)$-martingale $\tilde{d}$ such that $S^\infty[d] \subseteq S^\infty[\tilde{d}]$.*

A sequence

$$\sum_{k=0}^{\infty} a_{j,k} \qquad (j = 0, 1, 2, \dots)$$

of series of terms $a_{j,k} \in [0, \infty)$ is *uniformly* p-*convergent* if there is a polynomial $m : \mathbb{N}^2 \to \mathbb{N}$ such that, for all $j, r \in \mathbb{N}$, $\sum_{k=m_j(r)}^{\infty} a_{j,k} \leq 2^{-r}$, where we write $m_j(r) = m(j, r)$. The following sufficient condition for uniform p-convergence is easily verified by routine calculus.

LEMMA 2.2. *Let $a_{j,k} \in [0, \infty)$ for all $j, k \in \mathbb{N}$. If there exist a real number $\epsilon > 0$ and a polynomial $g : \mathbb{N} \to \mathbb{N}$ such that $a_{j,k} \leq e^{-k^\epsilon}$ for all $j, k \in \mathbb{N}$ with $k \geq g(j)$, then the series $\sum_{k=0}^{\infty} a_{j,k}$ $(j = 0, 1, 2, \dots)$ are uniformly* p-*convergent.*

A uniform, resource-bounded generalization of the classical first Borel–Cantelli lemma was proved by Lutz [10]. Here we use the following precise variant of this result.

THEOREM 2.3. *Let $\alpha, \tilde{\alpha} \in \mathrm{R}$ with $1 \leq \alpha < \tilde{\alpha}$, and let*

$$d : \mathbb{N} \times \mathbb{N} \times \{0,1\}^* \to \mathbb{Q} \cap [0, \infty)$$

be an exactly $2^{(\log n)^\alpha}$-time-computable function with the following two properties.

(i) *For each $j, k \in \mathbb{N}$, the function $d_{j,k}$ defined by $d_{j,k}(w) = d(j, k, w)$ is a martingale.*

(ii) *The series $\sum_{k=0}^{\infty} d_{j,k}(\lambda)$ $(j = 0, 1, 2, \dots)$ are uniformly* p-*convergent.*

Then there is an exact $2^{(\log n)^{\tilde{\alpha}}}$-martingale $\tilde{d}$ such that

$$\bigcup_{j=0}^{\infty} \bigcap_{t=0}^{\infty} \bigcup_{k=t}^{\infty} S^1[d_{j,k}] \subseteq S^\infty[\tilde{d}].$$

Proof. Assume the hypothesis, and fix $\alpha' \in \mathbb{Q}$ such that $\alpha < \alpha' < \tilde{\alpha}$. Since $n \cdot 2^{(\log(2n+2))^{\alpha'}} = o(2^{(\log n)^{\tilde{\alpha}}})$, it suffices by Lemma 2.1 to show that there is a $2^{(\log n)^{\alpha'}}$-martingale d' such that

$$\bigcup_{j=0}^{\infty} \bigcap_{t=0}^{\infty} \bigcup_{k=t}^{\infty} S^1[d_{j,k}] \subseteq S^\infty[d']. \tag{2.1}$$

Fix a polynomial $m : \mathbb{N}^2 \to \mathbb{N}$ testifying that the series $\sum_{k=0}^{\infty} d_{j,k}(\lambda)$ $(j = 0, 1, 2, \dots)$ are uniformly p-convergent, and define

$$d'(w) = \sum_{j=0}^{\infty} \sum_{t=0}^{\infty} \sum_{k=m_j(2t)}^{\infty} 2^{t-j} d_{j,k}(w)$$

for all $w \in \{0,1\}^*$. Thus, for each $w \in \{0,1\}^*$,

$$\begin{aligned} d'(w) &\le \sum_{j=0}^{\infty}\sum_{t=0}^{\infty}\sum_{k=m_j(2t)}^{\infty} 2^{t-j+|w|}d_{j,k}(\lambda) \\ &\le 2^{|w|}\sum_{j=0}^{\infty}2^{-j}\sum_{t=0}^{\infty}2^t\cdot 2^{-2t} \\ &= 2^{|w|+2}, \end{aligned}$$

so $d' : \{0,1\}^* \to [0,\infty)$. It is clear by linearity that d' is a martingale. To see that (2.1) holds, assume that $A \in \cup_{j=0}^{\infty}\cap_{t=0}^{\infty}\cup_{k=t}^{\infty}S^1[d_{j,k}]$, and let $c \in \mathbb{N}$ be arbitrary. Then there exist $j \in \mathbb{N}$ and $k \ge m_j(2j+2c)$ such that $A \in S^1[d_{j,k}]$. Fix $w \sqsubseteq A$ such that $d_{j,k}(w) \ge 1$. Then $d'(w) \ge 2^{c+j-j}d_{j,k}(w) \ge 2^c$. Since c is arbitrary here, it follows that $A \in S^\infty[d']$, confirming (2.1).

To see that d' is $2^{(\log n)^{\alpha'}}$-time-computable, define $d_A, d_B, d_C : \mathbb{N}\times\{0,1\}^* \to [0,\infty)$ as follows, using the abbreviation $s = r + |w| + 2$.

$$\begin{aligned} d_A(r,w) &= \sum_{j=0}^{s}\sum_{t=0}^{\infty}\sum_{k=m_j(2t)}^{\infty} 2^{t-j}d_{j,k}(w), \\ d_B(r,w) &= \sum_{j=0}^{s}\sum_{t=0}^{2s}\sum_{k=m_j(2t)}^{\infty} 2^{t-j}d_{j,k}(w), \\ d_C(r,w) &= \sum_{j=0}^{s}\sum_{t=0}^{2s}\sum_{k=m_j(2t)}^{m_j(2s^2+4s+t)} 2^{t-j}d_{j,k}(w). \end{aligned} \tag{2.2}$$

For all $r \in \mathbb{N}$ and $w \in \{0,1\}^*$, it is clear that

$$d_C(r,w) \le d_B(r,w) \le d_A(r,w) \le d'(w),$$

and it is routine to verify the inequalities

$$\begin{aligned} d'(w) - d_A(r,w) &\le 2^{-(r+1)}, \\ d_A(r,w) - d_B(r,w) &\le 2^{-(r+2)}, \\ d_B(r,w) - d_C(r,w) &\le 2^{-(r+2)}, \end{aligned}$$

whence we have

$$d'(w) - 2^{-r} \le d_C(r,w) \le d'(w) \tag{2.3}$$

for all $r \in \mathbb{N}$ and $w \in \{0,1\}^*$. Using formula (2.2), the time required to compute $d_C(r,w)$ exactly is no greater than

$$O((s+1)(2s+1)m(s,2s^2+4s+2s)2^{(\log n)^\alpha}) = O(q(n)\cdot 2^{(\log n)^\alpha}),$$

where $n = r + |w|$ and q is a polynomial. Since $q(n)\cdot 2^{(\log n)^\alpha} = o(2^{(\log n)^{\alpha'}})$, it follows that $d_C(r,w)$ is exactly $2^{(\log n)^{\alpha'}}$-time-computable. By (2.3), then, d' is a $2^{(\log n)^{\alpha'}}$-martingale. □

The proof of our main theorem uses the techniques of weak stochasticity and martingale dilation, which we briefly review here.

As usual, an *advice function* is a function $h : \mathbb{N} \to \{0,1\}^*$. Given a function $q : \mathbb{N} \to \mathbb{N}$, we write $\mathrm{ADV}(q)$ for the set of all advice functions h such that $|h(n)| \leq q(n)$ for all $n \in \mathbb{N}$. Given a language B and an advice function h, we define the language

$$B/h = \{x \in \{0,1\}^* \mid \langle x, h(|x|)\rangle \in B\},$$

where $\langle \cdot\ ,\ \cdot \rangle$ is a standard string-pairing function, e.g., $\langle x, y\rangle = 0^{|x|}1xy$. Given functions $t, q : \mathbb{N} \to N$, we define the advice class

$$\mathrm{DTIME}(t)/\mathrm{ADV}(q) = \{B/h \mid B \in \mathrm{DTIME}(t) \text{ and } h \in \mathrm{ADV}(q)\}.$$

Definition (Lutz and Mayordomo [11], Lutz [12]). *For $t, q, \nu : \mathbb{N} \to \mathbb{N}$, a language A is* weakly (t, q, ν)-stochastic *if, for all $B, C \in \mathrm{DTIME}(t)/\mathrm{ADV}(q)$ such that $|C_{=n}| \geq \nu(n)$ for all sufficiently large n,*

$$\lim_{n\to\infty} \frac{|(A \triangle B) \bigcap C_{=n}|}{|C_{=n}|} = \frac{1}{2}.$$

We write $\mathrm{WS}(t, q, \nu)$ for the set of all weakly (t, q, ν)-stochastic languages.

The following result resembles the weak stochasticity theorems proved by Lutz and Mayordomo [11] and Lutz [12] but gives a more careful upper bound on the time complexity of the martingale.

Theorem 2.4 (weak stochasticity theorem). *Assume that $\alpha, \beta, \gamma, \tau \in \mathrm{R}$ satisfy $\alpha \geq 1, \beta \geq 1, \gamma > 0$, and $\tau > \alpha\beta$. Then there is an exact $2^{(\log n)^\tau}$-martingale d such that*

$$S^\infty[d] \cup \mathrm{WS}(2^{n^\alpha}, n^\beta, 2^{\gamma n}) = \mathbf{C}.$$

Proof. Assume the hypothesis, and assume without loss of generality that $\alpha, \beta, \gamma, \tau \in \mathbb{Q}$. Fix $\alpha', \tau', \tau'' \in Q$ such that $\alpha < \alpha'$ and $\alpha'\beta < \tau'' < \tau' < \tau$. Let $U \in \mathrm{DTIME}(2^{n^{\alpha'}})$ be a language that is universal for $\mathrm{DTIME}(2^{n^\alpha}) \times \mathrm{DTIME}(2^{n^\alpha})$ in the following sense. For each $i \in \mathbb{N}$, let

$$C_i = \{x \in \{0,1\}^* | \langle s_i, 0x\rangle \in U\},$$

$$D_i = \{x \in \{0,1\}^* | \langle s_i, 1x\rangle \in U\}.$$

Then $\mathrm{DTIME}(2^{n^\alpha}) \times \mathrm{DTIME}(2^{n^\alpha}) = \{(C_i, D_i) | i \in \mathbb{N}\}$.

Define a function $d' : \mathbb{N}^3 \times \{0,1\}^* \to \mathbb{Q} \cap [0, \infty)$ as follows. If k is not a power of 2, then $d'_{i,j,k}(w) = 0$. Otherwise, if $k = 2^n$, where $n \in \mathbb{N}$, then

$$d'_{i,j,k}(w) = \sum_{y,z \in \{0,1\}^{\leq n^\beta}} \Pr(Y_{i,j,k,y,z} | \mathbf{C}_w),$$

where the sets $Y_{i,j,k,y,z}$ are defined as follows. If $|(C_i/y)_{=n}| < 2^{\gamma n}$, then $Y_{i,j,k,y,z} = \emptyset$. If $|(C_i/y)_{=n}| \geq 2^{\gamma n}$, then $Y_{i,j,k,y,z}$ is the set of all $A \in \mathbf{C}$ such that

$$\left| \frac{|(A \triangle (D_i/z)) \cap (C_i/y)_{=n}|}{|(C_i/y)_{=n}|} - \frac{1}{2} \right| \geq \frac{1}{j+1}.$$

The definition of conditional probability immediately implies that, for each $i, j, k \in \mathbb{N}$, the function $d'_{i,j,k}$ is a martingale. Since $U \in \mathrm{DTIME}(2^{n^{\alpha'}})$ and $\alpha'\beta < \tau''$, the time required to compute each $\Pr(Y_{i,j,k,y,z}|\mathbf{C}_w)$ using binomial coefficients is at most $O(2^{(\log(i+j+k))^{\tau''}})$ steps, so the time required to compute $d'_{i,j,k}(w)$ is at most $O((2^{n^\beta}+1)^2 \cdot 2^{(\log(i+j+k))^{\tau''}}) = O(2^{(\log(i+j+k))^{\tau'}})$ steps. Thus d' is exactly $2^{(\log n)^{\tau'}}$-time-computable.

As in [11] and [12], the Chernoff bound tells us that, for all $i, j, n \in \mathbb{N}$ and $y, z \in \{0,1\}^{\leq n^\beta}$, writing $k = 2^n$,

$$\Pr(Y_{i,j,k,y,z}) \leq 2e^{-k^\gamma/2(j+1)^2},$$

whence

$$\begin{aligned} d'_{i,j,k}(\lambda) &\leq (2^{n^\beta}+1)^2 \cdot 2e^{-k^\gamma/2(j+1)^2} \\ &< e^{2n^\beta+3-k^\gamma/2(j+1)^2}. \end{aligned}$$

Let $a = \lceil \frac{1}{\gamma} \rceil$, let $\epsilon = \frac{\gamma}{4}$, and fix $k_0 \in \mathbb{N}$ such that

$$k^{2\epsilon} > k^\epsilon + 2(\log k)^\beta + 3$$

for all $k \geq k_0$. Define $g : \mathbb{N} \to \mathbb{N}$ by

$$g(j) = 4^a(j+1)^{4a} + k_0$$

for all $j \in \mathbb{N}$. Then g is a polynomial and, for all $i, j, n \in \mathbb{N}$, writing $k = 2^n$,

$$\begin{aligned} k \geq g(j) \Rightarrow \begin{cases} k^\gamma &= k^{2\epsilon}k^{2\epsilon} \\ &> [4^a(j+1)^{4a}]^{2\epsilon}(k^\epsilon + 2(\log k)^\beta + 3) \\ &\geq 2(j+1)^2(k^\epsilon + 2n^\beta + 3) \end{cases} \\ \Rightarrow d'_{i,j,k}(\lambda) < e^{-k^\epsilon}. \end{aligned}$$

It follows by Lemma 2.2 that the series $\sum_{k=0}^\infty d'_{i,j,k}(\lambda)$, for $i, j \in \mathbb{N}$, are uniformly p-convergent. Since $1 < \tau'' < \tau$, it follows by Theorem 2.3 that there is an exact $2^{(\log n)^\tau}$-martingale d such that

$$\bigcup_{i=0}^\infty \bigcup_{j=0}^\infty \bigcap_{t=0}^\infty \bigcup_{k=t}^\infty S^1[d'_{i,j,k}] \subseteq S^\infty[d]. \tag{2.4}$$

Now assume that $A \notin \mathrm{WS}(2^{n^\alpha}, n^\beta, 2^{\gamma n})$. Then, by the definition of weak stochasticity, we can fix $i, j \in \mathbb{N}$, functions $h_1, h_2 \in \mathrm{ADV}(n^\beta)$, and an infinite set $J \subseteq \mathbb{N}$ such that, for all $n \in J$, $A \in Y_{i,j,k,h_1(n),h_2(n)}$, where $k = 2^n$. For each $n \in J$, then, there is a prefix $w \sqsubseteq A$ such that $\mathbf{C}_w \subseteq Y_{i,j,k,h_1(n),h_2(n)}$, whence

$$d'_{i,j,k}(w) \geq \Pr(Y_{i,j,k,h_1(n),h_2(n)}|\mathbf{C}_w) = 1,$$

i.e., $A \in S^1[d'_{i,j,k}]$. This argument shows that

$$\bigcup_{i=0}^\infty \bigcup_{j=0}^\infty \bigcap_{t=0}^\infty \bigcup_{k=t}^\infty S^1[d'_{i,j,k}] \cup \mathrm{WS}(2^{n^\alpha}, n^\beta, 2^{\gamma n}) = \mathbf{C}.$$

If follows by (1.4) that

$$S^\infty[d] \cup \mathrm{WS}(2^{n^\alpha}, n^\beta, 2^{\gamma n}) = \mathbf{C}. \qquad \square$$

The technique of martingale dilation was introduced by Ambos-Spies, Terwijn, and Zheng [3]. It has also been used by Juedes and Lutz [9] and generalized considerably by Breutzmann and Lutz [6]. We use the notation of [9] here.

The *restriction* of a string $w = b_0 b_1 \cdots b_{n-1} \in \{0,1\}^*$ to a language $A \subseteq \{0,1\}^*$ is the string $w\restriction A$ obtained by concatenating the successive bits b_i for which $s_i \in A$. If $f : \{0,1\}^* \to \{0,1\}^*$ is strictly increasing and d is a martingale, then the *f-dilation* of d is the function $f\hat{}d : \{0,1\}^* \to [0,\infty)$ defined by

$$f\hat{}d(w) = d(w\restriction range(f))$$

for all $w \in \{0,1\}^*$.

LEMMA 2.5 (martingale dilation lemma—Ambos-Spies, Terwijn, and Zheng [3]). *If $f : \{0,1\}^* \to \{0,1\}^*$ is strictly increasing and d is a martingale, then $f\hat{}d$ is also a martingale. Moreover, for every language $A \in \{0,1\}^*$, if d succeeds on $f^{-1}(A)$, then $f\hat{}d$ succeeds on A.*

Finally, we summarize the most basic ideas of resource-bounded measures in E and E_2. A p-*martingale* is a martingale that is, for some $k \in \mathbb{N}$, an n^k-martingale. A p_2-*martingale* is a martingale that is, for some $k \in \mathbb{N}$, a $2^{(\log n)^k}$-martingale.

DEFINITION (Lutz [10]).

1. *A set X of languages has* p-measure 0*, and we write $\mu_{\mathrm{p}}(X) = 0$, if there is a* p-*martingale d such that $X \subseteq S^\infty[d]$.*
2. *A set X of languages has* p_2-measure 0*, and we write $\mu_{\mathrm{p}_2}(X) = 0$, if there is a* p_2-*martingale d such that $X \subseteq S^\infty[d]$.*

DEFINITION (Lutz [10]).

1. *A set X of languages has* measure 0 *in* E*, and we write $\mu(X|\mathrm{E}) = 0$, if $\mu_{\mathrm{p}}(X \bigcap \mathrm{E}) = 0$.*
2. *A set X of languages has* measure 0 *in* E_2*, and we write $\mu(X|\mathrm{E}_2) = 0$, if $\mu_{\mathrm{p}_2}(X \bigcap \mathrm{E}_2) = 0$.*
3. *A set X of languages has* measure 1 *in* E*, and we write $\mu(X|\mathrm{E}) = 1$, if $\mu(X^c|\mathrm{E}) = 0$. In this case, we say that X contains* almost every *element of* E*.*
4. *A set X of languages has* measure 1 *in* E_2*, and we write $\mu(X|\mathrm{E}_2) = 1$, if $\mu(X^c|\mathrm{E}_2) = 0$. In this case, we say that X contains* almost every *element of* E_2*.*
5. *The expression $\mu(X|\mathrm{E}) \neq 0$ means that X does* not *have measure* 0 *in* E*. Note that this does* not *assert that "$\mu(X|\mathrm{E})$" has some nonzero value. Similarly, the expression $\mu(X|\mathrm{E}_2) \neq 0$ means that X does not have measure* 0 *in* E_2*.*

It is shown in [10] that these definitions endow E and E_2 with internal measure structure. This structure justifies the intuition that, if $\mu(X|\mathrm{E}) = 0$, then $X \cap \mathrm{E}$ is a *negligibly small* subset of E (and similarly for E_2).

3. Results. The key to our main theorem is the following lemma, which says that languages that are $\leq^{\mathrm{P}}_{n^\alpha-\mathrm{T}}$-reducible to nondense languages cannot be very stochastic.

LEMMA 3.1 (main lemma). *For all real numbers $\alpha < 1$ and $\beta > 1 + \alpha$,*

$$\mathrm{P}_{n^\alpha-\mathrm{T}}(\mathrm{DENSE}^c) \cap \mathrm{WS}(2^n, n^\beta, 2^{\frac{n}{2}}) = \emptyset.$$

Proof. Let $\alpha < 1$ and $\beta > 1+\alpha$, and assume without loss of generality that α and β are rational. Let $A \in \mathrm{P}_{n^\alpha-\mathrm{T}}(\mathrm{DENSE}^c)$. It suffices to show that A is not weakly $(2^n, n^\beta, 2^{\frac{n}{2}})$-stochastic.

Since $A \in \mathrm{P}_{n^\alpha-\mathrm{T}}(\mathrm{DENSE}^c)$, there exist a nondense language S, a polynomial $q(n)$, and a $q(n)$-time-bounded oracle Turing machine M such that $A = L(M^S)$ and, for every $x \in \{0,1\}^*$ and $B \subseteq \{0,1\}^*$, M makes exactly $\lfloor |x|^\alpha \rfloor$queries (all distinct) on input x with oracle B. Call these queries $Q^B(x,1), \ldots, Q^B(x, \lfloor |x|^\alpha \rfloor)$ in the order in which M makes them.

For each $B \in \{0,1\}^*$ and $n \in \mathbb{N}$, define an equivalence relation $\approx_{B,n}$ on $\{0,1\}^{\leq q(n)}$ by

$$u \approx_{B,n} v \Leftrightarrow (\forall w)[u \leq w \leq v \Rightarrow [\![w \in B]\!] = [\![u \in B]\!]]$$

and an equivalence relation $\equiv_{B,n}$ on $\{0,1\}^n$ by

$$x \equiv_{B,n} y \Leftrightarrow (\forall i)[1 \leq i \leq n^\alpha \Rightarrow Q^B(x,i) \approx_{B,n} Q^B(y,i)].$$

Note that $\approx_{B,n}$ has at most $2|B_{\leq q(n)}| + 1$ equivalence classes, so $\equiv_{B,n}$ has at most $(2|B_{\leq q(n)}| + 1)^{n^\alpha}$ equivalence classes.

Let $\epsilon = \frac{1-\alpha}{2}$, and let J be the set of all $n \in \mathbb{N}$ for which the following three conditions hold.

(i) $2|S_{\leq q(n)}| + 1 \leq 2^{n^\epsilon}$.
(ii) $n^{\alpha+\epsilon} \leq \frac{n}{2}$.
(iii) $n^\alpha(2n+1) \leq n^\beta$.

Since $\alpha + \epsilon < 1$ and $\beta > 1 + \alpha$, conditions (ii) and (iii) hold for all sufficiently large n. Since $\epsilon > 0$ and S is not dense, condition (i) holds for infinitely many n. Thus the set J is infinite.

Define an advice function $h : \mathbb{N} \to \{0,1\}^*$ as follows. If $n \notin J$, then $h(n) = \lambda$. If $n \in J$, then let D_n be a maximum-cardinality equivalence class of the relation $\equiv_{S,n}$. For each $1 \leq i \leq \lfloor n^\alpha \rfloor$, fix strings $y_{n,i}, z_{n,i} \in D_n$ such that, for all $x \in D_n$,

$$Q^S(y_{n,i}, i) \leq Q^S(x,i) \leq Q^S(z_{n,i}, i).$$

Let

$$\begin{aligned} h_1(n) &= y_{n,1} \cdots y_{n,\lfloor n^\alpha \rfloor}, \\ h_2(n) &= z_{n,1} \cdots z_{n,\lfloor n^\alpha \rfloor}, \\ h_3(n) &= [\![Q^S(y_{n,1}, 1) \in S]\!] \cdots [\![Q^S(y_{n,\lfloor n^\alpha \rfloor}, \lfloor n^\alpha \rfloor) \in S]\!], \\ h(n) &= h_1(n)h_2(n)h_3(n). \end{aligned}$$

Note that $|h(n)| = \lfloor n^\alpha \rfloor (2n+1) \leq n^\beta$ for all $n \in J$, so $h \in \mathrm{ADV}(n^\beta)$.

For each $n \in \mathbb{N}$, let $t = \lfloor n^\alpha \rfloor$, and let C_n be the set of all coded pairs

$$\langle x, y_1 \cdots y_t z_1 \cdots z_t b_1 \cdots b_t \rangle$$

such that $x, y_1, \ldots, y_t, z_1, \ldots, z_t \in \{0,1\}^n$, $b_1, \ldots, b_t \in \{0,1\}$, and, for each $1 \leq i \leq t$,

$$Q^{b_1 \cdots b_t}(y_i, i) \leq Q^{b_1 \cdots b_t}(x,i) \leq Q^{b_1 \cdots b_t}(z_i, i),$$

where $Q^{b_1 \cdots b_t}(w,i)$ denotes the ith query of M on input w when the successive oracle answers are $b_1, \ldots, b_t$. Let B_n be the set of all such coded pairs in C_n such that M

accepts on input x when the successive oracle answers are $b_1, \ldots, b_t$. Finally, define the languages

$$B = \{\langle x, v\rangle \mid v = \lambda \text{ or} \langle x, v\rangle \in B_{|x|}\},$$

$$C = \{\langle x, v\rangle \mid v = \lambda \text{ or} \langle x, v\rangle \in C_{|x|}\}.$$

It is clear that $B, C \in \mathrm{DTIME}(2^n)$. Also, by our construction of these sets and the advice function h, for each $n \in \mathbb{N}$, we have

$$(C/h)_{=n} = \begin{cases} D_n & \text{if } n \in J, \\ \{0,1\}^n & \text{if } n \notin J \end{cases}$$

and

$$(B/h)_{=n} = \begin{cases} A \cap D_n & \text{if } n \in J, \\ \{0,1\}^n & \text{if } n \notin J. \end{cases}$$

For each $n \in J$, if $\kappa(n)$ is the number of equivalence classes of $\equiv_{S,n}$, then

$$\kappa(n) \leq (2|S_{\leq q(n)}| + 1)^{n^\alpha} \leq (2^{n^\epsilon})^{n^\alpha} = 2^{n^{\alpha+\epsilon}},$$

so

$$|D_n| \geq \frac{2^n}{\kappa(n)} \geq 2^{n - n^{\alpha+\epsilon}} \geq 2^{\frac{n}{2}}.$$

It follows that $|(C/h)_{=n}| \geq 2^{\frac{n}{2}}$ for all $n \in \mathbb{N}$.

Finally, for all $n \in J$,

$$(A \triangle (B/h)) \cap (C/h)_{=n} = (A \triangle (A \cap D_n)) \cap D_n = \emptyset.$$

Since J is infinite, it follows that

$$\frac{|(A \triangle (B/h)) \cap (C/h)_{=n}|}{|(C/h)_{=n}|} \not\to \frac{1}{2}$$

as $n \to \infty$. Since $B, C \in \mathrm{DTIME}(2^n)$, $h \in \mathrm{ADV}(n^\beta)$, and $|(C/h)_{=n}| \geq 2^{\frac{n}{2}}$ for all $n \in \mathbb{N}$, this shows that A is not weakly $(2^n, n^\beta, 2^{\frac{n}{2}})$-stochastic. □

We now prove our main result.

THEOREM 3.2 (main theorem). *For every real number $\alpha < 1$,*

$$\mu_{\mathrm{p}}(\mathrm{P}_{n^{\alpha/2}\text{-T}}(\mathrm{DENSE}^c)) = \mu_{\mathrm{p}_2}(\mathrm{P}_{n^\alpha\text{-T}}(\mathrm{DENSE}^c)) = 0.$$

Proof. Let $\alpha < 1$, and let $\beta = \frac{3+\alpha}{2}$, so that $1 + \alpha < \beta < 2$. By Theorem 2.4, there is an exact $2^{(\log n)^2}$-martingale d such that

$$S^\infty[d] \cup \mathrm{WS}(2^n, n^\beta, 2^{\frac{n}{2}}) = \mathbf{C}.$$

By Lemma 3.1, we then have

$$\mathrm{P}_{n^\alpha\text{-T}}(\mathrm{DENSE}^c) \subseteq S^\infty[d].$$

Since d is a p_2-martingale, this implies that $\mu_{\mathrm{p}_2}(\mathrm{P}_{n^\alpha\text{-T}}(\mathrm{DENSE}^c)) = 0$.

Define $f : \{0,1\}^* \to \{0,1\}^*$ by

$$f(x) = 0^{|x|^2-|x|-1}1x.$$

Then f is strictly increasing, so $f\hat{}d$, the f-dilation of d, is a martingale. The time required to compute $f\hat{}d(w)$ is

$$O(|w|^2 + 2^{(\log |w'|)^2})$$

steps, where $w' = w\restriction range(f)$. (This allows $O(|w|^2)$ steps to compute w' and then $O(2^{(\log |w'|)^2})$ steps to compute $d(w')$.)

Now $|w'|$ is bounded above by the number of strings x such that $|x|^2 \leq |s_{|w|}| = \lfloor \log(1 + |w|) \rfloor$, so

$$|w'| < 2^{1+\sqrt{\log(1+|w|)}}.$$

Thus the time required to compute $f\hat{}d(w)$ is

$$O(|w|^2 + 2^{(1+\sqrt{\log(1+|w|)}\,)^2}) = O(|w|^2)$$

steps, so $f\hat{}d$ is an n^2-martingale.

Now let $A \in \mathrm{P}_{n^{\alpha/2}-\mathrm{T}}(\mathrm{DENSE}^c)$. Then $f^{-1}(A) \in \mathrm{P}_{n^{\alpha}-\mathrm{T}}(\mathrm{DENSE}^c) \subseteq S^\infty[d]$, so $A \in S^\infty[f\hat{}d]$ by Lemma 2.5. This shows that $\mathrm{P}_{n^{\alpha/2}-\mathrm{T}}(\mathrm{DENSE}^c) \subseteq S^\infty[f\hat{}d]$. Since $f\hat{}d$ is an n^2-martingale, it follows that $\mu_{\mathrm{p}}(\mathrm{P}_{n^{\alpha/2}-\mathrm{T}}(\mathrm{DENSE}^c)) = 0$. □

We now develop a few consequences of the main theorem. The first is immediate.

Corollary 3.3. *For every real number $\alpha < 1$,*

$$\mu(\mathrm{P}_{n^{\alpha/2}-\mathrm{T}}(\mathrm{DENSE}^c) \mid \mathrm{E}) = \mu(\mathrm{P}_{n^{\alpha}-\mathrm{T}}(\mathrm{DENSE}^c) \mid \mathrm{E}_2) = 0.$$

The following result on the density of weakly complete (or weakly hard) languages now follows immediately from Corollary 3.3.

Corollary 3.4. *For every real number $\alpha < 1$, every language that is weakly $\leq^{\mathrm{P}}_{n^{\alpha/2}-\mathrm{T}}$-hard for* E *or weakly $\leq^{\mathrm{P}}_{n^{\alpha}-\mathrm{T}}$-hard for* E_2 *is dense.*

Our final two corollaries concern consequences of the strong hypotheses $\mu_{\mathrm{p}}(\mathrm{NP}) \neq 0$ and $\mu_{\mathrm{p}_2}(\mathrm{NP}) \neq 0$. The relative strengths of these hypotheses are indicated by the known implications

$$\mu(\mathrm{NP} \mid \mathrm{E}) \neq 0 \Rightarrow \mu(\mathrm{NP} \mid \mathrm{E}_2) \neq 0 \Leftrightarrow \mu_{\mathrm{p}_2}(\mathrm{NP}) \neq 0 \Leftrightarrow \mu_{\mathrm{p}}(\mathrm{NP}) \neq 0 \Rightarrow \mathrm{P} \neq \mathrm{NP}.$$

(The leftmost implication was proven by Juedes and Lutz [9], and the fact that $\mu_{\mathrm{p}}(\mathrm{NP}) \neq 0$ implies $\mu_{\mathrm{p}_2}(\mathrm{NP}) \neq 0$ was proven by Ambos-Spies, Terwijn, and Zheng [3]. The remaining implications follow immediately from elementary properties of resource-bounded measure.)

Corollary 3.5. *Let $\alpha < 1$. If $\mu_{\mathrm{p}}(\mathrm{NP}) \neq 0$, then every language that is $\leq^{\mathrm{P}}_{n^{\alpha}-\mathrm{T}}$-hard for* NP *is dense.*

We conclude by considering the densities of languages to which SAT can be adaptively reduced.

Definition. *A function $g : \mathbb{N} \to \mathbb{N}$ is* subradical *if $\log g(n) = o(\log n)$.*

It is easy to see that a function g is subradical if and only if, for all $k > 0$, $g(n) = o(\sqrt[k]{n})$. (This is the reason for the name "subradical.") Subradical functions

include very slow-growing functions such as $\log n$ and $(\log n)^5$, as well as more rapidly growing functions such as $2^{(\log n)^{0.99}}$.

COROLLARY 3.6. *If* $\mu_{\mathrm{p}}(\mathrm{NP}) \neq 0$, $g : \mathbb{N} \to \mathbb{N}$ *is subradical, and SAT* $\leq^{\mathrm{P}}_{g(n)-\mathrm{T}} H$, *then* H *is dense.*

Proof. Assume the hypothesis. Let $A \in \mathrm{NP}$. Then there is a $\leq^{\mathrm{P}}_{\mathrm{m}}$-reduction f of A to SAT. Fix a polynomial $q(n)$ such that, for all $x \in \{0,1\}^*$, $|f(x)| \leq q(|x|)$. Composing f with the $\leq^{\mathrm{P}}_{g(n)-\mathrm{T}}$-reduction of SAT to H that we have assumed to exist then gives a $\leq^{\mathrm{P}}_{g(q(n))-\mathrm{T}}$-reduction of A to H. Since g is subradical, $\log g(q(n)) = o(\log q(n)) = o(\log n)$, so for all sufficiently large n, $g(q(n)) \leq 2^{\frac{\log n}{4}} = n^{\frac{1}{4}}$. Thus $A \leq^{\mathrm{P}}_{n^{\frac{1}{4}}-\mathrm{T}} H$.

The above argument shows that H is $\leq^{\mathrm{P}}_{n^{\frac{1}{4}}-\mathrm{T}}$-hard for NP. Since we have assumed $\mu_{\mathrm{p}}(\mathrm{NP}) \neq 0$, it follows by Corollary 3.5 that H is dense. □

To put the matter differently, Corollary 3.6 tells us that if SAT is polynomial-time reducible to a nondense language with at most $2^{(\log n)^{0.99}}$ adaptive queries, then NP has measure 0 in E and in E_2.

4. Questions. As noted in the introduction, the relationships between weak hardness notions for E and E_2 under reducibilities such as $\leq^{\mathrm{P}}_{\mathrm{T}}, \leq^{\mathrm{P}}_{n^\alpha-\mathrm{T}}$ and $\leq^{\mathrm{P}}_{n^\alpha-\mathrm{tt}}$ remain to be resolved. Our main theorem also leaves open the question whether $\leq^{\mathrm{P}}_{n^\alpha-\mathrm{T}}$-hard languages for E must be dense when $\frac{1}{2} \leq \alpha < 1$. We are in the curious situation of knowing that the classes $\mathrm{P}_{n^{0.99}-\mathrm{tt}}(\mathrm{DENSE}^c)$ and $\mathrm{P}_{n^{0.49}-\mathrm{T}}(\mathrm{DENSE}^c)$ have p-measure 0, but not knowing whether the class $\mathrm{P}_{n^{0.50}-\mathrm{T}}(\mathrm{DENSE}^c)$ has p-measure 0. Indeed, at this time we cannot even prove that $\mathrm{E} \not\subseteq \mathrm{P}_{n^{0.50}-T}(\mathrm{SPARSE})$. Further progress on this matter would be illuminating.

A FINITE STATE VERSION OF THE KRAFT–MCMILLAN THEOREM*

FRÉDÉRIQUE BASSINO†, MARIE-PIERRE BÉAL†, AND DOMINIQUE PERRIN†

Abstract. The main result is a finite-state version of the Kraft–McMillan theorem characterizing the generating sequence of a k-ary regular tree. The proof uses a new construction called the *multiset construction*, which is a version with multiplicities of the well-known subset construction of automata theory.

Key words. generating series, regular trees, nonnegative matrices

1. Introduction. The Kraft inequality $\sum_{n\geq 0} s_n k^{-n} \leq 1$ characterizes the generating sequences $(s_n)_{n\geq 0}$ of leaves in a k-ary tree. It is used in connection with the Huffman algorithm to build prefix codes or search trees and usually restricted to the case of finite trees. We are interested here in the case of infinite sequences corresponding to infinite trees. These infinite trees arise, for example, as search trees in infinite sets. They also appear in the context of finite automata having nested loops to represent the set of first returns to a given state. The tree thus obtained is called a *regular* tree. It has only a finite number of nonisomorphic subtrees since two subtrees corresponding to the same state of the automaton are isomorphic. The generating sequences of such infinite trees are of interest in the applications of finite automata to text compression or channel coding.

Our main result is a characterization of the generating sequences of leaves of regular k-ary trees. Its essence is that the two conditions of being the generating sequence of

(i) a k-ary tree, and

(ii) a regular tree

are independent in the sense that their conjunction is enough to guarantee that a sequence is the generating sequence of a regular k-ary tree.

The proof uses a new construction on graphs called the *multiset construction*, which is a counterpart for automata with multiplicities of the well-known subset construction of automata theory.

Our results have a connection with symbolic dynamics. Actually, in both cases, the emphasis is on the space of paths in a finite graph. Even if we do not use results from symbolic dynamics, some of the methods used, like state-splitting or the Perron theory, are similar. Using an expression of Lind and Marcus [15], our treatment is "dynamical in spirit." The relationship with symbolic dynamics is discussed more closely in [7] and [8].

The paper is organized as follows. Section 2 contains preliminary results and definitions on graphs, trees, regular sequences, and the Perron–Frobenius theory. In

section 3, we present the multiset construction. Section 4 contains the proof of our main result (Theorem 16). Section 5 treats a similar problem, with the set of leaves replaced by the set of all nodes.

The results contained in this paper represent the terminal point of a series of steps. In a previous paper [7] (with a preliminary version in [5]), we proved Theorem 16 in the particular case of a strict inequality. The proof uses the technique of state-splitting from symbolic dynamics. In the same paper, we also give a proof of Theorem 19 which is different from the proof given here, which is based on the multiset construction and is more simple. Finally, the survey paper [8] gives an overview of length distributions and regular sequences.

2. Definitions and background. In this section, we fix our notation concerning graphs, trees, and regular sequences. We also recall some notions concerning positive matrices.

We give a word on the terminology used here. We constantly use the term *regular* where a richer terminology is often used. In particular, what we call a regular sequence here is, in Eilenberg's terminology, an $\mathbb{N}$-rational sequence (see [11], [19], or [10]).

2.1. Graphs and trees. In this paper, we use directed multigraphs, i.e., graphs with possibly several edges with the same origin and the same end. We simply call them graphs in all of what follows. We denote $G = (Q, E)$ a graph with Q as a set of vertices and E as a set of edges. We also say that G is a graph on the set Q.

A *tree* T on a set of nodes N with a *root* $r \in N$ is a function $T : N - \{r\} \longrightarrow N$, which associates to each node distinct from the root its father $T(n)$, in such a way that, for each node n, there is a nonnegative integer h such that $T^h(n) = r$. The integer h is the *height* of the node n.

A tree is k-ary if each node has at most k children. A node without children is called a *leaf*. A node which is not a leaf is called *internal*. A node n is a *descendant* of a node m if $m = T^h(n)$ for some $h \geq 0$. A k-ary tree is *complete* if all internal nodes have exactly k children and have at least one descendant which is a leaf.

For each node n of a tree T, the *subtree* rooted at n, denoted T_n, is the tree obtained by restricting the set of nodes to the descendants of n.

Two trees S, T are isomorphic, denoted $S \equiv T$, if there is a map which transforms S into T by permuting the children of each node. Equivalently, $S \equiv T$ if there is a bijective map $f : N \to M$ from the set of nodes of S onto the set of nodes of T such that $f \circ S = T \circ f$. Such a map f is called an isomorphism.

If T is a tree with N as set of nodes, the *quotient graph* of T is the graph $G = (Q, E)$ where Q and E are defined as follows. The set Q is the quotient of N by the equivalence $n \equiv m$ if $T_n \equiv T_m$. Let $\bar{m}$ denote the class of a node m. The number of edges from $\bar{m}$ to $\bar{n}$ is the number of children of m equivalent to n.

Conversely, the set of paths in a graph with given origin is a tree. Indeed, let $G = (Q, E)$ be a graph. Let $r \in Q$ be a particular vertex, and let N be the set of paths in G starting at r. The tree T having N as a set of nodes and such that $T(p_0, p_1, \ldots, p_n) = (p_0, p_1, \ldots, p_{n-1})$ is called the *covering tree* of G starting at r.

Both constructions are mutually inverse in the sense that any tree T is isomorphic to the covering tree of its quotient graph starting at the image of the root.

PROPOSITION 1. *Let T be a tree with root r. Let G be its quotient graph, and let i be the vertex of G which is the class of the root of T. For each vertex q of G and for each $n \geq 0$, the number of paths of length n from i to q is equal to the number of nodes of T at height n in the class of q.*

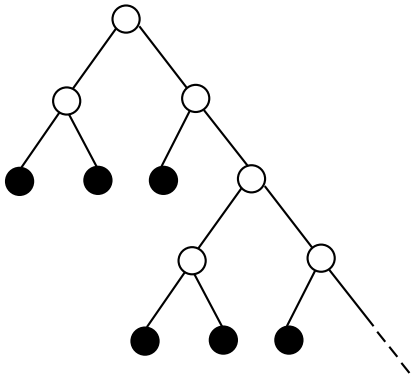

FIG. 1. *A regular tree.*

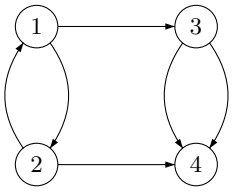

FIG. 2. *And its quotient graph.*

A tree is said to be *regular* if it admits only a finite number of nonisomorphic subtrees, i.e. if its quotient graph is finite.

For example, the infinite tree represented in Figure 1 is a regular tree. Its quotient graph is represented in Figure 2.

There is also a close connection between trees and sets of words on an alphabet. Let X be a set of words on the alphabet $\{0, 1, \dots, k-1\}$. The set X is said to be *prefix-closed* if any prefix of an element of X is also in X. When X is prefix-closed, we can build a tree $T(X)$ as follows. The set of nodes is X, the root is the empty word ϵ, and $T(a_1 a_2 \cdots a_n) = a_1 a_2 \cdots a_{n-1}$.

Let, for example, $X = \{\epsilon, 0, 1, 10, 11\}$. The tree $T(X)$ is represented in Figure 3.

2.2. Regular sequences. We consider sequences of natural integers $s = (s_n)_{n\geq 0}$. We shall not distinguish between such a sequence and the formal series $s(z) = \sum_{n\geq 0} s_n z^n$.

We usually denote a vector indexed by elements of a set Q, also called a Q-vector, with boldface symbols. For $\mathbf{v} = (v_q)_{q\in Q}$ we say that $\mathbf{v}$ is nonnegative, denoted $\mathbf{v} \geq 0$, (resp., positive, denoted $\mathbf{v} > 0$) if $v_q \geq 0$ (resp., $v_q > 0$) for all $q \in Q$. The same conventions are used for matrices. A nonnegative $Q \times Q$-matrix M is said to be *irreducible* if, for all indices p, q, there is an integer m such that $(M^m)_{p,q} > 0$. The matrix is *primitive* if there is an integer m such that $M^m > 0$.

The *adjacency matrix* of a graph $G = (Q, E)$ is the $Q \times Q$-matrix M such that, for each $p, q \in Q$, the integer $M_{p,q}$ is the number of edges from p to q. The adjacency matrix of a graph G is irreducible iff the graph is strongly connected. It is primitive if, moreover, the greatest commom divisor (g.c.d.) of lengths of cycles in G is 1.

Let G be a finite graph and let I, T be two sets of vertices. For each $n \geq 0$, let s_n

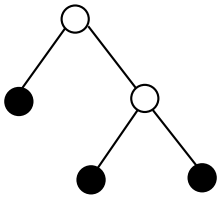

FIG. 3. *The tree* $T(X)$.

be the number of distinct paths of length n from a vertex of I to a vertex of T. The sequence $s = (s_n)_{n\geq 0}$ is called the sequence *recognized* by (G, I, T) or also by G if I and T are already specified. When $I = \{i\}$ and $T = \{t\}$, we simply denote (G, i, t) instead of $(G, \{i\}, \{t\})$.

A sequence $s = (s_n)_{n\geq 0}$ of nonnegative integers is said to be *regular* if it is recognized by such a triple (G, I, T), where G is finite. We say that the triple (G, I, T) is a *representation* of the sequence s. The vertices of I are called *initial* and those of T *terminal*. Two representations are said to be *equivalent* if they recognize the same sequence.

A representation (G, I, T) is said to be *trim* if every vertex of G is on some path from I to T. It is clear that any representation is equivalent to a trim one.

A well-known result in theory of finite automata allows one to use a particular representation of any regular sequence s such that $s_0 = 0$. One can always choose in this case a representation (G, i, t) of s with a unique initial vertex i and a unique final vertex $t \neq i$ such that no edge is entering vertex i and no edge is going out of vertex t. Such a representation is called a *normalized representation* (see, for example, [17, p. 14]).

Let (G, i, t) be a trim normalized representation. If we merge the initial vertex i and the final vertex t in a single vertex still denoted by i, we obtain a new graph denoted by $\overline{G}$, which is strongly connected. The triple $(\overline{G}, i, i)$ is called the *closure* of (G, i, t).

Let s be a regular sequence such that $s_0 = 0$. The *star* s^* of the sequence s is defined by

$$s^*(z) = \frac{1}{1 - s(z)}.$$

PROPOSITION 2. *If* (G, i, t) *is a normalized representation of* s*, its closure* $(\overline{G}, i, i)$ *recognizes the sequence* s^**.*

Proof. The sequence s is the length distribution of the paths of first returns to vertex i in $\overline{G}$, that is, of finite paths going from i to i without going through vertex i. The length distribution of the set of all returns to i is thus $1 + s(z) + s^2(z) + \cdots = 1/(1 - s(z))$. □

An equivalent definition of regular sequences uses vectors instead of the sets I, F. Let $\mathbf{i}$ be a Q-row vector of nonnegative integers, and let $\mathbf{t}$ be a Q-column vector of nonnegative integers. We say that $(G, \mathbf{i}, \mathbf{t})$ recognizes the sequence $s = (s_n)_{n\geq 0}$ if for each integer $n \geq 0$

$$s_n = \mathbf{i}M^n\mathbf{t},$$

where M is the adjacency matrix of G. The proof that both definitions are equivalent follows from the fact that the family of regular sequences is closed under addition (see

FIG. 4. *The Fibonacci graph.*

[11]). A triple $(G, \mathbf{i}, \mathbf{t})$ recognizing a sequence s is also called a representation of s, and two representations are called equivalent if they recognize the same sequence.

A sequence $s = (s_n)_{n\geq 0}$ of nonnegative integers is *rational* if it satisfies a recurrence relation with integral coefficients. Equivalently, s is rational if there exist two polynomials $p(z), q(z)$ with integral coefficients and with $q(0) = 1$ such that

$$s(z) = \frac{p(z)}{q(z)}.$$

Any regular sequence is rational. The converse is, however, not true (see section 5). For example, the sequence s defined by $s(z) = \frac{z}{1-z-z^2}$ is the sequence of Fibonacci numbers also defined by $s_0 = 0, s_1 = 1$, and $s_{n+1} = s_n + s_{n-1}$. It is recognized by the graph of Figure 4 with $I = \{1\}$ and $T = \{2\}$.

2.3. Regular sequences and trees. If T is a tree, its *generating sequence of leaves* is the sequence of numbers $s = (s_n)_{n\geq 0}$, where s_n is the number of leaves at height n. We also simply say that s is the *generating sequence* of T.

The following result is a direct consequence of the definitions.

THEOREM 3. *The generating sequence of a regular tree is a regular sequence.*

Proof. Let T be a regular tree, and let G be its quotient graph. Since T is regular, G is finite. The leaves of T form an equivalence class t. By Proposition 1, the generating sequence of T is recognized by (G, i, t), where i is the class of the root of T. □

We say that a sequence $s = (s_n)_{n\geq 1}$ satisfies the Kraft inequality for the integer k if

$$\sum_{n\geq 0} s_n k^{-n} \leq 1,$$

i.e., using the formal series $s(z) = \sum_{n\geq 0} s_n z^n$, if

$$s(1/k) \leq 1.$$

We say that s satisfies the strict Kraft inequality for k if $s(1/k) < 1$. The following result is well known (see [3, p. 35], for example).

THEOREM 4. *A sequence s is the generating sequence of a k-ary tree iff it satisfies the Kraft inequality for the integer k.*

Proof. Let first T be a k-ary tree, and let s be its generating sequence. It is enough to prove that, for each $n \geq 0$, the sequence $(s_0, \ldots, s_n)$ satisfies the Kraft inequality. It is the generating sequence of the finite tree obtained by restricting T to the nodes at height at most n. We may thus suppose T to be a finite tree. We have

$$s(z) = zt_1(z) + \cdots + zt_k(z),$$

where $t_1, \ldots, t_k$ are the generating sequences of leaves of the (possibly empty) subtrees rooted at the children of the root of T. By induction on the number of nodes, we have $t_i(1/k) \leq 1$, whence the desired result.

Conversely, we use an induction on n to prove that there exists a k-ary tree with generating sequence $(s_0, \dots, s_n)$. For $n = 0$, we have $s_0 \leq 1$ and T is either empty or reduced to one node. Suppose by induction hypothesis that we have already built a tree T with generating sequence $(s_0, s_1, \dots, s_{n-1})$. We have

$$\sum_{i=0}^{n} s_i k^{-i} \leq 1;$$

then

$$\sum_{i=0}^{n} s_i k^{n-i} \leq k^n,$$

and thus

$$s_n \leq k^n - \sum_{i=0}^{n-1} s_i k^{n-i}.$$

This allows us to add s_n leaves at height n to the tree T. □

Let us consider the Kraft equality case. If $s(1/k) = 1$, then any tree T having s as generating sequence is complete. The converse property is not true in general (see [11, p. 231]). However, it is a classical result that when T is a complete regular tree, its generating sequence satisfies $s(1/k) = 1$ (see Proposition 8).

For the sake of a complete description of the construction described above in the proof of Theorem 4, we have to specify the choice made at each step among the leaves at height n. A possible policy is to choose to give as many children as possible to the nodes which are not leaves and are of maximal height.

If we start with a finite sequence s satisfying the Kraft inequality, the above method builds a finite tree with a generating sequence equal to s. It is not true that this incremental method gives a regular tree when we start with a regular sequence, as shown in the following example.

Let $s(z) = z^2/(1-2z^2)$. Since $s(1/2) = 1/2$, we may apply the Kraft construction to build a binary tree with length distribution s. The result is the tree $T(X)$, where X is the set of prefixes of the set

$$Y = \bigcup_{n \geq 0} 01^n 0\{0,1\}^n,$$

which is not regular.

If s is a regular sequence such that $s_0 = 0$, there exists a regular tree T having s as a generating sequence. Indeed, let (G, i, t) be a normalized representation of s. The generating sequence of the covering tree of G starting at i is s. If s satisfies, moreover, the Kraft inequality for an integer k, it is, however, not true that the regular covering tree obtained is k-ary, as shown in the following example.

Let s be the regular sequence recognized by the graph of Figure 5 on the left with $i = 1$ and $t = 4$. We have $s(z) = 3z^2/(1 - z^2)$. Furthermore, $s(1/2) = 1$, and thus s satisfies Kraft's equality for $k = 2$. However, there are four edges going out of vertex 2 and its regular covering tree starting at 1 is 4-ary. A solution for this example is given by the graph of Figure 5 on the right. It recognizes s, and its covering tree starting at 1 is the regular binary tree of Figure 1.

The aim of section 4 is to build from a regular sequence s that satisfies the Kraft inequality for an integer k a tree with a generating sequence s which is both regular and k-ary.

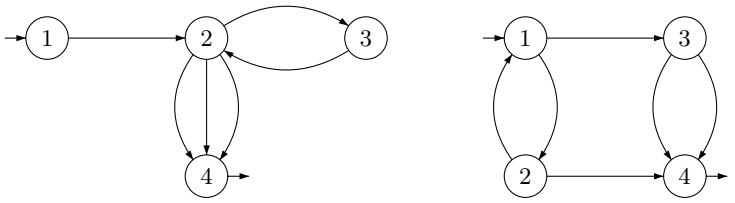

FIG. 5. *Graphs recognizing* $s(z) = 3z^2/(1-z^2)$.

2.4. Approximate eigenvector. Let M be the adjacency matrix of a graph G. By the Perron–Frobenius theorem (see [12] for a general presentation and [15], [14], or [9] for the link with graphs and regular sequences), the nonnegative matrix M has a nonnegative real eigenvalue of maximal modulus denoted by λ, also called the spectral radius of the matrix.

When G is strongly connected, the matrix is irreducible and the Perron–Frobenius theorem asserts that the dimension of the eigenspace of the matrix M corresponding to λ is equal to one, and that there is a positive eigenvector associated to λ.

Let k be an integer. A *k-approximate* eigenvector of a nonnegative matrix M is, by definition, an integral vector $\mathbf{v} \geq 0$ such that

$$M\mathbf{v} \leq k\mathbf{v}.$$

One has the following result (see [15, p. 152]).

PROPOSITION 5. *An irreducible nonnegative matrix M with spectral radius λ admits a positive k-approximate eigenvector iff $k \geq \lambda$.*

For a proof, see [15, p. 152]. When M is the adjacency matrix of a graph G, we also say that $\mathbf{v}$ is a k-approximate eigenvector of G. The computation of an approximate eigenvector can be obtained by the use of Franaszek's algorithm (see, for example, [15]). It can be shown that there exists a k-approximate eigenvector with elements bounded above by k^{2n}, where n is the dimension of M [4]. Thus the size of the coefficients of a k-approximate eigenvector is bounded above by an exponential in n and can be in the worst case of this order of magnitude.

The following result is well known. It links the radius of convergence of a sequence with the spectral radius of the associated matrix.

PROPOSITION 6. *Let s be a regular sequence recognized by a trim representation (G, I, T). Let M be the adjacency matrix of G. The radius of convergence of s is the inverse of the maximal eigenvalue of M.*

Proof. The maximal eigenvalue λ of M is $\lambda = \limsup_{n\geq 0} \sqrt[n]{\|M^n\|}$, where $\|\ \|$ is any of the equivalent matrix norms. Let ρ be the radius of convergence of s and, for each $p, q \in Q$, let ρ_{pq} be the radius of convergence of the sequence $u_{pq} = (M^n_{pq})_{n\geq 0}$. Then $1/\lambda = \min \rho_{pq}$. Since (G, I, T) is trim, we have $\rho_{pq} \geq \rho$ for all $p, q \in Q$. On the other hand, $\rho \geq \min \rho_{pq}$ since s is a sum of some of the sequences u_{pq}. Thus $\rho_s = \min \rho_{pq}$, which concludes the proof. □

As a consequence of this result, the radius of convergence ρ of a regular sequence s is a pole. Indeed, with the above notation, $s(z) = \mathbf{i}(1 - Mz)^{-1}\mathbf{t}$. Then $\det(I - Mz)$ is a denominator of the rational fraction s, and the poles of s are among the inverses of the eigenvalues of M. And since $1/\lambda$ is the radius of convergence of s, it has to be a pole of s. In particular, s diverges for $z = \rho$.

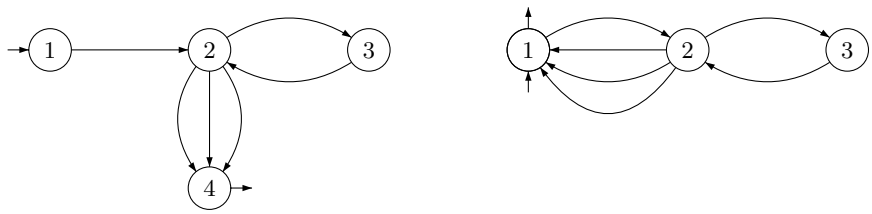

FIG. 6. *The graphs G and $\overline{G}$.*

The following result, due to Berstel, is also well known. It allows one to compute the radius of convergence of the star of a sequence.

PROPOSITION 7. *Let s be a regular sequence. The radius of convergence of the series $s^*(z) = 1/(1 - s(z))$ is the unique real number r such that $s(r) = 1$.*

For a proof, see [11, pp. 211–214], [10, p. 82], or [9, p. 84]. As a consequence, we obtain the following result.

PROPOSITION 8. *Let s be a regular sequence and let λ be the inverse of the radius of convergence of s^*. The sequence s satisfies the Kraft strict inequality $s(1/k) < 1$ (resp., equality $s(1/k) = 1$) iff $\lambda < k$ (resp., $\lambda = k$).*

We have thus proved the following result, which is the basis of the constructions of the next sections.

PROPOSITION 9. *Let s be a regular sequence satisfying Kraft's inequality $s(1/k) \leq 1$. Let (G, i, t) be a normalized representation of s and let $(\overline{G}, i, i)$ be the closure of (G, i, t). The adjacency matrix M of $\overline{G}$ admits a k-approximate eigenvector.*

Actually, under the hypothesis of Proposition 9, the graph G itself also admits a k-approximate eigenvector. Indeed, let $\overline{\mathbf{w}} = (\overline{w}_q)_{q \in Q-t}$ be a k-approximate eigenvector of $\overline{G}$. Then the vector $\mathbf{w} = (w_q)_{q \in Q}$, defined by $w_q = \overline{w}_q$ for $q \neq t$ and $w_t = \overline{w}_i$, is a k-approximate eigenvector of G. This is illustrated in the following example.

Let us, for example, consider again $s(z) = 3z^2/(1 - z^2)$ (see Figure 5). The sequence s is recognized by the normalized representation $(G, 1, 4)$, where G is the graph represented on the left of Figure 6. The graph $\overline{G}$ is represented on the right. The vectors

$$\mathbf{w} = \begin{bmatrix} 3 \\ 2 \\ 1 \\ 3 \end{bmatrix}, \overline{\mathbf{w}} = \begin{bmatrix} 3 \\ 2 \\ 1 \end{bmatrix}$$

are 2-approximate eigenvectors of G and $\overline{G}$, respectively.

3. The multiset construction. In this section, we present the main construction used in this paper. It can be considered as a version with multiplicities of the subset construction used in automata theory to replace a finite automaton by an equivalent deterministic one. We use only unlabeled graphs, but the construction can be easily generalized to graphs with edges labeled by symbols from an alphabet.

Our construction is also linked with one used by D. Lind to build a positive matrix with given spectral radius (see [15, especially Lemma 11.1.9]).

We use, for convenience, the term *multiset* of elements of a set Q as a synonym of Q-vector. If $\mathbf{u} = (u_q)_{q \in Q}$ is such a multiset, the coefficient u_q is also called the

multiplicity of q. The *degree* of $\mathbf{u}$ is the sum $\sum_{q\in Q} u_q$ of all multiplicities.

We start with a triple $(G, \mathbf{i}, \mathbf{t})$, where $G = (Q, E)$ is a finite graph and $\mathbf{i}$ (resp., $\mathbf{t}$) is a row (resp., column) Q-vector. We denote by M the adjacency matrix of G.

Let m be a positive integer. We define another triple $(H, \mathbf{J}, \mathbf{X})$ which is said to be obtained by the *multiset construction*. The graph H is called an *extension* of the graph G. The extension is not unique and depends as we shall see on some arbitrary choices. The set S of vertices of H is formed of multisets of elements of Q of total degree at most m. Thus, an element of S is a nonnegative vector $\mathbf{u} = (u_q)_{q\in Q}$ with indices in Q such that $\sum_{q\in Q} u_q \leq m$. This condition ensures that H is a finite graph.

We now describe the set of edges of the graph H by defining its adjacency matrix N. Let U be the $S \times Q$-matrix defined by $U_{\mathbf{u},q} = u_q$. Then N is any nonnegative $S \times S$-matrix which satisfies

$$NU = UM.$$

Equivalently, for all $\mathbf{u} \in S$,

$$\sum_{\mathbf{v}\in S} N_{\mathbf{u},\mathbf{v}}\mathbf{v} = \mathbf{u}M.$$

Let us comment informally on the above formula. We can describe the construction of the graph H as a sequence of choices. If we reach a vertex $\mathbf{u}$ of H, we partition the multiset $\mathbf{u}M$ of vertices reachable from the vertices composing $\mathbf{u}$ into multisets of degree at most m to define the vertices reachable from $\mathbf{u}$ in H. The integer $N_{\mathbf{u},\mathbf{v}}$ is the multiplicity of $\mathbf{v}$ in the partition. The formula simply expresses the fact that the result is indeed a partition. In general, there are several possible partitions. The matrix U is called the *transfer matrix* of the extension.

We further define the S-row vector $\mathbf{J}$ and the S-column vector $\mathbf{X}$. Let $\mathbf{J}$ be the S-row vector such that $J_{\mathbf{i}} = 1$ and $J_{\mathbf{u}} = 0$ for $\mathbf{u} \neq \mathbf{i}$. Let $\mathbf{X}$ be the S-column vector such that $X_{\mathbf{u}} = \mathbf{u} \cdot \mathbf{t}$.

Thus

$$\mathbf{J}U = \mathbf{i}, \quad \mathbf{X} = U\mathbf{t}.$$

To avoid unnecessary complexity, we only keep in S the vertices reachable from $\mathbf{i}$. Thus, we replace the set S by the set of elements $\mathbf{u}$ of S such that there is a path from $\mathbf{i}$ to $\mathbf{u}$.

The number of multisets of degree at most m on a set Q with n elements is $\frac{n^{m+1}-1}{n-1}$. Thus the number of vertices of a multiset extension is of order n^m. It is polynomial in n if m is taken as a constant.

Let, for example, G be the graph represented on Figure 7 on the left. The graph H represented on the right is a multiset extension of G with

$$\mathbf{i} = \begin{bmatrix} 1 & 0 \end{bmatrix}, \quad \mathbf{j} = \begin{bmatrix} 0 \\ 1 \end{bmatrix}.$$

The matrices M, N, and U are

$$M = \begin{bmatrix} 2 & 1 \\ 0 & 1 \end{bmatrix}, N = \begin{bmatrix} 1 & 1 \\ 0 & 2 \end{bmatrix}, U = \begin{bmatrix} 1 & 0 \\ 1 & 1 \end{bmatrix}, \mathbf{J} = \begin{bmatrix} 1 & 0 \end{bmatrix}, \mathbf{X} = \begin{bmatrix} 0 \\ 1 \end{bmatrix}.$$

In this case, the matrix U is invertible, and the matrices M, N are conjugate.

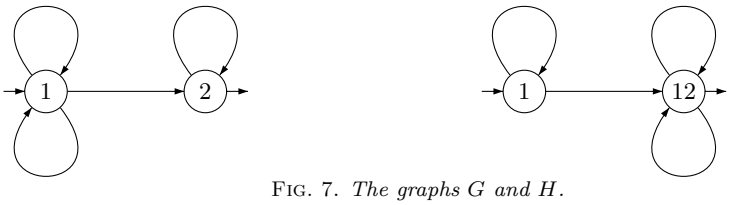

FIG. 7. *The graphs G and H.*

The basic property of an extension is the following one.

PROPOSITION 10. *Let H be an extension of G. The triple $(H, \mathbf{J}, \mathbf{X})$ is equivalent to $(G, \mathbf{i}, \mathbf{t})$.*

Proof. For each $n \geq 0$, we have

$$UM^n = N^n U.$$

Consequently, for each integer $n \geq 0$,

$$\begin{aligned} \mathbf{J}N^n\mathbf{X} &= \mathbf{J}N^nU\mathbf{t} \\ &= \mathbf{J}UM^n\mathbf{t} \\ &= \mathbf{i}M^n\mathbf{t}. \end{aligned}$$

This shows that $(H, \mathbf{J}, \mathbf{X})$ recognizes s. □

We will also make use of the following additional property of extensions.

PROPOSITION 11. *Let H be an extension of G. Let M (resp., N) be the adjacency matrix of G (resp., H), and let U be the transfer matrix. If $\mathbf{w}$ is a k-approximate eigenvector of M, the vector $\mathbf{W} = U\mathbf{w}$ is a k-approximate eigenvector of N. If $\mathbf{w}$ is positive, then $\mathbf{W}$ is also positive.*

Proof. We have

$$N\mathbf{W} = NU\mathbf{w} = UM\mathbf{w} \leq kU\mathbf{w} = k\mathbf{W}.$$

Since all rows of U are distinct from $\mathbf{0}$, the vector $\mathbf{W}$ is positive whenever $\mathbf{w}$ is positive. □

In the next section, we will choose a particular extension of the graph G called admissible which is defined as follows. Let $\mathbf{w}$ be a positive Q-vector, and let m be a positive integer. Let H be an extension of G, let U be the transfer matrix, and let $\mathbf{W} = U\mathbf{w}$. We say that H is *admissible* with respect to $\mathbf{w}$ and m if, for each $\mathbf{u} \in S$, all but possibly one of the vertices $\mathbf{v}$ such that $(\mathbf{u}, \mathbf{v})$ is an edge of H satisfy $W_{\mathbf{v}} \equiv 0 \bmod m$.

THEOREM 12. *For any graph G on Q, any positive Q-vector $\mathbf{w}$, and any integer $m > 0$, the graph G admits an admissible extension with respect to $\mathbf{w}$ and m.*

The proof relies on the following combinatorial lemma. This lemma is also used in a similar context by Adler, Coppersmith, and Hassner [1] and Marcus [16]. It is actually presented in [2] as a nice variant of the pigeon-hole principle.

LEMMA 13. *Let $w_1, w_2, \ldots, w_m$ be positive integers. Then there is a nonempty subset $S \subset \{1, 2, \ldots, m\}$ such that $\sum_{q \in S} w_q$ is divisible by m.*

Proof. The partial sums $w_1, w_1 + w_2, w_1 + w_2 + w_3, \ldots, w_1 + w_2 + \cdots + w_m$ either are all distinct (mod m), or two are congruent (mod m). In the former case,

at least one partial sum must be congruent to 0 (mod m). In the latter, there are $1 \leq p < r \leq m$ such that

$$w_1 + w_2 + \cdots + w_p \equiv w_1 + w_2 + \cdots + w_r (\text{mod } m).$$

Hence $w_{p+1} + w_{p+2} + \cdots + w_r \equiv 0 \pmod{m}$. □

Proof of Theorem 12. We build progressively the set of edges of H. Let $\mathbf{u}$ be an element of S. We prove by induction on the degree $d(\mathbf{u}M) = \sum_{q \in Q} (\mathbf{u}M)_q$ of $\mathbf{u}M$ that there exists $\mathbf{v}_1, \ldots, \mathbf{v}_n \in S$ such that $\mathbf{u}M = \sum_{i=1}^{n} \mathbf{v}_i$ and $W_{\mathbf{v}_i} \equiv 0 \bmod m$ for $1 \leq i \leq n-1$. If $\mathbf{u}M \in S$, i.e., if $d(\mathbf{u}M) \leq m$, we choose $n = 1$ and $\mathbf{v}_1 = \mathbf{u}M$. Otherwise, there exists a decomposition $\mathbf{u}M = \mathbf{v} + \mathbf{u}'$ such that $d(\mathbf{v}) = m$. Let $w_1, w_2, \ldots, w_m$ be the sequence of integers formed by the w_q repeated v_q times. By Lemma 13 applied to the sequence of integers w_i, there is a decomposition $\mathbf{v} = \mathbf{v}' + \mathbf{r}$ with $\mathbf{v}' \neq 0$ such that $W_{\mathbf{v}'} \equiv 0 \bmod m$. We have $\mathbf{u}M = \mathbf{v}' + \mathbf{w}'$ with $\mathbf{w}' = \mathbf{r} + \mathbf{u}'$. Since $d(\mathbf{w}') < d(\mathbf{u}M)$, we can apply the induction hypothesis to $\mathbf{w}'$, giving the desired result. □

For an S-vector $\mathbf{W}$, we denote by $\lceil \frac{\mathbf{W}}{m} \rceil$ the S-vector $\mathbf{Z}$ such that for each $\mathbf{u}$ in S,

$$Z_{\mathbf{u}} = \left\lceil \frac{W_{\mathbf{u}}}{m} \right\rceil.$$

Summing up the previous results, we obtain the following statement.

PROPOSITION 14. *Let H be an admissible extension of G with respect to $\mathbf{w}$ and m. Let M (resp., N) be the adjacency matrix of G (resp., H), let U be the transfer matrix, and let $\mathbf{W} = U\mathbf{w}$. If $\mathbf{w}$ is a positive k-approximate eigenvector of M, then $\lceil \frac{\mathbf{W}}{m} \rceil$ is a positive k-approximate eigenvector of N.*

Proof. By Proposition 3, the vector $\mathbf{W}$ is a positive k-approximate eigenvector of N. Thus

$$N\mathbf{W} \leq k\mathbf{W}.$$

Let $\mathbf{u}$ be an element of S. We have $W_{\mathbf{v}} \equiv 0 \bmod m$ for all indices $\mathbf{v}$ such that $N_{\mathbf{u},\mathbf{v}} > 0$ except possibly for an index $\mathbf{v}_0$. The previous inequality implies that

$$\sum_{\mathbf{v} \in S - \{\mathbf{v}_0\}} N_{\mathbf{u},\mathbf{v}} \frac{W_{\mathbf{v}}}{m} + N_{\mathbf{u},\mathbf{v}_0} \frac{W_{\mathbf{v}_0}}{m} \leq k \ \frac{W_{\mathbf{u}}}{m}.$$

Since $\frac{W_{\mathbf{v}}}{m}$ is a nonnegative integer for $\mathbf{v} \in Q - \{\mathbf{v}_0\}$, we get

$$\sum_{\mathbf{v} \in S - \{\mathbf{v}_0\}} N_{\mathbf{u},\mathbf{v}} \frac{W_{\mathbf{v}}}{m} + N_{\mathbf{u},\mathbf{v}_0} \left\lceil \frac{W_{\mathbf{v}_0}}{m} \right\rceil \leq k \ \left\lceil \frac{W_{\mathbf{u}}}{m} \right\rceil.$$

This proves that

$$N \left\lceil \frac{\mathbf{W}}{m} \right\rceil \leq k \left\lceil \frac{\mathbf{W}}{m} \right\rceil. \qquad \square$$

4. Generating sequence of leaves. In what follows, we state and prove, using the multiset construction, our main result concerning the generating sequences of regular trees. We begin with the following lemma, which is also used in the next section. We use the term leaf for a vertex of a graph without outgoing edges.

LEMMA 15. *Let G be a graph on a set Q of vertices. Let $i \in Q$ and $T \subset Q$. If G admits a k-approximate eigenvector $\mathbf{w}$, there is a graph G' and a set of vertices I' of G' such that the following hold.*

1. *G' admits the k-approximate eigenvector $\mathbf{w}'$ with all components equal to* 1.
2. *The triple $(G, i, \mathbf{w})$ is equivalent to the triple $(G', I', \mathbf{w}')$.*
3. *If $w_p = 1$ for all $p \in T$, there is a set of vertices T' of G' such that the triple (G, i, T) is equivalent to the triple (G', I', T'). Moreover, if T is the set of leaves of G, we can choose for T' the set of leaves of G'.*

Proof. We first show that one can replace G by a graph without multiplicities, i.e., such that the adjacency matrix has coefficients 0 or 1.

For this, let n be the maximal value of the coefficients of M. Let Q' be the set of all pairs (p, j) for $p \in Q$ and $1 \leq j \leq n$. Let E' be the set of all pairs $((p, j), (q, h)) \in Q' \times Q'$ such that $1 \leq j \leq n$ and $1 \leq h \leq M_{p,q}$. Let $i' = (i, 1)$ and $T' = \{(t, j) \mid t \in T, 1 \leq j \leq n\}$. Let $G' = (Q', E')$. The triple (G', i', T') recognizes the same sequence as (G, i, T). Let $w'_{(p,j)} = w_p$ for all $p \in Q$ and all $1 \leq j \leq n$. The triple $(G', i', \mathbf{w}')$ recognizes the same sequence as $(G, i, \mathbf{w})$. The vector $\mathbf{w}'$ is a k-approximate eigenvector of M'.

We may thus suppose that all coefficients of M are 0 or 1, i.e., that the set E of edges of G can be identified with a subset of $Q \times Q$. We now transform the graph G into a graph G' such that there are at most k edges going out of every vertex. For this, let Q' be the set of pairs (q, j) with $q \in Q$ and $1 \leq j \leq w_q$. For each $p \in Q$, we have

$$\sum_{q|(p,q)\in E} w_q \leq k w_p.$$

We may thus partition the pairs $(q, h) \in Q'$ in such a way that $(p, q) \in E$ in w_p groups $X_1, X_2, \ldots, X_{w_p}$ of at most k elements. The edges going out of (p, j) are all the pairs $((p, j), (q, h))$ such that $(q, h) \in X_j$. One can actually identify G with a multiset extension of G', where the set of multisets is $\{\bigcup_{1\leq j\leq w_p}(p, j) \mid p \in Q\}$ that we identify to Q. Let $I' = \{(i, j) \mid 1 \leq j \leq w_i\}$. Let $w'_{(p,j)} = 1$ for all (p, j) with $p \in Q$ and $1 \leq j \leq w_p$. Then, according to Proposition 10, the triple $(G', I', \mathbf{w}')$ recognizes the same sequence as $(G, i, \mathbf{w})$. Moreover, if $w_p = 1$ for all $p \in T$, let T' be set of all $(p, 1) \in Q'$ with $p \in T$. Then the triple (G', I', T') recognizes the same sequence as (G, i, T). If T is the set of vertices which have no outgoing edges, it is clear that the same holds for T'. ∎

We now come to our main result.

THEOREM 16. *Let $s = (s_n)_{n\geq 0}$ be a regular sequence of nonnegative integers, and let k be a positive integer such that $\sum_{n\geq 0} s_n k^{-n} \leq 1$. Then there is a k-ary rational tree having s as its generating sequence.*

Proof. Let us consider a regular sequence s and an integer k such that $\sum_{n\geq 0} s_n k^{-n} \leq 1$. Since the result holds trivially for $s(z) = 1$, we may suppose that $s_0 = 0$. Let (G, i, t) be a normalized representation of s, and let $\overline{G}$ be the closure of G as defined at the beginning of section 2.2. We denote by M (resp., $\overline{M}$) the adjacency matrix of G (resp., $\overline{G}$). Let $\overline{Q} = Q - \{t\}$ be the vertex set of $\overline{G}$. Let λ be the spectral radius of $\overline{M}$. By Proposition 8, the matrix $\overline{M}$ admits a positive k-approximate eigenvector $\overline{\mathbf{w}}$. By definition, we have $\overline{M}\overline{\mathbf{w}} \leq k\overline{\mathbf{w}}$.

Let $\mathbf{w}$ be the Q-vector defined by $w_q = \overline{w}_q$ for all $q \in \overline{Q}$ and $w_t = \overline{w}_i$. Then, since there is no edge going out of t in G, $\mathbf{w}$ is a positive k-approximate eigenvector of M. Let $\mathbf{t}$ be the Q-vector which is the characteristic vector of the vertex t. Let $m = w_i$.

By Theorem 12 there exists an admissible extension H of G with respect to $\mathbf{w}$ and m. Let U be the transfer matrix, and let $\mathbf{W} = U\mathbf{w}$. Since $w_t \equiv 0 \bmod m$, we

may choose H with the following additional property. For all $\mathbf{u} \in S$, either $u_t = 0$ or $\mathbf{u} = \mathbf{t}$.

According to Proposition 10, the sequence s is recognized by $(H, \mathbf{J}, \mathbf{X})$, where $\mathbf{J}$ is the characteristic row vector of $\mathbf{i}$ and $\mathbf{X}$ is the characteristic column vector of $\mathbf{t}$. This means that s is recognized by the normalized representation consisting of the graph H, the initial vertex $\mathbf{i}$ that we identify to i, and the terminal vertex $\mathbf{t}$ that we identify to t.

Let N be the adjacency matrix of H. By Proposition 14, the vector $\lceil \frac{\mathbf{W}}{m} \rceil$ is a positive k-approximate eigenvector of N. Remark that $\lceil \frac{\mathbf{W}}{m} \rceil_i = \lceil \frac{\mathbf{W}}{m} \rceil_t = 1$.

We may now apply Lemma 15 to construct a triple (H', I', T') equivalent to (H, i, t). The set T' is the set of leaves of H'. Since $\lceil \frac{\mathbf{W}}{m} \rceil_i = 1$, I' is reduced to one vertex i'. Since H' admits a k-approximate eigenvector with all components equal to one, the graph H' is of outdegree at most k. Finally, s is the generating sequence of the covering tree of H' starting at i'. This tree is k-ary and regular. □

Let us consider the above constructions in the particular case of the equality in Kraft's inequality. In this case, the result is a complete k-ary tree. Indeed, by Proposition 8, the matrix $\overline{M}$ admits a positive integral eigenvector $\mathbf{w}$ for the eigenvalue k. We have, for all $p \in \overline{Q}$,

$$\sum_{q \in \overline{Q}} M_{p,q} w_q = k w_p.$$

As a consequence, for any $\mathbf{u} \neq \mathbf{t}$, we have

$$\sum_{\mathbf{v} \in S} N_{\mathbf{u},\mathbf{v}} W_{\mathbf{v}} = k W_{\mathbf{u}}.$$

Then the graph constructed in Lemma 15 is of constant outdegree k. Thus the k-ary tree obtained is complete.

Let us consider the complexity of the construction used in the proof of Theorem 16. Let n be the number of vertices of the graph G giving a normalized representation of s. The size of the integer $m = w_i$ is exponential in n (see section 2.4). Thus the number of vertices of the graph H is bounded by a double exponential in n. The final regular tree is the covering tree of a graph whose set of vertices has the same size in order of magnitude.

Let, for example, s be the sequence defined by

$$s(z) = \frac{z^2}{(1 - z^2)} + \frac{z^2}{(1 - 5z^3)}.$$

Since $s(1/2) = 1$, it satisfies the Kraft equality for $k = 2$. The sequence s is recognized by (G, i, t), where $G = (Q, E)$ is the graph given in Figure 8 with $Q = \{1, 2, 3, 4, 5, 6, 7\}$, $i = 1$, $t = 4$. The adjacency matrix of G admits the 2-approximate eigenvector represented in Figure 8, where the coefficients of $\mathbf{w}$ are represented in squares beside the vertices. Thus $m = 3$.

An admissible extension H of G with respect to $\mathbf{w}$ and m is given in Figure 9. In this figure, each multiset of S is represented by a sequence of vertices with repetitions corresponding to the multiplicity. For example, the multiset $\mathbf{u} = (0, 0, 1, 0, 0, 2, 0)$ is represented by $(3, 6, 6)$. The sequence s is recognized by the normalized representation $(H, 1, 4)$, where the initial and final vertices are named as they appear in Figure 9. The coefficients of $\lceil \frac{\mathbf{W}}{m} \rceil$ are represented in squares beside the vertices.

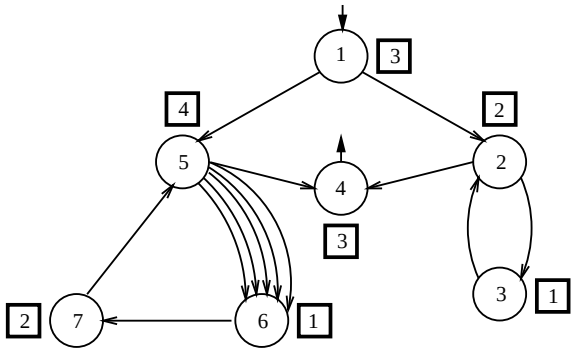

FIG. 8. *A normalized representation of s.*

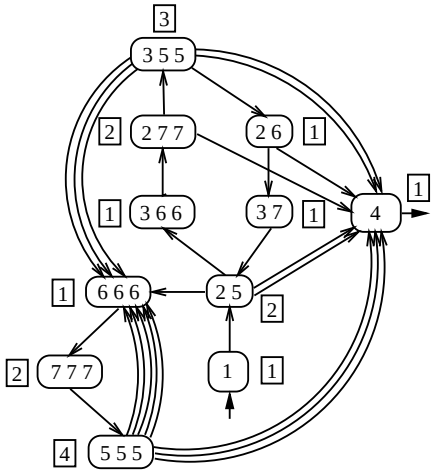

FIG. 9. *An admissible extension H.*

A regular binary tree T having s as a generating sequence of leaves is given in Figure 10. In this figure, the nodes have been renumbered, with the children of a node with a given label represented only once. The leaves of the tree are indicated by black boxes. The tree itself is obtained from the graph of Figure 9 by application of the construction of Lemma 15. For example, the vertex $(2, 5)$, which has coefficient 6 in $\mathbf{W}$, is split into two vertices named 2 and 3 in the tree.

This example was suggested to us by Christophe Reutenauer [18].

5. Generating sequence of nodes. In this section, we consider the generating sequence of the set of all nodes in a tree instead of just the set of leaves. This is motivated by the fact that in search trees, the information can either be carried by the leaves or by all the nodes of the tree. We will see that the complete characterization of the generating sequences of nodes in regular trees (Theorem 17) is more complicated than the one for leaves.

Soittola (see [19, p. 104]) has characterized the series which are the generating sequences of nodes in a regular tree. We characterize the ones that correspond to k-ary trees (Theorem 17). We also give a more direct construction in a particular case (Theorem 19).

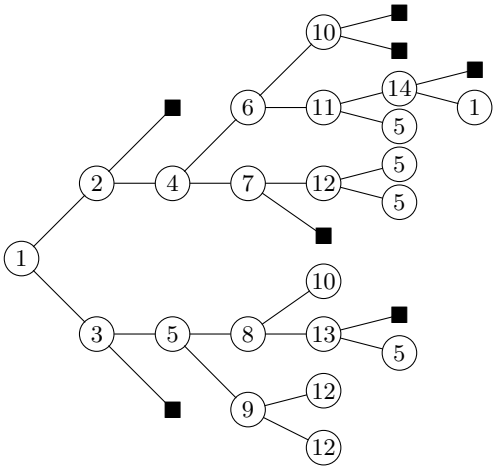

FIG. 10. *A regular binary tree with length distribution s.*

Let T be a tree. The generating sequence of nodes of the tree T is the sequence $t = (t_n)_{n\geq 0}$, where t_n is the number of nodes of T at height n. The sequence t satisfies $t_0 \leq 1$ and, moreover, if T is a k-ary tree, the condition

$$t_n \leq kt_{n-1}$$

for all $n \geq 1$. If T is a regular tree, then t is a regular sequence. We now completely characterize the regular sequences t that are the generating sequences of nodes of a k-ary regular tree.

THEOREM 17. *Let $t = (t_n)_{n\geq 0}$ be a regular sequence, and let k be a positive integer. The sequence $(t_n)_{n\geq 0}$ is the generating sequence of nodes of a k-ary regular tree iff it satisfies the following conditions.*

(i) *The convergence radius of t is strictly greater than $1/k$.*

(ii) *The sequence $s(z) = t(z)(kz-1)+1$ is regular.*

Proof. Let us first show that the conditions are necessary. Let $\overline{T}$ be the complete k-ary tree obtained by adding i new leaves to each node that has $k-i$ children. Since T is a regular tree, $\overline{T}$ is also regular.

Let s be the generating sequence of leaves of $\overline{T}$. Since $\overline{T}$ is complete, $s(1/k) = 1$. Since $kt_n = s_{n+1} + t_{n+1}$ for all $n \geq 0$, we have

$$1 - s(z) = t(z)(1 - kz).$$

Since s is a regular sequence, its radius of convergence is strictly larger than $1/k$ (see section 2.4). Since the value of the derivative of s at $z = 1/k$ is $kt(1/k)$, the same holds for t. This proves the necessity of the conditions.

Conversely, if t satisfies the conditions of the theorem, the regular series $s(z) = t(z)(kz-1)+1$ satisfies $s(1/k) = 1$. Thus, by Theorem 16, s is the generating sequence of leaves of a complete k-ary regular tree. The internal nodes of this tree form a k-ary regular tree whose generating sequence of nodes is t. □

The sequence s defined by condition (ii) is rational as soon as t is regular and therefore rational. Given a regular sequence t, condition (ii) is decidable in view of

a theorem of Soittola [19], also found independently in [13] and recalled below. We say that a rational sequence has a *dominating root*, either if it is a polynomial or if it has a real positive pole which is strictly smaller than the modulus of any other one. A sequence r is a *merge* of the sequences r_i if there is an integer p such that

$$r(z) = \sum_{i=0}^{p-1} z^i r_i(z^p).$$

THEOREM 18 (Soittola). *A sequence of nonnegative integers $r = (r_n)_{n\geq 0}$ is regular iff it is a merge of rational sequences having a dominating root.*

This result shows that it is decidable if a rational series is regular (see [19]). In the positive case, there is an algorithm computing a representation of the sequence.

We may observe that condition (ii) of the theorem implies the nonnegativity of the coefficients of the series s and thus the inequality for all $n \geq 1, t_n \leq kt_{n-1}$. It also implies that $t_0 \leq 1$.

We now show that there are regular sequences t satisfying $t_n \leq kt_{n-1}$ for all $n \geq 1$, and condition (i) of the theorem and such that the sequence $s(z) = t(z)(kz-1)+1$ is not regular. The example is based on an example of a rational sequence with nonnegative coefficients and which is not regular (see [10, p. 95]). Let

$$r_n = b^{2n}\cos^2(n\theta)$$

with $\cos(\theta) = \frac{a}{b}$, where the integers a, b are such that $b \neq 2a$ and $0 < a < b$. The sequence r is rational, has nonnegative integer coefficients, and is not regular. Its poles are $\frac{1}{b^2}$, $\frac{1}{b^2}e^{2i\theta}$, and $\frac{1}{b^2}e^{-2i\theta}$. We now define the sequence t as follows:

$$\begin{aligned} t_{2h} &= k^h, \\ t_{2h+1} &= k^h + r_h. \end{aligned}$$

We also assume that $b^2 < k$. By Soittola's theorem, the sequence t is regular since it is a merge of rational sequences having a dominating root. The convergence radius of t is $\frac{1}{\sqrt{k}} > \frac{1}{k}$. Therefore, the sequence t satisfies the first condition of Theorem 17. Let s be the sequence defined by $s(z) = t(z)(kz-1)+1$. If $h = 2p$ is even,

$$\begin{aligned} s_h &= kt_{h-1} - t_h \\ &= kk^{p-1} + kr_{p-1} - k^p + 1 = kr_{p-1} + 1. \end{aligned}$$

Thus the sequence s is not regular.

The above example does not work for the small values of k (the least value is $k = 10$). We do not know of similar examples for $2 \leq k \leq 9$.

We finally describe a particular case of Theorem 17 in which one has a relatively simple method, based on the multiset construction, to build the regular tree with a given generating sequence of nodes. This avoids the use of Soittola's characterization which leads to a method of higher complexity.

A *primitive* representation of a regular sequence s is a representation $(G, \mathbf{i}, \mathbf{t})$ such that the adjacency matrix of G is primitive. The following result is proved in [7] with a different proof using the state-splitting method of symbolic dynamics. The proof given here relies on a simpler construction.

THEOREM 19. *Let $t = (t_n)_{n\geq 0}$ be a regular sequence, and let k be a positive integer such that $t_0 = 1$, $t_n \leq kt_{n-1}$ for all $n \geq 1$, and such that*

(i) *the convergence radius of t is strictly greater than $1/k$, and*
(ii) *t has a primitive representation.*

Then $(t_n)_{n\geq 0}$ is the generating sequence of nodes by height of a k-ary regular tree.

We are going to give a proof of the theorem which uses the multiset construction. We shall use the following lemma that we establish first.

LEMMA 20. *Let M be a primitive matrix with spectral radius λ. Let $\mathbf{v}$ be a nonnull and nonnegative integral vector, and let k be an integer such that $\lambda < k$. Then there is a positive integer n such that $M^n\mathbf{v}$ is a positive k-approximate eigenvector of M.*

Proof. For a primitive matrix M with spectral radius λ, it is known that the sequence $((\frac{M}{\lambda})^n)_{n\geq 0}$ converges to $\mathbf{r}.\mathbf{l}$, where $\mathbf{r}$ is a positive right eigenvector and $\mathbf{l}$ is a positive left eigenvector of M for the eigenvalue λ with $\mathbf{l}\cdot\mathbf{r} = 1$ (see, for example, [15, p. 130]). Thus $(\frac{M^n}{\lambda^n}\mathbf{v})_{n\geq 0}$ converges to $\mathbf{r}.\mathbf{l}.\mathbf{v}$, which is equal to $\rho\mathbf{r}$, where ρ is a nonnegative real number. Since $M\mathbf{r} = \lambda\mathbf{r}$, we get, for a large enough integer n,

$$M\frac{M^n}{\lambda^n}\mathbf{v} \leq k\frac{M^n}{\lambda^n}\mathbf{v},$$

or, equivalently, $MM^n\mathbf{v} \leq kM^n\mathbf{v}$. If n is large enough, we moreover have $M^n\mathbf{v} > 0$ since M is primitive. □

We now give the proof of Theorem 19. It uses a shift of indices of the sequence to obtain a new sequence to which a simple application of the multiset construction can be applied.

Proof. Since t is regular, it is recognized by a triple $(G, \mathbf{i}, \mathbf{t})$, where $G = (Q, E)$ is a finite graph. Let M be the adjacency matrix of G.

For each $n \geq 0$, we have

$$t_n = \mathbf{i}M^n\mathbf{t}.$$

We denote by λ the spectral radius of M. By Proposition 6 the positive real number $1/\lambda$ is the radius of convergence of t. Thus $\lambda < k$ by hypothesis (i). Since M is a primitive matrix, by Lemma 20, there exists a positive integer n_0 such that $M^{n_0}\mathbf{t}$ is a positive k-approximate eigenvector of M.

Let $\mathbf{w} = M^{n_0}\mathbf{t}$, and let t' be the sequence defined by $t'_n = t_{n+n_0}$ for $n \geq 0$. Thus, for each $n \geq 0$,

$$t'_n = \mathbf{i}M^n\mathbf{w}.$$

The sequence t' is thus recognized by the triple $(G, \mathbf{i}, \mathbf{w})$. Note that $t'_0 = \mathbf{i}\cdot\mathbf{w}$.

Let $H = (S, R)$ be the extension of G obtained by the multiset construction in the following way. When we reach a vertex $\mathbf{u}$ of H, we partition $\mathbf{u}M$ in multisets $\mathbf{v}$ of degree 1, i.e., such that $\mathbf{v}$ is a 0, 1-vector with $v_q = 0$ for all $q \in Q$ except one. All elements of S are thus elements of Q except perhaps the initial vertex $\mathbf{i}$. If $\mathbf{i}$ is of degree 1, the number of elements of S is then equal to the number of elements of Q.

Let U be the transfer matrix of the extension. Since $\mathbf{w}$ is a positive k-approximate eigenvector of M, by Proposition 11, the vector $\mathbf{W} = U\mathbf{w}$ is a positive k-approximate eigenvector of the adjacency matrix of H. By Proposition 10, the triple $(H, \mathbf{i}, \mathbf{W})$ is equivalent to $(G, \mathbf{i}, \mathbf{w})$.

We now apply Lemma 15 to the graph H. We use $\mathbf{i}$ as initial vertex and the k-approximate eigenvector $\mathbf{W}$. Since we only use the first assertion of the lemma, we will not use any set T of terminal states. According to the lemma, we construct a graph H' and a set of vertices I' of H' such that H' admits the k-approximate vector

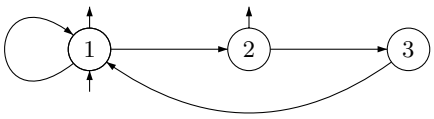

FIG. 11. *A primitive representation G of t.*

$\mathbf{W}'$ with all components equal to 1, and $(H', I', \mathbf{W}')$ is equivalent to $(H, \mathbf{i}, \mathbf{W})$. Thus H' is k-ary. Note that I' has $W_{\mathbf{i}} = \mathbf{i} \cdot \mathbf{w} = t_{n_0}$ elements.

Let T_p be the covering tree of H' starting at the state p of I'. Each T_p is a regular k-ary tree. Then t' is the sum of the generating sequences of nodes of the trees T_p for $p \in I'$.

Finally, we build a finite k-ary tree T' whose generating sequence of nodes is $(t_0, t_1, \ldots, t_{n_0})$. This can actually be done since $t_0 = 1$ and $t_n \leq kt_{n-1}$ for $n \geq 1$. We then identify bijectively each leaf at height n_0 of T' to the root of a tree T_j. We get a regular k-ary binary tree whose generating sequence of nodes is t. □

Let, for example, t be the series recognized by the graph G of Figure 11 with

$$\mathbf{i} = \begin{bmatrix} 1 & 0 & 0 \end{bmatrix} \text{ and } \mathbf{t} = \begin{bmatrix} 1 \\ 1 \\ 0 \end{bmatrix}.$$

The adjacency matrix M of G is the primitive matrix

$$M = \begin{bmatrix} 1 & 1 & 0 \\ 0 & 0 & 1 \\ 1 & 0 & 0 \end{bmatrix}.$$

Its spectral radius is less than 2. The hypotheses of Theorem 19 are thus satisfied. We apply the method described above. We have

$$M^2\mathbf{t} = \begin{bmatrix} 2 \\ 1 \\ 2 \end{bmatrix} \text{ and } M^3\mathbf{t} = \begin{bmatrix} 3 \\ 2 \\ 2 \end{bmatrix}.$$

Since $M^3\mathbf{t} \leq 2M^2\mathbf{t}$, $M^2\mathbf{t}$ is an approximate eigenvector of M. We thus set $n_0 = 2$ and $\mathbf{w} = M^2\mathbf{t}$. The graph H is the same as the graph G of Figure 11. The vector $\mathbf{W}$ is thus

$$\mathbf{W} = \begin{bmatrix} 2 \\ 1 \\ 2 \end{bmatrix}.$$

The graph H' is represented on the left side of Figure 12. We finally obtain the binary regular tree T represented on the right side of Figure 12. (The nodes of the tree have been renumbered.)

Acknowledgments. The authors would like to thank Jean Berstel, Christophe Reutenauer, and the anonymous referees for their help to improve the presentation of our paper.

AN 8-APPROXIMATION ALGORITHM FOR THE SUBSET FEEDBACK VERTEX SET PROBLEM*

GUY EVEN†, JOSEPH (SEFFI) NAOR‡, AND LEONID ZOSIN§

Abstract. We present an 8-approximation algorithm for the problem of finding a minimum weight *subset feedback vertex set* (or SUBSET-FVS, in short). The input in this problem consists of an undirected graph $G = (V, E)$ with vertex weights $c(v)$ and a subset of vertices S called *special* vertices. A cycle is called *interesting* if it contains at least one special vertex. A subset of vertices is called a SUBSET-FVS with respect to S if it intersects every interesting cycle. The goal is to find a minimum weight SUBSET-FVS. The best previous algorithm for the general case provided only a logarithmic approximation factor. The minimum weight SUBSET-FVS problem generalizes two NP-complete problems: the minimum weight feedback vertex set problem in undirected graphs and the minimum weight multiway vertex cut problem. The main tool that we use in our algorithm and its analysis is a new version of multicommodity flow, which we call *relaxed multicommodity flow*. Relaxed multicommodity flow is a hybrid of multicommodity flow and multiterminal flow.

1. Introduction.

We consider in this paper the problem of finding a minimum weight *subset feedback vertex set* (or SUBSET-FVS, in short). The input in this problem consists of an undirected graph $G = (V, E)$ with vertex weights $c(v)$ and a subset of vertices S called *special* vertices. A cycle is called *interesting* if it contains at least one special vertex. A subset of vertices is called a SUBSET-FVS with respect to S if it intersects every interesting cycle. The goal is to find a minimum weight SUBSET-FVS.

The minimum weight SUBSET-FVS problem generalizes two NP-complete problems: When $S = V$, this is simply the minimum weight feedback vertex set problem in undirected graphs [16, 9], and when S contains a single special vertex, the SUBSET-FVS problem is equivalent to the minimum weight vertex multiway cut problem [5]. In the multiway cut problem, the input consists of a weighted graph and a set T of terminals, and the goal is to disconnect the terminals from each other by removing a set of vertices of minimum weight. The multiway cut problem is reduced to the SUBSET-FVS problem by adding a special (infinite-weight) vertex to the graph and connecting it to all the terminals. Conversely, the SUBSET-FVS problem with a single special vertex is reduced to a multiway cut problem by defining all the neighbors of the special vertex as terminals and removing the special vertex. Thus, the SUBSET-FVS problem

defines a full spectrum of feedback set problems which are categorized by the number of special vertices. Another motivation for the SUBSET-FVS problem is that heuristics for genetic linkage analysis require solving instances of the SUBSET-FVS problem [8].

Our main result in this paper is an algorithm that approximates the SUBSET-FVS problem by a factor of 8. This improves on the approximation algorithm for the SUBSET-FVS problem presented in [8] that achieves a factor of $\min\{\log|S|, \log\tau^*, 2\Delta\}$, where τ^* denotes the value of an optimal fractional solution, and Δ is the maximum degree. Our result almost matches the 2-approximation algorithms known for the vertex multiway cut problem [10] and for the feedback vertex problem [3, 2]. We remark that our algorithm requires solving linear programs exactly, and in this sense it is not a combinatorial algorithm.

The main tool that we use in our algorithm is a new version of multicommodity flow which we call *relaxed multicommodity flow*. Relaxed multicommodity flow is a hybrid of multicommodity flow and multiterminal flow. In multicommodity flow, for each edge, the capacity constraints apply to the total flow of all the commodities. In multiterminal flow, for each edge, the capacity constraints only apply to each commodity separately.

In relaxed multicommodity flow, there are two types of capacity constraints. First, the *intracommodity* constraints are single commodity capacity constraints that apply to each commodity separately. Second, the *intercommodity* constraints are constraints on the joint flow of the commodities. The intercommodity constraints used here are defined as follows: For every edge we consider the maximum flow, among all the commodities, which is shipped along it; we require that for every vertex, the sum of the maximum flows shipped along the edges incident to it is bounded by four times the weight of the vertex.

Even et al. [8] formulate the subset feedback set problem as an integer linear program and show that the gap between an optimal integral solution and an optimal (fractional) solution to the linear relaxation of this program can be as large as $\Omega(\log|S|)$. This means that an approximation algorithm which is based on rounding a fractional solution to an integral solution cannot achieve a constant approximation factor. Since the linear program for the subset feedback set problem is a "covering" problem, the dual problem is a "packing" problem, which in fact can be interpreted as a multicommodity flow problem. In the context of approximation algorithms for covering problems, the dual packing program usually serves as a lower bound on the optimal integral solution, and the approximation factor is measured with respect to this lower bound. This motivates replacing (standard) multicommodity flow by relaxed multicommodity flow as the dual problem of the SUBSET-FVS problem. This relaxation allows us to increase the total amount of flow shipped in the graph. We show that this provides a better lower bound on the optimal solution, yielding a constant approximation factor.

Suppose that a demand vector specifies for each source-sink pair (commodity) the amount of flow that needs to be shipped from the source to the sink. We say that a flow function *realizes* a demand vector if it ships for each commodity the amount of flow specified by the demand vector. A *tight* cut in the context of a relaxed multicommodity flow problem is a multiset of vertices which are tight with respect to the intracommodity constraints, called *intrasaturated vertices*, and also a set of vertices for which the intercommodity constraints are tight, called *intersaturated vertices*.

Tight cuts play an important role in identifying an approximate SUBSET-FVS

in our algorithm. Clearly, the weight of the intrasaturated vertices in a tight cut can be at most the sum of the demands. Thus, the key notion in the analysis of the approximation algorithm is bounding the weight of the intersaturated vertices in a tight cut. Indeed, our main theorem (Theorem 4.4) bounds the weight of the vertices that are intersaturated in every realization of a demand vector by the sum of the demands. Loosely speaking, Theorem 4.4 functions as an approximate "min-cut max-flow" theorem and implies that the total weight of the saturated vertices (both intersaturated and intrasaturated) in the cut is at most twice the sum of the demands.

1.1. Related work. Minimum weight feedback sets and subset feedback sets in *directed* graphs were considered in several papers [18, 20, 17, 6, 7]. Note that in the directed case, the vertex and edge versions are equivalent. The best known approximation factor for the subset feedback set in the directed case is $O(\min\{\log \tau^* \log\log \tau^*, \log |S| \log\log |S|\})$, where τ^* denotes the value of an optimal fractional solution [6]. Factor two approximation algorithms for the feedback vertex set problem in undirected graphs were given by [3, 2]. An approximation algorithm with a factor of two for the subset feedback edge set problem was given by [8]. Recently, Goemans and Williamson [11] considered a generalization of the SUBSET-FVS problem in undirected planar graphs and obtained a 9/4-approximation algorithm for their problem.

The approximation algorithm for the SUBSET-FVS problem turns out to be much more complicated than the approximation algorithm for the subset feedback edge problem presented by [8]. This is in accordance with conventional wisdom that in undirected graphs, optimization problems on vertices are harder than their counterparts on edges. For example, recall that the multiway cut problem is a special case of the subset feedback set problem. For the edge version, there is a rather simple 2-approximation algorithm [5]. (Recently, better bounds were obtained by [4, 15].) For the vertex version, [10] gives a *noncombinatorial* 2-approximation algorithm which is based on the observation that there exists an optimal solution in half-integers for the linear program for multiway cuts.

Recently, Naor and Zosin [19] improved the approximation factor for the directed multiway cut problem from $2 \log k$ to 2 using the relaxed multicommodity flow technique. However, [19] uses a completely different relaxation.

Organization. In section 2, a Gomory–Hu transformation and simplifying assumptions are presented. In section 3, the algorithm is overviewed. In section 4, the main theorem providing a bound on the sum of the weights of the vertices that are intersaturated by every relaxed multicommodity flow that supplies the demand vector is proved. In section 5, the approximation algorithm is presented. In section 6, the approximation factor is proved.

2. Preliminaries. In this section we define a transformation which is used by our algorithm and provide some simplifying assumptions. We henceforth refer sometimes to the weight of a vertex as its *capacity*, depending on the context.

2.1. A Gomory–Hu transformation. Let $G = (V, E)$ be an undirected graph where both edges and vertices are capacitated. Let C be a minimum cut separating source x from sink y in G. The cut C may contain both edges and vertices. Let $E(C)$ denote the edges in C, and let $V(C)$ denote the vertices in C. The removal of C from the graph partitions it into two parts, X and Y, where $x \in X$ and $y \in Y$ as can be seen in Figure 2.1.

Let R_x be the graph obtained from G by condensing the vertices in Y into a

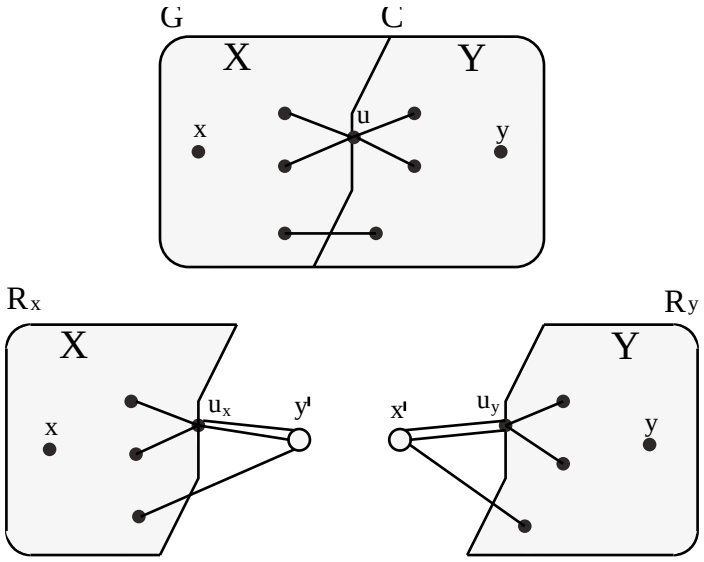

FIG. 2.1. *A Gomory–Hu transformation.*

single vertex denoted by y' which has infinite capacity. Let R_y be the graph obtained from G by condensing the vertices in X into a single vertex denoted by x' which has infinite capacity. Each vertex $u \in V(C)$ appears now in both R_x and R_y. We denote by u_x the copy of u in R_x, and by u_y the copy of u in R_y. We refer to u_x and u_y as *virtual copies* of u. We refer to the edges in R_x and R_y that correspond to edges in $E(C)$ or are adjacent to virtual copies of vertices in $V(C)$ as *virtual edges*. This construction is essentially the same as the condensation of a minimum cut performed by Gomory and Hu [12] (see also [14], and Granot and Hassin for the vertex version [13]).

The following two lemmas follow directly from [14, Lemma 5, p. 66; Lemma 6, p. 68] and from [13, Lemmas 4, 5, and 6].

LEMMA 2.1. *Let R_x and R_y denote the graphs obtained from applying a Gomory–Hu transformation to graph G with respect to minimum cut C between vertices x and y. Let $a \in X$ and $b \in Y$, and suppose that the capacity of C is at least d. Then, flow of value d can be shipped in G from a to b if and only if flow of value d can be shipped in R_x from a to y', and flow of value d can be shipped in R_y from b to x'.*

LEMMA 2.2 (under the same premises of Lemma 2.1). *Let $a, b \in X$ (or Y). Then, flow of value d can be shipped in R_x (or R_y) from a to b if and only if flow of value d can be shipped in G from a to b.*

2.2. Simplifying assumptions. For ease of presentation, we can assume without loss of generality the following assumptions.

(A) The set of finite weight vertices in the graph constitutes an independent set. This can easily be achieved by adding an infinite weight vertex on each edge.
(B) For each special vertex:
  (B1) It has infinite weight.
  (B2) It has degree two.
  (B3) Its two neighbors are not special vertices and have infinite weight.

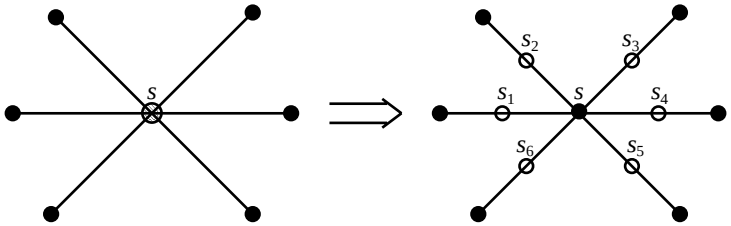

FIG. 2.2. *Transforming a special vertex with large degree.*

We justify Assumptions (B1), (B2), and (B3) as follows. Let s be a special vertex that does not satisfy (B1) or (B2). We insert a new vertex with infinite weight on each edge adjacent to s, add all new vertices to S, and delete s from S, as can be seen in Figure 2.2. Note that the new vertices are assigned infinite weight while vertex s retains its original weight.

Assumption (B3) can be satisfied by adding an infinite weight vertex on each edge in the graph. Thus, the set of special vertices constitutes an independent set, and each special vertex has degree two. Clearly, this transformation does not change the set of interesting cycles, nor does it change the optimal SUBSET-FVS.

Let $S = s_1, \ldots, s_k$ denote henceforth the set of special vertices. We denote the two neighbors of special vertex s_i for $1 \leq i \leq k$ by x_i and y_i.

3. Overview. In this section we overview the spirit of the algorithm and its proof. Our algorithm follows the basic framework suggested by [8] for approximating the SUBSET-FES problem. We first review the algorithm of [8].

Algorithm SUBSET-FES

Input: Graph $G = (V, E)$ with special vertices $s_1, \ldots, s_k$;
Output: SUBSET-FES M of G;

Notation: $V_i \triangleq V - \{s_i, \ldots, s_k\}$;
for $i = 1$ to k do
    $M_i \leftarrow$ minimum cut between x_i and y_i in the graph $G_i = (V_i, E - \cup_{j=1}^{i-1} M_j)$.
$M \leftarrow M_1 \cup \cdots \cup M_k$.

It is easy to see that the algorithm finds a feasible solution to the SUBSET-FES problem. Even et al. [8] show that the solution found by the algorithm approximates the optimal solution by a factor of 2. Algorithm SUBSET-FES can also be interpreted from a multicommodity flow perspective. Let each pair x_i, y_i, $1 \leq i \leq k$, define a commodity. The algorithm considers the commodities one-by-one and at each step maximizies the flow of the considered commodity. Notice that at the end of step i, $1 \leq i \leq k$, min-cut M_i is deleted from the graph and special vertex s_i is added back to the graph. In the end, we obtain a multicommodity flow function, where the flow of the different commodities is independent or nonaggregating.

The vertex version of Algorithm SUBSET-FES is not a good approximation algorithm for the SUBSET-FVS problem, as shown by the example depicted in Figure 3.1. To keep the drawing simple, the special vertices are not shown in Figure 3.1 (recall that special vertex s_i is connected to x_i and y_i). Assume that vertices $v_1, \ldots, v_k$ and $u_1, \ldots, u_k$ have unit weight. Let the weight of vertex w be $1+\epsilon$. The algorithm would

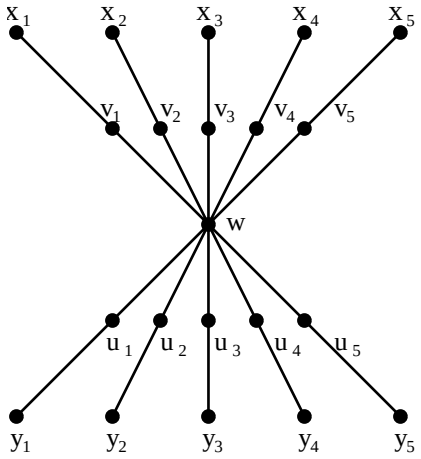

FIG. 3.1. *An example showing that the vertex version of Algorithm* SUBSET-FES *may only be a k-approximation for the* SUBSET-FVS *problem.*

proceed by assigning $M_i = \{v_i\}$, and the cost of the computed solution would be 5 (i.e., k, the number of special vertices), compared to the optimum solution that only contains vertex w.

Loosely speaking, we refine Algorithm SUBSET-FES by replacing the independence between the commodities by a relaxed multicommodity flow function. This means that in the ith iteration, the maximum flow (of value d_i) from x_i to y_i is computed such that $d^i = \{d_1, \ldots, d_i\}$ can be realized by a relaxed multicommodity flow function. A minimum cut (corresponding to the flow of the ith commodity) that disconnects x_i from y_i is computed with respect to the relaxed multicommodity flow function. The minimum cut contains vertices which are intersaturated by *every* relaxed multicommodity flow that realizes d^i, as well as vertices which are intrasaturated with respect to a commodity (one or more). The algorithm augments its solution by incrementally adding to the SUBSET-FVS the vertices belonging to the minimum cuts computed in each iteration.

It is crucial that the minimum cuts computed at each iteration are not deleted from the graph. Instead, a construction similar to the one used by Gomory and Hu [12] is employed with respect to the minimum cut computed at each iteration. This allows the flow which is computed in later iterations to either reuse a minimum cut computed at a previous iteration or go through the corresponding special vertex (but not both). We note that if we had deleted the minimum cuts from the graph (as in Algorithm SUBSET-FES), the value of the multicommodity flow function would have been much smaller than the weight of the minimum cuts $M_1, \ldots, M_k$.

The analysis rests on three key components. (a) The weight of the intersaturated vertices in a solution of a relaxed multicommodity flow problem is bounded by the sum of the demands (Theorem 4.4). (b) The relaxed flow which realizes $\boldsymbol{d}$ can be reconfigured so that the new source-sink pairs satisfy a separation property with respect to an optimal SUBSET-FVS (section 6.2). (c) The sum of the demands of a relaxed flow whose source-sink pairs satisfy a separation property with respect to a SUBSET-FVS is bounded by 4 times the weight of the SUBSET-FVS (Theorem 6.2).

The weight of the solution found by the algorithm equals the intersaturated vertices and intrasaturated vertices that are added to the solution. The weight of the intersaturated vertices, as well as the weight of the intrasaturated vertices, is bounded by the sum of the demands. The sum of the demands is then bounded by 4 times the weight of an optimal SUBSET-FVS using components (b) and (c), yielding an approximation factor of 8.

4. Relaxed multicommodity flow. In this section we define relaxed multicommodity flow which is a hybrid between multicommodity flow and multiterminal flow. In multicommodity flow, each commodity is subject to the capacity and preservation constraints, and the congestion constraints require that the sum of the flows of the different commodities do not exceed the edge/vertex capacities. In multiterminal flow, each commodity is subject to the capacity and preservation constraints, but there are no congestion constraints between them.

The source-sink pair of the ith commodity is denoted by a_i (source) and b_i (sink). We denote by $c(e)$ the capacity of edge e and by $c(v)$ the capacity of vertex v. We denote by $f_i(e)$ the amount of flow of commodity i on edge e. Denote by d_i, for $1 \le i \le k$, the amount of flow of commodity i shipped in the graph from a_i to b_i. Denote by $N(v)$ the set of edges adjacent to v, and for any $V' \subset V$, denote by $N(V')$ the set of edges which have at least one endpoint in V'. Denote by $f_{\max}(e)$ the value $\max_{1\le i\le k} f_i(e)$, i.e., $f_{\max}(e)$ equals the maximum flow along the edge e among all the commodities. To simplify notation, we also refer to the flow vector $(f_1, \ldots, f_k)$ as the flow f.

DEFINITION 4.1. *A multiterminal flow $f = (f_1, \ldots, f_k)$ between source-sink pairs $\{(a_i, b_i)\}_{i=1}^k$ is a* relaxed multicommodity flow *that realizes a demand vector $\boldsymbol{d} = (d_1, \ldots, d_k)$, if, for every $1 \le i \le k$, the flow supplied by f_i from a_i to b_i equals d_i, and the following constraints are satisfied.*

Intracommodity constraints. Each flow f_i is a single commodity flow. Namely,

(1) *for all $e \in E : f_i(e) \le c(e)$, and*

(2) *for all $v \in V : \sum_{e\in N(v)} f_i(e) \le 2 \cdot c(v)$.*

Intercommodity constraints. For all $v \in V : \sum_{e\in N(v)} f_{\max}(e) \le 4 \cdot c(v)$.

The intracommodity constraints are standard single commodity constraints. The sum of the flows of commodity i going through vertex v is bounded by $c(v)$. Note that in (2), each flow path passing through a nonterminal contributes twice its value to the left-hand side (LHS) and therefore the right-hand side (RHS) is $2 \cdot c(v)$. (As for sources and sinks, Assumption (B1) implies that they have infinite capacity.) The intercommodity constraints differ from (standard) multicommodity flow constraints in two respects. (i) For each edge e, the maximum, taken over all commodities on e, replaces the sum. (ii) The capacity of each vertex is multiplied by two and therefore the RHS is $4 \cdot c(v)$.

The relaxation of the intercommodity constraints is crucial for the success of the technique used in this paper in which flows of commodities are maximized one-by-one. The example depicted in Figure 4.1 shows that, without this relaxation, maximizing the flows of the commodities one-by-one could yield a total flow which is $1/(k-1)$ times smaller than the minimum cut that separates all source-sink pairs. Assume that vertices $v_1, v_2, \ldots, v_{k-1}$ have unit capacities. A unit flow between x_1 and y_1 would intersaturate the unit capacity vertices along the path, and no more flow could be pushed for the other commodities. This example shows that the intercommodity constraints need to be relaxed by a parameter α, where $\alpha > 1$. In section 6.4, we explain the choice $\alpha = 2$.

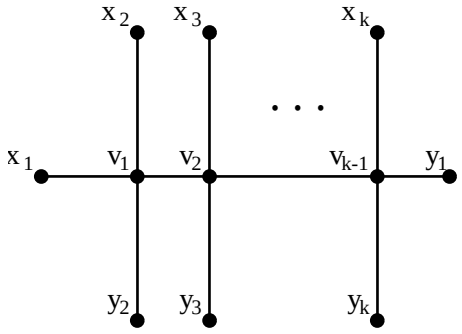

FIG. 4.1. *Relaxed multicommodity flow example.*

We define two types of *saturated* vertices with respect to f:

- Vertex $v \in V$ is called *intrasaturated* with respect to i if the intracommodity constraint corresponding to commodity i is tight with respect to v.
- Vertex $v \in V$ is called *intersaturated* if the intercommodity constraint with respect to v is tight.

Note that a vertex can be both intersaturated and intrasaturated with respect to more than one commodity.

Consider a network $N = (G, c)$, where G is a graph and c is a capacity function defined on the vertices and edges. We now define the notions of a *restricted* function $h : E \to R^{\geq 0}$ with respect to a network $N = (G, c)$ and the *restricted* network N^h with respect to a restricted function h.

DEFINITION 4.2. *Function h is called a restricted function for a network $N = (G, c)$ if*

(1) *for all $e \in E : h(e) \leq c(e)$, and*
(2) *for all $v \in V : \sum_{e \in N(v)} h(e) \leq 4 \cdot c(v)$.*

The restricted network N^h has the same vertex and edge set as N. The vertex capacities in N^h are the same as in N; the capacity of each edge e in N^h is set to $h(e)$.

Whenever it is clear which capacity function is attached to the edges of a network, we refer to the network as a graph. In particular, for simplicity we denote by G^f the restricted network N^f, where $N = (G, c)$.

The next claim follows directly from the previous definitions.

CLAIM 4.3. Let h be a restricted function for a graph G and suppose that for each $1 \leq i \leq k$, flow function f_i is a single commodity flow function in G^h that satisfies the capacity constraints. Then, $(f_1, \ldots, f_k)$ is a relaxed multicommodity flow in G.

4.1. Flow vs. intersaturated vertices. Consider source-sink pairs (a_i, b_i), $1 \leq i \leq k$, and a demand vector $\boldsymbol{d} = \{d_1, \ldots, d_k\}$. For simplicity of presentation, assume that all edges are uncapacitated, and there are no two finite weight vertices that are adjacent. Let I denote the set of intersaturated vertices that are saturated in *every* realization of $\boldsymbol{d}$. Note that in the case of single commodity flow, an edge that is saturated by every maximum flow function must belong to a minimum cut. We now state our main theorem which can be interpreted as an approximate "min-cut max-flow" theorem in the context of relaxed multicommodity flow.

THEOREM 4.4. *Suppose that a demand vector* $\boldsymbol{d} = \{d_1, \ldots, d_k\}$ *can be realized by a relaxed multicommodity flow function. Then,*

$$\sum_{v \in I} c(v) \leq \sum_{i=1}^{k-1} d_i.$$

The tightness of Theorem 4.4 follows from the example depicted in Figure 4.1. The relaxed multicommodity constraints enable one to push one unit of flow per commodity. Hence $\sum_{i=1}^{k-1} d_i = k-1$. The vertices $v_1, \ldots, v_{k-1}$ are all intersaturated by such a relaxed multicommodity flow, and hence $\sum_{v \in I} c(v) = k-1$, and tightness follows.

We need the following definition, claim, and lemma for proving the theorem.

DEFINITION 4.5. *A relaxed multicommodity flow function* f *is called simple if it has the following "minimal" property. For each commodity* i*, and for each edge* $e \in E$ *for which* $f_{\max}(e) = f_i(e)$*, if we decrease* $f_i(e)$ *by rerouting the flow (of possibly all commodities), then there exists an edge* $e' \in E$ *for which* $f_{\max}(e')$ *has to be increased.* Intuitively, a simple relaxed multicommodity flow function f does not contain spurious cycles for each commodity, and it "overlays" flow paths of different commodities as much as possible.

CLAIM 4.6. Let f be a relaxed multicommodity flow function that realizes demand vector $\boldsymbol{d}$. Then, there exists a simple relaxed multicommodity flow function f' that realizes demand vector $\boldsymbol{d}$ such that $f'_{\max}(e) \leq f_{\max}(e)$ for each edge $e \in E$.

Proof. Let g be a relaxed multicommodity flow function that realizes demand vector $\boldsymbol{d}$ and satisfies $g_{\max}(e) \leq f_{\max}(e)$ for all $e \in E$ such that it is impossible to decrease $g_{\max}(e)$ on some edge e without increasing $g_{\max}(e')$ on some other edge e'. We can obtain such a relaxed multicommodity flow function from f by subsequent minimization of $f_{\max}(e)$ on each edge $e \in E$ without increasing $f_{\max}(e')$ on some other edge e'.

Now we show that the following relaxed multicommodity flow function f' satisfies the claim. Flow function f' minimizes

$$\sum_{e \in E} |\{i | f'_i(e) = g_{\max}(e)\}|, \tag{4.1}$$

subject to the constraints that $f'_{\max}(e) \leq g_{\max}(e)$, and f' realizes demand vector $\boldsymbol{d}$.

We need only to show that f' is simple. Suppose that it is not simple. Then, there exists an edge e and commodity i for which $f'_{\max}(e) = f'_i(e)$ such that we can decrease $f'_i(e)$ by rerouting the flow without increasing $f'_{\max}(e')$ for any other edge $e' \in E$. Let f'' be the rerouted flow function, and let h denote the flow function which is the average (taken over each commodity) of f' and f''.

We claim that since h is the average of f' and f'', we have that for all edges $e' \in E$, $\{i | h_i(e') = g_{\max}(e')\} \subseteq \{i | f'_i(e') = g_{\max}(e')\}$. We also have that for edge e, $\{i | h_i(e) = g_{\max}(e)\} \subset \{i | f'_i(e) = g_{\max}(e)\}$. Clearly, h contradicts the objective function that f' minimizes. □

LEMMA 4.7. *Suppose that a simple relaxed multicommodity flow function* f *realizes demand vector* $\boldsymbol{d} = \{d_1, \ldots, d_k\}$*. Let* $V' \subseteq V$ *contain only finite weight vertices. (By Assumption* (A)*,* V' *is an independent set.) Then, there exists a relaxed multicommodity flow function* g *that also realizes demand vector* $\boldsymbol{d}$ *satisfying that for each*

edge $e \in E$, $g_{\max}(e) \leq f_{\max}(e)$, *and*

$$\sum_{e \in N(V')} g_{\max}(e) - 2 \cdot \sum_{v \in V'} c(v) \leq 2 \cdot \sum_{i=1}^{k-1} d_i. \tag{4.2}$$

Proof. The proof is by induction on k. For $k = 1$, f is a single commodity flow function, and thus the RHS of (4.2) is 0. The LHS of (4.2) is not positive because of the intracommodity constraints. We assume the induction hypothesis holds for $k-1$, and we prove it for k. Without loss of generality, let d_1 denote the minimum demand in $\boldsymbol{d}$. Let V'' contain all vertices $v \in V'$ for which there exists an edge $e \in N(v)$ such that $f_1(e) < f_{\max}(e)$. We show that it suffices to prove the induction hypothesis for vertices in V'' only. Let g be a relaxed multicommodity flow function that satisfies the induction hypothesis (or the lemma) for V''. Since $g_{\max}(e) \leq f_{\max}(e)$ for all $e \in E$, we have that $g_{\max}(e) \leq f_{\max}(e) = f_1(e)$ for all $e \in N(V' - V'')$. By the intracommodity constraint for commodity 1, for all $v \in V$, $\sum_{e \in N(v)} f_1(e) \leq 2 \cdot c(v)$. Therefore, g satisfies

$$\sum_{e \in N(V' - V'')} g_{\max}(e) - 2 \cdot \sum_{v \in V' - V''} c(v) \leq 0,$$

implying that g satisfies the induction hypothesis for V' too.

An edge $e = (u, v)$, where $c(v)$ is finite and $v \in V''$ is called *critical* with respect to commodity 1 if: (i) $f_{\max}(e) = f_1(e)$; (ii) $f_{\max}(e) > f_i(e)$ for all $i > 1$.

The *easy case* is when each flow path of commodity 1 contains at most two critical edges. In this case, remove the flow of commodity 1 from the graph. The relaxed multicommodity flow $(f_2, \ldots, f_k)$ is not necessarily simple. Let f' be a simple relaxed multicommodity flow function that realizes demand vector $\{d_2, \ldots, d_k\}$ and satisfies that for each edge $e \in E$, $f'_{\max}(e) \leq f_{\max}(e)$. By Claim 4.6, flow function f' exists.

The induction hypothesis states that there exists a relaxed multicommodity flow function g' that satisfies demand vector $\{d_2, \ldots, d_k\}$ such that for all $e \in E$, $g'_{\max}(e) \leq f'_{\max}(e)$. Flow function g' also satisfies, for V'',

$$\sum_{e \in N(V'')} g'_{\max}(e) - 2 \cdot \sum_{v \in V''} c(v) \leq 2 \cdot \sum_{i=2}^{k-1} d_i. \tag{4.3}$$

Now extend g' to g by adding commodity 1 back to the graph, i.e., $g_1(e) = f_1(e)$ for all $e \in E$. We claim that $g_{\max}(e) > g'_{\max}(e)$ only if e is critical with respect to commodity 1: if $g_{\max}(e) > g'_{\max}(e)$, then $f_1(e) = g_1(e) > g'_i(e)$. Since e is not critical, there exists a commodity $i > 1$ such that

$$f_i(e) = f_{\max}(e) \geq f_1(e).$$

Hence, $f_i(e) > g'_i(e) = g_i(e)$. Thus, the construction of g contradicts the fact that f is simple, yielding that if $g_{\max}(e) > g'_{\max}(e)$, then e is critical, as claimed.

The effect of extending g' to g in (4.3) is as follows. The RHS increases by $2d_1$. The LHS increases due to the critical edges: we change $g'_{\max}(e)$ to $f_1(e) = g_1(e)$ in $\sum_{e \in N(V'')} g'_{\max}(e)$ only in terms corresponding to critical edges. Since every flow path of commodity 1 contains at most two critical edges, the increase of the LHS is also bounded by $2d_1$.

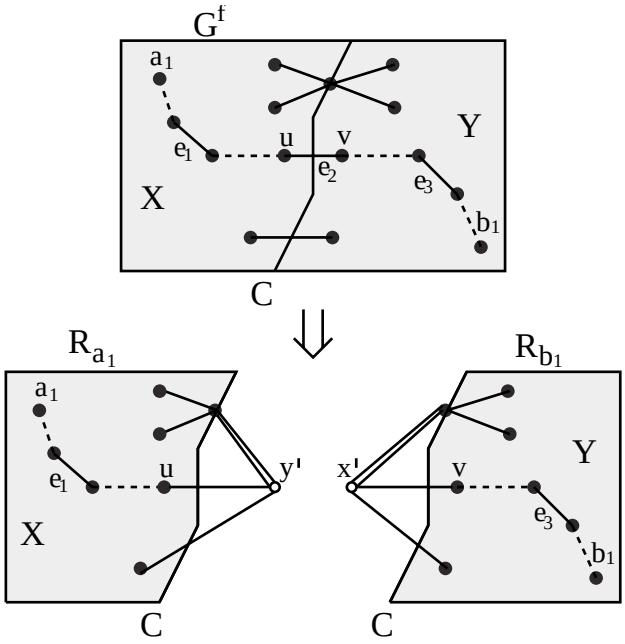

FIG. 4.2. *Construction of R_{a_1} and R_{b_1} from $G^{f_{\max}}$.*

However, the RHS of (4.3) is increased by $2d_1$. This completes the proof of the induction hypothesis for k in this case.

The *harder case* is when there exists a flow path of commodity 1 containing at least three critical edges, e_1, $e_2 = (u, v)$, and e_3, appearing in this order along the path from a_1 to b_1. By Definition 4.2, we may interpret $f_{\max}$ also as a restricted function for G. Construct the restricted graph $G^{f_{\max}}$. Commodity f_1 is a standard single commodity flow in $G^{f_{\max}}$. We claim that in $G^{f_{\max}}$, any standard single commodity flow function that ships d_1 units of flow from a_1 to b_1 must saturate edge e_2. Otherwise, in $G^{f_{\max}}$ there exists a single commodity flow f_1' that ships d_1 units of flow from a_1 to b_1 and $f_1'(e_2) < f_1(e_2)$. Therefore, by Claim 4.3, there exists in G a relaxed multicommodity flow $f' = (f_1', f_2, \ldots, f_k)$ that contradicts the fact that f is simple. Therefore, in $G^{f_{\max}}$ there exists a minimum cut C separating u from v (the endpoints of e_2) which is saturated by flow f_1. Note that cut C may contain both edges and vertices. The removal of C from the graph partitions it into two parts, X and Y, where $u \in X$ and $v \in Y$. Since cut C is saturated by f_1, it also separates a_1 from b_1 in $G^{f_{\max}}$. Apply now the Gomory–Hu transformation (see section 2.1) to cut C and graph $G^{f_{\max}}$. We obtain two graphs, R_{a_1} with condensed vertex y' and R_{b_1} with condensed vertex x', as depicted in Figure 4.2. We assign capacity to edges $V(C) \times \{y'\}$ and $V(C) \times \{x'\}$ equal to the flow of f_1 along these edges, and zero capacity to edges in $V(C) \times V(C)$.

Before we can apply the induction hypothesis to R_{a_1} and R_{b_1}, we prove the following claim.

CLAIM 4.8.

(a) Each source-sink pair (for $i > 1$) must belong to either R_{a_1} or R_{b_1}.

(b) Each of the graphs R_{a_1} and R_{b_1} must contain at least one source-sink pair (for $i > 1$).

Proof of Claim 4.8. We first prove that for each commodity $i > 1$ we have that

either $a_i, b_i \in R_{a_1}$, or $a_i, b_i \in R_{b_1}$. Otherwise, suppose $a_i \in R_{a_1}$ and $b_i \in R_{b_1}$. Since $f_1(e_2) > f_i(e_2)$ and cut C is saturated by commodity 1, we get that $d_1 > d_i$, which contradicts the assumption that d_1 is the smallest demand.

We prove that each side must contain a source-sink pair. Assume without loss of generality that source-sink pairs (a_i, b_i) for $2 \le i \le t$ are in R_{a_1}, and source-sink pairs (a_i, b_i) for $t+1 \le i \le k$ are in R_{b_1}. We first claim that from Lemma 2.2, there exists in R_{a_1} a relaxed multicommodity flow function f^x that satisfies demand vector $\{d_1, d_2, \ldots, d_t\}$, where the source and sink of commodity 1 are a_1 and y'. Similarly, in R_{b_1} there exists a relaxed multicommodity flow function f^y that satisfies demand vector $\{d_1, d_{t+1}, \ldots, d_k\}$, where the source and sink of commodity 1 are x' and b_1. We note that for all edges $e \in R_{a_1}$, $f^x_{\max}(e) \le f_{\max}(e)$, and for all edges $e \in R_{b_1}$, $f^y_{\max}(e) \le f_{\max}(e)$.

We now show that $1 < t < k$. Let z_1 and z_2 denote the endpoints of e_1; suppose that z_1 has finite weight. By the definition of critical edges, it follows that $z_1 \in V''$. Hence, there exists an edge $e' \in N(z_1)$ and commodity $j > 1$ such that $f_{\max}(e') = f_j(e') > f_1(e')$. We show that the source-sink pair $a_j, b_j \in R_{a_1}$. If $a_j, b_j \in R_{b_1}$, then some of the flow paths of commodity j pass through cut C. In this case, we contradict the simplicity of f by rerouting flow as follows. For each flow path P_j of commodity j that passes through the cut C, we can take two flow paths P_1 and P_1' of commodity 1 that pass through the same edges or vertices of the cut C that P_j uses. Now, we can reroute each flow path P_j which is crossing the cut C in the following way. It will go from the cut C to a_1 using path P_1 and continue from a_1 to the cut C using path P_1'. Thus, we can reroute commodity j in R_{a_1} using the flow paths of commodity 1, yielding that $f_j(e') \le f_1(e')$. Therefore, $f_j(e')$ is decreased without increasing $f_{\max}(e'')$ for any other edge e''. This contradicts the fact that f is simple and hence $a_j, b_j \in R_{a_1}$ as claimed. Similarly, using critical edge e_3, we can prove that there exists a commodity j' such that $a_{j'}, b_{j'} \in R_{b_1}$. (Note that the fact that each side of the cut must contain at least one terminal pair implies that in the special case of two commodities the hard case does not occur.)

Now we can apply the induction hypothesis to graphs R_{a_1} and R_{b_1} and vertex sets $V'' \cap R_{a_1}$ and $V'' \cap R_{b_1}$ with respect to simple flow functions obtained from f^x and f^y. (Denote by $V(C)$ the vertices in C; note that each vertex $z \in V(C)$ appears in both R_{a_1} and R_{b_1}.) Denote by g^x the flow function in R_{a_1} that exists by the induction hypothesis and for which $g^x_{\max}(e) \le f^x_{\max}(e)$ for all $e \in R_{a_1}$. We get from the induction hypothesis that

$$\sum_{e \in N(V(C) \cap V'')} g^x_{\max}(e) + \sum_{e \in N(X \cap V'')} g^x_{\max}(e) - 2 \cdot \sum_{v \in V(C) \cap V''} c(v) - 2 \cdot \sum_{v \in X \cap V''} c(v) \le 2 \cdot \sum_{i=1}^{t-1} d_i. \tag{4.4}$$

Denote by g^y the flow function in R_{b_1} that exists by the induction hypothesis and for which $g^y_{\max}(e) \le f^y_{\max}(e)$ for all $e \in R_{b_1}$. We now get from the induction hypothesis that

$$\sum_{e \in N(V(C) \cap V'')} g^y_{\max}(e) + \sum_{e \in N(Y \cap V'')} g^y_{\max}(e) - 2 \cdot \sum_{v \in V(C) \cap V''} c(v) - 2 \cdot \sum_{v \in Y \cap V''} c(v) \le 2 \cdot \left(\sum_{i=t+1}^{k-1} d_i + d_1 \right). \tag{4.5}$$

By rerouting flow, similarly to the rerouting of flow in the proof of Claim 4.8, we can obtain, without loss of generality, that

(a) neither g^x nor g^y deliver flow along edges in $V(C) \times V(C)$;
(b) if terminal pair (a_i, b_i) is in X, and $e \in V(C) \times \{y'\}$, then $g_1^x(e) \geq g_i^x(e)$. A similar property holds for a terminal pair in Y and an edge in $V(C) \times \{x'\}$.

We now form a relaxed multicommodity flow function g in graph G by gluing together g^x and g^y. For commodity 1, $g_1(e) = g_1^x(e)$ for all $e \in R_{a_1} \cap G$, $g_1(e) = g_1^y(e)$ for all $e \in R_{b_1} \cap G$, and $g_1(e) = g_1^x(e)$ for all edges in G corresponding to virtual edges in R_{a_1} and R_{b_1}. Recall that virtual edges correspond to edges in the minimum cut C, and hence, for every virtual edge e, $g_1^x(e) = g_1^y(e)$. Consider a source-sink pair (a_j, b_j), $j > 1$. Suppose that $a_j, b_j \in R_{a_1}$. By Lemma 2.2 and by rerouting flow, we may assume that for every edge $e \in R_{b_1}$, $g_j(e) \leq g_1^y(e)$. Moreover, the construction of g_j implies that $g_j(e) = g_j^x(e)$ for every $e \in R_{a_1}$. The analogous property holds when a source-sink pair is in R_{b_1}.

We now apply Claim 4.3 to the flow functions $g_1, \ldots, g_k$ in graph G to obtain relaxed multicommodity flow function g such that it realizes demands $\{d_1, \ldots, d_k\}$, and it satisfies $g_{\max}(e) \leq g_{\max}^x(e)$ if $e \in R_{a_1}$, and $g_{\max}(e) \leq g_{\max}^y(e)$ if $e \in R_{b_1}$.

Divide the edges $N(V(C) \cap V'')$ into groups:

Group (a): edges incident to y' or x';

Group (b_x): edges incident to vertices in X;

Group (b_y): edges incident to vertices in Y;

Group (c): edges in $V(C) \times V(C)$.

Our assumption on g^x implies that edges of group (a) in X are saturated by g_1^x. Therefore, for every vertex $v \in V(C)$,

$$\sum_{e \in N(v) \cap \text{ group(a)}} g_{\max}^x(e) = c(v).$$

In addition, our assumption on g^x implies that the flow of g^x along edges of group (c) is zero. Therefore,

$$\sum_{e \in N(V(C) \cap V'')} g_{\max}^x(e) = \sum_{v \in V(C) \cap V''} c(v) + \sum_{e \in \text{ group}(\mathrm{b}_x)} g_{\max}^x(e). \tag{4.6}$$

The same applies for the other side of the cut. Therefore,

$$\sum_{e \in N(V(C) \cap V'')} g_{\max}^y(e) = \sum_{v \in V(C) \cap V''} c(v) + \sum_{e \in \text{ group}(\mathrm{b}_y)} g_{\max}^y(e). \tag{4.7}$$

Summing up inequalities (4.4) and (4.5), substituting summations of g^x and g^y with the RHSs of (4.6) and (4.7), and replacing g^x and g^y by g, we get that

$$\begin{aligned} 2 \cdot \sum_{v \in V(C) \cap V''} c(v) + \sum_{e \in N(V'')} g_{\max}(e) - 2 \cdot \sum_{v \in V''} c(v) - 2 \cdot \sum_{v \in V(C) \cap V''} c(v) \\ \leq 2 \cdot \sum_{i=1}^{k-1} d_i + 2 \cdot (d_1 - d_t). \end{aligned}$$

Therefore, we get that

$$\sum_{e \in N(V'')} g_{\max}(e) - 2 \cdot \sum_{v \in V''} c(v) \leq 2 \cdot \sum_{i=1}^{k-1} d_i,$$

proving the lemma. □

Proof of Theorem 4.4. By Lemma 4.7 there exists a flow function g such that

$$\sum_{e \in N(I)} g_{\max}(e) - 2 \cdot \sum_{v \in I} c(v) \leq 2 \cdot \sum_{i=1}^{k-1} d_i,$$

where V' is chosen to be I. For each vertex $v \in I$, $\sum_{e \in N(v)} g_{\max}(e) = 4 \cdot c(v)$ by the intercommodity constraints. Substituting in the above yields the theorem. □

Remark 1. Let α denote the factor by which the intercommodity constraints are relaxed. (In this paper, $\alpha = 2$.) Then, the bound in Theorem 4.4 can be generalized to

$$\sum_{v \in I} c(v) \leq \frac{1}{\alpha - 1} \cdot \sum_{i=1}^{k-1} d_i.$$

5. The approximation algorithm. In this section we describe a primal-dual algorithm for approximating the SUBSET-FVS problem. The algorithm computes a relaxed multicommodity flow in the graph, iteratively, for k iterations. The algorithm constructs a sequence of graphs $H_0, H_1, \ldots, H_k$, where H_i is constructed in the end of the ith iteration. Initially, we start with a graph H_0 which is obtained from G by removing all special vertices from it. All edges in H_0 are assigned infinite capacity. The graph H_i is constructed from H_{i-1} by a Gomory–Hu transformation based on the minimum cut that is computed in the ith iteration. Note that this transformation replaces the source-sink pair x_i, y_i with a new source-sink pair denoted by x'_i, y'_i. Moreover, capacities are assigned to virtual edges in H_i as described later.

We now describe iteration $i+1$ for $0 \leq i \leq k-1$ of the algorithm. The input is graph H_i and demand vector $d^i = \{d_1, \ldots, d_i\}$ which was realized in H_{i-1} in the ith iteration.

1. Compute a relaxed multicommodity flow function $f = (f_1, \ldots, f_{i+1})$ in H_i that
   (i) realizes demand vector d^i for commodities $1, \ldots, i$, for source-sink pairs x'_j, y'_j, $1 \leq j \leq i$ and
   (ii) maximizes d_{i+1}, the amount of flow of commodity $i+1$ shipped from x_{i+1} to y_{i+1}.
2. Compute a minimum cut C and deduce from it a subset of vertices $F_{i+1} = A_{i+1} \cup B_{i+1}$, where A_{i+1} is a subset of the vertices intrasaturated by f_{i+1}, and B_{i+1} is a subset of the vertices intersaturated by f.
3. Derive graph H_{i+1} from graph H_i by applying the Gomory–Hu construction to minimum cut C between x_{i+1} and y_{i+1}, and by adding back special vertex s_{i+1}.

The algorithm returns as a SUBSET-FVS the set $F \triangleq F_1 \cup \cdots \cup F_k$.

We now elaborate on the steps of the algorithm. In step 1, we compute a relaxed multicommodity flow function f that realizes demand vector d^i and maximizes d_{i+1}, the amount of flow of commodity $i+1$. The flow function f can be computed using a linear program. The objective function maximizes d_{i+1}. The constraints of the linear program are standard and include constraints for encoding the intercommodity requirements. These constraints use a new variable $f_{\max}(e)$ for every edge and are defined as follows. For each vertex $v \in V$ for which $c(v)$ is finite, we have

$$\forall\, e \in N(v),\ \ \forall\, j,\ 1 \le j \le (i+1):\ \ f_j(e) \le f_{\max}(e),$$
$$\forall v:\ \ \sum_{e \in N(v)} f_{\max}(e) \le 4 \cdot c(v).$$

We are interested in identifying the set of vertices in H_i that are intersaturated by every relaxed multicommodity flow function that realizes demand vector $\{d_1, \ldots, d_{i+1}\}$. Let this set be denoted by I_{i+1}. The vertices belonging to I_{i+1} can be identified as follows. For each vertex $v \in V$ where $c(v)$ is finite, independently solve the linear program that minimizes $\sum_{e \in N(v)} f^v_{\max}(e)$ subject to the constraints that f^v is a legal relaxed multicommodity flow function that realizes demand vector $\{d_1, \ldots, d_{i+1}\}$. Clearly, if v is intersaturated in f^v, then $v \in I_{i+1}$. By taking the flow function f to be the average over all flows $\{f^v\}_{v \in V}$, we get that f intersaturates only vertices in I_{i+1}.

We now elaborate on step 2 in the algorithm. Consider graph H_i with a single source-sink pair, edge capacities, and vertex weights. We note that edge capacities in H_i (which will be described in step 3) are defined during the construction of $H_0, \ldots, H_{i-1}$, and only virtual edges have been assigned finite capacity (vertices maintain their original capacities). Our goal is to compute a minimum cut with respect to the source-sink pair x_{i+1}, y_{i+1}. We define additional temporary capacities for the sake of computing the minimum cut as follows: For every vertex v in I_{i+1} and edge $e \in N(v)$, define $c(e) = f_{\max}(e)$. Since d_{i+1} is maximum, it follows that f_{i+1} is a max-flow between x_{i+1} and y_{i+1} in H_i. Let C denote a minimum cut between x_{i+1} and y_{i+1} in H_i. The cut C consists of vertices, denoted by $V(C)$, and of edges, denoted by $E(C)$. Vertices in $V(C)$ must be intrasaturated by f_{i+1}. Define $A_{i+1} = V(C)$. Edges in $E(C)$ must be either virtual or incident to a vertex in I_{i+1}. Virtual edges in $E(C)$ contribute nothing to B_{i+1} (or F_{i+1}). However, for every nonvirtual edge in $E(C)$, we add its endpoint which belongs to I_{i+1} to the set B_{i+1}, unless this vertex is already in A_{i+1}. Thus, A_{i+1} consists of vertices that are intrasaturated by f_{i+1}, B_{i+1} consists of vertices that are intersaturated by $f = (f_1, \ldots, f_{i+1})$, and these sets are disjoint. The set F_{i+1} is the union of these two sets.

We now elaborate on step 3 in the algorithm. We apply the Gomory–Hu transformation (section 2.1) to the graph H_i with (a) the original vertex capacities and the edge capacities that have been assigned to the virtual edges in the previous iterations; (b) the cut C; and (c) source-sink pair (x_{i+1}, y_{i+1}). This reduction yields two graphs, $R_{x_{i+1}}$ with condensed vertex y'_{i+1} and $R_{y_{i+1}}$ with condensed vertex x'_{i+1}. Connect now $R_{x_{i+1}}$ with $R_{y_{i+1}}$ by inserting special vertex s_{i+1} and connecting it to its two neighbors $x_{i+1} \in R_{x_{i+1}}$ and $y_{i+1} \in R_{y_{i+1}}$, as can be seen in Figure 5.1.

The resulting graph is denoted by H_{i+1}. Edge capacities are assigned to edges in H_{i+1} as follows: If an edge is a virtual edge in one of the graphs $H_1, \ldots, H_i$ and not in H_{i+1}, then it keeps its capacity. If an edge is a virtual edge in H_{i+1}, then it is assigned capacity $c(e) = f_{\max}(e)$. All other (nonvirtual) edges are assigned infinite capacity.

5.1. Properties. The following two claims follow directly from the construction of H_{i+1}.

CLAIM 5.1. The graph induced by $G - \cup_{j=1}^{i+1} F_j - \{s_{i+2}, \ldots, s_k\}$ is a subgraph of H_{i+1}.

CLAIM 5.2. Graph H_{i+1} does not contain any interesting cycles.

The following theorem guarantees that the first step in each iteration of the algorithm is feasible.

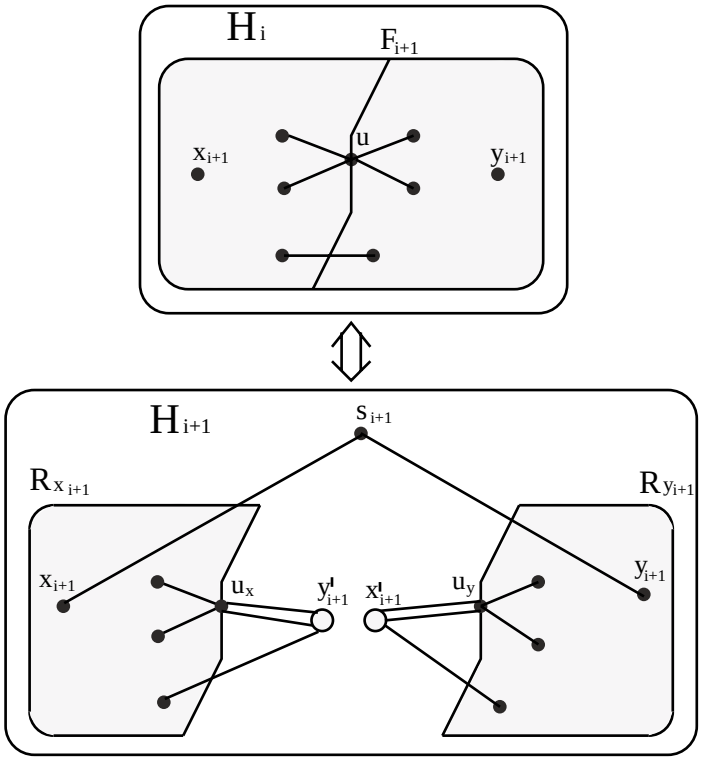

FIG. 5.1. *Obtaining graph H_{i+1} from H_i (and vice-versa).*

THEOREM 5.3. *Suppose there exists a relaxed multicommodity flow function in graph H_i that realizes demand vector $\{d_1, \ldots, d_{i+1}\}$ for source-sink pairs (x'_j, y'_j), $1 \le j \le i$, and (x_{i+1}, y_{i+1}). Then there exists a relaxed multicommodity flow function that realizes demand vector $\{d_1, \ldots, d_{i+1}\}$ for source-sink pairs (x'_j, y'_j), $1 \le j \le i+1$, in graph H_{i+1}.*

Proof. Let $f = (f_1, \ldots, f_{i+1})$ denote the relaxed multicommodity flow computed in iteration $i+1$, in graph H_i. It is obvious that $f_{\max}$ is a restricted function for both graph H_i and graph H_{i+1}. Let H^f_{i+1} denote the restricted graph with respect to graph H_{i+1} and the restricted function $f_{\max}$. We show that for each commodity j, $1 \le j \le i+1$, we can ship d_j units of flow from x'_j to y'_j, and therefore by Claim 4.3, we conclude that there exists a relaxed multicommodity flow function in H_{i+1} that realizes demand vector $\{d_1, \ldots, d_{i+1}\}$ for source-sink pairs (x'_j, y'_j), $1 \le j \le i+1$.

We start with commodity $i+1$. In graph H^f_i, the restricted graph with respect to graph H_i and function $f_{\max}(e)$, d_{i+1} units of flow from x_{i+1} to y_{i+1} went through the cut C. This means that in graph H^f_{i+1} we can ship d_{i+1} units of flow from x_{i+1} to y'_{i+1} and from x'_{i+1} to y_{i+1}. Thus, we can ship the flow of commodity $i+1$ in H^f_{i+1} from x'_{i+1} to y_{i+1}, then to x_{i+1} through s_{i+1}, and then from x_{i+1} to y'_{i+1}.

Suppose that $j < i+1$. We need to distinguish between two cases. The first case is when $x'_j \in R_{x_{i+1}}$ and $y'_j \in R_{y_{i+1}}$ (or vice-versa). We first observe that $d_j \le d_{i+1}$ since the flow of commodity j goes from x'_j to y'_j through cut C in H^f_i. In graph H^f_i, we can ship via cut C flow of commodity j of value d_j from x'_j to y'_j, and flow of commodity $i+1$ of value d_{i+1} from x_{i+1} to y_{i+1}. Therefore, by Lemma 2.1 in the graph H^f_{i+1}, we can ship flow of value d_j from x'_j to y'_{i+1}, and flow of value d_{i+1} from

x_{i+1} to y'_{i+1}. Hence, since $d_j \le d_{i+1}$, we can ship flow of value d_j from x'_j to x_{i+1}. Similarly, we can ship flow of value d_j from y'_j to y_{i+1}. Thus we can ship the flow of commodity j of value d_j from x'_j to y'_j via s_{i+1} in graph H^f_{i+1}. The second case is when both x'_j and y'_j belong to $R_{x_{i+1}}$ (or $R_{y_{i+1}}$). In this case, f_j is a flow of value d_j from x'_j to y'_j in H^f_i. By Lemma 2.2 we get that there exists a flow function of value d_j from x'_j to y'_j in H^f_{i+1}. □

5.2. Correctness. There are three issues that need to be addressed regarding the correctness of the algorithm. First, we need to show that step 1(i) of the algorithm can be implemented, i.e., demand vector $d^i = \{d_1, \ldots, d_i\}$ can be realized in H_i. This can be proved inductively. The basis ($i = 0$) is immediate. Theorem 5.3 guarantees that if d^i can be realized in H_{i-1}, then it can also be realized in H_i.

We prove that at the end of the kth iteration, the set F produced by the algorithm is a SUBSET-FVS in graph G. It follows from Claim 5.1 that $G - F$ is a subgraph of H_k. Claim 5.2 states that H_k does not contain interesting cycles. Therefore, F is a SUBSET-FVS in G.

5.3. Complexity. We show that there is no exponential blowup in the number of vertices in graph H_i as a result of the Gomory–Hu transformation. We claim that the number of virtual vertices in each graph H_i, $1 \le i \le k$, is at most $i \cdot |V|$. For vertex $u \in G$, define the set V_u recursively. Initially, V_u contains u. If, during the run of the algorithm, a vertex $x \in V_u$ generates two virtual copies of itself, then delete x from V_u and add the two virtual copies of x to V_u. We claim that $|V_u| \le k$ for all $u \in G$. This follows by observing that the set of edges in a minimum cut is contained in a biconnected component. The reason for this is as follows: consider two edges in a minimum cut; there are two paths that connect the source with those edges and two paths that connect the sink with those edges. Therefore, they have to be in the same biconnected component. Since every two vertices of V_u belong to different biconnected components of H_i for all $i \ge 0$, it follows that at most one vertex from V_u will belong to a minimum cut in some iteration of the algorithm. Thus, in each iteration, at most one vertex from V_u can generate two new virtual copies, yielding that $|V_u|$ grows by at most 1 at each iteration.

6. Analysis of the algorithm. The analysis of the algorithm is divided into four parts.

1. We define a separation property of source-sink pairs with respect to an optimal SUBSET-FVS. We show that if the separation property is satisfied, then the sum of the demands which can be supplied is bounded by four times the weight of the SUBSET-FVS.
2. We reconfigure the relaxed multicommodity flow in H_k to a relaxed multicommodity flow in $G - \{s_1, \ldots, s_k\}$ with respect to new source-sink pairs. Moreover, the reconfiguration causes the source-sink pairs to satisfy a separation property with respect to an optimal SUBSET-FVS.
3. We show that all the intersaturated vertices chosen in the course of the algorithm are also intersaturated in H_k. This property will allow us to use Theorem 4.4 in order to bound the weights of the chosen intersaturated vertices.
4. We combine the previous parts to obtain the 8-approximation factor.

6.1. Separation of source-sink pairs. Let F^* denote an optimal SUBSET-FVS in graph G. For $0 \le i \le k$, define the graph $G_i = (V_i, E_i)$ to be the subgraph of G

induced by $V - F^* - \{s_{i+1}, \ldots, s_k\}$. We define the following separation property.

DEFINITION 6.1. *Source-sink pairs* $\{(a_j, b_j)\}_{j=i+1}^{k}$ *are* separated *by* F^* *in the subgraph of* G *induced by* $V - \{s_{i+1}, \ldots, s_k\}$ *if they satisfy the following two conditions.*

1. *For every* $i + 1 \leq j \leq k$, *the vertices* a_j *and* b_j *belong to different connected components of graph* G_i.
2. *For every* $i+1 \leq j, j' \leq k$, *the vertices* a_j *and* $a_{j'}$ *belong to different connected components of graph* G_i.

The following theorem enables bounding the sum of the realized demands by the weight of a separating subset of vertices.

THEOREM 6.2. *Suppose that the source-sink pairs* $\{(a_i, b_i)\}_{i=1}^{k}$ *are separated by* F^* *in the subgraph* G' *of* G *induced by* $V - \{s_1, \ldots, s_k\}$. *Then, for every demand vector* $(d_1, \ldots, d_k)$ *in* G' *with respect to the source-sink pairs* (a_i, b_i), *which is realizable by a relaxed multicommodity flow function, the following holds:*

$$\sum_{i=1}^{k} d_i \leq 4 \cdot c(F^*).$$

Proof. Let $f = (f_1, \ldots, f_k)$ denote a relaxed multicommodity flow that realizes the demand vector $(d_1, \ldots, d_k)$. Let C_i denote the connected component in $G' - F^*$ that contains the source a_i. Let T_i denote the set of edges which have one endpoint in F^* and the other endpoint in C_i. By definition, $f_i(e) \leq f_{\max}(e)$ for each edge e. Since $b_i \notin C_i$, the flow of f_i along the edges of T_i cannot be less than d_i, namely, $d_i \leq \sum_{e \in T_i} f_i(e)$. Therefore,

$$d_i \leq \sum_{e \in T_i} f_{\max}(e).$$

Summing up over all commodities, we get that

$$\sum_{i=1}^{k} d_i \leq \sum_{e \in \cup_{i=1}^{k} T_i} f_{\max}(e).$$

Since the sets $\{T_i\}_{i=1}^{k}$ are disjoint,

$$\sum_{e \in \cup_{i=1}^{k} T_i} f_{\max}(e) \leq \sum_{v \in F^*} \sum_{e \in N(v)} f_{\max}(e).$$

By the intercommodity constraints, we get that

$$\sum_{i=1}^{k} d_i \leq 4 \cdot c(F^*). \qquad \square$$

Remark 2. Let α denote the factor by which the intercommodity constraints are relaxed. (In this paper, $\alpha = 2$.) Then, the bound in Theorem 6.2 can be generalized to

$$\sum_{i=1}^{k} d_i \leq 2\alpha \cdot c(F^*).$$

6.2. Reconfiguring flow paths. Let $f = (f_1, \ldots, f_k)$ denote the relaxed multicommodity flow with source-sink pairs $\{(x'_i, y'_i)\}_{i=1}^k$ and demand vector $\boldsymbol{d}$ in the graph H_k computed in the last iteration of the algorithm. Our goal is to define relaxed multicommodity flow $f = (f_1, \ldots, f_k)$ with (new) source-sink pairs $\{(a_i, b_i)\}_{i=1}^k$ and the same demand vector $\boldsymbol{d}$ in the subgraph of G induced by $V - \{s_1, \ldots, s_k\}$ such that the source-sink pairs $\{(a_i, b_i)\}_{i=1}^k$ are separated by F^* in this subgraph.

We construct this relaxed multicommodity flow inductively. For each i, $0 \leq i \leq k$, construct in the graph H_i a relaxed multicommodity flow $f = (f_1, \ldots, f_k)$ with source-sink pairs (x'_j, y'_j), for commodities $1 \leq j \leq i$, and with source-sink pairs (a_j, b_j), for commodities $i + 1 \leq j \leq k$ and demand vector $\boldsymbol{d}$, such that source-sink pairs $\{(a_j, b_j)\}_{j=i+1}^k$ are separated by F^* in the subgraph of G induced by $V - \{s_{i+1}, \ldots, s_k\}$.

Clearly for $i = k$ the relaxed multicommodity flow f is the flow computed in the last iteration of the algorithm. And for $i = 0$ the relaxed multicommodity flow f is the required relaxed multicommodity flow.

Assume that for $i + 1$ we construct such relaxed multicommodity flow $f = (f_1, \ldots, f_k)$ with source-sink pairs (x'_j, y'_j) for commodities $1 \leq j \leq i + 1$, and with source-sink pairs (a_j, b_j) for commodities $i + 2 \leq j \leq k$. Now we construct from it a relaxed multicommodity flow for i.

Overview. Our construction will consist of two steps. In the first step, we choose source-sink pairs (a_j, b_j) for $j \geq i+1$ that satisfy the following. (1) They are separated in G_i. (2) In graph H_{i+1}, demand vector $\{d_1, \ldots, d_k\}$ can be realized with source-sink pairs (x'_j, y'_j) for $1 \leq j \leq i + 1$, and (a_j, b_j) for $j \geq i + 2$, such that flow from (a_j, b_j) for $j \geq i + 2$ should not go through special vertex s_{i+1}.

In the second step, we restrict flow function $f = (f_1, \ldots, f_k)$ to flow paths from (new) source a_j to (new) sink b_j, for $i + 2 \leq j \leq k$. This flow function is henceforth referred to as f. Note that f satisfies, for (a_j, b_j), for $i + 2 \leq j \leq k$: All flow paths from a_j to b_j are subpaths of the flow paths in f prior to the modification. Hence, the amount of flow of commodity j shipped from a_j to b_j in f remains d_j. Thus, we generate the required flow f in H_i from flow function f in H_{i+1}.

Step 1. The construction proceeds by replacing systematically each flow path by a subpath of itself, so that all flow paths in f continue to share a common source and sink.

We assign $a_{i+1} \leftarrow x_{i+1}, b_{i+1} \leftarrow y_{i+1}$ or $a_{i+1} \leftarrow y_{i+1}, b_{i+1} \leftarrow x_{i+1}$. The choice is made so that the sources $a_{i+1}, \ldots, a_k$ belong to different connected components in the graph G_i. Note that since $s_{i+1} \in G_{i+1}$ and both x_{i+1} and y_{i+1} have infinite weight, x_{i+1} and y_{i+1} belong to the same connected component in graph G_{i+1}. Hence, at most one source a_t $(t > i + 1)$ may belong to this connected component. If no source belongs to this component, then both assignments of a_{i+1} and b_{i+1} are good. If a_t belongs to this connected component, then it is either separated from x_{i+1} or from y_{i+1} in graph G_i. In such a case, define a_{i+1} to be the neighbor of s_{i+1} that is separated from a_t in graph G_i.

The assignment of a_{i+1} and b_{i+1} satisfies the property that $\{a_j, b_j\}_{j=i+1}^k$ are separated by F^* in the subgraph of G_i induced by $V - \{s_{i+1}, \ldots, s_k\}$. However, the flow paths of some commodity j for $j > i + 1$ may not satisfy the requirement (2) that they use only vertices in $H_{i+1} - s_{i+1}$. Namely, the flow paths from a_j to b_j $(j > i + 1)$ might pass through special vertex s_{i+1}. (Note that at this stage, the flow paths pass only through vertices in H_{i+1}.) Otherwise, there is no need to update a_j and b_j. Since the special vertex s_{i+1} is about to be removed, this will disconnect all flow paths flowing through it. By construction, s_{i+1} is an articulation vertex of degree

two (i.e., the removal of s_{i+1} partitions H_{i+1} into two connected components), and thus, if a flow path from a_j to b_j passes through s_{i+1}, then all flow paths between a_j and b_j pass through s_{i+1} in H_{i+1}. Hence, it suffices to consider the case where all these paths go through s_{i+1}. We consider two cases.

1. All flow paths enter s_{i+1} from a_{i+1} and exit s_{i+1} to b_{i+1}. In this case, we assign $b_j \leftarrow a_{i+1}$. Since a_j and a_{i+1} do not belong to the same connected component in G_i, a_j and (the updated) b_j also belong to different connected components in G_i.
2. All flow paths enter s_{i+1} from b_{i+1} and exit s_{i+1} to a_{i+1}. There are two subcases: If a_j and b_{i+1} belong to different connected components in G_i, then we assign $b_j \leftarrow b_{i+1}$. Note that now, a_j and b_j are still in different components and that all subpaths of the flow paths that go from a_j to b_j avoid s_{i+1}. If a_j and b_{i+1} are in the same connected component, then a_{i+1} and b_j cannot belong to the same connected component since, otherwise, a_j and b_j would belong to the same connected component of G_{i+1}. In this case, we update $a_j \leftarrow a_{i+1}$; swap a_{i+1} and b_{i+1}, that is, $a_{i+1} \leftarrow b_{i+1}$; and $b_{i+1} \leftarrow a_{i+1}$. Note that now, a_j and a_{i+1} belong to different components, and so do a_j and b_j. Also, all subpaths of the flow paths that go from a_j to b_j avoid s_{i+1}. The swap between a_{i+1} and b_{i+1} does not conflict with separating a_{i+1} from the rest of the sources, because a_j is the only source that belongs to the connected component of a_{i+1} and b_{i+1} in the graph G_{i+1}.

Step 2. Now we generate the required flow f in H_i from flow function f in H_{i+1}. Recall the Gomory–Hu transformation through which graph H_{i+1} was obtained from H_i. Let C denote the minimum cut in the Gomory–Hu transformation. The removal of vertex s_{i+1} from H_{i+1}^f separates the graph into two parts denoted by $R_{x_{i+1}}$ and $R_{y_{i+1}}$. Note that flow function $f_{\max}$ in H_{i+1} is a restricted function for graph H_i. Thus, restricted graph H_i^f (for graph H_i and restricted function f) is a well-defined graph.

We now show that in H_i^f for $i+1 \le j \le k$, there exists a standard single commodity flow function that ships d_j units of flow from a_j to b_j, and for $1 \le j \le i$, there exists a standard single commodity flow function that ships d_j units of flow from x'_j to y'_j. We need to consider several cases.

The easiest case is when $j = i+1$. Recall that vertices x'_{i+1} and y'_{i+1} represent condensed subgraphs in H_i^f. In H_{i+1}, commodity $i+1$ is shipped from x'_{i+1} to y_{i+1} and then, via s_{i+1}, from x_{i+1} to y'_{i+1}. By Lemma 2.1, we can ship in H_i^f flow of value d_{i+1} from x_{i+1} to y_{i+1}. Vertices a_{i+1} and b_{i+1} were already matched to x_{i+1} and to y_{i+1} (or vice-versa) in the first part of the proof, and thus we show that d_{i+1} units of flow can be shipped from a_{i+1} to b_{i+1}.

Suppose that $j < i+1$. We need to distinguish between two cases. The first case is when $x'_j \in R_{x_{i+1}}$ and $y'_j \in R_{y_{i+1}}$ (or vice-versa). We first observe that $d_j \le d_{i+1}$ since the flow of commodity j went from x'_j to y'_j through cut C in H_i in iteration $i+1$ of the algorithm. By Lemma 2.1, in graph $R_{x_{i+1}}$, d_j units of flow can be shipped from x'_j to x_{i+1}. Also, in graph $R_{x_{i+1}}$, d_{i+1} units of flow can be shipped from x_{i+1} to y'_{i+1}. Thus, since $d_j \le d_{i+1}$, in graph $R_{x_{i+1}}$, d_j units of flow can be shipped from x'_j to y'_{i+1}. Similarly, in graph $R_{y_{i+1}}$, d_j units of flow can be shipped from x'_{i+1} to y'_j. Therefore, by Lemma 2.1, in graph H_i^f we can ship d_j units of flow of commodity j from x'_j to y'_j.

The second case is when both x'_j and y'_j belong to $R_{x_{i+1}}$ (or $R_{y_{i+1}}$). By Lemma 2.1, in graph $R_{x_{i+1}}$, there exists a flow of value d_j from x'_j to y'_j. Therefore, by

Lemma 2.2, in graph H_i^f, we can ship d_j units of flow of commodity j from x'_j to y'_j.

The last case is for commodities j for $i+1 < j \leq k$. It follows from the construction described in Step 1 that a_j and b_j are not separated by cut C in graph H_i^f. This case can be handled similarly to the previous subcase.

We have now established that in H_i^f for $i+1 \leq j \leq k$, there exists a standard single commodity flow function that ships d_j units of flow from a_j to b_j, and for $1 \leq j \leq i$, there exists a standard single commodity flow function that ships d_j units of flow from x'_j to y'_j. Notice that for each vertex $v \in H_i^f$, the capacity of the edges in $N(v)$ is either obtained from f in H_{i+1}, or, all the edges adjacent to v are virtual edges whose capacity is obtained from some legal relaxed multicommodity flow function in H_i. Therefore, we have that for each vertex $v \in H_i^f$, $\sum_{e \in N(v)} c(e) \leq 4 \cdot c(v)$. Now by Claim 4.3 we can superposition all the single commodity flow functions obtained for each commodity and get a legal relaxed multicommodity flow function f that realizes demand vector $d_1, \ldots, d_k$ in H_i. This completes the construction of required relaxed multicommodity flow function f in H_i.

6.3. Intersaturated vertices.

THEOREM 6.3. *Intersaturated vertices chosen by the algorithm are also intersaturated in H_k, namely,*

$$\bigcup_{i=1}^{k} B_i \subseteq I_k.$$

Proof. The proof follows by observing that for each edge e, $f_{\max}(e)$, which we constructed in the previous subsection in H_i, cannot be larger than $f_{\max}(e)$ in H_{i+1}. Thus, if a vertex is not intersaturated in H_{i+1}, then it is also not intersaturated in H_i. Therefore if a vertex is intersaturated in H_i for some $1 \leq i \leq k$, then it is intersaturated in H_k. ∎

6.4. The approximation factor. We are now ready to finish the analysis of the approximation factor of the algorithm. Our goal is to bound the weight of the chosen feedback set, namely, $c(F)$. To meet this end, we consider separately the chosen intrasaturated vertices and the chosen intersaturated vertices. Recall that in the ith iteration we add to F a subset $F_i = A_i \cup B_i$. The vertices in A_i are a subset of a minimum cut corresponding to the flow f_i, and hence, $c(A_i) \leq d_i$. Using Theorem 6.3, we bound $c(\cup_{i=1}^{k} B_i)$ by $c(I_k)$. We apply Theorem 4.4 to the graph H_k and obtain $c(I_k) \leq \sum_{i=1}^{k} d_i$. Therefore,

$$c(F) \leq 2 \cdot \sum_{i=1}^{k} d_i.$$

We now provide an upper bound on the sum of the demands. It follows from reconfiguration of the flow paths that in the graph $G - \{s_1, \ldots, s_k\}$ there exists a relaxed multicommodity flow function with source-sink pairs $\{(a_i, b_i)\}_{i=1}^{k}$ that realizes demand vector $(d_1, \ldots, d_k)$. Moreover, these source-sink pairs are separated by F^*, and thus by Theorem 6.2,

$$\sum_{i=1}^{k} d_i \leq 4 \cdot c(F^*),$$

yielding that $c(F) \leq 8 \cdot c(F^*)$.

We now can explain the choice of the relaxation factor of the intercommodity constraints. Let this factor be denoted by α. It follows from Remarks 1 and 2 that the approximation factor of the algorithm with respect to α is

$$2\alpha \cdot \left(1 + \frac{1}{\alpha - 1}\right).$$

This expression is minimized for $\alpha = 2$.

Acknowledgment. We would like to thank Naveen Garg for many helpful discussions.

COMPUTATIONALLY SOUND PROOFS*

SILVIO MICALI†

Abstract. This paper puts forward a new notion of a proof based on computational complexity and explores its implications for computation at large.

Computationally sound proofs provide, in a novel and meaningful framework, answers to old and new questions in complexity theory. In particular, given a random oracle or a new complexity assumption, they enable us to

1. prove that verifying is easier than deciding for all theorems;
2. provide a quite effective way to prove membership in computationally hard languages (such as $\mathcal{C}o$-$\mathcal{NP}$-complete ones); and
3. show that every computation possesses a short certificate vouching its correctness.

Finally, if a special type of computationally sound proof exists, we show that Blum's notion of program checking can be meaningfully broadened so as to prove that $\mathcal{NP}$-complete languages are checkable.

Key words. interactive proofs, probabilistically checkable proofs, random oracles, Merkle trees

PII. S0097539795284959

1. Introduction.

CS proofs. Proofs are fundamental to our lives, and as for all things fundamental we should expect that answering the question of what a proof is will always be an on going process. Indeed, we wish to put forward the new notion of a *computationally sound proof* (CS proof) which achieves new and important goals, not attained or even addressed by previous notions.

Informally, a CS proof of a statement S consists of a short string, σ, which (1) is as easy to find as possible, (2) is very easy to verify, and (3) offers a strong computational guarantee about the verity of S. By "as easy to find as possible" we mean that a CS proof of a *true* statement (i.e., for the purposes of this paper, *derivable* in a given axiomatic theory) can be computed in a time close to that needed to Turing-accept S. By "very easy to verify" we mean that the time necessary to inspect a CS proof of a statement S is substantially smaller than the time necessary to Turing-accept S. Finally, by saying that the guarantee offered by a CS proof is "computational" we mean that false statements either do not have any CS proofs, or such "proofs" are practically impossible to find.

Implementations of CS proofs. The value of a new notion, of course, crucially depends on whether it can be sufficiently exemplified. We provide two main implementations of our notion. The first is based on a random oracle and provably yields a CS proof system without any unproven assumption. The second relies on a new complexity conjecture: essentially, that it is possible to replace the random oracle of the first construction with a cryptographic function and obtain, mutatis mutandis, similar results.

Applications of CS proofs. In either implementation, CS proofs provide, in a new and meaningful framework, very natural answers to some of our oldest questions in complexity theory. In particular, they imply not only that the time necessary to verify is substantially smaller than the time necessary to accept, but, more importantly,

†Laboratory for Computer Science, MIT, Cambridge, MA 02139 (silvio@theory.lcs.mit.edu).

that this "speed-up" occurs for *all* theorems (rather than just *a few* theorems). In addition, they provide a quite effective way for proving membership in computationally hard languages (e.g., $\mathcal{C}o$-$\mathcal{NP}$ complete ones).

CS proofs also possess novel and important implications for computational correctness. In particular, in either implementation, they imply that every computation possesses a short certificate vouching for its correctness. In addition, if implementable in the second manner, CS proofs also imply that any heuristic or program for an $\mathcal{NP}$-complete problem is cryptographically checkable. This application at the same time extends and demonstrates the wide applicability of Blum's [11] original framework for checking program correctness.

Origins of CS proofs. In conceiving and constructing CS proofs, we have benefited from the research effort in interactive and zero-knowledge proofs. In particular, the notion of a probabilistically checkable proof [3, 17] and that of a zero-knowledge argument [13] have been the closest sources of inspiration in conceiving the new notion itself. In exemplifying the new notion, most relevant has been a construction of Kilian's [23], and, to a lesser extent, the works of [18] and [9].

Naturalness of CS proofs. We wish to emphasize that, from the above starting point, the mentioned applications of CS proofs to computation at large have been obtained by means of surprisingly simple arguments. Indeed, after setting up the stage for the new notion, the results about computational correctness follow quite naturally. This simplicity, in our opinion, lends support to our new perspective.

2. New goals for efficient proofs.

Proofs without demands for efficiency: Semirecursive languages. Truth and proofs have been traveling hand in hand. As formalized in the first half of this century by a brilliant series of works, the classical notion of a proof [1] is inseparable from that of a true statement. Given any finite set of axioms and inference rules, the corresponding true statements form a *semirecursive* set.[2] In the expressive and elegant approach of Turing, such sets possess two equivalent characterizations particularly important for our enterprise, one in terms of accepting algorithms and one in terms of verifying algorithms.

1. A language (set of binary strings) L is semirecursive if and only if there exists an *(accepting)* Turing machine A such that
$$L = \{x \ : \ A(x) = YES\}.$$
2. A language L is semirecursive if and only if there exists a *(verifying)* Turing machine V, halting on all inputs, such that
$$L = \{x \ : \ \exists \sigma \in \{0,1\}^* \text{ such that } V(x,\sigma) = YES\}.$$

Establishing the verity of a statement is thus a purely algorithmic process, and (at least formally) classical proofs—the σs of the second definition—are just strings. Because in this paper a "true" theorem simply is one derivable in a given theory, for

[1] Thinking that the intuitive notion of a proof has remained unchanged from the times of classic Greece (i.e., thinking that people like Peano, Zermelo, Frankel, Church, Turing, and Gödel have only contributed its rigorous formalization and the discovery of its inherent limitations) is certainly appealing, but unrealistic. Personally, we believe that no notion so fundamental and so human can remain, not even intuitively, the same across so different spiritual experiences and historical contexts. No doubt, our yearning for permanence (dictated by our intrinsically transient nature) predisposes us to perceive more continuity in our endeavors than may actually exist.

[2] Again, throughout this work, *true* is considered equivalent to *derivable*.

variety of discourse we may call a member of a semirecursive language a *theorem* or a *true statement*, and a classical proof a *derivation*.

Finally, we also wish to recall the definition of a recursive language. Namely,

3. a language L is recursive (decidable) if and only if there exists a *(deciding)* Turing machine D, halting on all inputs, such that

$$L = \{x \ : \ D(x) = YES\}.$$

Most of the semirecursive languages considered later on are actually recursive, in which case we may refer to their accepting algorithms as deciding algorithms.

Prior demands for efficiency: $\mathcal{NP}$, $\mathcal{IP}$, and $\mathcal{PCP}$. The two classical definitions of semirecursiveness are syntactically different, but they are not formally distinct from the point of view of "computational efficiency." Indeed, though in many natural cases verifying a classical proof is computationally preferable to finding it, classical proofs are more a way of expressing what is *in principle true* rather than a way of capturing what is *efficiently provable*. Providing a derivation is certainly a way to convince someone that a given theorem is true but not necessarily an efficient one: a classical proof may be arbitrarily long, or its relative verifying algorithm may take arbitrarily many computational steps to verify it.

Therefore, the now familiar notions of $\mathcal{NP}$ (due to Cook [16] and, independently, to Levin [24]) and $\mathcal{IP}$ (due Goldwasser, Micali, and Rackoff [21] and, independently, to Babai and Moran [4]) have been put forward in an effort to capture the essence of an efficient proof. Despite the notable differences between $\mathcal{NP}$ and $\mathcal{IP}$, in both cases this effort consists of *demanding that verifying be easy*.

Our notion too demands ease of verification (and in a *stronger* sense), but also broadens the perceived essence of an efficient proof by demanding some novel properties.

Another type of "proof efficiency" is provided by the notion of $\mathcal{PCP}$ [3, 17] (which we shall discuss in some detail later on). Quite succinctly, this notion consists of an explicit algorithm transforming an $\mathcal{NP}$-witness, σ, into a new proof (i.e., string), τ, which is polynomially longer, but whose correctness can be detected in probabilistic polylogarithmic time by random accessing (at unit cost) selected bits of τ. This immediately yields the following $\mathcal{NP}$-like proof system: the prover transforms an $\mathcal{NP}$-witness σ into a longer but samplable proof-string τ, and sends τ to the verifier, who then will verify τ by selectively sampling its bits.

In terms of overall verifying time, however, such a proof system is not more efficient than its $\mathcal{NP}$ counterpart (i.e., than just sending σ). Indeed, though few chosen bits of τ will be "truly checked," to ensure that he is truly dealing with, say, the ith bit of τ, the verifier must *read/receive* every bit of τ and keep precise track of the order in which it is read/received. And such read/receiving operations, according to any natural measure, have in themselves a cost proportional to τ's length, which is greater than the length of σ.[3]

(Notice that having the prover not send τ at all, but rather having him answer any question the verifier may ask about specific bits of τ, does not work: a dishonest prover may cheat successfully with probability 1.)

Our demands for efficiency. Our notion of an efficient proof system is expressed in relation to Turing acceptability. We believe this to be a necessary step.

[3]This continues to be true if the prover sends to the verifier a piece of randomly-accessible hardware containing τ, if such a transmission is deemed preferable.

Indeed, we perceive *accepting* as the solitary process of determining what is true and *proving* as the social process of conveying to others the results of this determination.

Let us begin with the desideratum common to prior notions of our proof: ease of verification. Both $\mathcal{NP}$ and $\mathcal{IP}$ interpret ease of verification in *absolute terms*, namely, by requiring that verifiers run in polynomial-time. This interpretation automatically and strictly narrows the class of the efficiently provable theorems. By contrast, we believe that efficient verifiability should be expressed in *relative* rather than absolute terms, namely, by comparing the complexities of (1) *verifying* the proof of a given statement S and (2) *accepting* S (i.e., establishing S's verity without any help).

In addition, we perceive two new desiderata. First, because a proof system specifies (implicitly or explicitly) two processes, that of verifying and that of *proving*, we believe that proving too should be efficient, and this latter efficiency should again be relative to the complexity of accepting. Second, while $\mathcal{NP}$ and $\mathcal{IP}$ narrow the provable theorems to a small subset of all true statements (e.g., $\mathcal{PSPACE}$), we believe that *all* true statements (i.e., all Turing-acceptable languages) should be efficiently provable.

Our main goals. In sum, at the highest and informal level, the objective of our new notion of a proof is *finding the right relationship between* accepting, efficiently proving, *and* efficiently verifying *a true statement.* We articulate this general objective in the following goals.

1. *(Relative) efficiency of verifying.* Construct proof systems so that, for *all* theorems, the complexity of verifying is substantially smaller than that of accepting.
2. *(Relative) efficiency of proving.* Construct proof systems so that the prover's complexity is close to that of accepting.
3. *(Recursive) universality.* Construct proof systems capable of efficiently proving membership in *every* semirecursive language.

As we shall point out in what follows, our notion of a CS proof system also achieves additional goals, but we do not consider them essential to the "right" notion of an efficient proof.

2.1. Efficiency of verifying.

The relative nature of efficient verifiability. As outlined above, we regard a proof system to be efficient if it makes verifying a given statement easier than Turing accepting it (i.e., easier than establishing its verity without the help from any prover). Ignoring a small, fixed polynomial, we demand that the complexity of verifying be polylogarithmic in that of accepting. Though somewhat arbitrary, the latter choice stems from two simple reasons: "logarithmic" because we wish the advantage of verifying over accepting to be *substantial* (whenever the accepting time is substantial!), and "poly" because we wish such an advantage to be reasonably *independent* from any specific computational model.

The ubiquitous nature of efficient verifiability. There is an additional and novel aspect to our goal of efficient verifiability, namely, that such efficiency should arise for *all* theorems and not for just some of them. Let us explain this point focusing on the $\mathcal{NP}$ proof system.

To begin with, within $\mathcal{P}$, the $\mathcal{NP}$ mechanism does not guarantee that verification is computationally easier than acceptance (which in this case coincides with decision). For instance, in principle, for infinitely many positive constants c there could be a language L_c decidable in time $O(n^c)$ but for which any type of $\mathcal{NP}$-witness needs $\Omega(n^c)$ steps to be verified. If this were the case, the $\mathcal{NP}$ proof system could not make

verifying membership in these languages any easier than deciding them.

In addition, in principle again, assuming $\mathcal{P} \neq \mathcal{NP}$ only entails the existence of a superpolynomial gap between the complexities of Turing accepting and verifying for some, *but possibly rare*, inputs, such as certain instances of satisfiability. By contrast, according to our present point of view, a proof system does not make verification sufficiently efficient unless it makes it polylogarithmically easier than accepting for essentially *all* theorems.

2.2. Efficiency of proving.

The relative nature of efficient provability. As mentioned already, implicitly or explicitly, proofs involve *two* agents, a prover and a verifier. We thus believe that the right notion of a proof should require efficiency for *both* agents and that the efficiency of a prover should not be measured in absolute terms but relatively to the complexity of Turing accepting the problem at hand.

Measuring prover efficiency relative to the complexity of accepting is a quite natural choice. Indeed, based on our intuition that the complexity of convincing someone else cannot be lesser than that of convincing ourselves (and based on our view that accepting is the process of convincing ourselves), the complexity of proving cannot be lower than that of accepting, while it could be much greater. We thus demand that our proof systems satisfy the following two properties.

(i) The prover must succeed in convincing the verifier whenever the theorem at hand is true (the old completeness property of an interactive proof system).

(ii) The amount of computation needed by the prover to convince the verifier must be polynomially close to that needed to accept that the given theorem is true.

In property (ii), we demand that the two amounts of computation be polynomially close to ensure a reasonable robustness.

We refer to the simultaneous holding of these two properties as *feasible completeness*. Feasible completeness is a novel *requirement* for proof systems. But do any of the prior proof systems "happen" to enjoy it anyway? Quite possibly, the answer is no. Consider, for instance, an $\mathcal{NP}$ language L (preferably not $\mathcal{NP}$-complete[4]) decidable by an algorithm D in, say, $n^{\log n}$ time. Then, in the $\mathcal{NP}$ mechanism, proving that a given string x belongs to L entails finding a polynomially long and polynomial-time inspectable witness w_x. But the complexity necessary to find such an *insightful* string may vastly exceed that of running algorithm D on input x for $|x|^{\log |x|}$ steps! Indeed, finding such an insightful string w_x might in the worst case require $O(2^{|x|})$ steps. In other words, while a few months of hard work may suffice for proving to ourselves (i.e., for accepting) that a given mathematical statement is true, it is conceivable that a lifetime may not be enough for finding an explanation followable by a verifier with a limited attention span.

Efficient provability might also not hold for the $\mathcal{IP}$ proof mechanism. Indeed, often the best way to prove membership in an $\mathcal{IP}$ language consists of invoking the general $\mathcal{IP} = \mathcal{PSPACE}$ protocol [26, 33], which is extremely wasteful of prover resources.

Realizing the importance of feasible completeness in a proof system allows us

[4]Above, we assume that L is not $\mathcal{NP}$-complete to avoid raising two issues at once. Indeed, due to our current complexity measures, $\mathcal{NP}$-proving membership in an $\mathcal{NP}$-complete language *appears* feasible. In fact, because of self-reducibility, if L is $\mathcal{NP}$-complete and decidable in $n^{\log n}$ time, then an $\mathcal{NP}$-witness of $x \in L$ is findable in $poly(|x|) \cdot |x|^{\log |x|}$ time. However, as we shall see in subsection 5.8, $\mathcal{NP}$ may not enjoy feasible completeness even when one focuses solely on $\mathcal{NP}$-complete languages.

to raise a variety of intriguing questions about $\mathcal{NP}$ and $\mathcal{IP}$.[5] But our point is not determining which proof systems *happen* to enjoy feasible completeness. Our point is that *feasible completeness must be* required *from any notion of a proof system that aims at achieving an adequate level of generality and meaningfulness.*

Related notions of feasible provability. Related notions of "feasible" provability have been considered in the past. In particular, Bellare and Goldwasser [6] discuss demonstrating membership in certain languages L by provers working in polynomial time and having access to an oracle for membership in L. Their notion, however, is weaker than ours because, in order to demonstrate membership in L of some given input x, their prover can query the oracle about other inputs x' for which accepting membership in L might be "much harder" than for x (despite the fact that such x' have been polynomial-time computed from x). Thus, if accessing the oracle for L were to be substituted with running an algorithm deciding L, then their provers may work much harder than needed for accepting that a specific x belongs to L.

Less relevantly, the protocols of [20] and [13] show that, if a prover were given for free an $\mathcal{NP}$ witness that an input x belongs to an $\mathcal{NP}$-complete language L, then proving in zero-knowledge that $x \in L$ only requires polynomial (in $|x|$) work. (In a sense, therefore, theirs is an example of feasible provability, but relative to the "nondeterministic complexity of x." That is, the prover complexity of a zero-knowledge proof system for $\mathcal{NP}$ is shown to be feasible relative to the prover complexity of another proof system: the $\mathcal{NP}$ one.) Such notion is nonetheless adequate when the prover is not handed the statement of a theorem (e.g., $x \in L$) as an input, but rather generates it together with suitable auxiliary information (e.g., an $\mathcal{NP}$-witness of $x \in L$) that enables feasible proving.

By contrast, our notion of feasible completeness refers to (1) *individual* inputs and (2) the *deterministic complexity* of these inputs.

2.3. Recursive universality. The previous proof systems discussed above have only a limited "range of action." For instance, an interactive proof system (P, V) is defined only with respect to proving membership in a *specific* language L. Different languages have, therefore, different interactive proof systems, or none. Moreover, as mentioned above, even considering the classes of all languages having an interactive proof system, one obtains a set of languages, $\mathcal{IP}$, that is quite small with respect to the set of all semirecursive languages.

We instead consider *universality* (i.e., the capability of handling the entire range of semirecursive languages) to be a necessary property of a "sufficiently right" proof system. By this we do not just mean that every semirecursive language should admit a proof system of the "right" type. We actually mean that a "right" proof system should be able to prove membership in *any* semirecursive language. That is, for any language L and any member x of L, on input x and a suitable description of L, a right proof system should be able to prove, *efficiently*, that x belongs to L. (As will be seen, we consider an accepting algorithm for L to be a suitable description of L

[5] For instance, in an intuitive language,

$\mathcal{Q}1$: *What is the computational complexity required from any $\mathcal{IP}$-prover of unsatisfiability?*

$\mathcal{Q}2$: (In light of better-than-exhaustive-search algorithms for graph isomorphism) *What is the complexity required from any $\mathcal{NP}$-prover of, say, graph isomorphism?*

$\mathcal{Q}3$: *Are there $\mathcal{NP}$-languages L, such that proving membership in L may require much less computation from an $\mathcal{IP}$-prover than from an $\mathcal{NP}$-prover?*
(i.e., can giving a prover "more freedom" save him much work?) In particular,

$\mathcal{Q}3'$: *What is the computational complexity required from any $\mathcal{IP}$-prover of satisfiability?*

and one that facilitates our establishing the efficient provability and verifiability of a proof system.)

3. CS proofs with a random oracle. To approximate our new goals, we put forward the notion of a CS proof system. As we shall see, this actually is a family of closely related notions. The first of such notions, that of a CS proof with a random oracle, will be presented and implemented in detail in this section; the others will be more briefly discussed in section 4. All these proof systems aim at proving membership in the following special language.

3.1. The CS language.

Encodings. Throughout this paper, we assume usage of a standard binary encoding, and often identify an object with its encoding. (In particular, if A is an algorithm, we may—meaningfully, if informally—give A as an input to another algorithm.) The length of an (encoded) object x is denoted by $|x|$. If q is a quadruple of binary strings, $q = (a, b, c, d)$, then our quadruple encoding is such that, for some positive constant c,

$$1 + |a| + |b| + |c| + |d| < |q| < c(1 + |a| + |b| + |c| + |d|).$$

Steps. If M is a Turing machine and x an input, we denote by $\#M(x)$ the number of steps that M takes on input x.

DEFINITION 3.1. *We define the* CS language*, denoted by $\mathcal{L}$, to be the set of all quadruples $q = (M, x, y, t)$, such that M is (the description of) a Turing machine, x and y are a binary strings, and t a binary integer such that*

1. $|x|, |y| \leq t$;
2. $M(x) = y$; and
3. $\#M(x) = t$.

Notice that, as long as M reads each bit of its inputs and writes each bit of its outputs, the above property 1 is not a real restriction. Notice too that, due to our encoding, if $q = (M, x, y, t) \in \mathcal{L}$, then $t < 2^{|q|}$.

3.2. The notion of a CS proof-system with a random oracle.

Oracles and oracle-calling algorithms. We denote the set of all binary strings having length i by Σ^i, and the set of all functions from a-bit strings to b-bit strings by $\Sigma^a \to \Sigma^b$. By an *oracle* we mean a function in $\Sigma^a \to \Sigma^b$, for some choice of a and b.

We consider algorithms making calls to one or two oracles. To emphasize that an algorithm A makes calls to a single oracle, we write $A^{(\cdot)}$. If A is such an algorithm and f an oracle, we write A^f to denote the algorithm obtained by answering A's queries according to function f, that is, by answering each query α with $f(\alpha)$. Similarly, to emphasize that an algorithm A makes calls to two oracles, we write $A^{(\cdot,\cdot)}$. If A is such an algorithm and (f_1, f_2) a pair of oracles, we write $A^{(f_1,f_2)}$ to denote the algorithm obtained by answering A's queries to the first oracle according to function f_1, and those to the second oracle according to function f_2.

For complexity purposes, in a computation of an oracle-calling algorithm, the process of writing down a query and receiving its answer from the proper oracle f is counted as a single step. No result of this paper would change in any essential way if this process costed $poly(a, b)$ steps whenever $f \in \Sigma^a \to \Sigma^b$.

An algorithm that, in any possible execution, makes exactly N calls to each of its oracles will be referred to as a *N-call algorithm.*

Integer presentation. If x is an integer given as an input to an algorithm A, unless otherwise clarified it is assumed that x is presented in binary to A. We only make an exception for the security paramenter, denoted by k, that is always presented in unary to all our algorithms: accordingly, we shall denote by 1^k (i.e., the concatenation of k 1s) the unary representation of integer k.[6]

DEFINITION 3.2. *Let $P^{(\cdot)}$ and $V^{(\cdot)}$ be two oracle-calling Turing machines, the second of which is running in polynomial time. We say that (P, V) is a* CS proof system with a random oracle *if there exists a sequence of six positive constants, $c_1, \ldots, c_6$ (referred to as the* fundamental constants *of the system), such that the following two properties are satisfied.*

1′. *Feasible completeness.* For all $q = (M, x, y, t) \in \mathcal{L}$, for all k, for all $f \in \Sigma^{k^{c_1}} \to \Sigma^{k^{c_1}}$, (1′.*i*) $P^f(q, 1^k)$ halts within $(|q|kt)^{c_2}$ computational steps, outputting a binary string $\mathcal{C}$ whose length is $\leq (|q|k)^{c_3}$, and (1′.*ii*) $V^f(q, 1^k, \mathcal{C}) = YES$.

2′. *Computational soundness.* For all $\widetilde{q} \notin \mathcal{L}$, for all k such that $2^k > |q|^{c_4}$, and for all (cheating) deterministic $2^{c_5 k}$-call algorithm $\widetilde{P}$, for a random oracle $\rho \in \Sigma^{k^{c_1}} \to \Sigma^{k^{c_1}}$,

$$Prob_\rho[V^\rho(\widetilde{q}, 1^k, \widetilde{P}^\rho(\widetilde{q}, 1^k)) = YES] \leq 2^{-c_6 k}.$$

Thus, an execution of (P, V) requires a common oracle f and two common inputs: a quadruple of binary strings q (allegedly a member of $\mathcal{L}$) and a unary-presented integer k. We refer to q as *the CS input*, and to k as *the security parameter*. Such an execution consists of first running P^f on inputs q and 1^k, so as to produce a binary output $\mathcal{C}$, and then running V^f on inputs q, 1^k and $\mathcal{C}$. If $q = (M, x, y, t)$ and $V^f(q, 1^k, \mathcal{C}) = YES$, we may call string $\mathcal{C}$ a *random-oracle CS proof of $M(x) = y$*, or, more precisely, a *random-oracle CS proof, of security k, of $M(x) = y$ in less than t steps*. For variation of discourse, we may sometimes refer to such a $\mathcal{C}$ as a CS *witness* or a CS *certificate*. If it is clear from the context that we are dealing with CS proof systems with a random oracle, we may simplify our language by dropping the qualification "random-oracle."

Discussion.

Controlled inconsistency. CS proofs (similarly to zero-knowledge arguments discussed later on) allow the existence of false proofs but ensure that these are computationally hard to find. That is, *false CS proofs may exist, but they will "never" be found.*

Equivalently, CS proof systems are deliberately inconsistent but practically indistinguishable from consistent systems. Indeed, each CS proof specifies a security parameter, controlling the amount of computing resources necessary to "cheat" in the proof, so that these resources can be made arbitrarily high. Accordingly, CS proofs are meaningful only if we believe that the provers who produced them, though more powerful than their corresponding verifiers, are themselves computationally bounded.[7] From a practical point of view, this is hardly a limitation. As long we restrict our attention to physically implementable processes, no prover in our universe can perform $2^{1,000}$ steps of computation, at least during the existence of the human race. Thus, "practically speaking" all provers are computationally bounded.

[6] This is to ensure that a polynomial-time algorithm is guaranteed to be able to make "*poly(k)*" steps when the security parameter is k.

[7] The transition from an interactive proof system to a CS proof system is analogous to the transition from a perfect zero-knowledge proof system to a computational zero-knowledge proof system [21], which has proved to be a more flexible and powerful notion [20].

Deterministic cheating. In the above definition of a CS proof system with a random oracle, we have considered cheating provers $\widetilde{P}$ to be deterministic because probabilism does not help in our context. Indeed, since we are not concerned about the size of the description of $\widetilde{P}$, nor about its running time (except for the number of oracle calls it may make), $\widetilde{P}$ may easily have built in any "lucky" sequence of coin tosses.

Security parameters. Informally, the security parameter k controls the probability of something going wrong, and CS proofs become more meaningful as k grows. But, at a minimum, we require that k be large enough so that $2^k > |q|^{c_4}$. This "mild" lower-bound is relied upon in our proof of Theorem 3.8.[8] At the same time, it is also reasonable in that, on input a quadruple q, the honest prover P is allowed at least $poly(|q|)$ steps of computation, and it would thus be strange not to assume that a cheating prover can make a similar number of steps.

Running time. A member of $\mathcal{L}$, $q = (M, x, y, t)$, includes the exact number of steps, t, in which M outputs y on input x. More simply, however, we could have demanded that t upperbounds $\#M(x)$. But since the CS proof system with a random oracle of section 3.4.2, $(\mathcal{P}, \mathcal{V})$, actually proves the exact value of $\#M(x)$, it would have been a pity to loose this exact information.[9]

A paradox. CS proofs are paradoxical in that a computationally bounded prover appears able to "prove more theorems" than an unbounded one. Indeed, if we choose k's value as a suitable function of the input length, then a properly-bounded CS prover can demonstrate membership in any $\mathcal{EXPTIME}$ language to a verifier whose running time is upperbounded by a fixed polynomial in the input length alone. By contrast, the unbounded prover of an interactive proof system can only prove membership in $\mathcal{PSPACE}$ languages to a polynomial-time verifier, and it is widely believed that $\mathcal{PSPACE}$ is a proper subset of $\mathcal{EXPTIME}$.

However, at a second thought, there is no paradox. Indeed, a prover, being someone more powerful than us, may be a potentially useful *ally* (willing to enlarge our state of knowledge by letting us verify that some very difficult theorems are indeed true), but may also be a potentially dangerous *enemy* (wishing to trick us into believing some false statements). It is thus not too surprising that, when a prover is powerful but not-too-powerful, we can "trust him to a larger extent" and can thus "critically receive" from him more theorems than before.

Achieving our goals. Let us now point out how CS proofs achieve our main goals for the notion of an efficient proof.

1. *Efficient verifiability.* Our first goal required that, for every theorem, verifying should be polylogarithmically easier than accepting. This goal is approximated by a CS proof system (P, V) in the following sense. Let L be a semirecursive language, x a member of L, and A an accepting algorithm for L. Then the theorem $x \in L$ can be verified by running A on input x and verifying that $A(x) = YES$. Assume now that the latter computation takes t steps and that (P, V) is a CS proof system with a random oracle. Then, by choosing a proper security parameter k and running P on inputs

[8] Roughly, for proving Theorem 3.5 it suffices that $2^k > poly(|t|)$, which it is implied by $2^k > poly(|q|)$, because $|t| < |q|$.

[9] In any case, he who considers more natural choosing t as an upperbound to $\#M(x)$ may notice that with minor changes all of the results of this paper, including those about CS checking, remain true. In particular, a CS proof that some $q = (M, x, y, T)$ belongs to the modified CS language is computable in $poly(|q|k\#M(x))$ even when $\#M(x) << T$.

$q = (A, x, YES, \#A(x))$ and 1^k, and access to a random oracle ρ, one obtains a CS certificate of $x \in L$, $\mathcal{C}$ that (a) is length-bounded by a fixed polynomial in $|q|$ and k, and (b) is accepted by V^ρ running on additional inputs q and 1^k. Therefore, because V is polynomial time (and because k is unary-presented), V accepts within a number of steps that are bounded by a fixed polynomial in $|q|$ and k. Thus, because $\#A(x)$ enters q in binary representation and because of our quadruple-encoding conventions, V accepts in time polynomial in $|x|$ and k (as well as in $|A|$) but polylogarithmic in $\#A(x)$.

2. *Efficient provability.* Our second goal called for the complexity of proving being polynomially close to that of accepting. This property is immediately guaranteed by the feasible completeness of a CS proof system. Feasible completeness in fact states that there exists a fixed constant c_2 such that, if an algorithm A accepts that a string x belongs to a semirecursive language L (in $\#A(x)$ steps), then a CS prover can, on inputs $q = (A, x, YES, \#A(x))$ and 1^k and with access to a random oracle, find a CS proof of $x \in L$ within $(|q|k\#A(x))^{c_2}$ steps. That is, a CS prover can find a CS proof of $x \in L$ in a time that is polynomial in $\#A(x)$ and k (as well as in $|A|$ and $|x|$).
3. *Recursive universality.* Our third goal called for proof systems capable of proving membership in all possible semirecursive languages. In apparent contrast with this requirement, a CS proof system is defined to prove membership only in the CS language $\mathcal{L}$. But $\mathcal{L}$ is designed so as to encode membership questions relative to any possible semirecursive language. In fact, to each semirecursive language L corresponds a Turing machine M_L so that $x \in L$ if and only if M_L, on input x, outputs YES in some number of steps t. Thus $x \in L$ if $(M_L, x, YES, t) \in \mathcal{L}$, thus achieving the third goal.

Efficient verifiability within $\mathcal{P}$. Note that a CS proof system with a random oracle makes verifying computationally preferable to accepting even for polynomial-time languages.

The process behind the curtains. In a classical proof system, what convinces us of the verity of a given statement is the existence of a string satisfying a proper syntactic property. By contrast, in an interactive proof system there are no strings that do the convincing: the "proof is in the process." Differently from both scenarios, in a noninteractive CS proof system, proofs are strings possessing a special property, but such strings may exist also for false statements. Therefore, what is convincing is not the existence of such strings but our belief that the *process* behind the generation/selection of such strings had computationally limited resources.[10]

Comparison with zero-knowledge arguments. Goldwasser, Micali, and Rackoff [21] introduced and first exemplified the notion of a zero-knowledge proof system, and Goldreich, Micali, and Wigderson[20] showed that all languages in $\mathcal{NP}$ possess

[10]Indeed, when debating whether a given statement is true, we do not have "serendipitous" access to some CS proof of it, if any. Thus, if we are given such a string, then there must have been an active process that generated/selected it. For instance, assume that, while walking on a beach pondering our favorite statement S, we encounter a sand pattern that looks like the sequence of bits of a CS proof, σ, of S. Then, we may consider that the grains of sand have been arranged in such a σ-shape by natural elements (such as wind, waves, and sun), and view the universe as a computer and its age as computing time, so that, in a final analysis, our σ has been found in a few billion years: an unlikely event if we have chosen our parameters so that the age of the universe is negligible with respect to the time necessary to find a good-looking CS proof of a false statement.

a (computationally) zero-knowledge proof, under a general complexity assumption.[11] Brassard, Chaum, and Crépeau [13] then put forward a related notion, that of a *zero-knowledge argument for* $\mathcal{NP}$, and proved a related theorem: under a specific complexity assumption, there exist zero-knowledge arguments for all $\mathcal{NP}$ languages.[12]

We wish to disregard the zero-knowledge component of the latter protocols and focus instead on their proof-system component, which we call the *argument (proper)*. Such arguments in fact provide an earlier example of proof systems which (as our CS proofs) are "convincing if its provers are *computationally bounded*." Let us explain.

In a (zero-knowledge) argument system for an $\mathcal{NP}$ language L, all agents, the prover P, the verifier V, and any possible malicious prover $\widetilde{P}$, are assumed to be polynomial-time machines. Before proving that a given input x belongs to L, P is *assumed* to have available, on a special tape inaccessible by V, an $\mathcal{NP}$-witness of $x \in L$, w. (Without this assumption, such a w might be uncomputable by the polynomial-time P.) During the protocol, P is provided by V with a special encryption scheme and uses it so as to convince V of the existence of w (without revealing it) by means of an interactive process that is less efficient than merely sending w. Vice versa, if $x \notin L$, no such w exists, and it is hard for a malicious $\widetilde{P}$ to convince V of the opposite. In fact, succeeding in such a malicious convincing entails "breaking" the provided encryption scheme, and the chance that a polynomial-time $\widetilde{P}$ may do that is quite remote.

Arguments, therefore, do not enlarge (nor aim at enlarging) the class of theorems that are efficiently provable. Rather, they constitute an alternative way of proving membership in $\mathcal{NP}$, a way that is less efficient than simply providing the witness but satisfies an additional property, *zero-knowledgeness* (which is in fact an integral part of their very definition).

Note that, leaving aside zero-knowledgeness and interaction (there are, after all, interactive CS proof systems), our CS proofs with a random oracle differ from the arguments of Brassard, Chaum, and Crépeau in the following ways.

- *Their arguments for $\mathcal{NP}$ may not enjoy efficient verifiability.* As discussed above, such $\mathcal{NP}$ arguments are less efficient than classical $\mathcal{NP}$ proof systems, and, as pointed out in subsection 2.1, the latter systems may not satisfy (ubiquitous efficiency, and thus) efficient verifiability.
- *Their arguments for $\mathcal{NP}$ may not enjoy efficient provability.* As discussed above, on input a member x of an $\mathcal{NP}$ language L, the prover of an $\mathcal{NP}$ argument is assumed to have "for free" (as an additional input) an $\mathcal{NP}$-witness w of $x \in L$. But, as we have pointed out in subsection 2.2, the time necessary for a prover to find such a witness w may vastly exceed that necessary to accept that $x \in L$.
- *Their arguments for $\mathcal{NP}$ do not enjoy recursive universality.* $\mathcal{NP}$ languages are a proper subset of all recursive languages.

3.3. The intuition behind our CS proof-system with a random oracle. Our construction is based on an earlier one of Kilian's [23], which is itself based on

[11] Informally, they exhibit interactive protocols enabling a prover to convince a polynomial-time verifier that an input belongs to an $\mathcal{NP}$ language L, but without conveying any more knowledge than the mere fact that a given witness of such a membership exists. Their protocols privilege the "proof aspect" rather than the "zero-knowledge aspect". Indeed, even if endowed with unbounded computational power, their provers cannot convince their verifiers that inputs outside L are in L (but with a negligible probability). However, for their verifiers to gain no information about inputs of L (other than their belonging to L) it is crucial that they be time-bounded.

[12] Differently from Goldreich, Micali, and Rackoff, rather then the proof aspect, they privilege the zero-knowledge aspect (see previous footnote).

Merkle's trees [27] and probabilistically checkable proofs [3, 17]. Let us thus start by recalling the latter two notions.

3.3.1. Probabilistically checkable proofs. Babai, Fortnow, Levin, and Szegedy [3], and Feige, Goldwasser, Lovasz, Safra, and Szegedy [17] have put forward, independently and with different aims,[13] some related and important ideas sharing a common technique: *proof-samplability.*[14] In essence, they present two algorithms. The first transforms an $\mathcal{NP}$-witness, w, into a slightly longer "samplable proof," w'. The second algorithm can check the correctness of such a string w' by "random" accessing (i.e., accessing at unit cost) selected few of its bits. In our paper, we refer to these two algorithms as the (sampling-enabling) prover and the (sampling) verifier, which we, respectively and consistently, denote by SP and SV, so as to differentiate them from other types of provers and verifiers.

The following version of their result has proved useful in most applications so far.

THEOREM 3.3 (samplable proofs: Version 0). *For all $\mathcal{NP}$ languages L there exist two polynomial-time algorithms, a deterministic SP, a probabilistic SV, and a polynomial Q, such that*

(a) *For all n-bit strings $x \in L$ and for all $\mathcal{NP}$-witness w of $x \in L$, $SP(x, w) = w'$, wherein string w' is such that, on input x and access to any $Q(\log n)$ bits of w' of its choice, algorithm SV accepts; and*

(b) *for all $x \notin L$ and for all w', algorithm SV, on input x and access to any $Q(\log n)$ bits of w' of its choice, rejects with probability $\geq 1/2$.*

We shall, however, rely on a more precise and general version of their result, namely the following theorem.

THEOREM 3.4 (samplable proofs: Version 1). *For any polynomial-time relation R over $\Sigma^* \times \Sigma^*$, there exist a deterministic polynomial-time algorithm $SP(\cdot, \cdot)$, a probabilistic polynomial-time algorithm $SV(\cdot, \cdot)$, and two polynomials $L(\cdot)$ and $\Lambda(\cdot)$, such that the following hold.*

1. *For all strings x and y such that $R(x, y)$ holds, $SP(x, y)$ outputs a string y' such that*
   1.1. *$y' < L(|x| + |y|)$, and*
   1.2. *$SV(x, |y'|)$, having a random tape of length $\Lambda(\log |y'|)$ and random access to y', accepts.*
2. *For all strings x such that for all y $R(x, y) = 0$, and for any string σ, the probability (computed over SV's coin tosses) that $SV(x, |\sigma|)$, having a random tape of length $\Lambda(\log |\sigma|)$, having random access to σ, and actually accessing $\Lambda(\log |\sigma|)$ bits of σ, accepts is $\leq 1/2$.*

In the statement of Theorem 3.4, as customary, inputs $|y'|$ and $|\sigma|$ are presented to SV in binary. (Thus the second input of SV is polylogarithmically shorter than $|x|+|y|$.) Note that, unlike in the case of $\mathcal{NP}$, $R(x, y) = 1$ may not imply any a priori

[13] The authors of [3] focus on proofs of membership in $\mathcal{NP}$ languages and show that it is possible to construct verifiers that work in time poly-logarithmic in the length of the input. (Since in such a short time the verifier could not even read the whole input—and thus check that the proof he is going to sample actually relates to the "right" theorem—these authors have devised a special error-correcting format for the input and assume that it is presented in that format. An input that does not come in that format can be put into it in polynomial-time.)

The authors of [17] use proof-samplability to establish the difficulty of finding approximate solutions to important $\mathcal{NP}$-complete problems. (With this goal in mind, these other authors do not mind verifiers working in time polynomial in the length of the input and do not use or need the fact that inputs appear in any special format.)

[14] Though improved in [2, 1, 35, 29], the original proof-samplability techniques of [3] and [17] suffice for our purposes.

bound for the length of y relative to that of x.

3.3.2. Merkle's trees. Recall that a binary tree is a tree in which every node has at most two children, hereafter called the 0-*child* and the 1-*child*. A *collision-free hash function* is, informally speaking, a polynomial-time computable function H mapping binary strings of arbitrary length into reasonably short strings, so that it is computationally infeasible to find any *collision (for H)*, that is, any two different strings x and y for which $H(x) = H(y)$. (Popular candidate collision-free hash function is the standardized *secure hash function* [32] and Rivest's MD4 [31].)

A *Merkle tree* [27] then is a binary tree whose nodes store (i.e., are associated to) values, some of which are computed by means of a collision-free hash function H in a special manner. A leaf node can store any value, but each internal node should store a value that is the one-way hash of the concatenation of the values in its children.[15] Thus, if the collision-free hash function produces k-bit outputs, each internal node of a Merkle tree, including the root, stores a k-bit value. Except for the root value, each value stored in a node of a Merkle tree is said to be a 0-value if it is stored in a node that is the 0-child of its parent, and a 1-value otherwise.

The crucial property of a Merkle tree is that, unless one succeeds in finding a collision for H, *it is computationally hard to change any value in the tree (and, in particular, a value stored in a leaf node) without also changing the root value.* This property allows a party A to "commit" to n values, $v_1, \ldots, v_n$ (for simplicity assume $n = 2^a$ for some integer a), by means of a single k-bit value. That is, A stores value v_i in the ith leaf of a full binary tree of depth d, and uses a collision-free hash function H to build a Merkle tree, thereby obtaining a k-bit value, rv, stored in the root. This root value rv "implicitly defines" what the n original values were. Assume in fact that, as some point in time, A gives rv, but not the original values, to another party B. Then, whenever, at a later point in time, A wants to "prove" to B what the value of, say, v_i was, he may just reveal all n original values to B, so that B can recompute the Merkle tree and then verify that the newly computed root-value indeed equals rv. More interestingly, A may "prove" what v_i was by revealing just $d+1$ (i.e., $\log n + 1$) values: v_i together with its *authentication path*, that is, the values stored in the siblings of the nodes along the path from leaf i (included) to the root (excluded), $Y_1, \ldots, Y_d$. Party B verifies the received alleged leaf-value v_i and the received alleged authentication path $Y_1, \ldots, Y_d$ as follows. She sets $X_1 = v_i$ and, letting $i_1, \ldots, i_d$ be the binary expansion of i, computes the values $X_2, \ldots, X_d$ as follows: if $i_j = 0$, she sets $X_{j+1} = H(Y_j X_j)$; otherwise, she sets $X_{j+1} = H(X_j Y_j)$. Finally, B checks whether the computed k-bit value X_d equals rv.

3.3.3. Kilian's construction. In [23], Kilian presents a special zero-knowledge argument for $\mathcal{NP}$, (P, V), exhibiting a polylogarithmic amount of communication, where prover P uses a Merkle tree in order to provide to V "virtual access" to a samplable proof.[16]

In essence, disregarding zero-knowledge aspects, the polynomial-time prover P, as in any zero-knowledge argument, possesses a polynomially long witness, w, proving

[15] i.e., if an internal node has a 0-child storing the value U and a 1-child storing a value V, then it stores the value $H(UV)$. If a child of an internal node does not exist, we assume by convention that it stores a special value, denoted by EMPTY.

[16] Essentially the same construction (minus its zero-knowledge aspects) was independently discovered by the author and privately comunicated to Shafi Goldwasser prior to Kilian's publication that same year. (It was not, however, written up or circulated until after Kilian's publication, and then only in the context of a broader notion of an efficient proof.)

that a given input x belongs to a given $\mathcal{NP}$-language L. In virtue of Theorem 3.3, P then transforms w into a longer, but still polynomially long in the length of x, "samplable proof" w' by running on inputs x and w the algorithm SP of Theorem 3.3. In order to yield more efficient verifiability, P cannot send V witness w, nor can he send him the longer samplable proof w'. Rather, P uses a Merkle tree with a collision-free hash function H, producing k-bit outputs, as above, to compute a k-bit string, rv, that commits him to w' and then sends rv to the verifier V. (For instance, disregarding further efficiency considerations, if w' is n-bit long and, for simplicity, n is a power of 2, the ith bit of w' is set to be the value v_i in the above described construction, the Merkle tree is a full binary tree of depth $\log n$, and rv is the k-bit value stored in its root.)

Verifier V runs as a subroutine the algorithm SV of Theorem 3.3. When SV wishes to consult the jth bit of w', V asks P for it, and P responds by providing the original value b_j together with its authentication path. V then checks whether b_j's authentication path is correct relative to rv, and, if so, he is assured that b_j is the original value because he trusts that P, being polynomial-time, cannot find a collision for H. V then feeds b_j to SV. The computation proceeds this way until V finds that an authentication path is incorrect, in which case it halts and rejects, or until SV halts, in which case V rejects if SV does and accepts otherwise. Because SV "virtually" accesses a polylogarithmic (in n) number of bits of w', and because each such a virtual access is answered by $k\,poly(\log n)$ bits of authentication path, the overall amount of communication is polylogarithmic in n and thus in the length of x.

Notice that the above construction only shows how a verifier can be given virtual access to w'. Let us reiterate that, in order to obtain a communication efficient zero-knowledge argument, Kilian's construction is actually more complicated, but the additional zero-knowledge constraint is irrelevant for our goals.

3.3.4. Our modifications. Like all prior argument systems, Kilian's is not a CS proof system (nor even an interactive one, as defined later on). To begin with, it only proves membership in $\mathcal{NP}$ languages and thus does not satisfy recursive universality. Further, even relative to the $\mathcal{NP}$ languages, it may not satisfy feasible completeness. Indeed, in his construction, in order to convince verifier V that x belongs to an $\mathcal{NP}$ language L, prover P needs an $\mathcal{NP}$-witness, w, of $x \in L$. But, again, the time necessary to compute w on input x may vastly exceed that necessary to accept (in this case, *decide*) that $x \in L$ (in a way that does not produce an $\mathcal{NP}$-witness).

We do, however, obtain a CS proof system with a random oracle, $(\mathcal{P}, \mathcal{V})$, by modifying his argument system. First, as a necessary step towards recursive universality, we assume that an input to $(\mathcal{P}, \mathcal{V})$ consists of a member of the CS language $\mathcal{L}$, (M, x, y, t).[17] On such a CS input, $(\mathcal{P}, \mathcal{V})$ works as follows. First, $\mathcal{P}$ runs machine M on input x so as to generate, in t steps, the history (i.e., sequence of instantaneous configurations), σ, of a computation of $M(x)$ in which string y is produced as an output. Such a history σ is then thought of as a proof that $M(x) = y$. This proof will not be insightful, and, because no restriction is put on M, can be arbitrarily long relative to x. (Notice that $\mathcal{P}$'s computation so far satisfies, by definition, feasible completeness.)

Next, $\mathcal{P}$ will put such a proof σ in samplable form. Consider in fact the following relation R.

[17] Again, in order to prove membership in a given semirecursive language L, M will then be a Turing machine accepting L, and y will be the special string YES.

$R(q, \sigma) = 1$ *if and only if* σ *is the* t*-step history of a computation of* M *outputting* y *on input* x.

Then, notice that R is $poly(|q|, |\sigma|)$-time computable. Thus, due to Theorem 3.4 proof σ can be put in a probabilistically checkable form τ by algorithm SP within $poly(|q|)$ —and thus $poly(t)$— steps. Given random access to the so obtained τ, algorithm SV, on inputs q and τ, then efficiently checks its correctness using polylog$(|\tau|)$ queries and a random tape, RT, whose length is $polylog(|\tau|)$. (Notice that also this second piece of $\mathcal{P}$'s computation satisfies feasible completeness.)

Though proving that "$M(x) = y$ in t steps," such τ is again too long. Thus, $\mathcal{P}$ "Merkle hashes" τ as in [23] using a collision-free hash function H and gives $\mathcal{V}$ only virtual access to it (something that still preserves feasible completeness). The verifier is thus guaranteed that he is properly accessing τ (i.e., that $\mathcal{P}$ is not choosing on-line the bits of τ based on the bit-locations that $\mathcal{V}$ wishes to access) *provided* that $\mathcal{P}$ is computationally incapable of finding a collision in H.[18] To provide such a "guarantee," for a *specific* input $q = (M, x, y, t) \in \mathcal{L}$, it is possible to choose the security parameter k big enough so that finding a collision in a k-bit-output H requires a number of steps enormously bigger than those required above from $\mathcal{P}$ on the input q at hand, but not too big so as to violate feasible completeness.[19] In sum, therefore, we propose to keep honest a prover working on a given *individual* problem by means of another much harder *individual* problem, that of finding a collision for H (though the latter problem may belong to a "much lower" complexity class than the first one[20]).

So far, our $(\mathcal{P}, \mathcal{V})$ satisfies both recursive universality and feasible completeness but still is interactive. Indeed, recall that, to give $\mathcal{V}$ virtual access to τ, $\mathcal{P}$ uses function H to Merkle-hash the samplable proof τ and sends $\mathcal{V}$ the resulting root value RV. In response, $\mathcal{V}$ runs the sampling verifier SV with a random tape RT. During this execution SV computes which bits of τ it wishes to see; CS verifier $\mathcal{V}$ then sends these requests to CS prover $\mathcal{P}$; and prover $\mathcal{P}$ replies with both the requested bits and their authentication paths relative to RV. Because RT is genuinely random, if the input $(M, x, y, t) \notin \mathcal{L}$ and if $\mathcal{V}$ interacts with a malicious prover $\widetilde{\mathcal{P}}$ that does not succeed in finding a collision for H, then SV (and thus $\mathcal{V}$) accepts with probability at most $1/2$.

Let us now introduce further modifications in order to dispense with any interaction between $\mathcal{P}$ and $\mathcal{V}$ during the proving process. We first decrease the probability of SV accepting a false statement to less than 2^{-k} by repeating the above process k times, each time using an independently-selected random tape RT. We then use a random oracle, as follows, to retain more or less this same probability, while eliminating any interaction between $\mathcal{P}$ and $\mathcal{V}$.

In some sense, we have the CS prover $\mathcal{P}$ "choose" the k random tapes of SV, so that $\mathcal{V}$ is no longer needed. In fact, given these tapes, $\mathcal{V}$ runs deterministically, and

[18] In Kilian's case such guarantee stemmed from the fact that the prover was polynomial-time, while collision finding is assumed not to be (and to enable him to prove membership in $\mathcal{NP}$-complete languages it was assumed that he had access to an $\mathcal{NP}$ witness for free). In our case, however, $\mathcal{P}$ cannot be assumed to be polynomial-time, because it ought to be able to run M on x for t steps for all possible $(M, x, y, t) \in \mathcal{L}$, and t may vastly exceed $|(M, x, y, t)|$.

[19] Assume, for instance, that the complexity of finding an H-collision for a k-bit output H is $\Omega(2^{k^d})$ for some constant d between 0 and 1. Then, because the honest prover works in time polynomial in t, setting $k = (\log t)^{2/d}$ seems a reasonable choice. This choice in fact increases only by a $poly((\log t)^{2/d})$ factor the amount of work of the honest prover but forces any malicious prover to work in time $2^{(\log t)^2}$.

[20] Accordingly, we view a prover working on a given input as an *individual* device, endowed with a fixed amount of computational resources, rather than a mechanism capable of handling all members of a given complexity class.

thus a prover $\mathcal{P}$ who knows them can simulate perfectly $\mathcal{V}$'s actions (and in particular compute the bit locations of τ that SV wishes to see). Of course, however, this a dangerous way of proceeding. In fact, it is already dangerous having a malicious CS prover $\widetilde{\mathcal{P}}$ simply *know* these k random tapes (let alone choose them), or even just predict the bit locations that SV wishes to see in its k runs. In fact:

> Letting λ denote the number of bit-locations of τ SV wishes to access in a single run, the total number of such bit-locations will be $k\lambda$. Now, if $k\lambda$ is sufficiently small with respect to the total number of bits in τ (which we would like to be our case in order to satisfy efficient verifiability), it is not hard to see that if $\widetilde{\mathcal{P}}$ knows in advance these $k\lambda$ bit-locations, then he could provide (1) a root value RV for the Merkle tree, (2) bit values for said locations, and (3) authetication paths for these values relative to RV, so as to cheat $\mathcal{V}$ with probability 1.

Notice too, however, that, if the k random tapes are selected *after* $\widetilde{\mathcal{P}}$ provides the root value RV, then, roughly said, unless he succeeds in finding at least one collision for H, his probability of cheating still is $< 2^{-k}$. (This continues to be true even if $\widetilde{\mathcal{P}}$ knows the so-selected k tapes in their entirety, rather than just the bit-requests that the sampling verifier computes from them.) This suggests replacing interaction in the above proof system as follows. On input $(M, x, y, t) \in \mathcal{L}$, prover $\mathcal{P}$, as before, (a) computes a classical proof of it by running M on input x and costructing a history σ of such computation, (b) puts σ in a samplable form τ, and (c) stores τ in the leaves of a suitable binary tree and constructs a corresponding Merkle tree, using a collision-free hash function H, so as to compute a root value RV. At this point, $\mathcal{P}$ uses the random oracle on input RV so as to compute k suitably-long random tapes, $RT_1, \ldots, RT_k$. He then runs ("in his head") verifier $\mathcal{V}$ and its subroutine SV as in the whole process described above for k times, using RT_i as SV's random tape in the ith iteration. Therefore, he computes (in his head) all the bit-locations of the samplable proof that SV requests to access. Then, it outputs, as a CS proof with a random oracle for $(M, x, y, t) \in \mathcal{L}$, the value RV and the requested bits, each with its own authentication path relative to RV. Such proof can be verified, in the obvious way, by using verifier $\mathcal{V}$ (with subroutine SV) and the same random oracle.

The intuition that this strategy works is quite strong. Consider a malicious prover trying to "CS-prove with a random oracle" a false statement. Of course, he can choose a root value RV' of his liking and consult the oracle so as to see whether he can produce a good-looking CS proof relative to RV'. However, roughly said, because for each RV' (as long as he does not succeed in finding a collision for the random oracle), his chance of finding a good-looking proof is at most 2^{-k}, we expect that he tries 2^k times before he succeeds. Thus, if k is large enough, and the running time of the malicious prover is properly and meaningfully upperbounded, his chance of finding a CS proof of a false statement is negligible. (Despite this simple and strong intuition, however, formally proving that this strategy works appears to be more difficult.)

Our strategy is reminiscent of a step used by Fiat and Shamir [18]. Indeed, they construct their digital signature scheme by starting with an interactive two-party protocol, in which the first party sends a first message to the second party and the second party responds with a random string, and then replacing the random message of the second party by evaluating a collision-free hash function on the first party's message. (By now, similar strategies have been discussed in the literature in many a context.)

As a final modification, in lieu of k-bit-output collision-free hash function H,

we construct our Merkle tree using a random oracle mapping $2k$-bit strings to k-bit ones. Indeed, finding collisions for random oracles is provably hard in a precisely quantifiable way, and adoption of such oracles also for this task dispenses us for relying on additional complexity assumptions (i.e., the existence of a collision-free H).

Note that the random oracle used for removing the interaction between prover and verifier and that used for building the Merkle tree had better be different. Alternatively, using standard techniques, one may use a single random oracle to "extract" two independent ones: one for each of these two tasks.

3.4. Description of $(\mathcal{P}, \mathcal{V})$: Our CS proof-system with a random oracle. Having presented all the ideas entering in our construction at an intuitive level, let us now proceed more formally.

3.4.1. Preliminaries.

From one oracle to two oracles. According to our definition, in a CS proof system with a random oracle, prover and verifier have oracle access to a single function f, where feasible completeness holds for any f, and computational soundness for a random f.

It will be easier, however, to exhibit a CS proof system with a random oracle $(\mathcal{P}, \mathcal{V})$ by having $\mathcal{P}$ and $\mathcal{V}$ have oracle access to two distinct functions, f_1 and f_2, where feasible completeness holds for any possible choice of f_1 and f_2, while computational soundness holds when f_1 and f_2 are random and independent.

Oracle access to these two functions can be simulated by accessing a single, properly selected, function f: to ensure that f_1 and f_2 are randomly and independently selected when f is random, it suffices to arrange that whenever $(i, x) \neq (j, y)$, no query made to f in order to compute $f_i(x)$ coincides with a query made to f in order to compute $f_j(y)$.[21]

From k runs to one run: Sampling proof systems and their length bounds. Rather than having the probability of successful cheating be less than $1/2$, let us restate Theorem 3.4 so as to reduce this probability to 2^{-k} by means of a sampling verifier that (at least formally) still uses a single random tape but receives an additional, independent security parameter.

THEOREM 3.5 (samplable proofs: Version 2). *There exists a deterministic polynomial-time algorithm $SP(\cdot, \cdot)$, a probabilistic polynomial-time algorithm $SV(\cdot, \cdot, \cdot)$, and two polynomials $L(\cdot)$ and $\Lambda(\cdot)$ such that, for any polynomial-time relation R over $\Sigma^* \times \Sigma^*$, the following two properties hold.*

1. *For all strings x and y such that $R(x, y)$ holds, $SP(x, y)$ outputs a string y' such that*
   - 1.1. *$y' < L(|x| + |y|)$, and*
   - 1.2. *for every security parameter k, $SV(x, |y'|, 1^k)$, having a random tape of length $k \cdot \Lambda(\log |y'|)$ and random access to y', accepts.*
2. *For all strings x such that for all y $R(x, y) = 0$ and for any string σ, the probability (computed over SV's coin tosses) that $SV(x, |\sigma|, 1^k)$, having a random tape of length $k \cdot \Lambda(\log |\sigma|)$, having random access to σ, and actually accessing $k \cdot \Lambda(\log |\sigma|)$ bits of σ, accepts is $\leq 2^{-k}$.*

The CS-history relation. In what follows we shall use Theorem 3.5 only for a specific relation $\mathcal{H}$, the *CS-history relation*, defined as follows.

[21] For instance, if, for $i = 1, 2$, $f_i : \{0,1\}^{a_i} \to \{0,1\}^{b_i}$ (for some positive integer values a_i and b_i, $i = 1, 2$), letting f map $\{0,1\}^{1+max(a_1+a_2)}$ into $\{0,1\}^{max(b_1+b_2)}$ allows us to achieve our goal quite straightforwardly.

$\mathcal{H}(q,h) = 1$ *if and only if string* $q = (M,x,y,t) \in \mathcal{L}$ *and string* h *is an encoding of the history of the execution of* M *on input* x.

Notice that, assuming the use of a proper encoding for these histories, not only is $\mathcal{H}$ polynomial-time computable, but there also is a fixed polynomial Q such that $\mathcal{H}(q,h) = 1$ implies $|h| \leq Q(2^{|q|})$. (In fact, our quadruple conventions imply that $|t| < |q|$, and thus that $t < 2^{|q|}$.) Let us now use the CS-history relation to restate Theorem 3.5 in the following form more directly useful to us.

THEOREM 3.6 (samplable proofs: Version 3). *There exists a deterministic polynomial-time algorithm* $SP(\cdot,\cdot)$, *a probabilistic polynomial-time algorithm* $SV(\cdot,\cdot)$, *and two polynomials* $\ell(\cdot)$ *and* $\lambda(\cdot)$ *such that, letting* $\mathcal{H}$ *be the history relation, the following two properties hold.*

1. *For all strings* q *and* h *such that* $\mathcal{H}(q,h) = 1$, $SP(q,h)$ *halts within* $\ell(|q|)$ *steps outputting a string* h' *such that*
   1.1. $\log |h'| < \ell(|q|)$, *and*
   1.2. *for every security parameter* k, $SV(q,|h'|,1^k)$, *having a random tape of length* $k \cdot \lambda(|q|)$ *and random access to* h', *accepts.*
2. *For all strings* q *such that for all* h $\mathcal{H}(x,h) = 0$, *for any security parameter* k, *and for any string* σ, *the probability (computed over* SV*'s coin tosses) that* $SV(q,|\sigma|,1^k)$, *having a random tape of length* $k \cdot \lambda(|q|)$, *having random access to* σ, *and actually accessing* $k \cdot \lambda(|q|)$ *bits of* σ, *accepts is* $\leq 2^{-k}$.

DEFINITION 3.7. *Let* SP, SV, ℓ, *and* λ *be as in Theorem* 3.6. *Then, we shall refer to* (SP,SV) *as a* sampling proof system (for the CS-history relation)*, and to* ℓ *and* λ *as its* length bounds *(respectively, for the samplable proof produced by* SP *and the number of queries and length of the random tape used by* SV*).*

Notation.

- *Basics.* We denote the empty word by ε, the set $\{0,1\}$ by Σ, the set of all natural numbers by $\mathcal{N}$, the set of all positive integers by Z^+, the concatenation of two strings x and y by $x|y$ (or more simply by xy), and the complement of a bit b by $\bar{b}$.
- *Strings.* If α is a binary string, then $|\alpha|$ denotes α's length; $\alpha_1 \cdots \alpha_i$ denotes α's i-bit prefix; and $\alpha_1 \cdots \bar{\alpha}_i$ denotes α's i-bit prefix with the last bit complemented.
- *Labeled trees.* If N is a power of two, we let $\mathcal{T}_N$ denote the complete binary tree with N leaves, whose vertices are labeled by binary strings whose lengths range from 0 to $\log N$ as follows. Vertex v_ε is the root, v_0 and v_1 are, respectively, its the left and right child, and, more generally, for all $i \in [0, \log N)$ and for all $\alpha \in \Sigma^i$, $v_{\alpha 0}$ and $v_{\alpha 1}$ are, respectively, the left and right child of node v_α. (Consequently, $v_{\alpha_1 \cdots \alpha_j}$ and $v_{\alpha_1 \cdots \bar{\alpha}_j}$ are siblings whenever $0 < |\alpha| \leq \log N$ and $0 < j \leq |\alpha|$.)
  The leaves of $\mathcal{T}_N$ are thought to be ordered "from left to right." Within the context of a tree $\mathcal{T}_N$, we denote by $[j]$ the $(\log_2 N)$-bit binary representation of integer j, with possible leading 0s. (Accordingly, the jth leaf of $\mathcal{T}_N$ is node $v_{[j]}$.)

3.4.2. Algorithms $\mathcal{P}$ and $\mathcal{V}$. Let us now describe two oracle-calling algorithms, $\mathcal{P}$ and $\mathcal{V}$, and then prove that they are, respectively, the prover and verifier of a CS proof system with a random oracle, $(\mathcal{P},\mathcal{V})$.

Common inputs: $q = (M,x,y,t)$, an n-bit (alleged) member of $\mathcal{L}$, and 1^k, a security parameter.

{*Comment:* For the purpose of the code of (honest) prover $\mathcal{P}$, $q = (M, x, y, t) \in \mathcal{L}$ and thus $t = \#M(x)$.}

Common subroutines: (SP, SV), a sampling proof system—as per Definition 3.7—with length bounds ℓ and λ.

Common oracles: $f_1 \in \Sigma^{2k} \to \Sigma^k$ and $f_2 \in \Sigma^{k+n} \to \Sigma^{k \cdot \lambda(n)}$.

{*Comment:* The first oracle, when randomly selected, is used as a collision-free hash function of a Merkle tree, by which $\mathcal{P}$ commits to a samplable proof of $q \in \mathcal{L}$. The second oracle, when randomly selected, is used to generate the random tape of sampling verifier SV.}

$\mathcal{P}$'s output: $\mathcal{C}$, a CS certificate that $q \in \mathcal{L}$.

$\mathcal{V}$'s additional input: $\mathcal{C}$.

ALGORITHM $\mathcal{P}$

$P1$. (Commit to a samplable proof of $q \in \mathcal{L}$.)

$P1.1$ (Find a proof, denoted by σ, of $x \in \mathcal{L}$.)
Run machine M on input x so as to output y in $\#M(x)$ steps and generate an encoding, σ, of M's computational history.
{*Comment:* σ can be considered a proof that $x \in \mathcal{L}$.}

$P1.2$ (Compute a samplable form, denoted by τ, of proof σ.)
$\tau \leftarrow SP(q, \sigma)$.
{*Comment:* Theorem 3.6, our quadruple encoding, and $n = |q|$ imply $|\tau| \le \ell(n)$.}

$P1.3$ (Commit to τ by means of a k-bit value R_ε.)
Assume, for simplicity only, that $|\tau|/k = N$, where N is an integral power of 2. Then, we shall associate to (figuratively speaking, "store in") each node v_α of a labeled tree $\mathcal{T}_N$ a value R_α computed as follows. Subdivide τ into the concatenation of N substrings, each k-bit long, $\tau = \tau_1 \cdots \tau_N$, and for $0 \le j < N$, assign to the jth leaf, $v_{[j]}$, the k-bit value

$$R_{[j]} = \tau_j. \tag{3.1}$$

Then, in a bottom-up fashion, assign to each interior node v_α of $\mathcal{T}_N$ the k-bit value

$$R_\alpha = f_1(R_{\alpha 0} | R_{\alpha 1}). \tag{3.2}$$

{*Comment:* R_ε thus is the k-bit value assigned to the root of $\mathcal{T}_N$. R_ε is considered a commitment to all values stored in the vertices of $\mathcal{T}_N$ and thus a comitment to all of τ.}

$P2$. (Build a CS certificate, $\mathcal{C}$, of $q \in \mathcal{L}$.)

$P2.1$ (Start building the CS certificate with the k-bit commitment R_ε as prefix.)
$\mathcal{C} \leftarrow R_\varepsilon$.

$P2.2$ (Choose a random tape, T, for SV.)
$T \leftarrow f_2(q | R_\varepsilon)$.

$P2.3$ (Run SV with random tape T and virtual access to τ.)
Run SV with random tape T, inputs q and $|\tau|$, and virtual access to τ. Whenever SV wishes to access bit-location i of τ, perform the following instructions.

$P2.3.1$ (Find the index, I, of the substring of τ containing b_i.)
$I \leftarrow \lceil i/k \rceil$;

$P2.3.2$ (Add leaf I to the CS certificate.)
$\mathcal{C} \leftarrow \mathcal{C}|R_{[I]}$; and

$P2.3.3$ (Add to the certificate the authentication path of leaf I.)
Set $\alpha = [I]$;
{*Comment:* $|\alpha| = \log_2 N$.}
Set $AUTHPATH_I = R_{\alpha_1 \cdots \bar{\alpha}_{\log N}} | \cdots | R_{\alpha_1 \bar{\alpha}_2} | R_{\bar{\alpha}_1}$;
{*Recall:* The authentication path of leaf I consists of the values stored in the siblings of the vertices of the path from leaf I to the root.}
$\mathcal{C} \leftarrow \mathcal{C}|AUTHPATH_I$.
{*Example:* if $N = 8$ and $I = 3$, then $[I] = 011$ and $AUTHPATH_I = (R_{010}, R_{00}, R_1)$.}

$P3$. (Output a certificate for $q \in \mathcal{L}$.)
Output $\mathcal{C}$.
{*Comment:* $\mathcal{C}$'s k-bit prefix is R_ε.}

ALGORITHM $\mathcal{V}$

$V1$. (Read and delete R_ε from certificate $\mathcal{C}$, and compute SV's random tape T.)
$ALLEGEDROOT \leftarrow \mathcal{C}_1 \cdots \mathcal{C}_k$;
$\mathcal{C} \leftarrow \mathcal{C}_{k+1} \cdots$; and
$T \leftarrow f_2(q|R_\varepsilon)$.

$V2$. (Run SV with random tape T, inputs q, $\ell(n)$ and 1^k, and virtual access to samplable proof τ.)
Execute $SV(q, \ell(n), 1^k)$ with random tape T. Whenever SV wishes to access bit-location i of the samplable proof, do the following.

$V2.1$ (Find the index, I, of the k-bit segment of τ containing b_i, and read the value of leaf I from the certificate.)
$I \leftarrow \lceil i/k \rceil$; $\alpha \leftarrow [I]$; and $R_\alpha \leftarrow \mathcal{C}_1 \cdots \mathcal{C}_k$.
Provide SV with the $(i - kI)$th bit of R_α.

$V2.2$ (Delete the value of leaf I from the certificate.) $\mathcal{C} \leftarrow \mathcal{C}_{k+1} \cdots$.

$V2.3$ (Check and remove from the certificate the authentication path of leaf I.)
For $m = 1$ to $\log N$,
$R_{\alpha_1 \cdots \bar{\alpha}_m} \leftarrow \mathcal{C}_1 \cdots \mathcal{C}_k$ and
$\mathcal{C} \leftarrow \mathcal{C}_{k+1} \ldots$.
For $m = \log N, \ldots, 1$, compute $R_{\alpha_1 \cdots \alpha_{m-1}}$ as follows:

$$R_{\alpha_1 \cdots \alpha_{m-1}} \leftarrow \begin{cases} f_1(R_{\alpha_1 \cdots \alpha_m} | R_{\alpha_1 \cdots \alpha_m^-}) & \text{if } \alpha_m = 1, \\ f_1(R_{\alpha_1 \cdots \alpha_m^-} | R_{\alpha_1 \cdots \alpha_m}) & \text{if } \alpha_m = 0 \end{cases}$$

and check whether the computed value R_ε equals the value $ALLEGEDROOT$.
{*Example:* If $N = 8$ and $I = 3$, then $[I] = 011$ and the verifier computes

$$\begin{aligned} R_{01} &= f_1(R_{010}|R_{011}), \\ R_0 &= f_1(R_{00}|R_{01}), \text{ and} \\ R_\varepsilon &= f_1(R_0|R_1), \end{aligned}$$

where values R_{011}, R_{010}, R_{00}, and R_1 are retrieved from $\mathcal{C}$.}

$V3$. (Accept if and only if SV accepts and the authentication path of each leaf is correct.)
If SV accepts and each $V2.3$ check is passed, output YES. Otherwise, output NO.

3.5. $(\mathcal{P}, \mathcal{V})$ works.

THEOREM 3.8. *$(\mathcal{P}, \mathcal{V})$ is a CS proof system with a random oracle.*

As per our Definition 3.2, to prove Theorem 3.8 we need to prove that $(\mathcal{P}, \mathcal{V})$ satisfies both feasible completeness and computational soundness.

3.5.1. Proof of feasible completeness. Adopting the two-oracle formulation of Definition 3.2 and recalling the domain and range of each of the two oracles in our construction of $(\mathcal{P}, \mathcal{V})$, what we need to prove is the following.

> *There exists $c_1, c_2, c_3 > 0$ such that for all $q = (M, x, y, t) \in \mathcal{L}$, for all k, for all $f_1 \in \Sigma^{2k} \to \Sigma^k$, and for all $f_2 \in \Sigma^{k+|q|} \to \Sigma^{k \cdot \lambda(|q|)}$:*
> (i) *$\mathcal{P}^{f_1, f_2}(q, 1^k)$ halts within $(|q|kt)^{c_2}$ computational steps, outputting a binary string $\mathcal{C}$ whose length is $\leq (|q|k)^{c_3}$, and*
> (ii) *$\mathcal{V}^{f_1, f_2}(q, 1^k, \mathcal{C}) = YES$.*

It is immediately seen that subproperty (ii) of feasible completeness holds. That is, for all $q = (M, x, y, t) \in \mathcal{L}$, for all security parameter k, and for all oracles f_1 and f_2, the certificate output by $\mathcal{P}$ convinces $\mathcal{V}$. Subproperty (i), that is, the fact that $\mathcal{P}$ performs only polynomially many (in n, k, and t) steps for producing a certificate, follows as easily. Indeed, prover $\mathcal{P}$ performs the following operations: (1) initially invests t steps of computation for running M on input x; (2) takes a number of steps polynomial in q's length (i.e., n) and t for computing the samplable proof τ; (3) makes less than $t \log t$ queries (each at unit cost) to the second random oracle for generating the Merkle tree; and, finally, (4) makes additional polynomially many steps for running $\mathcal{V}$ "in his head" and answering its queries so as to build the desired CS certificate.

Finally, let us argue that the length of $(\mathcal{P}, \mathcal{V})$'s certificates are in accordance to Definition 3.2. Namely, letting $q = (M, x, y, t)$ be a member of $\mathcal{L}$ and $\mathcal{C} = \mathcal{P}^{f_1, f_2}(q, 1^k)$, then $\mathcal{C}$'s length is polynomial in $|q|$ and k. To this end, notice that $\mathcal{C}$ contains a k-bit root value, plus one authentication path (in the constructed Merkle tree) for each bit that the samplable verifier SV wishes to access when run on inputs q and $|\tau|$ and (virtual) access to the samplable proof τ of "$M(x) = y$ in t steps." Now, because τ can be computed in a number of steps upperbounded by a fixed polynomial in $|q|$ and t, and because according to our conventions $t < 2^{|q|}$, it follows that the length of the binary representation of $|\tau|$ is upperbounded by some other fixed polynomial in $|q|$ alone. Therefore, because SV runs in polynomial time, the number of bits of τ it accesses (i.e., the number of authentication paths included in $\mathcal{C}$) is polynomial in $|q|$ alone. The claim about the length of $\mathcal{C}$ then follows from the fact that each authentication path contains a k-bit value for each level of the constructed Merkle tree and thus $k \log \tau < k|q|$ bits overall. □

3.5.2. Proof of computational soundness. Adopting the two-oracle formulation of Definition 3.2 and recalling the domain and range of each of the two oracles in our construction of $(\mathcal{P}, \mathcal{V})$, what we need to prove is the following.

> *There exist positive constants c_4, c_5, and c_6 such that for all $\widetilde{q} \notin \mathcal{L}$, for all k such that $2^k > |\widetilde{q}|^{c_4}$, and for all (cheating) deterministic $2^{c_5 k}$-call algorithm $\widetilde{P}$, for random oracles $\rho_1 \in \Sigma^{2k} \to \Sigma^k$ and $\rho_2 \in \Sigma^{k+|\widetilde{q}|} \to \Sigma^{k \cdot \lambda(|\widetilde{q}|)}$,*

$$Prob_{\rho_1;\rho_2}[V^{\rho_1,\rho_2}(\widetilde{q}, 1^k, \widetilde{P}^{\rho_1,\rho_2}(\widetilde{q}, 1^k)) = YES] \leq 2^{-c_6 k}.$$

We shall actually prove the following theorem.

THEOREM 3.9. *$(\mathcal{P}, \mathcal{V})$ satisfies the above condition for the following choice of c_4, c_5, and c_6:*

$$c_4 \stackrel{\text{def}}{=} 64c, \qquad c_5 \stackrel{\text{def}}{=} 1/8, \quad \text{and} \quad c_6 \stackrel{\text{def}}{=} 1/16,$$

where $c \stackrel{\text{def}}{=}$ the smallest positive integer C such that $n^C > \ell(n)$ for all integers $n > 1$.

Recall that ℓ is the first length-bound of our underlying sampling proof system (SP, SV).

Proof idea. In essence, the proof is by contradiction. Assume that $q \notin \mathcal{L}$, and that, nonetheless, we are given a cheating prover $\widetilde{\mathcal{P}}$ that has a nonnegligible probability of outputting a CS proof for $q \in \mathcal{L}$. Then, we derive a contradiction by using such $\widetilde{\mathcal{P}}$ to build a *samplable* proof for $q \in \mathcal{L}$. Let us explain.

By hypothesis, for many oracles ρ_1 and ρ_2, $\widetilde{\mathcal{P}}$ should be able to produce a CS proof $\mathcal{C}_{\rho_1,\rho_2}$ for $q \in \mathcal{L}$. Such string $\mathcal{C}_{\rho_1,\rho_2}$ allegedly includes the contents of a few bit-locations of an underlying samplable proof, τ_{ρ_1,ρ_2}. By varying ρ_1 and ρ_2, and looking at their corresponding $\mathcal{C}_{\rho_1,\rho_2}$, we obtain the contents of more and more bit-locations, until we discover the bits in all the locations having a nonnegligible probability of being queried by the sampling verifier on input q. Despite the fact that such contents are pieced together from different CS proofs (and thus potentially from different underlying samplable proofs), we shall prove that, with high probability, the discovered contents are consistent with a *single* samplable proof τ.

Local definition 1.

- *Probabilities.* Let $S_1, S_2, \ldots,$ be finite sets, and let E be an event. Then, by $PROB_{x_1 \in S_1; x_2 \in S_2; \ldots}[E]$ we denote the probability of E in the experiment consisting of selecting elements $x_1 \in S_1, x_2 \in S_2, \ldots$ randomly and independently. If, for some x_i, it is already clear that x_i ranges in S_i, we may omit specifying S_i and more simply denote the same probability by $PROB_{\ldots;x_i;\ldots}[E]$.
- *Pseudoexecutions.* We shall consider executing a cheating, N-call, prover $\widetilde{\mathcal{P}}^{(\cdot,\cdot)}$ by answering its queries to the first oracle by means of a function f, and its queries to the second oracles by means of a predetermined, N-long, sequence S (i.e., the ith query to the second oracle will be answered with the ith element of S). We shall call such a process a *pseudoexecution (of $\widetilde{\mathcal{P}}$)*, or an execution of *algorithm* $\widetilde{\mathcal{P}}^{f,S}$. When $\widetilde{\mathcal{P}}^{f,S}$ is run on an n-bit input ($q \notin \mathcal{L}$) and security parameter k, then each element of S will consist of a $k\lambda(n)$-bit string (i.e., a possible random tape for $\mathcal{V}$). If σ is a string and m an integer between 1 and N, by the expression $\widetilde{\mathcal{P}}^{f,S_m=\sigma}$ we denote the algorithm identical to $\widetilde{\mathcal{P}}^{f,S}$, except that the mth query to the second oracle is answered by σ (i.e., the mth element of S—no matter what it originally was—is "forced" to be σ). By the expression $\widetilde{\mathcal{P}}^{f,S_m=\sigma_1,\sigma_2}$ we denote the algorithm that first executes $\mathcal{P}^{f,S_m=\sigma_1}$ and then $\mathcal{P}^{f,S_m=\sigma_2}$.
- *Collisions.* Let f be an oracle, $A(\cdot)$ an oracle-calling algorithm, and z an input. Then, by the expression *an f-collision in* $A^f(z)$, we mean that executing A on z with oracle f, A queries f about two distinct strings a and b and obtains the same string, c $(= f(a) = f(b))$, in response.
- *Pseudocertificates and pseudoroots.* Without loss of generality, we assume that a cheating prover $\widetilde{\mathcal{P}}$ never asks the same query twice to the same oracle. Again, without loss of generality, we assume that each cheating prover $\widetilde{\mathcal{P}}$ verifies all its nonempty outputs. That is, if $\widetilde{\mathcal{C}}$ is a nonempty string and $\widetilde{\mathcal{P}}^{f_1,f_2}(\widetilde{q}, 1^{\widetilde{k}}) = \widetilde{\mathcal{C}}$, then, prior to outputting $\widetilde{\mathcal{C}}$, $\widetilde{\mathcal{P}}$ runs $\mathcal{V}$ making all required calls to f_1 and f_2 so as to verify that $\mathcal{V}^{f_1,f_2}(\widetilde{q}, 1^{\widetilde{k}}, \widetilde{\mathcal{C}}) = YES$, and thus that $\widetilde{\mathcal{C}}$ is a CS certificate for $\widetilde{q}$. If $\widetilde{q}$ does not belong to the CS language $\mathcal{L}$, to emphasize this fact we refer to $\widetilde{\mathcal{C}}$ itself as a *pseudocertificate (for $\widetilde{q}$)* and to

its $\widetilde{k}$-bit prefix as a *pseudoroot*.

In an execution of a cheating prover $\widetilde{\mathcal{P}}$ producing a pseudocertificate $\widetilde{\mathcal{C}}$ for $\widetilde{q}$, we say that $\widetilde{\mathcal{C}}$ is *relative to tape-number* m if (1) the pseudoroot of $\widetilde{\mathcal{C}}$ is a string $\widetilde{R}_\varepsilon$ such that the mth query of $\widetilde{\mathcal{P}}$ to its second oracle consists of the pair $(\widetilde{q}, \widetilde{R}_\varepsilon)$.

To indicate a generic pseudocertificate having pseudoroot $\widetilde{R}_\varepsilon$, we write $\widetilde{R}_\varepsilon \ldots$.

A proof by contradiction. We proceed by contradiction. Assume that Theorem 3.9 is incorrect; then, because $\widetilde{\mathcal{P}}$ verifies all its nonempty outputs, the following proposition holds.

PROPOSITION 3.10. *There exist an integer $\widetilde{n} > 1$, a $\widetilde{n}$-bit string $\widetilde{q} \notin \mathcal{L}$, an integer $\widetilde{k}$ such that $2^{\widetilde{k}} > \widetilde{n}^{64c}$, and a deterministic, $2^{\widetilde{k}/8}$-call, cheating prover $\widetilde{\mathcal{P}}$ such that, for random oracles $\rho_1 \in \Sigma^{2\widetilde{k}} \to \Sigma^{\widetilde{k}}$ and $\rho_2 \in \Sigma^{\widetilde{k}+\widetilde{n}} \to \Sigma^{\widetilde{k}\cdot\lambda(\widetilde{n})}$,*

(P1) $PROB_{\rho_1;\rho_2}[\widetilde{\mathcal{P}}^{\rho_1,\rho_2}(\widetilde{q}, 1^{\widetilde{k}}) \neq \varepsilon] > 2^{-\widetilde{k}/16}$.

We now show that Proposition 3.10 contradicts the fact that $(\mathcal{P}, \mathcal{V})$'s subroutine (SP, SV) is a sampling proof system. We start by stating without proof some easy probabilistic facts.

Basic lemmas. Let A and B be finite sets, $A \times B$ their Cartesian product, and E a subset of $A \times B$. Then, in the following two lemmas $PROB_{a;b}[(a,b) \in E]$ denotes the probability that (a,b) belongs to E by selecting uniformly and independently a in A and b in B, and $PROB_b[(a,b) \in E]$ denotes the probability that (a,b) belongs to E by selecting uniformly b in B.

LEMMA 3.11. *Assume $PROB_{a;b}[(a,b) \in E] > x$, and let $G = \{a : PROB_b[(a,b) \in E] > 2^{-1} \cdot x\}$. Then,*

$$PROB_a[a \in G] > x/2.$$

LEMMA 3.12. *Assume $PROB_{a;b}[(a,b) \in E] < x$, and let $L = \{a : PROB_b[(a,b) \in E] < nx\}$. Then,*

$$PROB_a[a \in L] > 1 - n^{-1}.$$

LEMMA 3.13. *For all positive integers k and N, for all N-call algorithms $\mathcal{A}(\cdot)$, and for all inputs z,*

$$PROB_{f \in \Sigma^{2k} \to \Sigma^k}[\text{ an } f\text{-collision in } \mathcal{A}^f(z)] < N^2 2^{-k}.$$

Note that Lemma 3.13 continues to hold if A has additional inputs and oracles, provided that f is randomly selected independently of them.

An averaging argument.

LEMMA 3.14. *Let $\widetilde{n}$, $\widetilde{q}$, and $\widetilde{k}$ be as in Proposition 3.10. Then, there exist an oracle $f_1 \in \Sigma^{2\widetilde{k}} \to \Sigma^{\widetilde{k}}$, a $2^{\widetilde{k}/8}$-long sequence S of $\widetilde{k} \cdot \lambda(\widetilde{n})$-bit strings, an integer $m \in [1, 2^{\widetilde{k}/8}]$, and a $\widetilde{k}$-bit (pseudoroot) $\widetilde{R}_\varepsilon$ such that*

(L1.1) $PROB_{\sigma \in \Sigma^{\widetilde{k}\cdot\lambda(\widetilde{n})}}[\widetilde{\mathcal{P}}^{f_1, S_m = \sigma}(\widetilde{q}, 1^{\widetilde{k}}) = \widetilde{R}_\varepsilon \cdots] > 2^{-1} \cdot 2^{-3\widetilde{k}/16}$, and

(L1.2) $PROB_{\sigma_1, \sigma_2 \in \Sigma^{\widetilde{k}\cdot\lambda(\widetilde{n})}}[\widetilde{\mathcal{P}}^{f_1, S_m = \sigma_1}(\widetilde{q}, 1^{\widetilde{k}}) = \widetilde{R}_\varepsilon \cdots = \widetilde{\mathcal{P}}^{f_1, S_m = \sigma_2}(\widetilde{q}, 1^{\widetilde{k}}) \wedge f_1\text{-collision}$ in $\mathcal{P}^{f_1, S_m = \sigma_1, \sigma_2}(\widetilde{q}, \widetilde{k})] < 32 \cdot 2^{-9\widetilde{k}/16}$.

Proof. Let ρ_1 and ρ_2 be oracles as in Proposition 3.10. Then, because $\widetilde{\mathcal{P}}^{\rho_1,\rho_2}$ verifies its nonempty outputs (and because it is $2^{\widetilde{k}/8}$-call), each of its pseudocertificates

is relative to some tape-number between 1 and $2^{\widetilde{k}/8}$. Thus, inequality P1 implies that there exists a positive integer $m \in [1, 2^{\widetilde{k}/8}]$ such that

(L1.3) $PROB_{\rho_1;\rho_2}[\widetilde{\mathcal{P}}^{\rho_1,\rho_2}(\widetilde{q}, 1^{\widetilde{k}}) \neq \varepsilon \ \wedge \ \widetilde{\mathcal{P}}^{\rho_1,\rho_2}(\widetilde{q}, 1^{\widetilde{k}})$ is relative to tape-number $m] \geq 2^{-\widetilde{k}/16}/2^{\widetilde{k}/8} = 2^{-3\widetilde{k}/16}$.

Therefore, by focusing our attention on tape-number m (i.e., on the mth answer of our random oracle $\rho_2 \in \Sigma^{\widetilde{k}+\widetilde{n}} \to \Sigma^{\widetilde{k}\cdot\lambda(\widetilde{n})}$) and by averaging, inequality L1.3 implies that there exists a $2^{\widetilde{k}/8}$-long sequence, S, of $\widetilde{k}\cdot\lambda(\widetilde{n})$-bit strings (i.e., of possible second-oracle answers), such that

(L1.4) $PROB_{\rho_1;\sigma\in\Sigma^{\widetilde{k}\cdot\lambda(\widetilde{n})}}[\widetilde{\mathcal{P}}^{\rho_1,S_m=\sigma}(\widetilde{q}, 1^{\widetilde{k}}) \neq \varepsilon \ \wedge \ \widetilde{\mathcal{P}}^{\rho_1,S_m=\sigma}(\widetilde{q}, 1^{\widetilde{k}})$ is relative to tape-number $m] > 2^{-3\widetilde{k}/16}$.

Define now an oracle $\rho_1 : \Sigma^{2\widetilde{k}} \to \Sigma^{\widetilde{k}}$ to be *good* if

$PROB_{\sigma\in\Sigma^{\widetilde{k}\cdot\lambda(\widetilde{n})}}[\widetilde{\mathcal{P}}^{\rho_1,S_m=\sigma}(\widetilde{q}, 1^{\widetilde{k}}) \neq \varepsilon \ \wedge \ \widetilde{\mathcal{P}}^{\rho_1,S_m=\sigma}(\widetilde{q}, 1^{\widetilde{k}})$ is relative to tape-number $m] > 2^{-1}\cdot 2^{-3\widetilde{k}/16}$.

Then, inequality L1.4 and Lemma 3.11 imply that

(L1.5) $PROB_{\rho_1}[\rho_1 \text{ good }] > 2^{-1}\cdot 2^{-3\widetilde{k}/16}$.

Note now that because both $\widetilde{\mathcal{P}}^{\rho_1,S_m=\sigma_1}$ and $\widetilde{\mathcal{P}}^{\rho_1,S_m=\sigma_2}$ make at most $2^{\widetilde{k}/8}$ oracle calls, algorithm $\widetilde{\mathcal{P}}^{\rho_1,S_m=\sigma_1,\sigma_2}$ makes at most twice as many calls to ρ_1. Thus, Lemma 3.13 implies that

(L1.6) $PROB_{\rho_1\in\Sigma^{2\widetilde{k}}\to\Sigma^{\widetilde{k}};\sigma_1,\sigma_2\in\Sigma^{\widetilde{k}\cdot\lambda(\widetilde{n})}}[\rho_1\text{-collision in } \widetilde{\mathcal{P}}^{\rho_1,S_m=\sigma_1,\sigma_2}(\widetilde{q}, 1^{\widetilde{k}})] < 4\cdot 2^{\widetilde{k}/4}\cdot 2^{-\widetilde{k}} = 4\cdot 2^{-3\widetilde{k}/4}$.

Define now an oracle $\rho_1 : \Sigma^{2\widetilde{k}} \to \Sigma^{\widetilde{k}}$ to be *lucky* if

$$PROB_{\sigma_1,\sigma_2\in\Sigma^{\widetilde{k}\cdot\lambda(\widetilde{n})}}[\rho_1\text{-collision in } \widetilde{\mathcal{P}}^{\rho_1,S_m=\sigma_1,\sigma_2}(\widetilde{q}, 1^{\widetilde{k}})] < (8\cdot 2^{3\widetilde{k}/16})\cdot(4\cdot 2^{-3\widetilde{k}/4}) = 32\cdot 2^{-9\widetilde{k}/16}.$$

Then, inequality L1.6 and Lemma 3.12 imply that

(L1.7) $PROB_{\rho_1}[\rho_1 \text{ lucky }] > 1 - 8^{-1}\cdot 2^{-3\widetilde{k}/16} > 1 - 2^{-1}\cdot 2^{-3\widetilde{k}/16} \geq 1 - PROB_{\rho_1}[\rho_1 \text{ good}] = PROB_{\rho_1}[\rho_1 \text{ not good}]$.

Because inequality L1.7 implies that there exist oracles in $\Sigma^{2\widetilde{k}} \to \Sigma^{\widetilde{k}}$ that are both good and lucky, let f_1 be one such oracle. Then, because F_1 is good, letting F_1 be oracle f_1 of Lemma 3.14 satisfies inequality L1.1. In fact, L1.1 simply states that f_1 is a good oracle. Let us now show that there exists a k-bit value $\widetilde{R}_\varepsilon$ such that letting F_1 be oracle f_1 of Lemma 3.14 satisfies inequality L1.2. In fact, notice that, for any possible choice of σ, the computation of $\widetilde{\mathcal{P}}^{F_1,S_m=\sigma}(\widetilde{q}, 1^{\widetilde{k}})$ is always identical up to its mth query to the second oracle, and thus that there exists a $\widetilde{k}$-bit value $\widetilde{R}_\varepsilon$ such that all mth queries consist of the same pair $(\widetilde{q}, \widetilde{R}_\varepsilon)$. Therefore, whenever an execution of $\widetilde{\mathcal{P}}^{f_1,S_m=\sigma}(\widetilde{q}, 1^{\widetilde{k}})$ produces a nonempty pseudocertificate with respect to tape-number m, $\widetilde{R}_\varepsilon$ will be the pseudoroot of this certificate. Now, because F_1 is lucky, we have

$PROB_{\sigma_1,\sigma_2\in\Sigma^{\widetilde{k}\cdot\lambda(\widetilde{n})}}[\widetilde{\mathcal{P}}^{F_1,S_m=\sigma_1}(\widetilde{q}, 1^{\widetilde{k}}) = \widetilde{R}_\varepsilon \cdots = \widetilde{\mathcal{P}}^{F_1,S_m=\sigma_2}(\widetilde{q}, 1^{\widetilde{k}}) \ \wedge \ F_1\text{-collision in } \widetilde{\mathcal{P}}^{F_1,S_m=\sigma_1,\sigma_2}(\widetilde{q}, 1^{\widetilde{k}})]$

$< PROB_{\sigma_1,\sigma_2\in\Sigma^{\widetilde{k}\cdot\lambda(\widetilde{n})}}[F_1\text{-collision in } \widetilde{\mathcal{P}}^{F_1,S_m=\sigma_1,\sigma_2}(\widetilde{q}, 1^{\widetilde{k}})] <$ (because F_1 is lucky) $32\cdot 2^{-9\widetilde{k}/16}$. □

A collision argument.

Local definition 2. If $\widetilde{\mathcal{C}}$ is a pseudocertificate, we write $\widetilde{\mathcal{C}} \ni (i,b)$ if $\widetilde{\mathcal{C}}$ indicates that location i (in the samplable proof that is allegedly Merkle-hashed to the pseudoroot of $\widetilde{\mathcal{C}}$) contains bit b.

LEMMA 3.15. *Let $\widetilde{n}$, $\widetilde{q}$, $\widetilde{k}$, $\widetilde{\mathcal{P}}$, f_1, S, m, and $\widetilde{R}_\varepsilon$ be as in Lemma* 3.14, *let σ_0 and σ_1 be two distinct $k \cdot \lambda(\widetilde{n})$-bit strings, and let E_0 be the execution of $\widetilde{\mathcal{P}}^{f_1,S_m=\sigma_0}(\widetilde{q}, 1^{\widetilde{k}})$ and E_1 the execution of $\widetilde{\mathcal{P}}^{f_1,S_m=\sigma_1}(\widetilde{q}, 1^{\widetilde{k}})$. Now, if E_0 and E_1 produce two pseudocertificates, respectively, $\mathcal{C}_0$ and $\mathcal{C}_1$, such that* (1) *both $\mathcal{C}_0$ and $\mathcal{C}_1$ have pseudoroot $\widetilde{R}_\varepsilon$ and* (2) *for some common location i, $\mathcal{C}_0 \ni (i,0)$ and $\mathcal{C}_1 \ni (i,1)$, then an f_1-collision occurs in $\widetilde{\mathcal{P}}^{f_1,S_m=\sigma_0,\sigma_1}(\widetilde{q}, 1^{\widetilde{k}})$.*

Proof. Recall that, supposedly, the underlying samplable-proof of $\widetilde{q} \in \mathcal{L}$ has been divided into N substrings, each $\widetilde{k}$-bit long and stored in a separate leaf of a Merkle tree of depth $\log N$. Thus bit-location i should be stored in the Ith leftmost leaf of the Merkle tree, where $I = \lceil i/\widetilde{k} \rceil$, or, equivalently, in the node whose $\log N$-bit name is $[I] = \alpha_1 \cdots \alpha_{\log N}$. According to our notation, the value stored in this node is denoted by $R_{[I]}$. Now, because they indicate different bit-values for location i, pseudocertificates $\mathcal{C}_0$ and $\mathcal{C}_1$ also indicate different $\widetilde{k}$-bit values for the content of node $[I]$, respectively, $R^0_{[I]}$ and $R^1_{[I]}$.

Pseudocertificates $\mathcal{C}_0$ and $\mathcal{C}_1$ also include two authentication paths for these values. Let them be, respectively,

$$R^0_{\alpha_1\cdots\alpha_{\log N-1}\bar{\alpha}_{\log N}} | R^0_{\alpha_1\cdots\bar{\alpha}_{\log N-1}} | \cdots | R^0_{\bar{\alpha}_1} | \widetilde{R}_\varepsilon$$
and
$$R^1_{\alpha_1\cdots\alpha_{\log N-1}\bar{\alpha}_{\log N}} | R^1_{\alpha_1\cdots\bar{\alpha}_{\log N-1}} | \ldots, R^1_{\bar{\alpha}_1} | \widetilde{R}_\varepsilon.$$

Because cheating prover $\widetilde{\mathcal{P}}$ verifies all its outputs, for each $j \in [1, \log N]$ it queries oracle f_1 about string S^0_j in the first execution, and about string S^1_j in the second execution, where $S^0_j = R^0_{\alpha_1\cdots\alpha_j} | R^0_{\alpha_1\cdots\bar{\alpha}_j}$ and $S^1_j = R^1_{\alpha_1\cdots\alpha_j} | R^1_{\alpha_1\cdots\bar{\alpha}_j}$.

This implies that there exists a value $j \in [1, \log N]$ such that S^0_j and S^1_j are different queries but oracle f_1 returns the same answer on them. In fact, for $j = 1$, the two queries $S^0_1 (= R^0_{\alpha_1} | R^0_{\bar{\alpha}_1})$ and $S^1_1 (= R^2_{\alpha_1} 1 | R^1_{\bar{\alpha}_1})$ are both answered by $\widetilde{R}_\varepsilon$, and for $j = \log N$ the two queries $S^0_{\log N} (= R^0_{[I]})$ and $S^1_{\log N} (= R^1_{[I]})$ are different, because they coincide with the two different values for leaf I. □

Reaching the desired contradiction.

Local definition 3. Letting $\widetilde{n}$, $\widetilde{q}$, $\widetilde{k}$, S, m, and $\widetilde{R}_\varepsilon$ be as in Lemma 3.14, define the following.

- *Conditional probabilities $P_{i,0}$ and $P_{i,1}$.* For each bit-location $i \in [1, \ell(\widetilde{n})]$, define
  $$P_{i,0} = PROB_{\sigma \in \widetilde{\Sigma^{k \cdot \lambda(n)}}} [\widetilde{\mathcal{P}}^{f_1,S_m=\sigma}(\widetilde{q}, 1^{\widetilde{k}}) = \widetilde{R}_\varepsilon \cdots \wedge \widetilde{R}_\varepsilon \cdots \ni (i,0)]$$
  and
  $$P_{i,1} = PROB_{\sigma \in \widetilde{\Sigma^{k \cdot \lambda(n)}}} [\widetilde{\mathcal{P}}^{f_1,S_m=\sigma}(\widetilde{q}, 1^{\widetilde{k}}) = \widetilde{R}_\varepsilon \cdots \wedge \widetilde{R}_\varepsilon \cdots \ni (i,1)].$$
- *String τ.* For each location $i \in [1, \ell(\widetilde{n})]$, define
  $\tau_i = 0$ if $P_{i,0} \geq P_{i,1}$ and $\tau_i = 1$ otherwise.
- *Probabilities P_i and $P_{\bar{i}}$.* For each bit-location $i \in [1, \ell(\widetilde{n})]$, define
  $P_i = P_{i,\tau_i}$ and $P_{\bar{i}} = P_{i,\bar{\tau}_i}$.
- *Event "all queries answered by τ."*
  If $\sigma \in \widetilde{\Sigma^{k \cdot \lambda(\widetilde{n})}}$, in a pseudoexecution of $\widetilde{\mathcal{P}}^{f_1,S_m=\sigma}(\widetilde{q}, 1^{\widetilde{k}})$ with no f_1-collision and producing a pseudocertificate $\widetilde{\mathcal{C}}$ with pseudoroot $\widetilde{R}_\varepsilon$, "all queries answered

by τ" denotes the event that, for all bit-locations $i \in [1, \ell(\widetilde{n})]$ and for all bit b, $\widetilde{\mathcal{C}} \ni (i,b)$ implies $b = \tau_i$.

LEMMA 3.16. *Let* $\widetilde{n}$, $\widetilde{q}$, $\widetilde{k}$, $\widetilde{\mathcal{P}}$, f_1, S, m, *and* $\widetilde{R}_\varepsilon$ *be as in Lemma* 3.14 *Then,*

$$PROB_{\sigma \in \widetilde{\Sigma^{k \cdot \lambda(n)}}}[\widetilde{\mathcal{P}}^{f_1, S_m = \sigma}(\widetilde{q}, 1^{\widetilde{k}}) = \widetilde{R}_\varepsilon \cdots \wedge \text{ all queries answered by } \tau] > 2^{-\widetilde{k}}.$$

Proof. We start by claiming that

(L3.1) $P_{\bar{i}} < 4 \cdot 2^{-9\widetilde{k}/32}$.

To prove our claim, consider selecting two $\widetilde{k} \cdot \lambda(\widetilde{n})$-bit strings, σ_0 and σ_1, and then executing $\widetilde{\mathcal{P}}^{f_1, S_m = \sigma_0, \sigma_1}(\widetilde{q}, 1^{\widetilde{k}})$. That is, consider executing first $\widetilde{\mathcal{P}}^{f_1, S_m = \sigma_0}(\widetilde{q}, 1^{\widetilde{k}})$ and then $\widetilde{\mathcal{P}}^{f_1, S_m = \sigma_1}(\widetilde{q}, 1^{\widetilde{k}})$. Then, by definition of P_i and $P_{\bar{i}}$, with probability $\geq 2P_iP_{\bar{i}}$, one of the latter two executions outputs a pseudocertificate $\mathcal{C}_0$ and the other a pseudocertificate $\mathcal{C}_1$ such that (1) $\mathcal{C}_0$ and $\mathcal{C}_1$ are nonempty pseudocertificates having pseudoroot $\widetilde{R}_\varepsilon$, and (2) $\mathcal{C}_0 \ni (i,0)$ and $\mathcal{C}_1 \ni (i,1)$. By Lemma 3.15, (1) and (2) imply that, with probability $\geq 2P_iP_{\bar{i}}$ (taken over the choices of σ_1 and σ_2), (3) an f_1-collision occurs in $\widetilde{\mathcal{P}}^{f_1, S_m = \sigma_0, \sigma_1}(\widetilde{q}, 1^{\widetilde{k}})$. Thus, by Lemma 3.14 (inequality L1.2), we have $2P_iP_{\bar{i}} < 32 \cdot 2^{-9\widetilde{k}/16}$. Now, because $P_{\bar{i}} \leq P_i$ by definition, we have $2P_{\bar{i}}^2 \leq 2P_iP_{\bar{i}} < 32 \cdot 2^{-9\widetilde{k}/16}$, and thus $P_{\bar{i}} < 4 \cdot 2^{-9\widetilde{k}/32}$ as initially claimed.

Define now $P_{\bar{\tau}}$ as the probability that "$\widetilde{\mathcal{P}}^{f_1, S_m = \sigma}(\widetilde{q}, 1^{\widetilde{k}}) = \widetilde{R}_\varepsilon \cdots$, but *not* all queries answered by τ", that is,

$$P_{\bar{\tau}} \stackrel{\text{def}}{=} PROB_{\sigma \in \widetilde{\Sigma^{k \cdot \lambda(n)}}}[\widetilde{\mathcal{P}}^{f_1, S_m = \sigma}(\widetilde{q}, 1^{\widetilde{k}}) = \widetilde{R}_\varepsilon \cdots \wedge \exists i \widetilde{R}_\varepsilon \cdots \ni (i, \bar{\tau}_i)].$$

Then, because there are at most $\ell(\widetilde{n})$ bit-locations i, and because (due to Proposition 3.10 and our definition of c) $\ell(\widetilde{n}) < (\widetilde{n})^c < 2^{\widetilde{k}/64}$, we have

(L3.2) $P_{\bar{\tau}} \leq \sum_{i=1}^{\ell(\widetilde{n})} P_{\bar{i}} < 4 \cdot 2^{-9\widetilde{k}/32} \cdot \ell(\widetilde{n}) < 4 \cdot 2^{-9\widetilde{k}/32} \cdot 2^{\widetilde{k}/64} = 4 \cdot 2^{-17\widetilde{k}/64}$.

Thus

(L3.3) $PROB_{\sigma \in \widetilde{\Sigma^{k \cdot \lambda(n)}}}[\widetilde{\mathcal{P}}^{f_1, S_m = \sigma}(\widetilde{q}, 1^{\widetilde{k}}) = \widetilde{R}_\varepsilon \cdots \wedge \text{ all queries answered by } \tau]$

$\geq PROB_{\sigma \in \widetilde{\Sigma^{k \cdot \lambda(n)}}}[\widetilde{\mathcal{P}}^{f_1, S_m = \sigma}(\widetilde{q}, 1^{\widetilde{k}}) = \widetilde{R}_\varepsilon \cdots] - P_{\bar{\tau}} \geq$ (by inequalities L1.1 and L3.2) $2^{-1} \cdot 2^{-3\widetilde{k}/16} - 4 \cdot 2^{-17\widetilde{k}/64} >$ (because $2^{\widetilde{k}} > n^{64c}$, $n \geq 2$ and $c \geq 1$ imply $\widetilde{k} > 64$) $2^{-\widetilde{k}}$. ∎

Notice now that Lemma 3.16 contradicts the fact that the underlying (SP, SV) is a sampling proof system according to Definition 3.7. In fact, because $\widetilde{\mathcal{P}}$ verifies all its nonempty outputs, we have

$2^{-\widetilde{k}} <$ (because of inequality L3.3) $PROB_{\sigma \in \widetilde{\Sigma^{k \cdot \lambda(n)}}}[\widetilde{\mathcal{P}}^{f_1, S_m = \sigma}(\widetilde{q}, 1^{\widetilde{k}}) = \widetilde{R}_\varepsilon \cdots \wedge \text{ all queries answered by } \tau] = PROB_{\sigma \in \widetilde{\Sigma^{k \cdot \lambda(n)}}}[\mathcal{V}^{f_1, S_m = \sigma}(\widetilde{q}, 1^{\widetilde{k}}, \widetilde{R}_\varepsilon \cdots) = YES \wedge \text{ all queries answered by } \tau]$.

But, by our construction of $\mathcal{V}$, the last inequality implies that, by running sampling verifier SV on inputs $\widetilde{q}$ ($\notin \mathcal{L}$), $|\tau|$ (i.e., $\widetilde{n}$), and $\widetilde{k}$, having a random tape of length $\widetilde{k} \cdot \lambda(|\tau|)$, and having random access to τ, SV accepts with probability $> 2^{-\widetilde{k}}$.

Because $\widetilde{q} \notin \mathcal{L}$, the existence of τ contradicts property 2 of Theorem 3.6. The contradiction establishes Theorem 3.9, and thus that our $(\mathcal{P}, \mathcal{V})$ enjoys computational soundness, completing our proof of Theorem 3.9. ∎

3.6. The significance of CS proofs with a random oracle. Random oracles may be quite theoretical, and, as discussed later on, one might consider implementing CS proofs cryptographically (with or without interaction). But the latter implementations would be meaningless if it turned out that $\mathcal{P} = \mathcal{NP}$. This would not be too

bad, one might say, because, if $\mathcal{P} = \mathcal{NP}$, the very notion of an "efficient" proof system would be meaningless, at least in any broad sense.[22]

Personally, we disagree: fundamental intuitions such as proofs being a notion that is both meaningful and separate (from that of accepting[23]) could not be shaken by a formal result such as $\mathcal{P} = \mathcal{NP}$. Indeed, the author's inclination to believe that $\mathcal{P} \neq \mathcal{NP}$ is only based on (1) his a priori *certainty* that proofs are a meaningful and separate notion, and (2) his *inclination* to believe that $\mathcal{NP}$ is a reasonable approximation of the notion of a proof. But if it turned out that $\mathcal{P} = \mathcal{NP}$, to the author this would only mean that $\mathcal{NP}$ did not provide such a reasonable approximation after all.

It is thus important to establish meaningful models for which we can *show* that *proofs do exist as an independent notion.* CS proofs with a random oracle provide us with such a model: indeed, they guarantee that

> *even if $\mathcal{NP} = \mathcal{P}$, given a sufficient amount of randomness in the proper form, fundamental intuitions like verification being polylogarithmically easier than decision are indeed true.*

4. Other types of CS proofs. Many variants of the basic notion of a CS proof exist. Below, we confine ourselves to briefly presenting just two additional ones: that of an interactive CS proof (because it can be implemented based on standard cryptographic assumptions) and that of a noninteractive CS proof (because it implies the existence of CS checkers for $\mathcal{NP}$-complete problems).

4.1. Interactive CS proofs.

The notion of an interactive CS proof system. Let us first quickly recall interactive Turing machines (ITMs) as defined by Goldwasser, Micali, and Rackoff [21]. Informally, an ITM is a probabilistic Turing machine capable of "sending and receiving messages." An ITM is meant to be run a number of times, each time starting with the internal configuration reached at the end of the previous run. Each run of an ITM starts by reading one incoming message—i.e., reading a string on a special tape—and ends by sending one outgoing message—i.e., writing a string on another special tape. (In an initial run we assume that the incoming message is the input, and that the internal configuration consists of a blank work tape and a distinguished start state.) An ITM halts when, in a given run, it enters a special halting state, from which it takes no further action. ITMs are meant to be executed in pairs. If A and B are ITMs, an execution of (A, B) on input x is obtained by having x be both A's and B's input and by running alternatively A and B, so that each outgoing message of A is B's incoming message in the next run of B, and vice versa. The number of rounds in an execution of (A, B) is the number of times in which either of the two ITMs sends a message. By convention, an execution of (A, B) starts and ends with a run of B. In its last run, B may *accept* by outputting the special symbol YES, or *reject* by outputting the special symbol NO. Except for their exchanged messages, in an execution of (A, B) neither ITM has access to the internal computation (in particular the coin tosses) of the other. The probability that, after a random execution of (A, B) on a given input x, B accepts is taken over all coin tosses of A and B.

[22] Though concurring with us that properly capturing efficient verification may require more than $\mathcal{P} \neq \mathcal{NP}$, one might also believe that if $\mathcal{P} = \mathcal{NP}$, there would be little or no notion of efficient verification to be captured.

[23] Again, he who is concerned about truth but not about time does not need proofs and provers: he may be equally happy to run a decision algorithm whenever he wishes to establish whether a given statement holds. Proofs cannot properly exist as a separate notion unless they succeed in making verification of truth much easier than accepting truth.

Slightly more generally, we shall also consider ITM pairs (A, B), where A actually is an *interactive circuit*. This allows us to use the size of A to bound more effectively the number of "steps" A may make in an execution with B.[24] Recall that a *circuit of size* $\leq s$ is a finite function computable by at most s Boolean gates, where each gate is either a NOT-gate (with one binary input and one binary output) or an AND-gate (with two binary inputs and one binary output).

Notice that an interactive circuit A may be taken to be deterministic, because it might have wired in any finite lucky sequence of coin tosses. (In this case the probability that B is convinced in a random execution with A on input x solely depends on B's coin tosses.)

DEFINITION 4.1. *Let (P, V) be a pair of ITMs, the second of which running in polynomial time, and let $\mathcal{L}$ be the CS language. We say that (P, V) is an* interactive CS proof system *if there are four positive constants a, b, c, and d such that the following two properties are satisfied.*

$1''$. Feasible completeness. *For all $q = (M, x, y, t) \in \mathcal{L}$, and for all integers k, in every execution of (P, V) on inputs q and 1^k,*
($1''$.i) *P halts within $(|q|kt)^a$ computational steps, and*
($1''$.ii) *V outputs YES.*

$2''$. Computational soundness. *For all $\widetilde{q} \notin \mathcal{L}$, for all k such that $2^k > |q|^b$, and for all (cheating) interactive circuit $\widetilde{P}$ of size $\leq 2^{ck}$, in a random execution of $\widetilde{P}$ with V on inputs $\widetilde{q}$ and 1^k,*

$$Prob[V \text{ outputs } YES] < 2^{-dk}.$$

The constructability of interactive CS proof systems. Let us make the mentioned notion of a collision-free hash function a bit more formal.

DEFINITION 4.2. *Let KG (for key generator) be a probabilistic polynomial-time algorithm, $KG : 1^* \to \Sigma^*$, and let E (for evaluator) be a polynomial-time algorithm, $E : \Sigma^* \times 1^* \to \Sigma^*$ (more precisely, $E : \Sigma^* \times 1^k \to \Sigma^k$ for all positive integers k). We say that the pair (KG, E) is a* collision-free hash function *if there exist positive constants r, s, and t such that for all $k > r$ and for all (collision-finding) circuits CF of size $< 2^{sk}$, letting h be a random output of KG on input k,*

$$Prob_h[CF(h, 1^k) = (x, y) \text{ such that } x \neq y \ \wedge \ E(h, x) = E(h, y)] < 2^{-tk}.$$

From the proof of Theorem 3.9 (indeed, even from the informal arguments of subsection 3.4) the reader can easily derive a proof of the following corollary.

COROLLARY 4.3. *Interactive CS proof systems exist if collision-free hash functions exist.*

(Notice that such CS proof systems would actually be four-round ones: in essence, the verifier runs KG to generate a random h and sends it to the prover as the first message; the prover uses h to construct the Merkle tree and sends its root to the

[24] An ITM making, say, at most s steps, may de facto make "many more steps" if it has a large description—e.g., by encoding a large finite function in its state control. For instance, factoring a randomly chosen k-bit integer appears to be computationally intractable when k is large, but not for an algorithm whose description is about 2^k-bit long! Indeed, the finite state control of such a Turing machine could easily encode the factorization of all k-bit integers. For this reason, in a cryptographic CS proof system, a cheating prover is envisaged to be an algorithm whose running time and description, in some standard encoding, are both bounded. Having a cheating prover be a Boolean combinatorial circuit with a bounded number of gates is actually just a specific but simple way to accomplish this.

verifier as the second message; the verifier runs the sampling algorithm SV to compute a sequence of bit-positions and sends them to the prover as the third message; and the prover returns to the verifier the bit-values of those positions—together with their authenticating paths—as the fourth message.)

Two-round CS proof systems. Informally, a *two-round CS proof system* is an interactive CS proof system (P, V) in every execution of which only two messages are sent: the first by V and the second by P. Such proof systems appear significantly more difficult to implement than general interactive ones. Nonetheless they could be constructed based on Cachin, Micali, and Staedler's new computationally private information-retrieval system [14]. Their construction relies on the difficulty of deciding, given a prime p and an integer n (whose factorization is unknown), whether p divides $\phi(n)$.

4.2. CS proof-systems sharing a random string.

The notion of a CS proof system sharing a random string. In a CS proof system sharing a random string, prover and verifier are ordinary (as opposed to oracle-calling) algorithms, sharing a short random string r. That is, whenever the security parameter is k, they share a string r that both believe to have been randomly selected among those having length k^c, where c is a positive constant. If string r is universally known, it can be shared by all provers and verifiers. (CS proof systems sharing a random string are a special case of one-round CS proof systems because r could be the message sent by the verifier to the prover.)

DEFINITION 4.4. *Let (P, V) be a pair of Turing machines, the second of which runs in polynomial time. We say that (P, V) is a* CS proof system sharing a random string *if there exists a sequence of five positive constants, $c_2, \ldots, c_6$ (referred to as the* fundamental constants *of the system*[25]*), such that the following two properties are satisfied.*

$1'''$. *Feasible completeness.* For all $q = (M, x, y, t) \in \mathcal{L}$ and for all binary string r,
($1'''.i$) on inputs q and r, P halts within $(|q| \cdot |r| \cdot t)^{c_2}$ computational steps outputing a binary string $\mathcal{C}$, whose length is $\leq (|q| \cdot |r|)^{c_3}$, such that
($1'''.ii$) $V(q, r, \mathcal{C}) = YES$.

$2'''$. *Computational soundness.* For all $\widetilde{q} \notin \mathcal{L}$, for all k such that $2^k > |q|^{c_4}$, and for all (cheating) circuits $\widetilde{P}$ whose size is $\leq 2^{c_5 k}$, for a random k^{c_1}-bit string r

$$Prob_r[\widetilde{P}(\widetilde{q}, r) = \widetilde{\mathcal{C}} \wedge V(\widetilde{q}, r, \widetilde{\mathcal{C}}) = YES] \leq 2^{-c_6 k}.$$

We refer to the above strings r and $\mathcal{C}$ as, respectively, a *reference string* and a *CS certificate (of $q \in \mathcal{L}$, relative to r and (P, V)).*

The constructability of CS proof systems sharing a random string. We conjecture that CS proof systems with a random string exist. In particular, their existence is guaranteed by an ad hoc (and stronger) assumption: informally the "replaceability," in Theorem 3.6's $(\mathcal{P}, \mathcal{V})$, of random oracles with (hopefully) adequate functions (e.g., collision-free hashing ones). Such replacements have been advocated,

[25] The "numbering" of these constants has been chosen to facilitate comparison with CS proof systems with a random oracle.

in more general contexts, by Bellare and Rogaway [7].[26]

5. Computationally sound checkers. CS proofs have important implications for validating one-sided heuristics for $\mathcal{NP}$. Generalizing a prior notion of Blum's, we put forward the notion of a *CS checker* and show that CS proofs with a random string imply CS checkers for $\mathcal{NP}$.

To begin with, we state the general problem of heuristic validation we want to solve, explain why prior notions of checkers may be inadequate for solving it, discuss the novel properties we want from a checker, and convey in a simple but *wishful* manner what our checkers are. Then we shall approximate this wishful version of a CS checker by a more formal definition and construction.

Warning. Approaching meaningfully the problem of validating efficient heuristics for $\mathcal{NP}$-complete problems is nontrivial (as we shall see, it entails reconciling "two opposites"), and our particular approach to it may prove quite subjective (if not outright controversial). Nonetheless, the problem at hand is so crucial that we might be excused for putting forward some quite preliminary contributions and ideas.

5.1. The problem of validating one-sided heuristics for $\mathcal{NP}$.

A general problem. $\mathcal{NP}$-complete languages contain very important and useful problems that we would love to solve. Unfortunately, it is extensively believed that $\mathcal{P} \neq \mathcal{NP}$ and $\mathcal{NP} \neq \mathcal{C}o\text{-}\mathcal{NP}$, and thus that our ability of successfully handling $\mathcal{NP}$-complete problems is severely limited. Indeed, if $\mathcal{P} \neq \mathcal{NP}$, then no efficient (i.e., polynomial-time) algorithm may decide membership in an $\mathcal{NP}$-complete language without making any errors. Moreover, if $\mathcal{NP} \neq \mathcal{C}o\text{-}\mathcal{NP}$, then no efficient algorithm may, in general, prove nonmembership in an $\mathcal{NP}$-complete language by means of "short and easy-to-verify" strings.

In light of the above belief, the "best natural alternative" to deciding $\mathcal{NP}$-complete languages efficiently and conveying efficiently to others the results of our determinations consists of tackling $\mathcal{NP}$-complete languages by means of efficient *heuristics* that are *one-sided*. Here by "heuristic" we mean a program (emphasizing that no claim is made about its correctness) and by "one-sided" we mean that such a program, on input a string x, outputs either (1) a proper $\mathcal{NP}$-witness, thereby *proving* that x is in the language, or (2) the symbol NO, thereby *claiming* (without proof) that x is not in the language.

But for an efficient one-sided heuristic to be really useful for tackling $\mathcal{NP}$-complete problems we should *know when it is right*. Of course, when such an heuristic outputs an $\mathcal{NP}$-witness, we can be confident of its correctness on the given input. However, when it outputs NO, skepticism is mandatory: even if the heuristic came with an a priori guarantee of returning the correct answer on most inputs, we might not know whether the input at hand is among those. Thus, in light of the importance of $\mathcal{NP}$-

[26] A word of caution is now due about such replacements. For certain tasks, it is now known how to replace random oracles successfully with ordinary algorithms based on traditional assumptions. For instance, a random oracle provably is "collision-free," but collision-free hash functions can be built, say, under the assumption that the integer factorization or the discrete logarithm problems are computationally intractable. On the other hand, "random-oracle replacement" does not always work: Canetti, Goldreich, and Halevi [15] show that it is possible to construct special algorithms that behave very differently when given access to a random oracle than they do when given access to *any* pseudorandom function. (In light of their result, it should be possible to construct, somewhat artificially, some CS proof systems sharing a random oracle that can never be transformed into CS proof systems sharing a random string by replacing their oracle with a pseudorandom function. But this does not imply that the same holds for every CS proof system with a random oracle, in particular for the $(\mathcal{P}, \mathcal{V})$ of Theorem 3.9).

complete languages and in light of the many efficient one-sided heuristics suggested for these languages, a fundamental problem naturally arises.

> *Given an efficient one-sided heuristic H for an $\mathcal{NP}$-complete language, is there a meaningful and efficient way of using H so as to validate some of its NO outputs?*

Interpreting the problem. The solvability of the above general problem critically depends on its specific interpretation.

One such interpretation was proposed by Manuel Blum when, a few years ago, he introduced the beautiful notion of a checker [11][27], and asked whether $\mathcal{NP}$-complete languages are checkable. Under this interpretation, the general problem still is totally open. Moreover, as we shall argue below, unless this interpretation is suitably broadened, even a positive solution might have a limited usefulness.

In this paper we thus propose a new interpretation of the general problem and, assuming the existence of CS proofs with a random string, provide its first (and positive) solution.

5.2. Blum checkers and their limitations.

The notion of a Blum checker. Intuitively, a Blum checker for a given function f is an algorithm that either (a) determines with arbitrarily high probability that a given program, run on a given input, correctly returns the value of f at that input, or (b) determines that the program does not compute f correctly (possibly, at some other input). Let us quickly recall Blum's definition.

DEFINITION 5.1. *Let f be a function and C a probabilistic oracle-calling algorithm running in expected polynomial time. Then, we say that C is a Blum checker for f if, on input an element x in f's domain and oracle access to any program P (allegedly computing f), the following two properties hold.*

1. *If $P(y) = f(y)$ for all y (i.e., if P correctly computes f for every input), then $C^P(x)$ outputs YES with probability* 1.
2. *If $P(x) \neq f(x)$ (i.e., if P does not compute f correctly on the given input x), then $C^P(x)$ outputs YES with probability $\leq 1/2$.*

The probabilities above are taken solely over the coin tosses of C whenever P is deterministic, and over the coin tosses of both algorithms otherwise.

The above notion of a Blum checker slightly differs from the original one.[28] In particular, according to our reformulation any correct program for computing f immediately yields a checker for f, though not necessarily a useful one (because such a checker may be too slow, or because its correctness may be too hard to establish).[29]

Despite their stringent requirements, Blum checkers have been constructed for a variety of specific functions (see, in particular, the works of Blum, Luby, and Rubinfeld [12] and Lipton [25]).

Note that the notion of a checker is immediately extended to languages: an algorithm C is a Blum checker for a language L if it is a Blum checker for L's characteristic function. Indeed, the interactive proof systems of [26] and [33] yield Blum checkers

[27] We shall call his notion a *Blum checker* to highlight its difference from ours.

[28] Disregarding minor issues, Blum's original formulation imposes an additional condition, roughly, that C run asymptotically faster than the fastest known algorithm for computing f—or asymptotically faster than P when checking P. This additional constraint aims at rebuffing a natural objection: who checks the checker? The condition is in fact an attempt to guarantee, in practical terms, that C is sufficiently different from (and thus "independent" of) P, so that the probability that both C and P make an error in a given execution is smaller than the probability that just P makes an error.

[29] Thus, running a checker C (as defined by us) with a program P may be useful only if C is much faster than P, or if C's correctness is much easier to prove—or believe—than that of P.

for, respectively, any $\#\mathcal{P}$- or $\mathcal{PSPACE}$-complete language.[30]

Blum checkers vs. efficient heuristics for $\mathcal{NP}$-complete problems. We believe that the question of whether Blum checkers for $\mathcal{NP}$-complete languages exist should be interpreted more broadly than originally intended. We in fact argue that, even if they existed, Blum checkers for $\mathcal{NP}$-complete languages might be less relevant than desirable.

DEFINITION 5.2 (informal). *We say that a Blum checker A for a function f is* irrelevant *if, for all efficient heuristics H for f, and for all x in f's domain, with high probability $A^H(x) = NO$ without ever calling H on input x.*

Note that, if $\mathcal{P} \neq \mathcal{NP}$, then no efficient heuristic for an $\mathcal{NP}$-complete language is correct on all inputs. Thus it is quite legitimate for a Blum checker for an $\mathcal{NP}$-complete language to output NO whenever its oracle is an efficient heuristic, without ever calling it on the specific input at hand: a NO-output simply indicates that the efficient heuristic is incorrect on some inputs (possibly different from the one at hand). However, constructing an irrelevant Blum checker for the characteristic function of SAT (the language consisting of all Boolean formulae in conjunctive normal form) under the assumption that $\mathcal{P} \neq \mathcal{NP}$ is not trivial. The difficulty lies in the fact that a checker does not know whether it is accessing a polynomial-time program (in which case, if $\mathcal{P} \neq \mathcal{NP}$, it could always output NO), or an exponential-time program that is correct on all inputs (in which case it should always output YES). We can, however, construct such an irrelevant Blum checker under the assumption that one-way functions exist. This assumption appears to be stronger than $\mathcal{P} \neq \mathcal{NP}$ but is widely believed and provides the basis of all modern cryptography.

DEFINITION 5.3 (informal). *We say that a function f mapping binary strings to binary strings is* one-way *if it is length-preserving, polynomial-time computable, but not polynomial-time invertible in the following sense: for any polynomial-time algorithm A, if one generates at random a sufficiently long input z and computes $y = f(z)$, then the probability that $A(y)$ is a counter-image of f is miniscule.*

THEOREM 5.4 (informal). *If one-way functions and Blum checkers for $\mathcal{NP}$-complete languages exist, then there exist irrelevant Blum checkers for $\mathcal{NP}$-complete languages.*

Proof (informal). Let SAT be the $\mathcal{NP}$-complete language of all satisfiable formulae in conjunctive normal form, let P be a program allegedly deciding SAT, let C be a Blum checker for SAT, let f be a one-way function, and let $\mathcal{C}$ be the following oracle-calling algorithm.

On input an n-variable formula F in conjunctive normal form, and oracle access to P, $\mathcal{C}$ works in two stages. In the first stage, $\mathcal{C}$ randomly selects a (sufficiently long) string z and computes (in polynomial time) $y = f(z)$. After that, $\mathcal{C}$ utilizes the completeness of SAT to construct, and feed to P, n formulae in conjunctive normal form, $F_1, \ldots, F_n$, whose satisfiability "encodes a counter-image of y under f."

(For instance, F_1 is constructed so as to be satisfiable if and only if there exists a counter-image of y whose first bit is 0. The checker feeds such an F_1 to P. If P outputs "F_1 is satisfiable," then $\mathcal{C}$ constructs F_2 to be a formula that is satisfiable if and only if there exists a counter-image of y whose 2-bit prefix is 00. If, instead, P responds

[30] In fact, the definition of a Blum checker for a language L is analogous to a restricted kind of interactive proof for L: one whose prover is a probabilistic polynomial-time algorithm with access to an oracle for membership in L. Indeed, whenever a language L possesses such a kind of interactive proof system, a checker C for L is constructed as follows. On inputs P (a program allegedly deciding membership in L) and x, the checker C simply runs both prover and verifier on input x, giving the prover oracle access to program P. C outputs YES if the verifier accepts, and rejects otherwise.

"F_1 is not satisfiable," then $\mathcal{C}$ constructs F_2 to be a formula that is satisfiable if and only if there exists a counter-image of y whose 2-bit prefix is 10. And so on, until all formulae $F_1, \ldots, F_n$ are constructed and all outputs $P(F_1), \ldots, P(F_n)$ are obtained.)

Because string y is, by construction, guaranteed to be in the range of f, at the end of this process one either finds (a) a counter-image of y under f, or (b) a proof that P is wrong (because if no f-inverse of y has been found, then P must have provided a wrong answer for at least one of the formulae F_i). If event (b) occurs, $\mathcal{C}$ halts outputting NO. Otherwise, in a second phase, $\mathcal{C}$ runs Blum checker C on input the original formula F and with oracle access to P. When C halts so does $\mathcal{C}$, outputting the same YES/NO value that C does.

Let us now argue that $\mathcal{C}$ is a Blum checker for SAT. First, it is quite clear that $\mathcal{C}$ runs in probabilistic polynomial time. Then there are two cases to consider.

1. *P correctly computes SAT's characteristic function.* In this case, a counter-image of y is found, and thus $\mathcal{C}^P$ does not halt in the first phase. Moreover, in the second phase, $\mathcal{C}$ runs Blum checker C with the same correct program P. Therefore, by property 1 of a Blum checker, C^P will output YES no matter what the original input formula F might be, and, by construction, so will $\mathcal{C}^P$. This shows that $\mathcal{C}$ enjoys property 1 of a Blum checker for SAT.
2. *$P(F)$ provides the wrong answer about the satisfiability of F.* In this case, either $\mathcal{C}^P$ halts in phase 1 outputting NO, or it executes phase 2 by running $C^P(F)$, that is, the original Blum checker for SAT, C, on the same input F and the same oracle P. Therefore, by property 2 of a Blum checker, the probability that $C^P(F)$ will halt outputting YES is no greater than 1/2. By construction, the same holds for $\mathcal{C}^P(F)$. This shows that $\mathcal{C}$ enjoys property 2 of a Blum checker for SAT.

Finally, let us argue that, for any input F and any efficient P (no matter how well it may approximate SAT's characteristic function), almost always $\mathcal{C}^P(F) = NO$, without even calling P on F. In fact, because $\mathcal{C}$ runs in polynomial time, whenever P is polynomial-time, so is algorithm $\mathcal{C}^P$. Therefore, $\mathcal{C}^P$ has essentially no chance of inverting a one-way function evaluated on a random input. Therefore, $\mathcal{C}$ will output NO in phase 1, where it does not call P on F. □

In sum, differently from many other contexts, the notion of a Blum checker may not be too useful for handling efficient heuristics for $\mathcal{NP}$-complete languages, either because no such checkers exist[31] or because they may exist but not be too useful.

Blum checkers are not complexity-preserving. The lesson we derive from the above sketched proof of Theorem 5.4 is that Blum's notion of a checker lacks a new property that we name *complexity preservation*. Intuitively, a Blum checker for satisfiability, when given a "not-so-difficult" formula F, may ignore it altogether and instead call the to-be-tested efficient heuristic on *very special* and *possibly much harder* inputs, thus forcing the heuristic to make a mistake and justifying its own outputting NO (i.e., "the heuristic is wrong").

The possibility of calling a given heuristic H on inputs that are harder than the given one essentially erodes the chances of meaningfully validating H's answer whenever it happens to be correct.[32] Such a possibility may not matter much if "the

[31] Notice that this possibility does not contradict the fact that $\mathcal{NP}$ is contained in both $\#\mathcal{P}$ and $\mathcal{PSPACE}$ and that $\#\mathcal{P}$- and $\mathcal{PSPACE}$-complete languages are Blum checkable!

[32] Note that such possibility not only is present in the *definition* of a Blum checker but also in all known *examples* of a Blum checker. Typically, in fact, a Blum checker works by calling its given heuristic on random inputs, and these may be more difficult than the specific, original one.

difference in computational complexity between any two inputs of similar length" is somewhat bounded. But it may matter a lot if such a difference is enormous—which may be the case for $\mathcal{NP}$-complete languages, as they encode membership in both easy and hard languages. We thus wish to develop a notion of a "complexity-preserving" checker.

5.3. New checkers for new goals.

The old goal. Blum checkers are very useful to catch the occasional mistake of programs believed to be correct on all inputs. That is, they are ideally suited to check *fast programs for easy functions* (or slow program for hard functions). In fact, if f is an efficiently computable function, then we know a priori that there are efficient and correct programs for f. Therefore, if a reputable software company produces a program P for f, it might be reasonable to expect that P is correct. In this framework, by running a Blum checker for f, with oracle P, on a given input x we have nothing to lose[33] and something to gain. Indeed, if the checker answers YES, we have "verified our expectations" about the correctness of P at least on input x (a small knowledge gain), and if the checker answers NO, we have proved our expectations about P to be wrong (a big knowledge gain).

The new goal. We instead want to develop checkers for a related but different goal: validating efficient heuristics that are known to be incorrect on some inputs. That is, we wish to develop checkers suitable for handling *fast programs for hard functions.* Now, if f is a function hard to compute, then we know a priori that no efficient program correctly computes it. Therefore, obtaining from a checker a proof that such an efficient program does not compute f correctly would be quite redundant. We instead want checkers that, at least occasionally, if an efficient heuristic for f happens to be correct on some input x, are capable of convincing us that this is the case.

Interpreting the new goal. Several possible valid interpretations of this general constraint are possible. In this paper we focus on a single one: namely, we want checkers that are *complexity-preserving.* Let f be a function that is hard to compute (at least in the worst case). Then, intuitively, a complexity-preserving checker for f will, on input x, call a candidate program for f only on inputs for which evaluating f is essentially as difficult as for x.

Our point is that, while a given heuristic for satisfiability, $\mathcal{H}$, may make mistakes on some formulae, it may return remarkably accurate answers on some class of formulae (e.g., those decidable in $O(2^{cn})$ time, for some constant $c < 1$, by a given deciding algorithm D). Intuitively, therefore, checkers should be defined (and built!) so that, if the input formula belongs to that class and $\mathcal{H}$ happens to be correct on the input formula, they call $\mathcal{H}$ only on additional formulae in that class.

5.4. The wishful version of a CS checker. The spirit of a CS checker is best conveyed wishfully assuming (for a second) that $\mathcal{NP}$ equaled $Co\text{-}\mathcal{NP}$. In that case, our CS checkers would take the following simple and appealing form.

Wishful checkers. Define a *wishful checker* to be a polynomial-time algorithm C that, on input a Boolean formula F, outputs a Boolean formula $\mathcal{F}$ satisfying the following two properties.

1. *Membership reversion.* $\mathcal{F} \in$ SAT if and only if $F \notin$ SAT.

[33] Blum checkers are often so fast (e.g., running in time sublinear in that of the algorithm they check) that not even this is much of a concern.

2. *Complexity preservation.* "The satisfiability of $\mathcal{F}$ is as hard to decide as that of F."

How to use a wishful checker. We interpret the above algorithm C as a kind of checker because it immediately yields the following algorithm C' (more closely matching our intuition of a checker).

C' : Given an efficient one-sided heuristic for SAT, H, and an input formula, F, compute $\mathcal{F} = C(F)$. Then, call H so as to obtain the two values $H(F)$ and $H(\mathcal{F})$. If either value is different than NO, then (H being one-sided) a satisfying assignment has been computed either proving that $F \in$ SAT or that $F \notin$ SAT. Otherwise, $H(F) = H(\mathcal{F}) = NO$ proves that H is incorrect.

Note that, by the very definition of a wishful checker, the above proof that H is incorrect has been obtained without querying H on formulae harder than the original input F.

5.5. The notion of a CS checker. Let us now informally explain how, without assuming $\mathcal{NP} = Co\text{-}\mathcal{NP}$, CS checkers may approximate wishful ones to a sufficiently close extent. Renouncing to achieving greater generality, we limit our discussion to CS checkers for SAT.

CS checkers. Informally speaking, a *CS checker* is a polynomial-time algorithm $\mathcal{C}$ that, on input a formula F, outputs a Boolean formula $\mathcal{F}$, called the *coinput*, satisfying the following properties.

1. *Membership semireversion.*
   1.1. At least one of F and $\mathcal{F}$ is satisfiable.
   1.2. If F is satisfiable, then no efficient algorithm has a nonnegligible chance of finding a satisfying assignment for $\mathcal{F}$.
2. *Complexity semipreservation.* If $F \notin$ SAT, then the satisfiability of $\mathcal{F}$ is as hard to decide as that of F.
   (Note: We explain why complexity preservation is restricted to the "$F \notin$ SAT" case a few lines below.)

How to use CS checkers. We interpret the above $\mathcal{C}$ as a checker because it immediately yields the following algorithm $\mathcal{C}'$ (that better matches what we may intuitively expect from a checker).

$\mathcal{C}'$: Given an efficient one-sided heuristic for SAT, H, and an input formula, F, do the following.
- Compute the coinput $\mathcal{F} = \mathcal{C}(F)$.
- Call H so as to obtain $H(F)$.
- If $H(F) \neq NO$, HALT.
- If $H(F) = NO$, call H so as to obtain $H(\mathcal{F})$ and HALT.

The usefulness of CS checkers. The usefulness of the above $\mathcal{C}'$ stems from the following two properties.

(a) $\mathcal{C}'$ is informative about the satisfiability of F or the correctness of H.

(b) If H is correct on F, then $\mathcal{C}'$ never calls H on a formula harder than F.

Indeed, a computation of $\mathcal{C}'$ results in (1) showing a satisfying assignment of F, (2) showing a satisfying assignment of $\mathcal{F}$, or (3) showing that $H(F) = H(\mathcal{F}) = NO$.

A type-1 result clearly proves that $F \in$ SAT.

A type-2 result is interpretable as saying that F is unsatisfiable. This is so because if F belonged to SAT, then either a satisfying assignment of coinput $\mathcal{F}$ does not exist, or (by the very definition of a CS checker) the probability that it can be obtained in polynomial time is negligible. (Notice, in fact, that $\mathcal{C}'$ is efficient because both $\mathcal{C}$ and H are.)

A type-3 result proves that H is wrong. In fact, if $H(F) = NO$ is correct, then (by property 1.1 of a CS checker) $\mathcal{F} \notin$ SAT, and thus $H(\mathcal{F}) = NO$ is incorrect. Let us now argue that *if H is correct on F*, our proof of H's incorrectness has been obtained in a complexity-preserving manner. We distinguish two cases.

1. If H is correct on F and $H(F) \neq NO$, then $H(F)$ is an (easy-to-verify) satisfying assignment of F, and thus $\mathcal{C}'$ does not call H on any coinput. Therefore, $\mathcal{C}$ vacuously does not call H on any $\mathcal{F}$ harder than F.
2. If H is correct on F and $H(F) = NO$, then $F \notin$ SAT, in which case (by property 2 of a CS checker) $\mathcal{F}$ is guaranteed to have the same complexity as F.

If instead H is *not* correct about our original input F, then $H(F) = H(\mathcal{F}) = NO$ still is a proof of H's incorrectness, but not necessarily one obtained in a complexity-preserving manner. Notice, however, that lacking complexity preservation in this case is of no concern: *if H happens wrong about our own original input, we are happy to prove that H is wrong in any manner.* Recall that in checking we care about our own original input x more than about H. Thus if $H(x)$ is correct, we aim at "proving" this fact, and we do not want to throw H away by calling it on much harder inputs. But if $H(x)$ is wrong, we do not mind dismissing H in any way. Least of all, we want to be convinced that $H(x)$ is right!

The complexity preservation of a CS checker. To complete our informal discussion of CS checkers we must explain in what sense, whenever $F \notin$ SAT, the complexity of F is close to that of $\mathcal{F}$. That is, we must explain (1) how we measure the complexity of the original input, and (2) how the coinput preserves this complexity.

1. *Complexity meters.* The complexity of the original input F is defined to be the number of steps made by a chosen deciding algorithm for SAT, D, on input F. That is, when a CS checker for SAT is given an input formula F, it is also given as an additional input the description of this chosen D. We refer to D as *the complexity meter*. In fact, by specifying D, we (implicitly) pin down the complexity of the original formula F. By insisting that D be a decider for SAT (i.e., that D be correct) we insist that the complexity of the original input be a "genuine" one.[34]

   By properly choosing the complexity meter, one may be able to force the complexity of the original input to be small (and thus force the checker to query its given heuristic on a coinput of similarly small complexity). Choosing D to be the algorithm that tries all possible satisfying assignments for F is certainly legitimate but not too meaningful. (Because any formula would have "maximum complexity" relative to such a complexity meter, the checker would essentially be free to call its given heuristic on any possible coinput.) Quite differently, if the original input F is known to belong to a class of formulae for which a given SAT algorithm performs very well (e.g., runs in subexponential time), by specifying that algorithm as our complexity meter, we force the checker to call its given heuristic only on a coinput of similarly low complexity.

   Let us stress that we do not require that the checker, or someone choosing a complexity meter D, know how many steps D takes on the original input F. Nor do we require that one distinguish (somehow) for which inputs, if any, algorithm D (slow in the worst case) may be reasonably fast. Rather, we require that, if F happens to belong to those inputs on which D is fast, then

[34] In particular, if D were allowed to make errors, all formulae F could have constant complexity.

it is this lower (and possibly unknown) complexity that should be preserved by a CS checker.

By specifying D one specifies implicitly *the complexity of F, whatever it happens to be.*

For technical reasons, however, we require that D's running time be upper-bounded by 2^{2n}, a bound that essentially poses no real restrictions. Within these bounds, any algorithm for satisfiability could always be "timed-out" and then converted to an exhaustive search for a satisfying assignment).

2. *Complexity cometers.* The complexity of a coinput $\mathcal{F}$ is defined to be the number of steps taken on input $\mathcal{F}$ by a decider for SAT, $\mathcal{D}$, specified before hand. We refer to such a $\mathcal{D}$ as *the complexity cometer.*

   Thus a complexity cometer is independent of the chosen complexity meter: the first is fixed once and for all (in fact, it could be made part of the very definition of a CS checker), while the second is chosen afresh each time a CS checker is run. Under these circumstances, at first glance, it may appear surprising that a CS checker may succeed in keeping the complexity of the coinput close to that of the original input. But the fixed cometer $\mathcal{D}$ includes the code of the universal algorithm, so that, in a sense, the complexity of a coinput is measured relative to a "decider for SAT that is easily constructed on input D."

   Notice that one could conceive stating complexity preservation by simply saying that the number of steps taken by a chosen D on the original input is polynomially close to the number of steps taken by the same D on the coinput. This would be a simpler way of having the cometer easily depend on the meter. However, we needed to endow CS checkers with a bit more room to maneuver than that. In any case, we believe it preferable to have the meter that is a fixed component of the CS checker to be a *universal meter.*

5.6. The actual definition of a CS checker.

Preliminaries.

- We let CNF denote the language of all formulae in conjunctive normal form, and SAT the set of all satisfiable formulae in CNF. If $F \in \mathrm{SAT}$, then we denote by $\mathrm{SAT}(F)$ the set of all satisfiable assignments of F. For any positive integer n, CNF_n and SAT_n will denote, respectively, all formulae in CNF and SAT whose binary length is n.
- By an SAT *decider* we mean an algorithm that (correctly) decides the language SAT. (Deciders need not output a satisfying assignment in case the input formula is satisfiable.) We say that an SAT decider D is *reasonable* if, for all $F \in \mathrm{CNF}$, $\#D(F) \leq 2^{|F|}$.
- If A is a probabilistic algorithm and E an event (involving executions of A on specified inputs), by $Prob_A[E]$ we denote the probability of E, taken over all possible coin tosses of A.

DEFINITION 5.5. *Let Φ be a probabilistic polynomial-time algorithm, $\mathcal{D}$ an SAT decider, and $\mathcal{Q}(.,.,.,.)$ a positive polynomial. We say that $(\Phi, \mathcal{D}, \mathcal{Q})$ is a* CS checker *if, for all positive constant c, for all CNF formulae F, for all reasonable SAT deciders D, and for all sufficiently large k, on input $(F, D, 1^k)$ Φ outputs a formula $\mathcal{F}$ such that:*

1. $F \vee \mathcal{F} \in \mathrm{SAT}$;
2. $F \in \mathrm{SAT} \Rightarrow$ *for all k^c-size circuits A, $Prob_\Phi[A(\mathcal{F}) \in \mathrm{SAT}(\mathcal{F})] < 2^{-k}$; and*
3. $F \notin \mathrm{SAT} \Rightarrow \#\mathcal{D}(\mathcal{F}) < \mathcal{Q}(|F|, |D|, 1^k, \#D(F))$.

If $\mathcal{C} = (\Phi, \mathcal{D}, \mathcal{Q})$ is a CS checker, we refer to Φ as the *reducer*, to $\mathcal{D}$ as the *complexity cometer*, and to $\mathcal{Q}$ as the *complexity slackness*.

Remark. Note that even the existence of triplets $(\Phi, \mathcal{D}, \mathcal{Q})$ satisfying just properties 1 and 2 alone constitutes a surprising statement about SAT. Informally, they say that any formula F can be efficiently transformed to a formula $\mathcal{F}$ such that (1) at least one of them is satisfiable, while (2) every efficient algorithm can find a satisfying assignments for at most one them. That is,

properties 1 *and* 2 *"almost" say that* $\mathcal{NP} = Co\text{-}\mathcal{NP}$,

in the sense that, to convince a verifier V that a formula F is not satisfiable, a prover P may first run Φ on input $(F, D, 1^k)$ so as to compute $\mathcal{F}$, and then (because if $F \notin$ SAT, then, by property 1, $\mathcal{F}$ is satisfiable) produce a satisfying assignment for $\mathcal{F}$. The verifier is convinced because, if also F were satisfiable, then a satisfying assignment for F could be found in less than 2^k steps, which would violate property 2 whenever P is poly(k) size, and k is large enough!

5.7. Implementing CS checkers for SAT. Let us recall some known properties of Cook's [16] and Levin's [24] $\mathcal{NP}$-completeness constructions.

Key properties of Cook's and Levin's constructions. Given a polynomial-time predicate $A(\cdot, \cdot)$ and a positive constant b, these constructions consist of a polynomial-time algorithm that, on input a binary string x, outputs a CNF formula ϕ that is satisfiable if and only if there is a binary string σ such that $|\sigma| \leq |x|^b$ and $A(x, \sigma) = YES$. We refer to such a string σ as a *witness (for x)*. The construction further enjoys the following extra properties (which are actually required by Levin's definition of $\mathcal{NP}$-completeness):

(i) x is polynomial-time retrievable from ϕ;
(ii) a proper witness for x is polynomial-time computable from any satisfying assignment for ϕ (if one exists); and
(iii) a satisfying assignment for ϕ is polynomial-time computable from any proper witness for x (if one exists).

THEOREM 5.6. *If CS proof systems sharing a random string exist, then CS checkers for SAT exist.*

Proof. Let (P, V) be a CS proof system sharing a random string with fundamental constants $c_2, \ldots, c_6$, and consider the following algorithm.

ALGORITHM Φ

Inputs: F, a CNF formula, D, a reasonable SAT solver, and 1^k, a security parameter.
Subroutines: P and V.
Output: a CNF formula $\mathcal{F}$.

Code: Randomly select a k-bit (reference) string r for (P, V), and use Cook's (or Levin's) construction to compute a CNF formula $\mathcal{F}$ that is satisfiable if and only if there exist two binary strings t and σ such that, setting $q = (F, D, NO, t)$, the following three properties hold: (1) $|t| \leq 2|F|$,[35] (2) $|\sigma| \leq (|q| \cdot k)^{c_3}$, and (3) $V(q, r, \sigma) = YES$.
{*Comment:* If it exists, σ is a CS certificate of $(D, F, NO, t) \in \mathcal{L}$, relative to (P, V) and reference string r. The existence of such a σ, however, does not guarantee that $D(F) = NO$.[36]}

[35] i.e., because D is reasonable, considering t as an integer, $t = \#D(F) \leq 2^{|F|}$.

[36] In fact, we "expect" that σ exists (and thus that $\mathcal{F}$ is satisfiable) with "overwhelming probability," even when F is satisfiable. But σ is hard to find.

Let us now show that there exist an SAT decider $\mathcal{D}$ and a positive polynomial $\mathcal{Q}$ such that $\mathcal{C} = (\Phi, \mathcal{D}, \mathcal{Q})$ is a CS checker.

To begin with, notice that, because of the polynomiality of V and of Cook's construction, Φ is polynomial-time.[37]

Further, because properties 1 and 2 of a CS checker (as per Definition 5.5) only depend on its reducer, let us show that they hold for our Φ prior to defining $\mathcal{D}$ and $\mathcal{Q}$.

Property 1 holds trivially if $F \in$ SAT. Assume therefore that $F \notin$ SAT. Then, because of the correctness and running time of the complexity meter D, we have $D(F) = NO$ within $t \leq 2^{2n}$ steps. Thus, by the (feasible) completeness of (P, V) for any possible reference string r there is a CS certificate σ of $q = (D, F, NO, t) \in \mathcal{L}$. Thus, $\mathcal{F} \in$ SAT, proving that property 1 holds in all cases.

Property 2 is established by contradiction. Assume that there exists an input formula $F \in$ SAT and a poly(k)-size circuit A that, with nonnegligible probability, computes a satisfying assignment of a so-constructed coinput $\mathcal{F}$. Then, by property (ii) of Cook's construction, from such a satisfying assignment (if it exists and is found) one computes in polynomial time both t and a CS certificate σ of $q = (D, F, NO, t) \in \mathcal{L}$. But if $F \in$ SAT, then for no t is $q = (D, F, NO, t) \in \mathcal{L}$. Therefore, this contradicts the computational soundness of (P, V).

Let us finally show that there exist an SAT decider $\mathcal{D}$ and a positive polynomial $\mathcal{Q}$ such that, for all formulae $F \notin CNF$, for all complexity meters D, and for all security parameters k, if D, on input F, takes t ($\leq 2^{2|F|}$) steps to decide that no satisfying assignment for F exists, then, given any coinput $\mathcal{F}$ of F, $\mathcal{D}$ finds a satisfying assignment for $\mathcal{F}$ in at most $Q(|F|, |D|, k, t)$ steps.

Algorithm $\mathcal{D}$ works in four phases as follows.

$\mathcal{D}1$. Computes F, D, and r from $\mathcal{F}$.
(Due to property (i) of Cook's construction, $\mathcal{D}$ can execute this phase in time polynomial in $|\mathcal{F}|$. Thus, because $\mathcal{F}$ has been computed by $\mathcal{C}$ in time polynomial in $|F|$, $|D|$, and k, this phase is executable in time polynomial in $|F|$, $|D|$, and k.)

$\mathcal{D}2$. Runs D on input F to find the exact number of steps, t, taken by D to output NO on input F.
(Because D can be simulated with a slow-down polynomial in $|D|$, this phase takes time polynomial in $|D|$ and t.)

$\mathcal{D}3$. Run prover P on input $q = (D, F, NO, t)$ and reference string r to produce a CS certificate, σ, of $q \in \mathcal{L}$.
(Due to the feasible completeness of (P, V), this phase is executable in time polynomial in $|q|$, k, and t; and thus in time polynomial in $|F|$, $|D|$, k, and t.)

$\mathcal{D}4$. Use σ to compute a satisfying assignment for $\mathcal{F}$.
(Due to property (iii) of Cook's construction, this phase also can be implemented in time polynomial in $|F|$, $|D|$, and k.)

Because each phase is implementable in time polynomial in $|F|$, $|D|$, k, and t, there exists a polynomial $\mathcal{Q}$ such that $\mathcal{D}(\mathcal{F})$ outputs a satisfying assignment of $\mathcal{F}$ in $Q(|F|, |D|, k, t)$ steps.

---

[37] Indeed, define $A(\cdot, \cdot)$ as follows: $A((F, D, r), (t, \sigma)) \stackrel{\text{def}}{=} V((D, F, NO, t), r, \sigma)$. Notice now that A is polynomial-time: in fact, V is the verifier of a CS proof system with a random string. Notice also that $|\sigma|$ is polynomially bounded in $|F|$, $|D|$, and $|r|$: in fact $q = (D, F, NO, t)$, $|t| \leq 2|F|$, and $|\sigma| \leq (|q|k)^{c_3}$.

Finally, notice that the above four-phase procedure can be converted to an SAT decider by interleaving two different computations. In the first, an exhaustive search is conducted for deciding whether $\mathcal{F}$ is satisfiable. In the second, $\mathcal{F}$ is interpreted as a coinput of F, and the above four-phase procedure is run. The so-modified $\mathcal{D}$ halts when either computation halts and outputs what the halting computation does. □

5.8. Remarks.

An alternative formulation. As we said, any CS checker $\mathcal{C}$ (as per Definition 5.5) immediately yields an oracle-calling algorithm that, on input a formula F (a complexity meter D, and a security parameter k) and access to a one-sided efficient heuristic H, computes a coinput $\mathcal{F}$ and obtains $H(F)$ and $H(\mathcal{F})$.

With this in mind, we can rephrase Theorem 5.6 as follows (and obtain—implicitly—a definition of a CS checker that is more closely tailored to our implemetation).

COROLLARY 5.7. *If CS proof systems sharing a random string exist, then there exist* (1) *a polynomial-time oracle-calling algorithm* $\mathcal{C}^{(\cdot)}(\cdot,\cdot,\cdot)$ *that, whenever its first input is a CNF formula* F*, queries its oracle at most twice: once about* F*, and possibly a second time about a second CNF formula* $\mathcal{F}$*;* (2) *an SAT decider* $\mathcal{D}$ *and a polynomial* $Q(.,.,.,.)$ *such that*

for all one-sided heuristics H *for SAT, for all* $F \in CNF$*, for all reasonable SAT deciders* D *solving* F *in* $\leq 2^{2|F|}$ *steps, for all sufficiently long random binary strings* r*, the following two properties hold.*

rm 1. Individual-complexity preservation. *If* H *is correct on* F *and* $\mathcal{C}^H(F,D,r)$ *queries* H *about a second CNF formula* $\mathcal{F}$*, then*

$$\#\mathcal{D}(\mathcal{F}) \leq Q(|F|,|D|,|r|,\#D(F)).$$

2. Computational meaningfulness. $\mathcal{C}^H(F,D,r)$ *produces one of the following three outputs:*
   (a) *a satisfying assignment for* F *(i.e., a proof that* F *is satisfiable),*
   (b) *a CS proof, relative to* (P,V) *and reference string* r*, of* $D(F) = NO$ *(i.e., evidence that* F *is not satisfiable),*
   (c) *a formula* $\mathcal{F}$ *such that, by construction, either* F *or* $\mathcal{F}$ *is satisfiable, and yet* $H(F) = H(\mathcal{F}) = NO$ *(i.e., a proof that* H *is not correct).*

Unlike Blum checkers, the above oracle-calling algorithm $\mathcal{C}$ does not provide answers that are correct with arbitrarily high probability (computed over its possible coin tosses). The type-(a) and type-(c) outputs of $\mathcal{C}$ are errorless, at least in the sense that any error here can be efficiently detected. But a type-(b) output of $\mathcal{C}$, interpreted as a (computationally) meaningful explanation that F is nonsatisfiable, may be wrong in a noneasily detectable manner: if F is satisfiable, $\mathcal{C}$ could output a "false" CS proof of $D(F) = NO$ with positive probability. However, this probability is reasonably high only if an enormous amount of computation is performed; whereas, in our application, all computation is performed by $\mathcal{C}$ which is polynomial-time and by oracle H which is also polynomial-time. Therefore, the probability of a false type-(b) output is absolutely negligible.

Another advantage of one-sided heuristics. Our CS checkers only deal with one-sided heuristics for SAT. As already discussed, given the one-sided nature of $\mathcal{NP}$, this is a natural choice. On the other hand, could we have dealt with heuristics just outputting YES (i.e., "satisfiable, but with no proof") or NO?

So far, because of the self-reducibility property of $\mathcal{NP}$-complete problems, choos-

ing between either type of heuristics has often been a matter of individual taste. Indeed, it is well known that a decision oracle for SAT can, in polynomial time, be converted to a search oracle for SAT. As we explain below, however, this "equivalence" between decision and search relative to $\mathcal{NP}$-complete languages may cease to hold when one demands, as we do, that our reductions preserve the complexity of individual inputs, rather than just that of complexity classes.

When dealing with one-sided efficient heuristics H for SAT, assuming that H is correct on F, we need only to take care of complexity preservation when $H(F) \neq NO$. In fact, if $H(F) \in SAT(F)$, then there is no need to call H on any coinput $\mathcal{F}$, and thus there is no complexity to be preserved. Presumably, however, if H outputs just YES and NO, we would care about preserving F's complexity also when $H(F)$ is correct and $H(F) = YES$. Now, to convince ourselves that $H(F) = YES$ is correct, we could run the self-reducibility algorithm, calling H on a sequence of formulae $F_1, \ldots, F_n$ (obtained by "fixing" a new variable each time), so as to find a satisfying assignment of F, or prove that H is wrong (on either F or some F_i). The problem is, however, that this self-reducibility process may not be complexity-preserving: It may be the case that our F is relatively easy, while some of the F_i's are very hard. Indeed, it is conceivable that it is the "degree of freedom" of the variables of the original formula F that make it easy to decide (without finding any $\mathcal{NP}$-proof of it) that F is satisfiable. However, after sufficiently many variables of F have been fixed, the difficulty of deciding satisfiability may grow dramatically high (though later on, when sufficiently many variables have been fixed, it will dramatically drop).

Extra complexity preservation. Notice that, in the implementation of the proof of Theorem 5.6, the CS checker preserves the complexity of the original input F in a much closer manner than demanded by our definition. Indeed, the coinput $\mathcal{F}$ consists of the very encoding of the computation of the complexity meter D on input F (and we wonder whether this may yield a preferable formulation of complexity preservation).

Additional applications. We believe that complexity preservation, in different formulations, will be useful to other contexts as well. In particular, it will enhance the meaningfulness of many reductions in a complexity setting. For instance, using complexity preservation, [22] presents a more refined notion of a proof of knowledge [21, 36, 18, 6].

An open problem. Is it possible to (define and) construct CS checkers that, when given an heuristic H and an input x, also receive a concise algorithmic representation of a ("nontrivial") set S and call H only on x and elements of S? Such checkers could still be allowed to output a proof that the given heuristic H is wrong. But, if H happens to be correct on S, and the given input happens to belong to S, they should output a "validation" for $H(x)$ (rather than a proof that H is wrong).

6. Certified computation. In this section we reinterpret the results of sections 3 and 4 in terms of *computation* rather than proofs. More precisely, we aim at obtaining certificates ensuring that no error has occurred in a *given* execution of a *given* algorithm on a *given* input.

That is, certified computation does not deal with semantic questions such as "is algorithm A correct?" Rather it addresses the following syntactic question.

Is string y what algorithm A should output on input x (no matter what A is supposed to do)?

This question is quite crucial whenever we are confident in the design of a given algorithm A but less so in the physical computer that runs it. For instance, the computer

hardware may be defective. Alternatively, the hardware may function properly, but the operating system may be flawed. Alternatively yet, the hardware and software may be fine, but some α rays may succeed in flipping a bit together with its controls, so that the original bit value is not restored.

Moreover, even assuming that the physical computer is correct, after running A on input x so as to obtain a result y, can we convince someone else that y is indeed equal to $A(x)$ without having him redo the computation himself?

Certified computation provides a special way to answer these basic questions for any algorithm and for any input.

Defining certified computation. In view of our work so far, formalizing and exemplifying (at least given a random oracle) the notion of certified computation is rather straightforward but tedious indeed. We thus think that is best to proceed at a very intuitive level.

DEFINITION 6.1 (informal). *A* certified-computation system *is a compiler-verifier pair of efficient algorithms, $(\mathcal{C}, \mathcal{V})$. Given any algorithm A as input, $\mathcal{C}$ outputs an equivalent algorithm A' enjoying the following properties.*

1. *A' runs in essentially the same time as A does.*
2. *A' receives the same inputs applicable to A and produces the same outputs.*
3. *For each input x, algorithm A' produces the same output y as A, but also a short and easily inspectable string C vouching that indeed $y = A(x)$ in the following sense.*

   If $A(x)$ outputs y in t steps, then $\mathcal{V}(A, x, y, t, C) = YES$. Otherwise, it is very hard to find a string σ such that $\mathcal{V}(A, x, y, t, \sigma) = YES$.

Of course, one may ask who verifies the correctness of the verifier (i.e., either of algorithm $\mathcal{V}$ itself or of its executions). Note, however, that such a $\mathcal{V}$ is a *unique* program, capable of verifying certificates for the correct execution of *all* other programs. It is thus meaningful to invest sufficient time in proving the correctness of this particular algorithm (e.g., by verification methods). Also, being that $\mathcal{V}$ is quite efficient (and runs on short inputs) we may afford to execute it on very "conservative" hardware (i.e., with particular redundancy, resiliency, and so on), or even on a multiplicity of hardwares.

Constructing certified-computation systems. One possible way of constructing program certification systems essentially consists of giving a CS proof of the statement "$y = A(x)$ in t steps." Let us explain. On input x, algorithm $A' = \mathcal{C}(A)$ first runs A on x so that, after some number t of steps, an output y is obtained. Then A' outputs y and a CS proof of $(A, x, y, t) \in \mathcal{L}$. Thus the length of such a CS proof will be polynomial in $\log t$ (and, of course, $|A|$, $|x|$, $|y|$, and some suitable security parameter k). The additional time required to produce this CS proof is comparable to the running time of A. (This holds if one uses the construction of Theorem 3.8 rather than a generic CS proof system.) Indeed, while the definition of CS proofs allows a polynomial relation between these running times, the sketched construction actually yields a linear-time relation!

An alternative notion of certified computation. Another type of certified computation was previously proposed in [3] as an application of $\mathcal{PCP}$. In essence, in their notion, $A'(x)$ outputs both $A(x)$ and a string τ that vouches the correctness of $A(x)$. Though τ may be extraordinarily long (τ's length exceeds the number of steps taken by A on input x), it could be inspected in $\mathcal{PCP}$-style, by reading and verifying only selectively few of its bits. As we have argued in section 2, however, ensuring that one is really working with precisely these few bits of τ requires an overall verification

time that is linear in τ's length (and thus greater than the time necessary to run A on input x).

Pros and cons of certified computation. One may view some older algorithms as specialized forms of certified computation, (i.e., applicable to certain functions only). For instance, the classical extended GCD algorithm not only outputs the greatest common divisor c of two input integers a and b, but also two integers x and y such that $ax + by = c$. Blum views such extended output as a relatively simple way of checking the validity of c. That is, by checking that indeed (1) $ax + by = c$ and that (2) c divides both a and b, one verifies that there is no divisor of a and b greater than c, and so that c actually is the greatest common divisor. Thus x and y are a sort of certificate proving the correctness of c. This certificate, however, is not sufficiently short (with respect to a, b, and c) and not sufficiently easy to verify (with respect to ordinary GCD computation).

A certified computation system can, instead, be considered as an "extended" *universal* algorithm, in the sense that it shows that certified computability is not a property enjoyed only by some special functions (such as the GCD function) but is an *intrinsic property of computation.* It should be noticed that, in addition to such "universality," a certified computation system produces relatively shorter and more easily inspectable certificates (than, say, the special ones produced by the extended GCD algorithm), but has a weaker guarantee of correctness (i.e., false certificates exist but are hard to find).

Finally, it should be appreciated that our suggested certified computation system may be impractical (as it refers to the execution history of Turing machines). One way to improve its efficiency may consist of finding a more convenient, and yet sufficient for our purposes, version or representation of the execution history of an algorithm.

Assumptions and implementations. The constructability of certified computation systems is implied by CS proof systems with a random oracle or CS proof systems with a random string. As explained below, if the latter proof systems exist, then their use in the current context does not require trusting the randomness of the extra string or the computational limitation of the prover.

Indeed, in this application, the random string need not be agreed upon by both prover and verifier (by means of some possibly difficult negotiation) nor chosen by means of a trusted third party or process. When seeking reassurance that indeed $y = A(x)$, the user U of a certified computation system $(\mathcal{P}, \mathcal{V})$ controls both $\mathcal{P}$ and $\mathcal{V}$, and thus can choose their common string in a way that he believes to be genuinely random, without "asking for their consent."

In addition, the physical device D implementing algorithm $\mathcal{P}$ "sits on top of user U's desk" and produces its output within a "reasonable time" monitored by U. Therefore, user D knows for a fact that D does not comprise more than 2^k gates and that it takes less than 2^k steps of computation for a security parameter k set by U.

In sum, if CS proofs with a random string exist, they yield certified computation systems that de facto offer the same guarantees of a probabilistic algorithm.

Conceivable applications of certified computation. Certified computation can in principle be quite useful when "contracting out" computer time. Indeed, consider an algorithm A that we believe to be correct but is very time-consuming. Then, we can hire a supercomputing company for executing A on a given input x on their computers and agree that we will pay for their efforts if they give us back the value $y = A(x)$ together with a certificate of correct execution, that is, a CS certificate of "$A(x) = y$ in t steps." Note that, because such a certificate also vouches for the

number of steps taken by A's execution, it is easy for the supercomputing company to charge according to the amount of computation actually invested.

Certified computation may also facilitate the verification of certain mathematical theorems proven with the help of a computer search (as in the case of the four-color theorem). For instance, the proof may depend on a lemma stating that there is no sparse graph with less than fifty nodes possessing a given property, and the lemma could be proved by means of an exhaustive search taking a few years of computing. Often, algorithms performing an exhaustive search are sufficiently simple so that we can be confident of the correctness of their design. Thus rather than (1) asking the reader of trusting that such a search has been done and has returned a negative result, or (2) asking the reader to perform such an extensive computation himself, one might publish together with the rest of the proof a compact and easily verifiable certificate of correct execution relative to a random oracle. If the security parameter were chosen to be, say, 1,000, then even the most skeptic reader might believe that no one has invested $2^{1,000}$ steps of computation in order to find a false certificate nor that he has succeeded in finding one by relying on a probability of success less than $2^{-1,000}$.

7. Concluding remarks.

Are CS proofs really proofs? In our minds this question really goes together with an older one: do probabilistic algorithms [34, 30] really compute? There is a sense in which both answers should be NO. These negative answers, in our opinion, may stem from two different reasons: (1) a specific interpretation of the words "proof" and "computation," and (2) our mathematical tradition. The first reason is certainly true but also "harmless." The second is more "dangerous" and less acceptable: not because it is false that these notions break with a long past, but because the unchallenged length of a tradition should not be taken as implying that specific formalizations of fundamental intuitions are "final." Indeed, we believe that even fundamental intuitions cannot be divorced from the large historical contexts in which they have arisen, and we expect that they will change with the changing of these contexts. And we believe and hope that, with time, CS proofs will be regarded to be as natural as probabilistic computations.

Truths versus proofs. According to our highest-level goal, CS proofs propose a new relationship between proving and deciding. In the thirties, Turing suggested that establishing (to yourself) the truthfulness of a mathematical statement consists of running a proper (accepting) algorithm. Today, we suggest that proving (to others) a mathematical statement consists of *feasibly speeding up* the verification of the result of any given accepting algorithm. That is, (1) proofs should make verifying the result of any accepting computation exponentially faster than the same accepting computation, but (2) proofs should not be more time-consuming to find than the accepting computations whose result verification they wish to facilitate. This, in our opinion, is an appealing relationship between proving and accepting, and one that guarantees that proving is both a useful and a distinct notion.

Living with error. In order to guarantee this "feasible speed up," CS proofs replace the traditional notion of a proof with a *computational* one. While CS proofs of true statements always exist, are suitably short, and are feasibly found, proofs of false statements either do not exist or are extraordinarily hard to find. Indeed, a CS proof is a short string that can be thought of as a "compressed version" of a long accepting computation. But the same conciseness that gives CS proofs their distinctive advantage also causes them to "lose quality" with respect to the accepting computations they compress: it makes them vulnerable to the possibility of error

(though in a controllable way).[38]

To be sure, the possibility of inconsistency should not be taken lightly. But after realizing that the coherence of a sufficiently rich mathematical system cannot be decided within it, perhaps we should switch to *managing error* rather than trying desperately to ban it!

Acknowledgments. This paper is dedicated to Oded Goldreich, friend, scientist, and vigilant guardian angel. Most sincere thanks also go to Allan Borodin, Steve Cook, Shafi Goldwasser, Leonid Levin, and Michael Rabin for encouraging and criticizing this research in different ways and at various stages of its development. Thanks also to Shai Halevi, Leo Reyzin, Janos Makowski, and Ray Sidney for their useful comments.

[38] Let me emphasize that, though very natural and useful, the computational boundedness of a cheating prover is not, per se, a goal of our notion of a proof. Rather, it is the Trojan horse that lets us sneak in and achieve our desiderata. (It is actually very important to establish whether some types of CS proofs exist when a cheating prover can compute for an unbounded amount of time.)

In sum, the notion of a true theorem has not changed. What we advocate changing is the notion of what it means to *prove that a theorem is true*.

THE COMPLEXITY OF MODULAR GRAPH AUTOMORPHISM*

V. ARVIND†, R. BEIGEL‡, AND A. LOZANO§

Abstract. Motivated by the question of the relative complexities of the graph isomorphism and the graph automorphism problems, we define and study the modular graph automorphism problems. These are the decision problems mod_k-GA which consist, for each $k > 1$, of deciding whether the number of automorphisms of a graph is divisible by k. The mod_k-GA problems all turn out to be intermediate in difficulty between graph automorphism and graph isomorphism.

We define an appropriate search problem corresponding to mod_k-GA and design an algorithm that polynomial-time reduces the mod_k-GA search problem to the decision problem. Combining this algorithm with an IP protocol, we obtain a randomized polynomial-time checker for mod_k-GA $\forall k > 1$.

Key words. graph isomorphism, graph automorphism, decision problems, search problems, IP protocols, program checking

1. Introduction.

The graph isomorphism (GI) problem consists of determining whether two graphs are isomorphic. It is well known that GI is in NP, but despite decades of study by mathematicians and computer scientists, it is not known whether GI is in P or is NP-complete. Many researchers conjecture that GI's complexity lies somewhere between P and NP-complete. There are several other decision problems (some graph-theoretic and others group-theoretic in nature) that also are not known to be in P or NP-complete. One such problem which is closely related to GI is graph automorphism (GA) which consists of deciding whether a graph has a nontrivial automorphism. Regarding the relative complexities of GA and GI, it is known that GA is polynomial-time many-one reducible to GI. On the other hand, GI is not known to be even polynomial-time Turing reducible to GA (see [15] for these and related results). However, in [17] it is shown that GI is polynomial-time reducible to the problem of computing the number of automorphisms of a graph.

The notion of program checking was introduced by Blum and Kannan [7] as an algorithmic alternative to program verification. Since then, the design of efficient checkers for various computational problems has rapidly grown into a discipline of algorithm design [7, 8]. One of the first program checkers in [7] was a randomized polynomial-time checker for GI. It is an outstanding open question in the area if NP-complete problems have efficient program checkers. This can be construed as ad-

ditional evidence that GI is not NP-complete. Later, in [16] it was shown that GA has a *nonadaptive* checker. In other words, the checker can make all its queries to the program in parallel, hence enabling it to be fast in parallel (in NC, to be precise). It is an open question whether GI too has a nonadaptive checker. The apparent bottleneck here is that the search problem for GI is not known to be polynomial-time truth-table reducible to the decision problem for GI; i.e., it is not known if the search problem is reducible to the decision problem via parallel (nonadaptive) queries. A related question is that of computing automorphisms of a graph in polynomial time with oracle access to either GI or GA. Indeed, it is shown in [16] that with nonadaptive queries to GA, the lexicographically first automorphism of a graph can be computed in polynomial time, whereas computing the lexicographically last automorphism is as hard as GI. Also see [1], in which the complexity of computing k nontrivial automorphisms of a graph is studied.

With these issues in mind, a natural next step in investigating the relationship between GI and GA is to consider exactly how much we need to know about the number of automorphisms of a graph in order to solve the GI problem. This motivates us to define and study modular GA problems. Let $Aut(G)$ denote the automorphism group of the graph G.

DEFINITION 1. *For any k, let* $\text{mod}_k\text{-GA} = \{G : |Aut(G)| \equiv 0 \pmod{k}\}$.

We show in Theorems 4 and 5 that for any $k > 1$, GA $\leq_m^p$ mod_k-GA $\leq_m^p$ GI; thus the mod_k-GA problems are intermediate in difficulty between GA and GI. It is an open question whether any of the mod_k-GA problems is polynomial-time equivalent to GA or GI. We conjecture that mod_k-GA is *not* polynomial-time equivalent to GA or GI for any $k > 1$. An evidence that some of the mod_k-GA problems could be actually harder than GA is the observation that tournament isomorphism (GI for tournament graphs) is many-one reducible to mod_2-GA. This follows from the fact that the automorphism group of any tournament is of odd size [15], which in turn implies that two tournaments are isomorphic if and only if the automorphism group of their disjoint union contains an order-2 permutation (which must switch the two graphs).

The proof technique we use is a combination of elementary properties of finite graphs (see, e.g., [12]) and the theory of finite groups of prime-power order (see, e.g., a group theory text like [18]).

The layout of the paper is as follows. Section 2 contains the preliminaries. In section 3, we prove that the mod_k-GA problems are located between GA and GI. In section 4, we show that search is polynomial-time Turing equivalent to decision for $\underline{\text{mod}_k\text{-GA}}$, and in section 5 we use this result in combination with an IP protocol for $\overline{\text{mod}_p\text{-GA}}$ to obtain an efficient program checker for mod_k-GA. Notice that although both GA and GI have program checkers ([16] and [7], resp.) and mod_k-GA is intermediate in complexity, it does not necessarily imply that mod_k-GA has a program checker [7].

2. Preliminaries. In this paper, by a graph we mean a finite directed graph[1] (see, for example, [12] or any other standard text on graph theory for basic definitions). For a graph G, let $V(G)$ denote its vertex set and $E(G)$ denote its edge set. A permutation π on $V(G)$ is an automorphism of the graph G if $(u, v) \in E(G) \iff (\pi(u), \pi(v)) \in E(G)$. The set of automorphisms $Aut(G)$, of a graph G, is a subgroup

[1] We consider the problems GI, GA, and mod_k-GA on directed graphs. However, our results hold for these problems on undirected graphs as well.

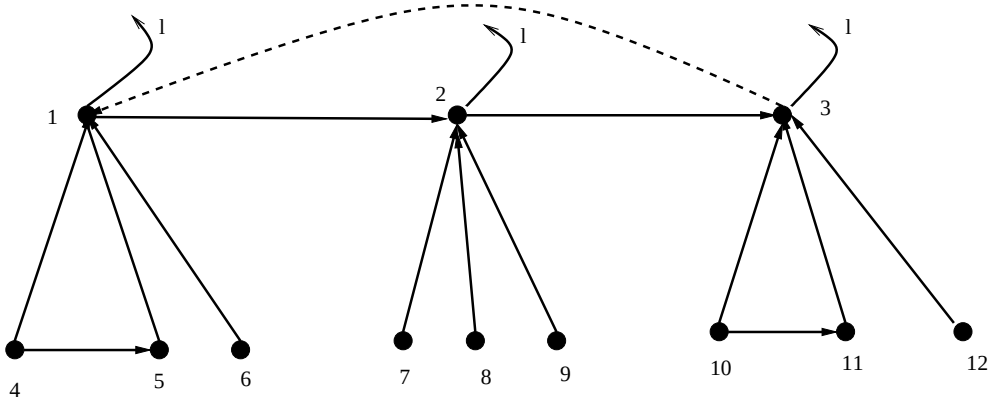

FIG. 1. *Examples of Cycle and Path: The above graph, including the dashed edge, is Cycle*(G_1, G_2, G_3)*, where* G_1*,* G_2*, and* G_3 *are the graphs induced by* $\{4, 5, 6\}$*,* $\{7, 8, 9\}$*, and* $\{10, 11, 12\}$*, respectively. Excluding the dashed edge in the above graph gives Path*(G_1, G_2, G_3)*. The underlying cycle* C_3 *(resp., path* P_3*) is induced by vertices* 1*,* 2*, and* 3*, which are labeled* l*.*

of the permutation group on $V(G)$. The identity automorphism of any graph will be denoted by id.

Let X be a list of vertices in $V(G)$ for a graph G. By $G_{[X]}$ we mean the graph G with distinct labels attached to the vertices in X. We can define these labels as given in [15, p. 8]: If $|V(G)| = n$, label j, $1 \leq j \leq n$, is defined as a graph L_j consisting of $2n+j+3$ vertices which has a directed path P of length $2n+3$ and a directed path of length j emanating from the $(n+2)$nd vertex of path P. Notice that L_j is *rigid* (i.e., it has no nontrivial automorphisms). The size of $G_{[X]}$ is $O(n^2)$. This definition of labels guarantees that every automorphism of $G_{[X]}$ must pointwise fix the vertices of X. Thus $Aut(G_{[X]})$ is isomorphic to the subgroup of $Aut(G)$ which pointwise fixes the vertices in X. Furthermore, given an automorphism of $Aut(G_{[X]})$, the corresponding automorphism of $Aut(G)$ can be efficiently (i.e., in polynomial time) constructed. Given two lists of vertices $X, Y \subseteq V(G)$, we usually assume that the graphs $G_{[X]}$ and $G_{[Y]}$ have the same labels in vertices occupying the same relative positions in X and Y.

DEFINITION 2. *Let* $G_1, \ldots, G_n$ *be* n *graphs.*

- *Let* P_n *be a directed simple path of* n *new vertices* $v_1, v_2, \ldots, v_n$*, where each vertex* v_i *is labeled with a single label* l*. The graph Path*$(G_1, \ldots, G_n)$ *is obtained by taking one copy of each of the graphs* $G_1, \ldots, G_n$ *and, for* $1 \leq i \leq n$*, attaching all the vertices of* G_i *to* v_i*. See Figure* 1 *for an example.*
- *Let* C_n *be the directed simple cycle on* n *new vertices* $v_1, v_2, \ldots, v_n$*, with each vertex* v_i*,* $1 \leq i \leq n$*, labeled with a single label* l*. The graph Cycle*$(G_1, \ldots, G_n)$ *is obtained by taking one copy of each of the graphs* $G_1, \ldots, G_n$ *and, for* $1 \leq i \leq n$*, attaching all the vertices of* G_i *to* v_i*. See Figure* 1 *for an example.*

In both $Path(G_1, \ldots, G_n)$ and $Cycle(G_1, \ldots, G_n)$, since vertices $v_1, v_2, \ldots, v_n$ are labeled with l, any automorphism of these graphs must map $\{v_1, v_2, \ldots, v_n\}$ onto itself. Thus, any automorphism of $Path(G_1, \ldots, G_n)$ ($Cycle(G_1, \ldots, G_n)$) when restricted to $\{v_1, v_2, \ldots, v_n\}$ is an automorphism of P_n (respectively, C_n). It follows that an automorphism of $Path(G_1, \ldots, G_n)$ cannot permute the copies of $G_1, \ldots, G_n$, while an automorphism of $Cycle(G_1, \ldots, G_n)$ can permute them but only along the cycle C_n.

The reducibilities discussed in this paper are the standard polynomial-time Turing

and many-one reducibilities. Formal definitions of these and other standard notions in complexity theory can be found in [3, 2].

We now recall some useful complexity-theoretic concepts. A set $A \subseteq \Sigma^*$ is a *d-cylinder* if there is a polynomial-time computable function OR that takes a list of strings $x_1, x_2, \ldots, x_m$ as argument and produces a string y such that

$$\mathrm{OR}(x_1, x_2, \ldots, x_m) = y \in A \iff \exists i \ : \ 1 \leq i \leq m \ : \ x_i \in A.$$

Similarly, a set $A \subseteq \Sigma^*$ is a *c-cylinder* if there is a polynomial-time computable function AND that takes a list of strings $x_1, x_2, \ldots, x_m$ as argument and produces a string y such that

$$\mathrm{AND}(x_1, x_2, \ldots, x_m) = y \in A \iff (\forall i \ : \ 1 \leq i \leq m)[x_i \in A].$$

PROPOSITION 3 (see [10, 16]). GI *is a d-cylinder and a c-cylinder.*

It is interesting to note here that GA is known to be a d-cylinder [15], but it is open whether it is also a c-cylinder. The relative complexity of decision and search for NP problems is well studied [9, 4, 19, 6]. For instance, it is known that search and decision are polynomial-time Turing equivalent for all NP-complete problems. In particular, we recall that for GI search is polynomial-time Turing reducible to decision [19], whereas for GA a stronger result holds: search is *nonadaptively* polynomial-time reducible to decision [16].

3. Locating the mod$_k$-GA problems. We show in this section that mod$_k$-GA is located between GA and GI $\forall k > 1$.

THEOREM 4. *For all* $k > 1$, GA $\leq_m^p$ mod$_k$-GA.

Proof. Given a graph G, we define for every i, j with $1 \leq i < j \leq n$ the graph $H_{i,j} = \mathit{Cycle}(G_{[\{i\}]}, G_{[\{j\}]}, \ldots, G_{[\{j\}]})$ which contains one copy of $G_{[\{i\}]}$ and $k-1$ copies of $G_{[\{j\}]}$. Further, let H be obtained by applying the *Path* operator to all the graphs $H_{i,j}$ with $1 \leq i < j \leq n$. We claim that G has a nontrivial automorphism if and only if H is in mod$_k$-GA.

Suppose that G has a nontrivial automorphism φ. There exist two vertices i and j such that $\varphi(i) = j$. Notice that $H_{i,j}$ has a nontrivial automorphism α that cyclically permutes the k graphs in $\mathit{Cycle}(G_{[\{i\}]}, G_{[\{j\}]}, \ldots, G_{[\{j\}]})$ as follows. The automorphism α maps the first graph $G_{[\{i\}]}$ to $G_{[\{j\}]}$ by φ. It maps each of the first $k-2$ copies of $G_{[\{j\}]}$ to the next copy of $G_{[\{j\}]}$ by the identity automorphism. Finally, α maps the last copy of $G_{[\{j\}]}$ back to $G_{[\{i\}]}$ by the automorphism φ^{-1}.

The order of α is k since the vertices in $H_{i,j}$ are moved in a cyclic way through the k subgraphs. In fact, α is a product of k-cycles. Thus, $H_{i,j} \in$ mod$_k$-GA. Since $|\mathit{Aut}(H)| = \prod_{1 \leq i < j \leq n} |\mathit{Aut}(H_{i,j})|$, it follows that $H \in$ mod$_k$-GA.

For the converse, assume that $H \in$ mod$_k$-GA. Then H has a nontrivial automorphism, say, α. Notice that α must induce a nontrivial automorphism β in one of its subgraphs $H_{i,j}$. Since $H_{i,j} = \mathit{Cycle}(G_{[\{i\}]}, G_{[\{j\}]}, \ldots, G_{[\{j\}]})$, there are two possibilities: either β induces a nontrivial automorphism of $G_{[\{i\}]}$ or $G_{[\{j\}]}$, or β maps $G_{[\{i\}]}$ to some copy of $G_{[\{j\}]}$. In either case we get a nontrivial automorphism of G. □

Mathon [17] has shown that $|\mathit{Aut}(G)|$ is polynomial-time computable with GI as oracle. From this it easily follows that mod$_k$-GA $\leq_T^p$ GI. In the next theorem, we strengthen this to a $\leq_m^p$-reduction using some permutation group theory.

THEOREM 5. *For all* $k > 1$, mod$_k$-GA $\leq_m^p$ GI.

We need a couple of definitions and group-theoretic lemmas before we prove Theorem 5. Let A be a subgroup of S_n and let $[n]$ denote the set $\{1, 2, \ldots, n\}$. A subset

$X \subseteq [n]$ is *A-invariant* if $g(X) = X\ \forall g \in A$. If $X \subseteq [n]$ is A-invariant, then consider the action of A *restricted* to X. This gives rise to a subgroup of the symmetric group S_X, which we denote by A^X. A useful obvious property is that $|A^X| \leq |A|$ $\forall A$-invariant sets X.

LEMMA 6. *Let A be a subgroup of S_n such that $|A| = m$. Then there exists an A-invariant subset $X \subseteq [n]$ with $|X| \leq m \log m$, such that A is isomorphic to A^X.*

Proof. Consider the following procedure for constructing the set X:

$X := \emptyset$;
while $\exists i \notin X : |A^X| < |A^{X \cup A(i)}|$ **do**
    ($A(i)$ denotes the orbit of i under A *)*
    Pick such an i;
    $X := X \cup A(i)$
endwhile

First we claim that, as a loop invariant, X is always an A-invariant subset of $[n]$. To see this, notice that it holds at the beginning when X is empty, and if X is A-invariant, then so is $X \cup A(i)$ since we are including an entire A-orbit in the set.

Next, suppose X is A-invariant and $i \notin X$ is some index. Consider the mapping φ from $A^{X \cup A(i)}$ to A^X which maps an element of $A^{X \cup A(i)}$ to its restriction to X. Since X is A-invariant, it is easy to verify that φ is a surjective homomorphism from $A^{X \cup A(i)}$ to A^X. It follows that $|A^X|$ divides $|A^{X \cup A(i)}|$. Suppose now, at some stage of the while loop, i is an index such that $|A^X| < |A^{X \cup A(i)}|$. Then it must hold that $2|A^X| \leq |A^{X \cup A(i)}|$. Thus we have argued that every time X increases by including an orbit $A(i)$ in it, the size of the group A^X increases by at least a factor of 2. Thus the assignment $X := X \cup A(i)$ is executed at most $\log m$ times, implying also that the procedure must terminate. Since the size of any orbit $A(i)$ is bounded by $|A|$, it follows that the procedure terminates with an A-invariant set X such that $|X| \leq m \log m$. Let X be the set computed when the while-loop is exited. To complete the proof we must show that A^X is isomorphic to A. Consider the canonical surjective homomorphism ψ from A to A^X, which maps a given element of A to its corresponding restriction to X. To show that this homomorphism is an isomorphism we must argue that $Ker(\psi)$ is (id). Suppose $g \in Ker(\psi)$ is a nontrivial element. Then there is $i \notin X$ such that $g(i) \neq i$. This in turn implies that the surjective homomorphism φ from $A^{X \cup A(i)}$ to A^X, which maps an element of $A^{X \cup A(i)}$ to its restriction to X, has a nontrivial kernel with $g \in Ker(\varphi)$. Consequently, $|A^X| < |A^{X \cup A(i)}|$. Thus, both X and i satisfy the while-loop condition, contradicting the fact that the while-loop has terminated. This completes the proof of this lemma. □

LEMMA 7. *Let A be a finite group. Let $X = \{a_1, a_2, \ldots, a_t\}$ and $Y = \{b_1, b_2, \ldots, b_t\}$ be two subsets of A such that $\langle X \rangle \cap \langle Y \rangle = \{\text{id}\}$ and $a_i b_j = b_j a_i$ for $1 \leq i, j \leq t$. Then $|\langle X \rangle|$ divides the order of the group $\langle \{a_i b_i : 1 \leq i \leq t\} \rangle$.*

Proof. Let H denote the subgroup of A generated by $\{a_i b_i \mid 1 \leq i \leq t\}$, K denote the subgroup of A generated by $\{a_i \mid 1 \leq i \leq t\}$, and L denote the subgroup of A generated by $\{b_i \mid 1 \leq i \leq t\}$. Notice that since $a_i b_j = b_j a_i$ for $1 \leq i, j \leq t$, we have $KL = LK$, and therefore the set KL is actually a subgroup of A. Next, notice that, by definition of H, any $x \in H$ can be written as a product of elements from the generator set $\{a_i b_i \mid 1 \leq i \leq t\}$. Using $a_i b_j = b_j a_i$ for $1 \leq i, j \leq t$ as a rewrite rule, this product of generators expressing x can be rewritten as ay, where $a \in K$ and $y \in L$. It follows that $H \subseteq KL$. Consider the following map ψ from the group H to the group K, defined as follows:

$$\forall x \in H\ :\ \psi(x) = a \text{ where } x = ay, \text{ with } a \in K \text{ and } y \in L.$$

We claim that ψ is a well-defined surjective homomorphism from H to K. We first show that ψ is well defined. Suppose there are two distinct elements $a, a' \in K$ such that $x = ay = a'y'$ for elements $y, y' \in L$. This implies, by cancellation laws, that $a^{-1}a' = yy'^{-1}$, which belongs to both K and L. Since $K \cap L = \{\mathrm{id}\}$, we have $a = a'$. Thus ψ is well defined. To see that ψ is a homomorphism is routine: we can easily check that $\psi(xx') = \psi(x)\psi(x')$ and that $\psi(x^{-1}) = (\psi(x))^{-1}$ hold using the rewrite rules $a_ib_j = b_ja_i$ for $1 \le i, j \le t$. To see that ψ is surjective, let $a \in K$ be any element. We can express a as a product $\Pi_{1\le r\le m}a_{i_r}$ for indices $i_r \in [t]$. Consider the element $x = \Pi_{1\le r\le m}a_{i_r}b_{i_r} \in H$. It is easy to see that $\psi(x) = a$.

Thus, by the fundamental theorem of homomorphisms, it follows that $H/Ker(\psi)$ is isomorphic to K. Therefore, $|H/Ker(\psi)| = |K|$. It follows that $|K|$ divides $|H|$, which proves the lemma. □

Proof of Theorem 5. First, we argue that it suffices to show that mod_{p^l}-GA $\le^p_m$ GI for all prime p and $l > 0$. To see this, let $\prod_{1\le j\le r} p_j^{l_j}$ be the prime factorization of k. Clearly, a graph $G \in \mathrm{mod}_k$-GA if and only if $G \in \bigcap_{j=1}^{r} \mathrm{mod}_{p_j^{l_j}}$-GA. Thus, if $\mathrm{mod}_{p_j^{l_j}}$-GA $\le^p_m$ GI for $1 \le j \le r$, it follows that mod_k-GA $\le^p_m$ GI, since GI is a c-cylinder.

We next prove a useful group-theoretic claim. Let G be a graph on n vertices and let f be a partial permutation on $[n]$ (i.e., f is defined on a subset of the domain $[n]$ and can be extended to a permutation in S_n). Then we call f a *partial automorphism* of G if f can be extended to an automorphism of G.

Claim. *Let p be a fixed prime and $l > 0$. A graph G on n vertices is in* mod_{p^l}-GA *if and only if there exist a set $X \subseteq [n]$ with $|X| \le p^l(\log p^l)$ and a subgroup $K = \{a_1, a_2, \ldots, a_{p^l}\}$ of S_X such that each $a_i \in K$ is a partial automorphism of G.*

Proof. Let $G \in \mathrm{mod}_{p^l}$-GA be an n vertex graph. Since p^l divides $|Aut(G)|$, by Sylow's theorem $Aut(G)$ has a subgroup A of size p^l. By Lemma 6, there is an A-invariant set $X \subseteq [n]$ with $|X| \le p^l(\log p^l)$, such that A^X is isomorphic to A. Let $A^X = \{a_1, a_2, \ldots, a_{p^l}\}$. Furthermore, it also follows that A^X is a subgroup of S_X where each $a_i \in A^X$ is a partial automorphism of G. Conversely, suppose there is $X \subseteq [n]$ with $|X| \le p^l(\log p^l)$ and a subgroup $K = \{a_1, a_2, \ldots, a_{p^l}\}$ of S_X where each $a_i \in K$ is a partial automorphism of G. Then for each i with $1 \le i \le p^l$, there is a $b_i \in S_{[n]-X}$ such that $a_ib_i \in Aut(G)$. We can now apply Lemma 7 to the elements $\{a_i\}_{1\le i\le p^l}$ and $\{b_i\}_{1\le i\le p^l}$, since therequired conditions are fulfilled. Consequently, $|\langle\{a_ib_i : 1 \le i \le p^l\}\rangle|$ is divisible by p^l. Since $\langle\{a_ib_i : 1 \le i \le p^l\}\rangle$ is a subgroup of $Aut(G)$, it follows that p^l divides $|Aut(G)|$.

Now, note that the language $B = \{(G, f) : f$ is a partial automorphism of the graph $G\}$ is $\le^p_m$-equivalent to GI (for details, see [15, Theorem 1.18]). We will give a truth-table reduction from mod_{p^l}-GA to B, where the truth-table is a disjunction of conjunctions. Since the language B is $\le^p_m$-reducible to GI and since GI is both a c-cylinder and a d-cylinder, it follows that mod_{p^l}-GA is $\le^p_m$-reducible to GI. We describe below the said reduction of mod_{p^l}-GA to B as a logical expression, which is easily seen to describe a disjunction-of-conjunctions truth-table reduction:

$$G \in \mathrm{mod}_{p^l}\text{-GA} \iff (\exists\, X \subseteq [n] : |X| \le p^l \log p^l)$$
$$(\exists \text{ subgroup } K < S_X : |K| = p^l)(\forall a \in K)[(G, a) \in B].$$

This completes the proof of Theorem 5. □

Since GA is not known to be a c-cylinder and, moreover, the set B defined above is $\le^p_m$-equivalent to GI, it is unlikely that the approach taken in the above proof can

be used to show that mod_k-GA is $\leq_m^p$-reducible to GA.

We next show a useful result relating the complexity of mod_k-GA to mod_l-GA when l is a factor of k.

LEMMA 8. *For $k, l > 1$ such that l divides k, mod_l-GA $\leq_m^p$ mod_k-GA.*

Proof. Let G be an instance of mod_l-GA, where $k = lm$ for some $m > 1$. Let C_m denote the directed cycle of length m. Consider the graph $Path(G, C_m)$. By construction, any automorphism of $Path(G, C_m)$ must map G to itself and C_m to itself. Thus, $|Aut(Path(G, C_m))| = |Aut(G)||Aut(C_m)| = |Aut(G)|m$. Thus k divides $|Aut(Path(G, C_m))|$ if and only if l divides $|Aut(G)|$. It follows that $G \mapsto Path(G, C_m)$ is a $\leq_m^p$-reduction from mod_l-GA to mod_k-GA. ∎

4. Computing solutions for mod_k-GA instances. Let $\prod_{1 \leq j \leq m} p_j^{e_j}$ be the prime factorization of k. We define an NP *witness* of the membership of a graph G in mod_k-GA as m subgroups $\{A_1, A_2, \ldots, A_m\}$ of $Aut(G)$, where A_i is listed as a set of permutations and $|A_i| = p_i^{e_i}$ for each i. We are interested in the *search* problem of computing an NP witness for $G \in \mathrm{mod}_k$-GA. Clearly, given a collection $\{A_1, A_2, \ldots, A_m\}$ of permutation sets, it can be verified to be a witness for G in time polynomial in $|V(G)|$. Notice that, for an instance G in mod_k-GA, it is straightforward to design a polynomial-time algorithm with GI as oracle for computing a witness. This can be done, for instance, by adapting ideas in the proof of Theorem 5 of the previous section where we showed how mod_k-GA is many-one reducible to GI. The result of this section is stronger since we will use the weaker oracle mod_k-GA for the same task. Hence, for the above definition of search problem, it follows that search is polynomial-time Turing reducible to decision for mod_k-GA.

Intuitive description of the algorithmic task. Our aim is to design a polynomial-time algorithm that, given G in mod_k-GA as input, computes the NP witness described above with oracle access to mod_k-GA. Clearly, a graph $G \in \mathrm{mod}_k$-GA if and only if $G \in \bigcap_{j=1}^{m} \mathrm{mod}_{p_j^{e_j}}$-GA. Also, by Lemma 8, $\mathrm{mod}_{p_j^{e_j}}$-GA is $\leq_m^p$-reducible to mod_k-GA $\forall j$. Thus, it suffices to design a polynomial-time algorithm for the case when $k = p^l$ for some prime p. In this case, given $G \in \mathrm{mod}_{p^l}$-GA as input, the witness that the algorithm must compute with oracle mod_{p^l}-GA is a p^l-subgroup A of $Aut(G)$. (We actually do better; the oracle our algorithm will access is mod_p-GA, which is $\leq_m^p$-reducible to mod_{p^l}-GA by Lemma 8.) By Sylow's theorem, such a subgroup A exists. By standard p-group theory, if A is a p^l-subgroup of $Aut(G)$, we have a subgroup chain: $A_0 = (\mathrm{id}) < A_1 < \cdots < A_l = A$, where $|A_i| = p^i$ and $\forall i$, A_i is a normal subgroup of A_{i+1}. Our algorithm will compute such a subgroup A inductively by computing each subgroup in such a sequence $A_1, \ldots, A_i$ in increasing order of i until finally $A_l = A$ is computed. Thus it suffices to perform the following algorithmic task: Given a p^i-subgroup A_i of $Aut(G)$ for a graph G and $0 \leq i \leq p-1$, compute a p^{i+1}-subgroup of $Aut(G)$ if $G \in \mathrm{mod}_{p^{i+1}}$-GA.

The following results about finite groups of prime-power order indicate how this can be done. First, we recall a stronger form of the third Sylow theorem [14, Theorem 11.1.1, p. 66]: if p^{i+1} divides $|Aut(G)|$, then for each subgroup of order p^i there is some subgroup of order p^{i+1} containing it.

THEOREM 9. (Sylow's theorem [14]). *If p^{i+1} divides the order of a finite group H, then for each subgroup K of H of order p^i there is some subgroup of H of order p^{i+1} containing K.*

We derive from this the following easy fact, which is useful for our particular application.

FACT 10. *Let A_i be a p^i-subgroup of $Aut(G)$. A graph G is in* $\mathrm{mod}_{p^{i+1}}$-GA *if*

and only if the following three conditions hold for some $g \in Aut(G)$.

(a) $g \notin A_i$.

(b) *g has order p^s for some $s \leq i+1$.*

(c) $gA_ig^{-1} = A_i$.

Moreover, if $t+1$ is the smallest positive integer such that $g^{p^{t+1}} \in A_i$ for $g \in Aut(G)$ satisfying (a), (b), *and* (c), *the set $A_{i+1} = \bigcup_{j=0}^{p-1} A_i g^{jp^t}$ is a p^{i+1}-subgroup of $Aut(G)$ containing A_i as a normal subgroup.*

Proof. Suppose $G \in \mathrm{mod}_{p^{i+1}}$-GA and A_i is a p^i-subgroup of $Aut(G)$. By Theorem 9, there is a p^{i+1}-subgroup A_{i+1} of $Aut(G)$ containing A_i. Furthermore, A_i is normal in A_{i+1} since every p^i-subgroup of a p^{i+1}-subgroup is normal (see, e.g., [18, Theorem 4.6, p. 75]). Thus, the quotient group A_{i+1}/A_i exists and is a cyclic group of order p. Let A_ig be a generator for A_{i+1}/A_i for some $g \in A_{i+1} - A_i$. Such an element g clearly fulfills the conditions (a), (b), and (c).

To prove the reverse implication suppose there exists $g \in Aut(G)$ satisfying the above three conditions. Let A be the group generated by $A_i \cup \{g\}$. Since $gA_ig^{-1} = A_i$, A_i is a normal subgroup of A. Furthermore, $o(A_ig) = p^{t+1}$ for some $0 \leq t < s$. It follows that $A_ig^{p^t}$ is an order-p element of the quotient group A/A_i. Let $A_{i+1} = \bigcup_{j=0}^{p-1} A_i g^{jp^t}$. Clearly, $A_i \subset A_{i+1} \subset A$. It is easy to check that A_{i+1} is a p^{i+1}-subgroup of $Aut(G)$. Consequently, A_i is a normal subgroup of A_{i+1}. ∎

By Fact 10 our algorithmic task is reduced to the following: Given as input $G \in \mathrm{mod}_{p^{i+1}}$-GA and A_i as a list of permutations, where A_i is a p^i-subgroup of $Aut(G)$, compute $g \in Aut(G)$ satisfying properties (a), (b), and (c) of Fact 10. We first design an algorithm for the case $i = 0$. We will use this as a subroutine in our algorithm for the general case.

We first describe a property of the graph gadget *Cycle* that we use extensively in this section.

LEMMA 11. *Let H and K be two graphs on n vertices, and p be a fixed prime. Consider $Cycle(H, K, \ldots, K)$ with $p-1$ copies of K. $Aut(Cycle(H, K, \ldots, K))$ is in bijective correspondence with*

$$Aut(H) \times (Aut(K))^{p-1} \cup Z_p^* \times (Aut(K))^{p-2} \times Iso(H, K) \times Iso(K, H),$$

where $\times$ denotes the Cartesian product, Z_p^* is $\{1, \ldots, p-1\}$, and $Iso(H, K)$ denotes the set of isomorphisms from H to K. Additionally, if a nontrivial $\pi \in Aut(Cycle(H, K, \ldots, K))$ is represented in $Aut(H) \times (Aut(K))^{p-1}$, then a nontrivial automorphism of either H or K can be computed from π in polynomial time. Similarly, if π is represented in $Z_p^* \times (Aut(K))^{p-2} \times Iso(H, K) \times Iso(K, H)$, then a nontrivial element of $Iso(H, K)$ can be computed from π in polynomial time. Furthermore,

$$(1)\quad |Aut(Cycle(H, K, \ldots, K))| = |Aut(H)| \cdot |Aut(K)|^{p-1} \cdot (1 + (p-1)\chi[H \cong K]),$$

where $\chi[H \cong K]$ is defined as 1 if H is isomorphic to K, and 0 otherwise.

Proof. Any automorphism of $Cycle(H, K, \ldots, K)$ induces an automorphism in the underlying directed p-cycle to which the graphs H and K are attached. The automorphism group of the directed p-cycle is isomorphic to $Z_p = \{0, \ldots, p-1\}$ under addition modulo p, where the element $k \in Z_p$ represents a forward rotation of the directed p-cycle by k positions.

Consider $\pi \in Aut(Cycle(H, K, \ldots, K))$. If the underlying p-cycle is pointwise fixed (represented by 0), then π maps H to itself, and also each copy of K to itself.

Thus, π can be represented as an element of the product $Aut(H) \times (Aut(K))^{p-1}$. Suppose the automorphism induced on the p-cycle is a rotation by some $k > 0$. Then π can be represented by an element of $Z_p^* \times (Aut(K))^{p-2} \times Iso(H,K) \times Iso(K,H)$, where the first component represents the k by which the underlying p-cycle is rotated by π, the second component represents the $p-2$ permutations used by π to successively map one copy of K into the next (corresponding to the rotate by k), $Iso(H,K)$ represents the mapping by π of H into the kth copy of K, and finally $Iso(K,H)$ represents the mapping of the $(p-k)$th copy of K back to H. Clearly, in this representation of $Aut(Cycle(H,K,\ldots,K))$, the part $Z_p^* \times (Aut(K))^{p-2} \times Iso(H,K) \times Iso(K,H)$ is nonempty if and only if H and K are isomorphic. It is clear from the above description that given a nontrivial $\pi \in Aut(Cycle(H,K,\ldots,K))$, if π can be represented as an element of the product $Aut(H) \times (Aut(K))^{p-1}$, then it induces a nontrivial automorphism, either on H or on some copy of K which can be computed in polynomial time from π. Similarly, if π is represented in $Z_p^* \times (Aut(K))^{p-2} \times Iso(H,K) \times Iso(K,H)$, then π induces an isomorphism from H to K which can be computed in polynomial time from π.

Since $Aut(H) \times (Aut(K))^{p-1} \cup Z_p^* \times (Aut(K))^{p-2} \times Iso(H,K) \times Iso(K,H)$ is a disjoint union and $|Iso(H,K)| = |Iso(K,H)|$ we get

$$|Aut(Cycle(H,K,\ldots,K))| = |Aut(H)| \cdot |Aut(K)|^{p-1} + (p-1) \cdot |Aut(K)|^{p-2} \cdot |Iso(H,K)|^2.$$

The expression for $|Aut(Cycle(H,K,\ldots,K))|$ in the lemma statement follows by observing additionally that if $H \cong K$, then $|Iso(H,K)| = Aut(H) = Aut(K)$, and if $H \ncong K$, then $|Iso(H,K)| = 0$. □

LEMMA 12. *For any prime p, there is a polynomial-time algorithm $\mathcal{A}$ with* mod$_p$-GA *as oracle such that given a graph G as input, $\mathcal{A}$ rejects G if $G \notin$* mod$_p$-GA*, and $\mathcal{A}$ outputs an element of order p contained in $Aut(G)$ if $G \in$* mod$_p$-GA*.*

Proof. We first give an intuitive description of $\mathcal{A}$. Let $G \in$ mod$_p$-GA. Any order-p automorphism of G is a product of disjoint p-cycles. Given G as input, algorithm $\mathcal{A}$ will compute an order-p automorphism of G by successively determining all its p-cycles. In order to find the p-cycles of an order-p automorphism we will use the *Cycle* gadget of Lemma 11 as follows. Let X be a *maximal* fixed point set for G such that $G_{[X]} \in$ mod$_p$-GA, and let $H = G_{[X]}$. For a vertex list $C = \{i_1, \ldots, i_p\}$ in a graph G, let its rotate shift $r(C)$ be the vertex list $\{i_2, \ldots, i_{p-1}, i_p, i_1\}$. By the maximality of X in the definition of H, identity (1) of Lemma 11 implies that $Cycle(H_{[C]}, H_{[r(C)]}, \ldots, H_{[r(C)]}) \in$ mod$_p$-GA, with $p-1$ copies of $H_{[r(C)]}$, if and only if $H_{[C]} \cong H_{[r(C)]}$. In turn, $H_{[C]} \cong H_{[r(C)]}$ if and only if G has an automorphism with C as a p-cycle. This property of *Cycle* is repeatedly exploited in algorithm $\mathcal{A}$ to build the desired order-p automorphism. The algorithm is formally described in Figure 2.

Correctness. If $G \notin$ mod$_p$-GA, then G is clearly rejected by $\mathcal{A}$. In order to prove correctness we must establish the following claims for any input $G \in$ mod$_p$-GA.

CLAIM 1. *The while-loop invariant: At the beginning of each iteration of the while-loop, there is an order-p automorphism of G that fixes X pointwise and contains each $C \in \mathcal{C}$ as a cycle.*

CLAIM 2. *Termination: Eventually each vertex in $S = V(G) - X$ will be covered by some cycle in $\mathcal{C}$ and the while-loop is exited.*

Clearly, if Claims 1 and 2 are true, then the algorithm will output an order-p automorphism ψ.

The first for-loop computes $G_{[X]} \in$ mod$_p$-GA where X is a maximal set (of fixed points) preserving membership of $G_{[X]}$ in mod$_p$-GA.

input G;
if $G \notin \mathrm{mod}_p$-GA **then reject** and **stop**;
$X := \emptyset$;
for $i := 1$ **to** $|V(G)|$ **do**
  if $G_{[X\cup\{i\}]} \in \mathrm{mod}_p$-GA **then** $X := X \cup \{i\}$
endfor;
$S := V(G) - X$;
$\mathcal{C} := \emptyset$;
$G' := G_{[X]}$; $G'' := G_{[X]}$;
while $S \neq \bigcup_{D\in\mathcal{C}} D$ **do**
  find a p-cycle $C \subseteq S - \bigcup_{D\in\mathcal{C}} D$ such that $Cycle(G'_{[C]}, G''_{[r(C)]}, \ldots, G''_{[r(C)]}) \in \mathrm{mod}_p$-GA;
  (There are $p-1$ copies of $G''_{[r(C)]}$ in the above Cycle definition *)*
    $G' := G'_{[C]}$; $G'' := G''_{[r(C)]}$;
    $\mathcal{C} := \mathcal{C} \cup \{C\}$;
endwhile;
output ψ and **stop**.

FIG. 2. *Algorithm* $\mathcal{A}$.

Proof of Claim 1. Claim 1 clearly holds at the beginning of the first iteration of the while-loop when $\mathcal{C}$ is empty. Now, suppose it holds at the beginning of some iteration of the while-loop for a set of p-cycles $\mathcal{C}$, and a new p-cycle C gets added in that iteration. Since the algorithm adds C to $\mathcal{C}$, we have $Cycle(G'_{[C]}, G''_{[r(C)]}, \ldots, G''_{[r(C)]}) \in \mathrm{mod}_p$-GA.

Observe that by construction of G' and G'' in $\mathcal{A}$ we have at any stage of the algorithm

$$Aut(G'_{[C]}) = Aut(G''_{[r(C)]}) = \left\{ \pi \in Aut(G) \mid \forall x \in \bigcup_{D\in\mathcal{C}} D \cup C \ : \ \pi(x) = x \right\}.$$

Hence, by identity (1) of Lemma 11 we have

$$|Aut(Cycle(G'_{[C]}, G''_{[r(C)]}, \ldots, G''_{[r(C)]}))| = |Aut(G'_{[C]})|^p \cdot (1 + (p-1)\chi[G'_{[C]} \cong G''_{[r(C)]}]).$$

From the above identity, $Aut(Cycle(G'_{[C]}, G''_{[r(C)]}, \ldots, G''_{[r(C)]})) \in \mathrm{mod}_p$-GA if and only if either $G'_{[C]} \in \mathrm{mod}_p$-GA or $G'_{[C]} \cong G''_{[r(C)]}$. Notice that $G'_{[C]} \notin \mathrm{mod}_p$-GA, since maximality of X implies that no order-p element of $Aut(G)$ can pointwise fix $X \cup C$. Thus, $G'_{[C]} \cong G''_{[r(C)]}$. Let $\psi \in Iso(G'_{[C]}, G''_{[r(C)]})$. Then ψ induces a $\phi \in Aut(G)$ which pointwise fixes X, and $\mathcal{C} \cup \{C\}$ is contained in the p-cycle set of ϕ. Let $o(\phi) = p^s m$ for positive integers m and s with $(p, m) = 1$. Notice that $s = 1$, for if $s > 1$, then $\phi^{p^{s-1}m}$ is an order-p automorphism of G that pointwise fixes not only X but each point in the cycles in $\mathcal{C}\cup\{C\}$, contradicting maximality of X. As $(p, m) = 1$, there are integers α, β such that $p\alpha + m\beta = 1$. Notice that $\phi^{m\beta}$ has order p, because $o(\phi) = pm$ and p does not divide $m\beta$. We claim that $\phi^{m\beta}$ is an order-p automorphism of G that contains $\mathcal{C} \cup \{C\}$ in its p-cycle set. To see this, let ρ_1 be the product of the p-cycles in $\mathcal{C} \cup \{C\}$. Then $\phi = \rho_1\rho_2$ for some permutation ρ_2 whose nontrivial cycles are disjoint from $\mathcal{C} \cup \{C\}$. We have $\phi^{m\beta} = \rho_1^{m\beta}\rho_2^{m\beta}$ as ρ_1 and ρ_2 commute. Since $o(\rho_1) = p$ we have $\rho_1^{m\beta} = \rho_1^{1-p\alpha} = \rho_1$. Thus, $\phi^{m\beta} = \rho_1\rho_2^{m\beta}$, implying that $\phi^{m\beta}$ is an order-p automorphism of G which contains $\mathcal{C} \cup \{C\}$ as p-cycles and also pointwise fixes X. This finishes the proof of Claim 1.

Proof of Claim 2. To prove Claim 2 it suffices to show that after every iteration of the while-loop a new p-cycle gets added to $\mathcal{C}$. Since X is a maximal fixed point set for the graph G preserving membership in mod$_p$-GA, notice that for $\psi \in Aut(G_{[X]})$ of order p, $\psi(x) \neq x\ \forall x \in V(G) - X$. That is, each vertex in $V(G) - X$ is in some p-cycle of ψ. Consider the beginning of some iteration of the while-loop such that $S \neq \bigcup_{D\in\mathcal{C}} D$. By Claim 1 there is an order-p automorphism ψ of $G_{[X]}$ containing each $D \in \mathcal{C}$ as a cycle. Let $C \subseteq S - \bigcup_{D\in\mathcal{C}} D$ be a p-cycle of ψ. Clearly, $\psi \in Iso(G'_{[C]}, G''_{[r(C)]})$, and hence $Cycle(G'_{[C]}, G''_{[r(C)]}, \ldots, G''_{[r(C)]}) \in$ mod$_p$-GA. Thus, there is at least one p-cycle C for which the "find" will succeed. So, a new p-cycle will get included in $\mathcal{C}$ at the end of this iteration. It follows that the while-loop iteration will terminate in $|V(G) - X|/p$ iterations. This completes the proof of Claim 2.

Finally, observe that $\mathcal{A}$ has polynomially bounded running time, since the while-loop iterates at most n/p times, and each "find" operation takes time $O(n^p)$ (implemented as an exhaustive search of all p-cycles contained in $S - \bigcup_{D\in\mathcal{C}} D$). □

For the general case we need two additional graph gadgets. The first of these, *Paste*, is built out of t n-vertex graphs, $G_1, \ldots, G_t$. The gadget $Paste(G_1, G_2, \ldots, G_t)$ has the property that any $\psi \in Aut(Paste(G_1, G_2, \ldots, G_t))$ induces on each G_j, $1 \leq j \leq t$ the same automorphism $\pi \in \bigcap_{j=1}^{t} Aut(G_j)$. In the next lemma we formally describe *Paste* and state relevant properties.

LEMMA 13. *Given t graphs $G_1, G_2, \ldots, G_t$, each with n nodes, we can construct in polynomial time a new graph $Paste(G_1, G_2, \ldots, G_t)$ with vertex set a disjoint union of $V(G_i)$, $1 \leq i \leq t$, such that the following properties hold.*

1. *ψ is an isomorphism from $Paste(G_1, G_2, \ldots, G_t)$ to $Paste(H_1, H_2, \ldots, H_t)$ if and only if there is a permutation $\pi \in \bigcap_{i=1}^{t} Iso(G_i, H_i)$ such that ψ restricted to G_i is π for $1 \leq i \leq t$. In fact, $\psi \leftrightarrow \pi$ is a bijective correspondence between $Iso(Paste(G_1, G_2, \ldots, G_t), Paste(H_1, H_2, \ldots, H_t))$ and $\bigcap_{i=1}^{t} Iso(G_i, H_i)$.*
2. *Given $\psi \in Iso(Paste(G_1, G_2, \ldots, G_t), Paste(H_1, H_2, \ldots, H_t))$, we can construct in polynomial time the corresponding $\pi \in \bigcap_{i=1}^{t} Iso(G_i, H_i)$.*
3. *Let p be a prime. $Paste(G_1, G_2, \ldots, G_t) \in$ mod$_p$-GA if and only if there is an order-p permutation $\pi \in \bigcap_{i=1}^{t} Aut(G_i)$.*

Proof. We define $Paste(G_1, G_2, \ldots, G_t)$ for t graphs $G_1, G_2, \ldots, G_t$, with n vertices each. It has one copy of each of the graphs $G_1, G_2, \ldots, G_t$. Furthermore, we label all the nodes of G_i using a distinct label c_i which depends only on the index i (see Figure 3 for an example). In particular, for two graphs $Paste(G_1, G_2, \ldots, G_t)$ and $Paste(H_1, H_2, \ldots, H_t)$, the nodes of both G_i and H_i get the same label c_i by construction for each i. This forces each isomorphism from $Paste(G_1, G_2, \ldots, G_t)$ to $Paste(H_1, H_2, \ldots, H_t)$ to map the copy of G_i to H_i for every i. Next, for each $i < t$ and $1 \leq j \leq n$, we put a directed edge from the jth node of G_i to the jth node of G_{i+1}. This ensures that for each isomorphism ψ from $Paste(G_1, G_2, \ldots, G_t)$ to $Paste(H_1, H_2, \ldots, H_t)$, if node j_1 in G_i is mapped to node j_2 in H_i, then for each $i' \neq i$, the corresponding node j_1 of G'_i gets mapped to the node j_2 of H'_i. It follows that there is a $\pi \in S_n$ such that for each i, ψ maps G_i to H_i via π. Thus, the construction guarantees the property claimed in part 1.

Notice that parts 2 and 3 of the lemma are both direct consequences of part 1 and the above gadget construction. This proves the lemma. □

We give some intuitive explanation before proceeding further. Recall that in the general case the input are $G \in$ mod$_{p^{i+1}}$-GA and A_i as a list of permutations, where A_i is a p^i-subgroup of $Aut(G)$. By Fact 10 we need to compute $g \in Aut(G) - A_i$ such that $o(g)$ divides p^{i+1} and $gA_ig^{-1} = A_i$. For this purpose, we will design the last

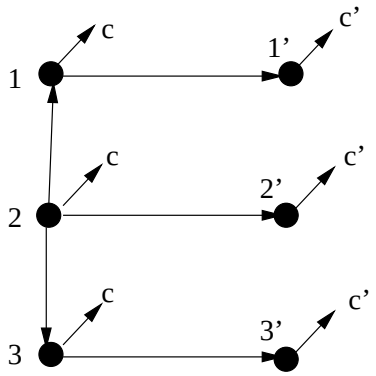

FIG. 3. *An example of Paste: The entire graph is Paste(G, G'), where G is induced by* 1, 2, *and* 3, *and G' is induced by* $1'$, $2'$, *and* $3'$. *Nodes of G and G' are labeled by c and c', respectively.*

of our graph gadgets *Combine* which is built from G and A_i using *Paste* and *Cycle*. Essentially, *Combine* has the property that allows us to easily extract the desired element g from an order-p automorphism of *Combine*. We explain the underlying ideas before giving the formal details. First, we transform the algebraic requirement $gA_ig^{-1} = A_i$ into the setting of GAs. For this we need a crucial definition and a lemma of Hoffman from [13].

DEFINITION 14 (see [13]). *Let $\pi \in S_n$ be a permutation. The* cycle graph *of π is the directed graph $G = ([n], E)$, where $(i, j) \in E$ if and only if $\pi(i) = j$ for $i \neq j$.*

LEMMA 15 (see [13]). *Let G and H be the cycle graphs of π and ψ in S_n, respectively. Then, Aut(G) is precisely the set of all permutations in S_n that commute with π. Furthermore, Iso(G, H) is precisely the set of permutations g such that $g\pi g^{-1} = \psi$.*

Let $A_i = \{g_1, g_2, \ldots, g_t\}$. Let G_i be the cycle graph of g_i for $1 \leq i \leq t$. Clearly, $gA_ig^{-1} = A_i$ if and only if $g \in \bigcap_{i=1}^{t} Iso(G_i, G_{\tau(i)})$ for some permutation τ of $[t]$. Let $H = Paste(G, G_1, G_2, \ldots, G_t)$ and $K = Paste(G, G_{\tau(1)}, G_{\tau(2)}, \ldots, G_{\tau(t)})$. The element g we are seeking is in $Iso(H, K)$ for some τ, with the additional properties that $g \notin A_i$ and $o(g)$ divides p^{i+1}. Since we must compute g with access to mod$_p$-GA as oracle (not GI), we will define *Combine* to be essentially $Cycle(H, K, \ldots, K)$ with $p - 1$ copies of K. Actually, we will incorporate in *Combine* more labels attached to H and the copies of K that allow us to identify cycles of g and also to ensure that the resulting element g is in $Aut(G) - A_i$. We now formally define *Combine* and establish some properties.

LEMMA 16. *Let G be a graph on n nodes and $S = \{g_1, g_2, \ldots, g_t\} \subseteq S_n$ be a set of permutations. Let $\mathcal{C} = \{C_1, C_2, \ldots, C_s\} \subseteq S_n$ be a set of pairwise disjoint cycles, p be a fixed prime, and τ be a permutation on $[t]$. Then we can compute in time polynomial in n, t, and s a graph Combine$(\tau, G, S, \mathcal{C}, p)$ such that Aut(Combine$(\tau, G, S, \mathcal{C}, p)$) is in bijective correspondence with*

$$A^p \cup Z_p^* \times A^{p-2} \times B^2,$$

where

1. *A is the set of automorphisms π of G such that $\pi(x) = x$ $\forall x \in \bigcup_{i=1}^{s} C_i$ and such that $\pi g_i \pi^{-1} = g_i$ for $1 \leq i \leq t$;*
2. *B is the set of all automorphisms π of G such that $C_1, C_2, \ldots, C_s$ are cycles of π and such that $\pi g_i \pi^{-1} = g_{\tau(i)}$ for $1 \leq i \leq t$.*

Furthermore, given a nontrivial $\psi \in Aut(Combine(\tau, G, S, \mathcal{C}, p))$, we can decide in polynomial time whether it has its representation in A^p, or in $Z_p^* \times A^{p-2} \times B^2$, and also compute its representation as an element of $A^p \cup Z_p^* \times A^{p-2} \times B^2$. If ψ has its representation in A^p, then we can compute in polynomial time a nontrivial element $\psi_G \in A$, and if ψ has its representation in $Z_p^* \times A^{p-2} \times B^2$, then we can compute in polynomial time a nontrivial element $\psi_G \in B$.

Proof. Let the composition $C_1 C_2 \cdots C_s$ of the cycles in $\mathcal{C}$ be $\psi \in S_n$. Let G' be the graph obtained from G by labeling each $x \in \bigcup_{i=1}^{s} C_i$ with a distinct label n_x. Similarly, let G'' be the graph obtained from G by labeling $\psi(x) \in \bigcup_{i=1}^{s} C_i$ with label n_x for each $x \in \bigcup_{i=1}^{s} C_i$.

Let $H = Paste(G', G_1, G_2, \ldots, G_t)$, where G_i is the cycle graph of g_i for $1 \le i \le t$. Similarly, let $K = Paste(G'', G_{\tau(1)}, G_{\tau(2)}, \ldots, G_{\tau(t)})$. Finally, we put one copy of H and $p-1$ copies of K together to build the graph $Cycle(H, K, \ldots, K)$. We define $Combine(\tau, G, S, \mathcal{C}, p)$ as $Cycle(H, K, \ldots, K)$. Clearly, $Combine(\tau, G, S, \mathcal{C}, p)$ can be computed in time polynomial in n, t, and s. See Figure 4 for an example graph.

Notice that by construction we have

$$Aut(G') = Aut(G'') = \left\{ \pi \in Aut(G) \mid \pi(x) = x \quad \forall x \in \bigcup_{i=1}^{s} C_i \right\}. \tag{2}$$

By Lemma 15 we have

$$Aut(G_i) = \{\pi \in S_n \mid \pi g_i \pi^{-1} = g_i\} \text{ for } 1 \le i \le t. \tag{3}$$

By construction we have

$$Iso(G', G'') = \{\pi \in Aut(G) \mid C_1, C_2, \ldots, C_s \text{ are cycles of } \pi\}. \tag{4}$$

Again, by Lemma 15 we have

$$Iso(G_i, G_{\tau(i)}) = \{\pi \in S_n \mid \pi g_i \pi^{-1} = g_{\tau(i)}\}. \tag{5}$$

By identities 2 and 3 and the definition of A we have

$$A = Aut(G') \cap \bigcap_{i=1}^{t} Aut(G_i) = Aut(G'') \cap \bigcap_{i=1}^{t} Aut(G_{\tau(i)}). \tag{6}$$

By identities 4 and 5 and the definition of B we have

$$B = Iso(G', G'') \cap \bigcap_{i=1}^{t} Iso(G_i, G_{\tau(i)}). \tag{7}$$

We now show that $Aut(Combine(\tau, G, S, \mathcal{C}, p))$ is in bijective correspondence with $A^p \cup Z_p^* \times A^{p-2} \times B^2$. By Lemma 11, $Aut(Combine(\tau, G, S, \mathcal{C}, p))$ can be represented as

$$Aut(H) \times (Aut(K))^{p-1} \cup Z_p^* \times (Aut(K))^{p-2} \times Iso(H, K) \times Iso(K, H).$$

First, consider $Aut(H) \times (Aut(K))^{p-1}$. By Lemma 13 and identity (6), $Aut(H)$ is in bijective correspondence with $Aut(G') \cap \bigcap_{i=1}^{t} Aut(G_i) = A$ and $Aut(K)$ is in

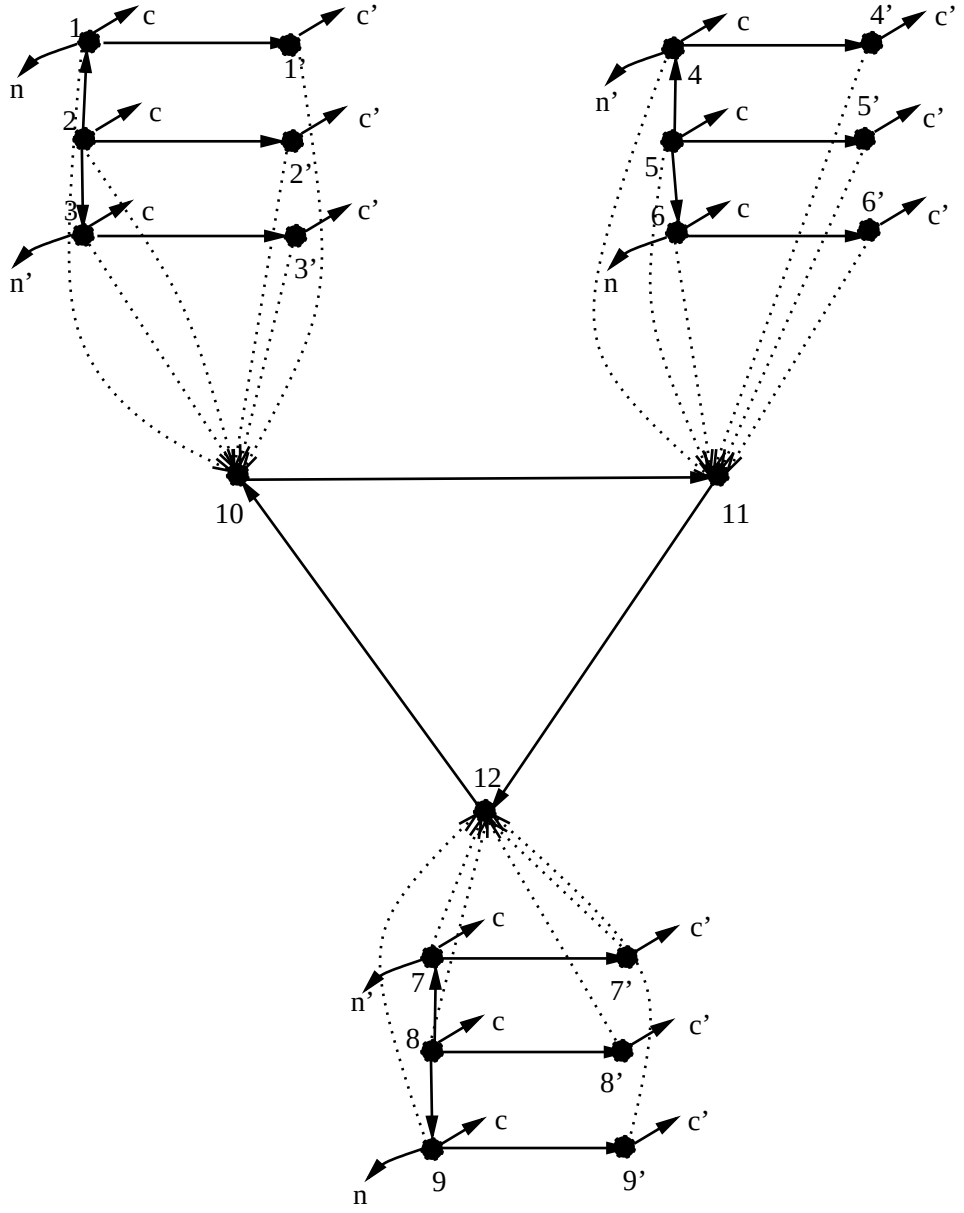

FIG. 4. *An example of Combine: The entire graph is Combine*$(\tau, G, S, \mathcal{C}, p)$*, where* $\tau = \mathrm{id}$*,* G *is the graph induced by nodes* 1*,* 2*, and* 3*,* $S = \{\mathrm{id}\}$*,* $\mathcal{C} = \{(1\ 3)\}$*, and* $p = 3$*. Notice that* G' *is the graph* G *with labels* n *and* n' *on nodes* 1 *and* 3*, respectively.* G'' *has labels* n' *and* n *on nodes* 1 *and* 3*, respectively. The graph induced by* $1'$*,* $2'$*, and* $3'$ *is the cycle graph* G_{id} *of* id*. The additional labels* c *and* c' *are for building* $H = Paste(G', G_{\mathrm{id}})$ *and* $K = Paste(G'', G_{\mathrm{id}})$*. Finally, the nodes* 10*,* 11*, and* 12 *induce the cycle underlying* $Cycle(H, K, K)$*. For clarity, some edges are shown with dashed lines.*

bijective correspondence with $Aut(G'') \cap \bigcap_{i=1}^{t} Aut(G_{\tau(i)}) = A$. Hence, $Aut(H) \times (Aut(K))^{p-1}$ is in bijective correspondence with A^p.

Next, consider $Z_p^* \times (Aut(K))^{p-2} \times Iso(H, K) \times Iso(K, H)$. Since $Aut(K)^{p-2}$ is in bijective correspondence with A^{p-2}, it suffices to show that $Iso(H, K) \times Iso(K, H)$

is in bijective correspondence with B^2. By Lemma 13, $Iso(H, K)$ is in bijective correspondence with $Iso(G', G'') \cap \bigcap_{i=1}^{t} Iso(G_i, G_{\tau(i)})$, which is B by identity (7). Since $Iso(K, H)$ is clearly in bijective correspondence with $Iso(H, K)$, it follows that $(Aut(K))^{p-2} \times Iso(H, K) \times Iso(K, H)$ is in bijective correspondence with $Z_p^* \times A^{p-2} \times B^2$.

Finally, by the properties of *Cycle* and *Paste* described in Lemmas 11 and 13, notice that given a nontrivial automorphism $\psi \in Aut(Combine(\tau, G, S, \mathcal{C}, p))$ we can decide in polynomial time whether its representation is in A^p or in $Z_p^* \times A^{p-2} \times B^2$. If the representation of ψ is in A^p, then, by Lemma 13, ψ induces a nontrivial automorphism on H or some copy of K. To be precise, we take the automorphism induced on H or the first such copy of K on which a nontrivial automorphism is induced. This automorphism of H or K yields a nontrivial automorphism $\psi_G \in A$ by identity (6) and the bijective correspondence of Lemma 13. Similarly, if ψ has its representation in $Z_p^* \times A^{p-2} \times B^2$, then, by Lemmas 11 and 13, ψ induces an isomorphism $\psi_G \in Iso(H, K) = B$. In either case, by Lemma 11, ψ_G is easily computable from ψ. □

COROLLARY 17. *$Combine(\tau, G, S, \mathcal{C}, p) \in \mathrm{mod}_p$-GA if and only if either A has an element of order p or B is not empty. Furthermore, given any order-p element $\psi \in Aut(Combine(\tau, G, S, \mathcal{C}, p))$, either $\psi_G \in A$ and ψ_G is of order p, or $\psi_G \in B$ (where A, B, and ψ_G are as defined in Lemma 16).*

Proof. Identity (1) in Lemma 11 and the bijective correspondence of Lemma 16 immediately yields

$$|Aut(Combine(\tau, G, S, \mathcal{C}, p))| = |A|^p(1 + (p-1)\chi[B \neq \emptyset]), \tag{8}$$

where $\chi[B \neq \emptyset]$ is 1 if $B \neq \emptyset$ and is 0 otherwise.

For the first part, by identity (8), notice that $Combine(\tau, G, S, \mathcal{C}, p) \in \mathrm{mod}_p$-GA if and only if p divides $|A|$ or B is not empty. Since A is a group, it has an element of order p if and only if p divides $|A|$ (by Sylow's theorem (Theorem 9)).

Next, by Lemma 16 $\psi_G \in A \cup B$. Notice that $\psi_G \in A$ precisely when ψ has its representation in A^p. In that case, ψ induces an order-p automorphism on H or some copy of K. Consequently, by identity (6) and the bijective correspondence of Lemma 13, ψ_G is an order-p element in A. □

We are ready to prove the main result of this section.

THEOREM 18. *For any prime p, there is a polynomial-time algorithm $\mathcal{B}$ with mod_p-GA as oracle such that, given a graph G and a p^i-subgroup A_i of $Aut(G)$ as input, if $G \notin \mathrm{mod}_{p^{i+1}}$-GA, then $\mathcal{B}$ rejects, and if $G \in \mathrm{mod}_{p^{i+1}}$-GA, then $\mathcal{B}$ lists out the elements of an order-p^{i+1} subgroup of $Aut(G)$.*

Proof. The case $i = 0$ is proven in Lemma 12. We first give a brief intuitive description of algorithm $\mathcal{B}$. Given G and A_i as input, the algorithm exhaustively—but in time polynomial in $|V(G)|$—searches for a permutation τ of A_i and a cycle collection $\mathcal{C}$ of constant size (specified in the algorithm) such that $Combine(\tau, G, A_i, \mathcal{C}, p) \in \mathrm{mod}_p$-GA. Now, using algorithm $\mathcal{A}$ of Lemma 12 it computes an order-p element $\nu \in Aut(Combine(\tau, G, A_i, \mathcal{C}, p))$. Next, applying Lemma 16, $\nu_G \in Aut(G)$ is extracted from ν. The element g (defined in Fact 10) is computed from ν_G, and A_{i+1} is computed from g and A_i using Fact 10. In order to ensure that g is the desired element defined in Fact 10, the cycle collection $\mathcal{C}$ is picked by the algorithm in such a way that it fulfills two properties: First, the points of $\bigcup_{D \in \mathcal{C}} D$ witness that $\nu_G \notin A_i$, as $\mathcal{C}$ is picked such that ν_G differs from each element of A_i at some point in $\bigcup_{D \in \mathcal{C}} D$; this ensures that $g \notin A_i$. Second, only cycles whose size is a power of p are picked, which guarantees that $o(g) = p^s$ for some $s > 0$.

input G and a p^i-subgroup A_i of $Aut(G)$;
$X := \{m \mid 1 \leq m \leq p^{i+1} \text{ and } (p,m) = 1\}$;
for each pairwise disjoint cycle collection
$\{\{C_s\}_{s=1}^t \mid t \leq 2p^{2i+1}, \prod_{s=1}^t C_s \neq \text{id}, \text{ and } (\prod_{s=1}^t C_s)^{p^{i+1}} = \text{id}\}$
and each sequence $\{l_{m,j} \in M_j\}_{1<j\leq p^i, m\in X}$
and each sequence $\{f_{m,j} \in F_j\}_{j\in J, m\in X}$
and each permutation τ of A_i

Compute A_{i+1} defined in Fact 10;
Output A_{i+1} and **stop**
endif
endfor
reject and **stop**.

FIG. 5. *Algorithm* $\mathcal{B}$.

We now present the details. Let $A_i = \{g_1, \ldots, g_{p^i}\}$, where without loss of generality, $g_1 = \text{id}$. For $1 \leq j \leq p^i$, let $F_j = \{x \in [n] : g_j(x) = x\}$ and $M_j = [n] - F_j$. That is, F_j is the set of fixpoints of $g_j \in A_i$ and M_j is the set of points that are not fixed by g_j. Let $J \subseteq [p^i]$ denote the set of indices j such that $F_j \neq \emptyset$. Notice that $J \neq \emptyset$ since $1 \in J$. The algorithm is described in Figure 5.

Correctness. In order to prove the correctness of algorithm $\mathcal{B}$, it suffices to establish the following claims.

CLAIM 1. *If* $G \in \text{mod}_{p^{i+1}}\text{-GA}$*, then for some choice of the "for" loop parameters, the four "if" conditions* (a), (b), (c), *and* (d) *will be true.*

CLAIM 2. *If the "if" conditions* (a), (b), (c), *and* (d) *are met by some choice of the for-loop parameters, then the set* A_{i+1} *that is output is a* p^{i+1}*-subgroup of* $Aut(G)$.

Proof of Claim 1. Suppose $G \in \text{mod}_{p^{i+1}}\text{-GA}$ and A_i is a p^i-subgroup of $Aut(G)$. By Fact 10, there is a $\pi \in Aut(G) - A_i$ such that $\pi A_i \pi^{-1} = A_i$ and $o(\pi) = p^s$. Fix such a π. If $(p,m) = 1$, then π^m and π both generate the same cyclic group. It follows that $\forall m \in X \;:\; \pi^m \notin A_i$. Thus, for each $m \in X$, we have sequences $\{l_{m,j} \in M_j\}_{1<j\leq p^i}$ and $\{f_{m,j} \in F_j\}_{j\in J}$ such that $\forall j$, the following holds:

$$\pi^m(l_{m,j}) \neq g_j(l_{m,j}) \text{ or } \pi^m(f_{m,j}) \neq g_j(f_{m,j}).$$

Writing π as a product of disjoint cycles we need at most $2p^i$ cycles of π to verify as above that $\pi^m \notin A_i$ for a given $m \in X$, since in the worst case we may need to pick a distinct cycle for each point $l_{m,j}$ or $f_{m,j}$. Furthermore, since $|X| \leq p^{i+1}$ we

need to pick at most $2p^{2i+1}$ cycles of π to verify that $(\forall m \in X)[\pi^m \notin A_i]$. For such a choice of cycles $\mathcal{C} = \{C_1, \ldots, C_t\}$ of π and sequences $\{l_{m,j}\}$ and $\{f_{m,j}\}$, conditions (a), (b), and (c) in the "if" statement are fulfilled.

Next, observe that since $\pi A_i \pi^{-1} = A_i$ there is a permutation τ of A_i such that $\pi g_j \pi^{-1} = g_{\tau(j)}$ for each $g_j \in A_i$. We claim that $\mathit{Combine}(\tau, G, A_i, \mathcal{C}, p) \in \mathrm{mod}_p\text{-GA}$. To see this, recall by Lemma 16 that $\mathit{Aut}(\mathit{Combine}(\tau, G, A_i, \mathcal{C}, p))$ has the representation $A^p \cup Z_p^* \times A^{p-2} \times B^2$. It is easy to verify that $\pi \in B$. Since $B \neq \emptyset$, by Corollary 17 we have $\mathit{Combine}(\tau, G, A_i, \mathcal{C}, p) \in \mathrm{mod}_p\text{-GA}$. Thus, condition (d) in the "if" statement is fulfilled by $\mathit{Combine}(\tau, G, A_i, \mathcal{C}, p)$. This completes proof of Claim 1.

Proof of Claim 2. Let ν be the order-p automorphism of $\mathit{Combine}(\tau, G, A_i, \mathcal{C}, p)$ computed by algorithm $\mathcal{A}$. Consider $\nu_G \in \mathit{Aut}(G)$, defined in Lemma 16. Let $o(\nu_G) = rp^s$, $(p, r) = 1$. Let $g = \nu_G^r$. Then $o(g) = p^s$.

By Lemma 16 and Corollary 17, either ν_G is an order-p element in A or $\nu_G \in B$. We show in each case that the algorithm outputs a p^{i+1}-subgroup A_{i+1} of $\mathit{Aut}(G)$.

- Suppose ν_G is an order-p element of A. In this case, $g = \nu_G$. Now, by definition of A, we have $\nu_G A_i \nu_G^{-1} = A_i$ and $\nu_G(x) = x \ \forall x \in \bigcup_{j=1}^t C_j$. Since $\{l_{1,j} \in M_j\}$ is contained in $\bigcup_{j=1}^t C_j$, we have $\nu_G(l_{1,j}) = l_{1,j} \ \forall j > 1$, which implies that $g = \nu_G \notin A_i$. Thus, by Fact 10, A_{i+1} is a p^{i+1}-subgroup of $\mathit{Aut}(G)$.
- Suppose $\nu_G \in B$. By Lemma 16, $\nu_G A_i \nu_G^{-1} = A_i$, and $C_1, \ldots, C_t$ are cycles of ν_G. The algorithm $\mathcal{B}$ picks $C_1, \ldots, C_t$ such that $\prod_{j=1}^t C_j \neq \mathrm{id}$ and $(\prod_{j=1}^t C_j)^{p^{i+1}} = \mathrm{id}$. Since $(\prod_{j=1}^t C_j)^{p^{i+1}} = \mathrm{id}$ and $(p, r) = 1$, we have $(\prod_{j=1}^t C_j)^r = (\prod_{j=1}^t C_j)^{m'}$ for some m' such that $1 \leq m' < p^{i+1}$ and $(p, m') = 1$. Therefore,

$$(9) \qquad \forall x \in \bigcup_{j=1}^t C_j \ : \ g(x) = \nu_G^r(x) = \left(\prod_{j=1}^t C_j\right)^r(x) = \left(\prod_{j=1}^t C_j\right)^{m'}(x).$$

  Since the "if" conditions (a), (b), and (c) are fulfilled, the sequences $\{l_{m',j} \in M_j\}$ and $\{f_{m',j} \in F_j\}$ are both contained in $\bigcup_{j=1}^t C_j$, and we also have

$$\left(\prod_{j=1}^t C_j\right)^{m'}(l_{m',j}) \neq g_j(l_{m',j}) \ \textbf{or} \ \left(\prod_{j=1}^t C_j\right)^{m'}(f_{m',j}) \neq g_j(f_{m',j}), \quad 1 \leq j \leq p^i.$$

  By identity (9) this is equivalent to

$$g(l_{m',j}) \neq g_j(l_{m',j}) \ \textbf{or} \ g(f_{m',j}) \neq g_j(f_{m',j}), \quad 1 \leq j \leq p^i.$$

  Hence, $g \notin A_i$. Finally, since $\nu_G A_i \nu_G^{-1} = A_i$, we have $g A_i g^{-1} = \nu_G^r A_i \nu_G^{-r} = A_i$. Putting it all together, it follows from Fact 10 that the output set A_{i+1} is a p^{i+1}-subgroup of $\mathit{Aut}(G)$.

This completes the proof of Claim 2.

Running time. Let $|V(G)| = n$, where G is the input graph. An easy analysis shows that the running time of algorithm $\mathcal{B}$ is polynomial in n (treating p and i as constants): Notice that each of the four nested for-loops has a polynomial (in n) range. The following computations involved are within for-loops: checks of the "if" conditions, calls to algorithm $\mathcal{A}$ of Lemma 12, invoking the procedure described in

Lemma 16, and computing powers of permutations. Each of these has polynomial running time. Hence, the overall algorithm has polynomial running time. □

Notice the following immediate consequence of Theorem 18 and Lemma 8. Interestingly, it is analogous to the well-known result that $\mathrm{Mod}_p\mathrm{P}$ and $\mathrm{Mod}_{p^k}\mathrm{P}$ are identical [5].

COROLLARY 19. *For any prime p and any $k > 0$, mod_p-GA and mod_{p^k}-GA are polynomial-time Turing equivalent.*

The main consequence of Theorem 18 is stated below. In the beginning of the section we argued how it follows easily from Theorem 18.

THEOREM 20. *Let $\prod_{1\le j\le m} p_j^{e_j}$ be the prime factorization of k. There is a polynomial-time oracle algorithm with oracle access to mod_k-GA that computes, for input $G \in \mathrm{mod}_k$-GA, a list of m subgroups $\{A_1, A_2, \ldots, A_m\}$ of $Aut(G)$, where each A_i is listed as a set of permutations and $|A_i| = p_i^{e_i}$.*

5. A program checker for mod_k-GA. As mentioned in the introduction, both GI and GA have polynomial-time program checkers. Since mod_k-GA sits between GA and GI with respect to many-one reducibility, it is natural to ask if mod_k-GA is also polynomial-time checkable. This does not follow from the results of GI and GA as polynomial-time checkability is known to be preserved only under polynomial-time Turing *equivalence* [7]. We show that mod_k-GA has a polynomial-time program checker for each $k > 1$.

DEFINITION 21 (see [7]). *A program checker C_A for a decision problem A is a probabilistic oracle algorithm that takes as input an instance x_0 of A and a positive integer k (the security parameter) given in unary such that, given any program P (purportedly for A) that halts on all instances, the following properties are satisfied:*

1. *If P is a correct program, that is, if $P(x) = A(x)$ for all instances x, then with probability $\ge 1 - 2^{-k}$, $C_A(x_0, P, k) =$ Correct.*
2. *If $P(x_0) \ne A(x_0)$, then with probability $\ge 1 - 2^{-k}$, $C_A(x_0, P, k) =$ Incorrect.*

The probability is computed over the internal coin-tosses of the checker C_A, and C_A is allowed to make oracle queries to the program P on some instances.

DEFINITION 22 (see [11]). *An interactive proof system consists of a prover-verifier pair $P \leftrightarrow V$. The verifier V is a probabilistic polynomial-time machine, and the prover P is, in general, a machine of unlimited computational power which shares the input tape and a communication tape with V. $P \leftrightarrow V$ is an interactive (i.e., IP) protocol for a language L if for every $x \in \Sigma^*$,*

$$x \in L \Rightarrow \mathrm{Prob}[P \text{ makes } V \text{ accept }] > 3/4,$$

$$x \notin L \Rightarrow \text{ for all provers } P' : \mathrm{Prob}[P' \text{ makes } V \text{ accept }] < 1/4.$$

The design of our checker for mod_k-GA is based on the following theorem.

THEOREM 23 (see [7]). *If a decision problem A and its complement have both interactive proof systems, in each of which the honest prover can be simulated in polynomial time with queries to A, then A has a polynomial-time program checker.*

We first consider mod_p-GA for prime p. Notice that Lemma 12 already gives an IP protocol for mod_p-GA with the prover polynomial-time Turing reducible to mod_p-GA. Thus, it suffices to design an IP protocol for $\overline{\mathrm{mod}_p\text{-GA}}$ with requisite properties.

LEMMA 24. *For any prime p, there is an IP protocol for $\overline{\mathrm{mod}_p\text{-GA}}$ in which the honest prover is polynomial-time Turing reducible to mod_p-GA.*

Proof. We will build the desired IP protocol from the above IP protocol for the

input (G, C);
$Y := [n] - \{i : i \in C\}$;
1. Verifier:
Pick $\psi \in S_Y$ and $b \in \{0, 1\}$, both uniformly at random;
if $b = 0$ **then send** $G' = \psi(G)$ to the Prover
else send $G' = \psi \circ C(G)$ to the Prover
endif
2. Prover:
if there is $\pi \in S_Y$ such that $\pi(G) = G'$ **then send** $c = 0$
else send $c = 1$
endif;
if $c = b$ **then** the Verifier **accepts**
else the Verifier **rejects**
endif

FIG. 6. 2-*round IP protocol for* L.

related language $L = \{(G, C) : |V(G)| = n,\ C \in S_n$ is a p-cycle and G has no automorphism with C as one of its cycles$\}$ (see Figure 6).

We first show that if the prover is honest, then the protocol accepts an input $(G, C) \in L$ with probability 1. Suppose $b = 0$ and the graph $\psi(G) = G'$ is sent to the prover. Then clearly the prover will find a permutation, namely, ψ, such that $\psi(G) = G'$ and send back $c = 0$, leading to the acceptance of the input. Next, suppose $b = 1$. In that case we claim that there does not exist any permutation $\pi \in S_Y$ such that $\pi(G) = G'$. Suppose there exists such a π. Then, since $\pi(G) = \psi \circ C(G)$, it follows that $(\pi)^{-1}\psi \circ C$ is in $Aut(G)$, which contradicts the assumption that $(G, C) \in L$. In this case the prover will send back $c = 1$ and the verifier will again accept.

Next, to prove that the protocol is sound, we must show that the verifier rejects an input $(G, C) \notin L$ with probability at least $3/4$ for any prover. In what follows we denote the set $\{i : i \in C\}$ by X and use Y to denote $[n] - X$.

CLAIM A. *If* $\tau \in Aut(G)$ *such that* τ *has* C *as a cycle, then the random graphs* $\psi(G)$ *and* $\psi \circ C(G)$ *are identically distributed, where* ψ *is picked uniformly at random from* S_Y.

Proof of Claim A. Let $\tau = \rho \circ C$, where $\rho \in S_Y$. Since S_Y is a group and $\rho \in S_Y$, if α is uniformly distributed in S_Y, then so is $\beta = \alpha \circ \rho$. Therefore, for any graph H

$$Prob_\alpha[\alpha(G) = H] = Prob_\alpha[\alpha\tau(G) = H]$$

and, replacing τ by $\rho \circ C$, we have

$$Prob_\alpha[\alpha\tau(G) = H] = Prob_\alpha[(\alpha \circ \rho) \circ C(G) = H] = Prob_\beta[\beta \circ C(G) = H],$$

where α and β are picked uniformly at random from S_Y. This completes the proof of Claim A.

It follows from Claim A that if $(G, C) \notin L$, the prover cannot distinguish between whether G' came from the case $b = 0$ or from $b = 1$. In fact, whether $b = 0$ or $b = 1$ the prover will find a $\pi \in S_Y$ such that $\pi(G) = G'$. Therefore, the bit c that is sent back by any (even a cheating) prover can agree with b with probability at most $1/2$. Consequently, the verifier will reject an input $(G, C) \notin L$ with probability at least $1/2$. The error probability can be made exponentially small (say, 2^{-n}) in the

input G; (* G has n nodes *)
for each p-cycle $C \in S_n$ **do**
    if the IP protocol for L rejects (G, C) **then reject** (and stop)
endfor;
accept

FIG. 7. *IP protocol for* $\overline{\text{mod}_p\text{-GA}}$.

above protocol by repeating the protocol[2] (in parallel or sequentially). In Figure 7 we describe the IP protocol for $\overline{\text{mod}_p\text{-GA}}$.

Notice that since p is constant, the total number of p-cycles in S_n is bounded by qn^p for a constant q. Thus the for-loop in the above protocol is bounded by a polynomial in n. It is easy to see that this IP protocol accepts $G \in \overline{\text{mod}_p\text{-GA}}$ with probability 1 and rejects $G \in \text{mod}_p\text{-GA}$ with probability larger than 3/4. The following claim completes the proof of the lemma.

CLAIM B. *There is an honest prover that is polynomial-time Turing reducible to* mod_p-GA *for the above IP protocol for* $\overline{\text{mod}_p\text{-GA}}$.

Proof of Claim B. It suffices to describe a polynomial-time algorithm with mod_p-GA as oracle that simulates the honest prover correctly for inputs $G \in \overline{\text{mod}_p\text{-GA}}$. Since the IP protocol for $\overline{\text{mod}_p\text{-GA}}$ invokes the protocol for L, it is enough to give a polynomial-time algorithm, with oracle mod_p-GA, that simulates the honest prover of the IP protocol for L for each input in the set $\{(G, C) : C \text{ is a } p\text{-cycle in } S_n\}$, where $G \in \overline{\text{mod}_p\text{-GA}}$. The honest prover's task in the protocol for L is to compute $\pi \in S_Y$ such that $\pi(G) = G'$, where $Y = [n] - C$. We have already argued in the correctness proof that for $G \in \overline{\text{mod}_p\text{-GA}}$ such a $\pi \in S_Y$ exists if and only if the outcome of b is 0 and $G' = \psi(G)$ for the random permutation $\psi \in S_Y$. Thus, we can assume that the honest prover is sent a graph G' by the verifier, where $G' = \psi(G)$ for some $\psi \in S_Y$ (ψ is not known to the prover). Since $Y \cap C = \emptyset$, it follows that $G_{[C]}$ and $G'_{[C]}$ are isomorphic (take the isomorphism that pointwise fixes C and is defined as ψ on Y). Thus, $|Aut(G_{[C]})| = |Aut(G'_{[C]})|$. Now, consider $G'' = Cycle(G_{[C]}, G'_{[C]}, \ldots, G'_{[C]})$ with $p-1$ copies of $G'_{[C]}$. By identity (1) in Lemma 11, we have

$$|Aut(G'')| = |Aut(G_{[C]})|^p \cdot (1 + (p-1)\chi[G_{[C]} \cong G'_{[C]}]).$$

It follows that $G'' \in \text{mod}_p\text{-GA}$ since $G_{[C]}$ and $G'_{[C]}$ are isomorphic.

The honest prover simply invokes algorithm $\mathcal{A}$ on input G'' (which is in mod_p-GA) and computes an order-p automorphism ν of G''.

Recall, by Lemma 11, that $Aut(G'')$ can be represented as

$$Aut(G_{[C]}) \times (Aut(G'_{[C]}))^{p-1} \cup Z_p^* \times (Aut(G'_{[C]}))^{p-2} \times Iso(G_{[C]}, G'_{[C]}) \times Iso(G'_{[C]}, G_{[C]}).$$

Since $G_{[C]} \notin \text{mod}_p\text{-GA}$ and $G'_{[C]} \notin \text{mod}_p\text{-GA}$, by Lemma 11 each order-p element $\nu \in Aut(G'')$ has its representation in $Z_p^* \times (Aut(G'_{[C]}))^{p-2} \times Iso(G_{[C]}, G'_{[C]}) \times Iso(G'_{[C]}, G_{[C]})$, and from ν an element $\pi' \in Iso(G_{[C]}, G'_{[C]})$ can be computed in polynomial time. Clearly, π' when projected on Y yields a $\pi \in S_Y$ such that $\pi(G) = G'$. The honest prover computes π as described and sends it back to the verifier.

As claimed, we have shown that there is an honest prover of the IP protocol for L that is polynomial-time Turing reducible to mod_p-GA. □

[2]With some modifications we can easily get constant round IP protocols.

THEOREM 25. *For any prime p,* mod_p-GA *has a polynomial-time program checker.*

Proof. Note that, from Lemma 12, we get an IP protocol for mod_p-GA with the prover polynomial-time Turing reducible to mod_p-GA and that, by Lemma 24, an IP protocol with requisite properties exists for $\overline{\mathrm{mod}_p\text{-GA}}$. Now, by Theorem 23 it follows that there is an efficient checker for mod_k-GA. □

THEOREM 26. *For each $k > 1$,* mod_k-GA *has a polynomial-time program checker.*

Proof. Let $\prod_{1 \le i \le m} p_i^{e_i}$ be the prime factorization of k. Because the class of checkable sets is closed under join and under Turing equivalence [7], by Theorem 25 it suffices to show that $\mathrm{mod}_k\text{-GA} \equiv_T^p \mathrm{mod}_{p_1}\text{-GA} \oplus \cdots \oplus \mathrm{mod}_{p_m}\text{-GA}$. Observe that a graph G belongs to mod_k-GA if and only if $(\forall i \le m)[G \in \mathrm{mod}_{p_i^{e_i}}\text{-GA}]$. Since, by Corollary 19, $\mathrm{mod}_{p_i^{e_i}}\text{-GA} \equiv_T^p \mathrm{mod}_{p_i}\text{-GA}$ for each i, we have $\mathrm{mod}_k\text{-GA} \le_T^p \mathrm{mod}_{p_1}\text{-GA} \oplus \cdots \oplus \mathrm{mod}_{p_m}\text{-GA}$. Recall from Lemma 8 that $\mathrm{mod}_{p_i}\text{-GA} \le_m^p \mathrm{mod}_k\text{-GA}$ for each i. Therefore, $\mathrm{mod}_{p_1}\text{-GA} \oplus \cdots \oplus \mathrm{mod}_{p_m}\text{-GA} \le_T^p \mathrm{mod}_k\text{-GA}$ as well. □

6. Concluding remarks. We define the modular GA problems (mod_k-GA) and locate them between GA and GI. We also design an efficient program checker for mod_k-GA based on an algorithm that reduces search to decision for mod_k-GA and an IP protocol for $\overline{\mathrm{mod}_k\text{-GA}}$. The bottleneck in making our checker nonadaptive is essentially the following: Can search be reduced to decision via parallel queries for mod_p-GA for prime p? Indeed, our initial motivation in studying the mod_k-GA problems was to understand the difference between GI and GA by introducing problems of intermediate difficulty. In this context, a challenging problem is whether search reduces to decision via parallel queries for GI (hence yielding nonadaptive checkers for GI). We believe that this question will be easier to answer for mod_p-GA.

Acknowledgments. We are grateful to the referees for their thoughtful comments. In particular, we are indebted to a referee for pointing out a flaw in an earlier proof of Theorem 18. His insightful suggestions, especially the use of identity (1), have helped us considerably to improve the readability of section 4.

APPROXIMATING SHORTEST PATHS ON A NONCONVEX POLYHEDRON*

KASTURI R. VARADARAJAN† AND PANKAJ K. AGARWAL‡

Abstract. We present an approximation algorithm that, given the boundary P of a simple, nonconvex polyhedron in $\mathbb{R}^3$ and two points s and t on P, constructs a path on P between s and t whose length is at most $7(1+\varepsilon)d_P(s,t)$, where $d_P(s,t)$ is the length of the shortest path between s and t on P, and $\varepsilon > 0$ is an arbitrarily small positive constant. The algorithm runs in $O(n^{5/3}\log^{5/3} n)$ time, where n is the number of vertices in P. We also present a slightly faster algorithm that runs in $O(n^{8/5}\log^{8/5} n)$ time and returns a path whose length is at most $15(1+\varepsilon)d_P(s,t)$.

1. Introduction. Problem statement. Let P be the boundary (surface) of a simple, possibly nonconvex polyhedron in $\mathbb{R}^3$ with n vertices, and let s and t be two points on P. (A polyhedron is *simple* if it is homeomorphic to a ball in $\mathbb{R}^3$.) Let $\pi_P(s,t)$ denote any shortest path between s and t on P, and $d_P(s,t)$ denote its length. Let us call a path between s and t on P λ-*approximate*, for $\lambda \geq 1$, if its length is at most $\lambda d_P(s,t)$. In this paper, we consider the problem of computing an *approximate shortest path* on P from s to t. See Figure 1.

Computing a shortest path on a polyhedral surface is a central problem in numerous areas, including robotics, geographic information systems, medical imaging, low-altitude flight simulation, and water flow analysis. In most of these applications, a simple, efficient algorithm for computing an approximate shortest path is preferable to an expensive algorithm that computes an exact shortest path, since the input surfaces are rather large, efficiency is critical, and the polyhedral surface is typically an approximation of the real surface.

Previous results. Motivated by these applications, many researchers have studied the problem of computing a shortest path on a polyhedral surface [2, 3, 6, 10, 11, 12, 13, 17, 22, 25, 27]. Sharir and Schorr [27] gave an $O(n^3 \log n)$ algorithm for computing a shortest path on the boundary of a convex polyhedron, exploiting the property that a shortest path "unfolds" into a straight line. Mitchell, Mount, and Papadimitriou [22] improved the running time to $O(n^2 \log n)$; their algorithm works for nonconvex polyhedra as well. Chen and Han [6] gave another algorithm with an improved running time of $O(n^2)$. Although several heuristics have been proposed (see [2, 10, 11, 13, 17, 25], for example), it is a long-standing and intriguing open problem whether a subquadratic algorithm can be developed even for computing an

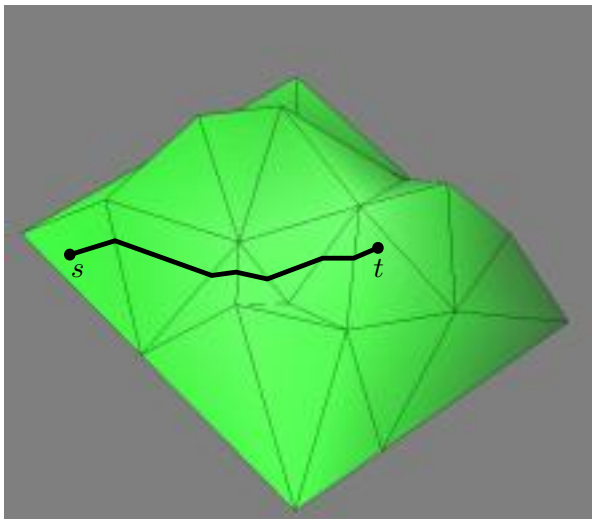

FIG. 1. *A path on a polyhedral surface.*

approximate shortest path. Hershberger and Suri [16] presented a simple algorithm that computes a 2-approximate path on a *convex* polyhedron in $O(n)$ time. Agarwal et al. [1] presented an algorithm that computes a $(1+\varepsilon)$-approximate path on a convex polyhedron in $O(n \log 1/\varepsilon + 1/\varepsilon^3)$ time for any given $\varepsilon > 0$. However, both these algorithms heavily exploit the convexity of the polyhedron and do not extend to nonconvex polyhedra.

For the three-dimensional Euclidean shortest path problem—where we are given a set of polyhedral obstacles and we want to compute the shortest collision-free path between two given points—there are some approximation algorithms due to Papadimitrou [24], Clarkson [8], and Choi, Sellen, and Yap [7]. All these algorithms compute a $(1+\varepsilon)$-approximate path, but their running times are superquadratic in n. Recently, Lanthier, Maheshwari, and Sack [19] and Mata and Mitchell [21] had considered the problem of computing the *weighted* shortest path problem on polyhedral surfaces. In this problem, each face of the given polyhedral surface has a weight associated with it, and the cost of traversing a face is the distance traveled on the face times the weight of the face. In this scenario, they give approximation algorithms for computing a minimum-cost path between two given points on the polyhedral surface. Their algorithms compute a $(1+\varepsilon)$-approximate path for the unweighted case in superquadratic time.

Our results. In this paper, we present an algorithm that runs in $O(n^{5/3} \log^{5/3} n)$ time and computes a $7(1+\varepsilon)$-approximate path on P from s to t. (Throughout the rest of this paper, we will assume that $\varepsilon > 0$ is an arbitrarily small, positive number.) We also present a second algorithm that computes in $O(n^{8/5} \log^{8/5} n)$ time a $15(1+\varepsilon)$-approximate path between s and t on P. Although our approach falls short of giving a simple, near-linear-time algorithm for this problem, it is an important step because the problem of computing an approximate shortest path in subquadratic time has been open for quite some time.

The basic idea of our algorithm is rather simple: we choose a parameter r and partition P into $O(n/r)$ "patches," each consisting of at most r faces. For each patch R_i, we carefully choose a set of points on the "boundary edges" of R_i and construct

a graph G_i that approximates a shortest path between any two points lying on the boundary edges of R_i. We merge these graphs G_i into a single graph G; s and t are guaranteed to be vertices of G. We then compute a shortest path from s to t in G using Dijkstra's algorithm and prove that the length of this path is at most $7(1+\varepsilon)d_P(s,t)$. There are two nontrivial steps in the algorithm: how to choose points on the boundary edges and how to construct the graphs G_i's. Using a scheme based on the planar separator theorem [20] to partition P into patches, we ensure that there are only $O(\sqrt{r})$ boundary edges per patch, which allows us to put only a small number of points on the boundary of each patch R_i. In order to compute the graph G_i efficiently, we need the idea of computing shortest paths on R_i from *edge sources*.

The paper is organized as follows. In section 2, we give basic definitions and properties related to shortest paths, and in section 3, we describe how to partition P into patches. Section 4 describes the overall algorithm. Sections 5 and 6 describe how to choose points on the edges of each patch and how to construct the graphs G_i's, respectively. Section 7 describes how the algorithm of Mitchell, Mount, and Papadimitriou [22] can be generalized to compute shortest paths from edge sources; the generalized algorithm is used in the construction of the G_i's. Although this is a rather technical extension of the algorithm of Mitchell, Mount, and Papadimitriou [22], we include it for completeness. We conclude in section 8 by mentioning some exciting recent developments.

2. Geometric preliminaries. We assume that the polyhedral surface P is specified by a set of faces, edges, and vertices that form a simplicial complex, with each edge occurring in exactly two faces, and two faces intersecting either at a common edge, vertex, or not at all. We consider faces to be closed polygons and edges to be closed line segments. Without loss of generality, we assume that all faces are triangles (otherwise, we can use any polygon triangulation algorithm to triangulate the faces, thus introducing at most $O(n)$ additional edges), and that s and t are vertices of P. Since P is the boundary of a polyhedron, we will sometimes refer to a path on P as a path on the polyhedron. If π is a path on P, we let $|\pi|$ denote its length. For any two points $a, b \in \pi$, let $\pi[a,b]$ denote the portion of π between a and b. For any two points u, v in P, let $\pi_P(u,v)$ denote the shortest path on P between u and v. We refer to $d_P(u,v) = |\pi_P(u,v)|$ as the *shortest path distance* on P between u and v. We denote by $d(p,q)$ the Euclidean distance between points p and q in $\mathbb{R}^3$.

We review some relevant properties of shortest paths on polyhedral surfaces. A detailed analysis can be found in [22, 27].

Unfolding. Two faces f and f' of P are said to be *edge-adjacent* if they share a common edge. A *sequence of edge-adjacent faces* is a list of one or more faces $\mathcal{F} = (f_1, f_2, \ldots, f_{k+1})$ such that the face f_i is edge-adjacent to the face f_{i+1} for $1 \le i \le k$. Let e_i be the edge shared by the faces f_i and f_{i+1}. We then refer to the (possibly empty) list of edges $\mathcal{E} = (e_1, e_2, \ldots, e_k)$ as an *edge sequence*. If no face (resp., edge) appears more than once in $\mathcal{F}$ (resp., $\mathcal{E}$), then we call the sequence *simple*.

We associate with each face a two-dimensional coordinate system. If faces f and f' are edge-adjacent sharing an edge e, we define the *planar unfolding of f' onto f* as the image of points of f' when f' is rotated about the line through e until f and f' become coplanar and lie on *opposite* sides of e; see Figure 2. Points in the planar unfolding of f' onto f are represented in the coordinate system of f. We *unfold an edge sequence* $\mathcal{E}$ as follows: Rotate f_{k+1} around e_k until its plane coincides with f_k, rotate f_{k+1} (already unfolded around e_k) and f_k around e_{k-1} until their plane

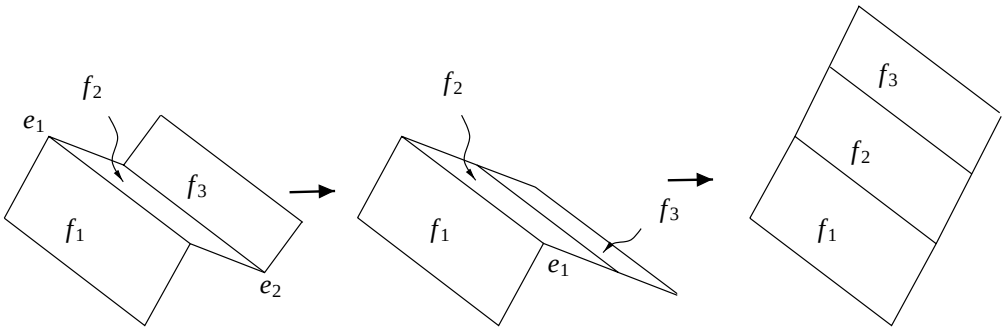

FIG. 2. *Unfolding an edge sequence.*

coincides with that of f_{k-2}, and continue in this manner until all faces $f_2, \ldots, f_{k+1}$ lie in the plane of f_1. If x is a point on face f_i, then the *unfolded image of x along $\mathcal{E}$* (written in the coordinate system of face f_1) is the image of x when we unfold the edge sequence $\mathcal{E}$.

Let v_i be a point that lies in the interior of edge e_i for $1 \leq i \leq k$. Let v (resp., v') be a point on face f_1 (resp., f_{k+1}) so that one of the following three conditions hold. (There are nine possibilities allowed here, three each for v and v'.)

(i) v (resp., v') is the vertex of f_1 (resp., f_{k+1}) that is opposite edge e_1 (resp., e_k).
(ii) v (resp., v') lies in the interior of f_1 (resp., f_{k+1}).
(iii) v (resp., v') coincides with v_1 (resp., v_k).

Then we say that the path π given by the concatenation of the segments $vv_1, v_1v_2, \ldots, v_{k-1}v_k, v_kv'$ *connects the edge sequence* $\mathcal{E}$. If π connects edge sequence $\mathcal{E}$, then the *planar unfolding of π along $\mathcal{E}$* is simply the unfolded image of π along $\mathcal{E}$.

Shortest paths. A *geodesic* is a path that is locally optimal; that is, it cannot be shortened by slight perturbations. A shortest path is obviously a geodesic. We now state a few relevant properties of geodesics and shortest paths.

LEMMA 2.1. *The intersection of a shortest path with a face is a (possibly empty) line segment. If π is a geodesic path that connects (two points along) the edge sequence $\mathcal{E}$, then the planar unfolding of π along $\mathcal{E}$ is a straight line segment.*

Unlike the case of convex polyhedra, where a geodesic cannot pass through a vertex of the polyhedron, a geodesic on the boundary of a nonconvex polyhedron can pass through a vertex. The subpath of a geodesic π between any two vertices v and v' of P that are consecutive on π connects some edge sequence $\mathcal{E}$. (If $\mathcal{E} = \emptyset$, then v and v' are the endpoints of some edge e which is contained in π.) By Lemma 2.1, the subpath from v to v' is completely determined by giving the edge sequence $\mathcal{E}$. Thus, we have the following characterization of geodesics and shortest paths.

LEMMA 2.2. *We can describe a geodesic path π from s to t by writing it as a list*

$$\Phi(\pi) = (v_1 = s, \mathcal{E}_1, v_2, \mathcal{E}_2, v_3, \ldots, v_k, \mathcal{E}_k, v_{k+1} = t),$$

where $v_1, \ldots, v_k$ are the vertices (in order) through which π passes, and each $\mathcal{E}_i$ is the (possibly empty) edge sequence which $\pi[v_i, v_{i+1}]$ connects. The planar unfolding of $\pi[v_i, v_{i+1}]$ along $\mathcal{E}_i$ is a straight line segment. If π is a shortest path, no edge of P appears in more than one edge sequence $\mathcal{E}_i$, and each edge sequence $\mathcal{E}_i$ is simple.

3. Partitioning the polyhedral surface. We can associate with the polyhedral surface P a graph G_P, the dual graph of the 1-skeleton of P, defined as follows. (We use "nodes" and "arcs" in the context of graphs and use "vertices" and "edges" when speaking of polyhedral features.) For each face f of P, there is a node n_f in G_P. There is an arc between two nodes n_f and $n_{f'}$ in G_P if the corresponding faces f and f' share an edge. Since P is a simple polyhedron, its 1-skeleton is a planar graph; therefore, G_P is also planar. Since each face of P is a triangle, the degree of each node of G_P is 3.

Our algorithm exploits a scheme that was developed by Frederickson [14] for partitioning any planar graph $G = (V, E)$. Let $(V_1, V_2, \ldots, V_k)$ be a cover of the node set V, that is, $V_i \subseteq V$ and $\bigcup_i V_i = V$. We refer to each V_i as a *region*. A node in V is *interior* to a region if all its adjacent nodes are in that region; a *shared* node is one that is present in at least two regions. For a given parameter r, an *r-partition* of G is a covering of the node set V by $\Theta(|V|/r)$ regions, so that the following two conditions hold (see Figure 3).

(i) Any node is either a shared node or an interior node of some region; and

(ii) each region contains at most r nodes and $O(\sqrt{r})$ shared nodes.

Based on the separator theorem of Lipton and Tarjan [20], Frederickson [14] showed that r-partitions exist and can be constructed in $O(|V| \log |V|)$ time.

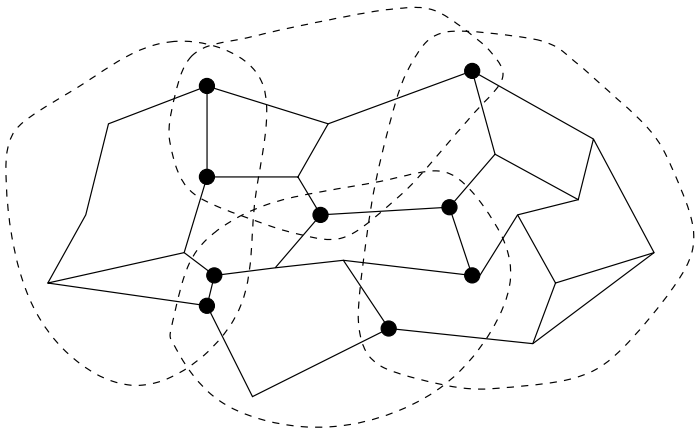

FIG. 3. *An r-partition of a planar graph. The shared nodes are highlighted.*

An r-partition of G_P induces a subdivision of the polyhedral surface P, which we describe below. A *polyhedral patch* of P (or simply, a patch of P) is just the portion of P comprised of a subset of the faces of P. Given an r-partition of G_P, we designate any face that corresponds to a shared node of G_P as a *buffer face*. For each region V_i, we associate a polyhedral patch P_i consisting of the faces corresponding to the interior nodes of V_i. (That is, each shared node defines one buffer face, and each region defines one polyhedral patch.) Thus, an r-partition of G_P induces a partition P into $O(n/\sqrt{r})$ buffer faces and $O(n/r)$ polyhedral patches, with each patch containing at most r faces. Abusing terminology slightly, we refer to this partition of P as an *r-partition* of P. An r-partition of P can be computed in $O(n \log n)$ time.

An edge of P incident to a buffer face is called a *frontier* edge. It is easily seen that an r-partition satisfies the following properties:

1. If a face f in a patch shares an edge e with another face f', then either f' belongs to the same patch as f, or f' is a buffer face. In the latter case, e is

a frontier edge.

2. Each patch has only $O(\sqrt{r})$ frontier edges.

Note that the frontier edges of a polyhedral patch constitute its boundary, so we can also refer to them as the *boundary* edges of the patch. The total number of frontier edges is at most $cn/\sqrt{r}$ for some constant $c > 0$. Let $\alpha = cn/\sqrt{r}$. The following lemma describes the main application of the above partitioning scheme, but first we need a definition.

DEFINITION 3.1. *An ε-portal set on an edge e of P is a collection $\phi(e)$ of points (or portals) on e so that the following holds: For any point x on e that lies on the shortest path $\pi_P(s,t)$, there exists $p \in \phi(e)$ whose distance from x is at most $(\varepsilon/2\alpha) \times d_P(s,t)$. For simplicity, we assume that $\phi(e)$ includes the endpoints of edge e. Given an r-partition of P and an ε-portal set on each frontier edge of the r-partition, a path is legal if it lies completely within a single patch (resp., buffer face), and each of its two endpoints is either s, t, or a portal on a frontier edge of the patch (resp., buffer face).*

LEMMA 3.2. *Given an r-partition of the polyhedron P and an ε-portal set on each frontier edge of the r-partition, there is a path π^* on P between s and t such that (1) its length is at most $(1+\varepsilon)d_P(s,t)$, and (2) it is a concatenation of legal paths.*

Proof. Let $\pi = (v_1 = s, \mathcal{E}_1, v_2, \mathcal{E}_2, v_3, \ldots, v_k, \mathcal{E}_k, v_{k+1} = t)$ represent the shortest path between s and t, where $v_1, \ldots, v_k$ are the vertices (in order) through which π passes, and each $\mathcal{E}_i$ is the (possibly empty) edge sequence which $\pi[v_i, v_{i+1}]$ connects. Let e be a frontier edge that occurs in some edge sequence $\mathcal{E}_i$ above. Let x be the (unique) point on e that lies on π, and let p be the portal on e so that $d_P(x,p) = d(x,p) \le \varepsilon/2 \times d_P(s,t)/\alpha$. We alter π slightly by introducing a loop from x to p and back. This increases the length of the path by at most $\varepsilon d_P(s,t)/\alpha$. If we perform this surgery on every frontier edge that occurs in some edge sequence, we get a path π^* whose length is at most $(1+\varepsilon)d_P(s,t)$. It is clear that π^* is a concatenation of legal paths, since s and t are assumed to be vertices of P. ∎

4. The overall algorithm. In this section, we present our algorithm for computing a path between s and t on P whose length is at most $7(1+\varepsilon)d_P(s,t)$. For the sake of clarity, we first present an algorithm that approximates the shortest path distance, i.e., it returns a quantity that is at least $d_P(s,t)$ and at most $7(1+\varepsilon)d_P(s,t)$. Subsequently, we modify this algorithm to compute an approximate shortest path.

4.1. Approximating the shortest path distance. In order to describe the algorithm, we need to define a β-approximator, which is similar to the well-studied notion of a spanner (see [5, 26]) with Steiner points.

DEFINITION 4.1. *Let R be a polyhedral patch and S a set of points on R. A β-approximator for S on R is a weighted graph $G = (S \cup S', E)$, where S' is a set of additional points on R, that has the following properties.*

(P1) *The weight $w(u,v)$ of any arc $(u,v) \in E$ is $d_R(u,v)$, the length of the shortest path between u and v on R.*

(P2) *For any $u, v \in S$, the length of the shortest path in G between u and v, denoted $d_G(u,v)$, is at most $\beta d_R(u,v)$.*

ALGORITHM. APPROXIMATE-DISTANCE.

1. We compute an r-partition of P, where $r = n^{1/3}\log^{1/3} n$. Let $R_1, \ldots, R_{k_1}$ denote the resulting buffer faces, $R_{k_1+1}, \ldots, R_{k_1+k_2}$ denote the resulting patches, and B denote the set of resulting frontier edges. Here, $k_1 = O(n/\sqrt{r})$, $k_2 = O(n/r)$, and $|B| \le \alpha = O(n/\sqrt{r})$. Recall that the boundary of each

buffer face consists of three frontier edges, and the boundary of each patch R_i consists of at most $O(\sqrt{r})$ frontier edges.

2. On each frontier edge $e \in B$, we compute an $\varepsilon/2$-portal set.
3. Let V denote the set of vertices of P, and let M denote the set of all the portals introduced in step 2. For each $i \leq k_1 + k_2$, let $V_i = V \cap R_i$ be the set of vertices in R_i, and let $M_i = M \cap R_i$ be the set of portals on the frontier edges of R_i. Set $|M_i| = m_i$ and $\beta = 7(1+\varepsilon/3)$. We compute a β-approximator $G_i = (M_i \cup M_i', E_i)$ for M_i on R_i, where M_i' is a set of additional Steiner points on R_i.
4. We compute the graph $G = (N, E)$, where $N = \bigcup_i (M_i \cup M_i')$ and $E = \bigcup_i E_i$. Using Dijkstra's algorithm [9], we compute the shortest path $\pi_G(s,t)$ between s and t in G, and return its length $d_G(s,t)$ as our estimate of $d_P(s,t)$.

A critical component of the algorithm is the procedure for computing the β-approximators in step 3, which we describe in section 6. The procedure for computing the portal sets in step 2, which we outline in section 5, is comparitively straightforward.

THEOREM 4.2. (i) $d_P(s,t) \leq d_G(s,t) \leq 7(1+\varepsilon)d_G(s,t)$. (ii) *The algorithm runs in* $O(n^{5/3}\log^{5/3} n)$ *time.*

Proof. Assuming the correctness of the various subprocedures, it follows from Lemma 3.2 that the algorithm returns an estimate $d_G(s,t)$ such that $d_P(s,t) \leq d_G(s,t) \leq 7(1+\varepsilon)d_P(s,t)$, provided ε is chosen sufficiently small.

We now analyze the running time of the algorithm. In step 1 of the algorithm, we can compute an r-partition in $O(n \log n)$ time. The number of frontier edges in the r-partition is $\alpha = O(n/\sqrt{r})$.

Using the algorithm described in the next section (see Lemma 5.2), we can compute an $\varepsilon/2$-portal set of size $O((n/\sqrt{r})\log n)$ on a frontier edge in $O((n/\sqrt{r})\log n)$ time. Summing up over all frontier edges, step 2 takes $O((n^2/r)\log n)$ time. Moreover, $M = O((n^2/r)\log n)$.

To analyze step 3, we consider the buffer faces and patches separately. For each buffer face R_i, $1 \leq i \leq k_1$, we compute a β-approximator G_i using any algorithm for computing spanners in the plane. Using Clarkson's algorithm [8], for instance, we obtain a graph $G_i = (M_i, E_i)$ (without Steiner points), with $|E_i| = O(m_i/\beta)$, in $O(m_i \log m_i)$ time. A buffer face R_i has at most three frontier edges incident on it, so $m_i = O((n/\sqrt{r})\log n)$. Hence, the running time for computing G_i using Clarkson's algorithm is $O((n/\sqrt{r})\log^2 n)$. The time taken in step 3 over all buffer faces is thus $O((n^2/r)\log^2 n)$.

For a patch R_i, $k_1+1 \leq i \leq k_1+k_2$, we use the algorithm described in section 6.1 to construct a $7(1+\varepsilon)$-approximator for M_i on R_i. The algorithm introduces a set M_i' of at most $O(m_i)$ Steiner points and constructs a graph $G_i = (M_i \cup M_i', E_i)$ with $O(r^2 + m_i)$ arcs. Furthermore, the algorithm takes $O(r^3 \log r + m_i \log r + m_i \log m_i)$ time to construct G_i. Since the boundary of R_i consists of $O(\sqrt{r})$ frontier edges and each edge has $O((n/\sqrt{r})\log n)$ portals, $m_i = O(n \log n)$. The running time for computing G_i is then $O(r^3 \log r + n \log^2 n)$, and the running time for step 3 summed over all patches is $O(nr^2 \log r + (n^2/r)\log^2 n)$.

To compute the time taken in step 4, we first estimate the size of the graph G. Each buffer face contributes $O(n/\sqrt{r})$ nodes and arcs to G, so the contribution to G from all buffer faces is $O(n^2/r)$ nodes and arcs. Each patch contributes $O(r + n\log n)$ nodes and $O(r^2 + n \log n)$ arcs, so the overall contribution to G from all patches is $O((n^2/r)\log n)$ nodes and $O(nr + (n^2/r)\log n)$ arcs. Running Dijkstra's algorithm on

G takes $O(nr + (n^2/r)\log^2 n)$ time [9].

Summing up, the overall running time of the algorithm is $O(nr^2 \log r + (n^2/r)\log^2 n)$. Substituting $r = n^{1/3}\log^{1/3} n$, the running time of the algorithm is $O(n^{5/3}\log^{5/3} n)$. □

The running time of the above algorithm is constrained by the procedure used in step 3 for computing the β-approximators. By using the slightly faster procedure that is described in section 6.3 for computing 15-approximators and choosing $r = n^{2/5}\log^{2/5} n$ in step 1, we obtain the following result.

THEOREM 4.3. *Given the boundary P of a simple, possibly nonconvex polyhedron in $\mathbb{R}^3$ with n vertices, and two points $s, t \in P$, we can compute in $O(n^{8/5}\log^{8/5} n)$ time a quantity between $d_P(s,t)$ and $15(1+\varepsilon)d_P(s,t)$.*

4.2. Computing an approximate shortest path. We now describe the modifications to the algorithm presented above that will allow us to compute an approximate shortest path from s to t. Let G_i be the β-approximator, computed in step 3, for M_i on R_i. We want to be able to answer the following *path query* for an arc in G_i: given $(p, p') \in E_i$, compute a path on R_i between p and p' whose length is at most the weight of (p, p'). If R_i is a buffer face, we can answer such a query by simply taking the line segment joining p and p'. For a patch R_i, we augment G_i with a data structure that can answer a path query in $O(r)$ time. It will be evident in section 6 that such a data structure can be computed within the time bound for computing G_i.

Let π_G be the shortest path in G that is computed by step 4 of the algorithm. We can compute a path π in P between s and t by simply doing a path query for each arc traversed by π_G and concatenating the resulting paths. But this is expensive if π_G traverses too many arcs of G. However, as described below, we really need to do path queries for only a few arcs in π_G. For a face f of P, if p_1 and p_2 are the first and last nodes in f that appear in π_G, we can bypass the arcs in π_G between p_1 and p_2 by including in π the line segment joining p_1 and p_2. If we perform this step for every face, we will be left with only $O(n)$ arcs of π_G for which we have to perform path queries; performing these takes a total of $O(nr)$ time. Thus we get the main result of this paper.

THEOREM 4.4. *Given the boundary P of a simple, possibly nonconvex polyhedron with n vertices, and points $s, t \in P$, we can compute in $O(n^{5/3}\log^{5/3} n)$ (resp., $O(n^{8/5}\log^{8/5} n)$) time a path on P between s and t whose length is at most $7(1+\varepsilon)d_P(s,t)$ (resp., $15(1+\varepsilon)d_P(s,t)$).*

5. Computing portal sets. In this section, we present an algorithm that, given an edge e of P and $\varepsilon > 0$, computes an ε-portal set $\phi(e)$ on e. We first describe a scheme for computing a rough estimate ρ^* of the shortest path distance $d_P(s,t)$ such that

$$\rho^* \le d_P(s,t) \le O(n)\rho^*.$$

The estimate ρ^* will be useful in constructing portal sets. Let $C(s,\omega)$ be the axis-parallel cube with edge-length 2ω centered at s, and let $P(\omega)$ be the portion of P lying within $C(s,\omega)$, i.e., $P(\omega) = P \cap C(s,\omega)$. Note that $P = P(\infty)$. For a face f of P, let $f(\omega) = f \cap C(s,\omega)$. Since f is a triangle, $f(\omega)$ is convex. This implies that $P(\omega)$ consists of $O(n)$ faces. Let ρ^* be the smallest value of ω for which s and t are connected by a path lying completely in $P(\omega)$.

LEMMA 5.1. (i) *$\rho^* \le d_P(s,t) \le c_1 n\rho^*$ for some constant c_1, and* (ii) *ρ^* can be computed in $O(n\log n)$ time.*

Proof. (i) We claim that any shortest path $\pi_P(s,t)$ must intersect the boundary of $C(s,\rho^*)$. Suppose, on the contrary, that the claim is false. Then there exists a $\rho' < \rho^*$ such that $\pi_P(s,t)$ lies completely within $C(s,\rho')$. Thus, $\pi_P(s,t)$ connects s and t in $P(\rho')$, contradicting the fact that ρ^* is the smallest value of ω for which s and t are path-connected within $P(\omega)$. Since $\pi_P(s,t)$ intersects the boundary of $C(s,\rho^*)$, we have $d_P(s,t) = |\pi_P(s,t)| \geq \rho^*$.

To establish the second inequality, consider the shortest path π' between s and t in $P(\rho^*)$. Since $P(\rho^*)$ consists of at most $O(n)$ faces and π' intersects each of these faces in a single (possibly empty) line segment, π' can be specified as a concatenation of at most $O(n)$ such line segments. Each such line segment lies completely within $C(s,\rho^*)$ and so has length at most $2\sqrt{3}\rho^*$. It follows that $|\pi'| \leq c_1 n\rho^*$ for some constant c_1. Since π' is also a path on P, $d_P(s,t) \leq |\pi'| \leq c_1 n\rho^*$.

(ii) For any ω, $P(\omega)$ is a disjoint union of path-connected components. For each face f of P, $f(\omega)$ is contained in at most one such component. For a path-connected component Ψ of $P(\omega)$, let F_Ψ be the collection f of faces of F such that $f(\omega) \neq \emptyset$ and $f(\omega)$ is a face of Ψ. Note that $\Psi = \bigcup_{f \in F_\Psi} f(\omega)$. Observe that the sets F_Ψ partition the set of faces of P that have a nonempty intersection with $C(s,\omega)$.

Let f^s (resp., f^t) be a face of P containing s (resp., t). Then ρ^* is the smallest value of ω for which (i) $s,t \in C(s,\omega)$, and (ii) $f^s(\omega)$ and $f^t(\omega)$ belong to the same path-connected component of $P(\omega)$. Thus, computing ρ^* reduces essentially to finding the smallest ω when (ii) occurs. We sketch below an algorithm to do this.

Our algorithm represents each connected component Ψ of $P(\omega)$ implicitly by the set F_Ψ. As ω increases from zero, our representation changes. Two sets F_{Ψ_i} and F_{Ψ_j} may get merged. A new face f may be added to one of the already existing sets F_Ψ. A set consisting of just a single new face f may be created if $f(\omega)$ forms a single path-connected component in $P(\omega)$. Clearly, such changes in our representation occur only when some vertex, edge, or face of P first intersects $C(s,\omega)$. Hence, there are only $O(n)$ critical values of ω at which our representation needs to be updated.

We first compute and sort (in increasing order) these critical values of ω. Starting from $\omega = 0$, we go through them in order, updating our representation of the path-connected components of $P(\omega)$ appropriately. We stop and report the value of ω when f^s and f^t are in the same set in our representation. If we use any data structure for disjoint sets [9] to represent the path-connected components, the entire procedure can be implemented in $O(n \log n)$ time. □

Using Lemma 5.1, we can show the following.

LEMMA 5.2. *Let B be the set of frontier edges in an r-partition of P, where $|B| \leq \alpha$. Given any edge $e \in B$, we can compute an ε-portal set $\phi(e)$ of size $O((\alpha/\varepsilon)\log n)$ in time $O((\alpha/\varepsilon)\log n)$.*

Proof. We use the estimate ρ^* to compute $\phi(e)$ as follows. For $1 \leq i \leq \lceil \log c_1 n \rceil$, where c_1 is the constant defined in Lemma 5.1, we add a set S_i of $O(\alpha/\varepsilon)$ portals so that they subdivide $e \cap C(s,\rho^* 2^i)$ into equal-sized intervals, each of length $(\varepsilon/2\alpha)\rho^* 2^i$.

Clearly, this procedure adds a total of $O((\alpha/\varepsilon)\lg n)$ portals. To see that $\phi(e)$ constructed above is an ε-portal set, let x be any point on $\pi_P(s,t) \cap e$. Since $d_P(s,t) \leq c_1 n\rho^*$, $x \in C(s,\rho^* 2^i)$ for some $1 \leq i \leq \lceil \log c_1 n \rceil$. Let i_x be the smallest such i. If $i_x = 1$, then there is a portal $p \in S_1$ so that

$$d(p,x) \leq (\varepsilon/2\alpha)\rho^* \leq (\varepsilon/2\alpha) d_P(s,t).$$

If $i_x > 1$, then x does not lie in $C(s,\rho^* 2^{i_x - 1})$, so $d(s,x) \geq \rho^* 2^{i_x - 1}$. There is a portal

$p \in S_{i_x}$ so that

$$d(p,x) \le (\varepsilon/2\alpha)2^{i_x-1}\rho^* \le (\varepsilon/2\alpha)d(s,x) \le (\varepsilon/2\alpha)d_P(s,t).$$

Hence there is always a portal p on e such that $d(p,x) \le (\varepsilon/2\alpha)d_P(s,t)$, as required. □

6. Approximating legal paths. Let R be a polyhedral patch with r (triangular) faces, V the set of its vertices, and B the set of its boundary edges. We assume that $|B| = O(\sqrt{r})$. Let M be a set of m points (portals) lying on the edges in B. In this section, we describe algorithms for computing a β-approximator (introduced in Definition 4.1) on R for M, the set of portals on R. That is, we construct a weighted graph $G = (M \cup M', E)$, where M' is a set of additional points on R, that has the following properties:

1. The weight $w(u,v)$ of any arc $(u,v) \in E$ is $d_R(u,v)$, the length of the shortest path between u and v on R.
2. For any $u, v \in V^B \cup M$, the length of the shortest path in G between u and v, denoted $d_G(u,v)$, is at most $\beta d_R(u,v)$.

The key to computing an approximator is the notion of shortest paths from edge sources, which we introduce below. In order to present the main ideas clearly, we first describe an algorithm for computing a 13-approximator for $V^B \cup M$ on R. We then show how this algorithm can be modified so that it returns a $7(1+\varepsilon)$-approximator. Finally, we present a faster algorithm for computing a 15-approximator.

Mount [23] showed that the single-source shortest path algorithm of Mitchell, Mount, and Papadimitriou [22] can be generalized to obtain the following result.

LEMMA 6.1. *Given a polyhedral patch R and a subset $U \subseteq V$ of "vertex sites," we can preprocess it in $O(r^2 \log r)$ time, where r is the number of faces in R, so that given a query point x lying on any edge e of R, we can compute the vertex $u \in U$ that is closest to x, and the distance $d_R(q,x)$ in $O(\log r)$ time. We can also compute in $O(r)$ time a shortest path between q and x.*

Let Q be the region of the patch R given by a union of a subset of vertices of R ("vertex sites") and a subset of boundary edges of R ("edge sites"). We will regard Q as a set of points (which is infinite if there is an edge site). We define the distance $d_R(Q,x)$ of a point $x \in R$ from Q to be the minimum $\min_{q \in Q} d_R(q,x)$. In section 7, we show that we can preprocess the patch R in $O(r^2 \log r)$ time so that we can quickly compute the shortest distance between Q and a query point lying on the edge of the patch. This result, stated in Lemma 7.4, is obtained by fairly straightforward modifications to the algorithms of Mitchell, Mount, and Papadimitriou [22] and Mount [23]. (Note that Lemma 6.1 is a special case of Lemma 7.4 where there are no edge sites.) As we shall see below, allowing edge sites is a useful idea in constructing β-approximators.

6.1. Computing a 13-approximator. We now present our algorithm for computing a 13-approximator $G = (M \cup M', E)$ for the portals M on the polyhedral patch R.

ALGORITHM. 13-APPROXIMATOR.

1. For each pair $u, v \in V$ of vertices in the path R, we compute the shortest path distance $d_R(u,v)$ on R between u and v and introduce an arc $(u,v) \in E$ whose weight is $d_R(u,v)$. We can easily compute these distances in $O(r^3 \log r)$ time by invoking the algorithm of Mitchell, Mount, and Papadimitriou [22] for each vertex of R.

2. We run the preprocessing algorithm of Lemma 6.1 with $U = V$. For each $p \in M$, we find the vertex $v \in V$ that is closest to p. We compute the distance $d_R(v, p)$ and introduce an arc (p, v) in G with weight $d_R(v, p)$.
3. We repeat the following for every boundary edge $e \in B$: We let Q be the set of points on R consisting of the union of all the vertices V and all the boundary edges except edge e and run the preprocessing algorithm of Lemma 7.4. For each $p \in M$ that lies in e, we find the $q \in Q$ that is closest to p. We introduce in G a new node q, and an arc (p, q) with weight $d_R(p, q)$.
4. Let M' be the set of points that are introduced as nodes in G in the above steps. For each edge $e \in B$, we sort the points $(M \cup M') \cap e$ along e and add an arc (p, p') of weight $d(p, p')$ if p and p' are consecutive in the sorted order.

LEMMA 6.2. *The algorithm constructs in $O(r^3 \log r + m \log r + m \log m)$ time a graph with $O(r + m)$ nodes and $O(r^2 + m)$ arcs.*

Proof. Step 1 of the algorithm requires $O(r^3 \log r)$ time. In this step, we introduce $O(r^2)$ arcs. In step 2, the preprocessing algorithm of Lemma 6.1 takes $O(r^2 \log r)$ time. The computation involving a single $p \in M$ takes $O(\log r)$ time, so the overall computation for every $p \in M$ takes $O(m \log r)$ time. Running the preprocessing algorithm of Lemma 7.4 once takes $O(r^2 \log r)$ time. Since we run this algorithm $O(\sqrt{r})$ times in step 3, once for each boundary edge, we spend $O(r^{5/2} \log r)$ time. We can perform the computation for each $p \in M$ in a total of $O(m \log r)$ time. We introduce at most m new nodes and arcs in this step. After these steps, we have a total of $O(r + m)$ nodes in G. So we can implement step 4 in $O(r + m \log m)$ time. We introduce only $O(r + m)$ arcs in this step.

Summing up, we spent $O(r^3 \log r + m \log m + m \log r)$ time and constructed a graph G with $O(r + m)$ nodes and $O(r^2 + m)$ arcs. □

The following lemma plays a crucial role in proving that the above algorithm computes a 13-approximator.

LEMMA 6.3. *Let e be a boundary edge of the patch R, and let Q be the set of points of R consisting of all the vertices of R and all the boundary edges of R except e. Let $e' \in B$ be a boundary edge of R distinct from e, and let $x \in e$ and $y \in e'$. Let $\pi(x, y)$ be a shortest path, of length l, between x and y. If $d_R(x, v) > 3l$ for every vertex $v \in V$, then the closest point q in Q to x lies on edge e', and $d_R(Q, x) \leq l$.*

Figure 4 illustrates the situation in Lemma 6.3. We first establish a preliminary claim before proving Lemma 6.3. We refer to any path that originates from x and that has length at most l as a *short* path. Since $d_R(x, v) > 3l$ for every $v \in V$, no short path passes through a vertex. It follows that every short, geodesic path connects some edge sequence beginning with the edge e. Let $\mathcal{E} = e\mathcal{E}_0 e'$ be the edge sequence that $\pi(x, y)$ connects (e and e' are, respectively, the first and last edges of $\mathcal{E}$).

CLAIM 6.4. *The edge sequence connected by any short, geodesic path is a prefix of $\mathcal{E}$.*

Proof. Suppose, on the contrary, that the claim is false. That is, there is a short, geodesic path π' that connects $\mathcal{E}' e_1 e_3$, whereas the edge sequence connected by $\pi(x, y)$ is $\mathcal{E} = \mathcal{E}' e_1 e_2 \mathcal{E}''$.

Since both paths unfold into straight lines, the edges e_1, e_2, and e_3 must be incident on the same (triangular) face, say, f. Let v_i be the vertex of f opposite e_i. Let $a_1 \in \pi(x, y) \cap e_1$, $a_2 \in \pi(x, y) \cap e_2$, and $a_3 \in \pi' \cap e_3$. Then

$$d(a_i, a_j) \leq d_R(a_i, x) + d_R(x, a_j) \leq 2l.$$

In triangle f, suppose that the angle at vertex v_1 is at least as large as the angles at v_2 and v_3. (The other cases are treated identically.) Using the fact that the angle

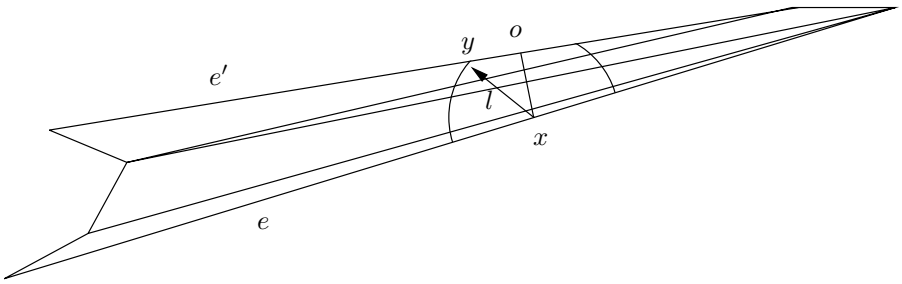

FIG. 4. *Illustration of Lemma* 6.3.

at v_1 is at least $\pi/3$,

$$\min\{d(v_1, a_2), d(v_1, a_3)\} \leq d(a_2, a_3) \leq 2l.$$

It follows from the triangle inequality that $d_R(x, v_1) \leq 3l$. This contradicts the assumption that $d_R(x, v) > 3l$ for every $v \in V$. □

We can now prove Lemma 6.3.

Proof of Lemma 6.3. Since $\pi(x, y)$ is a shortest path, the edge sequence $\mathcal{E} = e\mathcal{E}_0 e'$ is simple. Since $\pi(x, y)$ is geodesic, it unfolds into a straight line, and so there can be no boundary edge in $\mathcal{E}_0$. As a consequence of the claim, e' is the only edge site in Q that can be reached by a short, geodesic path. We have already established that no short path can reach a vertex site. Thus, the closest point to x in Q lies in edge e', and $d_R(e', x) \leq l$. □

LEMMA 6.5. *The graph G constructed by the algorithm is a* 13*-approximator for $V^B \cup M$ on the polyhedral patch R.*

Proof. Clearly, $d_G(p, p') = d_R(p, p')$ for any two vertices $p, p' \in V$ (step 1) or for any two points $p, p' \in (M \cup M')$ lying on the same boundary edge $e \in B$ (step 4).

Let π be the shortest path on R between $p, p' \in V^B \cup M$, and let $|\pi| = l$. We will show that $d_G(p, p') \leq 13l$. Let $w, w' \in V$ be the vertices in R that are closest (along R) to p and p', respectively. We consider two cases.

Case 1. $\max\{d_R(p, w), d_R(p', w')\} \leq 3l$. In step 2 of the algorithm, we introduce an arc (p, w) with weight $d_R(p, w)$ in G, so $d_G(p, w) = d_R(p, w) \leq 3l$. Similarly, $d_G(p', w') = d_R(p', w') \leq 3l$. Now,

$$d_R(w, w') \leq d_R(w, p) + d_R(p, p') + d_R(p', w') \leq 7l.$$

Since $w, w' \in V$, $d_G(w, w')$ is also at most $7l$. Finally, we have

$$d_G(p, p') \leq d_G(p, w) + d_G(w, w') + d_G(w', p') \leq 13l.$$

Case 2. $\max\{d_R(p, w), d_R(p', w')\} > 3l$. Assume, without loss of generality, that $d_R(p, w) > 3l$. In this case, neither p nor p' is a vertex. Let e (resp., e') be the boundary edge containing p (resp., p') in its interior. If e and e' are the same edge, the lemma follows because $d_G(p, p') = d_R(p, p')$.

Let us assume that e and e' are distinct. Let Q be the region consisting of all the vertices and boundary edges of the patch except edge e. Then, by Lemma 6.3, the closest point $q \in Q$ to p lies on edge e', and $d_R(q,p) \leq l$. When we processed p in step 3 of the algorithm, we had to introduce point $q \in e'$ as a node of G, and we also had to add an arc (q,p) with weight $d_R(q,p)$. Thus, $d_G(q,p) = d_R(q,p) \leq l$. By the triangle inequality, $d_R(q,p') \leq d_R(q,p) + d_R(p,p') \leq 2l$.

Since q and p' both lie on e', $d_G(q,p') \leq 2l$. Finally, we have $d_G(p,p') \leq d_G(p,q) + d_G(q,p') \leq 3l$. □

6.2. Computing a $7(1+\varepsilon)$-approximator. Using a scheme based on recent work of Har-Peled [15] for computing approximate shortest path maps on a polyhedron, we modify algorithm 13-APPROXIMATOR, as described below, so that it returns a $7(1+\varepsilon)$-approximator (for any $\varepsilon > 0$) for M on the polyhedral patch R. For a given source point v on R and an edge e, Har-Peled's algorithm computes a set $W(v,e)$ of $O((1/\varepsilon)\log 1/\varepsilon)$ points on e so that for any $q \in e$, there is a $p \in W(v,e)$ with

$$d_R(v,p) + d(p,q) \leq (1+\varepsilon) d_R(v,q).$$

The modification involves replacing steps 1 and 2 of algorithm 13-APPROXIMATOR by the following procedure, which is repeated for each $v \in V$. We compute the sets $W(v,e)$ for each edge $e \in B$; using Har-Peled's algorithm, we can do this in $O(r^2 \log r)$ time. We add each point $p \in \bigcup_{e \in B} W(v,e)$ to the node set M' of G and also include an arc (v,p) in G with weight $d_R(v,p)$. We can compute all the distances $d_R(v,p)$ in $O(r^2 \log r)$ time using the algorithm of Mitchell, Mount, and Papadimitriou [22].

It is easy to see that the running time of the new algorithm is the same as that of algorithm 13-APPROXIMATOR. To show that the graph G it computes is a $7(1+\varepsilon)$-approximator, we analyze Case 1 of Lemma 6.5 as follows. In this case, there is a vertex w of R such that $d_R(p,w) \leq 3l$. The path on R obtained by concatenating the shortest paths from p to w, w to p, and p to p' has length at most $7l$. The modifications ensure that there is a path in G between p and p' that uses w and whose length is at most $7(1+\varepsilon)l$.

6.3. Computing a 15-approximator. We now present a slightly different algorithm that computes a 15-approximator $G = (M \cup M', E)$ for M on the patch R. This algorithm, which we call 15-APPROXIMATOR, runs in $O(r^{5/2} \log r + m \log r + r \log r)$ time. Algorithm 15-APPROXIMATOR is identical to 13-APPROXIMATOR, except that we replace step 1 by the following procedure. From each $e \in B$, we let Q consist of just the edge site e and run the $O(r^2 \log r)$-time preprocessing algorithm of Lemma 7.4. For each vertex $v \in V$, let $o \in e$ be the closest point in e to v. We introduce o as a new node in G and add an arc (o,v) with weight $d_R(o,v)$. We can show the following lemma.

LEMMA 6.6. *We can compute, in time $O(r^{5/2} \log r + m \log m + m \log r)$, a 15-approximator for M on the polyhedral patch R.*

Proof. The analysis of the algorithm's running time is quite straightforward. We argue that it returns a 15-approximator. Let π be the shortest path on R between $p, p' \in V^B \cup M$ and let $|\pi| = l$. We modify the analysis of Case 1 of Lemma 6.5 as follows to show that $d_G(p,p') \leq 15l$; the analysis of Case 2 is unchanged.

In Case 1, $d_R(p,w) \leq 3l$. In step 2 of the algorithm, we introduce an arc (p,w) with weight $d_R(p,w)$ in G, so $d_G(p,w) = d_R(p,w) \leq 3l$.

Now $d_R(p',w) \leq d_R(p',p) + d_R(p,w) \leq 4l$. Let $e \in B$ be the boundary edge containing p' and let $o \in e$ be the closest point in e to w. Clearly, $d_R(w,o) \leq d_R(w,p')$. Also from the triangle inequality, $d_R(o,p') \leq d_R(o,w) + d_R(w,p') \leq 2d_R(w,p')$.

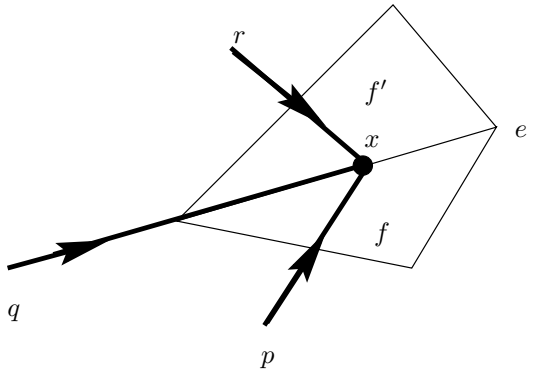

FIG. 5. *Three geodesic paths to x on edge e: p is monotone with respect to (e, f) but not with respect to (e, f'); q is monotone with respect to both (e, f) and (e, f'); r is monotone with respect to (e, f') but not with respect to (e, f).*

The new algorithm introduces in step 1 an arc (w, o) with weight $d_R(w, o)$ in G, so $d_G(w, o) = d_R(w, o)$. Since p' and o are on the same edge, $d_G(o, p') = d_R(o, p')$. Thus

$$d_G(w, p') \le d_G(w, o) + d_G(o, p') = d_R(w, o) + d_R(o, p') \le 3d_R(w, p') \le 12l.$$

Finally, $d_G(p, p') \le d_G(p, w) + d_G(w, p') \le 15l$. □

7. Shortest path computation. Let R be a polyhedral patch with r triangular faces, and let V, E, and B denote, respectively, the set of vertices, edges, and boundary edges of the patch. Let $F \subseteq E$ be a collection of boundary edges and $U \subseteq V$ be a collection of vertices. Let Q denote the portion of the patch consisting of the edges in F and the vertices in U. Since the edges in E include their endpoints, Q is a closed set. For any point x on the patch, the closest point to x in Q is any $y \in Q$ such that $d_R(y, x) = \min_{q \in Q} d_R(q, x)$. In this section, we describe a variant of the algorithms of Mount [23] and Mitchell, Mount, and Papadimitriou [22] that preprocesses R in $O(r^2 \log r)$ time into a data structure so that for any query point x lying on a boundary edge, the closest point q in Q to x and the distance $d_R(q, x)$ can be computed in $O(\log r)$ time. If desired, the shortest path between q and x can also be returned in an additional $O(r)$ time.

Given a face f, and e, one of the three edges incident to it, we refer to (e, f) as an *edge-face pair*. Every nonboundary edge is part of two edge-face pairs, while every boundary edge is part of one edge-face pair. With respect to an edge-face pair (e, f), a path π to $x \in e$ from any $q \in Q$ is *monotone* if the following hold.

1. Any subpath π' of π that does not pass through a vertex unfolds into a straight line. This means that we can represent π as a list

$$\Phi(\pi) = (v_1 = q, \mathcal{E}_1, v_2, \mathcal{E}_2, v_3, \ldots, v_k, \mathcal{E}_k, v_{k+1} = x),$$

   where $v_2, \ldots, v_k$ are the vertices (in order) through which π passes, and each $\mathcal{E}_i$ is the (possibly empty) edge sequence which $\pi[v_i, v_{i+1}]$ connects.
2. The path π reaches x through face f. This means that if x lies in the interior of edge e, the path π lies in face f just before it reaches x. (See Figure 5.)

The second condition is assumed to hold trivially if x is one of the endpoints of e. If e is a nonboundary edge incident also to face f' and x lies in the interior of e,

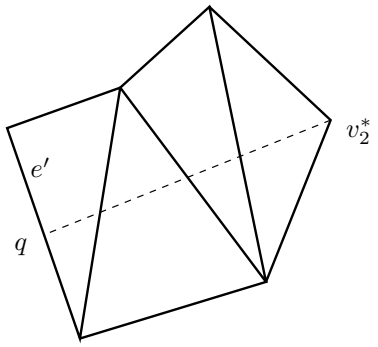

FIG. 6. *In Proposition* 7.1*, the segment* qv_2^* *is perpendicular to* e'.

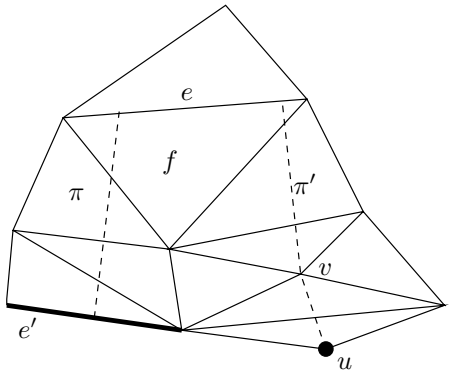

FIG. 7. *The anchor of* π *is the boundary edge-site* e'*; the anchor of* π' *is the vertex* v.

the second condition says that the path π reaches x through f and not through f'. The *shortest monotone path* from Q to a point $x \in e$ (with respect to (e, f)) is the smallest-length monotone path (with respect to (e, f)) from any $q \in Q$ to x. It is easy to see that the shortest path from Q to x is monotone with respect to either (e, f) or (e, f'). If e is a boundary edge that is not part of Q, a shortest path to x is the same as a shortest monotone path to x with respect to (e, f).

Let $\Phi(\pi) = (v_1 = q, \mathcal{E}_1, v_2, \ldots, v_k, \mathcal{E}_k, v_{k+1} = x)$ denote any monotone path π with respect to the edge-face pair (e, f) from $q \in Q$ to $x \in e$. Suppose q lies in the interior of a boundary edge $e' \in F$. Let v_2^* denote the unfolded image of v_2 when the edge sequence $\mathcal{E}_1$ is unfolded; note that the segment qv_2^* is the unfolded image of the subpath $\pi[q, v_2]$. The following proposition states a local optimality criterion for π to be a shortest monotone path. (See Figure 6.)

PROPOSITION 7.1. *Let* q*,* e'*, and* v_2^* *be the same as above. If* π *is the shortest montone path (with respect to* (e, f)*) from* Q *to* x *, then the segment* qv_2^* *is perpendicular to the edge* e'.

In the list $\Phi(\pi)$, if v_k is a vertex, we call it the *anchor* of π and $\mathcal{E}_k$ the *last edge sequence*. If v_k is not a vertex, the list is of the form $(q, \mathcal{E}, x)$, where q is a point lying in the interior of a boundary site e'. In this case, we call the edge e' the anchor of π and $\mathcal{E}$ the last edge sequence of π. See Figure 7. We now state some important properties of monotone paths.

The following lemma is analogous to Lemma 4.4 of Mitchell, Mount, and

Papadimitriou [22].

LEMMA 7.2. *For edge-face pair (e, f), edge sequence $\mathcal{E}$, and anchor r, the set I of points x on e for which there is a shortest monotone path from Q with r as the anchor and $\mathcal{E}$ as the last edge sequence is connected (and, therefore, a subsegment of e).*

We refer to I as the *interval of optimality* for r and $\mathcal{E}$ with respect to (e, f). Let $\overline{r}$ denote the unfolded image of r when $\mathcal{E}$ is unfolded onto the plane containing f. For any $x \in I$, let $\pi(x)$ denote the shortest monotone path to x (which has anchor r and last edge sequence $\mathcal{E}$). We define the *distance of x to r along $\mathcal{E}$* to be the Euclidean distance of x to $\overline{r}$. Note that this distance is the same as the length of the subpath of $\pi(x)$ from r to x. The following lemma can be proved using techniques similar to Lemmas 4.5 and 7.1 of Mitchell, Mount, and Papadimitriou [22] and Lemma 3.2 of Mount [23].

LEMMA 7.3. *Intervals of optimality with respect to edge-face pair (e, f) cover the edge e and have mutually disjoint interiors. Moreover, there are only $O(r)$ such intervals.*

7.1. The algorithm. We now describe an algorithm that computes the intervals of optimality with respect to each edge-face pair (e, f) of the polyhedral patch. If I is an interval of optimality with anchor r and last edge sequence $\mathcal{E}$, the algorithm also computes $\overline{r}$, the unfolded image of r when $\mathcal{E}$ is unfolded onto the plane containing f.

The algorithm maintains the following information. We keep a list of *candidate* intervals of optimality on each edge-face pair. A candidate interval (or interval for short) is a segment on an edge-face pair (e, f) which is a supersegment of some (possibly empty) interval of optimality. A candidate interval I has associated with it the anchor r_I and the last edge sequence $\mathcal{E}_I$ along which monotone paths from Q reach the points in I. We also store with each candidate interval I its unfolded anchor $\overline{r}_I$. We also store with each interval its *frontier point* α_I, which is the point in I that mimimizes the distance to r_I along $\mathcal{E}_I$ (the point that is closest to the unfolded anchor $\overline{r}_I$). If the anchor r_I is one of the edge sites, we define the *priority* of the frontier point α_I to be its distance to r_I along $\mathcal{E}_I$. If the anchor is a vertex, the algorithm will have already computed a value $d(r_I)$ (which is the shortest path distance to r_I). In this case, we define the priority of α_I to be $d(r_I)$ plus the distance between α_I and r_I along $\mathcal{E}_I$.

The algorithm also maintains a priority queue called the *event queue*. The event queue contains the frontier point α_I of each candidate interval I, with its priority, if α_I has not already been "permanently labeled."

We are now ready to describe the overall algorithm. It makes use of two procedures, `project` and `insert-interval`, which we describe after the overall algorithm. In the initialization phase, we perform the following steps.

1. On each boundary edge e in Q, we insert a candidate interval I extending over the entire edge. Since e has only one face f incident on it, we can think of I as being on the edge-face pair $(e, \emptyset)$, where $\emptyset$ is a "dummy" face. The anchor of I is the edge e itself, and its last edge sequence is empty. Note that the priority of this interval is zero.
2. For each vertex v in Q, we set $d(v) = 0$. For each face f incident to v and each edge e of f, we insert a candidate interval I, whose extent is the entire edge e, on the edge-face pair (e, f); the anchor of I is v and its last edge sequence is empty; we refer to v as the *predecessor* $\mathrm{pred}(I)$ of I. (By predecessor of an interval I, we mean the candidate interval or vertex whose "propagation" gives rise to I.) We then call the procedure `insert-interval`(I, e).

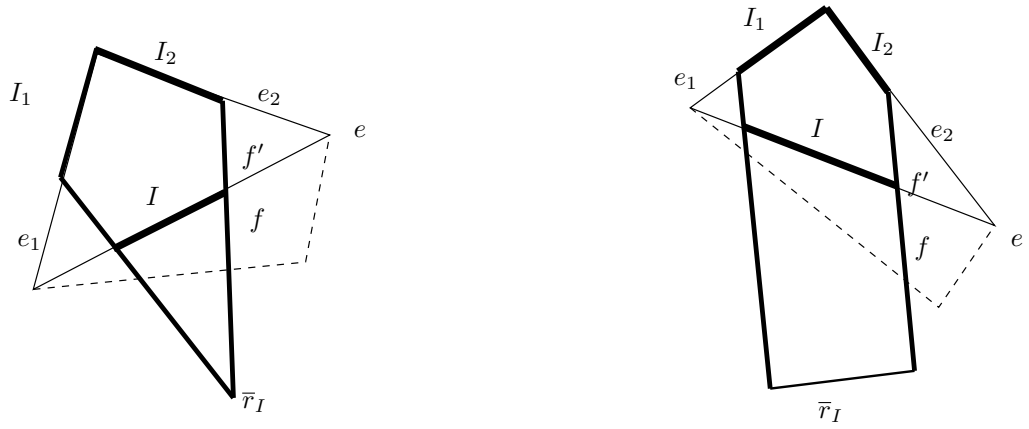

FIG. 8. *Projecting an interval I:* (i) *r_I is a vertex;* (ii) *r_I is an edge site.*

The main loop of the algorithm consists of iterating the following steps until the event queue becomes empty.

1. We remove from the event queue the frontier point α_I that has the smallest priority. Suppose that α_I belongs to candidate interval I on edge-face pair (e, f). We permanently label α_I with its priority.
2. If α_I is a vertex v, and a value has not already been assigned to $d(v)$, we assign $d(v)$ to be the priority of $v = \alpha_I$. We store a pointer $ptr(v)$ from v to the candidate interval I. We look at each face f' incident to v, and each edge e' on f'. We insert a candidate interval I on edge-face pair (e', f') whose extent is the entire edge e'. The anchor of I is v, and its last edge sequence is empty. We set v to be the predecessor $\text{pred}(I)$ of I. We then call the procedure `insert-interval`(I, e). If $d(v)$ has already been assigned to vertex v, we can skip the above steps.
3. Whether α_I is a vertex or not, we find the other face f' incident to e. If there is no such face, we do nothing. Let e_1 and e_2 be the two other edges of f'. We call `project`(I, e_1) to find the interval I_1 on e_1 that is hit by monotone paths through I. We set I to be the predecessor of $\text{pred}(I_1)$ of I_1. We then call the procedure `insert-interval`(I_1, e_1). We do the same with e_2.

We now describe the two procedures `project` and `insert-interval`. Let e be an edge incident to two faces f and f', and let e_1 and e_2 be the other two edges of f'. Suppose I is a candidate interval on the edge-face pair (e, f), with anchor r_I and last edge sequence $\mathcal{E}_I$. The procedure `project`(I, e_1) simply finds the interval I_1 on e_1 that is hit by the monotone paths through I. If r_I is a vertex, we just use the fact that monotone paths unfold into straight lines to determine how the "wedge" of paths with anchor r_I and edge sequence $\mathcal{E}_I$ is extended into f'. (See Figure 8.) If r_I is a boundary edge site, we also use the fact that an optimal monotone path extends onto f' such that it is perpendicular to the unfolded image (along $\mathcal{E}_I$) of r_I onto f'. (This is depicted in Figure 8.)

A call to the procedure `insert-interval`(I, e) restores the following invariants for the candidate intervals on an edge-face pair (e, f):

1. The intervals have pairwise disjoint interiors, which means they can be ordered along the edge e.
2. The ordering of the intervals along e is consistent with the ordering of the

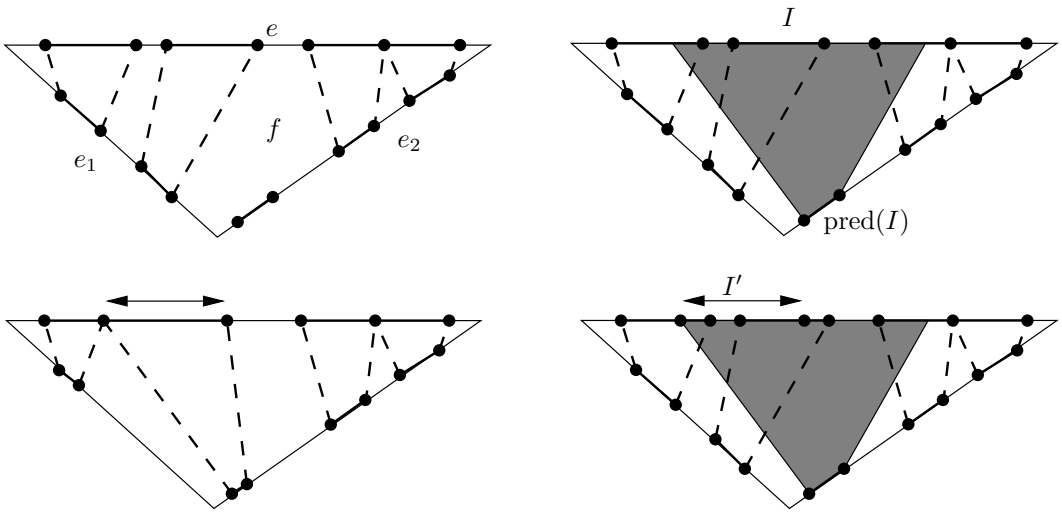

FIG. 9. *Clockwise from top left:* (1) *the candidate intervals on edge-face pair* (e, f)*, and (portions of) their predecessors on edges* e_1 *and* e_2 *on* f*;* (2) *the interval* I *is propagated from pred*(I) *and* `insert-interval`(I, e) *is called;* (3) *the trimmed subinterval* I' *of* I*; and* (4) *the list of intervals on* (e, f) *after the call is completed.*

predecessors of the intervals on the other two edges of f.

Suppose that the procedure `insert-interval`(I, e) is invoked on the edge-face pair (e, f), and that e_1 and e_2 are the other two edges of f. We assume that prior to the newly introduced interval I, the above invariants hold for the list of candidate intervals $\mathcal{I}$ on (e, f). Let us orient the edge e in an arbitrary way; this fixes an ordering $\prec$ of $\mathcal{I}$ and a corresponding ordering $\prec$ of the predecessors of intervals in $\mathcal{I} \cup I$. Let $\mathcal{L} \subseteq \mathcal{I}$ be the set of intervals I_j such that $\text{pred}(I_j) \prec \text{pred}(I)$, and let $\mathcal{R} = \mathcal{I} - \mathcal{L}$.

Let $I' \subseteq I$ be the set of points x such that the distance of x from Q through $\text{pred}(I)$ is smaller than the distance from Q through $\text{pred}(I_j)$ for any $I_j \in \mathcal{I}$. We can show that I' will be an interval. We introduce I' into the list of candidate intervals on (e, f). We truncate each $I_j \in \mathcal{L}$ (resp., $I_j \in \mathcal{R}$) to the subinterval that precedes (resp., succeeds) I' according to the $\prec$ ordering. This completes the description of procedure `insert-interval`(I, e). (See Figure 9 for an illustration.) At the end of the procedure, the invariants are restored. The key property of the procedure is that in restoring the invariants, it never trims a shortest monotone path. The implementation details of the procedure are identical to the corresponding procedure in Mitchell, Mount, and Papadimitriou [22].

This completes the description of the algorithm. At termination, we are left with a bunch of candidate intervals on each edge-face pair. The correctness of the algorithm, that is, the claim that these are actually the intervals of optimality, follows from the fact we never trim a shortest monotone path in any of the calls to `insert-interval`.

7.2. Running time analysis. To bound the running time of the algorithm, we first bound the number of events. An event corresponds to the "permanent labeling" of a frontier point α_I of candidate interval I on edge-face pair (e, f). Suppose I has anchor r_I and last edge sequence $\mathcal{E}_I$. Using the fact that we always pick the interval with the smallest priority, we can show that a portion of I (that includes α_I) is in fact an interval of optimality on (e, f) with anchor r_I and last edge sequence $\mathcal{E}_I$.

(This argument is similar in spirit to the argument for the correctness of Dijkstra's algorithm.) We charge the event to this interval of optimality I. Each interval of optimality is charged only once, so by Lemma 7.3, we get a charge of $O(r)$ per edge-face pair. As there are only $O(r)$ edge-face pairs, it follows that there are only $O(r^2)$ events. From this, we can show that the running time of the algorithm is $O(r^2 \log r)$, as in Mitchell, Mount, and Papadimitriou [22].

We now describe how the output of the algorithm is used to answer shortest distance queries. Given a query point x which is either a vertex of R or a point on the boundary edge of R, we locate the interval of optimality I in which it lies. (For a vertex v, I is the interval that $ptr(v)$ points to.) Suppose I is an interval on edge-face pair (e, f) with anchor r_I and last edge sequence $\mathcal{E}_I$. If r_I is a vertex, the distance of x from Q is $d(r_I)$ plus the distance of r_I from x along $\mathcal{E}_I$. If r_I is an edge, the distance of x from Q is the shortest distance of r_I to x along $\mathcal{E}_I$. These distances can be computed in constant time since $\overline{r_I}$, the image of r_I when $\mathcal{E}_I$ is unfolded onto f, is known. Since I can be found in $O(\log r)$ time using a binary search, we can answer shortest distance queries in $O(\log r)$ time. With minor modifications, we can also report the point $q \in Q$ that is closest to x in $O(\log r)$ time. If we desire a shortest path between x and q, we go back along the edge sequence $\mathcal{E}_I$ to r and find the shortest path between r and q. This "back-tracing" takes $O(r)$ time. Note that all these queries can be answered within the same time bounds even if x is a point on an internal edge e: we simply consider both intervals of optimality in which it lies and choose the one which gives the shorter distance to Q. We conclude by stating the main result of this section.

LEMMA 7.4. *Suppose that we are given a polyhedral patch R and a region (set of points) Q on R specified as a union of some vertices of R and some boundary edges of R. We can preprocess the patch in $O(r^2 \log r)$ time, where r is the number of faces of the patch, so that the following queries can be performed. Given a point x on any edge of the patch, we can report the closest point $q \in Q$ to x and the shortest path distance of q from x in $O(\log r)$ time. We can also report a shortest path between q and x in $O(r)$ time.*

8. Conclusions. After the initial submission of this paper, there have been some remarkable developments on computing shortest paths on a terrain. Kapoor [18] has claimed an $O(n \log^2 n)$-time algorithm for the exact shortest path problem, but his algorithm is complex, and we await the full version of the paper to verify the details. Aleksandrov, Maheshwari, and Sack [4] describe an $O((n/\varepsilon) \log n)$-time algorithm for computing a $(1 + \varepsilon)$-path, provided that the edges of the terrain satisfy certain geometric properties.

TAKING A WALK IN A PLANAR ARRANGEMENT*

SARIEL HAR-PELED†

Abstract. We present a randomized algorithm for computing portions of an arrangement of n arcs in the plane, each pair of which intersect in at most t points. We use this algorithm to perform online walks inside such an arrangement (i.e., compute all the faces that a curve, given in an online manner, crosses) and to compute a level in an arrangement, both in an output-sensitive manner. The expected running time of the algorithm is $O(\lambda_{t+2}(m+n)\log n)$, where m is the number of intersections between the walk and the given arcs.

No similarly efficient algorithm is known for the general case of arcs. For the case of lines and for certain restricted cases involving line segments, our algorithm improves the best known algorithm of [M. H. Overmars and J. van Leeuwen, *J. Comput. System Sci.,* 23 (1981), pp. 166–204] by almost a logarithmic factor.

1. Introduction.

Let $\hat{S}$ be a set of n x-monotone arcs in the plane, each pair of which intersect in at most t points. Computing the whole (or parts of the) arrangement $\mathcal{A}(\hat{S})$, induced by the arcs of $\hat{S}$, is one of the fundamental problems in computational geometry, and has received a lot of attention in recent years [26]. One of the basic techniques used for such constructions is based on *randomized incremental* construction of the *vertical decomposition* of the arrangement (see [5]).

If we are interested in computing only parts of the arrangement (e.g., a single face or a zone), the randomized incremental technique can still be used, but it requires nontrivial modifications [9, 11]. Intuitively, the added complexity is caused by the need to "trim" parts of the plane as the algorithm advances, so that it will not waste energy on regions which are no longer relevant. In fact, this requirement implies that such an algorithm has to know in advance which regions we are interested in at any stage during the randomized incremental construction.

A variation of this theme, with which the existing algorithms cannot cope efficiently, is the following *online* scenario: We start from a point $p = p(0) \in \mathbb{R}^2$, and we find the face f of $\mathcal{A}(\hat{S})$ that contains $p(0)$. Now the point p starts moving and traces a connected curve $\{p(t)\}_{t\geq 0}$. As our walk continues, we wish to keep track of the face of $\mathcal{A}(\hat{S})$ that contains the current point $p(t)$. The collection of these faces constitutes the *zone* of the curve $p(t)$. However, the function $p(t)$ is not assumed to be known in advance, and it may change when we cross into a new face or abruptly change direction in the middle of a face (see [4] for an application where such a scenario arises). The only work we are aware of that can deal with this problem efficiently is due to Overmars and van Leeuwen [25], and it only applies to the case of lines (and, with some simple modifications, to certain restricted cases involving line segments as

well).[1] It can compute such a walk in (deterministic) $O((n+m)\log^2 n)$ time, inside an arrangement of n lines, where m is the number of intersections of the walk with the lines of $\hat{S}$. This is done by maintaining dynamically the intersection of half-planes that corresponds to the current face.

In this paper, we propose a new randomized algorithm that computes the zone of the walk in a general arrangement of arcs, as above, in $O(\lambda_{t+2}(n+m)\log n)$ expected time, where $\lambda_{t+2}(n+m)$ is the maximum length of a Davenport–Schinzel sequence of order $t+2$ having $n+m$ symbols [26]. The new algorithm can be interpreted as a third "online" alternative to the algorithms of [9, 11]. The algorithm is rather simple and appears to be practical. As a matter of fact, we had implemented and experimented with a variant of the algorithm [3].

As an application of the new algorithm, we present an algorithm for computing a level in an arrangement of arcs. It computes a single level in $O(\lambda_{t+2}(n+m)\log n)$ expected time, where m is the complexity of the level. We also show how to adapt the main algorithm to obtain a point-location algorithm that locates m points in an arrangement of n arcs, as above, in expected time $O(\lambda_{t+2}(n+m+w)\log n)$, where w is the minimum number of intersections between a spanning tree connecting those query points and the given arcs.

Both results improve by almost a logarithmic factor over the best previous result of [25] for the case of lines (and for certain cases involving line segments).[2] For the case of general arcs, we are not aware of any similarly efficient previous result.

The paper is organized as follows. In section 2 we describe the algorithm. In section 3 we analyze its performance. In section 4 we mention a few applications of the algorithm, including the construction of a single level, and multiple point location. Concluding remarks are given in section 6.

2. The algorithm. In this section, we present the algorithm for performing an online walk inside a planar arrangement.

Randomized incremental construction of the zone using an oracle. Given a set $\hat{S}$ of n x-monotone arcs in the plane, so that any pair of arcs of $\hat{S}$ intersect at most t times (for some fixed constant t), let $\mathcal{A}(\hat{S})$ denote the arrangement of $\hat{S}$; namely, the partition of the plane into faces, edges, and vertices as induced by the arcs of $\hat{S}$ (see [26] for details). In the following, we need two basic geometric primitives for splitting and merging vertical trapezoid, `SplitGeom`, `MergeGeom`, illustrated in Figure 1. We assume that $\hat{S}$ is in general position, meaning that no three arcs of $\hat{S}$ have a common point, and that the x-coordinates of the intersections and endpoints of the arcs of $\hat{S}$ are pairwise distinct. The *vertical decomposition* of $\mathcal{A}(\hat{S})$, denoted by $\mathcal{A}_{\mathcal{VD}}(\hat{S})$, is the partition of the plane into vertical pseudotrapezoids, obtained by erecting two vertical segments up and down from each vertex of $\mathcal{A}(\hat{S})$ (i.e., each point of intersection between a pair of arcs and each endpoint of an arc), and by extending each of them until it either reaches an arc of $\hat{S}$, or otherwise all the way to infinity. See, e.g., [5, 26] for more details concerning vertical decompositions. To simplify (though slightly abuse) the notation, we refer to the cells of $\mathcal{A}_{\mathcal{VD}}(\hat{S})$ as *trapezoids*. A *selection* R of $\hat{S}$ is an ordered sequence of distinct elements of $\hat{S}$. By a slight abuse of notation, we also denote by R the unordered set of its elements. Let $\sigma(\hat{S})$ denote

[1] Recently, an improvement was given by Chan [7], and further improvement was given by Brodal and Jacob [6]; their algorithm can perform an update in $O(\log n \log\log n)$ amortized time and answer queries (of the kind used in this application) in $O(\log n)$ time per query.

[2] Our results are also asymptotically faster and much simpler to implement than what is yielded by the recent results of Chan [7, 8] and Brodal and Jacob [6].

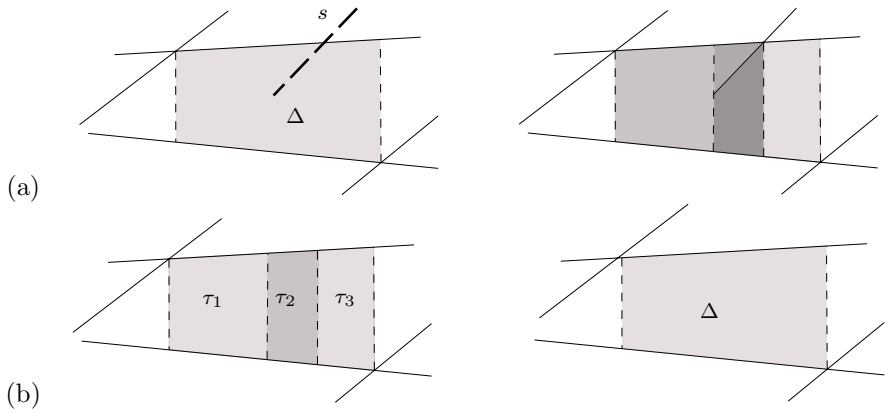

FIG. 1. *Geometric primitives:* (a) `SplitGeom`(Δ, s) *splits* Δ *into an* $O(1)$ *vertical trapezoids that cover the original trapezoid and their interior is not crossed by* s. (b) `MergeGeom`$(\{\tau_1, \tau_2, \tau_3\})$ *merge the adjacent trapezoids* τ_1, τ_2, τ_3 *with the same top and bottom arcs into a single trapezoid* Δ.

the set of all selections of $\hat{S}$. For a permutation S of $\hat{S}$, let S_i denote the subsequence consisting of the first i elements of S for $i = 0, \ldots, n$.

Computing the decomposed arrangement $\mathcal{A}_{\mathcal{VD}}(\hat{S})$ can be done in a randomized incremental manner (see [5]). Let γ be the curve traced by the walk. For a selection $R \in \sigma(\hat{S})$, let $\mathcal{D}_\gamma(R)$ (resp., $\mathcal{Z}_\gamma(R)$) denote the *district* (resp., *zone*) of γ in $\mathcal{A}(R)$; these are, respectively, the set of all trapezoids of $\mathcal{A}_{\mathcal{VD}}(R)$ and the set of all faces of $\mathcal{A}(R)$ that have a nonempty intersection with γ. Let $\mathcal{A}_{\gamma,\mathcal{VD}}(R)$ denote the set of all trapezoids in $\mathcal{A}_{\mathcal{VD}}(R)$ that cover $\mathcal{Z}_\gamma(R)$. Our goal is to compute $\mathcal{A}_{\gamma,\mathcal{VD}}(\hat{S})$. (Alternatively, we may be interested only in computing the district $\mathcal{D}_\gamma(\hat{S})$ of γ.)

We assume for the moment that we are supplied with an oracle $\mathcal{O}(S_i, \gamma, \Delta)$, which can decide in constant time whether a given vertical trapezoid Δ is in $\mathcal{A}_{\gamma,\mathcal{VD}}(S_i)$. Equipped with this oracle, computing $\mathcal{A}_{\gamma,\mathcal{VD}}(S)$ is fairly easy, using a variant of the randomized incremental construction, outlined above. The algorithm, called `CompZoneWithOracle`, is depicted in Figure 2. We present this algorithm at a conceptual level only, because this is not the algorithm that we shall actually use. It is given to help us describe and analyze the actual online algorithm that we shall present later.

Note that the set of trapezoids $\mathcal{C}_i$ maintained by the algorithm in the ith iteration is a superset of $\mathcal{A}_{\gamma,\mathcal{VD}}(S_i)$. There might be trapezoids in $\mathcal{C}_i$ that are no longer in $\mathcal{Z}_\gamma(S_i)$. (Typically these are trapezoids that are separated from $\mathcal{Z}_\gamma(S_i)$ by an arc that does not cross their interior and is intersected after they have been created.) However, this implies that any such trapezoid will be eliminated the first time an arc that crosses it will be handled, or, if no such arc exists, at the final clean-up step of the algorithm. Moreover, the algorithm `CompZoneWithOracle` can be augmented to compute a *history* DAG (as in [12, 26]), whose nodes are the trapezoids created by the algorithm and where each trapezoid destroyed during the execution of the algorithm points to the trapezoids that were created from it. Let $\mathcal{HT}_\gamma(S_i)$ denote this structure after the ith iteration of the algorithm. Note that the out-degree of each node of $\mathcal{HT}_\gamma$ is bounded by a constant that depends on t.

Definitions. A trapezoid created by the `SplitGeom` operation of `CompZoneWithOracle` is called a *transient* trapezoid if it is later merged (in the same iteration) to form a larger trapezoid. A trapezoid generated by `CompZoneWithOracle` is

ALGORITHM `CompZoneWithOracle`($\hat{S}$, γ, $\mathcal{O}$).
`Input:` A set $\hat{S}$ of n arcs, a curve γ, an oracle $\mathcal{O}$
`Output:` $\mathcal{A}_{\gamma,\mathcal{VD}}(\hat{S})$
begin
Choose a random permutation $S = \langle s_1, s_2, \ldots, s_n \rangle$ of $\hat{S}$.
$\mathcal{C}_0 \leftarrow \{\mathbb{R}^2\}$
for i from 1 to n **do**
$\mathcal{D}_i \leftarrow \{\Delta \mid \Delta \in \mathcal{C}_{i-1}, int\,\Delta \cap s_i \neq \emptyset\}$
$Temp \leftarrow \emptyset$
for each $\Delta \in \mathcal{D}_i$ **do**
$Temp \leftarrow Temp \cup$ `SplitGeom`(Δ, s_i),
where `SplitGeom`(Δ, s) is the operation of splitting a vertical trapezoid Δ crossed by an arc s into a constant number of vertical trapezoids, as in [12], such that the new trapezoids cover Δ, and they do not intersect s in their interior.
end for
Merge all the adjacent trapezoids of $Temp$ that have the same top and bottom arcs. Let $Temp_1$ be the resulting set of trapezoids.
Let $Temp_2$ be the set of all trapezoids of $Temp_1$ that are in $\mathcal{A}_{\gamma,\mathcal{VD}}(S_i)$. Compute this set using $|Temp_1|$ calls to $\mathcal{O}$.
$\mathcal{C}_i \leftarrow (\mathcal{C}_{i-1} \setminus \mathcal{D}_i) \cup Temp_2$
end for
Remove from $\mathcal{C}_n$ all trapezoids not belonging to $\mathcal{A}_{\gamma,\mathcal{VD}}(\hat{S})$, by checking with $\mathcal{O}$ each trapezoid of $\mathcal{C}_n$.
return $\mathcal{C}_n$
end `CompZoneWithOracle`

FIG. 2. *A randomized incremental algorithm for constructing the zone of a walk in an arrangement of arcs, using an oracle.*

final if it is not transient. The *rank* $\mathrm{rank}(\Delta)$ of a trapezoid Δ is the maximum of the indices i, j of the arcs containing the bottom and top edges of Δ in the permutation S. We denote by $D(\Delta)$ the *defining set of a final trapezoid* Δ; this is the minimal set D such that $\Delta \in \mathcal{A}_{\mathcal{VD}}(D)$. It is easy to verify that $|D(\Delta)| \leq 4$. We can also define $D(\Delta)$ for a transient trapezoid Δ to be the minimal set D such that Δ can be transient during an incremental construction of $\mathcal{A}_{\mathcal{VD}}(D)$. Here it is easy to verify that $|D(\Delta)| \leq 6$. The *index* $\mathrm{index}(\Delta)$ of a trapezoid Δ is the minimum i such that $D(\Delta) \subseteq S_i$. For a trapezoid Δ, we denote by $\mathrm{cl}(\Delta)$ the *conflict list* of Δ, that is, the set of arcs of $\hat{S}$ that intersect Δ in its interior. $\mathrm{next}(\Delta)$ denotes the first element of $\mathrm{cl}(\Delta)$, according to the ordering of S.

In the algorithm, whenever we compute a trapezoid, we also compute its conflict list. The overall running time of the algorithm is dominated by the time required to compute and manipulate those conflict lists. Generally speaking, if a trapezoid is created from a parent trapezoid by splitting, we can compute the conflict list by scanning the parent conflict list and checking each arc to see if it intersects the new trapezoid. If a trapezoid is formed by merging several trapezoids, its conflict list can be computed by merging the trapezoid's conflict-list. This can be done in linear time in the size of the input conflict lists, as described below. Since a conflict list participates only in a constant number of such merge/split operations, the overall time required to manipulate those conflict lists is proportional to their overall size.

For a trapezoid Δ generated by `CompZoneWithOracle`, which was not merged into a larger trapezoid, we denote by $\mathrm{father}(\Delta)$ the trapezoid that Δ was generated from. A vertical side of a trapezoid Δ is called a *splitter*. A splitter ν is *transient* if it is not incident to the intersection point (or endpoint) that induced the vertical edge that

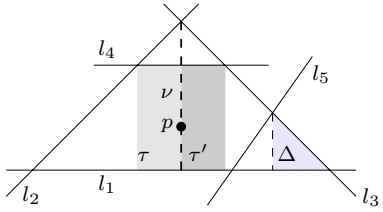

FIG. 3. *Illustration of the definitions:* ν *is a transient splitter, and thus* τ, τ' *are both transient. We have* $\mathrm{rank}(\tau) = \mathrm{index}(\tau) = 4$, $\mathrm{rank}(\Delta) = 3$, *and* $\mathrm{index}(\Delta) = 5$, *where* $S = \langle l_1, l_2, l_3, l_4, l_5 \rangle$.

contains ν. (This means that the two trapezoids adjacent to ν are transient and will be merged into a larger final trapezoid.) See Figure 3 for an illustration of some of these definitions. It is easy to verify that a trapezoid Δ is transient if and only if at least one of its bounding splitters is transient. Thus, one can decide whether a trapezoid is transient, by inspecting its splitters, in constant time.

The online algorithm constructs portions of $\mathcal{HT}_\gamma(S)$ incrementally, as they are needed. This is done by performing a sequence of point locations in the arrangement, where each such query constructs the final trapezoid of $\mathcal{A}_{\mathcal{VD}}(\hat{S})$ that contains the query point, plus all ancestor trapezoids that lie on paths of $\mathcal{HT}_\gamma(S)$ from the root to that trapezoid. Informally, instead of building $\mathcal{HT}_\gamma(S)$ layer by layer, as is done by `CompZoneWithOracle`, the online algorithm constructs the DAG in an "orthogonal" depth-first search manner. The intuition behind the design and efficiency of the algorithm is that the expected number of nodes in $\mathcal{HT}_\gamma(S)$ is only $O(\lambda_{t+2}(n+m))$, whereas the overall expected running time of `CompZoneWithOracle` is $O(\lambda_{t+2}(n+m)\log n)$ (this is the expected overall size of the conflict lists of the computed nodes, which the algorithm needs to construct and manipulate). Both bounds are easy consequences of known results and will be discussed in section 3.2. Thus, in our quest to usurp the oracle, we can afford to pay an extra $O(\log n)$ time during the search for and construction of each node of $\mathcal{HT}_\gamma(S)$. This indeed will be the cost of a point-location query (ignoring the time required for constructing any new node of $\mathcal{HT}_\gamma(S)$ that the query has to pass through). Informally, the online algorithm performs essentially the same operations as the preceding algorithm, except that it executes them in a different order, and, in addition, it may revisit again and again portions of the DAG that have already been constructed as it searches down the DAG while performing point locations. However, since this extra cost is only logarithmic, it does not increase the asymptotic complexity of the algorithm.

An online algorithm for constructing the zone. Before describing the algorithm in detail, we refer the reader to Appendix A, which provides a pseudocode for some relevant procedures used by the algorithm, and Appendix B, which presents an example of how the following algorithm works. The reader is encouraged to consult with the appendices whenever the definitions and the descriptions become too vague.

Let us assume that the random permutation S of $\hat{S}$ has been fixed in advance. Note that S predetermines $\mathcal{HT}_\gamma = \mathcal{HT}_\gamma(S)$. The key observation in the online algorithm is that in order to construct a specific leaf of $\mathcal{HT}_\gamma(S)$ we do not have to maintain the entire DAG, and it suffices to compute only the parts of the DAG that lie on paths connecting the leaf with the root of $\mathcal{HT}_\gamma$. (There might be several such paths, since our structure is a DAG and not a tree.)

To facilitate this computation, we maintain a *partial history* DAG, denoted by T. The nodes of T are of two types: (i) *final nodes*, whose corresponding trapezoids

appear in $\mathcal{HT}_\gamma = \mathcal{HT}_\gamma(S)$; and (ii) *transient nodes,* which are some of the leaves of T, whose corresponding trapezoids are transient. A transient node can be easily detected since its trapezoid is transient. A final node is simply a node which is not transient. In particular, all the internal nodes of T are copies of identical nodes of $\mathcal{HT}_\gamma$ (whose corresponding trapezoids are final), while some of the leaves of T might be transient. Intuitively, T stores the portion of $\mathcal{HT}_\gamma$ that we have computed explicitly so far. The transient leaves of T delimit portions of $\mathcal{HT}_\gamma$ that have not been expanded yet. Inside each node of T, we also maintain the conflict list of the corresponding trapezoid Δ and its first element $\mathrm{next}(\Delta)$.

Suppose we wish to compute a leaf of $\mathcal{HT}_\gamma$ that contains a given point p. We denote this operation by `PointLocate`(p). We first locate the leaf of T that contains p. This is done by traversing a path in T, starting from the root of T, and going downward in each step into the child of the current trapezoid that contains p (each such step requires $O(1)$ time, because, as already noted, the out-degree of any node of $\mathcal{HT}_\gamma$, and thus of T, is bounded by a constant that depends on t). (A technical issue that we face is that usually p lies on some trapezoid boundary, so we need additional local information to determine which child to descend to at each of the above steps—see below for more details.) At the end we either reach a final leaf (with an empty conflict list), which is the required leaf of $\mathcal{HT}_\gamma$, or encounter a leaf v of T. In the latter case, we need to expand T further below v. If v represents a transient trapezoid, then the first step is to replace v by the corresponding node v^* of $\mathcal{HT}_\gamma$, obtained by merging the transient trapezoid of v with adjacent transient trapezoids, with identical top and bottom arcs, to form the final trapezoid associated with v^*. If v is a final node we expand it by splitting it with the first arc that crosses its trapezoid, using steps (iv) and (v) below.

Assume for the moment that we are supplied (for the case where v is transient) with a method (to be described shortly) to generate all those adjacent transient trapezoids, whose union forms the final trapezoid that is stored at v^* in $\mathcal{HT}_\gamma$. Then we do the following: (i) Merge all those transient trapezoids into a new (final) trapezoid Δ; (ii) compute the conflict list $\mathrm{cl}(\Delta)$ from the conflict lists of the transient trapezoids; (iii) compute the first element $s_\Delta = \mathrm{next}(\Delta)$ in $\mathrm{cl}(\Delta)$ according to the permutation S; (iv) compute all the transient or final trapezoids generated from Δ by splitting it by s_Δ (this generates $O(1)$ new trapezoids); and (v) extract from $\mathrm{cl}(\Delta)$ the conflict list $\mathrm{cl}(\Delta')$ of each new trapezoid Δ' and compute $\mathrm{next}(\Delta')$ as well.

Overall, this requires $O(k+l)$ time, where k is the number of transient trapezoids that are merged, and l is the total length of the conflict lists of these transient trapezoids. This is trivial to show for steps (i), (iii), (iv), and (v). To perform in step (ii) the merging of the conflict lists in linear time, one may use a global bit-vector structure. Namely, we initialize before the execution of the algorithm a bit-vector b of size n to be everywhere zero. To merge several conflict lists $L_1, \ldots, L_k$, we scan each list in turn, and for each of its elements s_j, we first test whether $b_j = 0$; if so, we add s_j to the output conflict list and change b_j to 1. After creating the output conflict list in this manner, we scan the output list, turning off all the bits that got turned on.

In this manner, we have upgraded a transient leaf v of T into a final node v^*. We denote this operation by `Expand`(v). We can now continue going down in T, passing to the child of Δ that contains p and repeating recursively the above procedure at that child, until constructing and reaching the desired leaf of $\mathcal{HT}_\gamma$ that contains p (namely, until we reach a node that is final and had empty conflict list).

To complete the presentation of this point-location mechanism, we describe `Expand`(v), the procedure that computes the "sibling" transient trapezoids that are adjacent to the transient trapezoid of v.

Let τ be the transient trapezoid. Then either the top arc or the bottom arc of τ are the cause of the splitting that generated τ. In particular, next(τ_f) is either the top or bottom arc of τ, where $\tau_f = \text{father}(\tau)$ denotes the trapezoid that τ was generated (split) from. This also implies that $\text{rank}(\tau) = \text{index}(\tau)$. Since τ is transient, one of the splitters of τ must be transient. Let ν denote such a transient splitter, and let us assume that ν is the right edge of τ. Note also that τ_f must be a final trapezoid, so in particular ν was generated from a final splitter (by the insertion of an arc that separated ν from the vertex that induced the bigger final splitter).

We compute the transient trapezoid τ' that lies to the right of τ and has the same top and bottom arcs, by taking the midpoint p of ν, and by performing a point-location query of p in T using (recursively) the same mechanism described above. During this point-location process, we always go down into the trapezoid Δ that contains p in its interior or on its left edge; see below for details. We stop as soon as we encounter a transient trapezoid τ' that has a left edge identical to ν. This happens when τ and τ' have the same top and bottom edges; namely, we stop when $\text{rank}(\tau) = \text{rank}(\tau')$. (Intuitively, if the trapezoid τ' has rank smaller than $\text{rank}(\tau)$, then either it fully contains ν in its interior or its left edge is longer than (and contains) ν; the first time when both τ and τ' have the same connecting edge is when their top and bottom edges are identical, namely, when $\text{rank}(\tau) = \text{rank}(\tau')$.) See below for more details in the proof of correctness of the algorithm. We continue this process of collecting adjacent transient trapezoids using point-location queries on midpoints of transient splitters, until the two extreme splitters (the left splitter of the leftmost trapezoid in the sequence and the right splitter of the rightmost trapezoid) are nontransient. We take the union of those trapezoids to be the new expanded trapezoid. See Figure 3 for a scenario where such a merging occurs. A more detailed illustration is given in Appendix B below.

Of course, during this point-location process, we might be forced into going into parts of $\mathcal{HT}_\gamma$ that are rather remote from the point p. In such a case, we will compute those parts in an online manner, by performing `PointLocate` and `Expand` calls on the relevant trapezoids that we encounter while going down T. Thus, the point-location process is recursive and might be quite substantial. Nevertheless, as will be argued below, the overall cost of the `PointLocate` and `Expand` operations is not excessive, so these operations are efficient in an amortized sense.

Let γ be the curve of the online walk whose zone we wish to compute. We consider γ to be a directed curve, supplied to us by the user through a function $\texttt{EscapePoint}_\gamma$. The function $\texttt{EscapePoint}_\gamma(p, \Delta)$ receives as input a point $p \in \gamma$, and a trapezoid Δ that contains p, and outputs the next intersection point of γ with $\partial\Delta$ following p. If γ ends before we reach $\partial\Delta$, the function returns `nil`. We assume (although this is not crucial for the algorithm) that γ does not intersect itself.

Let G_S denote the adjacency graph of $\mathcal{A}_{\mathcal{VD}}(\hat{S})$. This is a graph having a vertex for each trapezoid in $\mathcal{A}_{\mathcal{VD}}(\hat{S})$, such that an edge connects two vertices if their corresponding trapezoids share a common vertical side. Under general position assumptions, each vertex in G_S has degree at most 4. It is easy to verify that a connected component of G_S corresponds to a face of $\mathcal{A}(\hat{S})$. Given a final leaf-trapezoid Δ, we can compute the face of $\mathcal{A}(\hat{S})$ that contains Δ by performing a depth-first search in G_S. This is done by performing point-location queries on appropriate points on

ALGORITHM `CompZoneOnline`($\hat{S}$, p, `EscapePoint`$_\gamma$).
`Input:` A set $\hat{S}$ of n arcs, a starting point p of the walk,
and a function `EscapePoint`$_\gamma$ that represents the walk
`Output:` The decomposed zone $\mathcal{A}_{\gamma,\mathcal{VD}}(\hat{S})$ of γ in $\mathcal{A}(\hat{S})$
begin
Choose a random permutation $S = \langle s_1, s_2, \ldots, s_n \rangle$ of $\hat{S}$.
$T \leftarrow \{(\mathbb{R}^2, S)\}$ - a partial history DAG with a root corresponding to
the whole plane; the conflict list of the root is the whole S.
$v \leftarrow$ `PointLocate`$(p, \cdot)$,
where `PointLocate`$(p, \cdot)$ is the leaf of $\mathcal{HT}_\gamma$ whose associated trapezoid
contains p. (The procedure has an additional flag parameter
that we ignore here; it is used in cases where p lies on trapezoid
boundaries; see Appendix A and below.)
/* All the paths in $\mathcal{HT}_\gamma$ from v to the root now exist in T. */
$\mathcal{D} \leftarrow \{\Delta_v\}$ (Δ_v is the trapezoid stored at v.)

FIG. 4. *Algorithm for constructing the zone of a walk in an arrangement of arcs in an online manner. See Appendix A for the pseudocode of the main subroutines used by* `CompZoneOnline`*, and Appendix B for an illustration of the execution of* `CompZoneOnline`.

the splitters of Δ, in a manner similar to that used in the `Expand` operation. This yields all the neighbors of Δ in G_S, and we continue in this manner until the entire connected component of G_S containing Δ is constructed.

Thus, given a walk γ, we can compute its zone by the algorithm `CompZoneOnline` depicted in Figure 4. See Appendix A for the pseudocode of the main subroutines used by `CompZoneOnline`, and Appendix B for an illustration of the execution of `CompZoneOnline`.

As will be shown in section 3.1, by the time the algorithm terminates, the final parts of T are contained in $\mathcal{HT}_\gamma$. (A proper inclusion might arise; see Remark 3.13.) In analyzing the performance of the algorithm, we first bound the overall expected time required to compute $\mathcal{HT}_\gamma$, which can be done by bounding the expected running time of `CompZoneWithOracle` (in an appropriate model of computation). Next, we will bound the additional time spent by the algorithm in traversing between adjacent trapezoids (i.e., the additional time spent in performing the point-location queries).

REMARK 2.1. *By skipping the expansion of the face that contains the current point p in* `CompZoneOnline`*, we get a more efficient algorithm that only computes the district $\mathcal{D}$ of the walk, that is, the collection of trapezoids in $\mathcal{A}_{\mathcal{VD}}(\hat{S})$ that γ crosses.*

There are cases where this will be sufficient; see section 4 *(e.g., in the adaptation of the algorithm for computing a level in an arrangement).*

3. Analysis of `CompZoneOnline`.

3.1. Correctness. In this section, we establish the correctness of `CompZoneOnline`. Before starting, we note that the correctness of `CompZoneWithOracle` is easier to establish and follows routinely from standard considerations. We therefore omit any further details concerning this issue.

The main technical issues that arise in the proof of correctness have to do with the potentially complex patterns of exploring the DAG T that can arise during the recursive execution of the `PointLocate` and `Expand` routines. The first main step in the proof is to show that the `Expand` routine always terminates properly, with a transient trapezoid that is compatible with the input one. Once this is shown, the rest of the proof is a routine, though somewhat involved, task, which employs induction on the structure of T and on the sequence of steps executed by the algorithm.

LEMMA 3.1. *During the execution of* `CompZoneOnline`*, the union of trapezoids of the leaves of* T *form a pairwise disjoint covering of the plane by vertical trapezoids.*

Proof. By induction on the steps of `CompZoneOnline`, noting that this is true initially, and that each step that modifies T either merges leaf trapezoids into a larger leaf trapezoid or splits a leaf trapezoid into subtrapezoids. □

COROLLARY 3.2. *Each conflict list, as computed for a (transient or final) trapezoid* Δ *by the procedure* `CompZoneOnline`*, is the list of all arcs of* S *that cross (the interior of)* Δ.

Proof. We prove the corollary by induction on the steps of `CompZoneOnline`. Observe that the region(s) from which Δ was generated cover Δ, and thus the union of their conflict lists must contain, by the induction hypothesis, the correct conflict list of Δ, which is thus correctly constructed by the appropriate `Expand` or `PointLocate` step. □

COROLLARY 3.3. *For a trapezoid* Δ *created by* `CompZoneOnline`*, all the arcs of* $D(\Delta)$ *appear in* S *before all the arcs of* $\mathrm{cl}(\Delta)$.

Consider an `Expand` operation that is triggered by point location at the midpoint p of a transient splitter ν that bounds a transient trapezoid τ, where τ has already been generated in T, and we wish to find the transient trapezoid τ' that shares ν with τ as a common splitter. (It is easily verified that τ' uniquely defined, given the permutation S.) Let i denote the rank of τ. As noted, i is also the index of τ. Clearly s_i must be either the top or the bottom arc of τ. Assume, without loss of generality, that ν is the right splitter of τ and that s_i is the top edge of τ. Let s_j be the bottom arc of τ, with $j < i$.

LEMMA 3.4. *During the execution of this* `Expand` *step, ignoring recursive calls, all the trapezoids that are either visited or generated fully contain* ν *either in their interior or within their left edge. Consequently, for any such trapezoid, except for the last one, either its conflict list contains* s_i *and* s_j*, or it contains* s_i *and* s_j *is the bottom arc of the trapezoid. Moreover, if this sequence of trapezoids includes a trapezoid that does contain* ν *on its left edge, then all subsequent trapezoids in the sequence have this property.*

Proof. This is shown by induction on the sequence of steps of this (nonrecursive portion of the) execution of `Expand`. For this proof, we assume that during this execution, any recursive call to `Expand` terminates correctly, with a transient trapezoid that is adjacent to the trapezoid that initiated the recursive call and has the same top and bottom arcs. If this is not the case, we assume that the algorithm aborts at

that point, and from that point on there is nothing to prove. (We thus modify the algorithm for the purpose of the proof, but a subsequent argument (in Lemma 3.5 below) will show that the algorithm never aborts.)

The first node that the `Expand` procedure visits is the root of T, and the claims clearly hold in this case. Assume they hold for all trapezoids up to and including a trapezoid Δ. Suppose first that Δ is final, and let $s_k = \text{next}(\Delta)$. By induction hypothesis, the conflict list of Δ contains s_i, so we must have $k \leq i$. Then Corollary 3.3 implies that s_k does not cross the relative interior of ν. This implies that the subtrapezoid Δ' of Δ that is split from it by s_k and contains (a point slightly to the right of) the midpoint of ν must fully contain ν in its closure. If Δ contained ν on its left side, then clearly this also holds for Δ'.

If Δ is transient, then there are two subcases: If the top and bottom edges of Δ are, respectively, s_i and s_j, then the `Expand` procedure terminates and returns Δ; the claims clearly hold in this case. Otherwise, the `Expand` procedure executes a recursive call with the midpoint of some (transient) splitter of Δ. As argued above, we may assume that this recursive call returns a transient trapezoid compatible with Δ, in the above sense. We repeat this step, if needed, until we obtain a sequence of compatible transient trapezoids, including Δ, which cannot be expanded any further. We then merge all these trapezoids into a trapezoid Δ', which clearly must be final. It is obvious, by construction, that Δ' satisfies the first assertion of the lemma.

To prove the second assertion (for transient trapezoids), assume that Δ contains ν on its left edge ν_0. It suffices to show that ν_0 is not transient (which will imply that Δ is not merged with other trapezoids on its left, so that this left splitter will be contained in ν_0), so assume to the contrary that it is transient. As already noted, a transient splitter like ν_0 is generated when we insert an arc s_ℓ that delimits ν_0 and separates it from the vertex w that induced it. Once this occurs, ν_0 will trigger a call to `Expand` which, if properly terminated, will erase ν_0 as it merges Δ with adjacent transient trapezoids. As argued above, we have $\ell < i$ (because $s_i \in \text{cl}(\Delta)$).

The same argument also implies that the trapezoid τ_f from which τ has been split (by the insertion of s_i) has a nontransient right splitter ν^* that contains ν and extends all the way to the vertex w. Thus, by Corollary 3.2, the conflict list of τ_f contains s_ℓ, so $\text{next}(\tau_f)$ cannot be s_i, contrary to assumption.

This induction step completes the proof of the lemma. □

As a consequence, it is easily verified by induction that, during the execution of this `Expand` step, including all recursive calls, no arc s_k with $k > i$ is processed.

We now show that each call to `Expand` terminates correctly.

LEMMA 3.5. *Each point-location query at the midpoint of a transient splitter generates a "compatible" transient trapezoid; that is, a transient trapezoid adjacent to the current transient trapezoid that has the same top and bottom arcs.*

Proof. Suppose the lemma is false, and consider the first call where this happens, where we order the calls in the order of returns from `Expand` (i.e., in postorder on the recursion forest). Let Δ be the transient trapezoid that initiated this call, and assume, without loss of generality, that the call started at the right splitter ν of Δ, and that the top and bottom edges of Δ are, respectively, s_i and s_j, with $i > j$. Arguing as in the proof of Lemma 3.4, we have that during the execution of the nonrecursive portion of this call, the procedure visits or generates a sequence Σ of trapezoids, each of which contains ν, and, by the induction hypothesis, all recursive calls that it executes terminate properly.

Let s_k, s_ℓ, with $k < \ell$, be the two arcs that intersect at the vertex w that induced

a splitter that contains ν (the case where w is an endpoint of an ark s_k is handled similarly). Clearly, we must have $k < \ell < i$. Moreover, w must lie above ν, or else the insertion of s_j would have disconnected ν from w; since s_i has not yet been inserted at that stage, it easily follows that ν could not have been formed at all. It is easily seen that any trapezoid $\tau \in \Sigma$ that contains ν in its interior must either contain s_k and s_ℓ in its conflict list or be bounded by s_k and contain s_ℓ in its conflict list. Hence, as can be easily verified, s_k and s_ℓ will eventually be processed in splitting operations during this execution and will consequently generate trapezoids in Σ that contain ν on their left edge. Moreover, either s_i and s_j appear in the conflict list of any such trapezoid, or s_i appears in the conflict list and s_j bounds the trapezoid on the bottom. Eventually, s_i will thus be inserted, and then the resulting trapezoid will be compatible with Δ and the procedure will terminate correctly, contrary to assumption. □

LEMMA 3.6. *For any final trapezoid Δ created by the* `Expand` *procedure, during the execution of* `CompZoneOnline`*, Δ is a trapezoid of $\mathcal{A}_{\mathcal{VD}}(S_i)$, where $i = \mathrm{index}(\Delta)$.*

Proof. The proof is shown by induction on the *depth* of the nodes in T, where the depth of a node is defined to be the length of the longest path from the root of T to this node.

The only node of depth 0 is the root of T, which is being computed during the initialization of the algorithm, and is also the only trapezoid in $\mathcal{A}_{\mathcal{VD}}(S_0)$.

Assume that the induction hypothesis holds for all trapezoids of depth $< k$, and let Δ be a final trapezoid of depth k in T. There are two cases to consider: (a) Δ has been generated by splitting a final trapezoid τ by inserting some arc s_i. (b) Δ has been obtained by merging several transient trapezoids.

In case (a), by induction hypothesis, τ is a trapezoid of $\mathcal{A}_{\mathcal{VD}}(S_j)$, where $j = \mathrm{index}(\tau)$. By Corollary 3.2, the conflict list of τ is computed correctly, so no arc s_ℓ, with $j < \ell < i$, crosses τ. Hence τ is also a trapezoid of $\mathcal{A}_{\mathcal{VD}}(S_{i-1})$, and, by construction, any final trapezoid obtained by splitting τ with s_i is a trapezoid of $\mathcal{A}_{\mathcal{VD}}(S_i)$. Since $i = \mathrm{index}(\Delta)$, this completes the induction step in this case.

In case (b), let $\tau_1, \ldots, \tau_m$ be the transient trapezoids whose merging forms Δ. By construction, all of them have the same top arc, say, s_i, and the same bottom arc, say, s_j. Suppose, without loss of generality, that $i > j$. Since these trapezoids are transient, we have, as argued above, $\mathrm{index}(\tau_\ell) = \mathrm{rank}(\tau_\ell) = i$ for each $\ell = 1, \ldots, m$. In particular, this also holds for the leftmost and rightmost trapezoids in this sequence, which is easily seen to imply that all the arcs in $D(\Delta)$ belong to S_i. Finally, since the conflict lists of the τ_ℓ's are computed correctly, and the conflict list of Δ is the union of these lists, it follows that no arc in that list belongs to S_i. In other words, Δ is a final trapezoid defined by arcs of S_i and no arc of S_i crosses its interior. This readily implies that Δ is a trapezoid of $\mathcal{A}_{\mathcal{VD}}(S_i)$, and this completes the induction step in this case, and thus completes the proof of the lemma. □

LEMMA 3.7. *All the (final) nonleaf nodes computed by* `CompZoneOnline` *appear in $\mathcal{HT}_\gamma$.*

Proof. What we really need to show is that each nonleaf-trapezoid Δ in T belongs to $\mathcal{A}_{\gamma,\mathcal{VD}}(S_{i-1})$, where s_i is the arc that has split Δ, thus making it a nonleaf. Indeed, any such trapezoid belongs to $\mathcal{HT}_\gamma$, by construction and by correctness of `CompZoneWithOracle`.

The proof proceeds by induction on the sequence of trapezoid-splitting steps taken by `CompZoneOnline`. That is, a final nonleaf-trapezoid Δ will be considered when it is split by an arc (thus becoming a nonleaf). The claim clearly holds initially for the

whole plane, stored at the root of T (and of $\mathcal{HT}_\gamma$). Let Δ be a nonleaf final trapezoid generated in T and then split by an arc s_i by `CompZoneOnline`, and suppose that all previously split nonleaf trapezoids in T appear in $\mathcal{HT}_\gamma$. The trapezoid Δ has been split as part of a point-location query with some point p. Suppose first that $p \in \gamma$ or p lies on a splitter of a final trapezoid of $\mathcal{A}_{\mathcal{VD}}(\hat{S})$. (The later case occurs when we expand the district of γ into its zone.) Since Δ is split at that point, it follows by construction that $p \in \Delta$ and therefore Δ belongs to $\mathcal{A}_{\gamma,\mathcal{VD}}(S_{i-1})$.

Otherwise, p is the midpoint of some transient splitter ν, and the point location of p is part of some `Expand` operation. Again, p (and in fact the whole segment ν) belongs to Δ. Let τ be the transient trapezoid bounded by ν that has triggered that `Expand` operation, and let τ_0 be the first transient trapezoid (in the execution order of `CompZoneOnline`) in the sequence of compatible trapezoids that includes τ. Let τ_f be the father of τ_0, which is a final (nonleaf) trapezoid from which τ_0 has been split by an arc s_j. By induction hypothesis, τ_f belongs to $\mathcal{A}_{\gamma,\mathcal{VD}}(S_{j-1})$. Hence τ_0 is fully contained (as a set) in the zone of γ in $\mathcal{A}(S_{j-1})$. By the preceding analysis, we know that (a) s_j is the top or bottom arc of τ_0 and of τ, and (b) during the whole `Expand` operation that started at τ_0 no arc beyond s_j is inserted. It follows that p belongs to the zone of γ in $\mathcal{A}(S_{j-1})$, and that s_i, the arc that has split Δ, must satisfy $i \leq j$. Hence Δ belongs to the zone of γ in $\mathcal{A}(S_{i-1})$, which establishes the induction step and thus completes the proof of the lemma. □

LEMMA 3.8. *All the trapezoids of $\mathcal{A}_{\gamma,\mathcal{VD}}(\hat{S})$ are computed by* `CompZoneOnline`.

Proof. Consider first the sequence of trapezoids of $\mathcal{A}_{\mathcal{VD}}(\hat{S})$ that constitute the district of γ in the full arrangement, in the order in which they are traversed by γ. The proof first proceeds by induction on this sequence, arguing that each of these trapezoids is produced by `CompZoneOnline`. As implied by the preceding analysis, each point-location query with a point p returns the trapezoid of $\mathcal{A}_{\mathcal{VD}}(\hat{S})$ that contains p. Hence, if the kth trapezoid in the above sequence has been generated, the $EscapePoint_\gamma$ function produces a point that lies in the next trapezoid, which will therefore also be produced by `CompZoneOnline`. A similar argument holds for the subsequent stage of the algorithm that expands the district of γ into its zone. □

3.2. Running time. In this subsection, we first analyze the performance of `CompZoneWithOracle` and then use this analysis to bound the expected running time of `CompZoneOnline`. We assume that `CompZoneWithOracle` maintains for each trapezoid Δ its conflict list $\mathrm{cl}(\Delta)$ that stores the set of arcs that cross it. We also assume that each conflict list $\mathrm{cl}(\Delta)$ stores its minimal element $\mathrm{next}(\Delta)$ in the ordering of S and that each yet uninserted arc s maintains a list of all current trapezoids Δ for which $\mathrm{next}(\Delta) = s$. Then it is easy to see that the running time of the algorithm is proportional to the overall size of all the conflict lists that it generates. We also assume that a call to the Oracle $\mathcal{O}$ takes $O(1)$ time.

LEMMA 3.9. *The algorithm* `CompZoneWithOracle` *computes the zone of γ in $\mathcal{A}_{\mathcal{VD}}(\hat{S})$ in $O\left(\lambda_{t+2}(n+m)\log n\right)$ expected time, and the expected number of trapezoids that it generates is $O\left(\lambda_{t+2}(n+m)\right)$.*

Proof. The proof is a straightforward adaptation of the proof of [9].[3] Specifically, we first make m cuts at the points where γ crosses the arcs of $\hat{S}$, thereby obtaining a collection of $m+n$ subarcs, so that $\mathcal{Z}_\gamma(\hat{S})$ becomes a single face in the new arrangement. We now insert the original arcs of $\hat{S}$ one by one in the random order S. It is easily checked that the expected number of subarcs of the r random arcs that have

[3]The algorithm of [9] has some additional overhead that is not required in `CompZoneWithOracle`.

been inserted is $O\left(r + \frac{m}{n}r\right)$. Thus, the expected number of trapezoids maintained in the rth iteration is $O\left(\lambda_{t+2}\left(r + \frac{m}{n}r\right)\right)$. Using the Clarkson–Shor sampling technique [10, 24] implies that the overall expected weight of those trapezoids in the rth iteration is $O(\lambda_{t+2}(n+m))$. However, the expected work in the rth iteration is the expected weight of the newly created trapezoids, and the probability of a trapezoid (that appears in the set of trapezoids maintained by the algorithm after the rth iteration) to be created in the rth iteration is $O(1/r)$. We conclude that the expected work in the rth iteration is $O(\lambda_{t+2}(n+m)/r)$. Summing over $r = 2, \ldots, n$, we conclude that the expected overall running time of the algorithm is $O(\lambda_{t+2}(n+m)\log n)$. ∎

LEMMA 3.10. *The expected number of transient trapezoids generated by* `CompZoneOnline` *is* $O(\lambda_{t+2}(n+m))$*, and the expected total size of their conflict lists is* $O(\lambda_{t+2}(n+m)\log n)$*.*

Proof. Each final trapezoid generated by `CompZoneOnline` might be split into $O(1)$ transient trapezoids. Each final (nonleaf) trapezoid computed by `CompZoneOnline` is also computed by `CompZoneWithOracle`, as follows from Lemma 3.7. By Lemma 3.9, the expected number of such trapezoids is $O(\lambda_{t+2}(n+m))$.

The second part of the lemma follows by a similar argument. ∎

DEFINITION 3.11. *A curve* γ *is* locally x-monotone *in* $\mathcal{A}(\hat{S})$ *if it can be decomposed inside each face of* $\mathcal{A}(\hat{S})$ *into a constant number of* x*-monotone curves.*

THEOREM 3.12. *The algorithm* `CompZoneOnline` *computes the zone of* γ *in* $\mathcal{A}(\hat{S})$ *in* $O\left(\lambda_{t+2}(n+m)\log n\right)$ *expected time, provided that* γ *is a locally* x*-monotone curve in* $\mathcal{A}(\hat{S})$*.*

Proof. The time spent by `CompZoneOnline` is bounded by the time required to construct the history DAG, by the time spent in maintaining the conflict lists of the trapezoids, and by the time spent on performing point-location queries, as we move from one trapezoid to another in $\mathcal{A}_{\gamma,\mathcal{VD}}(S)$.

By Lemmas 3.9 and 3.10, the expected time spent on maintaining the conflict lists of the trapezoids computed by the algorithm is $O(\lambda_{t+2}(n+m)\log n)$, since the total time spent on handling the conflict lists is proportional to their total length. By Lemma 3.10, the expected total size of those conflict lists is $O(\lambda_{t+2}(n+m)\log n)$.

Moreover, the depth of the history DAG constructed by the algorithm is $O(\log n)$ with a probability polynomially close to 1 [24]. Thus, the expected time spent directly on performing a single point-location query (that is, the number of trapezoids that contain the query point and are visited or generated during this point-location step) is $O(\log n)$. The curve γ is locally x-monotone, which implies that it intersects each splitter of any trapezoid of any $\mathcal{A}_{\gamma,\mathcal{VD}}(\hat{S})$ at most $O(1)$ times. Thus, the expected number of point-location queries performed by the algorithm is proportional to the expected number of transient and final trapezoids created, plus $O(m)$. By Lemma 3.10, we have that the expected running time is

$$O\left(\lambda_{t+2}(n+m)\log n + (\lambda_{t+2}(n+m)+m)\log n\right) = O\left(\lambda_{t+2}(n+m)\log n\right). \quad ∎$$

REMARK 3.13. *Note that* `CompZoneWithOracle` *computes the zone of* γ *in* $\mathcal{A}_{\mathcal{VD}}(S_i)$ *for each* $i = 1, \ldots, n$*. As a consequence, it might compute a trapezoid* $\Delta \in \mathcal{A}_{\gamma,\mathcal{VD}}(S_i)$ *that does not intersect the zone of* γ *in* $\mathcal{A}_{\gamma,\mathcal{VD}}(S)$*. In particular, such a trapezoid* Δ *will not be computed by* `CompZoneOnline`*. This is a slackness in our analysis that we currently do not know whether it can be exploited to further improve the analysis of the algorithm. (We suspect that it cannot improve the above asymptotic bound on the running time.)*

REMARK 3.14. *The only classical result of this type that we are aware of is due to Overmars and van Leeuwen* [25]. *It maintains dynamically the intersection of n half-planes in (deterministic) $O(\log^2 n)$ time for each insertion or deletion operation. This procedure can be used to perform walks inside line arrangements in (deterministic) $O((n+m)\log^2 n)$ time, where m is the number of intersections of the walk with the lines. Our algorithm is somewhat simpler and is faster than the algorithm of* [25] *by nearly a logarithmic factor, and, most importantly, applies to more general arrangements.*[4]

The technique of [25] *can also be used to perform* x-monotone *online walks in arrangement of segments. We simply regard each segment as the full line that contains it, but make it active only when the walk passes vertically above or below the segment. This means that, in addition to the usual updates that the algorithm performs, we also insert (resp., delete) segments when the walk becomes covertical with their left (resp., right) endpoint. (If the walk is not x-monotone, this may slow down the algorithm considerably.)*

As for general arcs (or nonmonotone walks in arrangements of segments), we are not aware of any result of this type in the literature. Of course, if the curve γ is known in advance (and is simple, in the sense that one can compute quickly its intersections with any arc of $\hat{S}$), we can compute the single face containing γ in an appropriately modified arrangement (as in the proof of the general planar zone theorem [26, *Theorem* 5.11]*; see also the proof of Lemma* 3.9 *using the algorithms of* [11, 9]. *These algorithms (especially the first one) are slightly simpler than the algorithm of Theorem* 3.12, *although they have the same expected performance. However, these algorithms are useless for online walks, and they are probably slower than our algorithm in practice, as they either maintain additional complicated data-structures* [9] *or perform additional redundant computation of regions that lie outside the zone of γ* [11].

Recently, several algorithms for performing online walks were implemented [3], *including a variant of the algorithm presented here, which exhibited satisfactory performance in practice.*

4. Applications. In this section we present several applications of the algorithm `CompZoneOnline`.

4.1. Computing a level in an arrangement of arcs. In this subsection we show how to modify the algorithm of the previous section to compute a level in an arrangement of x-monotone arcs.

DEFINITION 4.1. *Let $\hat{S}$ be, as above, a set of n x-monotone arcs in the plane, any pair of which intersect at most t times (for some fixed constant t). We also assume, as above, that $\hat{S}$ is in general position. The* level *of a point in the plane is the number of arcs of $\hat{S}$ lying strictly below it. Consider the closure E_l of the set of all points on the arcs of $\hat{S}$ having level l (for $0 \leq l < n$). E_l is an x-monotone (not necessarily connected) curve (which is polygonal in the case of lines or segments), which is called the* level l *of the arrangement $\mathcal{A}(\hat{S})$. At x-coordinates where a vertical line intersects less than $l+1$ arcs of S, we consider E_l to be undefined.*

Levels are a fundamental structure in computational and combinatorial geometry and have been subject to intensive research in recent years (see [1, 13, 27, 28]). Tight

[4]Recently, Chan [7] improved the result of [25], providing a data structure for maintaining intersection of half-planes in $O(\log^{1+\varepsilon} n)$ amortized time for each update. His data structure is considerably more complicated than ours and that of Overmars and van Leeuwen, and currently seems to be only of theoretical significance. Moreover, our algorithm is still faster than Chan's (by a factor of $O(\log^{\varepsilon} n)$). Very recently, this result was further improved by [6].

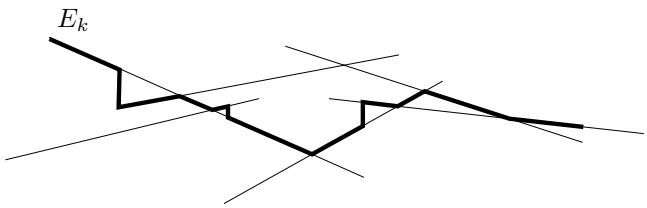

FIG. 5. *The first level in an arrangement of segments. (The vertical edges show the jump discontinuities of the level, but are not part of the level.)*

bounds on the complexity of a single level, even for arrarngements of lines, proved to be surprisingly hard to obtain. Currently, the best-known upper bound for the case of lines is $O(n(l+1)^{1/3})$ [13], while the lower bound is $\Omega(n \log(l+1))$ [14].[5] See also [1, 28] for weaker upper bounds for other classes of arcs.

First, note that if $\hat{S}$ is a set of lines, then, once we know the leftmost ray that belongs to E_l, the level l is locally defined: as we move from left to right along E_l, each time we encounter an intersection point (a vertex of $\mathcal{A}(\hat{S})$) we have to change the line that we traverse. (This is also depicted in Figure 5.) In particular, we can compute the level E_l in $O(\lambda_3(n+|E_l|)\log n)$ time using `CompZoneOnline`. The same procedure can be used to compute a level in an arrangement of more general arcs. The only nonlocal behavior we have to watch for are jump discontinuities of the level caused when an endpoint of an arc appears below the current level, or when the current level reaches an endpoint of an arc (see Figure 5). See below for details concerning the handling of those jumps.

In the following, let $0 \le l < n$ be a prescribed parameter. Let E_l denote the level l in the arrangement $\mathcal{A}(\hat{S})$.

The following adaptation of `CompZoneOnline` to our setting is rather straightforward, but we include it for the sake of completeness. We sort the endpoints of the arcs of $\hat{S}$ by their x-coordinates. Each time our walk reaches the x-coordinate of the next endpoint, we update E_l by jumping up or down to the next arc, if needed. This additional work requires $O(n \log n)$ time.

If the level reaches the x-coordinate x_0 of a right endpoint of an arc, past which there are fewer than $l+1$ arcs intersecting a vertical line, then the level lies on the highest arc just to the left of x_0 and it ceases to be defined just to the right of x_0. In this case, our walk climbs to the line $y = +\infty$ and moves along the line (effectively tracing a sequence of topmost trapezoids of $\mathcal{A}(\hat{S})$) until it reaches the x-coordinate of a left endpoint of an arc, following which we might have again $l+1$ arcs crossing a vertical line. If so, the walk then descends on the topmost arc and continues to trace the level l. For simplicity, we continue the discussion of the algorithm assuming that E_l is everywhere defined.

During the walk, we maintain the invariant that the top edge of the current trapezoid is part of E_l. To compute the first trapezoid in the walk, we compute the intersection of level l with the y-axis (this can be done by sorting the arcs according to their intersections with the y-axis). Let p_0 be this starting point. We perform a point-location query with p_0 in our virtual history DAG to compute the starting trapezoid Δ_0 (containing p_0 on its top arc).

Now, by walking to the right of Δ_0 we can compute the part of E_l lying to the

[5] Recently, a slightly larger lower bound has been announced by Tóth [29].

right of the y-axis. Let Δ be the current trapezoid maintained by the algorithm, such that its top edge is a part of E_l. Let $p(\Delta)$ denote the top right vertex of Δ. By performing point-location queries in our partial history DAG T, we can compute all the trapezoids of $\mathcal{A}_{\mathcal{VD}}(\hat{S})$ that contain $p(\Delta)$. (By our general position assumption, the number of such trapezoids is at most 6; this number materializes when $p(\Delta)$ lies in the intersection of two arcs.) By inspecting this set of trapezoids, one can decide where E_l continues to the right of Δ and determine the next trapezoid having E_l as its roof. The algorithm sets Δ to be this trapezoid.

If the algorithm reaches an x-coordinate of an endpoint of an arc, we have to update E_l by jumping up (if this is the right endpoint of an arc and it lies on or below the level) or down (if it is a left endpoint and lies below the level); namely, we set Δ to be the trapezoid lying above (or below) the current Δ.

The algorithm continues in this manner until reaching the rightmost edge of E_l. The algorithm then performs a symmetric walk to the left of the y-axis to compute the other portion of the level.

Let `CompLevel` denote this modified algorithm. We summarize our result as follows.

THEOREM 4.2. *The algorithm* `CompLevel` *computes the level l in $\mathcal{A}(\hat{S})$ in $O\left(\lambda_{t+2}(n+|E_l|)\log n\right)$ expected time.*

REMARK 4.3. *Since* `CompLevel` *is online, we can use it to compute the first m' edges or vertices of E_l in expected $O(\lambda_{t+2}(n+m')\log n)$ time.*

REMARK 4.4. *A straightforward extension of* `CompLevel` *allows us to compute any connected path within the union of $\hat{S}$ (i.e., we restrict our "walk" to the arcs of $\hat{S}$) in an online manner, in randomized expected time $O\left(\lambda_{t+2}(m+n)\log n\right)$, where m is the number of vertices of the path. As above, the extended version can also handle vertical jumps between adjacent arcs during the walk.*

REMARK 4.5. *For the case of lines, one can use the algorithm of* [25] *to construct a level E_l in $O(n\log n+|E_l|\log^2 n)$ deterministic time, as described, e.g., in* [15]. *The same technique, with a simple modification, also works for the case of line segments, with the same complexity bounds. Our algorithm is faster in these cases by nearly a logarithmic factor.*

As already mentioned, recently Chan [7] *presented a faster algorithm for the dynamic maintenance of the intersection of half-planes, requiring $O(\log^{1+\varepsilon} n)$ amortized time for each operation. Thus, one can compute the level l in $O(n\log n+|E_l|\log^{1+\varepsilon} n)$ deterministic time. Chan* [8] *also showed that by using the algorithm of* [2] *one can compute the level l in $O(n+|E_l|\alpha(n)^2\log n)$ randomized expected time. Those results were very recently improved by Brodal and Jacob* [6]. *We note, however, that our algorithm is still faster and simpler than those two algorithms.*

4.2. Other applications. In this subsection, we provide some additional applications of `CompZoneOnline` and `CompLevel`.

THEOREM 4.6. *Let L be a set of n lines in the plane, and let $0<\varepsilon\leq 1$ be a prescribed constant. Then one can compute a $(1/r)$-cutting of $\mathcal{A}(L)$, having at most $(1+\varepsilon)(8r^2-2r+4)$ trapezoids. The expected running time of the algorithm is $O\left(\left(1+\frac{1}{\varepsilon}\right)nr\alpha(n)\log n\right)$, where $\alpha(n)$ is the inverse of the Ackermann function* [26].

Proof. We obtain the proof by plugging the algorithm of Theorem 4.2 and Remark 4.3 into the algorithm described in [18]. □

For a discussion of cuttings of small asymptotic size and their applications, see [22, 18].

REMARK 4.7. *Theorem* 4.6 *improves the previous result of* [18] *by almost a logarithmic factor.*

Once we have computed the level l (in an arrangement of general arcs), we can clip the arcs to their portions below the level. Using those clipped arcs as input, we can compute the portion of the arrangement below the level l (i.e., the first l levels of $\mathcal{A}(\hat{S})$) in $O((m+n)\log n+r)$ time, where $m = |E_l|$ is the complexity of the level l, and r is the complexity of the first l levels of $\mathcal{A}(\hat{S})$, using, e.g., the algorithm described in [24]. This improves over the previous result of [16] that computes this portion of the arrangement of lines in $O(n \log n + nl)$ time. (Note that this running time is *not* output sensitive: It is easy to come up with examples where the complexity of the first l levels is only $O(l^2)$.)

5. Implementation. The algorithm described in this paper was implemented and compared to some other heuristics/algorithms for constructing zones in an online manner for an arrangement of lines; see [3]. The source code of our program is available from [19]. We had implemented a competing algorithm, the following variant `CompZonePoly`, which differs from `CompZoneOnline` in the following two key points:

- `CompZonePoly` does not perform merging of adjacent compatible regions. Thus, the history DAG is now a tree.
- Each node in the history tree corresponds to a convex polygon of bounded complexity. Namely, if the polygon that corresponds to a node has more than c edges (where c is a prescribed constant), then the polygon is being further split into two regions, and the corresponding node becomes the parent of two new nodes. The motivation for this variant is that the average number of vertices of a face in an arrangement of lines is about 4. Thus, in this representation most faces (and intermediate faces) will correspond to a single node in the history tree.

Currently, we do not have any bounds on the performance of `CompZonePoly` and we leave it as an open question for further research. Nevertheless, `CompZonePoly` performs extremely well in practice and was one of the two fastest algorithms tested in [3].

5.1. Geometric filtering. To overcome the problems of robustness and degeneracies, we had used the exact arithmetic as provided by the rational numbers of LEDA [23]. Unfortunately, using exact arithmetic in a naive way slows the program by a factor of 20–40 [18]. One possible way to achieve reasonable performance is to use filtering techniques. Here, one uses representation of numbers that maintain the history of the computations that generated them, so that if necessary the computations are recomputed using a higher level of precision. Such arithmetic types are provided by LEDA real and LEDA rational kernel. While filtering may be a carefree approach to this problem, as one can apply it easily to a program without rewriting, its performance is still inferior compared to the technique described below.

The idea is to implement filtering in the geometric level. Here each geometric entity has two representations: one is a floating-point representation (i.e., inexact) and the other one is an implicit exact representation. For example, a point is represented in its floating-point Cartesian representation and its logical representation; that is, the geometric operations and entities used to create it. For example, a point p might be defined to be the point lying on the line l and having the same x-coordinate as a point q.

Thus, when a geometric primitive is being called, it is first computed using floating-point arithmetic. If the computation result lies below a certain threshold,

then the algorithm recomputes the primitive using exact arithmetic. This might require computing the exact representation of the points and lines used in this primitive. While in general this is worse than arithmetic filtering, it performs better in our scenario, as the depth of computation of vertices and edges in planar arrangement is bounded.

Furthermore, since this representation preserves the combinatorial information, one can use this information to resolve geometric decisions without resorting to exact arithmetic. For example, consider a point p that is defined to be the intersection point between the lines l_1, l_2, and the algorithm calls a primitive `isOnLine` to decide if p lies on the line l_1. Here, after the floating-point predicate had failed, the predicate decides using the logical representation of $p = l_1 \cap l_2$ that it lies on l_1, and thus it return `true`.

Note that this is a scenario where arithmetic filtering will perform badly, for in this case the arithmetic filtering will first carry out the computations using floating-point arithmetic, and after those operations fail the computations will be reperformed using a higher level of precision, using some kind of a gap-bound so that it resolves the predicate correctly.

We refer to the above approach as *geometric filtering*. It seems to be the most natural approach to the problem of robustness, although the considerable benefits of this approach in practice are not widely known. For example, in the case of the algorithms of [3], the usage of geometric filtering speeded up the algorithms by a factor of 2–3. In practice, virtually all computations are performed using floating-point arithmetic, and only negligible part of the computations resort to exact arithmetic.

A very similar idea was recently implemented by Funke and Mehlhorn [17]. For further details about our approach, see [19].

5.2. Empirical results. The testing was carried out using the inputs of [3], and the results are depicted in Table 1. The tests were performed on a dual Pentium II 450MHz with 512MB memory using Linux. Each entry in the table is the average of 25 executions of the program on this input. As can be seen from the table, `CompZoneOnline` is considerably slower (by a factor 2–8) than `CompZonePoly`.

The disappointing performance provided by `CompZoneOnline` is mainly caused by the expensive `Expand` operations (involving repeated point-location queries in the DAG). Of course, `CompZonePoly` does not perform `Expand` operations. Furthermore, as testified by Table 1, the usage of vertical trapezoids by `CompZoneOnline` is inherently inefficient as it blows up the number of nodes in the associated history structure by a factor of 2–3 compared to the number of nodes created by `CompZonePoly`.

In addition, the implementation of `CompZonePoly` associates with each line l in the conflict list of a region P, the two edges of ∂P that l intersects. When computing the conflict lists of the children of the node that corresponds to P, one can sometimes compute what conflict lists l belongs to without executing a single geometric primitive. It is not clear how one can implement a similarly efficient scheme for the computation of the conflict lists of vertical trapezoids.

6. Conclusions. In this paper we have presented a new randomized algorithm for computing a zone in a planar arrangement in an online fashion. This algorithm is the first efficient algorithm for the case of planar arcs, it performs faster (by nearly a logarithmic factor) than the algorithm of [25] for the case of lines and for the case of an x-monotone walk in an arrangement of segments, and it is considerably simpler. (It is also faster and much simpler than the recent algorithm of [7].) We also presented an efficient randomized algorithm for computing a level in an arrangement of arcs in

TABLE 1

Results for the two implemntations. Running times are in seconds. The number of nodes created by `CompZoneOnline` *is considerably larger than the final number of nodes in the resulting DAG, as the algorithm merge nodes during its execution.*

the plane, whose expected running time is faster than any previous algorithm for this problem.

The main result of this paper relies on the application of point-location queries to compute the relevant parts of an "offline" structure (i.e., the history DAG). The author believes that this technique should have additional applications. In particular, this approach might be useful also for algorithms in higher dimensions. We leave this as an open question for further research.

Although the resulting algorithm seems to be only a minor variant of previous algorithms [11, 9], the author believes that the new algorithm supersedes those algorithms: (i) Implementing the new algorithm was quite easy and does not require any advanced data-structure. In particular, since the algorithm does not keep geometric adjacency information in the vertical decomposition (unlike previous algorithms) its implementation is thus considerably easier. (ii) The algorithm only computes what it *must* compute, while [11] performs a lot of redundant computations. (iii) The algorithm provides a powerful data-structure for online computation of parts of an arrangement, where the computation time is the same as a randomized incremental algorithm that uses an oracle. This enables one to compute a portion of an arrangement in a completely arbitrary order, in time identical to the time spent by a optimal randomized incremental algorithm. See [21, 20] for results that use this observation.

It is somewhat surprising that in most applications that use Overmars and van Leeuwen [25] (or Chan [7] improvement) data-structure—which is more flexible than our data-structures since it allows insertion and deletion—one can use our algorithm instead and the resulting algorithms are always faster. See [21] for more details.

The empirical results testify that this algorithm is practical, although it is slower than the heuristic `CompZonePoly` we had also tested. We currently do not have any proof of performance bounds for `CompZonePoly`, and we leave this as a question for further research. Another striking conclusion from the empirical tests is that using vertical decomposition in practice is not as efficient as using polygons having constant complexity; see [3, 18] for similar results. It seems that planar vertical decomposition should be avoided in practice, as they give inferior performance. An additional reason for avoiding vertical decompositions in practice is their vulnerability to degeneracies (for example, several vertices of the arrangement having the save x-coordinate, etc). However, if one computes the zone in arrangement of segments, or of general arcs, it seems that the usage of vertical trapezoids is most natural. We believe that in such scenarios `CompZoneOnline` will perform reasonably well compared to other algorithms.

Appendix A. Pseudocode for subroutines of `CompZoneOnline`. See Figures 6–9.

```
ALGORITHM Split(v).
   Input: A final node v in the partial history DAG T
begin
   s ← next(Δ_v), where Δ_v is the trapezoid associated with the node v
   L ← SplitGeom(Δ_v, s),
         where SplitGeom(Δ_v, s), as above, returns the collection of trapezoids
         that cover Δ_v, so that s does not intersect any of them in its interior.
   for each τ ∈ L do
      Create a new node w and attach it as a child of v in T.
      Set Δ_w to τ
      Compute cl(Δ_w) from cl(Δ_v)
      Compute next(Δ_w), the first element of cl(Δ_w)
   end for
end Split
```

FIG. 6. *Splitting a final node in T and creating its children.*

```
ALGORITHM PointLocateLeftCompatible(v, p, r).
   Input:  v - current node of T
           p - query point
           r - target rank of output trapezoid
   Output: A transient trapezoid of rank r having p on its left splitter
begin
   if rank(v) = r then
      return v
   if isTransient(v) then
      v ← Expand(v)
   if isLeaf(v) then
      Split(v)
   Let w be the child of v, so that Δ_w contains p either in its interior
         or on its left splitter
   return PointLocateLeftCompatible( w, p, r )
end PointLocateLeftCompatible
```

FIG. 7. *Computing a transient trapezoid in T that is left "compatible" with an input transient trapezoid by carrying out a point-location query in T. The algorithm also uses a symmetric routine,* `PointLocateRightCompatible`, *whose code is omitted.*

```
ALGORITHM Expand(v).
   Input:  v - current transient leaf node of T
   Output: A final node of T whose trapezoid contains Δ_v
begin
   if isFinal(Δ_v) then
      return v
   L ← {v}

   /* collect the sequence of transient trapezoids adjacent to each other
      to the right of Δ_v */
   temp ← v
   while isTransientRightSplitter(Δ_temp) do
      temp ← PointLocateLeftCompatible( root(T),
                    midPointRightSplitter( Δ_temp), rank(Δ_temp) )
      L ← L ∪ {temp}
   end while

   /* Similarly collect the sequence of transient trapezoids to the left of Δ_v */
   temp ← v
   while isTransientLeftSplitter(Δ_temp) do
      temp ← PointLocateRightCompatible( root(T),
                    midPointLeftSplitter( Δ_temp), rank(Δ_temp) )
      L ← L ∪ {temp}
   end while

   Δ ← ⋃_{u∈L} Δ_u
   Compute cl(Δ) and next(Δ) from the conflict lists of the
      nodes of L, using the global bit-vector technique.
   Add a new leaf node x to the partial history DAG T, mark x as final,
         and replace all nodes of L in T by x.
   Set Δ_x to Δ

   return x
end Expand
```

FIG. 8. *Expanding a transient leaf trapezoid of T to a final trapezoid containing it.*

```
ALGORITHM PointLocate( p, flag ).
   Input:  p - a query point
           flag - since p usually lies on the boundary of a trapezoid, flag
                  indicates the side of the splitter or arc that contains p
                  where the point location should take place
   Output: The trapezoid of A_VD(Ŝ) that contains p (in its interior
           or on the appropriate edge dictated by flag)
begin
   v ← root(T)

   while ( cl(Δ_v) ≠ ∅ ) do
      Expand(v)
      Split(v)
      v ← child of v whose trapezoid contains p; if p lies on
          the boundary of several children trapezoids, choose the one
          that is compatible with flag
   end while

   return Δ_v
end PointLocate
```

FIG. 9. *The function that performs a point-location query; that is, it computes the necessary parts of the partial history DAG T and returns the trapezoid of $\mathcal{A}_{\mathcal{VD}}(\hat{S})$ that contains a query point.*

Appendix B. Taking a walk in ten easy figures. In this appendix we illustrate step by step the action of processing a single point-location query by `CompZoneOnline`. (See Figures 10–19.)

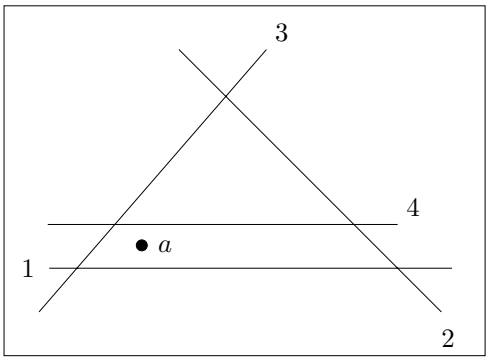

FIG. 10. *The input for* `CompZoneOnline` *is the set of segments $\hat{S} = \{1, 2, 3, 4\}$. We assume that the algorithm uses the permutation $S = (1, 2, 3, 4)$. We illustrate how* `CompZoneOnline` *carries out a point-location query to compute the trapezoid of $\mathcal{A}_{\mathcal{VD}}(\hat{S})$ that contains the point a. We assume that this is the first query processed by the algorithm.*

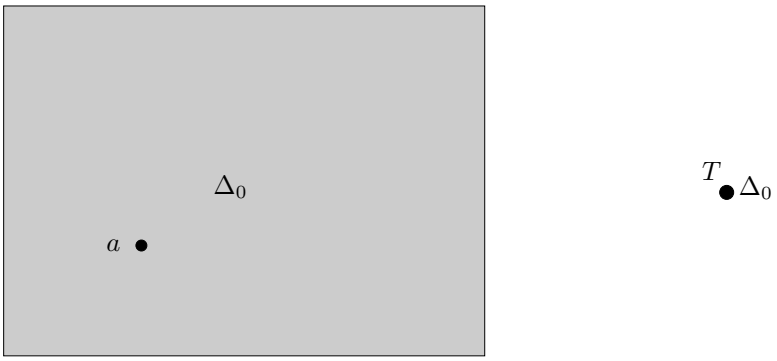

FIG. 11. `CompZoneOnline` *starts with the trapezoid* $\Delta_0 = \mathbb{R}^2$ *that corresponds to the root of the partial DAG* T.

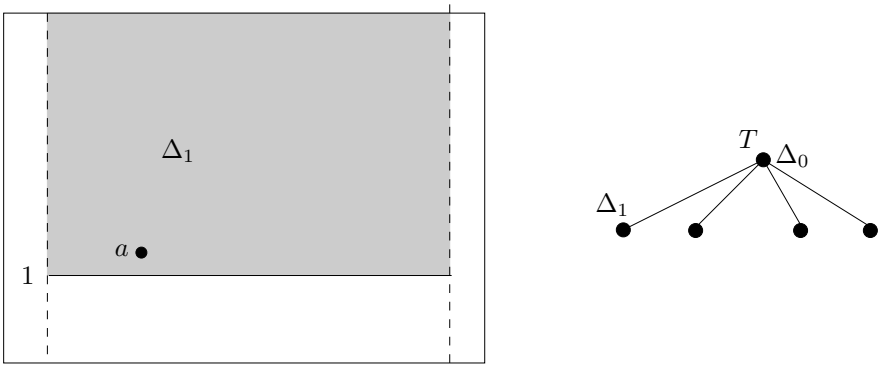

FIG. 12. `CompZoneOnline` *splits* Δ_0 *by the segment* $\text{next}(\Delta_0) = 1$, *and goes down in the DAG into the new node that corresponds to the trapezoid* Δ_1. *All children of* Δ_0 *(including* Δ_1*) are final.*

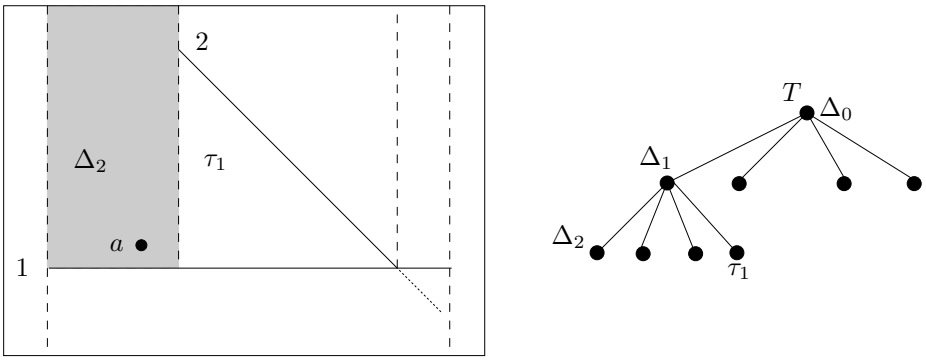

FIG. 13. *Since* Δ_1 *is final, it is split by* $\text{next}(\Delta_1) = 2$ *into four final subtrapezoids, and we go down to the child* Δ_2 *that contains* a.

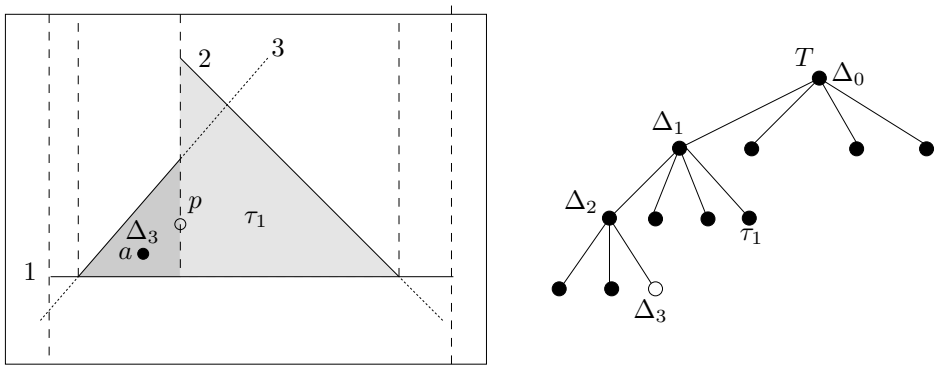

FIG. 14. `CompZoneOnline` *splits* Δ_2 *by* $\text{next}(\Delta_2) = 3$ *into three subtrapezoids. Two of them are final, and the third one,* Δ_3*, that contains* a *is transient (its right splitter is transient). We thus execute* `Expand`(Δ_3)*, which performs a point-location query (with the midpoint* p *of the right splitter). The point location goes down in the partial DAG, through* Δ_0 *and* Δ_1*, and reaches the (final) leaf that stores* τ_1*. Since* $\text{rank}(\Delta_3) = 3$ *and* $\text{rank}(\tau_1) = 2$*, those two trapezoids are not compatible (this holds also because* τ_1 *is final, whereas* Δ_3 *is not), and the algorithm continues by further splitting* τ_1 *by* $\text{next}(\tau_1) = 3$.

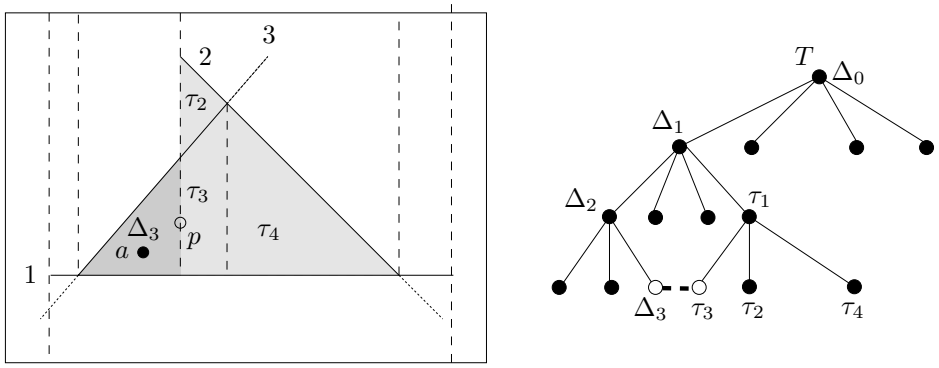

FIG. 15. *The splitting of* τ_1 *creates three children* τ_2, τ_3, τ_4*, of which* τ_2 *and* τ_4 *are final, whereas* τ_3 *is transient.* `CompZoneOnline` *goes down to the newly created* τ_3*, which contains* p *on its left splitter. Since* τ_3 *is transient and* $\text{rank}(\tau_3) = \text{rank}(\Delta_3)$*, it is compatible with* Δ_3*. Since the right splitter of* τ_3 *is final, and so is the (empty) left splitter of* Δ_3 *the execution of* `Expand`(Δ_3) *terminates.*

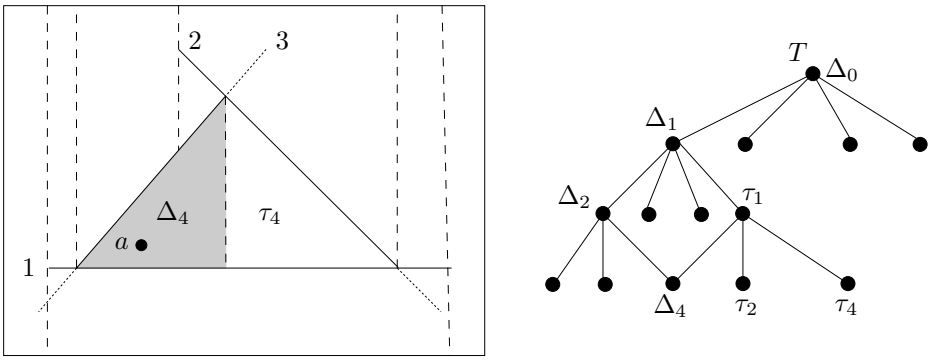

FIG. 16. *The trapezoids* Δ_3 *and* τ_3*, from the previous figure, are merged by* `CompZoneOnline` *to form the final trapezoid* Δ_4*. Since* $\mathrm{cl}(\Delta_4)$ *is not empty, we split it further by* $\mathrm{next}(\Delta_4) = 4$*.*

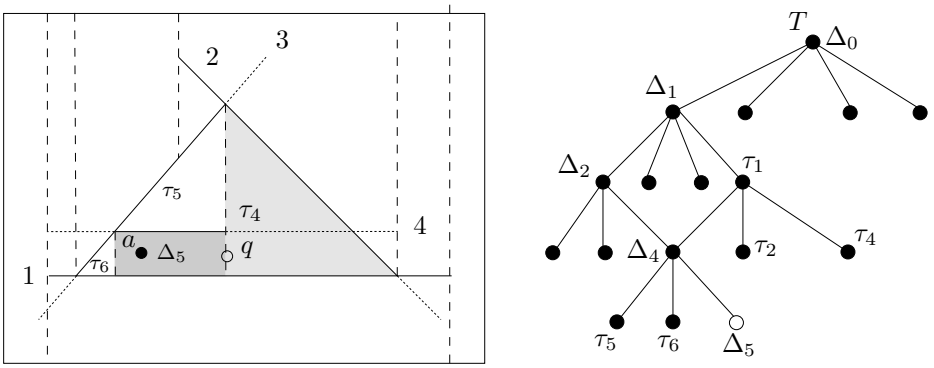

FIG. 17. *The splitting of* Δ_4 *creates three children* Δ_5, τ_5, τ_6*, of which* τ_5 *and* τ_6 *are final, whereas* Δ_5 *is transient and contains* a*.* `CompZoneOnline` *goes into* Δ_5*, and since it is transient,* `CompZoneOnline` *calls* `Expand`(Δ_5)*. A point-location query is performed at the midpoint* q *of the right splitter of* Δ_5*. This query traverses in* T *the path* $(\Delta_0, \Delta_1, \tau_1, \tau_4)$*. The (final) trapezoid* τ_4 *is not compatible with* Δ_5 *so it is further split by the segment* $\mathrm{next}(\tau_4) = 4$*.*

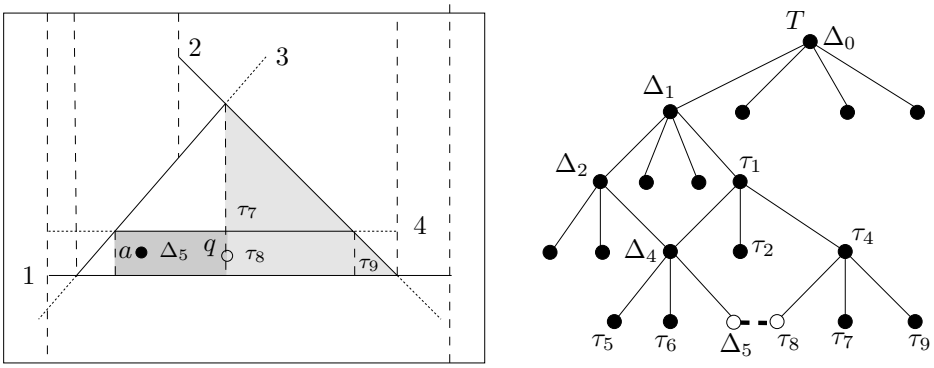

FIG. 18. τ_4 *is split into* τ_7, τ_8, τ_9*, of which only* τ_8 *is transient.* `CompZoneOnline` *goes into* τ_8*, which contains* q *on its left splitter. This trapezoid is compatible with* Δ_5*, and since both the left splitter of* Δ_5 *and the right splitter of* τ_8 *are final,* `Expand`(Δ_5) *terminates and merges both trapezoids.*

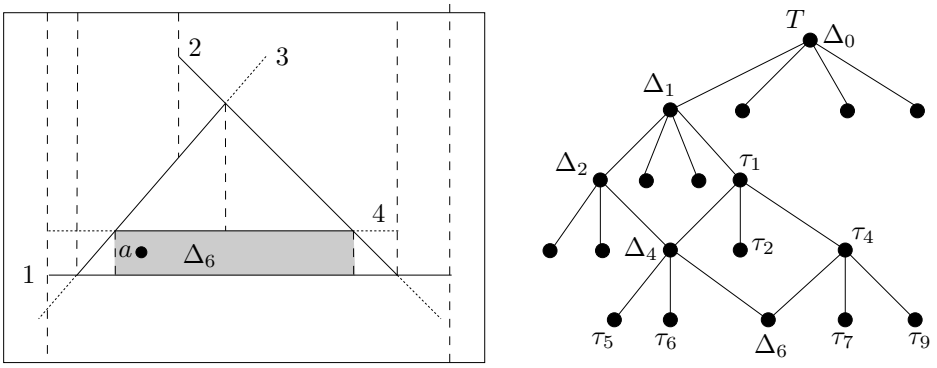

FIG. 19. *Voila! The newly formed final trapezoid Δ_6 contains our query point a, and its conflict list is empty. Thus, Δ_6 is the trapezoid of $\mathcal{A}_{\mathcal{VD}}(\hat{S})$ that contains a and is output as such by* `CompZoneOnline`.

Acknowledgments. The author wishes to thank Pankaj Agarwal, Danny Halperin, Chaim Linhart, and Micha Sharir for helpful discussions concerning the problems studied in this paper and related problems.

FINDING SETS COVERING A POINT WITH APPLICATION TO MESH-FREE GALERKIN METHODS*

XIAOXU HAN†, SUELY OLIVEIRA‡, AND DAVID STEWART†

Abstract. For a collection of sets in $\mathbf{R}^d$ we consider the task of finding all sets in the collection that cover or contain a given point. The algorithms introduced in this paper are based on quadtrees and their generalizations to $\mathbf{R}^d$. The advantages of our new splitting algorithm to find the covering sets of a point over the basic algorithm are detailed by means of hit rates and the expected depth traversed in the quadtree search, numerically and theoretically. This solves a difficult problem faced by mesh-free discretizations of partial differential equations.

Key words. quadtree and octree search methods, computational geometry

1. Introduction.

The task of this paper is, given a collection of support sets $S_i \subset \mathbf{R}^d$, $i = 1, 2, \ldots, N$, to efficiently answer the query "*Given a point $x \in \mathbf{R}^d$, find all S_i such that $x \in S_i$.*" This task arises when assembling the matrix for a mesh-free discretization of a partial differential equation. The sets S_i are the support sets of the basis functions used to solve the partial differential equation. They are typically rectangles with modest aspect ratios, or circles/spheres in $\mathbf{R}^d$ with d being 2, 3, or 4. An example of such a problem is illustrated in Figure 1.

One way to answer this query quickly is to organize the S_i using quadtrees and octrees [5, 9, 13]. Clearly the time needed to answer this query is at least $\Omega(\#\{\, i \mid x \in S_i \,\})$ where $\#A$ is the cardinality of the set A. The quantity $\#\{\, i \mid x \in S_i \,\}$ is the covering number of x; it is the number of support sets containing (that is, covering) the point x. Quadtrees and octrees have been found useful in geometric tasks such as finding which points from a collection belong to a given *range* [3]. For a task involving preprocessing a collection of points, quadtrees and octrees can be considered as *tries,* such as are used for string matching [2]. However, the task studied in this paper involves preprocessing a collection of *sets* $\{\, S_i \subset \mathbf{R}^d \mid i = 1, 2, \ldots, N \,\}$ rather than a collection of points. Also note that this task is not the point location problem previously studied [11, 12], in that here the sets S_i are usually not disjoint. Our analysis is also different to that of [11, 12] in that here we are concerned with the expected time for a random query point x, rather than with worst-case analysis. While the data structures described here are those of Samet [15], Samet considers their use only for the intersection problem: find all pairs (i, j) where $S_i \cap S_j \neq \emptyset$. Here we wish, given x, to find all i where $x \in S_i$.

For each point x and support set S_i, we assume that we can test if $x \in S_i$ in $\Theta(1)$ time. The point about using quadtrees/octrees or other similar data structures is that we can avoid doing unnecessary tests. The total time to answer a query can be

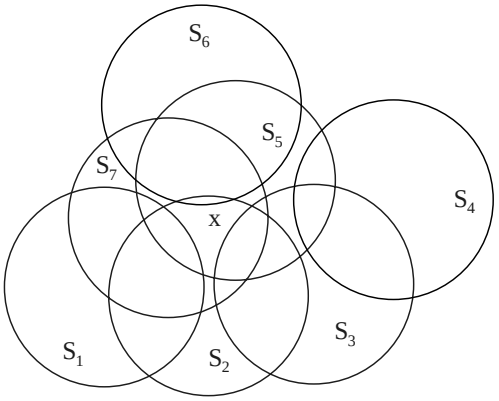

FIG. 1. *Example of distribution of support sets S_i.*

roughly divided up into the time needed to traverse the data structure plus the time to perform the tests to identify the support sets containing x. Since the best we can do is to have a "hit" (i.e., $x \in S_i$) whenever we test for "$x \in S_i$," we are interested in the "hit rate," which is the ratio of hits to the total number of tests, averaged over all the integration points. In particular, we don't want this to go to zero; and if the hit rate can be bounded away from zero, then the number of tests is, at worst, proportional to the average covering number of the sets $\{ S_i \mid i = 1, 2, \ldots, N \}$. We will show that the average time to traverse the quadtree is no worse than $O((\log N)/d)$ for both algorithms that we will present, so that the traversal time is a more easily controlled cost.

Worst-case deterministic bounds for the hit rate can be arbitrarily bad: the hit rate is zero if x is not covered by any support set and at least one test is done for x. If there are no restrictions on the shape of the support sets, then quadtrees/octrees can be made to perform badly, for example, by making the S_i's curves or thin ribbons. In practice, the support sets S_i are discs, balls, rectangles, rectangular solids, or similar shapes, with modest aspect ratios (the ratio between the longest and smallest dimension).

Our bounds on the hit rate are proven under the assumption that x is chosen randomly and uniformly over a set S which contains the union of the S_i's.

1.1. Application. Various new methods for solving partial differential equations have been introduced which do not require construction of grids or triangulations of regions in order to compute approximate solutions. These are known as mesh-free methods; there are a number of types of mesh-free methods such as *partition of unity finite element methods* (PUFEM), *reproducing kernel particle methods* (RKPM), *element free Galerkin* (EFG) methods, and *moving least squares* (MLS) methods. An overview of mesh-free methods in general can be found in [4].

All of these methods construct basis functions Ψ_i, $i = 1, 2, \ldots, N$, over the domain of interest $\Omega \subset \mathbf{R}^d$ from which a Galerkin discretization is developed. Thus, for example, for solving the partial differential equation

$$\begin{aligned} -\nabla^2 u(x) + u(x) &= f(x), \quad x \in \Omega, \\ u(x) &= 0, \quad x \in \partial\Omega, \end{aligned}$$

where $\partial\Omega$ is the boundary of Ω, we approximate $u \approx u^h$ where $u^h(x) = \sum_{i=1}^{N} u_i^h \Psi_i(x)$.

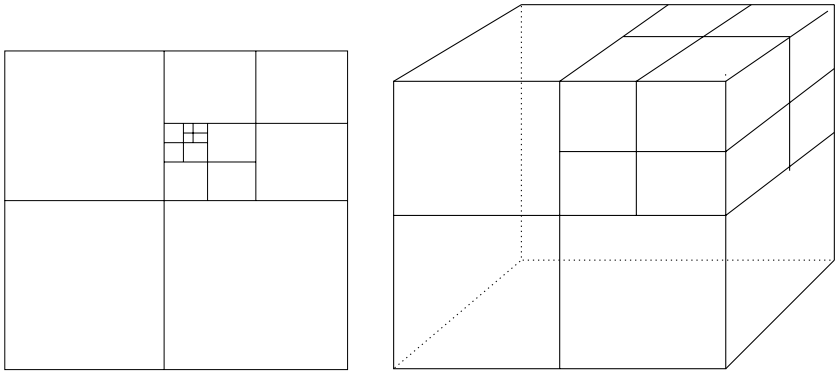

FIG. 2. *Quadtree and octree examples.*

Then we construct a linear system of equations for the unknown coefficients u_i^h: $\sum_{j=1}^{N} K_{ij} u_j^h = f_i$ for $i = 1, 2, \ldots, N$ where

$$K_{ij} = \int_\Omega \frac{1}{2} \left(\nabla \Psi_i(x)^T \nabla \Psi_j(x) + \Psi_i(x) \Psi_j(x) \right) \, dV(x).$$

For most mesh-free methods, either there are no analytical formulas available for $\Psi_i(x)$ or they are too complex to compute these integrals directly. Therefore numerical approximations of the form

$$K_{ij} \approx \sum_{k=1}^{P} \frac{1}{2} \left(\nabla \Psi_i(x_k)^T \nabla \Psi_j(x_k) + \Psi_i(x_k) \Psi_j(x_k) \right) \omega_k$$

are used to construct the linear system. In our notation, P is the number of integration points. Let $S_i = \operatorname{supp} \Psi_i = \overline{\{ z \mid \Psi_i(z) \neq 0 \}}$, the support of Ψ_i. Note that Ψ_i and all of its derivatives are zero outside its support S_i. The integration points x_k are scattered essentially uniformly throughout the region Ω. Rather than first looping over i and j where $S_i \cap S_j \neq \emptyset$ and then finding all k such that $x_k \in S_i \cap S_j$, we can compute the matrix K more efficiently by looping first over k and then finding all i where $x_k \in S_i$ by using quadtree/octree-type data structures. Note that the former strategy leads to both an intersection-finding problem and a range-searching problem. While finding all i and j where $S_i \cap S_j \neq \emptyset$ can be solved using quadtree structures (see, for example, Samet [15, pp. 199–225]), the costs are at least as high as for the task discussed here. The problem of finding all x_k where $x_k \in S_i \cap S_j$ is a range-searching problem which requires construction of a range-searching tree on the integration points. Apart from the fact that the number of integration points is usually much larger than the number of support sets in practice, these structures are complex and the searching time complexity is $O(\log^{d-1} P + \#\{ k \mid x_k \in S_i \cap S_j \})$ in d dimensions where P is the number of integration points. By contrast, the latter strategy can be accomplished with methods which have an expected time complexity of just $O(\log N + \mathbf{E}(\#\{ i \mid x_k \in S_i \}))$ in any fixed number of dimensions.

1.2. Quadtrees and octrees. Quadtrees and octrees are members of hierarchical decomposition data structures based on the principle of recursive decomposition of space. Examples of quadtrees and octrees are illustrated in Figure 2. They are widely used in image compression [14, 13], GIS (Geographic Information Systems)

[16, 6], computer vision [7], and computer graphics [8, 17]. Quadtrees can be used to represent a two-dimensional space. Similarly, octrees can be used to deal with the three-dimensional case. A quadtree is a tree data structure based on a rectangle with four children and an octree is a tree data structure based on a cube with eight children. However, both of them can be used in the generation of meshes for finite element analysis. Due to different applications, there are variants on this structure, such as region-based quadtrees and point quadtrees.

A quadtree can be described in this way using Java, for example:

```
class QtreeNode{
   private Object data;
   private QtreeNode children[2][2];
   private QtreeNode parent;
   private int depth;
   private int coords[2];
     ...
   }
```

An octree tree can be described in a similar way using Java:

```
class OctreeNode{
   private Object data;
   private OctreeNode parent;
   private OctreeNode children[2][2][2];
   private int depth;
   private int coords[3];
     ...
   }
```

We use the following notation and terminology to describe various aspects of quadtrees, octrees, and their d-dimensional analogues.

- A *support set* S_i is simply a bounded subset of $\mathbf{R}^d$; the quadtree or octree construction algorithm is, given a collection $\{S_i \mid i = 1, 2, \ldots, N\}$ of these sets, to build a corresponding quadtree or octree representation of these support sets S_i.
- A *rectangle* is a set of the form $[a_1, b_1] \times [a_2, b_2] \times \cdots \times [a_d, b_d]$ in $\mathbf{R}^d$; a *rectangle in a quadtree or octree* has the special property that $a_i = \gamma_i 2^{-k}$, $b_i = (\gamma_i + 1)2^{-k}$ for all i with k independent of i, and γ_i an integer. A *subrectangle* of a rectangle R in a quadtree or octree is a rectangle in the quadtree or octree contained in the rectangle R.
- We use *quadtree* to refer to quadtrees and their generalizations to 2^d-trees in $\mathbf{R}^d$. The term thus includes octrees in three dimensions and binary trees in one dimension.
- The *width* of a set A is the diameter of the set in the infinity norm; that is, $\text{width}(A) = \sup\{\, \|x - y\|_\infty \mid x, y \in A \,\} = \sup_{x,y \in A} \max_i |x_i - y_i|$.
- The *top* rectangle is the rectangle at the root of the quadtree or octree. It is usually considered to be the rectangle $[0, 1] \times [0, 1] \times \cdots \times [0, 1]$.
- The *expected value* of a random variable X is denoted $\mathbf{E}(X)$.
- The *d-dimensional volume*, or *d-volume* of a set S is denoted $\text{vol}_d(S)$.

Each rectangle in the quadtree has an associated linked list containing references to support sets S_i; if R is a rectangle in the quadtree whose linked list contains a reference to S_i, we say that S_i *is linked to* R, or that R *links* S_i.

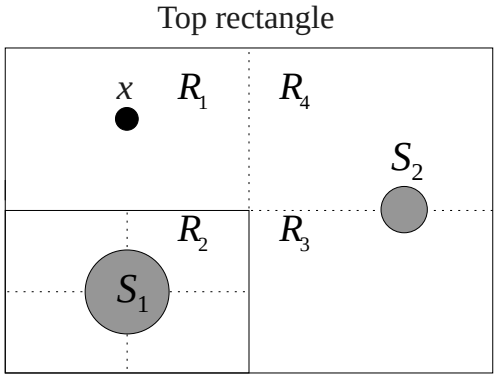

FIG. 3. *Example of the basic quadtree.*

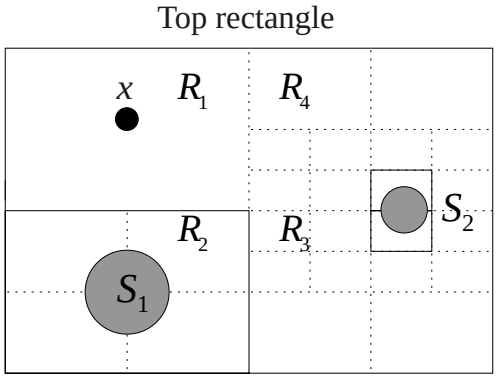

FIG. 4. *Example of the expanded quadtree.*

2. Algorithms. In this section we present two quadtree search algorithms to find the number of support sets covering each point x. In our application, x is an integration point and is part of a set of integration points x_k that are approximately uniformly distributed in a domain Ω. The first algorithm for building quadtree structures is the called the *basic algorithm*, and the second is called the *splitting algorithm*. These data structures constructed are discussed in Samet [15], where the former is called the MX-CIF quadtree and the latter the expanded MX-CIF quadtree. In this paper they will be referred to as the basic and expanded quadtrees, respectively. However, neither data structure was considered in Samet [15] in the context of identifying sets containing a given query point. The splitting algorithm has advantages over the basic algorithm in finding the number of support sets covering the integration point x. The total expected query time for randomly selected points x can be bounded in terms of the *hit rate* and the *expected depth traversed* in the quadtree. We will provide detailed theoretical analysis and numerical simulation in terms of these quantities later. We illustrate the basic and expanded quadtrees in Figures 3 and 4.

In both the basic algorithm and the splitting algorithm, each rectangle in the quadtree has a corresponding linked list. In the basic approach we try to link each S_i to a rectangle R in the quadtree if it is contained in R and there is no subrectangle of R in which S_i is completely contained. Note that S_i is not necessarily linked to a leaf node of the quadtree, even at the time of linking. Also note that there can be

more than one support set linked to a single rectangle R, creating a linked list. In the interests of efficiency, we usually want these linked lists to be short. When using this algorithm, in the worst case, the construction of the quadtree takes $O(N \log(1/\varepsilon))$ time where $\varepsilon = \min_i \operatorname{diam} S_i$.

The basic algorithm constructs a quadtree which is the MX-CIF quadtree discussed by Samet [15, pp. 200–213] and the data structure discussed by Abel and Smith [1]. Unlike Samet, however, we are interested here in finding sets S_i containing query points, rather than intersection detection.

PSEUDOCODE FOR BUILDING THE BASIC QUADTREE (BASIC ALGORITHM).

```
void basic(S,top,N)
/* Constructing a quadtree for support sets S_i. */
for i = 1, 2, ..., N
    R ← top
    repeat
        for each subrectangle R' of R
            if S_i ⊆ R'
              R ← R' & break for loop
            end if
        end for
    until (no subrectangle of R contains S_i)
    link S_i to the rectangle R
end for
```

For example, in Figure 3, S_1 is not linked to the top rectangle R but it is linked to the subrectangle R_2; since S_2 is not contained in any of the subrectangles of R, it is linked to R.

In our splitting algorithm (our second method), if a support set S_i is a subset of a rectangle R but is not a subset of any subrectangle of R in the quadtree and if $\operatorname{diam}(S_i) < \frac{1}{2}\operatorname{width}(R)$, then we don't link S_i to R; rather we "split" S_i for each subrectangle R' of R, if $S_i \cap R' \neq \emptyset$, and recursively call the splitting algorithm with $S_i \cap R'$. We give the pseudocode for the splitting algorithm below. Note that the splitting algorithm builds a recursive extension of the MX-CIF tree of Samet which is the expanded MX-CIF tree of Samet [15, pp. 213–215].

PSEUDOCODE FOR BUILDING THE EXPANDED QUADTREE (SPLITTING ALGORITHM).

```
procedure splitting(S_i,R)
/* Add support set S_i to quadtree
   using R as the root of the quadtree */
loop
   if R' is a subrectangle of R where S_i ⊂ R'
      R ← R'
    else if diam(S_i) < (1/2)width (R)
        for each subrectangle R' of R where R' ∩
        S_i ≠ ∅ (allocate R' if necessary)
          call splitting(S_i ∩ R',R')
   else
     link S_i to R and exit loop
end loop
```

The splitting algorithm is illustrated by Figure 5. The subscripts in this figure refer to the subrectangle number, being 1 (northwest), 2 (southwest), 3 (southeast), or 4 (northeast). In this figure $R^{j+p}_{k,l,\ldots}$ denotes the rectangle at level $j + p$, where

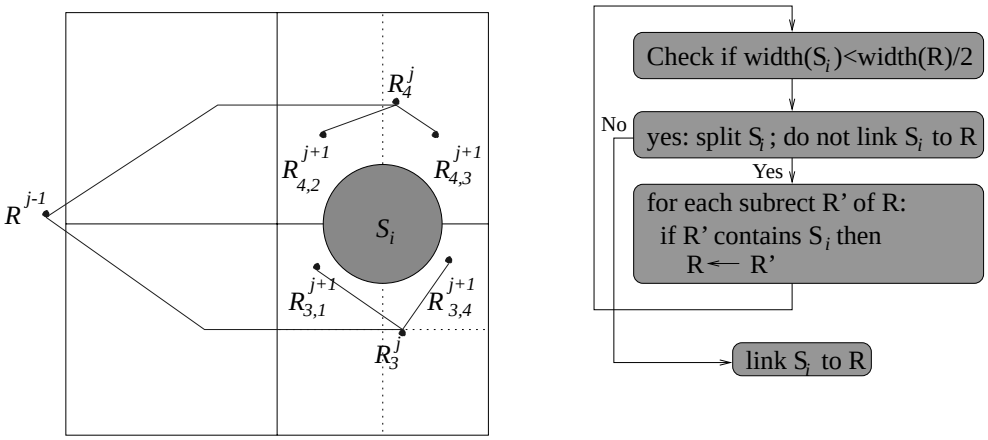

FIG. 5. *Example for describing the splitting algorithm.*

$k, l, \ldots$ denotes the path from R^{j-1} to this rectangle within the quadtree.

To construct the complete quadtree, we apply `splitting` to all support sets, i.e.,

```
for i = 1, 2, ..., N
    call splitting(S_i, top)
```

Note that in the expanded quadtree, each S_i can be linked to more than one rectangle in the quadtree. In fact, each S_i can be linked to at most 2^d rectangles. As given, the time and space requirements for the splitting algorithm are $O(2^d N\, h)$, where h is the depth (or height) of the expanded quadtree. Since splitting can produce very small sets in the computation of $R' \cap S_i$, the worst-case space and time requirements are unbounded. However, if *path compression* [2] is used so that rectangles with only one allocated subrectangle and no S_i linked to it are removed from the quadtree, the worst-case space requirements reduce to $O(2^d N)$. Furthermore, the depth of the path-compressed quadtree is bounded above by $c_{\max} + \lceil \log_2 N \rceil$, where $c_{\max} = \max_x \#\{\, i \mid x \in S_i \,\}$ is the maximum covering number. In applications, the maximum covering number is bounded, or grows polylogarithmically in N.

The path-compressed quadtree can be built incrementally using a number of different techniques. A path-compressed version of the basic quadtree can start by finding the depth and coordinates of the smallest enclosing quadtree rectangle. For each S_i we find a bounding box $[a_1, b_1] \times \cdots \times [a_d, b_d] \subseteq [0,1]^d$ and expand each coordinate a_i and b_i in binary. The number of leading bits of a_i and b_i that match is the depth of the smallest enclosing quadtree rectangle, and the matching bits are the (integer) coordinates of that rectangle. Using the Java data structures above, the current path-compressed quadtree can be traversed downwards until a rectangle is found at the correct depth, or the correct place to insert a new such rectangle can be found. Once this is found, standard techniques can insert a suitable rectangle in $O(1)$ time. A similar approach can be used to find the $\leq 2^d$ rectangles which are linked to a support set for the splitting algorithm by first finding matching bits. This makes the time to construct the quadtree for the splitting algorithm with path compression $O(2^d N(c_{\max} + \log N + d \log\log(1/\varepsilon)))$, where $\varepsilon = \min_i \operatorname{diam}(S_i)$ assuming $O(1)$ time bit operations (and, or, invert, and shift) on integers. Alternatives to pointer-based data structures include balanced trees and hash-tables using the tuple (depth, coord_1,..., coord_d) as the key, where coord_i is the ith coordinate of the rectangle.

Alternatively, if in the splitting algorithm the set $R' \cap S_i$ is expanded to have diameter no less than $0 < \eta \leq 1/2$ times the diameter of S_i, the maximum depth of the expanded quadtree is no more than $\log_2(1/\varepsilon) + \log_2(1/\eta)$. Choosing a particular value (e.g., $\eta = 1/4$) gives an upper bound on the depth of the expanded quadtree generated by the modified splitting algorithm with the same asymptotic behavior. Furthermore, the performance bounds for the search given below remain unaltered for the modified splitting algorithm.

Once the quadtree is constructed, we need to use it to find the support sets covering a given point x. Below is our pseudocode for doing this with a quadtree constructed using either the basic or splitting algorithms.

```
list function search(x,top)
/* Given x, find all S_i that cover x: x ∈ S_i */
R ← top
while R ≠ null
    for each S_i linked to R
    if x ∈ S_i then
        add S_i to list of covering support sets
        increment covering number
    R ←allocated subrectangle of R containing x, if any
    R ← null if there is no such subrectangle
end while
```

In Figure 3, we show the behavior of the basic algorithm. We need to make a test to determine if x is in S_2 or not because S_2 is linked to the top rectangle, though x is far from S_2.

In Figure 4, the advantages of the splitting algorithm are exemplified. We will test if a given $x \in S_2$ only if it is in the two smallest rectangles shown containing S_2.

2.1. The advantage of the expanded quadtree over the basic quadtree. Just as we discussed above, in the basic quadtree there are many unnecessary tests to obtain the sets covering each integration point. Here, we give the plot of the number of wasted tests (unnecessary tests) per integration point in two algorithms in Figure 6. Here, we randomly generate 2,000 support sets (circles) with radius = 0.2 and use 10,000 uniformly distributed integration points.

We observe that the number of wasted tests in the basic algorithm is 15–20 times the number in the expanded quadtree.

Figure 7 gives plots of the lengths of the linked lists in the basic and expanded quadtrees. We can see, for the chosen 200 support sets, that the linked lists are generally much shorter for the expanded quadtree, so that fewer tests are needed for each rectangle. Furthermore, the few rectangles with long linked lists in the basic quadtree are the top rectangles, and the rectangles near the top. All support sets linked to the top rectangle are tested for *any* integration point, making this data structure much less efficient. The expanded quadtree also links support sets deeper in the quadtree, as shown in Figure 8.

2.2. The hit rate. The hit rate is the ratio between the average number of sets covering integration point x and the average number of tests for finding all covering sets for all integration points x, where x is a point randomly chosen from a uniform distribution of points over the top rectangle.

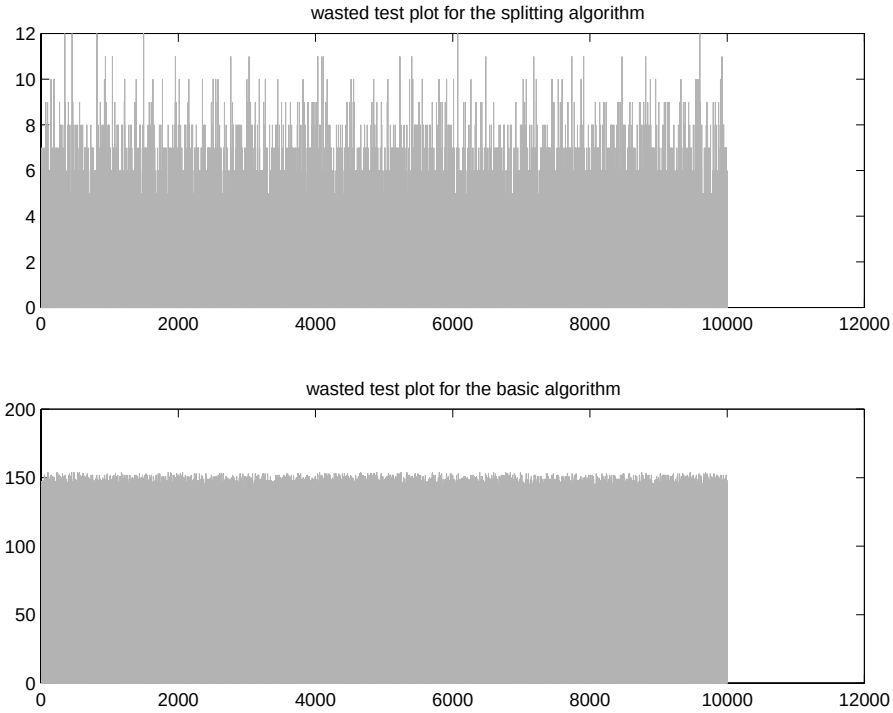

FIG. 6. *The number of wasted tests in the basic and expanded quadtrees.*

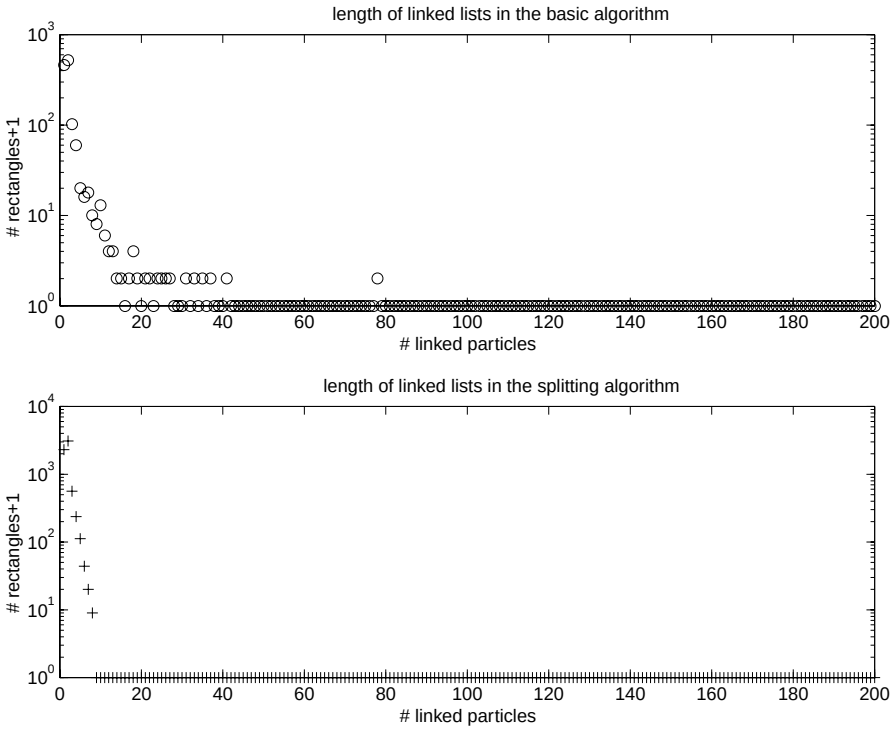

FIG. 7. *The length of linked lists in the basic and expanded quadtrees.*

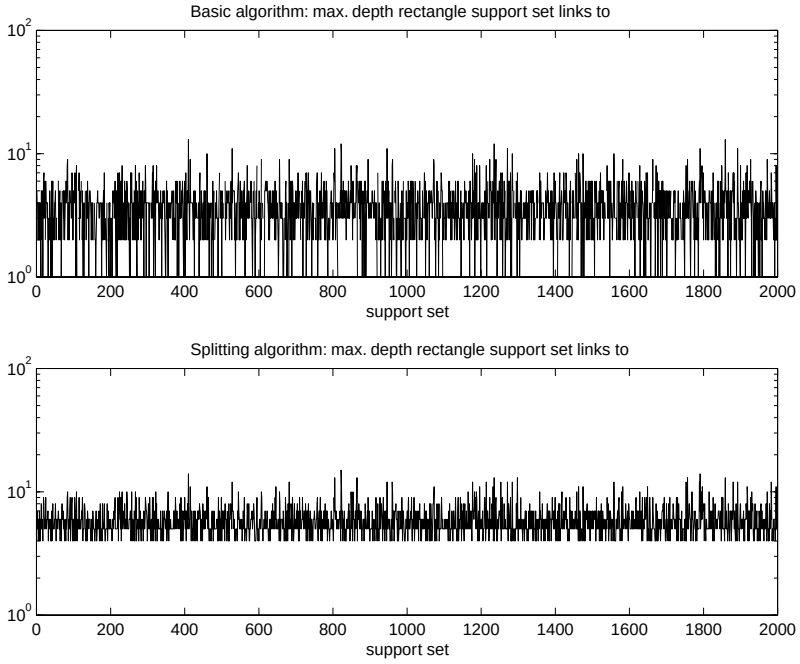

FIG. 8. *Depth of rectangle linked to each support set.*

We give a more precise definition of the hit rate:

$$\text{hit rate} = \frac{\mathbf{E}(covering\#)}{\mathbf{E}(\#tests)}.$$

Here *covering#* is the number of sets covering the randomly chosen point x, while $\#tests$ is the number of tests needed in the algorithms to determine the list of sets covering x. That is, hit rate is the ratio between the mathematical expectation of the covering (support sets) numbers of the integration points and the expectation of the number of tests to get the coverings for the randomly chosen and uniformly distributed integration points.

3. Analysis of the expected search time. We randomly choose integration points x and go down through the quadtree to find the sets S_i which contains x in our integration region. The total search time will depend on how many tests we will do for the integration points we use, and how deeply we traverse the tree structure. So our expected search time is

$$\mathbf{E}(\text{search time}) = O(\mathbf{E}(depth) + \mathbf{E}(\#tests)),$$

where *depth* is the depth traversed in the quadtree when searching for sets covering a given point x, and $\#tests$ is the number of tests $x \in S_i$ that are performed during the search. Since $\mathbf{E}(\#tests) = (\text{hit rate}) \times \mathbf{E}(covering\#)$, provided the hit rate is bounded away from zero, we get $O(\mathbf{E}(depth) + \mathbf{E}(covering\#))$ expected search time per query point.

We will show that, for both the splitting and basic algorithms, the expected depth is bounded above by $(\log N)/d$; i.e, $\mathbf{E}(depth) = O((\log N)/d)$. For the basic quadtree,

the hit rate can go to zero. In fact, for the basic quadtree the hit rate is $O(N^{-1/2})$ in two dimensions in practice. The expanded quadtree, however, has a hit rate that is bounded away from zero independently of N, although it can decrease exponentially as the dimension d increases. In the following sections we will analyze both the hit rate and the expected depth traversed in the quadtree.

3.1. Analysis of the hit rate. We assume bounds on the *aspect ratio*, which is the ratio of the longest to the shortest side. First, we give the lower and upper bounds of $\mathbf{E}(covering\#)$, then we get the inequality of reflecting relationship between $\mathbf{E}(covering\#)$ and $\mathbf{E}(\#tests)$. We combine these to bound the hit rate.

3.1.1. The hit rate for the basic algorithm. First, we note that the *hit rate* can be arbitrarily bad for the basic quadtree. In two dimensions, if every support set S_i was chosen to intersect either the horizontal or vertical lines bisecting the *top* rectangle, then every support set would be linked to the *top* rectangle of the quadtree. That would mean that all the support sets would have to be tested for all integration points $x \in top$. This would give a hit rate of $\mathbf{E}(covering\#)/N$, which can be arbitrarily close to zero, and goes to zero if the average covering number is bounded as $N \to \infty$.

Even for uniform or random distributions of the sets S_i, if $\mathrm{diam}(S_i)$ are all near $\varepsilon > 0$, the number of sets linked to the *top* rectangle is $\Theta(N\varepsilon)$; if $\varepsilon = \Omega(N^{-1/d})$ as we would expect if the S_i's covered *top*, then the number of sets linked to the *top* rectangle would be $\Omega(N^{1-(1/d)})$. While this is an improvement over the naive approach of directly testing a point x against all sets S_i, it is far from optimal. This confirms the $O(\sqrt{N})$ query time found in [1] for planar queries.

3.1.2. Using the number of links to express $\mathbf{E}(\#test)$ for the expanded quadtree. We work in d dimensions ($d = 2$ for quadtrees, $d = 3$ for octrees). Let $N_j = \#\text{links at level } j$. Also, let $\widehat{N}_j$ be the number of rectangles which have at least one support set linked at level j. Note that $\widehat{N}_j \le N_j$, and every support set has at most 2^d links to it. So, for all support sets N for the integration point x , we have

$$\sum_{j=0}^{\infty} N_j \le 2^d N.$$

Every rectangle at level j has d-volume 2^{-jd} times the volume of the *top* rectangle and each link from a rectangle requires a test for any point contained in that rectangle. Suppose that the rectangles at level j which are linked to a support set are $R_{j,1}, R_{j,2}, \ldots, R_{j,\widehat{N}_j}$. Since there are N_j links at level j, then the expected number of links to search from level j is

$$\begin{aligned}\mathbf{E}(\text{tests at level } j) &= \sum_{k=1}^{\widehat{N}_j} \Pr(x \in R_{j,k}) \times (\#\text{support sets linked to } R_{j,k}) \\ &= \sum_{k=1}^{\widehat{N}_j} 2^{-jd}(\#\text{support sets linked to } R_{j,k}) = 2^{-jd} N_j.\end{aligned}$$

So, $\mathbf{E}(\#tests)$ is the sum of the expected number of links in all levels: $\mathbf{E}(\#tests) = \sum_{j=0}^{\infty} 2^{-jd} N_j$.

3.1.3. Bounds on E(*covering#*) for the expanded quadtree. Adding total volumes of all support sets S_i, $i = 1, 2, \ldots, N$, in d dimensions, we get the value of $\mathbf{E}(covering\#) = \mathbf{E}(\#\{\, i \mid x \in S_i \,\})$. Let a be the maximum *aspect ratio (the ratio of the largest side to the shortest side for rectangles)* of the support sets. Assume that $\mathrm{vol}_d(top) = 1$. Then

$$\begin{aligned}\mathbf{E}(covering\#) &= \sum_{i=1}^{N} \mathrm{vol}_d(S_i) \geq \sum_{i=1}^{N} \frac{1}{a^{d-1}} \mathrm{width}(S_i)^d \\ &= \frac{1}{a^{d-1}} \sum_{i=1}^{N} \mathrm{width}(S_i)^d.\end{aligned}$$

We suppose that, at level j, S_i has n_{ij} links. Then the total links of S_i in the whole tree is less than 2^d:

$$\sum_{j=0}^{\infty} n_{ij} \leq 2^d \text{ for all } i.$$

On the other hand, the total number of links in level j for all supports of our integration points are $N_j = \sum_i n_{ij}$. Remember that for the expanded quadtree a support set S_i is not linked at level j if the width of S_i is no more than half the width of a rectangle at level j. That is,

$$n_{ij} = 0 \text{ if } \mathrm{width}(S_i) \leq 2^{-j-1} \mathrm{width}(top).$$

Since in the expanded quadtree, the volume of S_i is split into disjoint parts, if we add all volumes in each linked rectangle for S_i, we have the following bound:

$$\mathrm{vol}_d(S_i) \leq \sum_{j=0}^{\infty} n_{ij} 2^{-jd} \mathrm{vol}_d(top).$$

Assuming $\mathrm{vol}_d(top) = 1$, we have

$$\mathrm{vol}_d(S_i) \leq \sum_{j=0}^{\infty} n_{ij} 2^{-jd}.$$

An upper bound for $\mathbf{E}(covering\#)$ is easily obtained:

$$\begin{aligned}\mathbf{E}(covering\#) &\leq \sum_{i=1}^{N} \sum_{j=0}^{\infty} n_{ij} 2^{-jd} = \sum_{j=0}^{\infty} \left(\sum_{i=1}^{N} n_{ij} \right) 2^{-jd} \\ &= \sum_{j=0}^{\infty} N_j 2^{-jd}.\end{aligned}$$

However, what we really need is a lower bound. For each set S_i let $j_i^* = \min\{\, j \mid S_i \text{ is linked to a rectangle } R \text{ at level } j \,\}$. For at least one rectangle R on level j_i^*, the aspect ratio of $S_i \cap R$ is no more than $2a$. Then $\mathrm{vol}_d(S_i) \geq \mathrm{vol}_d(R \cap S_i) \geq (2a)^{1-d} \mathrm{width}(R \cap S_i)^d \geq (2a)^{1-d} 2^{-d} \mathrm{width}(S_i)^d \geq 2a(4a)^{-d} 2^{-(j_i^*+1)d}$. Since $\sum_{j=0}^{\infty} n_{ij} \leq 2^d$ and $n_{ij} = 0$ for $j < j_i^*$, $\mathrm{vol}_d(S_i) \geq \sum_{j=0}^{\infty} 2a(4a)^{-d} 2^{-(j+1)d} \times 2^{-d} n_{ij}$.

Then

$$\mathrm{vol}_d(S_i) \geq 2a(16a)^{-d} \sum_{j=0}^{\infty} n_{ij} 2^{-jd}.$$

So, we can get a lower bound of $\mathbf{E}(covering\#)$ as follows:

$$\begin{aligned}\mathbf{E}(covering\#) &= \sum_{i=1}^{N} \mathrm{vol}_d(S_i) \geq 2a(16a)^{-d} \sum_{j=0}^{\infty} \sum_{i=1}^{N} n_{ij} 2^{-jd} \\ &= 2a(16a)^{-d} \sum_{j=0}^{\infty} N_j 2^{-jd} = 2a(16a)^{-d} \mathbf{E}(\#tests).\end{aligned}$$

Thus the hit rate for the expanded quadtree is bounded away from zero for fixed d.

3.1.4. The lower bound of the average hit rate for the expanded quadtree. By the definition of the hit rate, we have lower bound for average hit rate:

$$\text{hit rate} = \frac{\mathbf{E}(covering\#)}{\mathbf{E}(\#tests)} \geq 2a(16a)^{-d}.$$

From here, we can see it is impossible to get zero hit rate in our quadtree search. That is to say, if each set S_i is a square in two dimensions, for each set S_i covering x, there will be an average of at most 128 tests using the splitting algorithm. However, this bound is not sharp: the hit rate is usually much larger, as can be seen in Figure 9 and Table 1.

3.2. The simulation results on hit rate. From the point of view of the *hit rate*, we can also demonstrate the advantage of the expanded over the basic quadtree. For 10,000 randomly chosen and uniformly distributed integration points and 2,000 support sets with radius 0.2, we get the following results. The average hit rate in the expanded quadtree is almost 30 times larger than that of in the basic case: *expanded quadtree:* 0.1694; *basic quadtree:* 0.0057. This result agrees with the result of the wasted tests counted in the two algorithms. Note that in this simulation, many of the support sets overlap, which can cause difficulties for other data structures.

Figure 9 shows the hit rate plots for the basic and expanded quadtrees.

Computational results were also obtained for actual mesh-free methods. In particular, for a two-dimensional elasto-plastic problem computations were done using a number of different levels of refinement. The particular mesh-free method used was the RKPM (reproducing kernel particle method) [10]. The basis functions were tensor products of B-splines (that is, $\Psi_i(x) = B_{i,1}(x_1)B_{i,2}(x_2)$, where $B_{i,1}$ and $B_{i,2}$ are cubic splines), so that the support sets were axis-aligned rectangles. The aspect ratios of the support sets were all similar and not extreme. However, each support set was relatively large, resulting in a great deal of overlap; the average covering number is around 15. Table 1 shows the main results. Note that "$\#R$" is the number of rectangles allocated for the quadtree, N is the number of sets, P is the number of integration (i.e., query) points, and h is the depth (or height) of the quadtree. The naive algorithm tests each point against each support set. This example does not show the full power of the data structures since the problems are relatively small and two-dimensional. However, the difference between the basic and expanded quadtrees is clearly evident. The average covering numbers for the problems are shown in Table 2. As expected, the basic quadtree's hit rate is roughly proportional to $N^{-1/2}$,

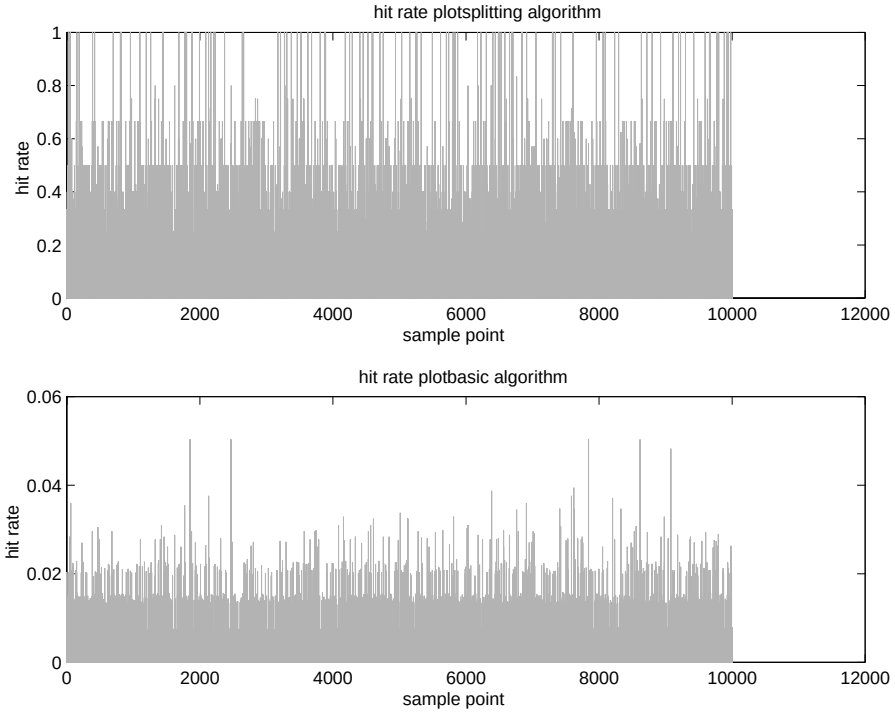

FIG. 9. *Hit rate plot in the basic and expanded quadtrees.*

TABLE 1
Quadtree statistics for mesh-free problems.

Data structure			Basic			Expanded			Naive
Problem	N	P	$\#R$	Hit rate	h	$\#R$	Hit rate	h	Hit rate
coarse	71	557	4	0.2372	2	16	0.3904	5	0.1998
medium	152	1286	5	0.1443	2	42	0.3033	7	0.1058
fine	349	3139	12	0.0775	3	106	0.2781	7	0.0419
fine2	605	5582	20	0.0516	3	223	0.2442	10	0.0246
fine3	985	8262	20	0.0396	3	240	0.1937	10	0.0155

and the naive algorithm's hit rate is roughly proportional to N^{-1}, while the expanded quadtree's hit rate is relatively stable. There is clearly additional overhead in setting up the quadtree using the splitting algorithm, but the number of rectangles allocated is much less than the number of support sets, and the depth of the resulting quadtree grows only slowly, probably logarithmically, in N. Note that the implementation of the splitting algorithm did not use any modifications to avoid deep quadtrees. Even so, path compression would achieve little here since the number of rectangles not linked by support sets for the splitting algorithm were, for the various problems, coarse 2; medium 6; fine 9; fine2 16. Thus for the largest problem (fine2), path compression could save no more than 16 of the 223 allocated rectangles. Thus it appears that for our application, path compression will save little in space or time.

3.3. The upper bounds of E(*depth*). As in the previous section, we let N_j denote the number of links at level j; $\widehat{N}_j$ denotes the number of rectangles linked to at least one support set in level j; and $\widetilde{N}_j$ denotes the number of allocated rectangles in

TABLE 2
Average covering numbers.

Problem	coarse	medium	fine	fine2	fine3
Avg. covering #	14.18	16.09	14.61	14.90	15.22

the quadtree at level j. Clearly, $\widehat{N}_j \le N_j$. Since every allocated rectangle must have a subrectangle that is linked to a support set, $\widetilde{N}_j \le \sum_{k=j}^{\infty} \widehat{N}_k \le \sum_{k=j}^{\infty} N_k$. On the other hand, $\widetilde{N}_j \le 2^{dj}$ since there are at most 2^{dj} rectangles in a quadtree at level j.

Note from the previous section that $\sum_{j=0}^{\infty} N_j \le N$ for the basic quadtree, but $\sum_{j=0}^{\infty} N_j \le 2^d N$ in the expanded quadtree.

3.4. Analysis of E(*depth*). Recall that *depth* is the depth of the quadtree traversed while searching for the sets covering a given point x, chosen at random. The basis of these calculations are bounds on the probability of *depth* having a particular value. A detailed discussion on related issues can be found in [2].

$$\begin{aligned}\mathbf{E}(depth) &= \sum_{j=0}^{\infty} j \Pr(depth = j) \\ &= \sum_{j=0}^{\infty} j \left[\Pr(depth \ge j) - \Pr(depth \ge j+1)\right] \\ &= \sum_{j=1}^{\infty} \Pr(depth \ge j).\end{aligned}$$

The problem now is to bound $\Pr(depth \ge j)$. This is the probability that x lies in an allocated rectangle at a depth j. A simple bound is

$$\Pr(depth \ge j) = 2^{-dj} \widetilde{N}_j \le 2^{-dj} \min(2^{dj}, 2^d N) = \min(1, 2^{-d(j-1)} N).$$

This leads to bounds of the form $\mathbf{E}(depth) = O(\log N)$:

$$\begin{aligned}\mathbf{E}(depth) &= \sum_{j=1}^{\infty} \Pr(depth \ge j) \\ &\le \sum_{j=1}^{\infty} \min(1, 2^{-d(j-1)} N).\end{aligned}$$

Suppose that $2^{d(j^*-1)} < N \le 2^{dj^*}$. Then for $j \ge j^*$, $2^{-d(j-1)} N \le 2^{-d(j-j^*-1)} \le 1$. Thus

$$\begin{aligned}\mathbf{E}(depth) &\le \sum_{j=1}^{j^*} 1 + \sum_{j=j^*+1}^{\infty} 2^{-d(j-j^*-1)} \\ &= j^* + \sum_{l=0}^{\infty} 2^{-dl} = j^* + \frac{1}{1-2^{-d}} \le j^* + 2.\end{aligned}$$

Note that $j^* = \lceil (\log_2 N)/d \rceil$, and so

$$\mathbf{E}(depth) \le \left\lceil \frac{\log_2 N}{d} \right\rceil + 2 = O\left(\frac{\log_2 N}{d} \right).$$

4. Conclusions. The expected total search time using the expanded quadtree for a random point $x \in top$ is $O(\mathbf{E}(depth)) + O(\mathbf{E}(\#tests))$. Since the number of tests needed is the covering number divided by the hit rate (which is bounded below by $2a(16a)^{-d}$) we get an expected search time which is $O((\log N)/d + (16a)^d \mathbf{E}(\#\{\, i \mid x \in S_i \,\}))$. For fixed d, this is $O(\log N + \mathbf{E}(\#\{i \mid x \in S_i\}))$. This means that for applications where the covering number grows at least as fast as $\log N$, we have an asymptotically optimal method. Otherwise, the expected time for the search grows like $O(\log N)$ which, while not asymptotically optimal, still gives good performance. By comparison, the expected total search time for the basic quadtree is $\Theta(N)$ for a worst-case collection of sets $\{S_i\}$, and $\Theta(N^{1-1/d})$ for collections of sets which occur in practical problems.

Acknowledgments. We would like to thank Prof. J. S. Chen and his students Hui-Ping Wang and Cheng-Tang Wu for providing the mesh-free method codes on which the computational results in Tables 1 and 2 are based. We would also like to thank the referees whose comments have helped to improve this paper.

AN $O(n \log n)$ ALGORITHM FOR THE MAXIMUM AGREEMENT SUBTREE PROBLEM FOR BINARY TREES*

RICHARD COLE†, MARTIN FARACH-COLTON‡, RAMESH HARIHARAN§, TERESA PRZYTYCKA¶, AND MIKKEL THORUP‖

Abstract. The maximum agreement subtree problem is the following. Given two rooted trees whose leaves are drawn from the same set of items (e.g., species), find the largest subset of these items so that the portions of the two trees restricted to these items are isomorphic. We consider the case which occurs frequently in practice, i.e., the case when the trees are binary, and give an $O(n \log n)$ time algorithm for this problem.

1. Introduction.

Suppose we are given two rooted trees T_1 and T_2 with n leaves each. The internal nodes of each tree have at least two children each. The leaves in each tree are labeled with the same set of labels, and further, no label occurs more than once in a particular tree. An *agreement subtree* of T_1 and T_2 is defined as follows. Let L_1 be a subset of the leaves of T_1, and let L_2 be the subset of those leaves of T_2 which have the same labels as leaves in L_1. The subtree of T_1 *induced* by L_1 is an agreement subtree of T_1 and T_2 if and only if it is *isomorphic* to the subtree of T_2 induced by L_2. The maximum agreement subtree problem (henceforth called $MAST$) asks for the largest agreement subtree of T_1 and T_2.

We need to define the terms *induced subtree* and *isomorphism* used above. Intuitively, the subtree of T induced by a subset L of the leaves of T is the topological subtree of T restricted to the leaves in L, with branching information relevant to L preserved. More formally, for any two leaves a, b of a tree T, let $\mathrm{lca}_T(a, b)$ denote their lowest common ancestor in T. If $a = b$, $\mathrm{lca}_T(a, b) = a$. The *subtree* U of T *induced* by a subset L of the leaves is the tree with leaf set L and interior node set $\{\mathrm{lca}_T(a, b) | a, b \in L\}$ inheriting the ancestor relation from T; that is, for all $a, b \in L$, $\mathrm{lca}_U(a, b) = \mathrm{lca}_T(a, b)$.

Intuitively, two trees are isomorphic if the children of each node in one of the trees can be reordered so that the leaf labels in each tree occur in the same order and the

shapes of the two trees become identical. Formally, we say two trees U_1 and U_2 with the same leaf labels are *isomorphic* if there is a 1–1 mapping μ between their nodes, mapping leaves to leaves with the same labels and such that for any two different leaves a, b of U_1, $\mu(\text{lca}_{U_1}(a,b)) = \text{lca}_{U_2}(\mu(a), \mu(b))$.

Motivation. The *MAST* problem arises naturally in biology and linguistics as a measure of consistency between two evolutionary trees over species and languages, respectively. An evolutionary tree for a set of *taxa*, either species or languages, is a rooted tree whose leaves represent the taxa and whose internal nodes represent ancestor information. It is often difficult to determine the true phylogeny for a set of taxa, and one way to gain confidence in a particular tree is to have different lines of evidence supporting that tree. In the biological taxa case, one may construct trees from different parts of the DNA of the species. These are known as *gene trees*. For many reasons, these trees need not entirely agree, and so one is left with the task of finding a consensus of the various gene trees. The maximum agreement subtree is one method of arriving at such a consensus. Notice that a gene is usually a binary tree, since DNA replicates by a binary branching process. Therefore, the case of binary trees is of great interest.

Another application arises in automated translation between two languages [GY95]. The two trees are the parse trees for the same meaning sentences in the two languages. A complication that arises in this application (due in part to imperfect dictionaries) is that words need not be uniquely matched, i.e., a word at the leaf of one tree could match a number (usually small) of words at the leaves of the other tree. The aim is to find a maximum agreement subtree; this is done with the goal of improving context-using dictionaries for automated translation. So long as each word in one tree has only a constant number of matches in the other tree (possibly with differing weights), the algorithm given here can be used and its performance remains $O(n \log n)$. More generally, if there are m word matches in all, the performance becomes $O((m+n)\log n)$. Note, however, that if there are two collections of equal meaning words in the two trees of sizes k_1 and k_2, respectively, they induce $k_1 k_2$ matches.

Previous work. Finden and Gordon [FG85] gave a heuristic algorithm for the *MAST* problem on binary trees which had an $O(n^5)$ running time and did not guarantee an optimal solution. Kubicka, Kubicki, and McMorris [KKM95] gave an $O(n^{(.5+\epsilon)\log n})$ algorithm for the same problem. The first polynomial time algorithm for this problem was given by Steel and Warnow [SW93]; it had a running time of $O(n^2)$. Steel and Warnow also considered the case of nonbinary and unrooted trees. Their algorithm takes $O(n^2)$ time for fixed degree rooted and unrooted trees and $O(n^{4.5}\log n)$ time for arbitrary degree rooted and unrooted trees. They also give a linear reduction from the rooted to the unrooted case. Farach and Thorup gave an $O(nc^{\sqrt{\log n}})$ time algorithm for the *MAST* problem on binary trees; here c is a constant greater than 1. For arbitrary degree trees, their algorithm takes $O(n^2 c^{\sqrt{\log n}})$ time for the unrooted case [FT95] and $O(n^{1.5}\log n)$ time for the rooted case [FT97]. Farach, Przytycka, and Thorup [FPT95a] obtained an $O(n\log^3 n)$ algorithm for the *MAST* problem on binary trees. Kao [Ka95] obtained an algorithm for the same problem which takes $O(n\log^2 n)$ time. This algorithm takes $O(\min\{nd^2 \log d \log^2 n, nd^{\frac{3}{2}}\log^3 n\})$ for degree d trees. Finally, Cole and Hariharan [CR96] improved the algorithm from [FPT95a] to an $O(n\log n)$ algorithm.

The *MAST* problem for more than two trees has also been studied. Amir and Keselman [AK97] showed that the problem is NP-hard for even 3 unbounded degree

trees. However, polynomial bounds are known [AK97, FPT95b] for three or more bounded degree trees.

Our contribution. This paper is the combined journal version of [FPT95a] and [CR96] and presents an $O(n \log n)$ algorithm for the *MAST* problem for two binary trees.

The $O(n \log^3 n)$ algorithm of [FPT95a] can be viewed as taking the following approach (although the authors do not describe it this way). It identifies two special cases and then solves the general case by interpolating between these cases.

Special case 1. The internal nodes in both trees form a path. The *MAST* problem reduces to essentially a size n longest increasing subsequence problem in this case. As is well known, this can be solved in $O(n \log n)$ time.

Special case 2. Both trees T_1 and T_2 are complete binary trees. For each node v in T_2, only certain nodes u in T_1 can be usefully mapped to v, in the sense that the subtree of T_1 rooted at u and the subtree of T_2 rooted at v have a nonempty agreement subtree. There are $O(n \log^2 n)$ such pairs (u, v). This can be seen as follows. Note that for (u, v) to be such a pair, the subtree of T_1 rooted at u and the subtree of T_2 rooted at v must have a leaf-label in common. For each label, there are only $O(\log^2 n)$ such pairs obtained by pairing each ancestor of the leaf with this label in T_1 with each ancestor of the leaf with this label in T_2. The total number of interesting pairs is thus $O(n \log^2 n)$.

For each pair, computing the *MAST* takes $O(1)$ time, as it is simply a question of deciding the best way of pairing their children.

The interpolation process takes a centroid decomposition of the two trees and compares pairs of centroid paths, rather than individual nodes as in the complete tree case. The comparison of a pair of centroid paths requires finding matchings with special properties in appropriately defined bipartite graphs, a nontrivial generalization of the longest increasing subsequence problem. This process creates $O(n \log^2 n)$ interesting (u, v) pairs, each of which takes $O(\log n)$ time to process.

In [CR96] two improvements are given, each of which gains a $\log n$ factor.

Improvement 1. The complete tree special case is improved to $O(n \log n)$ time as follows. A pair of nodes (u, v), $u \in T_1$, $v \in T_2$, is said to be *interesting* if there is an agreement subtree mapping u to v. As is shown below, for complete trees, the total number of interesting pairs (u, v) is just $O(n \log n)$. Consider a node v in T_2. Let L_2 be the set of leaves which are descendants of v. Let L_1 be the set of leaves in T_1 which have the same labels as the leaves in L_2. The only nodes that may be mapped to v are the nodes u in the subtree of T_1 induced by L_1. The number of such nodes u is O(size of the subtree of T_2 rooted at v). The total number of interesting pairs is thus the sum of the sizes of all subtrees of T_2, which is $O(n \log n)$.

This reduces the number of interesting pairs (u, v) to $O(n \log n)$. Again, processing a pair takes $O(1)$ time. (This is less obvious, for identifying the descendants of u which root the subtrees with which the two subtrees of v can be matched is nontrivial.) Constructing the above induced subtree itself can be done in $O(|L_1|)$ time, as will be detailed later. The basic tool here is to preprocess trees T_1 and T_2 in $O(n)$ time so that least common ancestor (LCA) queries can be answered in $O(1)$ time.

Improvement 2. As in [FPT95a], when the trees are not complete binary trees, we take centroid paths and match pairs of centroid paths. The $O(\log n)$ cost that the algorithm in [FPT95a] incurs in processing each such interesting pair of paths arises when there are large (polynomial in n size) instances of the generalized longest increasing subsequence problem. At first sight, it is not clear that large instances of

these problems can be created for sufficiently many of the interesting pairs; unfortunately, this turns out to be the case. However, these problem instances still have some useful structure. By using (static) weighted trees, we process pairs of interesting vertices in $O(1)$ time per pair, on the average, as is shown by an appropriately parameterized analysis.

The paper is organized as follows. Section 2 gives some basic definitions and primitives. Section 3 outlines the algorithm. Section 4 provides further details of the algorithm, and section 5 gives the analysis. The remaining sections deal with problems raised in sections 3–5.

2. Definitions and preliminaries. All trees henceforth refer to binary trees whose internal nodes have exactly two children.

The tree $T(x)$ denotes the subtree of T rooted at vertex x. The *size* of a tree T, denoted by $|T|$, is the number of leaves in it. In our problem, $|T_1| = |T_2| = n$.

Given a binary tree T, its *centroid decomposition* is a partitioning of its vertices into disjoint paths obtained as follows. First, for each internal node x in T, the edge to the child with the maximal number of leaves below it is called a *centroid edge*. Here ties are broken arbitrarily. Now, the centroid edges form a collection of disjoint paths, called *centroid paths*. The *beginning* of such a centroid path P is defined to be the vertex x closest to the root of T. Then, if we remove P from $T(x)$, we get a forest of trees called the *side trees* of $T(x)$, and then each side tree is of size at most $|T(x)|/2$. Note that the full centroid decomposition could also be found recursively by first finding the centroid path from the root, and then recursing on each side tree. Also note that the centroid decomposition of T can easily be found in $O(n)$ time.

A tree T can be preprocessed in $O(|T|)$ time so that given any subset L of its leaves in left to right order, the subtree induced by L can be computed in $O(|L|)$ time. The details of this procedure are described in section 8.

The set of labels at the leaves of T_1 is identical to that at the leaves of T_2. For a leaf l in one of these trees, the leaf with the same label in the other tree is called its *twin*. Two subtrees, one from each tree, are said to *intersect* if and only if some leaf in one subtree has a twin in the other. The subtree of T_2 induced by some subset of the leaves of T_1 is the subtree of T_2 induced by the twins of these leaves of T_1.

3. Algorithm outline. We need some definitions to outline the algorithm.

Definitions. Let π be the centroid path containing the root of T_1. Let $p = |\pi|$, and let $u_1, u_2, \ldots, u_{p-1}, u_p$ be the vertices on this path in order from the root. Let $M_1, M_2, \ldots, M_{p-1}$ comprise the forest of side trees created by the removal of π from T_1. Let $m_i = |M_i|$ be the number of leaves in M_i (see Figure 3.1). Recall that $m_i \leq n/2$ as π is a centroid path. For technical reasons, we define M_p to be the tree consisting of the vertex u_p and set $m_p = 1$. Then, $\sum_{i=1}^{p} m_i = n$.

Given trees T_1, T_2, our aim is to determine the maximum agreement subtree of T_1 and T_2 efficiently. To do so, we will need to compute not just this agreement subtree but the maximum agreement subtree of T_1 and $T_2(w)$ for each w in T_2. All these subtrees will be computed implicitly by a procedure *Agree*(T_1, T_2).

Agree(T_1, T_2) proceeds broadly as follows. See Figure 3.1. First, it recursively computes the maximum agreement subtree of $M_i, T_2(w)$ for each side tree M_i of T_1 and each vertex w in T_2. This is not done explicitly, though, as we will see shortly. Second, it uses the information gathered in this process to compute the maximum agreement subtree of $T_1, T_2(w)$ for each vertex w in T_2. Both steps together take $O(n \log n)$ time.

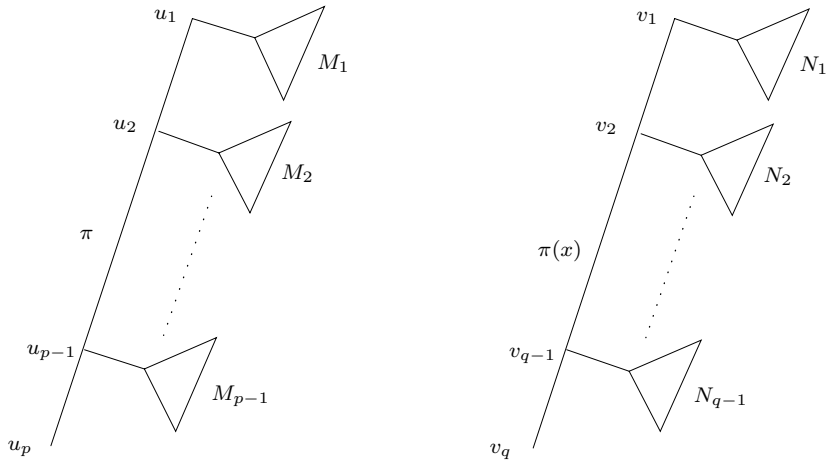

FIG. 3.1. *Centroid paths in T_1 and T_2 with π starting in root of T_1 and $\pi(x)$ starting in $x = v_1$ in T_2.*

We will describe $Agree(T_1, T_2)$ in detail shortly. Two observations will be used in this description.

First, as in the discussion of interesting pairs in Improvement 1, note that it is not necessary to compute the maximum agreement subtrees of $M_i, T_2(w)$ for all $w \in T_2$. The first reason is that the maximum agreement subtree of $M_i, T_2(w)$ is empty if M_i does not intersect with $T_2(w)$. The second reason is that the maximum agreement subtrees of $M_i, T_2(w)$ and $M_i, T_2(\text{parent}(w))$ are identical if M_i does not intersect with the the subtree of T_2 rooted at w's sibling. For these two reasons, it suffices to compute $Agree(M_i, S_i)$, where S_i is the subtree of T_2 induced by the leaves of M_i. This implicitly computes the maximum agreement subtrees of $M_i, T_2(w)$ for all $w \in T_2$.

Second, note that if the maximum agreement subtree of $T_1, T_2(w)$ does not have any vertex on the centroid path π of T_1, then all vertices in this agreement subtree belong to a single side tree M_i of T_1. For, if these vertices were distributed over two or more side trees of T_1, then these vertices would have a common ancestor on π which would be in the maximum agreement subtree as well. Thus, when the maximum agreement subtree of $T_1, T_2(w)$ does not have any vertex on π, it can be determined using some $Agree(M_i, S_i)$ from the previous paragraph.

Algorithm outline. $Agree(T_1, T_2)$ has three steps.

Step 1. The centroid decompositions of T_1 and T_2 are computed. This takes $O(n)$ time.

Step 2. For each i, $1 \le i \le p-1$, $Agree(M_i, S_i)$ is computed recursively, where S_i is the subtree of T_2 induced by the leaves of M_i. We will inductively assume that this takes $O(m_i \log m_i)$ for each i. Recall that if the maximum agreement subtree of T_1 and T_2 contains no vertex from π, then it will be found in Step 2. Step 3 handles the other case.

Step 3: *Matching π.* For each $w \in T_2$, the largest agreement subtree for the trees T_1 and $T_2(w)$ is found using information from Step 2. Informally, we call this the process of "matching" π at each of the vertices w of T_2. We will show how this is

done in $O(\sum_{i=1}^{p} m_i \log \frac{n}{m_i})$ time.

Clearly, the total time over all three steps is $O(n \log n)$. The following sections show how Step 3 is performed in $O(\sum_{i=1}^{p} m_i \log \frac{n}{m_i})$ time. Starting in the next section, we will define some bipartite graphs. Each graph will correspond to a particular centroid path in the centroid decomposition of T_2 and will be used to match π as in Step 3 at all the vertices in this centroid path. These graphs will have the property that a particular kind of matching, which can be computed efficiently, will correspond to the relevant agreement subtrees.

4. The matching graphs $G(x)$ and the π matching algorithm.

Definitions. Recall that the centroid decomposition of T_2 partitions its vertices into disjoint paths and that the beginning of such a path is defined to be the vertex closest to the root of T_2 in that path. Let X denote the set of vertices in T_2 at which paths in the above decomposition begin.

We define a number of bipartite graphs, one for each $x \in X$. The graph $G(x)$ corresponding to vertex x is defined as follows.

Vertices of $G(x)$. The left vertex set $L(x)$ of $G(x)$ is a subset of $\{u_1, \ldots, u_p\}$. Vertex u_i, $1 \leq i \leq p-1$, is in the set if and only if M_i and $T_2(x)$ intersect. Vertex u_p is in the set if and only if its twin is in $T_2(x)$.

The right vertex set $R(x)$ of $G(x)$ is exactly the set of vertices in the centroid path beginning at vertex x.

Since both sets of vertices are drawn from centroid paths, we order the vertices on each side in the order they occur on their respective centroid paths. The *topmost* vertex is the closest to the root and the *bottommost* is the farthest. Further, two edges (a, b) and (a', b') in $G(x)$ are said to *cross* if a is above a' and b is below b', or vice versa. In addition, edge (a, b) is said to *dominate* (a', b') in $G(x)$ if a is above a' and b is above b'. The *topmost* edge in a set of edges, if any, is the edge which dominates all other edges in that set.

Before defining the edges of $G(x)$, we need the following definitions.

Definitions. Let $\pi(x)$ be the centroid path containing x. Let q be the length of this path. Let $v_1, v_2, \ldots, v_q$ be the vertices on this path in order from the root. Let $N_1, N_2, \ldots, N_{q-1}$ comprise the forest of side trees of $T_2(x)$ created by the removal of $v_1, \ldots, v_q$ from $T_2(x)$. Let $n_i = |N_i|$ for $i = 1, \ldots, q-1$ (see Figure 3.1). For technical reasons, we define N_q to be the tree consisting of the vertex v_q and set $n_q = 1$. Then $\sum_{i=1}^{q} n_i = |T_2(x)|$.

4.1. Motivation for defining edges of $G(x)$.

We first motivate the definition of edges of the graph $G(x)$. The purpose of $G(x)$ is to determine maximum agreement subtrees of T_1 and $T_2(v_k)$ for each k, $1 \leq k \leq q$. The edges of $G(x)$ will be defined so that maximum weight matchings of a certain kind (called *agreement matchings*) in $G(x)$ will correspond to maximum agreement subtrees of T_1 and $T_2(v_k)$, $1 \leq k \leq q$. Clearly, the edges of $G(x)$ and the agreement matchings must capture the structural properties of these maximum agreement subtrees. We outline these structural properties next and show how they lead to the edge definitions.

Consider the maximum agreement subtree $\mathcal{A}$ of $T_1, T_2(v_k)$. Note that $\mathcal{A}$ has the following properties.

Case 1. If $\mathcal{A}$ has no vertices in $\pi(x)$, then it must be the maximum agreement subtree of (T_1, N_j) for some j, $k \leq j \leq q-1$.

Case 2. Similarly, if $\mathcal{A}$ has no vertices in π, then it must be the maximum agreement subtree of $(M_i, T_2(v_k))$ for some i, $1 \leq i \leq p-1$.

Case 3. Next, suppose $\mathcal{A}$ has at least one vertex both from π and from $\pi(x)$. In other words, there is at least one vertex in $\mathcal{A}$ which is in π and which maps to a vertex in $\pi(x)$.

Suppose vertex $u_i \in \pi$ is one such vertex and it maps to vertex $v_j \in \pi(x)$. If u_i is not the bottommost such vertex in π and z is the unique child of u_i in $\mathcal{A}$ which is not in π, then $\mathcal{A}(z)$ must be the maximum agreement subtree of (M_i, N_j).

Now if u_i is indeed the bottommost such vertex, we divide into subcases.

Case 3.0. If u_i is the leaf u_p, it must map to the other leaf v_q since leaves can only map to leaves. Then the subtree of $\mathcal{A}$ rooted at u_i is just the vertex u_i, which is also the maximum agreement subtree of $(T_1(u_i), N_q)$.

For the remaining subcases, we assume that u_i is not the leaf u_p.

Case 3.1. The subtrees of $\mathcal{A}$ rooted at the two children of u_i in $\mathcal{A}$ are the maximum agreement subtrees of the pairs $(T_1(u_{i+1}), N_j)$ and $(M_i, T_2(v_{j+1}))$. The following facts will be of use in this case. If M_i and N_{j+1} do not intersect, then the maximum agreement subtree of $(M_i, T_2(v_{j+1}))$ is identical to that of $(M_i, T_2(v_{j'}))$, where $j' > j$ is the topmost vertex below v_j in $\pi(x)$ such that M_i and $N_{j'}$ intersect. And if M_{i+1} and N_j do not intersect, then the maximum agreement subtree of $(T_1(u_{i+1}), N_j)$ is identical to that of $(T_1(u_{i'}), N_j)$, where $i' > i$ is the topmost vertex below u_i in π such that $M_{i'}$ and N_j intersect.

Note that if this subcase does not hold, then the subtree of $\mathcal{A}$ rooted at one of the two children of u_i is just the maximum agreement subtree of (M_i, N_j). In addition, all descendants of the other child of u_i in $\mathcal{A}$ must come from either a single side tree below v_j in T_2 or a single side tree below u_i in T_1. These situations are handled by the second and third cases, respectively.

Case 3.2. The subtrees of $\mathcal{A}$ rooted at the two children of u_i in $\mathcal{A}$ are the maximum agreement subtrees of (M_i, N_j) and $(T_1(u_{i+1}), N_{j'})$ for some j', $j < j' \leq q$.

Case 3.3. The subtrees of $\mathcal{A}$ rooted at the two children of u_i in $\mathcal{A}$ are the maximum agreement subtrees of (M_i, N_j) and $(M_{i'}, T_2(v_{j+1}))$, respectively, for some i', $i < i' \leq p$.

The following properties of $\mathcal{A}$ can be inferred from the above case analysis.

Property 1. $\mathcal{A}$ has a path (which is possibly empty) comprising vertices in π which map to vertices in $\pi(x)$, with the property that off-path subtrees are maximum agreement subtrees of the following three kinds: maximum agreement subtrees of (M_i, N_j) for some i, j, maximum agreement subtrees of $(T_1(u_i), N_j)$ for some i, j, and maximum agreement subtrees of $(M_i, T_2(v_j))$ for some i, j.

Property 2. $\mathcal{A}$ contains at most one maximum agreement subtree of the second kind and at most one of the third kind. $\mathcal{A}$ also contains at least one maximum agreement subtree of either the second or the third kind. More specifically, in Case 3.1, there is one of each kind, in Cases 1 and 3.2, there is one of the second kind but none of the third kind, and in Cases 2 and 3.3, there is one of the third kind but none of the second kind. Finally, Case 3.0 can be viewed as either kind since $M_p = T_1(u_p)$ and $N_q = T_1(v_q)$.

Property 3. In Case 3, there are zero or more maximum agreement subtrees of the first kind, all of which occur above subtrees of the second and third kinds. Here, by above we refer to the relative positions of the nearest ancestors u_i, v_j on the centroid paths. In Cases 1 and 2, there are no subtrees of the first kind.

Property 4. If two maximum agreement subtrees of the first kind occur in $\mathcal{A}$, for

instance, the maximum agreement subtrees of (M_i, N_j) and $(M_{i'}, N_{j'})$, then $i < i'$ implies $j < j'$.

Property 5. If subtrees of both the second kind and the third kind exist in $\mathcal{A}$, for instance, the maximum agreement subtrees of $(T_1(u_{i'}), N_j)$ and $(M_i, T_2(v_{j'}))$, respectively, then $i < i'$ and $j < j'$.

To model these three different kinds of maximum agreement subtrees, we need three different kinds of edges in $G(x)$, namely white edges, red edges, and green edges, respectively. The details of these edges are described next, followed by the definition of agreement matching which captures the above structural properties.

4.2. Edges of $G(x)$. $G(x)$ is actually a multigraph, where each multiedge consists of three edges—a *white* edge, a *red* edge, and a *green* edge—each of which has a distinct weight associated with it. A multiedge between $u_i \in L(x)$, $1 \leq i \leq p-1$, and $v_j \in R(x)$, $1 \leq j \leq q-1$, exists if and only if M_i and N_j intersect. The white edge in this multiedge has weight equal to the size of the maximum agreement subtree of M_i and N_j. The red edge in this multiedge has weight equal to the size of the maximum agreement subtree of $T_1(u_i)$ and N_j. The green edge in this multiedge has weight equal to the size of the maximum agreement subtree of M_i and $T_2(v_j)$. If $u_p \in L(x)$, then there is a multiedge between u_p and v_j such that either $j \neq q$ and u_p's twin is in N_j or $j = q$ and u_p's twin is v_q; all three edges in this multiedge have weight 1. In addition, there is a multiedge between u_i and v_q such that either $i \neq p$ and v_q's twin is in M_i or $i = p$ and v_q's twin is u_p; all three edges in this multiedge have weight 1.

4.3. Agreement matchings in $G(x)$.

Definitions. We define a *proper crossing* in $G(x)$ to be either a single red edge, a single green edge, or a red-green edge pair such that the two edges cross and, further, the endpoint of the green edge in $L(x)$ is above that of the red edge.

A matching in $G(x)$ is an *agreement matching* if

1. it has zero or more white edges and one proper crossing, and
2. no white edge crosses any other edge; further, all white edges dominate the edges in the proper crossing.

See Figure 4.1. The weight of such a matching is just the sum of the weights of its edges. The following property of agreement matchings in G is crucial.

The key property. Each maximum weight agreement matching corresponds to a maximum agreement subtree, and vice versa, as is made precise below.

LEMMA 4.1. *A maximum weight agreement matching $\mathcal{M}$ containing only edges incident upon or below vertex w in $R(x)$ corresponds to an agreement subtree $\mathcal{A}$ of $T_1, T_2(w)$, $w \in \pi(x)$, having the same weight.*

Proof. We associate with each white edge (u_i, v_j) the maximum agreement subtree of (M_i, N_j). Similarly, we associate with each red edge (u_i, v_j) the maximum agreement subtree of $(T_1(u_i), M_j)$ and with each green edge (u_i, v_j) the maximum agreement subtree of $(N_i, T_2(v_j))$. The tree $\mathcal{A}$ is defined as follows.

$\mathcal{A}$ will have a path containing one vertex for each white edge (see Figure 4.1). These vertices occur in the same sequence from top to bottom as their corresponding edges. The off-path children of these vertices will be the roots of the associated maximum agreement subtrees defined above. It remains to define the remaining child of the bottommost vertex on this path. This child will depend upon the nature of the proper crossing. We will define a tree $\mathcal{A}'$ for the proper crossing as follows. This child will be the root of $\mathcal{A}'$.

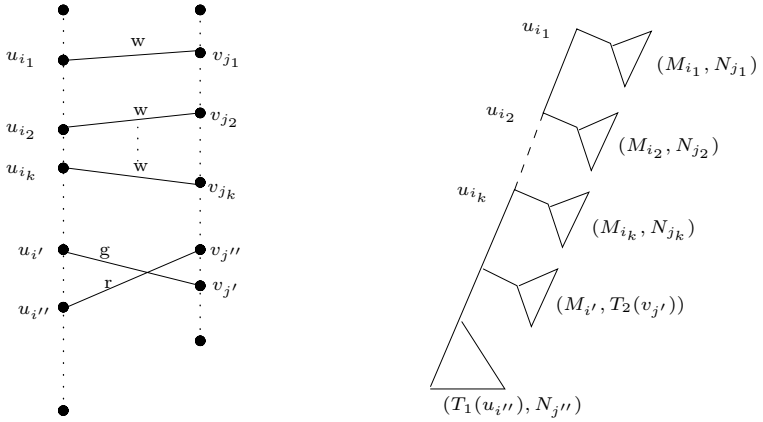

FIG. 4.1. *An agreement matching with the associated agreement tree.*

If the proper crossing has a green edge and a red edge, then $\mathcal{A}'$ is a tree whose left and right subtrees are the maximum agreement subtrees associated with the two edges. On the other hand, if the proper crossing has exactly one edge (red or green), then $\mathcal{A}'$ is just the maximum agreement subtree associated with that edge.

And finally, if there are no white edges at all, then $\mathcal{A} = \mathcal{A}'$. The equivalence of weights is easy to check in all cases. □

LEMMA 4.2. *A maximum agreement subtree $\mathcal{A}$ of T_1 and $T_2(w)$, $w \in \pi(x)$, has a unique corresponding agreement matching which has the same weight and contains only edges incident upon or below w in $R(x)$.*

Proof. We sketch how the agreement matching corresponding to $\mathcal{A}$ is constructed. Recall Cases 1–3 and Properties 1–5 in section 4.1.

If Case 1 occurs, then $\mathcal{A}$ is of the maximum agreement subtree of (T_1, N_j) for some v_j coinciding with or below w in $\pi(x)$. Let u_i be the topmost vertex in π such that M_i intersects with N_j. Then the maximum agreement subtree of $(T_1(u_i), N_j)$ has the same weight as that of (T, N_j). Further, there is a red edge between u_i and v_j in $G(x)$; this red edge constitutes the agreement matching. Clearly, the weight of this matching is identical to that of $\mathcal{A}$.

If Case 2 occurs, a similar argument shows that the matching comprises a solitary green edge with the same weight as $\mathcal{A}$. In Case 3, a similar argument can be used to show that the matching contains a sequence of zero or more noncrossing white edges, lying above a proper crossing. □

Thus, in order to determine the maximum agreement subtree of T_1 and $T_2(w)$, $w \in \pi(x)$, it suffices to determine the maximum weight agreement matching in $G(x)$ containing only edges incident upon or below vertex w in $R(x)$.

4.4. Finding maximum weight agreement matching in $G(x)$. To describe the algorithm for matching π, we need the following definitions followed by an important theorem. The theorem itself will be proved in section 7.

Definitions. The *degree* of a vertex in $G(x)$ is defined as the number of white edges incident on it. Let $d_x(u_i)$ denote the degree of u_i. A vertex in $L(x)$ is called a *singleton* vertex if it has degree one; the white edge incident on it is called a *singleton* edge. Let $nswe(x)$ denote the number of nonsingleton white edges in $G(x)$.

Let $nsav(x)$ denote the number of vertices in $R(x)$ which have at least one incident nonsingleton white edge. Let $SV(x)$ denote the set of singleton vertices in $L(x)$.

THEOREM 4.3. *Consider a particular $x \in X$. For each $u_i \in L(x)$, the largest weight agreement matching in $G(x)$ containing only edges incident on or below u_i in $L(x)$ can be found in time*

$$O\left(\sum_{i|d_x(u_i)>1} d_x(u_i)\log\frac{nsav(x)}{d_x(u_i)} + \sum_{(u_i,v_j)\in G(x)|d_x(u_i)=1} \log\frac{|T(x)|}{n_j}\right).$$

Further, for each $v_j \in R(x)$, the largest weight agreement matching in $G(x)$ containing only edges incident on or below v_j in $R(x)$ can also be found in the same time.

Theorem 4.3 is achieved by storing the vertices of $R(x)$ in an appropriately weighted search tree. The construction is described in section 7.

Algorithm outline for matching π. The matching graphs $G(x)$ for all $x \in X$ will be constructed in time proportional to the sum of the sizes of these graphs. This construction is described in section 6. Then each matching graph $G(x)$ is processed as follows (see Theorem 4.3). For each $u_i \in L(x)$, the largest weight agreement matching in $G(x)$ containing only edges incident on or below u_i in $L(x)$ is found. Further, for each $v_j \in R(x)$, the largest weight agreement matching in $G(x)$ containing only edges incident on or below v_j in $R(x)$ is also computed. This computation of agreement matchings is described in section 7. For each $w \in T_2$, the largest agreement subtree of T_1 and $T_2(w)$ can be determined easily from the above information as it is given by the largest weight agreement matching in $G(x)$ comprising only edges incident upon or below vertex w in $R(x)$. Section 5 shows that the total time taken above is $O(\sum_{i=1}^{p} m_i \log\frac{n}{m_i})$, as required.

Inferring maximum agreement subtrees. Consider a vertex $w \in T_2$; let x be the beginning of the centroid path in T_2 containing w. Then $w \in R(x)$. The maximum agreement subtree of T_1 and $T_2(w)$ is given by the largest weight agreement matching in $G(x)$ comprising only edges incident upon or below vertex w in $R(x)$.

5. The analysis. We need the following preliminary lemmas before beginning the analysis.

LEMMA 5.1. *Consider graph $G(x)$. Then*

$$\sum_{i|d_x(u_i)>1} d_x(u_i)\log\frac{nsav(x)}{d_x(u_i)} \le \sum_{i|d_x(u_i)>1} d_x(u_i)\log\frac{n}{m_i}.$$

Proof. Multiplying each side by $\ln 2$, we get the following equivalent inequality:

$$A = \sum_{i|d_x(u_i)>1} d_x(u_i)\ln\frac{nsav(x)}{d_x(u_i)} \le \sum_{i|d_x(u_i)>1} d_x(u_i)\ln\frac{n}{m_i} = B.$$

Note that $\sum_{i|d_x(u_i)>1} d_x(u_i) = nswe(x)$. Let $\alpha_i(x) > 0$ be such that $d_x(u_i) = \alpha_i(x)\frac{m_i}{n} nswe(x)$. Then $\sum_{i|d_x(u_i)>1} \alpha_i(x) m_i = n$. Also note that $nsav(x) \le nswe(x)$. Therefore,

$$A \le B - \sum_{i|d_x(u_i)>1} \alpha_i(x)\frac{m_i}{n} nswe(x)\ln\alpha_i(x).$$

It suffices to show that

$$C = \sum_{i|d_x(u_i)>1} \alpha_i(x) m_i \ln \alpha_i(x) \geq 0.$$

We split C into two terms:

$$C_1 = \sum_{i|d_x(u_i)>1, \alpha_i(x)\geq 1} \alpha_i(x) m_i \ln \alpha_i(x)$$

and

$$C_2 = \sum_{i|d_x(u_i)>1, 0<\alpha_i(x)<1} \alpha_i(x) m_i \ln \alpha_i(x),$$

$$C_1 \geq \sum_{i|d_x(u_i)>1, \alpha_i(x)\geq 1} (\alpha_i(x) - 1) m_i.$$

Further,

$$\sum_{i|d_x(u_i)>1, \alpha_i(x)\geq 1} (\alpha_i(x) - 1) m_i - \sum_{i|d_x(u_i)>1, \alpha_i(x)<1} (1 - \alpha_i(x)) m_i$$
$$= \sum_{i|d_x(u_i)>1} (\alpha_i(x) - 1) m_i = \sum_{i|d_x(u_i)>1} \alpha_i(x) m_i - \sum_{i|d_x(u_i)>1} m_i \geq n - n \geq 0.$$

Therefore $C \geq \sum_{i|d_x(u_i)>1, 0<\alpha_i(x)<1} (1 - \alpha_i(x) + \alpha_i(x) \ln \alpha_i(x)) m_i \geq 0$. □

Recall that S_i denotes the subtree of T_2 induced by the leaves of M_i.

LEMMA 5.2. $\sum_{x\in X|d_x(u_i)>1} d_x(u_i) = O(m_i)$.

Proof. Consider $G(x)$ such that $d_x(u_i) > 1$. Then all but one of the vertices of $R(x)$ adjacent to u_i are also in S_i; this is because M_i intersects both the right and the left subtrees of all but the bottommost of the vertices adjacent to u_i in $R(x)$. Since each vertex in S_i is in at most one matching graph $G(x)$ and since $|S_i| = m_i$, the lemma follows. □

Consider a vertex $u_i \in \pi$. From Theorem 4.3 and Lemma 5.1, the following work is assigned to u_i when considering the matching graph $G(x)$, $x \in X$.

1. If M_i and $T_2(x)$ do not intersect, then no work is assigned to u_i as u_i is not in $G(x)$.
2. If $d_x(u_i) = 1$, then the work assigned to u_i is $O(\log \frac{|T_2(x)|}{n_j})$, where v_j is the vertex in $\pi(x)$ adjacent to u_i.
3. If $d_x(u_i) > 1$, then the work assigned to u_i is $O(d_x(u_i) \log \frac{n}{m_i})$.

The following is a corollary of Lemma 5.2 and the above bounds.

COROLLARY 5.3. *The work assigned to vertex u_i over all matching graphs $G(x)$ with $d_x(u_i) > 1$ is $O(m_i \log \frac{n}{m_i})$.*

It now suffices to account for the work assigned to vertex u_i over all matching graphs $G(x)$ with $d_x(u_i) = 1$. Next, we show that this work is also $O(m_i \log \frac{n}{m_i})$. We use the tree S_i for this analysis.

Analyzing over S_i. Note that for each $x \in X$ such that $d_x(u_i) = 1$, x is not in S_i, i.e., either it lies on the path in T_2 between the endpoints of some edge e in S_i, or it lies on the path in T_2 between the root of S_i and the root of T_2. In the former case, x is said to *lie* on edge e of S_i. To handle the latter case, we add a dummy edge

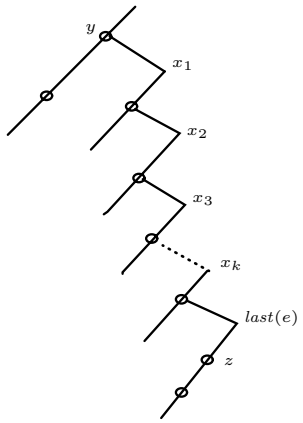

FIG. 5.1. *Portion of T_2 showing vertices in $H(e)$ and last(e).*

to S_i connecting its root to a new node, representing the root of T_2. This new node now becomes the root of S_i. This addition of the dummy edge is only for the next few paragraphs, until the work done on that edge is accounted for. Subsequent references to S_i will not have the dummy edge.

Consider the maximal subset $H(e)$ of vertices x in X which lie on edge e of S_i and for which $d_x(u_i) = 1$. Let $H(e) = \{x_1, x_2, \ldots, x_k\}$; here the vertices appear in increasing order of distance from the root of T_2. Let $e = (y, z)$, with y as the parent of z in S_i. Let *first*$(e) = x_1$. Let *last*(e) be the first vertex x in X such that $d_x(u_i) > 1$ and x is on the path from x_k to z in T_2, if any; otherwise, let *last*(e) be z (and then z is a leaf). See Figure 5.1.

LEMMA 5.4. *The sum of $|T_2($first$(e))|$ over any subset of edges of S_i, no two of which lie on the same root-to-leaf path in S_i, is $O(n)$.*

Proof. The above subtrees of T_2 are all disjoint. □

LEMMA 5.5. *The work assigned to u_i on edge e, i.e., in processing graphs $G(x)$, $x \in H(e)$, is $O(\log \frac{|T_2(\text{first}(e))|}{|T_2(\text{last}(e))|})$.*

Proof. The work assigned to u_i in processing $G(x_j)$ is $O(\log \frac{|T_2(x_j)|}{|T_2(x_{j+1})|})$ for $1 \leq j < k$ and $O(\log \frac{|T_2(x_k)|}{|T_2(\text{last}(e))|})$ for $j = k$. Thus the sum of the work assigned to u_i at the graphs $G(x_j)$ is $O(\log \frac{|T_2(\text{first}(e))|}{|T_2(\text{last}(e))|})$. □

COROLLARY 5.6. *The work assigned to u_i on the dummy edge e is $O(\log \frac{n}{m_i})$.*

Proof. $|T_2(\text{last}(e))| \geq m_i$. □

It remains to analyze the work assigned to u_i over the nondummy edges in S_i. From now onwards, we can ignore the dummy edge in S_i.

LEMMA 5.7. *Consider edges $e, e' \in S_i$ such that e is on the path from e' to the root of S_i. If $H(e), H(e')$ are nonempty, then $|T_2(\text{last}(e))| \geq |T_2(\text{first}(e'))|$.*

Proof. *first*(e') is a descendant of *last*(e) in T_2. □

We claim that sum of the work assigned to u_i over all the edges of S_i is $O(m_i \log \frac{n}{m_i})$. We show this next by applying tree contraction on S_i.

Removal step. First, remove all edges e in S_i incident upon leaves in S_i. The work done on these edges is bounded by the sum over all such edges e of $O(\log |T_2(\text{first}(e))|)$; further, the number of such edges is at most m_i. By Lemma 5.4, this sum is at most $O(m_i \log \frac{n}{m_i})$.

Contract step. Next, contract all paths consisting only of degree two vertices in S_i into a single edge. The H set for such an edge e is defined to be the union of the H sets for the edges comprising the path which was contracted to give e. The work done on e is also defined to be the sum of the work done on the relevant edges. *first*(e) and *last*(e) are again defined as before. As is easily seen, Lemmas 5.4, 5.5, and 5.7 hold for the new contracted tree as well. Further, this new tree has at most $m_i/2$ leaves.

Wrapping up. $O(\log m_i)$ phases of the removal and contract steps are performed. In the jth phase, the work done on the edges removed is $O(\frac{m_i}{2^{j-1}} \log \frac{n2^{j-1}}{m_i})$. Summing up over all phases, we get the following lemma.

LEMMA 5.8. *The work assigned to vertex u_i over all matching graphs $G(x)$ with $d_x(u_i) = 1$ is $O(m_i \log \frac{n}{m_i})$.*

The following lemma is needed in the next section.

LEMMA 5.9. *The total number of edges incident on u_i over all matching graphs is $O(m_i \log \frac{n}{m_i})$.*

Proof. Recall that the work attributed to a singleton edge is of the form $\log \frac{|T_2(x)|}{n_j} \geq 1$. Thus, Lemma 5.8 implies that there are $O(m_i \log \frac{n}{m_i})$ singleton edges incident to u_i, and by Lemma 5.2, there are $O(m_i)$ nonsingleton edges incident to u_i. ∎

THEOREM 5.10. *There is an algorithm for the MAST problem for two binary trees with an $O(n \log n)$ running time.*

Proof. Corollary 5.3 and Lemma 5.8 imply that the total work assigned to u_i is $O(m_i \log \frac{n}{m_i})$. Hence the total matching cost from Step 3 in section 3 is $O(\sum m_i \log \frac{n}{m_i})$. Further, Step 1 takes linear time. Also, in section 8, it will be shown that we can construct the recursive subproblems in Step 2 in linear time, so if we exclude the recursive calls, our cost is bounded by $c \sum m_i \log \frac{n}{m_i}$ for some sufficiently large c. Inductively, we assume that each recursive call takes at most $cm_i \log m_i$ time, and then the total time is at most

$$c \sum_i \left(m_i \log \frac{n}{m_i} + m_i \log m_i \right) = cn \log n,$$

as desired. ∎

The above analysis assumes (a) that we can construct the recursive subproblems in linear time, which will be done in section 8, (b) that we can construct the matching graphs in time proportional to their sizes, which will be done in sections 6 and 8, and (c) that Theorem 4.3 holds true, which will be proved in sections 7 and 9.

6. Constructing the matching graphs. We show how all the matching graphs can be set up in time proportional to the sum of their sizes, which by Lemma 5.9 is $O(\sum_{i=1}^{p-1} m_i \log \frac{n}{m_i})$. First, we show how to set up the vertices and edges in each graph. Then we show how the weights on the edges are computed.

Preprocessing. T_2 is preprocessed in linear time to compute a pointer from each vertex to the beginning of the centroid path containing it. It is also preprocessed to enable induced subtree computations in the same time bounds.

6.1. Setting up vertices and edges. The matching graphs in which vertex u_i appears along with the multiedges incident upon it in these graphs are determined in time proportional to the sum of the number of such multiedges over all such graphs as follows.

Processing u_p. First, consider the leaf u_p of T_1. The only matching graphs containing u_p are those which correspond to centroid paths beginning at vertices x of T_2 such that x is an ancestor of the twin of u_p in T_2. Further, if $u_p \in L(x)$, then there is a multiedge between u_p and vertex $y \in R(x)$ if and only if y is the nearest ancestor of u_p's twin in the centroid path beginning at x. Thus the matching graphs to which u_p belongs and the multiedges incident on u_p in these graphs can be determined in time proportional to the number of such graphs, given pointers from each vertex in T_2 to the beginning of the centroid path containing it.

Lemmas 6.1 and 6.2 are needed for the next step.

LEMMA 6.1. *If vertex v_j in the centroid path beginning at vertex x of T_2 is in S_i, then u_i is adjacent to v_j in $G(x)$.*

Proof. Clearly, if $j \neq q$, then M_i and N_j intersect, and if $j = q$, then v_j's twin is in M_i. □

LEMMA 6.2. *If vertex v_j in the centroid path beginning at vertex x of T_2 is not in S_i, then u_i is adjacent to v_j in $G(x)$ if and only if $v_j \neq v_q$ and there exists some vertex $y \in S_i$ which is in N_j.*

Proof. We assume that $j \neq q$. For if $j = q$, then $v_j = v_q$ is a leaf of T_2, and since it does not appear in S_i, its twin is not in M_i, and therefore, there is no edge between u_i and v_j.

First, suppose some vertex $y \in S_i$ is in N_j. Then, clearly, N_j intersects M_i. Therefore, there must be an edge between u_i and v_j in $G(x)$. Next, suppose that there is such an edge. Then N_j intersects M_i. Therefore, there exists some $y \in S_i$ which is in N_j. □

Processing $u_i, 1 \leq i \leq p-1$. The subtrees of T_2 induced by leaves of each M_i are computed in $O(\sum_1^{p-1} m_i)$ time as described in section 8. Let S_i denote this induced subtree. For each vertex z in S_i, perform the following in T_2 until a vertex in the centroid path containing the parent of z in S_i is reached: repeatedly jump to the parent of the beginning of the centroid path in T_2 containing the current vertex. By Lemmas 6.1 and 6.2, there is a multiedge from u_i to each vertex y of T_2 (in the corresponding matching graph containing y) encountered in this following procedure. Thus this procedure takes time proportional to the sum of the number of multiedges incident on u_i over all matching graphs it lies in, given pointers from each vertex in T_2 to the beginning of the centroid path containing it.

Remark. For an edge between u_i and v_j, $i \neq p$, $j \neq q$, define $map(i, j)$ as follows. If $v_j \in S_i$, then $map(i, j) = v_j$. Otherwise, if $v_j \notin S_i$, then $map(i, j)$ is that vertex in S_i which is closest to the root of S_i and a descendant of v_j in T_2. Note that $map(i, j)$ can be easily computed in the course of the above procedure.

6.2. Determining edge weights in $G(x)$. Recall that for a multiedge between u_i and v_j in $G(x)$, we need to determine the sizes of the maximum agreement subtrees of the following pairs of trees.

1. M_i, N_j: white edge weight.
2. $T_1(u_i)$, N_j: red edge weight.
3. M_i, $T_2(v_j)$: green edge weight.

Also recall that the multiedge itself indicates that M_i and N_j intersect.

Assume that the agreement matchings in graphs $G(x')$ have already been determined, where x' is a descendant of x in T_2. Using this information and the information computed in Step 2, we show how the above required information can be computed for multiedge (u_i, v_j) in graph $G(x)$ in constant time. Recall that in Step 2, the max-

imum agreement subtrees of M_i and the subtrees rooted at each vertex w of S_i were determined.

White edge weight. Let $y = map(i, j)$. If $y \neq v_j$, then the maximum agreement subtree of M_i and the subtree of S_i rooted at y gives the desired information. Suppose $y = v_j$, i.e., $y \in S_i$. Let z be the child of $y \in S_i$ such that $z \in N_j$. The maximum agreement subtree of M_i and the subtree of S_i rooted at z gives the desired information in this case. This takes constant time.

Green edge weight. The maximum agreement subtree of M_i and the subtree of S_i rooted at $y = map(i, j)$ gives the desired information in constant time.

Red edge weight. Let y be the root of N_j. Recall that the agreement matchings in graphs $G(x')$ have already been determined, where $x' \in X$ is a descendant of x in T_2. Since $y \in X$, agreement matchings in graph $G(y)$ would already have been computed. Recall from Theorem 4.3 that for each vertex in $L(y)$, the maximum weight agreement matching containing only edges incident on or below that vertex in $L(y)$ has been computed.

Note that since M_i intersects with $T_2(y)$ (since a multiedge exists between u_i and v_j), $u_i \in L(y)$. The largest weight agreement matching in $G(y)$ containing only edges incident on or below vertex u_i in $L(y)$ gives the desired information. This information is computed as graph $G(y)$ was processed, so it can be accessed in constant time now.

7. Computing agreement matchings. Consider graph $G(x)$. Recall that for each vertex in $L(x)$, we need to compute the largest weight agreement matching containing only edges incident on or below it in $L(x)$, and likewise for each vertex in $R(x)$. We outline the algorithm before giving details. The algorithm is similar to that in [FPT95a], but the data structure we use and the associated operations are different.

Algorithm outline. First, a weight balanced binary search tree $\mathcal{T}$ whose leaves are the vertices in $R(x)$ is set up; here, the vertices in $R(x)$ are given appropriate weights yet to be described. Next, the vertices in $L(x)$ are considered in turn in bottom-to-top order. For each vertex $u_i \in L(x)$, the vertices adjacent to it in $R(x)$ are searched for in $\mathcal{T}$; the largest weight agreement matching with each white edge incident on u_i as topmost edge is found in the course of this search, as is the largest weight proper crossing for each green edge incident on u_i. From the above information, the largest weight agreement matching containing only edges incident on or below u_i in $L(x)$ is easily found. Following the above search, the information stored in $\mathcal{T}$ is updated. The time taken for processing u_i will be $O(d_x(u_i) \log \frac{nsav(x)}{d_x(u_i)})$ if $d_x(u_i) > 1$ and $O(\log \frac{|T(x)|}{n_j})$ if $d_x(u_i) = 1$ and u_i is adjacent to v_j in $G(x)$. After all vertices in $L(x)$ have been processed, the vertices in $R(x)$ are processed. For all such vertices v_j, the largest weight agreement matching containing only edges incident on or below v_j in $R(x)$ are found in $O(|R(x)|)$ time by a single scan of $\mathcal{T}$. The bounds in Theorem 4.3 follow.

Weighted search tree $\mathcal{T}$. Vertex $v_j \in R(x)$ is given weight $n_j + \frac{|T(x)|}{nsav(x)}$ if some nonsingleton edge in $G(x)$ is incident upon it, and weight n_j otherwise. The sum of the weights of vertices in $R(x)$ is at most $2|T(x)|$. The construction of $\mathcal{T}$ using these weights is dealt with in section 9.

Tree $\mathcal{T}$ has the following three crucial characteristics.

1. $\mathcal{T}$ can be constructed in $O(|R(x)|)$ time.
2. Searching for v_j in $\mathcal{T}$ takes $O(\log \frac{|T(x)|}{n_j})$ time.

3. Searching for an ordered subset $\{v_{j_1}, \ldots, v_{j_k}\}$ of $R(x)$, each vertex in which has an incident nonsingleton edge, takes $O(k \log \frac{nsav(x)}{k})$ time. The procedure used here is to first search for v_{j_1}, starting at the root, and then to search for v_{j_2}, starting at v_{j_1} in the obvious way, and so on.

Auxiliary information in $\mathcal{T}$. We maintain the following auxiliary information at each internal vertex in $\mathcal{T}$. Recall that we process the vertices of $L(x)$ in order; an edge of $G(x)$ is said to be *in* $\mathcal{T}$ if its endpoint in $L(x)$ has already been processed. Further, we say that an edge of $G(x)$ is *in* $\mathcal{T}(z)$ if it is in $\mathcal{T}$ and its endpoint in $R(x)$ is located in $\mathcal{T}(z)$. Let $anc(z)$ denote the set of ancestors of z in $\mathcal{T}$, z inclusive. For a leaf $v_j \in \mathcal{T}$, $lfringe(v_j)$ is the set of vertices in $\mathcal{T}$ which are left children of vertices in $anc(v_j)$ but not themselves in $anc(v_j)$. $rfringe(v_j)$ is defined analogously.

The following information is maintained at each vertex z of $\mathcal{T}$.

1. $g(z)$: For each z, $\max_{z' \in anc(z)} g(z')$ will be the heaviest green edge in $\mathcal{T}$ which forms a proper crossing with each red edge in $\mathcal{T}(z)$.
2. $x(z)$: This is largest weight proper crossing among the edges in $\mathcal{T}(z)$.
3. $m(z)$: This is largest weight agreement matching containing a white edge such that the topmost white edge is in $\mathcal{T}(z)$.
4. $y(z)$: This the largest weight proper crossing such that the green edge in this crossing is in $\mathcal{T}$ but not in $\mathcal{T}(z)$, the red edge in this crossing is in $\mathcal{T}(z)$, and the green edge does not form a proper crossing with all the red edges in $\mathcal{T}(z)$.
5. $r(z)$: This is simply the heaviest red edge in $\mathcal{T}(z)$.

Next, we show how vertex u_i is processed, given that vertices below it in $L(x)$ have been processed. For the moment, assume that $d_x(u_i) = 1$. The case when $d_x(u_i) > 1$ will be addressed later.

Case 1. $d_x(u_i) = 1$. Let v_j be the only vertex to which u_i is adjacent. First, v_j is found in $\mathcal{T}$; this takes $O(\log \frac{|T(x)|}{n_j})$ time. Next, the white, red, and green edges incident on u_i are processed as described below in the same time bound. An important fact to note is that in each case, the information in $\mathcal{T}$ will be read and updated only at vertices in the set $anc(v_j)$ and vertices which are children of vertices in this set; the time taken in this process will be proportional to the depth of v_j, i.e., $O(\log \frac{|T(x)|}{n_j})$.

Processing white edge $e = (u_i, v_j)$. First, the largest weight agreement matching with e as the topmost edge is determined. Then the $m()$ values at vertices in $anc(v_j)$ are updated according to the weight of this matching. All other information remains unchanged.

The above desired matching is computed as follows. There are two cases. In the first case, this matching contains another white edge. The largest weight matching among all such matchings is given by $1 + \max_{z \in lfringe(v_j)} m(z)$. The other case occurs when this matching contains only edge e plus a proper crossing. Thus, it suffices to compute the largest proper crossing containing edges dominated by e. This is given by

$$\max \left\{ \max_{z \in lfringe(v_j)} x(z), \max_{z \in lfringe(v_j)} \left(\max_{z' \in anc(z)} g(z') \right) + r(z), \max_{z \in lfringe(v_j)} y(z) \right\}.$$

The first term here is the largest weight proper crossing in which both edges are in $\mathcal{T}(z)$ for some $z \in lfringe(v_j)$. The second term is the largest weight proper crossing in which the red edge is in $\mathcal{T}(z)$ for some $z \in lfringe(v_j)$; the green edge is not in this subtree but it forms a proper crossing with each red edge in this subtree. The third term is the largest weight proper crossing in which the red edge is in $\mathcal{T}(z)$ for some

$z \in \mathit{lfringe}(v_j)$; the green edge is not in this subtree and it does not form a proper crossing with some red edge in this subtree.

Processing red edge $e = (u_i, v_j)$. The $m()$ and $x()$ values remain unchanged in $\mathcal{T}$. Next, note that no green edge already in $\mathcal{T}$ can form a proper crossing with e. This implies that the $y()$ and $g()$ values for $z \in anc(v_j)$ need to be modified.

Consider $y(z)$ first, $z \in anc(v_j)$. A green edge in $\mathcal{T}$ which formed a proper crossing with all red edges in $\mathcal{T}(z)$ does not do so any more. So $y(z)$ is set to $\max\{y(z), (\max_{z' \in anc(z)} g(z')) + r(z)\}$.

Consider $g(z)$ next, $z \in anc(v_j)$. $g(z)$ is set to ϕ. Before this is done, $g(y)$ is updated to $\max_{y' \in anc(y)} g(y')$ for each $y \in \mathit{lfringe}(v_j)$ and $y \in \mathit{rfringe}(v_j)$. The invariant on $g()$ is easily seen to be maintained.

Finally, $r(z)$ is set to $\max\{r(z), wt(e)\}$ for each z, $z \in anc(v_j)$.

Processing green edge $e = (u_i, v_j)$. Note that e can form a proper crossing with only those red edges in $\mathcal{T}$ which are in $\mathcal{T}(z)$, $z \in \mathit{rfringe}(v_j)$; further, e forms a proper crossing with each such red edge. Therefore, $g(z)$ is set to

$$\max\left\{ \max_{z' \in anc(z)} g(z'), wt(e) \right\}$$

for each $z \in \mathit{rfringe}(v_j)$.

For each $z \in anc(v_j)$, $x(z)$ is then set to the larger of the current value and $\max(wt(e) + r(z'))$, the maximum being taken over all vertices $z' \in \mathit{rfringe}(v_j)$ which are descendants of z. Also note that $\max_{z \in \mathit{rfringe}(v_j)}(wt(e) + r(z))$ gives the largest weight proper crossing containing e.

Case 2. $d_x(u_i) = k > 1$. Suppose u_i is adjacent to $v_{j_1}, v_{j_2}, \ldots, v_{j_k}$, in bottom-to-top order. Then these vertices are searched for in sequence in $\mathcal{T}$. This takes $O(k \log \frac{nsav(x)}{k})$ time by the procedure mentioned earlier, i.e., first search for v_{j_1}, starting at the root, and then search for v_{j_2}, starting at v_{j_1} in the obvious way, and so on. In the above process, all vertices in the set $\{z | z \in (anc(v_{j_1}) \cup anc(v_{j_2}) \cup \cdots \cup anc(v_{j_k}))\}$ are traversed. Again, as in Case 1, only information at vertices in the above set and at children of vertices in the above set needs to be read and updated. This takes time proportional to the size of the above set, which, in turn, is $O(k \log \frac{nsav(x)}{k})$.

Processing $R(x)$. It remains to show how, for each $v_j \in R(x)$, the largest weight agreement matching containing only edges incident on or below v_j in $R(x)$ is computed.

For each $v_j \in R(x)$, we find the largest weight agreement matching with some white edge incident upon v_j as the dominant edge and the largest weight proper crossing containing some red edge incident on v_j. This information clearly suffices. The first of the above two is given simply by $m(v_j)$. The second is given by $\max\{y(z), \max_{z' \in anc(v_j)} g(z') + r(v_j)\}$. Over all $v_j \in R(x)$, the computation of the above two values can be accomplished in a single pass of $\mathcal{T}$ in $O(|R(x)|)$ time.

8. Computing induced subtrees. We show how to preprocess a tree in $O(|T|)$ time so that given any subset L of its leaves in order, the subtree induced by L can be computed in $O(|L|)$ time. The construction is a generalization of the proof of Lemma 5.2 in [FT95].

T is preprocessed for LCA queries in $O(|T|)$ time. This enables the computation of the LCA of any two leaves of T in constant time [HT84]. The distance of each vertex from the root of T is also computed; call this quantity the *depth* of a vertex.

Given the ordered set of leaves $L = l_1, l_2, \ldots, l_{|L|}$, the following steps are executed. First, the LCA l'_i of each pair of consecutive leaves l_i, l_{i+1}, $1 \leq i \leq |L| - 1$, is found; the l'_is will be the internal vertices in the subtree induced by L. Next, the edges between vertices are set up as follows.

For each vertex v in the sequence $l_1, l'_1, l_2, l'_2, \ldots, l_{|L|-1}, l'_{|L|-1}, l_{|L|}$, two vertices v_{left} and v_{right} are computed. v_{left} is the nearest vertex to the left of v, if any, which has depth strictly less than v. v_{right} is defined analogously. This computation is easily accomplished in $O(|L|)$ time. Finally, edges are put between v and one of v_{left}, v_{right}—whichever has greater depth. If exactly one of v_{left}, v_{right} is defined (this will happen only for vertices on the paths from the root to the leftmost and rightmost leaves in the induced subtree), then an edge is put between v and the vertex which is defined. The root of the induced tree will be the unique vertex for which both v_{left} and v_{right} are undefined; no edges need be put in this case.

Step 2 of the main algorithm. Step 2 (see section 3) requires finding the induced trees S_i for each M_i, $1 \leq i \leq p-1$, in $O(\sum_i^{p-1} m_i)$ time. This is done in two steps. (Essentially, this procedure is described in [FT95].) First, the leaves of each M_i are sorted by the order in which their twins occur in T_2. This is done by bucket sorting all the leaves of T_1 by the order in which their twins occur in T_2, and then bucket sorting them (in a stable way) by the order in which the trees M_i to which they belong occur in T_1. This takes $O(\sum_i^{p-1} m_i)$ time.

Next, for each M_i, $1 \leq i \leq p-1$, the subtree of T_2 induced by the leaves of M_i is found using the algorithm described above in $O(m_i)$ time. The total time taken is $O(\sum_i^{p-1} m_i)$.

9. The weighted search tree. We will now complete our solution to the *MAST* problem by describing the weighted search trees from section 7. Recall that we are given vertices $v_1, v_2, \ldots, v_{|R(x)|}$, such that vertex v_j has weight $w(v_j) = n_j + \frac{|T(x)|}{nsav(x)}$ if it has an incident nonsingleton edge, and weight $w(v_j) = n_j$ otherwise. The sum of the vertex weights is bounded by $2|T(x)|$.

Theorem 9.1 from [Fre75, Meh77] shows that the weight balanced tree $\mathcal{T}$ can be constructed in $O(|R(x)|)$ time.

THEOREM 9.1. *Given weights $w_1, \ldots, w_n$ with sum W, a binary tree such that the depth of the ith leaf is $O(1 + \log(W/w_i))$ can be constructed in $O(n)$ time. In this tree, the total weight of all leaves in the subtree rooted at any node z will be at most half of the corresponding weight for the subtree rooted at the grandparent of z.*

It follows from Theorem 9.1 that the time to search for v_j in $\mathcal{T}$ is $O(1+\log \frac{|2T(x)|}{w(v_j)}) = O(1 + \log \frac{|T(x)|}{n_j})$.

Next consider the case when an ordered subset $\{v_{j_1}, \ldots, v_{j_k}\}$ of vertices is given, each having an incident nonsingleton edge. The algorithm to search for these vertices is to first start from the root and search for v_{j_1}, then start from v_{j_1} and search for v_{j_2}, then start from v_{j_2} and search for v_{j_3}, and so on. Each search is performed in the obvious way. For technical reasons, we return to the root at the end.

Each edge in $\mathcal{T}$ is traversed at most twice during the above search, once in each direction.

Consider the topological subtree formed by the traversed edges. It has k leaves and $k-1$ internal nodes with two children. These nodes form a tree, with each edge

in the tree corresponding to a path in the search tree. We associate with a node in the topological subtree the path in the search tree corresponding to the edge from the node to its parent in the topological subtree. The associated path for the root node of the topological subtree is the path from this node to the root of the search tree. We will give an upper bound on the total number of vertices on these paths excluding their endpoints. To do this, we give a lower bound on the total weight of the "off-path" subtrees for each path. (An "off-path" subtree for a node is simply the subtree which does not contain the continuation of the path.)

Let l be the number of internal vertices on one such path associated with node v. By Theorem 9.1, the sum of the weights of every second root of the off-path subtrees is at least $(2w(v) - w(v)) + (4w(v) - 2w(v)) + \cdots + (2^{\lfloor l/2 \rfloor} w(v) - 2^{\lfloor l/2 \rfloor - 1} w(v)) = (2^{\lfloor l/2 \rfloor} - 1)w(v)$. But $w(v) \geq \frac{|T(x)|}{nsav(x)}$ and the total weight is at most $2T(x)$. Simple calculus shows that the sum of these lower bounds on the path lengths is maximized when the terms $w(v)$ are all at their minimum value and the path weights are all equal at $2T(x)/(2k-1)$. This gives path lengths of $O(\log \frac{nsav(x)}{2k-1})$ and hence a total path length of $O(k \log \frac{nsav(x)}{k})$.

10. Concluding remarks. We can generalize our technique to higher degree bounds $d > 2$ by combining it with techniques from [FT95, section 2] for unbounded degrees. This appears to yield an algorithm with running time $O(\min\{n\sqrt{d} \log^2 n, nd \log n \log d\})$. We conjecture, however, that there is an algorithm with running time $O(n\sqrt{d} \log n)$.

Acknowledgments. We would like to thank the referees for some very thorough comments.

THE WARM-UP ALGORITHM: A LAGRANGIAN CONSTRUCTION OF LENGTH RESTRICTED HUFFMAN CODES*

RUY LUIZ MILIDIÚ† AND EDUARDO SANY LABER‡

Abstract. Given an alphabet $\{a_1, \ldots, a_n\}$ with the corresponding list of weights $[w_1, \ldots, w_n]$, and a number $L \geq \lceil \log n \rceil$, we introduce the WARM-UP algorithm, a Lagrangian algorithm for constructing suboptimal length restricted prefix codes. Two implementations of the algorithm are proposed. The first one has time complexity $O(n \log n + n \log \overline{w})$, where $\overline{w}$ is the highest presented weight. The second one runs in $O(nL \log(n/L))$ time. The number of additional bits per symbol generated by WARM-UP when comparing to Huffman encoding is not greater than $1/\psi^{L-\lceil \log(n+\lceil \log n \rceil - L) \rceil - 2}$. Even though the algorithm is approximated it presents an optimal behavior for practical settings.

An important feature of the proposed algorithm is its implementation simplicity. The algorithm is basically a selected sequence of Huffman tree constructions for modified weights. The approach gives some new insights on the problem.

1. Introduction.

An important problem in the field of coding and information theory is the variable length code problem [10]. A particular case of relevant interest is the binary prefix code problem. Given an alphabet $\Sigma = \{a_1, \ldots, a_n\}$ and a corresponding list of weights $[w_1, \ldots, w_n]$, the problem is to find a prefix code for Σ that minimizes the *weighted length* of a code string, defined to be $\sum_{i=1}^{n} w_i l_i$, where l_i is the length of the code assigned to a_i. This problem is equivalent to the following problem: given a list of weights $[w_1, \ldots, w_n]$, find a tree T that minimizes the *weighted path length* $\sum_{i=1}^{n} w_i l_i$, where l_i is the height of the ith leaf of T. T must be chosen among all full binary trees[1] with n leaves. The equivalence is due to the fact that every binary prefix code can be represented by a full binary tree [4]. If the list of weights is sorted, this problem can be solved in $O(n)$ by one of the efficient implementations of Huffman's algorithm [10, 26, 21]. Any tree constructed by Huffman's algorithm is called a Huffman tree.

In this paper we consider the binary prefix code problem with restricted maximal length, that is, for a fixed $L \geq \lceil \log n \rceil$, we must minimize $\sum_{i=1}^{n} w_i l_i$ constrained to $l_i \leq L$ for $i = 1, \ldots, n$. Gilbert [8] recommends formulating this problem when the weights w_i are inaccurately known. Choueka, Klein, and Perl [3] suggest the use of length restricted codes to reduce the external path length $\sum_{i=1}^{n} l_i$. The objective is to allow space efficient decoding of optimal prefix codes without bit-manipulation. Zobel and Moffat [29] describe the use of word-based Huffman codes for compression of large textual databases. The application allows the maximum of 32 bits for each codeword. For the cases that exceed this limitation, it is recommended to use length restricted codes.

[1]In a full binary tree each internal node has exactly two children.

Some methods can be found in the literature to solve the binary prefix code problem with restricted maximal length [9, 27, 12, 5, 1, 23]. The first polynomial algorithm is due to Garey [7]. The algorithm is based on dynamic programming, and it has an $O(n^2L)$ complexity for time and space. Larmore and Hirschberg [12] presented the Package-Merge algorithm. This is an $O(nL)$ algorithm that requires linear space. The authors reduce the original problem to a coin collector's problem, using a nodeset representation of a binary tree. Turpin and Moffat [25] discuss some aspects about the implementation of the Package-Merge algorithm. Aggarwal, Schieber, and Tokuyama [1] have used Megiddo's parametric search paradigm [14] to obtain an $O(n\sqrt{L \log n} + n \log n)$ time algorithm. Currently, the fastest strongly polynomial time algorithm for the problem is due to Schieber [23]. This algorithm also utilizes a parametric search. However, it runs in $O(n2^{O(\sqrt{\log L \log\log n})})$ time and requires $O(n)$ space. These last two algorithms are based on a reduction of the binary prefix code problem to the concave least weight subsequence problem [13].

Some approximative algorithms have also been proposed in the literature [5, 15]. Milidiú and Laber proposed the build, remove, condense, and insert (BRCI) algorithm [15, 17]. This algorithm is $1/\psi^{L-\lceil \log(n+\lceil \log n \rceil - L)\rceil - 1}$-approximative and constructs prefix codes with restricted maximum length L in $O(n)$ time if the input weights are already sorted. The algorithm requires $O(n)$ space. BRCI first constructs a Huffman tree, and next it obtains a code tree with restricted maximal height L. The second tree is obtained by removing some leaves of the Huffman tree and condensing them into a complete binary tree. The strategy employed by the ROT algorithm is similar [5]. However, it does not provide a good theoretical approximation for the most important case, where $L = O(\log n)$.

In this paper we present an approximative algorithm that constructs length restricted prefix codes. The algorithm is called WARM-UP. It is based on Lagrangian relaxation [2], a powerful technique used to solve some important problems in *combinatorial optimization*. A very simple implementation of WARM-UP runs in $O(n \log n + n \log \overline{w})$ time, where n is the number of weights and $\overline{w}$ is the highest weight. A more elaborated implementation that uses Megiddo's parametric search runs in $O(nL \log(n/L))$ time. The algorithm requires $O(n)$ space and allows a very space-economical implementation [18]. We show that the number of additional bits per symbol generated by a WARM-UP code rather than a Huffman code is not greater than $1/\psi^{L-\lceil \log(n+\lceil \log n \rceil - L)\rceil - 2}$.

The first parametric search proposed in [1] is similar to the WARM-UP approach introduced here. Nevertheless, from a Lagrangian point of view, the former approach uses only one Lagrange multiplier, whereas the later uses a varying number of nonzero Lagrange multipliers throughout the WARM-UP process. Furthermore, Aggarwal's algorithm solves a sequence of concave least weight subsequence problems, while our algorithm constructs a sequence of Huffman trees. Due to the simplicity of Huffman's procedure, the WARM-UP algorithm has a small constant factor in its $O(n \log n + n \log \overline{w})$ time complexity. Furthermore, WARM-UP can take advantage of improvements in Huffman's procedure, such as the recent ones proposed in [22, 19].

WARM-UP is quite different from the other approximative algorithms presented in the literature. First, WARM-UP is able to recognize when it gets an optimal code during its execution, while the others are not. This capability is provided by the Lagrangian duality theory. Second, WARM-UP constructs optimal codes in almost all practical settings. This behavior does not happen with the algorithms proposed in [5, 15]. Although this fact is based on empirical results, it can be theoretically

explained somehow. Actually, the codes obtained by the WARM-UP algorithm are optimal codes either for the length restricted problem or for a related problem, where some codeword lengths cannot be longer than L and some others cannot be longer than $L-1$. This fact gives some insight on why WARM-UP is able to construct optimal codes so frequently. Hence, WARM-UP allows as simple implementations as the other approximate algorithms, and it is also able to produce length restricted codes with compression power similar to those produced by the exact algorithms.

The paper is organized as follows. In section 2, we give an integer programming formulation to the problem and develop the theoretical background needed to justify our algorithm. In section 3, we address the special case of constructing a Huffman tree with height exactly equal to L, given that the Huffman tree with maximum height has height greater than L, and the Huffman tree with minimum height has height smaller than L. In section 4, we introduce the WARM-UP algorithm. In section 5, we present a strong polynomial implementation for WARM-UP. In section 6, we analyze the approximation of the algorithm. In section 7, we present some experimental results. Finally, in section 8, we comment on our findings.

2. The Lagrangian approach. Our approach is based on an integer programming formulation to the problem. Given a sequence of n integer weights $w_1 \leq \cdots \leq w_n$ and a length $L \geq \lceil \log n \rceil$, the problem is to find a sequence of n integers $l_1, \ldots, l_n$ that minimizes

$$\sum_{i=1}^{n} w_i.l_i,$$

constrained to

$$\begin{cases} l_i \leq L, \\ \sum_{i=1}^{n} 2^{-l_i} = 1, & i = 1, \ldots, n. \\ l_i \in N, \end{cases} \tag{2.1}$$

We call this problem P_L. The restriction $\sum_{i=1}^{n} 2^{-l_i} = 1$ is satisfied if and only if $l_1, \ldots, l_n$ are the heights of the leaves of a full binary tree with n leaves [4]. In mathematical programming terms, we say that P_L is a primal problem [20].

Since $w_1 \leq \cdots \leq w_n$, there is a solution where $l_1 \geq \cdots \geq l_n$. Throughout this work we use this fact. For convenience, we use S_n to denote the points with integer coordinates that satisfy $\sum_{i=1}^{n} 2^{-l_i} = 1$, and we use $h(T)$ to denote the height of a tree T.

2.1. The Lagrangian relaxation. Let $\boldsymbol{\lambda} = (\lambda_1, \ldots, \lambda_n)$, with $\lambda_i \geq 0$ for $i = 1, \ldots, n$. The Lagrangian function associated to problem P_L is given by

$$L(\boldsymbol{l}, \boldsymbol{\lambda}) = \sum_{i=1}^{n} w_i.l_i + \sum_{i=1}^{n} \lambda_i.(l_i - L). \tag{2.2}$$

The values λ_i are called Lagrangian multipliers. A point $(\overline{\boldsymbol{l}}, \overline{\boldsymbol{\lambda}})$ is a saddle point of the Lagrangian function $L(\boldsymbol{l}, \boldsymbol{\lambda})$ if and only if

(a) $L(\overline{\boldsymbol{l}}, \overline{\boldsymbol{\lambda}}) \leq L(\boldsymbol{l}, \overline{\boldsymbol{\lambda}})$ for all $\boldsymbol{l} \in S_n$,
(b) $\overline{l_i} \leq L$ for $i = 1, \ldots, n$,
(c) $\overline{\boldsymbol{\lambda}}_i.(\overline{l_i} - L) = 0$ for $i = 1, \ldots, n$.

It is a well-known result [20] that if $(\bar{\boldsymbol{l}}, \overline{\boldsymbol{\lambda}})$ is a saddle point of the Lagrangian function $L(\boldsymbol{l}, \boldsymbol{\lambda})$, then $\bar{\boldsymbol{l}}$ is a global optimum to the primal problem, in this case to problem P_L.

Now, we can establish a sufficient condition for the sequence of integers $l_1, \ldots, l_n$ to be a solution to problem P_L.

THEOREM 2.1. *Let* $\overline{\boldsymbol{\lambda}} = (\overline{\lambda_1}, \ldots, \overline{\lambda_n})$, *with* $\overline{\lambda_i} \geq 0$ *for* $i = 1, \ldots, n$. *Let also* $\bar{\boldsymbol{l}} = (\bar{l_1}, \ldots, \bar{l_n})$ *be the heights of the leaves of a Huffman tree for the modified list of weights given by* $w_1 + \overline{\lambda_1}, \ldots, w_n + \overline{\lambda_n}$. *If*

$$\begin{cases} \bar{l}_i \leq L, \\ \bar{l}_i = L \text{ when } \overline{\lambda_i} \neq 0 \end{cases}$$

for $i = 1, \ldots, n$, *then* $\bar{\boldsymbol{l}}$ *solves problem* P_L.

Proof. We show that $(\bar{\boldsymbol{l}}, \overline{\boldsymbol{\lambda}})$ is a saddle point of the Lagrangian function $L(\boldsymbol{l}, \boldsymbol{\lambda})$ by proving conditions (a)–(c).

(a) Since $\bar{\boldsymbol{l}}$ corresponds to the heights of the leaves of a Huffman tree for the weights $w_1 + \overline{\lambda_1}, \ldots, w_n + \overline{\lambda_n}$, it follows that

$$\sum_{i=1}^{n} (w_i + \overline{\lambda}_i).\bar{l}_i \leq \sum_{i=1}^{n} (w_i + \overline{\lambda}_i).l_i \quad \text{for all } \boldsymbol{l} \in S_n.$$

Subtracting the expression $\sum_{i=1}^{n} \overline{\lambda}_i.L$ from both sides of the inequality above, we obtain that

$$\sum_{i=1}^{n} w_i.\bar{l}_i + \sum_{i=1}^{n} \overline{\lambda}_i(\bar{l}_i - L) \leq \sum_{i=1}^{n} w_i.l_i + \sum_{i=1}^{n} \overline{\lambda}_i(l_i - L),$$

and therefore,

$$L(\bar{\boldsymbol{l}}, \overline{\boldsymbol{\lambda}}) \leq L(\boldsymbol{l}, \overline{\boldsymbol{\lambda}}) \text{ for all } \boldsymbol{l} \in S_n.$$

Conditions (b) and (c) follow immediately from the theorem hypothesis. This result shows that $\bar{\boldsymbol{l}}$ is a global optimum to problem P_L. ∎

2.2. Finding the multipliers. Theorem 2.1 suggests a simple way to solve problem P_L. Find multipliers $\lambda_1, \ldots, \lambda_n$ such that the Huffman tree for the modified weights $w_1 + \lambda_1, \ldots, w_n + \lambda_n$ have height equal to L, and all the leaves associated to the effectively modified weights $w_i + \lambda_i$, with $\lambda_i > 0$, are arranged at height L. This Huffman tree is an optimal prefix code tree with height restriction L.

As an example, let us consider the list of weights $W = [1, 1, 2, 3, 5, 8, 13]$. Figure 1 (a) shows a Huffman tree for this list. Suppose that we add 0.5 to the two lowest weights of the given list. The tree in Figure 1 (b) is a Huffman tree for this modified list. Since all the leaves with modified weights are at height 4, then the tree in Figure 1 (b) is an optimal code tree with restricted maximal height 4 for the original list of weights W.

A natural question appears: *how to choose these multipliers?*

Our approach to choose these multipliers is to select a value x, with $w_1 < x < w_n$, and set

$$\lambda_i = \max\{0, x - w_i\}.$$

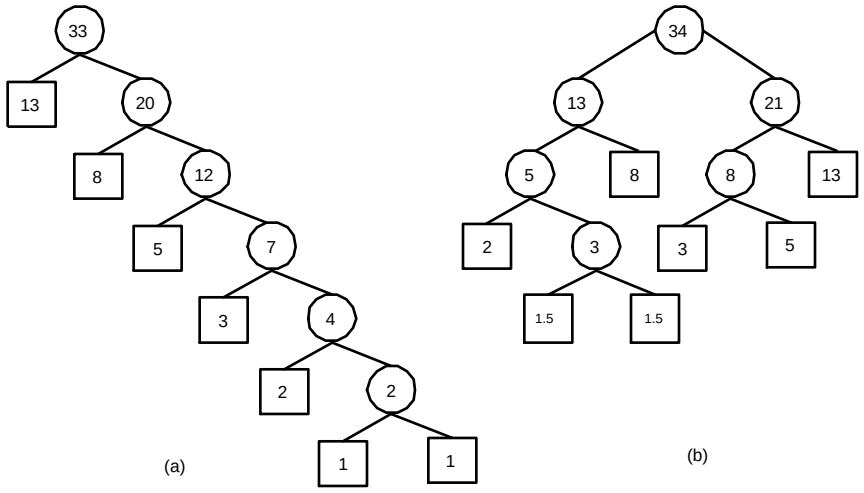

FIG. 1. (a) *A Huffman tree for the list of weights* $[1, 1, 2, 3, 5, 8, 13]$. (b) *An optimal tree with maximal restricted height* 4 *for the same list.*

Next, we use a test to verify if the chosen set of multipliers, defined by x, is adequate. Let $\boldsymbol{w}^x$ be the new list of weights obtained through this perturbation. Observe that $\boldsymbol{w}^x = (\max\{w_1, x\}, \ldots, \max\{w_n, x\})$. Let T_x be a Huffman tree for the list $\boldsymbol{w}^x$. We say that the leaves of T_x with weight x are the *warmed leaves.* A tree T_x has a useful property, given by the following lemma.

LEMMA 2.2. *If $h(T_x) = L$, then all the warmed leaves of T_x are either at height L or $L-1$ in T_x.*

Proof. Since x is the smallest weight of the list $\boldsymbol{w}^x$ and $h(T_x) = L$, then there is a warmed leaf arranged at height L. On the other hand, leaves with equal weights are always arranged in consecutive heights in a Huffman tree [28]. Hence, all the warmed leaves are either at height L or $L-1$ in T_x. □

If $h(T_x) = L$, then we are close to the conditions of Theorem 2.1. Actually, we can prove that a tree T_x with height L either solves P_L or a quite related problem.

THEOREM 2.3. *Let T_x be a tree such that $h(T_x) = L$, and let n_L and n_{L-1} be, respectively, the number of leaves at heights L and $L-1$ in T_x. Moreover, let $\overline{\boldsymbol{l}} = (\overline{l_1} \geq \cdots \geq \overline{l_n})$ be the heights of the leaves of T_x. We have the following.*

(a) *If $n_{L-1} = 0$, then $\overline{\boldsymbol{l}}$ solves the problem P_L.*

(b) *If $n_{L-1} > 0$, then $\overline{\boldsymbol{l}}$ solves the problem P_L with the additional list of constraints*

$$l_i \leq L - 1 \text{ for } i = n_L + 1, \ldots, n_L + n_{L-1}.$$

Proof. (a) Lemma 2.2 ensures that all warmed leaves can only be at heights L and $L-1$ in a T_x tree with height L. Since $n_{L-1} = 0$, it follows that all the warmed leaves are at height L. Hence, it follows from Theorem 2.1 that $\overline{\boldsymbol{l}}$ solves the problem P_L.

(b) The proof is analogous to that of Theorem 2.1. It suffices to prove that $(\overline{\boldsymbol{l}}, \overline{\boldsymbol{\lambda}})$, where $\overline{\lambda_i} = \max\{0, x - w_i\}$ for $i = 1, \ldots, n$, is a saddle point of the Lagrangian function associated to P_L with the additional list of constraints

$$l_i \leq L - 1 \text{ for } i = n_L + 1, \ldots, n_L + n_{L-1}. \qquad \square$$

We have given some insight explaining why a tree T_x with height L induces very good codes. One question arises: *how to select x?*

Let us define T_x^- as a Huffman tree with minimum height for the list $\boldsymbol{w}^x$, and T_x^+ as a Huffman tree with maximum height for the same list. Schwartz [24] shows how to construct both of these trees. The following theorem shows that if we increase the value of the parameter x, then the heights of the warmed leaves of the tree T_x cannot increase. In particular, the height of T_x cannot increase. This monotonicity suggests that we can determine an adequate value for x through a convenient binary search.

THEOREM 2.4. *Let s, t be two real numbers, with $0 < s < t$. Furthermore, let $\overline{\boldsymbol{l}} = (\overline{l_1} \geq \cdots \geq \overline{l_n})$ and $\boldsymbol{l}' = (l'_1 \geq \cdots \geq l'_n)$ be, respectively, the heights of the leaves of the trees T_s^- and T_t^+. Then*

$$l'_i \leq \overline{l_i}$$

for $i = 1, \ldots, k$, where k is the largest value such that $\max\{s, w_k\} = s$.

Proof. The optimality of $\overline{\boldsymbol{l}}$ and $\boldsymbol{l}'$ implies that

$$\sum_{i=1}^{n} \max\{w_i, s\}.(l'_i - \overline{l_i}) \geq 0, \tag{2.3}$$

$$\sum_{i=1}^{n} \max\{w_i, t\}.(\overline{l_i} - l'_i) \geq 0. \tag{2.4}$$

Let k' be the greatest integer value such that $\max\{t, w_k\} = t$. Adding inequalities (2.3) and (2.4), we obtain that

$$(t - s).\sum_{i=1}^{k}(\overline{l_i} - l'_i) + \sum_{i=k+1}^{k'} (t - w_i)(\overline{l}_i - l'_i) \geq 0. \tag{2.5}$$

Since we have k' equal weights in the tree T_t^+, it follows that $l'_1 \geq l'_i \geq l'_1 - 1$ for $i = 1, \ldots, k'$. Similarly, we have that $\overline{l_1} \geq \overline{l_i} \geq \overline{l_1} - 1$ for $i = 1, \ldots, k$.

Let us assume that $l'_i > \overline{l_i}$ for some $i \leq k$. We can show that this assumption implies that $l'_j \geq l_j$ for $j = 1, \ldots, k'$. In effect, if $j > i$, we have that $l'_j \geq l'_i - 1 \geq l_i \geq l_j$. On the other hand, if $j < i$, then $l'_j \geq l'_i \geq \overline{l_i} + 1 \geq \overline{l_j}$. Since $l'_j \geq \overline{l_j}$ for $j = 1, \ldots, k'$ and $l'_i > l_i$, then the inequality (2.5) is not satisfied. Since this contradiction was generated by the assumption that $l'_i > \overline{l_i}$ for some $i \leq k$, then we have that $l'_i \leq \overline{l_i}$ for $i = 1, \ldots, k$. ∎

COROLLARY 2.5 (WARM-UP theorem). *Let s, t be two real numbers with $0 < s < t$. Then we have that $h(T_t^+) \leq h(T_s^-)$.*

Proof. It follows immediately from Theorem 2.4, since $l'_1 = h(T_t^+)$ and $\overline{l_1} = h(T_s^-)$. ∎

We note that there may exist more than one value of x such that $h(T_x) = L$. Actually, this is the usual case. Hence, one could ask which value of x generates the best tree? The next theorem shows that $x^* = \min\{x | h(T_x^-) \leq L\}$ is the choice that produces the best tree.

THEOREM 2.6. *Let x^* be the smallest value of x such that $h(T_x^-) \leq L$, and let y be such that $h(T_y) \leq L$. Moreover, let $\overline{\boldsymbol{l}} = (\overline{l_1}, \ldots, \overline{l_n})$ and $\boldsymbol{l}' = (l'_1, \ldots, l'_n)$ be, respectively, the heights of the leaves of T_{x^*} and T_y. Hence*

$$\sum_{i=1}^{n} w_i \overline{l_i} \leq \sum_{i=1}^{n} w_i l'_i.$$

Proof. Let $\overline{k} = \max\{k | w_k < x^*\}$. Let $\overline{P}$ be the problem P_L augmented by the list of constraints $l_i \leq \overline{l_i}$ for $i = 1, \ldots, \overline{k}$. By using a saddle point argument one can show that $\overline{\boldsymbol{l}}$ solves the problem $\overline{P}$. Similarly, $\boldsymbol{l}'$ solves the problem P_L augmented by the list of constraints $l_i \leq l'_i$ for $i = 1, \ldots, k'$, where $k' = \max\{k | w_k < y\}$. We call this second problem P'.

Since $x^* < y$, it follows from Lemma 2.4 that $\overline{l_i} \geq l'_i$ for $i = 1, \ldots, \overline{k}$. Moreover, $\overline{k} \leq k'$. Hence, $\overline{P}$ is a relaxation of P', and as a consequence,

$$\sum_{i=1}^{n} w_i \overline{l_i} \leq \sum_{i=1}^{n} w_i l'_i. \qquad \square$$

2.3. Well-numbered trees. The WARM-UP theorem allows us to search for an appropriate value of x by performing a binary search on the interval (w_1, w_n). If for a given x, $h(T_x^-) > L$, then we must increase x. On the other hand, if $h(T_x^+) < L$, we must decrease x. The special case where $h(T_x^-) < L$ and $h(T_x^+) > L$ is addressed in the next section.

Now, we show that there exists x such that $h(T_x) = L$. In order to show this fact, we define the concept of *well-numbered trees.*

DEFINITION 2.7. *A weighted full binary tree is well numbered if and only if the following hold.*

(a) *To each node is assigned a different integer number i, with $1 \leq i \leq 2n-1$.*

(b) *A parent node weight is equal to the sum of the weights of its two children nodes.*

(c) *If $i > j$, then the weight of the node with number i is not smaller than the weight of the node with number j.*

(d) *Let $i > j$. If the node with number i is son of a node with number i', and the node with number j is son of a node with number j', then $i' \geq j'$.*

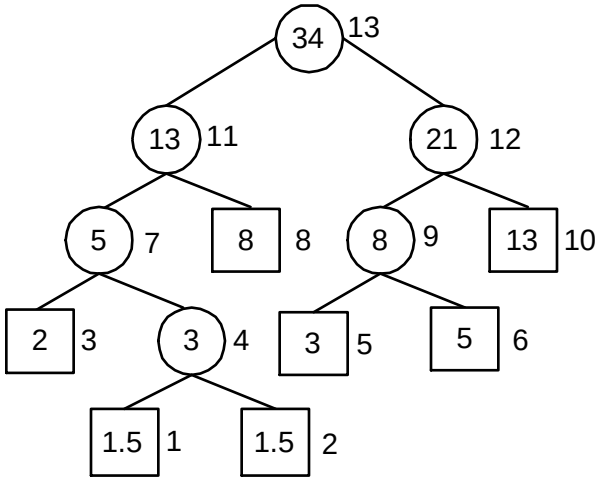

FIG. 2. *A well-numbered tree.*

The tree in Figure 2 is well numbered. Each number is drawn at the right side of the node. Now, we state three key properties concerning the well-numbered trees.

PROPOSITION 2.8. *Let $y_1, \ldots, y_{2n-1}$ be the nodes of a well-numbered tree T. Furthermore, let y_{i_1} and y_{i_2}, with $i_2 > i_1$, be the two children of node y_i, and let y_{i_3}*

and y_{i_4}, with $i_4 > i_3$, be the two children of node y_{i+1}. Under these assumptions, we have that $i_2 = i_1 + 1, i_3 = i_2 + 1$, and $i_4 = i_3 + 1$.

Proof. First, we prove that $i_2 = i_1 + 1$. Assume that $i_2 > i_1 + 1$. Let z be the node with number $i_1 + 1$. It follows that the parent of z has a number not smaller than the parent of y_{i_1} and a number not greater than the parent of y_{i_2}. Hence, the parent of z has number i, which contradicts the fact that each internal node has only two children. The proof that $i_4 = i_3 + 1$ is analogous and the proof that $i_3 = i_2 + 1$ follows by the same arguments already used. □

PROPOSITION 2.9. *Let $y_1, \ldots, y_{2n-1}$ be the nodes of a well-numbered tree T with corresponding heights $l_1, \ldots, l_{2n-1}$. Then, $0 \leq l_i - l_{i+1} \leq 1$ for $i = 1, \ldots, 2n-2$.*

Proof. First, let us prove that $l_{i+1} \leq l_i$ for $i = 1, \ldots, 2n-2$. It follows from properties (b) and (c) that y_{2n-1} is the heaviest node and hence the root of T. Hence, the result holds for $i = 2n-2$. Let us assume by induction that the result is valid for $i > p$, and then we prove it for $i = p$. Observe that the parent of y_p has a number smaller than or equal to the number of the parent of y_{p+1}. It follows by induction that the parent of y_p has a height not lower than the height of the parent of y_{p+1}. Since a parent's height is exactly one unit lower than the height of its children, the result holds for $i = p$.

Now, suppose that $l_i > l_{i+1} + 1$ for some i. In this case, the parent $y_{i'}$ of y_i has height $l_{i'} = l_i - 1$. Therefore, $i' \geq i + 1$ and $l_{i'} = l_i - 1 > l_{i+1}$, which contradicts the inequality $l_{i+1} \leq l_i$ for $i = 1, \ldots, 2n-2$, that we have already proved. Hence, $l_i \leq l_{i+1} + 1$. □

PROPOSITION 2.10. *If T is well numbered, then T is a Huffman tree.*

Proof. It follows from Proposition 2.8 that the tree T has the *sibling property*, defined by Gallager [6]. Therefore, T is a Huffman tree. □

2.4. The existence of a suitable x. Now, we are ready to prove that there is a value x, such that $h(T_x) = L$. This proof gives an insight about the effects in the tree generated by changing the parameter x.

THEOREM 2.11. *If $h(T^-_{w_1}) > L \geq \lceil \log n \rceil$, then there is a rational number $x=p/q$, with $q \leq n$ and $w_1 < x < w_n$, such that $h(T_x) = L$.*

Proof. Observe that $T^-_{w_1}$ is the Huffman tree for the original list of weights, since $\max\{w_1, w_i\} = w_i$ for $i = 1, \ldots, n$. Let us assume that $T^-_{w_1}$ is well numbered. In section 3 we show how to construct such a tree. We use y_i to denote the node with number i, ϕ_i to denote the weight of node y_i, and n_i to denote the number of descendent leaves of node y_i with weight x. We define $n_i = 1$ when y_i is a leaf with weight equal to x. We also define δ_i by $\delta_i = (\phi_{i+1} - \phi_i)/(n_i - n_{i+1})$.

The well-numbered tree in Figure 2 is a T_x tree, with $x = 1.5$. For this tree, we have $n_1 = n_2 = 1$, $n_4 = n_7 = n_{11} = n_{13} = 2$, and the others nodes have $n_i = 0$. We also have that $\phi_1 = 0$, $\phi_2 = 0.5$, $\phi_4 = 0$, and so on. Now, we prove that one of the trees obtained by the following algorithm is a T_x tree with $h(T_x) = L$.

```
x ← w_1
T ← T_x^-
Repeat
  Let I = {i | i = arg min {δ_i | n_i > n_{i+1}}}
  Define i* to be the smallest integer in I
  For each leaf y_j of T with φ_j = x do
      φ_j ← x + δ_{i*}
  Update all internal node weights to assure that a parent weight
  is equal to the sum of its children's weights.
```

`In` T `interchange`[2] `the subtrees with roots` y_{i^*} `and` y_{i^*+1}
`Assign number` i^* `to` y_{i^*+1} `and number` i^*+1 `to` y_{i^*}
$x \leftarrow x + \delta_{i^*}$
`Until` $I = \emptyset$

We divide the algorithm correctness proof into six parts.

(Part a) *All trees constructed by the algorithm are well numbered.*

Items (a) and (b) of Definition 2.7 are clearly respected by all trees T. Hence, we need to prove that items (c) and (d) are also respected.

For the initial tree, the result follows from the hypothesis under $T^-_{w_1}$. When the algorithm adds δ_{i^*} to the leaves with weight x, and after updating the internal node weights, we still have $\phi_j \leq \phi_{j+1}$ for $j = 1, \ldots, 2n-2$, since δ_{i^*} is the minimum value necessary to produce a tie between the weights of two nodes with consecutive numbers. Therefore, items (c) and (d) of Definition 2.7 hold. On the other hand, interchanging the two chosen subtrees and also their corresponding root node numbers will also ensure items (c) and (d).

(Part b) *In each cycle, the tree T is a T_x tree for the current value of x.*

It follows from (Part a) and Proposition 2.8 that each tree T is a Huffman tree. Thus, we must prove that the weights of the leaves of T are given by $\max\{w_1, x\}, \ldots, \max\{w_n, x\}$ for the current value of x. The leaves of the initial tree have these weights. Let T^m and x^m be, respectively, the tree T at the beginning of the mth cycle and the value of x at the beginning of this same cycle. We assume that the weights of the leaves of T^m are given by $\max\{w_1, x^m\}, \ldots, \max\{w_n, x^m\}$, and then we prove that the weights of the leaves of T^{m+1} are given by $\max\{w_1, x^{m+1}\}, \ldots, \max\{w_n, x^{m+1}\}$.

We can suppose that $w_i \leq x^m < w_{i+1}$. If $x^{m+1} \leq w_{i+1}$, then the result clearly holds. On the other hand, if $x^{m+1} > w_{i+1}$, the result doesn't hold, since T^{m+1} would have a leaf with weight $w_{i+1} < x^{m+1}$. However, if $x^{m+1} > w_{i+1}$, then the integer i^* chosen during the mth cycle is such that $\delta_{i^*} = (x^{m+1} - x^m) > (w_{i+1} - x^m)$. Let y_j be the node of tree T^m such that $\phi_{j+1} = w_{i+1}$. Since $\phi_j \geq x_m$, we have that $\delta_j \leq w_{i+1} - x^m$. It follows that i^* would not belong to I, and, as a consequence, the case $x^{m+1} > w_{i+1}$ is not possible.

(Part c) *Node y_{i^*+1} is always a leaf.*

First, let us assume that y_{i^*} is a leaf and that y_{i^*+1} is an internal node. In this case, $n_{i^*} = 1$; otherwise, i^* would not have been selected because $n_{i^*} = 0 \leq n_{i^*+1}$. As a consequence we get that $\phi_{i^*} = x$. The two children of y_{i^*+1} have numbers no greater than i^*. Therefore, these children must have weights x; otherwise, we contradict either item (c) of Definition 2.7 or the result of (Part b). Hence, $n_{i^*} = 1 < 2 = n_{i^*+1}$ and i^* would not belong to set I.

Now, let us assume that y_{i^*} and y_{i^*+1} are both internal nodes. Let $y_{i'}$, $y_{i'+1}$ be the sons of y_{i^*}, and let $y_{i'+2}$, $y_{i'+3}$ be the sons of y_{i^*+1}. It follows from the definition of δ_i that $\phi_{i'} + \phi_{i'+1} + (n_{i'} + n_{i'+1}).\delta_{i^*} = \phi_{i^*} + \delta_{i^*}.n_{i^*} = \phi_{i^*+1} + \delta_{i^*}.n_{i^*+1} = \phi_{i'+2} + \phi_{i'+3} + (n_{i'+2} + n_{i'+3}).\delta_{i^*}$. We also have that $\phi_{i'} + \delta_{i^*}.n_{i'} \leq \phi_{i'+1} + \delta_{i^*}.n_{i'+1} \leq \phi_{i'+2} + \delta_{i^*}.n_{i'+2} \leq \phi_{i'+3} + \delta_{i^*}.n_{i'+3}$; otherwise, there would be a node y_j with $n_j > n_{j+1}$ such that $\delta_j < \delta_{i^*}$. To satisfy the two previous expressions, we must have that $\phi_{i'} + \delta_{i^*}.n_{i'} = \phi_{i'+1} + \delta_{i^*}.n_{i'+1} = \phi_{i'+2} + \delta_{i^*}.n_{i'+2} = \phi_{i'+3} + \delta_{i^*}.n_{i'+3}$. Since $n_{i^*} > n_{i^*+1}$, $n_{i^*} = n_{i'} + n_{i'+1}$, and $n_{i^*+1} = n_{i'+2} + n_{i'+3}$, then either $n_{i'} > n_{i'+1}$ or $n_{i'+1} > n_{i'+2}$ or $n_{i'+2} > n_{i'+3}$. Hence, there is an index j with $i' \leq j < i'+3 \leq i$, such that $n_j > n_{j+1}$ and $\delta_{i^*} = \delta_j$. This contradiction establishes the result.

[2]When two subtrees are interchanged, the second subtree becomes a child of the root parent of the first subtree and vice-versa.

(Part d) *Let M be the sum of the numbers assigned to the leaves of T. The five statements below are true.*

(i) $(n^2 - n)/2 \leq M \leq (3n^2 - n)/2$.

(ii) *If the algorithm halts, then $M = (n^2 - n)/2$.*

(iii) *After each cycle the value of M either remains the same or decreases by exactly one unit.*

(iv) *In no more than $n^2 + n$ cycles, the value of M satisfies $M = (n^2 - n)/2$.*

(v) *If $M = (n^2 - n)/2$, then $h(T) = \lceil \log n \rceil$.*

Demonstrations. (i) There are n leaves in T, each leaf assigned a different number. Thus, $M \geq \sum_{j=1}^{n} j = (n^2 - n)/2$ and $M \leq \sum_{j=n}^{2n-1} j = (3n^2 - n)/2$.

(ii) In order to prove this item, we just need to show that $I \neq \emptyset$ whenever $M > (n^2 - n)/2$. If the sum of the numbers assigned to the leaves of T is greater than $n(n-1)/2$, then there is a leaf with number k, such that $k > n$. Since each number in the set $\{1, \ldots, 2n-1\}$ is a assigned to a node, then there is a node with number smaller than n.

It follows from item (d) of Definition 2.7 that the parent of y_1 is the internal node with minimum number. Let m be the number of y_1's parent. We have that $m < n < k$ and $n_m \geq 1$. Since $\phi_k \geq \phi_m > x$ and y_k is a leaf, then $n_k = 0$. As $n_m > n_k$, there exists an index i with $m \leq i < k$, such that $n_i > n_{i+1}$. Hence, the set I is not empty.

(iii) It follows from (Part c) that y_{i^*+1} is a leaf. If y_{i^*} and y_{i^*+1} are leaves, then the value of M remains the same. On the other hand, if y_{i^*} is an internal node, then the value of M decreases by exactly one unit, since we interchange the numbers.

(iv) First, we show that in no more than n cycles y_{i^*} is a leaf. If y_{i^*} is a leaf, then $\phi_{i^*} = x$; otherwise, $n_{i^*} = 0 \leq n_{i^*+1}$. Furthermore, $\phi_{i^*+1} > x$; otherwise $n_{i^*+1} = 1 = n_{i^*}$. In this case the value of x is updated to $x + \phi_{i^*+1} - \phi_{i^*} = \phi_{i^*+1}$. Hence, the number of leaves with weight x is increased by one unit. Therefore, this case can happen in no more than n cycles, otherwise we would obtain a tree with more than n leaves.

When y_{i^*} is an internal node, the value of M decreases by one unit. Since $(n^2 - n)/2 \leq M \leq (3n^2 - n)/2$, this second case can happen no more than $(3n^2 - n)/2 - (n^2 - n)/2 = n^2$. Therefore, in no more than $n^2 + n$ the value of M satisfies $M = (n^2 - n)/2$.

(v) If $M = (n^2 - n)/2$, then the numbers of all the leaves are not greater than n. Let l_j be the height of a generic leaf y_j. We have that the parent of y_1 has height $l_1 - 1$ and a number greater than n. It follows from Proposition 2.9 that the height of any leaf y_j satisfies $l_1 - 1 \leq l_j \leq l_1$. Therefore, all the leaves of T are arranged in consecutive heights. Hence, $h(T) = \lceil \log n \rceil$.

(Part e) *On each cycle the height of T either remains the same or decreases by one unit.*

If y_{i^*} has the same height as y_{i^*+1}, then the interchange does not modify $h(T)$. On the other hand, if the height of y_{i^*+1} is smaller than that of y_{i^*} by one unit, then the interchange either decreases $h(T)$ by one unit or does not modify $h(T)$, because y_{i^*+1} is a leaf.

(Part f) *The variable x assumes only rational values of the form p/q with $p, q \in N$ and $1 \leq q \leq n$ during the algorithm execution.*

Let x_m be the value of x at the beginning of the mth cycle. The first value of x is w_1, so x_1 is an integer. We observe that in the next assignment x assumes the value $x_m + ((\phi_{i^*+1} - \phi_{i^*})/n_{i^*}) = x_m + (\phi_{i^*+1} - A - x_m.n_{i^*})/n_{i^*} = (\phi_{i^*+1} - A)/n_{i^*}$, where A is the sum of the weights of the leaves that descend from y_{i^*} with corresponding weight values different from x_m. Since $\phi_{i^*+1} - A$ and n_{i^*} are positive integers and

$1 \leq n_{i^*} \leq n$, we get that x assumes only values in the form p/q with $p, q \in$N and q $\leq$ n.

Algorithm Correctness. It follows from (Part d) that the algorithm can only stop if $M = (n^2 - n)/2$. On the other hand, if $M = (n^2 - n)/2$, then $h(T) = \lceil \log n \rceil$. Since the first tree has height greater than L and after each cycle the height of T does not decrease by more than one unit, then the algorithm must obtain a tree T_x with height exactly L in no more than $n^2 + n$. Furthermore, (Part f) ensures that x is a rational number p/q with $q \leq n$. □

This result allows us to stop searching for a value x when the length of the search interval is smaller than $1/n^2$, since there is only one rational with denominator less than n in such an interval, and it can be easily determined.

3. The procedure Ties. Before describing our algorithm we must first consider a special case, where

$$h(T_x^-) < L \text{ and } h(T_x^+) > L.$$

For the same list of weights it is possible that more than one Huffman tree exists. This happens because when constructing the tree, Huffman's algorithm faces alternative choices on how to choose a node when there is more than one node with minimal weight.

Searching for an adequate value for x, we can face a situation where $h(T_x^-) < L$ and $h(T_x^+) > L$. If we increase x, then the new tree gets a height smaller than L. On the other hand, if we decrease the value of x, then we obtain a tree with height greater than L. Corollary 2.5 guarantees this fact. Since we have already shown that there is always a value x such that $h(T_x) = L$, then the current value of x is the one we are looking for. In this case, we can construct a Huffman tree with height exactly L for the current list of weights.

The trees in Figure 3 are T_3 trees for the weights $1, 2, 4, 6, 10, 16, 26$. The left tree is a T_3^+ tree and its height is 6, while the right tree is a T_3^- tree and its height is 4. If we have been trying to find a T_x tree with height 5, we would face the special case addressed in this section.

Let us consider the well-known implementation [26] of Huffman's algorithm that uses a stack S to store the leaves of the tree, and a queue Q to store the internal nodes. At the start, Q is empty and S contains the leaves of the tree sorted by weights, such that the leaf with lower weight is located at the top of S.

During the main step of this implementation, the weight of the leaf at the top of S is compared to the weight of the internal node at the head of Q. The node with smaller weight is selected. After the selection of two nodes, a new internal node is created. This new node is the parent of the selected nodes, and it is inserted at the tail of Q. Observe that whenever a node is selected, it is removed either from the top of S or from the head of Q. The main step is executed until S is empty and Q contains only one node.

We say that a tie occurs whenever a leaf at the top of S has the same weight as an internal node at the head of Q. If we choose a leaf whenever a tie occurs, we obtain a Huffman tree with minimum height. On the other hand, if we always choose an internal node, we get a Huffman tree with maximum height [24].

3.1. Procedure Ties description. Let T^- be a Huffman tree with minimum height, and let T^+ be a Huffman tree with maximum height. Both of these trees have the same list of weights. The procedure Ties constructs a Huffman tree with height L when $h(T^-) < L$ and $h(T^+) > L$.

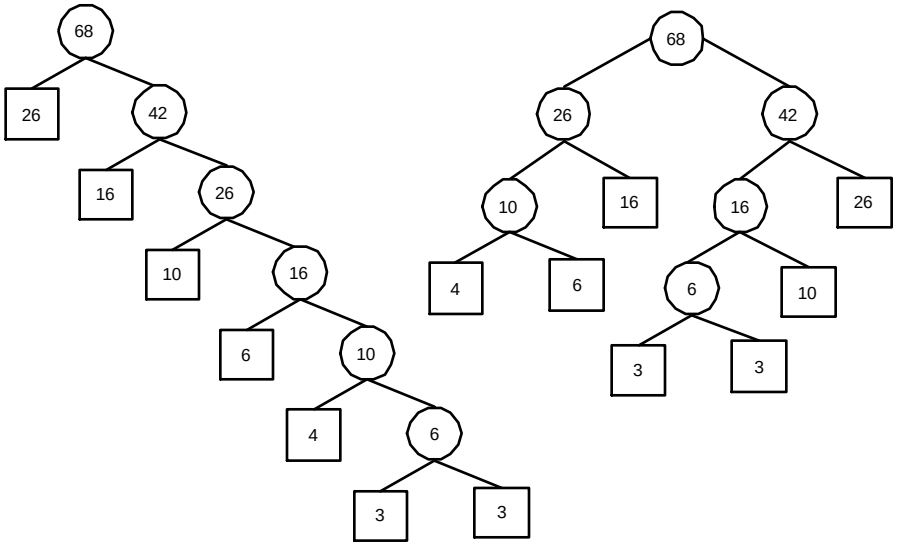

FIG. 3. *A T_3^+ tree and a T_3^- tree for the weights* $1, 2, 4, 6, 10, 16, 26$.

The procedure performs a binary search on the integers $1, \ldots, 2n-2$. For each selected integer k, it constructs a Huffman tree T^k using the implementation described above with an additional refinement: *choose a leaf on each one of the first* `k` *ties and then choose only internal nodes on all subsequent ties.* If it obtains the tree with height L, then the procedure ends. If the obtained tree has height lower than L, then the binary search proceeds with a decreased value of k. Otherwise, the binary search proceeds with an increased value of k.

3.2. Ties correctness. Let us suppose that procedure Ties produces also a numbering of the nodes as follows. Number 1 is assigned to the first node removed either from the top of S or from the head of Q. Number 2 is assigned to the second removed node, and so on. It is easy to see that the constructed tree is well numbered.

Now, let y_i denote the node with number i in T^k, with corresponding weight and height given by ϕ_i and l_i, respectively. Let us also assume that p is the number of the internal node selected when the $(k+1)$th tie occurs, and that q is the number of the first leaf selected after node y_p. Observe that $\phi_p = \phi_{p+1} = \cdots = \phi_q$ since the $(k+1)$th tie was between nodes y_p and y_q and T^k is well numbered. Furthermore, it follows from Proposition 2.9 that $l_p \geq l_{p+1} \cdots \geq l_q \geq l_p - 1$. Under these assumptions, the following steps are performed to obtain T^{k+1} from T^k.

```
For i = q down to p + 1
  Interchange the subtree rooted at y_i with the one rooted at y_{i-1}
  Assign number i to node y_{i-1}, and number i - 1 to node y_i
Next
```

Two cases can occur when the procedure interchanges the subtrees. If the leaf y_i has the same height as the internal node y_{i-1}, then the tree height is not affected. Otherwise, y_i has a height smaller than that of y_{i-1} by exactly one unit. In this second case, the interchange either reduces the tree height by one unit or keeps it the same. Since $l_p \geq \cdots \geq l_q \geq l_p - 1$, the second case can only happen once. Therefore, we have that $h(T^{k+1}) \leq h(T^k) \leq h(T^{k+1}) + 1$.

When $h(T^{2n-1}) < L$ and $h(T^0) > L$, one can find a value k such that $h(T^k) = L$, by performing a binary search on $1, \ldots, 2n$. Hence, the procedure Ties can be used to construct a T_x tree with $h(T_x) = L$, since $h(T_x^-) < L$ and $h(T_x^+) > L$.

3.3. Ties complexity. The binary search tries no more than $\lceil \log(2n-2) \rceil$ values for k. As we spend $O(n)$ to construct an optimal tree if the frequencies are already sorted, we have that the procedure spends an $O(n \log n)$ time in the worst case.

4. The WARM-UP algorithm. In this section, we describe the WARM-UP algorithm. A pseudocode for it is given in Figure 4. In Phase 0, the algorithm constructs a Huffman tree for the given list of weights. If this tree has a height not greater than L, then the algorithm halts since this tree is an optimal code tree with restricted maximal height L. Otherwise, the algorithm goes to Phase 1.

In Phase 1, WARM-UP executes a binary search, in the interval $(w_1, w_n]$, looking for a value x such that all the leaves with weight x in the tree T_x are at level L. If this happens, the algorithm halts, since this tree is known to be optimal from Theorem 2.1. In the pseudocode, "Is Optimal" accounts for the checking of this condition. If the current tree is not optimal, then the algorithm compares its height against L and uses this information to update the interval search limits and the value of x.

The binary search also stops when the length of the searching interval is smaller than $1/n^2$. Whenever this happens, the algorithm finds the unique rational number p/q with $q \leq n$ in the last searching interval. Setting $x = p/q$, the algorithm builds a T_x tree with height L. This last fact is assured by Theorem 2.11.

4.1. Complexity. In Phase 0, the algorithm spends an $O(n)$ time to construct the Huffman tree since the weights are already sorted.

In Phase 1, the algorithm can spend an $O(n \log(n^2.w_n))$ time in the worst case. That is true because in every cycle the length of the search interval is divided by 2. Hence, in no more than $\lceil \log n^2.(w_n - w_1) \rceil$ steps we have $\texttt{sup} - \texttt{inf} \leq 1/n^2$. Moreover, during each cycle we spend an $O(n)$ time to determine both a Huffman tree with minimum height and a Huffman tree with maximum height for the current list of weights. In Phase 1, the algorithm can also execute one call to procedure Ties. However, that does not affect the time complexity, since it represents an additional effort bounded by $O(n \log n)$.

If the algorithm reaches Phase 2, it spends an $O(n)$ time to find the adequate rational number p/q. Therefore, we conclude that the WARM-UP algorithm has an $O(n \log n + n \log w_n)$ worst case time complexity.

By using Moffat's runlength approach [22], the WARM-UP time complexity can be easily reduced to $O(n \log n + r \log(n/r) \log w_n)$, where r is the number of distinct weights in the given list of weights.

5. A strong polynomial time implementation. We can use Megiddo's parametric search [14] to devise a strong polynomial time implementation for WARM-UP. Instead of performing a binary search in the interval $(w_1, w_n]$, we use a parametric search to find a tree T_{x^*} with height L, where $x^* = \min\{x | h(T_x^-) \leq L\}$. Theorem 2.6 guarantees that this is the best choice for x.

The new search scheme is divided into two phases: the binary search phase and the parametric search phase. In the first phase, the algorithm performs a binary search in the list of weights $[w_1, \ldots, w_n]$. For each value of x, the algorithm checks if the height of T_x^- is greater than L or not. If the height is greater, then the value of x is increased; otherwise, it is decreased. The value of x^* is known to be in some

Phase 0: Trying a Huffman tree

If $h(T^-_{w_1}) \leq L$ **then** Return$(T^-_{w_1})$

Phase 1: Binary search

$inf \leftarrow w_1$; $sup \leftarrow w_n$; $x \leftarrow (inf + sup)/2$
While sup-inf $> 1/n^2$ **do**
  If T^-_x Is Optimal **then** Return(T^-_x)
  If $h(T^-_x) > L$ **then** $inf \leftarrow x$
  Else
    If T^+_x Is Optimal **then** Return(T^+_x)
    If $(h(T^+_x) > L$ and $h(T^-_x) < L)$ **then** Return(Ties(x))
    $sup \leftarrow x$
  End If
  $x \leftarrow (inf + sup)/2$
End While
If $h(T^+_{sup}) = L$ **then** Return(T^+_{sup})

Phase 2: Search for p/q

$q \leftarrow 1$; $p \leftarrow \lceil$q.inf$\rceil$
While ($p =$ q.inf or $p \geq$ q.sup) **do**
  $q \leftarrow q + 1$
  $p \leftarrow \lceil$q.inf$\rceil$
End While
  Return(Ties(p/q))

FIG. 4. *The WARM-UP Algorithm.*

interval $(w_{k-1}, w_k]$, where k is an integer, with $1 < k \leq n$. The objective of the first phase is to find out the value of k.

In the second phase, a Huffman tree is constructed for the list of warmed up weights $[w^*_1, \ldots, w^*_n]$, where $w^*_i = \max\{w_i, x^*\}$. At the beginning, the only information about x^* is that it belongs to the interval (inf, sup], where inf $= w_{k-1}$ and sup $= w_k$. In this phase, we construct the required Huffman tree T_{x^*}, using only an interval estimate of x^*. Phase 2 is based on a serialization of the parallel algorithm for constructing Huffman codes, proposed in [16]. Since the value of x^* is not known during the algorithm execution, it is not possible to directly compare weights that depend on x^*. Before explaining the second phase, we show how to compare such weights.

5.1. Comparing weights. Let s be a leaf, and let t be an internal node. Let us assume that the weight of s is a real number $w(s)$ and the weight of t is given by $w(t, x^*)$, a linear function of x^*, defined by $a_t x^* + b_t$, where a_t and b_t are known positive coefficients. If $a_t = 0$, then the comparison between $w(s)$ and $w(t, x^*)$ is immediate since $w(t, x^*) = b_t$. On the other hand, if $a_t > 0$, then the comparison is more elaborate since the value of $w(t, x^*)$ is not known with precision. The only information about x^* is that it belongs to a certain interval (inf, sup]. In order to

perform this parametric comparison, we need to use the concept of critical value (intersection point) [14] that we redefine for our purposes.

DEFINITION 5.1. *Let (s,t) be an ordered pair, where s is a leaf and t is an internal node. Furthermore, let $w(s)$ be the weight of s, and let $w(t,x^*) = a_t x^* + b_t$ be the weight of t. If $a_t > 0$, then the critical value γ associated to the pair (s,t) is the unique real number that solves the equation $w(s) = w(t,x^*)$; that is, $\gamma = (w(s) - b_t)/a_t$.*

As an example, if $w(s) = 17$ and $w(t,x^*) = 3x^* + 2$, then the critical value γ associated to the pair (s,t) is 5. In order to compare the weights of s and t, the Parametric WARM-UP uses the function **Compare** that we describe below.

Compare determines if either $w(s) < w(t,x^*)$ or $w(s) \geq w(t,x^*)$. In order to decide if either $w(s) < w(t,x^*)$ or $w(s) \geq w(t,x^*)$, it compares if either $\gamma < x^*$ or $\gamma \geq x^*$. If $\gamma < x^*$, then $w(s) = w(t,\gamma) < w(t,x^*)$; otherwise, $w(s) = w(t,\gamma) \geq w(t,x^*)$. If either $\gamma \leq \inf$ or $\gamma > \sup$, the comparison is straightforward. If $\inf < \gamma \leq \sup$, the function compares $h(T_\gamma^-)$ against L. If $h(T_\gamma^-) > L$, then $\gamma < x^*$; otherwise, $\gamma \geq x^*$. This last statement follows from the definition of x^* and from Corollary 2.5. The time complexity of **Compare** is $O(n)$, since it may construct a Huffman tree T_γ^-.

Compare also updates the interval (inf, sup] whenever the value of γ is in the interval (inf, sup]. Actually, if $\gamma < x^*$, the lower limit inf takes the value of γ; otherwise, the upper limit sup takes the value of γ.

5.2. The second phase. At the second phase, the algorithm maintains a list S of leaves and a queue Q of internal nodes, both sorted by the nondecreasing order of their weights. In some situations Q may contain one leaf. At the beginning Q is empty and S contains all the leaves. At each cycle, the algorithm performs the following steps.

Step 1. Compute the sum α of the two current smallest weights among the weights of the nodes in Q and S.

Step 2. Do an exponential search to determine the leaves with weights smaller than α in the list S.

Step 3. Let S' be the sublist of S with weights smaller than α. $U \leftarrow \text{Merge}(S', Q)$, $Q \leftarrow$ null, and $S \leftarrow S - S'$.

Step 4. If $|U|$ is odd, then remove the last node from U and insert it in Q.

Step 5. For $i = 1$ to $|U|/2$ do: create a parent p_i for the pair of nodes u_{2i-1} and u_{2i} in U; insert p_i in Q.

The algorithm ends if we get a T_x tree with all warmed leaves at height L during a call to **Compare**. Otherwise, it ends when the number of cycles reaches L.

At the end of the second phase the algorithm verifies if the height of T_{sup}^+ is equal to L. If that happens, it outputs the heights of the leaves of T_{sup}^+. Otherwise, the procedure **Ties** is called to construct a tree T_{sup} with height exactly L, and the algorithm outputs the leaf levels of this tree.

5.3. The merging step. All the operations but the merge are straightforward. Hence, we describe it now. At step 3, we merge S' and Q into an auxiliary list U. We can divide Q into two ordered lists. The first list Q' contains the nodes of Q whose weights depend on x^*. We observe that we do not allow nodes with equal weights in Q'. If two nodes have equal weights, we insert in Q' the one that appears first in Q. The second list Q'' is the list of the remaining nodes. For example, if $w(Q) = [2x^*, 2x^*, 33, 2x^*+7, x^*+30, x^*+30, 46, 64]$, then $w(Q') = [2x^*, 2x^*+7, x^*+30]$ and $w(Q'') = [2x^*, 33, x^*+30, 46, 64]$. In this case, $w()$ is a function that returns the node weights.

Let U' be the list obtained by merging S' and Q'. After obtaining U', the merge between Q'' and U' becomes straightforward. Hence, we should be concerned on merging S' and Q'. This merge is achieved through eight successive substeps that we describe below.

At step 3.1, we choose a suitable parameter p and then we consider the list $S'(p)$ of the nodes that appear at positions $p, 2p, \ldots, \lfloor S'(p)/p \rfloor p$ in the list S'. We observe that these positions split the list S' into $\lceil |S'|/p \rceil$ contiguous sublists of approximately equal sizes. Let $S'_1, \ldots, S'_{\lceil |S|/p \rceil}$ be these sublists. At step 3.1, we determine the critical values associated to all pairs in the cartesian product $S'(p) \times Q'$. For example, if $w(S'(p)) = [22, 26, 31]$ and $w(Q') = [2x^*, 2x^* + 7]$, then the critical values are $[11, 15/2, 13, 19/2, 31/2, 12]$.

At step 3.2, we sort the critical values obtained at step 3.1. Let $\gamma_1, \ldots, \gamma_{|Q'||S'(p)|}$ be the sorted list. At step 3.3, we perform a binary search on the sorted list to obtain an index j such that $\gamma_j < x^* \leq \gamma_{j+1}$. At step 3.4, we merge the lists $S'(p)$ and Q'. We use the fact that each critical value γ associated to a pair of nodes to be compared is such that either $\gamma \leq \gamma_j < x^*$ or $\gamma \geq \gamma_{j+1} \geq x^*$. Hence, all comparisons are made in $O(1)$.

Let q'_i be an element of Q'. We define $f(i)$ as the position of the smallest element of $S'(p)$ that is greater than or equal to q'_i. At the end of the step 3.4, the values of $f(i)$ are known. Hence, in order to know the position of q'_i in the list S', we need only to compare q'_i against the elements of the sublist $S'_{f(i)}$. At step 3.5, for $i = 1, \ldots, |Q'|$, we evaluate the critical values associated to all pairs of the cartesian product $[q'_i] \times S'_{f(i)}$. Let Γ be the list of all the critical values so obtained. We observe that $|\Gamma| \leq p|Q'|$ since $|S'_{f(i)}| \leq p$.

At step 3.6, we sort Γ obtaining a sorted list $\gamma_1, \ldots, \gamma_{|\Gamma|}$. At step 3.7, we perform a binary search on the sorted list of critical values to obtain and index j such that $\gamma_j < x^* \leq \gamma_{j+1}$.

At step 3.8, we merge S' and Q' into an auxiliary list U'. For that, we compare q'_i for $i = 1, \ldots, |Q'|$ against the elements of $S_{f(i)}$. The comparisons are made in $O(1)$ since all the critical values γ are such that $\gamma \leq \gamma_j < x^*$ or $\gamma \geq \gamma_{j+1} \geq x^*$. Finally, at step 3.9, we merge U' and Q'', obtaining an ordered list U.

5.3.1. Analysis of the merging step. Let us analyze the complexity of step 3. The most expensive steps are steps 3.2, 3.3, 3.6, and 3.7 since all the other steps are $O(n)$. Step 3.2 can be implemented in $O(|Q'||S'|/p \log(|Q'||S'|/p))$ time, by using an $O(n \log n)$ time sorting algorithm. Step 3.3 runs in $O(n \log(|Q'||S'|/p)))$ time. Furthermore, step 3.6 runs in $O(|Q'|p \log(|Q'|p))$ time, and step 3.7 runs in $O(n \log(|Q'|p))$ time.

If we set $p = \lfloor \sqrt{S'} \rfloor$, the complexity becomes

$$O(\max\{|\sqrt{S'}||Q'| \log(|\sqrt{S'}||Q'|), n \log(|\sqrt{S'}||Q'|)\}).$$

However, we can show that $|Q'| = O(\log n)$. Assuming that this is true, the complexity becomes $O(n \log(|\sqrt{S'}||Q'|))$, since steps 3.2 and 3.6 become $O(\sqrt{n} \log^2 n) = o(n)$. In addition, the space complexity is $O(n)$. The critical values require $O(|Q'|\sqrt{S'}) = O(\sqrt{n} \log n)$ space, and the other information requires $O(n)$ space. Hence, we can state the following theorem.

THEOREM 5.2. *Let $k(i)$ and $q(i)$ be, respectively, the number of leaves in S' and the number of nodes in Q at the beginning of the ith cycle of the parametric WARM-UP. Then, at the ith cycle, the merge operation runs in $O(n \log k(i) + n \log q(i))$ time, requiring $O(n)$ space.*

In order to complete the analysis, we show that $|Q'| = O(\log n)$.

PROPOSITION 5.3. *At every cycle of the parametric WARM-UP we have that* $|Q'| \leq 2\lceil \log n \rceil + 2$.

Proof. Let $Q(j) = [q_1(j), \ldots, q_{|Q|}(j)]$ and $Q'(j) = [q'_1(j), \ldots, q'_{|Q'|}(j)]$ be, respectively, the lists Q and Q' at the beginning of the jth cycle. Furthermore, let $n_i(j)$ be the number of nodes in the list $Q(j)$ with weight equal to $w(q'_i(j))$ at the beginning of the jth cycle. The list $N(j)$ is given by $N = [n_1(j), \ldots, n_{|Q'|}(j)]$. We use $\max(N(j))$ to denote the maximum value of $N(j)$. For example, if $w(Q(3)) = [2x^*, 33, 2x^*+7, 2x^*+7, 2x^*+7, x^*+30, 46, 64]$, then $w(Q'(3)) = [2x^*, 2x^*+7, x^*+30]$, $N(3) = [1, 3, 1]$, and $\max(N(3)) = 3$. For the sake of simplicity, during this proof, we use the term x^*-node to denote a node whose weight depends on x^*.

Since $|Q'(j)| = |N(j)|$, our approach is to bound $|N(j)|$. First, we consider the list $N(2)$ since $N(1)$ is empty. Let $k-1$ be the number of leaves with weight x^* at the beginning of the second phase of the parametric WARM-UP. At the beginning of the second cycle the list Q has $\lfloor (k-1)/2 \rfloor$ nodes with weights equal to $2x^*$, since the leaves with weight x^* are melded at the first cycle. If $k-1$ is odd, Q may also contain a node with weight equal to x^* or $x^* + w_k$. Hence, at the beginning of the second cycle, we have that either $N(2) = [\lfloor (k-1)/2 \rfloor, 1]$, or $N(2) = [1, \lfloor (k-1)/2 \rfloor]$, or $N(2) = [(k-1)/2]$. In order to prove that $|Q'| \leq 2\lceil \log n \rceil + 2$, it suffices to prove the three facts below.

(a) $\max(N(j+1)) \leq \lceil \max(N(j))/2 \rceil$.

(b) If $\max(N(j)) = 1$, then $|N(j+1)| \leq |N(j)|$.

(c) $|N(j+1)| \leq |N(j)| + 2$.

In effect, since $\max(N(2)) \leq \lceil (k-1)/2 \rceil$, it follows by (a) that after $\lceil \log(k-1)/2 \rceil$ cycles we have $\max(N(j)) = 1$. Hence, it follows by (b) and (c) that $|N(2)|$ can increase by at most $2\lceil \log(k-1)/2 \rceil$ units. Hence, $|Q'(j)| = |N(j)| \leq 2 + 2\lceil \log(k-1)/2 \rceil \leq 2 + 2\lceil \log(n) \rceil$ for all j.

Before proving that (a), (b), and (c) are correct, we should examine a special case. Let us assume that the list U obtained through the merge between $Q(j)$ and S' has an odd number of nodes. In addition, we assume that a x^*-node (say y) occupies the last position of U. In this case, step 4 of the parametric WARM-UP includes y at the beginning of the list $Q(j+1)$, and, as a result, y is not melded at the jth cycle. We use the term $Q(j)$-special to denote a node of $Q(j)$ with this unusual behavior. Furthermore, we define the parent of a $Q(j)$-special node as the node $q_1(j+1)$. This definition is useful because it forces every node in $Q(j)$ to have a representative in $Q(j+1)$. It can be proved by induction that the parent of a $Q(j)$-special node has a weight different from the weight of every other x^*-node in $Q(j+1)$.

Now, we prove that (a), (b), and (c) are correct. First, we prove (a). If $\max(N(j+1)) = 1$, then the result is obvious since $\max(N(j)) \geq 1$. Let $t > 1$. We assume that t x^*-nodes of $Q(j+1)$ have weights equal to $ax^* + b$. We observe that none of these nodes is a $Q(j)$-special parent, and, as a consequence, each of them has two children that belong to $Q(j)$. Moreover, all their $2t$ children must have equal weights. This is because the list U is sorted. Since at least one of the children of a x^*-node must be also a x^*-node, then those $2t$ children are x^*-nodes with weights equal to $a/2x^* + b/2$. Letting $t = \max(N(j+1))$, we establish the correctness of (a).

Now, we prove (b). The condition $\max(N(j)) = 1$ implies that all x^*-nodes of $Q(j)$ have different weights. Hence, $|N(j)|$ is given by the number of x^*-nodes in $Q(j)$. Since the number of x^*-nodes in $Q(j+1)$ is not greater than that of $Q(j)$, we obtain that $|N(j+1)| \leq |N(j)|$.

Now, we prove (c). Let $q_i(j)$ be an x^*-node, and let us assume that there are t nodes in $Q(j)$ with weights equal to that of $q_i(j)$. Under these conditions, we say that $q_i(j)$ contributes to $|N(j)|$ with $1/t$ units. The value of $|N(j)|$ is given by the sum of the contributions of the nodes in $Q(j)$. Furthermore, the value of $|N(j+1)|$ is given by the sum of the contributions of the parents of the x^*-nodes that belong to $Q(j)$. Hence, in order to give an upper bound on $|N(j+1)| - |N(j)|$, we must consider the nodes of $Q(j)$ that contribute with less than one unit. Let us assume that $Q(j)$ has t nodes, $q_{i_1}(j), \ldots, q_{i_t}(j)$, with weights equal to $ax^* + b$. All these nodes, together, contribute to $|N(j)|$ with one unit. In addition, these nodes are disposed at consecutive positions at the list U, and, as a consequence, they generate either $\lfloor t/2 \rfloor$ or $\lfloor t/2 \rfloor - 1$ parents with weights equal to $2(ax^* + b)$. If $q_{i_1}(j)$ is melded with a node whose weight does not depend on x^*, then its parent will have a weight different from the weight of every other x^*-node in $Q(j+1)$. In this case, its parent contributes to $|N(j)|$ with one unit. This may also occur either if $q_{i_t}(j)$ is melded with a node whose weight does not depend on x^* or if $q_{i_t}(j)$ is $Q(j)$-special. Hence $|N(j+1) - N(j)|$ can increase by at most two units from one cycle to another, which establishes the correctness of (a). We observe that the correctness of (a) is based on the fact that at most one element of $N(j)$ is greater than 1. This result can be proved by induction on the number of cycles, using the same kind of arguments presented throughout this proof. ∎

5.4. Algorithm analysis. We can state the following theorem concerning the behavior of the parametric WARM-UP.

THEOREM 5.4. *The parametric WARM-UP spends $O(nL\log(n/L))$ time to construct a tree T_{x^*} with height L, where x^* is the smallest value of x such that $h(T_x^-) \leq L$.*

Proof. The correctness of the algorithm follows from the properties of **Compare**. The decisions taken by **Compare** are equal to the ones taken by Huffman's algorithm when constructing a maximum height Huffman tree for the list of weights $[w_1^*, \ldots, w_n^*]$, where $w_i^* = \max\{x^*, w_i\}$.

Now, we consider its time complexity. The most expensive steps are steps 2 and 3. The exponential search takes $O(n \log k(i))$ time, where $k(i)$ is the number of leaves with weights smaller than α at the ith cycle. On the other hand, it follows from Theorem 5.2 that the merge operation takes $O(n \log k(i) + n \log q(i))$ time, where $q(i)$ is the number of nodes in Q at the ith cycle. Since the algorithm executes at most L cycles, the time complexity is upper-bounded by

$$\sum_{i=1}^{L} O(n \log k(i) + n \log q(i)). \tag{5.1}$$

Since $\sum_{i=1}^{L} k(i) = n$ and $\sum_{i=1}^{L} q(i) < 2n$, then an upper bound for the time complexity can be obtained by maximizing (5.1) as a function of $k(i)$ and $q(i)$, constrained to $\sum_{i=1}^{L} k(i) = n$ and $\sum_{i=1}^{L} q(i) < 2n$.

By Jensen's inequality, the maximum occurs for $k(i) = n/L$ and $k(i) = 2n/L$. Hence, the parametric WARM-UP runs in $O(nL\log(n/L))$ time. ∎

6. Approximation. In the previous sections we proposed a method to construct a prefix code tree T_x with height L. This tree is not necessarily an optimal prefix code tree with restricted maximal height L. Now, we give an upper bound for the

error of the code induced by this tree. Let us define this error ϵ by

$$\epsilon = \sum_{i=1}^{n} p_i l_i - \sum_{i=1}^{n} p_i \bar{l}_i,$$

where $\bar{l}_i$ is the height of ith leaf of an unrestricted Huffman tree, l_i is the height of ith leaf of the tree T_x constructed by the WARM-UP algorithm, and p_i is the probability of symbol a_i that is given by $w_i/(\sum_{j=1}^{n} w_j)$. The value $\sum_{i=1}^{n} p_i l_i$ is the *average code length*, and it represents the average number of bits used per symbol. Now, we state a theorem that gives an upper bound on ϵ.

THEOREM 6.1. *Let L be an integer such that $L > \lceil \log n \rceil + 1$. The average length difference ϵ between the code induced by a tree T_x with height L and an unrestricted Huffman code is such that*

$$\epsilon < 1/\psi^{L - \lceil \log(n + \lceil \log n \rceil - L) \rceil - 2},$$

where ψ is the golden ratio 1.618.

Proof. Let A_W, A_H, and A_L be, respectively, the average length of a code induced by a tree T_x with height L, the average length of a Huffman code, and the average length of an optimal prefix code with restricted maximal length L.

Theorem 2.3 shows that the heights of the leaves of a tree T_x with height L are optimal for problem P_L augmented by some constraints of type $l_i \leq L - 1$. Since this last problem is a relaxation of problem P_{L-1}, it follows that $A_W \leq A_{L-1}$. Nevertheless, Milidiú and Laber [15] show that if $L \geq \lceil \log n \rceil + 1$, then $A_L - A_H \leq 1/\psi^{L - \lceil \log(n + \lceil \log n \rceil - L) \rceil - 1}$. Hence, $\epsilon = A_W - A_H \leq A_{L-1} - A_H < 1/\psi^{L - \lceil \log(n + \lceil \log n \rceil - L) \rceil - 2}$. □

This result shows that the average code length difference is quite small for values of L not too close to $\lceil \log n \rceil$. For example, if $L - \lceil \log n \rceil \geq 15$, then the difference ϵ is less than 0.01. For $L - \lceil \log n \rceil \geq 20$, we have that $\epsilon < 0.0003$. Nevertheless, undesirable results like the difference being greater than 1 could occur. However, that would only happen if $L \leq \lceil \log n \rceil + 1$.

6.1. Limitations. Theorem 2.1 shows that if all the leaves with weight x in a T_x tree have height L, then T_x is an optimal code tree with restricted maximal height L. Unfortunately, for some list of weights there is no such x. For instance, consider $L = 3$ and the list of weights given by $[1, 1, 1, 13, 15]$. Figure 5 (a) shows the tree topology for all T_x with $1 \leq x \leq 5$, and Figure 5 (b) shows the tree topology for all T_x with $5 \leq x \leq 15$. Observe that, in the tree topology of picture (b), not all the leaves with weight less than 5 have height 3. Moreover, the average code length for this tree is 2.064. On the other hand, this measure is equal to 2.032 for the optimal code tree exhibited in Figure 5 (c).

One could ask what happens if we choose the multipliers in a different way. For the list of weights presented in Figure 5, it has been proved [11] that the optimal code tree can not be obtained, even if we try all the sets of multipliers.

7. Experimental results. The source data for our experiment was extracted from the *Calgary corpus*. This corpus is a collection of 14 files available from the University of Calgary, Canada. In order to generate the input vector of weights for each source data, we considered two different models to parse the data. The first method defines each single byte as a symbol of the alphabet. The second method packs

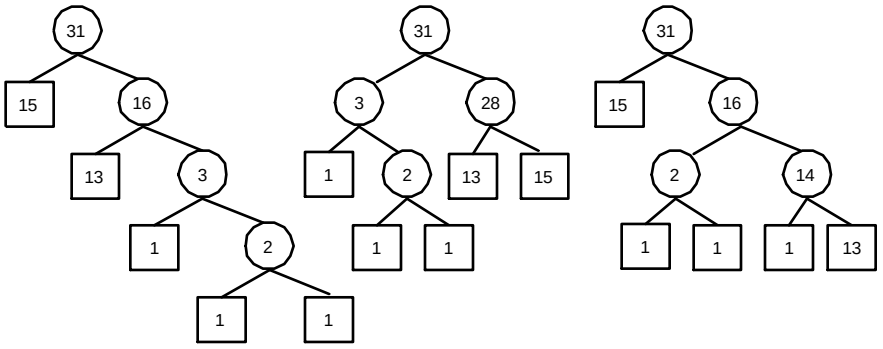

FIG. 5. (a) *Tree T_x for the list of weights $W = [1, 1, 2, 3, 5, 8, 13]$ and $1 \leq x \leq 5$.* (b) *Tree T_x for the list of weights W and $5 \leq x \leq 15$.* (c) *An optimal tree with restricted maximal height 3 for the list W.*

any sequence of alphanumeric American standard code for information interchange (ASCII) codes[3] into a single symbol. Each nonalphanumeric ASCII code is also considered a symbol. This second method is suitable for English text files and source code files. In order to generate each list of weights, the parsing method scans each source data counting the frequency of each distinct symbol. The first method is referred as the *Byte* method and the second as the *Word* method.

Table 1 shows the average codeword length, measured in bits, obtained by each algorithm for the Calgary corpus files. For each file, we considered L running from $\lceil \log n \rceil$ to $\lceil \log n \rceil + 6$. A letter (b) beside the file name indicates that the file was parsed through a Byte model, whereas the letter (w) indicates the word model. The second column in the table indicates the number n of different symbols. From this table, we get the following observations.

1. The average length of the codes produced by the WARM-UP algorithm was equal to that produced by the LazyPM algorithm, except for two cases. These two cases are printed in bold in Table 1.
2. In a few cases, the ROT algorithm generated very inefficient codes. In the worst case, the compression loss was 63.5% for the *pic* file and $L = \lceil \log n \rceil$. Optimal codes were generated on seven experiments.

In this section, we report some experiments involving three methods that generate length restricted prefix codes. The first method is the ROT Heuristics proposed in [5]. The second method is the WARM-UP, with the implementation presented in Figure 4, except that we removed Phase 2. The third one is the Package-Merge [12], an exact method to construct optimal length restricted prefix codes. In these experiments, we measured the average length of the codes obtained through these algorithms.

8. Conclusions. In this paper, we introduced the WARM-UP algorithm, a novel technique to construct length-restricted prefix codes. This algorithm is very easy to implement, since it consists of successive constructions of Huffman trees. Even though it is approximative, it has an optimal behavior for practical settings.

We believe that the techniques developed here can be useful to address the problem of constructing optimal prefix codes satisfying other kinds of constraints.

[3]The *underscore* character is treated as alphanumeric.

A NEAR-TIGHT LOWER BOUND ON THE TIME COMPLEXITY OF DISTRIBUTED MINIMUM-WEIGHT SPANNING TREE CONSTRUCTION*

DAVID PELEG† AND VITALY RUBINOVICH‡

Abstract. This paper presents a lower bound of $\Omega(D+\sqrt{n}/\log n)$ on the time required for the distributed construction of a minimum-weight spanning tree (MST) in weighted n-vertex networks of diameter $D=\Omega(\log n)$, in the bounded message model. This establishes the asymptotic near-optimality of existing time-efficient distributed algorithms for the problem, whose complexity is $O(D+\sqrt{n}\log^* n)$.

Key words. distributed algorithm, minimum weight spanning tree, lower bound

1. Introduction.

The study of distributed algorithms for minimum-weight spanning tree (MST) construction was initiated by the pioneering work of Gallager, Humblet, and Spira [GHS83], which introduced a basic distributed technique for the problem and presented a message-optimal algorithm with time complexity $O(n\log n)$ on an n-vertex network. This result was later improved to a message-optimal algorithm with time complexity $O(n)$ by Awerbuch [A87].

However, for many natural distributed network problems, the parameter controlling the time complexity is not the number of vertices but rather the network's diameter D, namely, the maximum distance between any two vertices (measured in hops). This holds, for example, for leader election and related problems [P90].

It is easy to verify that $\Omega(D)$ time is required for distributed MST construction in the worst case. More formally, for every two integers $n\geq 2$ and $1\leq D\leq \lfloor n/2\rfloor$ there exist weighted n-vertex networks of diameter D (say, based on a $2D$-vertex ring with $n-2D$ vertices attached to it as leaves) on which any distributed MST algorithm will require at least D time.

Hence, a natural question is whether $O(D)$-time algorithms exist for distributed MST construction as well. More generally, the problem of devising $o(n)$ (though possibly not message-optimal) distributed algorithms for MST construction was introduced in [GKP98].

Clearly, in the extreme model allowing the transmission of an unbounded-size message on a link in a single time unit (cf. [L92]), the problem can be trivially solved in time $O(D)$ by collecting the entire graph's topology and all the edge weights into a central vertex, computing an MST locally and broadcasting the result throughout the network. The problem thus becomes interesting in the more realistic, and rather

common, *B-bounded-message* model (henceforth referred to simply as the B model), in which message size is bounded by some value B (usually taken to be either constant or $O(\log n)$), and a vertex may send at most one message on each edge at each time unit.

The algorithm presented in [GKP98] for distributed MST construction in this model (with $B = O(\log n)$-bit messages) has time complexity $O(D + n^{\epsilon} \log^* n)$ for $\epsilon = \ln 6 / \ln 3 \approx 0.613$. This was later improved to $O(D+\sqrt{n}\log^* n)$ in [KP98]. Similar bounds were recently obtained by us using other algorithmic methods, but none of those methods were able to break the $\sqrt{n}$-time barrier, indicating that distributed MST might be harder than other distributed network problems such as leader election or breadth-first search (BFS) tree construction.

It is important to mention that the algorithms of [GHS83, A87, GKP98, KP98] discussed above were analyzed under the (natural) assumption that the weight of each edge can be represented as an integer small enough to be included in a single message. This assumption is adopted in the current paper.

The current paper concerns establishing the asymptotic near-optimality of the algorithm of [KP98], by showing that $\tilde{\Omega}(\sqrt{n})$ is a lower bound[1] as well, even on low diameter networks. Specifically, for any integers $K, m \geq 2$, we construct a family of $O(m^{2K})$-vertex networks of diameter $D = O(Km)$ for which $\Omega(m^K/(BK))$ time is required for constructing a minimum spanning tree in the B model. Fixing some positive integer $m \geq 2$, we get that for every integer $n \geq 1$ there exists a family of n-vertex networks of diameter $\Theta(\log n)$ for which MST construction requires $\Omega(\sqrt{n}/(B \log n))$ time in the B model.

While it is not clear that the $\Omega(\log n)$ limitation on the diameters for which the lower bound holds is essential, *some* limitation must apparently exist. This follows from the observation that the n-vertex complete graph ($D = 1$) admits a simple $O(\log n)$ time distributed MST construction algorithm.

Towards proving the lower bound on distributed MST construction, we first establish a lower bound on the time complexity of a problem referred to as the *mailing problem*, which can be informally stated as follows. Given a particular type of graph named F_m^K, for integers $m, K \geq 2$, and two vertices s and r in it, it is required to deliver an m^K-bit string $\mathcal{X}$ generated in s to r. The graph F_m^K has $n = O(m^{2K})$ vertices and diameter $O(Km)$, yet we show that the time required for mailing from s to r on F_m^K in the B model is considerably larger than the diameter, namely, $\Omega(m^K/(BK)) = \Omega(\sqrt{n}/(BK))$.

The rest of the paper is organized as follows. First, a definition of the model and the mailing problem is given in section 2. Section 3 handles the mailing problem for the case of $K = 2$. It defines the graphs F_m^2, having diameter $D = O(m) = O(n^{1/4})$ and shows a lower bound of $O(m^2) = O(\sqrt{n})$ on the time complexity of the mailing problem for m^2-bit strings. This result is then used in section 4 to prove that the same lower bound applies also to the time complexity of the MST problem on weighted versions of the graphs F_m^2. The next two sections extend these two results, respectively, to graphs F_m^K, $K \geq 3$ with diameters down to $O(\log n)$. Finally, section 7 discusses some open problems.

2. Preliminaries.

2.1. The model. A point-to-point communication network is modeled as an undirected graph $G(V, E)$, where the vertices of V represent the network processors

[1] $\tilde{\Omega}$ is a relaxed variant of the Ω notation that ignores polylog factors.

and the edges of E represent the communication links connecting them. Vertices are allowed to have unique identifiers. The vertices do not know the topology or the edge weights of the entire network, but they may know the IDs of their neighbors and the weights of the corresponding edges.

A weight function $\omega : E \to \mathbb{R}^+$ associated with the graph assigns a nonnegative integer weight $\omega(e)$ to each edge $e = (u, v) \in E$. The weight $\omega(e)$ is known to the adjacent vertices, u and v. The vertices can communicate only by sending and receiving messages over the communication links. Communication is carried out in a synchronous manner; i.e., all the vertices are driven by a global clock. Messages are sent at the beginning of each round and are received at the end of the round. (Clearly, our lower bounds hold for asynchronous networks as well.) At most one B-bit message can be sent on each link in one direction on every round. It is assumed that B is large enough to allow the transmission of an edge weight in a single message. The model also allows vertices to detect the absence of a message on a link at a given round, which can be used to convey information. Hence at each communication round, a link can be at one of $2^B + 1$ possible states, i.e., it can either transmit any of 2^B possible messages or remain silent.

The length of a path p in the network is the number of edges it contains. The *distance* between two vertices u and v is defined as the length of the shortest path connecting them in G. The *diameter* of G, denoted D, is the maximum distance between any two vertices of G.

2.2. The mailing problem. The mailing problem is defined in the following situation. We are given a graph G with two distinguished vertices s and r, referred to as the *sender* and the *receiver*, respectively. Both the sender s and the receiver r store b boolean variables each, $X_1^s, \ldots, X_b^s$ and $X_1^r, \ldots, X_b^r$, respectively, for some integer $b \geq 1$. An instance of the problem consists of an initial assignment $\mathcal{X} = \{x_i \mid 1 \leq i \leq b\}$, where $x_i \in \{0, 1\}$, to the variables of s, such that $X_i^s = x_i$. Given such an instance, the mailing problem requires s to deliver the string $\mathcal{X}$ to the receiver r, i.e., upon termination, the variables of r should contain the output $X_i^r = x_i$ for every $1 \leq i \leq b$. Henceforth, we refer to this problem as $\texttt{Mail}(G, s, r, b)$. Throughout sections 3 and 4, we consider this problem on graphs F_m^2 with $b = m^2$ for some integer $m \geq 2$. In sections 5 and 6, we deal with the problem on graphs F_m^K with $b = m^K$ for $K \geq 3$.

2.3. The distributed MST problem. Formally, the *minimum spanning tree (MST)* problem can be stated as follows. Given a graph $G(V, E)$ and a weight function ω on the edges, it is required to find a spanning tree $MST(G) \subseteq E$ whose total weight, $\omega(MST(G)) = \sum_{e \in MST(G)} \omega(e)$, is minimal. In the distributed model, the input and output of the MST problem are represented as follows. Each vertex knows the ID's of its closest neighbors and the weights of the corresponding edges. A degree-d vertex $v \in V$ with neighbors $u_1, \ldots, u_d$ has d *weight variables* $W_1^v, \ldots, W_d^v$, with W_i^v containing the weight of the edge connecting v to u_i, i.e., $W_i^v = \omega(v, u_i)$. The output of the MST problem at each vertex v is an assignment to the (boolean) output variables $Y_1^v, \ldots, Y_d^v$, assigning

$$Y_i^v = \begin{cases} 1, & (u_i, v) \in MST(G), \\ 0 & \text{otherwise.} \end{cases}$$

3. A lower bound for the mailing problem on F_m^2.

3.1. The graphs F_m^2. Let us now define the collection of graphs denoted F_m^2 for $m \geq 2$. The two basic units in the construction are the *ordinary path* $\mathcal{P}$ on m^2+1 vertices,

$$V(\mathcal{P}) = \{v_0, \ldots, v_{m^2}\} \quad \text{and} \quad E(\mathcal{P}) = \{(v_i, v_{i+1}) \mid 0 \leq i \leq m^2 - 1\},$$

and the *highway* $\mathcal{H}$ on $m+1$ vertices,

$$V(\mathcal{H}) = \{h_{im} \mid 0 \leq i \leq m\} \quad \text{and} \quad E(\mathcal{H}) = \{(h_{im}, h_{(i+1)m}) \mid 0 \leq i \leq m-1\}.$$

Each highway vertex h_{im} is connected to the corresponding path vertex v_{im} by a *spoke* edge (h_{im}, v_{im}), as in Figure 1.

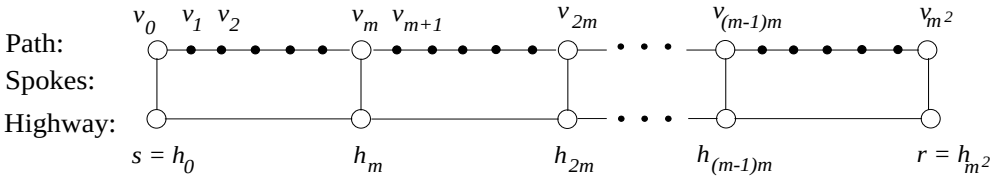

FIG. 1. *The connections between the path and the highway.*

The graph F_m^2 is constructed by taking m^2 copies of the ordinary path $\mathcal{P}$, denoted $\mathcal{P}^1, \ldots, \mathcal{P}^{m^2}$, and connecting all of them to the *same* highway $\mathcal{H}$. The vertex h_0 is the intended sender s, and the vertex h_{m^2} is the intended receiver r. (See Figure 2.)

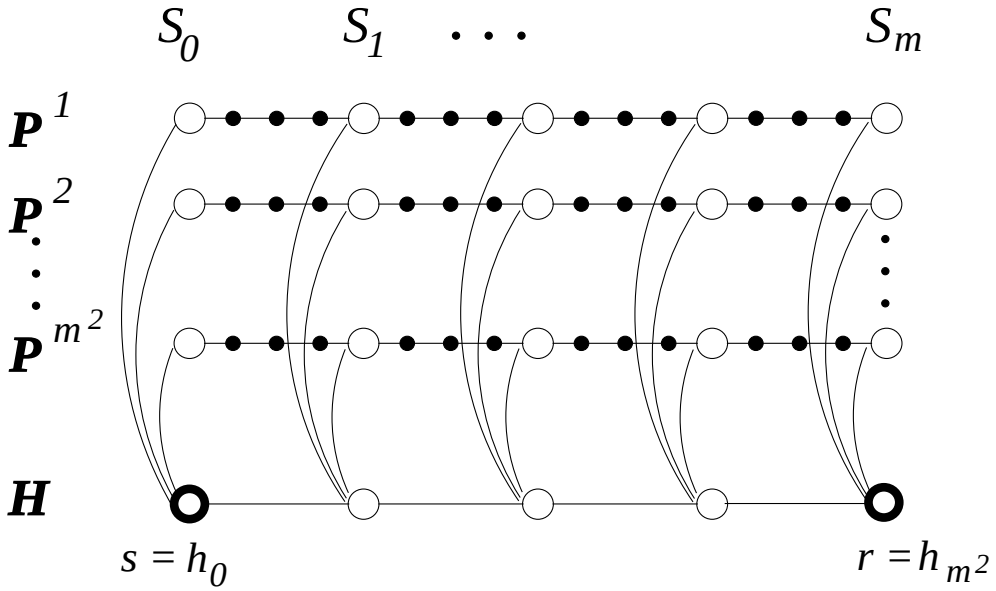

FIG. 2. *The graph* F_m^2.

Visualizing the graph F_m^2 as organized in a cylindrical shape, the spoke edges can be grouped into $m+1$ *stars* S_i, $0 \leq i \leq m$, where each star S_i consists of the highway vertex h_{im} and the m^2 vertices $v_{im}^1, \ldots, v_{im}^{m^2}$ connected to it by spoke edges. Hence

$$V(S_i) = \{h_{im}\} \cup \{v_{im}^1, \ldots, v_{im}^{m^2}\} \quad \text{and} \quad E(S_i) = \{(v_{im}^j, h_{im}) \mid 1 \leq j \leq m^2\}.$$

The vertex and edge sets of the graph F_m^2 are thus

$$V(F_m^2) = V(\mathcal{H}) \cup \bigcup_{j=1}^{m^2} V(\mathcal{P}^j) \quad \text{and} \quad E(F_m^2) = \bigcup_{i=0}^{m} E(S_i) \cup \bigcup_{j=1}^{m^2} E(\mathcal{P}^j) \cup E(\mathcal{H}).$$

FACT 3.1. *The graph F_m^2 consists of $n = \Theta(m^4)$ vertices, and its diameter is $\Theta(m)$.*

3.2. The lower bound. We would now like to prove that solving the mailing problem on the graph F_m^2 with a $b = m^2$-bit string $\mathcal{X}$ requires $\Omega(m^2/B)$ time in the B model. Intuitively, this happens because routing the string $\mathcal{X}$ from s to r along ordinary paths would be too slow; hence our only hope is to route the string along the highway, or at least use interleaved paths, mixing highway segments with segments of ordinary paths. However, F_m^2 does not have sufficient capacity for routing all m^2 bits from s to r along such short (or "relatively short") paths.

This intuition yields a rather simple proof of the claim if we limit ourselves to a restricted class of algorithms, referred to as *explicit delivery* algorithms. These are algorithms in which the input bits are required to be delivered in an explicit way, namely, each bit x_i must be shipped from s to t along some path p_i. (Naturally, the paths of different bits may be identical or partly overlap.) However, we would like the lower bound to apply also to *arbitrary* algorithms, in which the information can be conveyed from s to r in arbitrary ways. This may include applying arbitrary functions to the bits at s and sending the resulting values, possibly modifying and "recombining" these values in intermediate nodes along the way, in a way that will allow r to extract the original bits from the messages it receives. For handling such a general class of algorithms, the proof must be formalized in a more careful way.

Let us start with an outline of the proof. Consider the set of possible states a vertex v may be in at any given stage t of the execution of a mailing algorithm on some m^2-bit input $\mathcal{X}$. (The state of a vertex consists of all its local data; hence it is affected by its input, topological knowledge, and history, namely, all incoming messages.) As the computation progresses, the tree of possible executions grows, and thus the set of possible states of v becomes larger. In particular, when the execution starts at round 0, each of the vertices is in one specific initial local state, except for the sender s, which may be in any one of 2^{m^2} states, determined by the value of the input string $\mathcal{X}$. Upon termination, the string $\mathcal{X}$ should be known to the receiver r, meaning that r should be in one of 2^{m^2} states. Our argument is based on analyzing the growth process of the sets of possible states, and showing that this process is slow, forcing the algorithm to spend at least $\Omega(m^2/B)$ time until the set of possible states of r is of size 2^{m^2}.

We now continue with a more detailed and formal proof. Consider some arbitrary algorithm $\mathcal{A}_{\text{mail}}$, and let $\varphi_{\mathcal{X}}$ denote the execution of $\mathcal{A}_{\text{mail}}$ on an m^2-bit input $\mathcal{X}$ in the graph F_m^2. For $1 \leq i \leq m$, define the *tail set* of the graph F_m^2, denoted T_i, as follows. For every $1 \leq j \leq m^2$, define the *tail* of the path $\mathcal{P}^j$ as

$$T_i(\mathcal{P}^j) = \{v_l^j \mid i \leq l \leq m^2\}.$$

Let $\beta(i)$ denote the least integer δ such that $\delta m \geq i$, and define the tail of $\mathcal{H}$ as

$$T_i(\mathcal{H}) = \{h_{jm} \mid \beta(i) \leq j \leq m\}.$$

Now, the tail set of F_m^2 is the union of those tails,

$$T_i = T_i(\mathcal{H}) \cup \bigcup_j T_i(\mathcal{P}^j).$$

(See Figure 3.) For $i = 0$, the definition is slightly different, letting

$$T_0 = V \setminus \{h_0\}.$$

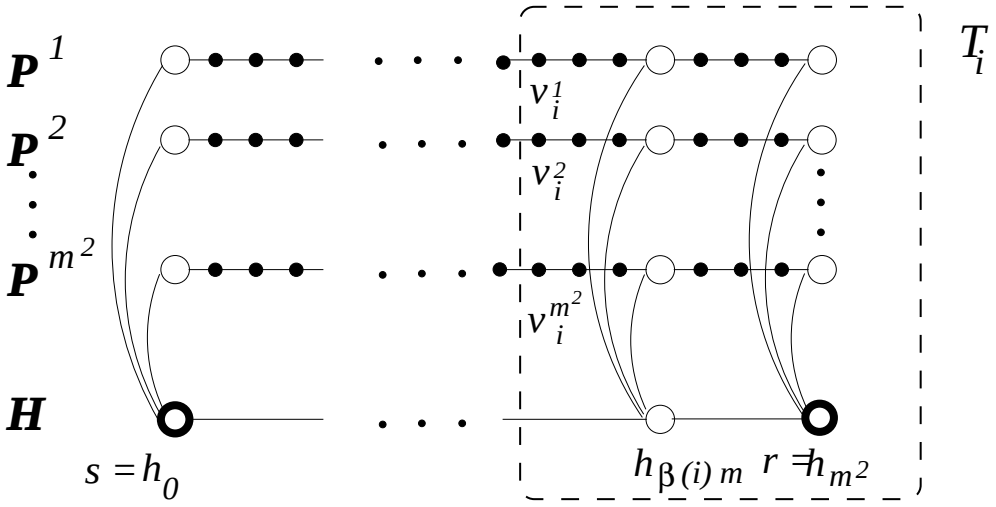

FIG. 3. *The tail set T_i in the graph F_m^2.*

Denote the *state* of the vertex v at the beginning of round t during the execution $\varphi_{\mathcal{X}}$ on the input $\mathcal{X}$ by $\sigma(v, t, \mathcal{X})$. In two different executions $\varphi_{\mathcal{X}}$ and $\varphi_{\mathcal{X}'}$, a vertex reaches the same state at time t, i.e., $\sigma(v, t, \mathcal{X}) = \sigma(v, t, \mathcal{X}')$, iff it receives the same sequence of messages on each of its incoming links; for different sequences, the states are distinguishable.

For a given set of vertices $U = \{v_1, \ldots, v_l\} \subseteq V$, a *configuration*

$$C(U, t, \mathcal{X}) = \langle \sigma(v_1, t, \mathcal{X}), \ldots, \sigma(v_l, t, \mathcal{X}) \rangle$$

is a vector of the states of the vertices of U at the beginning of round t of the execution $\varphi_{\mathcal{X}}$. Denote by $\mathcal{C}[U, t]$ the collection of all possible configurations of the subset $U \subseteq V$ at time t over all executions $\varphi_{\mathcal{X}}$ of algorithm $\mathcal{A}_{\text{mail}}$ (i.e., on all legal inputs $\mathcal{X}$), and let $\rho[U, t] = |\mathcal{C}[U, t]|$.

Prior to the beginning of the execution (i.e., at the beginning of round $t = 0$), the input string $\mathcal{X}$ is known only to the sender s. The rest of the vertices are found in some initial state, described by the configuration $C_{init} = C(T_0, 0, \mathcal{X})$, which is independent of $\mathcal{X}$. Thus, in particular, $\rho[T_0, 0] = 1$. (Note, however, that $\rho[V, 0] = 2^{m^2}$.)

Our main lemma is the following.

LEMMA 3.2. *For every $0 \leq t < m^2$,*

$$\rho[T_{t+1}, t+1] \leq (2^B + 1) \cdot \rho[T_t, t].$$

Proof. The lemma is proved by showing that in round $t+1$ of the algorithm, each configuration in $\mathcal{C}[T_t, t]$ branches off into at most $2^B + 1$ different configurations of $\mathcal{C}[T_{t+1}, t+1]$.

Fix a configuration $\hat{C} \in \mathcal{C}[T_t, t]$, and let $\delta = \beta(t+1)$. The tail set T_{t+1} is connected to the rest of the graph by the highway edge $f_{\delta-1} = (h_{(\delta-1)m}, h_{\delta m})$ and by the m^2 path edges $e_t^j = (v_t^j, v_{t+1}^j)$, $1 \le j \le m^2$. (See Figure 4.)

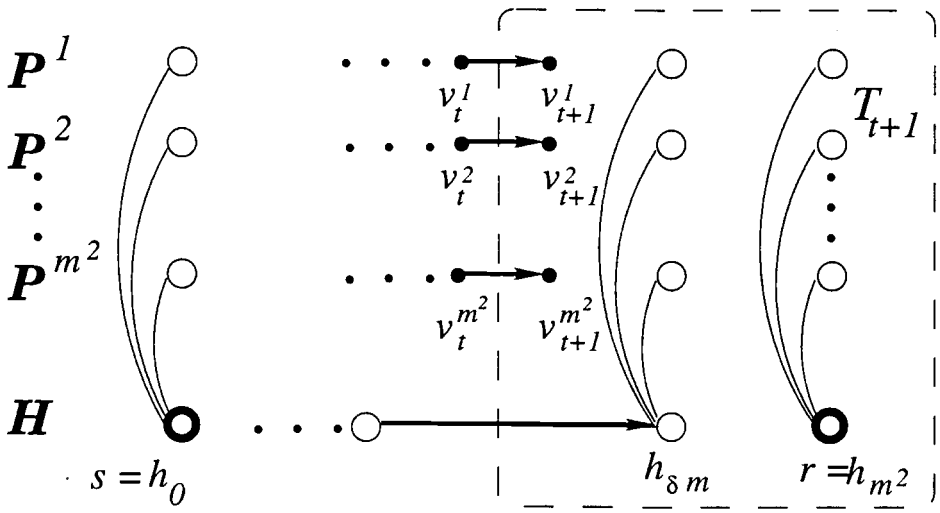

FIG. 4. *The edges entering the tail set* T_{t+1}.

Let us count the number of different configurations in $\mathcal{C}[T_{t+1}, t+1]$ that may result from the configuration $\hat{C}$. Starting from the configuration $\hat{C}$, each vertex v_t^j is restricted to a single state, and hence it sends a single (well determined) message over the edge e_t^j to v_{t+1}^j, thus not introducing any divergence in the execution. The same applies to all the edges internal to T_{t+1}. As for the highway edge $f_{\delta-1}$, the vertex $h_{(\delta-1)m}$ is not in the set T_t; hence it may be in any one of many possible states, and the value passed over this edge into the set T_{t+1} is not determined by the configuration $\hat{C}$. However, due to the restriction of the B-bounded-message model, at most $2^B + 1$ different behaviors of $f_{\delta-1}$ can be observed by $h_{\delta m}$. Thus altogether, the configuration $\hat{C}$ branches off into at most $2^B + 1$ possible configurations $\hat{C}_1, \ldots, \hat{C}_{2^B+1} \in \mathcal{C}[T_{t+1}, t+1]$, differing only by the state $\sigma(h_{\delta m}, t+1, \mathcal{X})$. The lemma follows. □

Applying Lemma 3.2 and the fact that $\rho[T_0, 0] = 1$, we get the following result.

COROLLARY 3.3. *For every* $0 \le t < m^2$,

$$\rho[T_t, t] \le (2^B + 1)^t.$$

Let t_{end} denote the time it takes algorithm $\mathcal{A}_{\text{mail}}$ to complete the mailing. As argued earlier, at that time, the receiver r may be in at least 2^{m^2} different states, hence necessarily $\rho[T_{t_{end}}, t_{end}] \ge 2^{m^2}$. Applying Corollary 3.3, we get that $(2^B + 1)^{t_{end}} \ge 2^{m^2}$, implying the following.

LEMMA 3.4. *For every* $m \ge 1$, *solving the mailing problem* $\texttt{Mail}(F_m^2, h_0, h_{m^2}, m^2)$ *in the* B *model requires* $\Omega(m^2/B)$ *time.*

4. A lower bound for the MST problem on $\mathcal{J}_m^2$. In this section, we use the results achieved in the previous sections and show that in the B model for $B \geq 3$, the distributed MST problem cannot be solved faster than $\Omega(m^2/B)$ on weighted versions of the graphs F_m^2. In order to prove this lower bound, we define in subsection 4.1 a family of weighted graphs $\mathcal{J}_m^2$, based on F_m^2 but differing in their weight assignments. Then in subsection 4.2, we show that any algorithm solving the MST problem on the graphs of $\mathcal{J}_m^2$ can also be used to solve the mailing problem on F_m^2 with the same time complexity. Subsequently, the lower bound for the distributed MST problem follows from the lower bound given in the previous section for the mailing problem in F_m^2.

4.1. The graph family $\mathcal{J}_m^2$. The graphs F_m^2 defined earlier were unweighted. In this subsection, we define for every graph F_m^2 a family of weighted graphs

$$\mathcal{J}_m^2 = \{J_{m,\gamma}^2 = (F_m^2, \omega_\gamma) \mid 1 \leq \gamma \leq 2^{m^2}\},$$

where ω_γ is an edge weight function.

Recall that in the graph F_m^2 there are three types of edges, namely, highway edges, edges of paths $\mathcal{P}^j$, and star spokes. In all the weight functions ω_γ, all the edges of the highway $\mathcal{H}$ and the paths $\mathcal{P}^j$ are assigned the weight 0. The spokes of all stars except S_0 and S_m are assigned the weight 4. The spokes of the star S_m are assigned the weight 2.

The only differences between different weight functions ω_γ occur on the m^2 spokes of the star S_0. Specifically, each of these m^2 spokes is assigned a weight of either 1 or 3; thus there are 2^{m^2} possible combinations of weight assignments. (See Figure 5.)

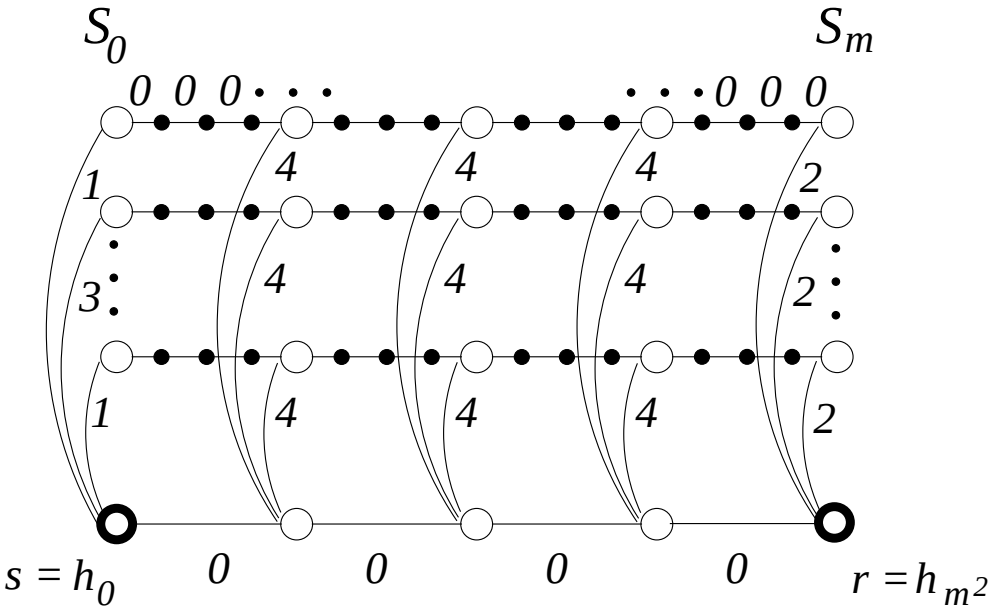

FIG. 5. *The edge weights assigned to* $J_{m,\gamma}^2$.

Since discarding all spoke edges of weight 4 from the graph $J_{m,\gamma}^2$ leaves it connected, and since every spoke edges of weight 4 is the heaviest edge on some cycle in the graph, the following is clear.

LEMMA 4.1. *No spoke edge of weight* 4 *belongs to the MST of* $J^2_{m,\gamma}$ *for every* $1 \le \gamma \le 2^{m^2}$.

Let us pair the spoke edges of S_0 and S_m, denoting the jth pair (for $1 \le j \le m^2$) by

$$PE^j = \{(s, v_0^j), (r, v_{m^2}^j)\}.$$

LEMMA 4.2. *For every* $1 \le \gamma \le 2^{m^2}$ *and* $1 \le j \le m^2$, *exactly one of the two edges of* PE^j *belongs to the MST of* $J^2_{m,\gamma}$, *namely, the lighter one.*

Proof. Since the MST must be connected, at least one of the two edges of PE^j must belong to it, as otherwise the path $\mathcal{P}^j$ is completely disconnected from the rest of the graph, by Lemma 4.1. It remains to show that the MST cannot contain both edges of PE^j.

The proof is by contradiction. Consider the cycle in $J^2_{m,\gamma}$ consisting of the edges of $\mathcal{H}$, PE^j, and $\mathcal{P}^j$, and suppose that *both* edges of PE^j are in the MST. In order for the MST to be cycle-free, at least one edge e of either the highway $\mathcal{H}$ or the path $\mathcal{P}^j$ must not belong to the MST. Since the edges of $\mathcal{H}$ and $\mathcal{P}^j$ have zero weight, $\omega_\gamma(e) = 0$. Hence deleting the heavier edge of the pair PE^j and adding the edge e instead leaves us with a lighter tree than the original one, leading us to contradiction. □

LEMMA 4.3. *For every* $m \ge 2$ *and* $1 \le \gamma \le 2^{m^2}$, *all the edges of the highway* $\mathcal{H}$ *and the paths* $\mathcal{P}^j$, *for* $1 \le j \le m^2$, *belong to the MST of* $J^2_{m,\gamma}$.

Figure 6 illustrates the remaining candidate edges to join the MST. Bold edges belong to the MST under any edge weight function. Of the remaining edges, exactly one of each pair will join the MST, depending on the particular weight assignment to the spoke edges of the star S_0.

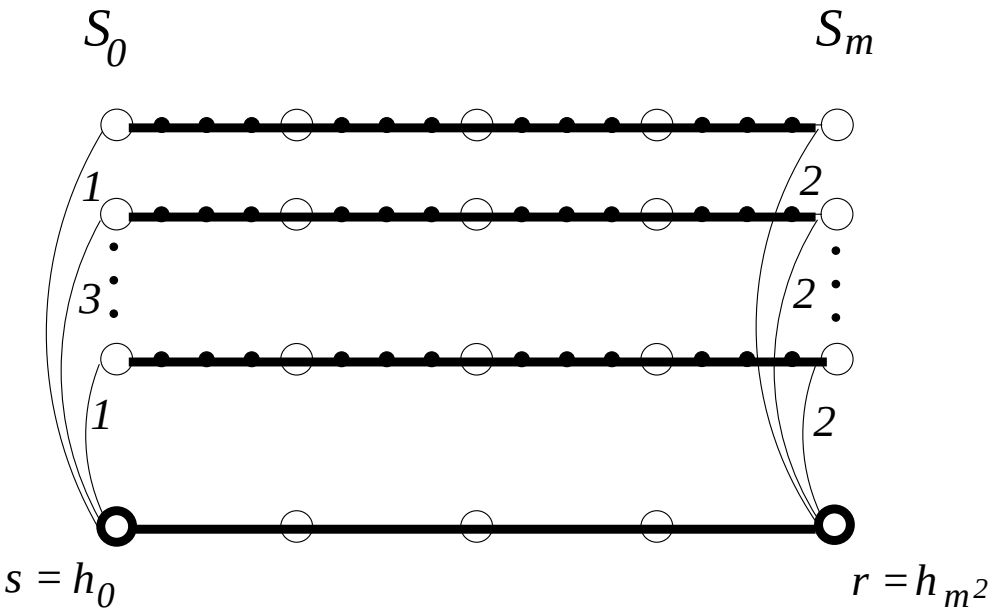

FIG. 6. *The remaining candidate edges to join the MST of* $J^2_{m,\gamma}$. *Bold edges belong to the MST under any edge weight function.*

4.2. The lower bound.

LEMMA 4.4. *Any distributed algorithm for constructing an MST on the graphs of the class $\mathcal{J}_m^2$ can be used to solve the* $\texttt{Mail}(F_m^2, h_0, h_{m^2}, m^2)$ *problem on F_m^2 with the same time complexity.*

Proof. Consider an algorithm $\mathcal{A}_{\rm mst}$ for the MST problem, and suppose that we are given an instance of the $\texttt{Mail}(F_m^2, h_0, h_{m^2}, m^2)$ problem with input string $\mathcal{X}$. We use the algorithm $\mathcal{A}_{\rm mst}$ to solve this instance of the mailing problem as follows. The sender $s = h_0$ initiates the construction of an instance of the MST by turning F_m^2 into a weighted graph from $\mathcal{J}_m^2$, setting the edge weights as follows: for each $x_i \in \mathcal{X}$, $1 \le i \le m^2$, it sets the weight variable W_i^s corresponding to the spoke edge $e_i \in E(S_0)$ to be

$$W_i^s = \begin{cases} 3, & x_i = 1, \\ 1, & x_i = 0. \end{cases}$$

The rest of the graph edges are assigned fixed weights as specified in subsection 4.1. Note that the weights for all the edges except those connecting s to its immediate neighbors in S_0 do not depend on the particular input instance at hand. Hence a single round of communication between s and its S_0 neighbors suffices for performing this assignment; s assigns its edges weights according to its input string $\mathcal{X}$, and needs to send at most one message to each of its neighbors on S_0, to notify it about the weight of the spoke connecting them.

Every vertex v in the network, upon receiving the first message of algorithm $\mathcal{A}_{\rm mst}$, assigns the values defined by the edge weight function ω_γ to its variables W_i^v. (As discussed earlier, this does not require v to know γ, as its assignment is identical under all weight functions ω_γ, $1 \le \gamma \le 2^{m^2}$.) From this point on, v may proceed with executing algorithm $\mathcal{A}_{\rm mst}$ for the MST problem.

Once algorithm $\mathcal{A}_{\rm mst}$ terminates, the receiver vertex r determines its output for the mailing problem, by setting $X_i^r \leftarrow Y_i^r$ for $1 \le i \le m^2$.

By Lemma 4.2, the lighter edge of each pair PE^j, for $1 \le j \le m^2$, belongs to the MST; thus in the set of variables $Y_1^r, \ldots, Y_{m^2}^r$ obtained by the vertex r as a result of solving the MST problem, $Y_j^r = 1$ corresponds to the assignment of $\omega(h_0, v_0^j) = 3$ to the jth edge of S_0, while $Y_j^r = 0$ corresponds to the assignment of 1 to that edge; hence for every j, Y_j^r equals x_j, the jth bit of $\mathcal{X}$. Hence the resulting algorithm has correctly solved the given instance of the mailing problem. □

Combined with Lemma 3.4, we now have the following theorem.

THEOREM 4.5. *For every $m \ge 1$, any distributed algorithm for constructing an MST on the graphs of the family $\mathcal{J}_m^2$ in the B model for $B \ge 3$ requires $\Omega(m^2/B)$ time.* □

COROLLARY 4.6. *Any distributed algorithm for the MST problem in the B model for $B \ge 3$ requires $\Omega(\sqrt{n}/B)$ time on some n-vertex graphs of diameter $O(n^{1/4})$.*

5. A lower bound on the mailing problem on F_m^K. This section generalizes the results of the previous section to the graphs F_m^K for $K \ge 3$, thus establishing the desired lower bound.

5.1. The graphs F_m^K. Given two integer parameters $m, K \ge 2$, construct the graph F_m^K as follows. The two basic units are still the path and the highway, with the following changes. The basic path $\mathcal{P}$ now has $m^K + 1$ vertices, i.e.,

$$V(\mathcal{P}) = \{v_0, \ldots, v_{m^K}\} \quad \text{and} \quad E(\mathcal{P}) = \{(v_i, v_{i+1}) \mid 0 \le i \le m^K - 1\}.$$

There are $K-1$ highways, denoted $\mathcal{H}^1,\ldots,\mathcal{H}^{K-1}$. The level-$\ell$ highway $\mathcal{H}^\ell$ consists of $m^\ell+1$ vertices, i.e.,

$$V(\mathcal{H}^\ell)=\{h^\ell_{im^{K-\ell}} \mid 0\le i\le m^\ell\} \quad \text{and}$$
$$E(\mathcal{H}^\ell)=\{(h^\ell_{im^{K-\ell}},h^\ell_{(i+1)m^{K-\ell}}) \mid 0\le i\le m^\ell-1\}.$$

Each highway vertex $h^\ell_{im^{K-\ell}}$ is connected to the corresponding path vertex $v^j_{im^{K-\ell}}$ by a spoke edge. Figure 7 depicts these connections for the case of $m=K=3$.

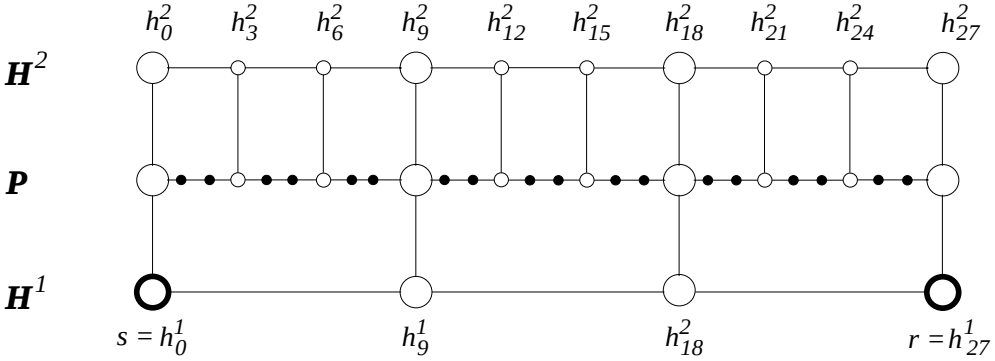

FIG. 7. *The connections between the path $\mathcal{P}$ and the highways $\mathcal{H}^1$ and $\mathcal{H}^2$ for $m=K=3$.*

The graph F^K_m is constructed by taking m^K copies of the path $\mathcal{P}$, denoted $\mathcal{P}^1,\ldots,\mathcal{P}^{m^K}$, and connecting them all to the same level-ℓ highway $\mathcal{H}^\ell$, for each $1\le\ell\le K-1$. The vertex h^1_0 is the intended sender s, and the vertex $h^1_{m^K}$ is the intended receiver r. (See Figure 8, showing the graph F^3_3.)

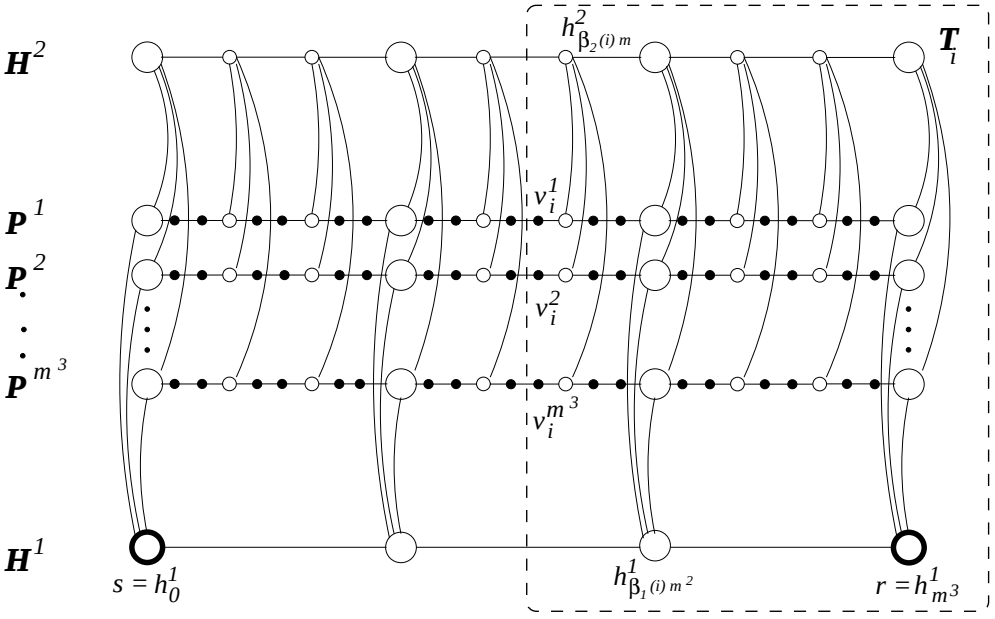

FIG. 8. *The graph F^3_m (here also $m=3$).*

The following two facts are easily verified.

LEMMA 5.1. *The cardinality of F_m^K is $n = \Theta(m^{2K})$ and its diameter is $\Theta(Km)$.*

5.2. The lower bound. The lower bound for the mailing problem can be extended from F_m^2 to F_m^K for $K \geq 3$ in a natural way. Consider some arbitrary algorithm $\mathcal{A}_{\text{mail}}$, and let $\varphi_{\mathcal{X}}$ denote the execution of $\mathcal{A}_{\text{mail}}$ on the input $\mathcal{X}$ in the graph F_m^K. The notion of a tail set is generalized to F_m^K for $K \geq 3$ as follows. For every $1 \leq j \leq m$, define the *tail* of the path $\mathcal{P}^j$ as before, i.e.,

$$T_i(\mathcal{P}^j) = \{v_l^j \mid i \leq l \leq m^K\}.$$

Let $\beta^\ell(i)$ denote the least integer δ such that $\delta m^{K-\ell} \geq i$, and define the tail of $\mathcal{H}^\ell$ as

$$T_i(\mathcal{H}^\ell) = \{h^\ell_{jm^{K-\ell}} \mid \beta^\ell(i) \leq j \leq m^\ell\}.$$

The tail set of F_m^K is the union of those tails,

$$T_i = T_i(\mathcal{H}) \cup \bigcup_j T_i(\mathcal{P}^j).$$

(See Figure 8.) Again, for $i = 0$ the definition is $T_0 = V \setminus \{h_0^1\}$.

The main lemma becomes the natural extension of Lemma 3.2, and its proof is similar. The notions of configuration, collection of configurations, and absolute size ρ of collections of possible configurations are defined in the same way as in section 3.2.

LEMMA 5.2. *For any $0 \leq t < m^K$,*

$$\rho[T_{t+1}, t+1] \leq (2^B + 1)^{K-1} \cdot \rho[T_t, t].$$

Proof. The lemma is proved by showing that in round $t+1$ of the algorithm, each configuration in $\mathcal{C}[T_t, t]$ branches off into at most $(2^B+1)^{K-1}$ different configurations of $\mathcal{C}[T_{t+1}, t+1]$.

Fix a configuration $\hat{C} \in \mathcal{C}[T_t, t]$. The tail set T_{t+1} is connected to the rest of the graph by the highway edges $f^\ell_{\beta^\ell(t+1)-1} = (h^\ell_{(\beta^\ell(t+1)-1)m^{K-\ell}}, h^\ell_{\beta^\ell(t+1)m^{K-\ell}})$, for every $1 \leq \ell \leq K-1$, and by the m^K path edges $e_t^j = (v_t^j, v_{t+1}^j)$, $1 \leq j \leq m^K$.

Consider the number of different configurations in $\mathcal{C}[T_{t+1}, t+1]$ that may result from $\hat{C}$. Starting from the configuration $\hat{C}$, each vertex v_t^j is restricted to a single state, and hence it sends a single (well determined) message over the edge e_t^j to v_{t+1}^j, thus not introducing any divergence in the execution. The same applies to all the edges internal to T_{t+1}.

The situation with highway edges $f^\ell_{\beta^\ell(t+1)-1}$ is different as there are K possible cases. When $\beta^\ell(t+1) = \beta^\ell(t)$ for $1 \leq \ell \leq K-1$, the vertices $h^\ell_{(\beta^\ell(t)-1)m^{K-\ell}}$ are not in the set T_t; hence their state is not defined by the choice of $\hat{C}$. The value passed over the edge $f^\ell_{\beta^\ell(t)-1}$ into the set T_{t+1} is thus unknown. However, due to the restriction of the B-bounded-message model, at most 2^B+1 different behaviors of can be observed by each vertex $h^\ell_{\beta^\ell(t)m^{K-\ell}}$, resulting in 2^B+1 possible states for each such node. Considering the entire set $\{h^\ell_{\beta^\ell(t)m^{K-\ell}} \mid 1 \leq \ell \leq K-1\}$, the single state $\hat{C}$ results in $(2^B+1)^{K-1}$ states of the tail set T_{t+1} at time $t+1$.

In the rest of the cases, $\beta^\ell(t+1) = \beta^\ell(t) + 1$ for at least one ℓ, when passing to the next tail set causes the exclusion of the highway point $h^\ell_{\beta^\ell(t)m^{K-\ell}}$ from the tail set. Here, a well defined message is sent over $f^\ell_{\beta^\ell(t+1)-1}$ since the state of $h^\ell_{\beta^\ell(t)m^{K-\ell}}$

is defined by the configuration $\hat{C}$. It follows that in these cases the number of possible states of T_{t+1} is less than $(2^B+1)^{K-1}$.

Altogether, the configuration $\hat{C}$ branches off into at most $(2^B+1)^{K-1}$ possible configurations $\hat{C}_1, \ldots, \hat{C}_{(2^B+1)^{K-1}} \in \mathcal{C}[T_{t+1}, t+1]$, differing by the states $\sigma(h^\ell_{\beta^\ell(t+1)m^{K-\ell}}, t+1, \mathcal{X})$. The lemma follows. □

COROLLARY 5.3. *For any* $0 \leq t < m^K$,

$$\rho[T_t, t] \leq (2^B+1)^{(K-1)t}.$$

Letting t_{end} denote the time it takes algorithm $\mathcal{A}_{\text{mail}}$ to complete the mailing, we derive, similar to the proof for $K=2$, that necessarily

$$(2^B+1)^{(K-1)t_{end}} \geq \rho[T_{t_{end}}, t_{end}] \geq 2^{m^K},$$

implying the following.

LEMMA 5.4. *For every* $K, m \geq 2$, *solving the mailing problem* $\texttt{Mail}(F^K_m, h^1_0, h^1_{m^K}, m^K)$ *in the* B *model requires* $\Omega(m^K/(BK))$ *time.*

6. A generalized lower bound on the MST on $\mathcal{J}^K_m$. Finally, we show the lower bound for the MST problem on the weighted versions of the graphs F^K_m.

6.1. The graph families $\mathcal{J}^K_m$. Let us define the families of weighted graphs $\mathcal{J}^K_m$. For every two integers $m, K \geq 2$, let

$$\mathcal{J}^K_m = \{J^K_{m,\gamma} = (F^K_m, \omega^K_\gamma) \mid 1 \leq \gamma \leq 2^{m^K}\},$$

where ω^K_γ is the weight function defined as follows. All the edges of the highways $\mathcal{H}^\ell$ for $1 \leq \ell \leq K-1$ and the paths $\mathcal{P}^j$ for $1 \leq j \leq m^K$ are assigned zero weight. It remains to assign the weights to the spoke edges.

Consider a subgraph of F^K_m, consisting of all the available paths $\mathcal{P}_j$, $1 \leq j \leq m^K$, a single highway $\mathcal{H}^\ell$ and all the connections of this highway to the paths. Consider a single node $h^\ell_{im^{K-\ell}}$ of the highway $\mathcal{H}^\ell$ and the set of all its connections to $\mathcal{P}^1, \ldots, \mathcal{P}^{m^K}$. Following the terminology of the case $K=2$, this is termed the *level-*ℓ *star* $S^{K,\ell}_{m,i}$. There are m^ℓ such stars at level ℓ.

Consider the collection of the stars $S^{K,\ell}_{m,i}$ for $1 \leq i \leq m^\ell$, $2 \leq \ell \leq K-1$ (excluding the first star of each level ℓ). The spokes of these stars are assigned the weight 4. The spokes of the first star of each level, $S^{K,\ell}_{m,0}$, are assigned as follows. The spokes connecting the star centers h^ℓ_0, $1 \leq \ell \leq K-1$ to the extreme vertex v^1_0 of the path $\mathcal{P}^1$ are assigned zero weight. The rest of the spokes are assigned the weight 4.

For the collection of the level-1 stars, $S^{K,1}_{m,i}$, the assignment is as follows. The spokes of all the stars except the two extreme ones, $S^{K,1}_{m,0}$ and $S^{K,1}_{m,m}$, are assigned the weight 4. The spokes of the last star $S^{K,1}_{m,m}$ are assigned weight 2. The weight assignment to the m^K spokes of the star $S^{K,1}_{m,0}$ depends on the particular function ω^K_γ, with each spoke assigned a value of either 1 or 3, as in section 4.2.

LEMMA 6.1. *No spoke edge of weight* 4 *belongs to the MST of* $J^K_{m,\gamma}$ *for every* $1 \leq \gamma \leq m^K$.

Proof. Following the proof of Lemma 4.1, it can be shown that the elimination of all spoke edges of weight 4 from the graph $J^K_{m,\gamma}$ leaves the graph connected. Since all the edges of all the highways and basic paths have zero weight, none of their edges is eliminated. Consider the connectivity of the highway $\mathcal{H}^1$ and the basic paths

$\mathcal{P}^1, \ldots, \mathcal{P}^{m^K}$. By construction, the spokes of two stars, namely, $S^{K,1}_{m,0}$ and $S^{K,1}_{m,m}$, have edges of weight at most 3, which guarantees that every basic path is connected to $\mathcal{H}_1$. The rest of the highways $\mathcal{H}^\ell$, for $2 \leq \ell \leq K-1$, are connected to the node v^1_0 of the basic path $\mathcal{P}^1$ by their nodes h^ℓ_0 via a zero-weight edge. Thus all the highways are connected to the path $\mathcal{P}^1$ and through it to the highway $\mathcal{H}^1$ and all the other basic paths.

Hence every spoke edge of weight 4 occurs as the heaviest edge on some cycle in the graph, implying the lemma. □

LEMMA 6.2. *For every $2 \leq \ell \leq K-1$, the edge (h^ℓ_0, v^1_0) belongs to the MST.*

Proof. By Lemma 6.1, no spoke edge of weight 4 belongs to the MST. By construction, each of the highways $\mathcal{H}^\ell$ for $2 \leq \ell \leq K-1$ is connected to the rest of the graph by spokes of weight 4 and by a single zero-weight spoke of the star $S^{K,\ell}_{m,0}$ connecting it to $\mathcal{P}^1$. Thus in order for the MST to be connected, the zero-weight edge must belong to the MST. □

Let us pair the spoke edges of $S^{K,1}_{m,0}$ and $S^{K,1}_{m,m}$ connecting $\mathcal{H}^1$ to $\mathcal{P}^j$ for $1 \leq j \leq m^K$, denoting the jth pair (for $1 \leq j \leq m^K$) by

$$PE^j = \{(s, v^j_0), (r, v^j_{m^K})\}.$$

By a proof similar to that of Lemma 4.2, we get the following lemma.

LEMMA 6.3. *For every $1 \leq j \leq m^K$, exactly one of the two edges of PE^j belongs to the MST of $J^K_{m,\gamma}$, namely, the lighter one.*

6.2. The generalized lower bound on distributed MST. We obtained an instance of the MST problem, in which the membership of edges in the MST is predetermined for all but the m^K edge pairs PE^j. Following the proof method of Lemma 4.4, we show that any algorithm solving the distributed MST problem on $\mathcal{J}^K_m$ can be used for solving the mailing problem in the same time complexity, implying the following.

THEOREM 6.4. *For every $m, K \geq 2$, any distributed algorithm for constructing an MST on the graphs of the family $\mathcal{J}^K_m$ in the B model for $B \geq 3$ requires $\Omega(m^K/(BK))$ time.*

Proof. Consider an algorithm $\mathcal{A}_{\mathrm{mst}}$ for the MST problem, and suppose that we are given an instance of the $\texttt{Mail}(F^K_m, h^1_0, h^1_{m^K}, m^K)$ problem with input string $\mathcal{X}$. We use the algorithm $\mathcal{A}_{\mathrm{mst}}$ to solve this instance of the mailing problem as follows. The sender $s = h^1_0$ initiates the construction of an instance of the MST by turning F^K_m into a weighted graph from $\mathcal{J}^K_m$, setting the edge weights as follows: for each $x_i \in \mathcal{X}$, $1 \leq i \leq m^K$, it sets the weight variable W^s_i corresponding to the spoke edge $e_i \in E(S^{K,1}_{m,0})$ (the first 1-level star), to be as in the proof of Lemma 4.4. The rest of the graph edges are assigned fixed weights as specified in section 6.1. Note that again, the weights for all the vertices except s and its immediate neighbors in $S^{K,1}_{m,0}$ do not depend on the particular input instance at hand; hence a single round of communication between s and its $S^{K,1}_{m,0}$ neighbors suffices for performing this assignment.

From this point on, we may proceed with executing algorithm $\mathcal{A}_{\mathrm{mst}}$ for the MST problem. Once algorithm $\mathcal{A}_{\mathrm{mst}}$ terminates, the receiver r determines its output for the mailing problem, by setting $X^r_i \leftarrow Y^r_i$ for $1 \leq i \leq m^K$.

The fact that the resulting algorithm has correctly solved the given instance of the mailing problem is established as in the proof of Lemma 4.4, relying on Lemma 6.3. The theorem now follows from Lemma 5.4. □

COROLLARY 6.5. *For every $K \geq 2$, there exists a family of n-vertex graphs of diameter $O(Kn^{1/(2K)},)$ such that any distributed algorithm for the MST problem in the B model for $B \geq 3$ requires $\Omega(\sqrt{n}/(BK))$ time on some of those graphs.*

COROLLARY 6.6. *For every $n \geq 2$, there exists a family of n-vertex graphs of diameter $O(\log n)$ such that any distributed algorithm for the MST problem in the B model for $B \geq 3$ requires $\Omega(\sqrt{n}/(B \log n))$ time on some of those graphs.*

Finally, let us comment that it has recently been shown that using Yao's method [Yao77] it is possible to extend the lower bound of Lemma 5.4 on the mailing problem into a lower bound on the expected time complexity of any *randomized* (Las Vegas) distributed algorithm for the mailing problem (see [P00, Chapter 24, Exercise 9]). This, in turn, yields the following lower bound on the time complexity of randomized algorithms for distributed construction: For every $n \geq 2$, there exists a family of n-vertex graphs of diameter $O(\log n)$ such that any randomized Las Vegas distributed algorithm for the MST problem in the B model requires $\Omega(\sqrt{n}/(B \log n))$ expected time on some of those graphs.

7. Open problems. Several interesting problems can be considered for future research. The first direction concerns the limitations of the presented lower bound. To begin with, the lower bound does not seem to extend to diameters lower than $O(\log n)$. As graphs with $D = 1$ admit an $O(\log n)$ distributed algorithm for MST construction, one may expect an interesting interdependence between the time to construct an MST and the network's diameter.

Second, one may consider a model allowing L-bit edge weights for $L > B$. While our lower bound still holds, stronger bounds may apply. Note that the transmission of an edge weight can be carried out in this model by sending $\Theta(L/B)$ separate messages. Hence each of the existing algorithms for distributed MST can be adapted to this model with a multiplicative slowdown of L/B. The algorithm of [KP98], for instance, will have time complexity $O((D + \sqrt{n} \log^* n)L/B)$. However, it is less clear whether this slowdown is necessary or if it can be avoided. It seems easy to verify (say, by considering a ring with two diametrically opposing edges having the extreme weights) that $\Omega(L/B)$ is indeed a lower bound on the time complexity of the problem in this model. However, it is plausible that the algorithm of [KP98] can be modified using pipelining ideas to yield a time complexity close to $O(D + \sqrt{n} \log^* n + L/B)$.

Another research direction is to try to reduce the *communication* complexity of the nearly time optimal algorithm of [KP98] from $O(|E| + n^{3/2})$ towards the lower bound of $O(|E| + n \log n)$.

Finally, one may consider the possibility of devising faster algorithms that construct an *approximation* to the MST, namely, a spanning tree whose total weight is near-minimum. To the best of our knowledge, nothing nontrivial is currently known about this problem, and little is known about distributed approximation algorithms in general, but this direction may well deserve further study.

FAST AND OPTIMAL PARALLEL MULTIDIMENSIONAL SEARCH IN PRAMS WITH APPLICATIONS TO LINEAR PROGRAMMING AND RELATED PROBLEMS*

MARTIN E. DYER† AND SANDEEP SEN‡

Abstract. We describe a deterministic parallel algorithm for linear programming in fixed dimension d that takes poly($\log\log n$) time in the common concurrent read concurrent write (CRCW) PRAM model and does optimal $O(n)$ work. In the exclusive read exclusive write (EREW) model, the algorithm runs in $O(\log n \cdot \log\log^{d-1} n)$ time. Our algorithm is based on multidimensional search and effective use of approximation algorithms to speed up the basic search in the CRCW model. Our method also yields very fast poly($\log\log n$) algorithms for smallest enclosing sphere and approximate ham-sandwich cuts and an $O(\log n)$ time work-optimal algorithm for exact ham-sandwich cuts of separable point sets. For these problems, in particular for fixed-dimensional linear programming, $o(\log n)$ time efficient deterministic PRAM algorithms were not known until very recently.

1. Introduction.

We consider the standard linear programming problem: given a set $\mathcal{H}$ of n half-spaces in $\mathbb{R}^d$ and a vector y, find a point $x \in \bigcap \mathcal{H}$ that minimizes $y \cdot x$. We restrict ourselves to the case where n is much larger than d, and we focus attention on parallel algorithms that achieve good performance with respect to n. Since the general problem is known to be P-complete [12], the restricted version assumes more relevance. For the most part we will regard d as a constant. However, since the running time of our algorithm grows rapidly with d, we will attempt to examine the exact nature of this dependence. Megiddo [32] described a linear-time algorithm for linear programming in fixed dimension d (hereafter referred to as LPd), using an elegant multidimensional search technique. The same search technique, also known as prune-and-search, yielded optimal algorithms for other optimization problems (see Megiddo [31] and Dyer [13, 14]). Following Megiddo's linear-time algorithm, there have been significant improvements in the constant factor (which was doubly exponential in d) due to Dyer [14] and Clarkson [4]. Further progress was made, using random sampling, by Clarkson [5]. This algorithm was later derandomized by Chazelle and Matoušek [9]. With more careful analysis and some additional ideas, Matoušek, Sharir, and Welzl [30] improved the algorithm further, achieving an expected running time of $O(d^2 \cdot n + e^{O(\sqrt{d \log d})})$, a "subexponential" dependence on d. Independently, Kalai [26] discovered an algorithm with matching performance, and these are presently the fastest known algorithms.

In the context of parallel algorithms for LPd, there have been a number of results in the direction of finding a fast analogue of Megiddo's linear-time sequential

method [1, 2, 11, 34]. A straightforward parallelization of Megiddo's method yields an $O(\log^d n)$ time n-processor exculsive read exclusive write (EREW) PRAM algorithm. (We write $\log^k n$ for $(\log n)^k$, and, similarly, $\log\log^k n$ for $(\log\log n)^k$.) However, this is far from the best that can be achieved. Alon and Megiddo [2] obtained an optimal parallel algorithm that runs in constant time (i.e., time depending only on d) on an n-processor randomized concurrent read concurrent write (CRCW) PRAM model. They used a variant of Clarkson's algorithm [5], which has smaller constants (in terms of d) than Megiddo's. More recently, Ajtai and Megiddo [1] developed a deterministic $O(\log\log^d n)$ algorithm in an n processor model which allows $O(\log\log n)$ time selection. Since there is an $\Omega(\log n/\log\log n)$ bound for exact selection [3], their model is considerably more powerful than the CRCW model, and partly nonuniform. It may also be noted that the work bound in the algorithm of Ajtai and Megiddo is superlinear, since they use a linear number of processors. Thus an $o(\log n)$ time optimal deterministic algorithm for LPd had hitherto proved elusive. Very recently, Goodrich [19] (see also Goodrich and Ramos [20]) independently obtained a poly$(\log\log n)$ time CRCW algorithm with optimal speed-up using fast parallel derandomization techniques. His approach is different from ours, being directly based on parallel derandomization techniques. His underlying randomized algorithm is similar to that of Dyer and Frieze [16]. This is derandomized using fast deterministic constructions of ε-approximations in $\mathbb{R}^d$. Here, we generalize the basic multidimensional search algorithm of Megiddo. Instead of pruning a constant fraction of the constraints in each round, we increase the rate of pruning as a function of *processor advantage*. The processor advantage is proportional to the ratio of the number of processors to the number of constraints, which increases monotonically during the course of the search. This allows us to improve the $\Omega(\log n)$ phases seemingly required by Megiddo's approach, and leads to a fast EREW algorithm. However, it does not directly yield a poly$(\log\log n)$ CRCW algorithm for the following reason. All known versions of multidimensional search algorithms rely on exact selection procedures, either deterministic or randomized. We make use of the observation that exact selection may be substituted by *approximate splitting* (defined formally in section 3) without significantly affecting the asymptotic convergence rate of the procedure. This is crucial in order to surmount the $\Omega(\log n/\log\log n)$ barrier for exact parallel selection: an impossibility in Ajtai and Megiddo' s approach. We apply this observation, using fast deterministic splitting algorithms in the CRCW model, to obtain a poly$(\log\log n)$ time algorithm. Moreover, we are able to achieve linear work simultaneously. Although all presently known poly$(\log\log n)$ approximate splitting algorithms are based on derandomization, they are relatively simpler and more efficient than constructing ε-nets in $\mathbb{R}^d$ as in Goodrich's algorithm [19]. However, it may be noted that the fastest algorithm known for approximate splitting follows from applying Goodrich's techniques. This could be used in our algorithm to save an $O(\log\log n)$ factor. However, we have chosen to ignore this in our later description. Rather, we feel that other poly$(\log\log n)$ time approximate splitting algorithms, like that of Hagerup and Raman [24], which are relatively simpler (although slower), are more in keeping with the basic simplicity of our approach. Our method also implies a very simple poly$(\log\log n)$ randomized CRCW algorithm, although this is asymptotically slower than Alon and Megiddo's algorithm. Our approach has immediate applications to other optimization problems where Megiddo's prune-and-search technique is effective. We are not aware of any previous poly$(\log\log n)$ time deterministic algorithms for problems like *minimum enclosing sphere* and *ham-sandwich cuts*. The latter especially has numerous applications to divide-and-conquer algorithms, including those for convex hulls and range

searching. The paper is organized as follows. In section 2, we describe our basic approach, generalizing Megiddo's multidimensional search technique. This directly yields a fast EREW algorithm. In section 3, we modify the algorithm of section 2, substituting some of the exact procedures by their faster approximate counterparts. In section 4, we analyze the algorithms for the EREW and CRCW PRAM and bound the total work by $O(n)$. In section 5, we present further applications of our search algorithm to problems like *Euclidean* 1-*center* and ham-sandwich cuts for separable planar point-sets. Because of the close similarity of these algorithms to that for LPd, we omit detailed analysis. In section 6, we make some observations regarding the relationship between *hyperplane cuttings* and our approach. We show the existence of a direct geometric construction for cuttings that does not require derandomization. However, the size of this cutting is probably too large for general application.

2. A parallel multidimensional search method. Without loss of generality, we assume that LPd has feasible region

$$\left\{ x \in \mathbb{R}^d : x_d \leq \sum_{j=1}^{d-1} \alpha_{ij} x_j + b_i \quad (i = 1, 2, \ldots, n) \right\},$$

and the objective is to minimize x_d. Megiddo [32] noted that LPd can be viewed as determining the *critical* linear constraints which define the optimal point x^*. If we assume nondegeneracy (no $(d+1)$-hyperplanes intersect in a point of the feasible region), then exactly d constraints define the optimal point, and the remaining constraints may be eliminated without affecting the optimum value. In its full generality, the LPd problem also requires us to report if the optimum is unbounded or if the feasible region is empty. In the description that follows, we do not discuss these conditions explicitly, noting that Megiddo's approach can handle these cases effectively. Suppose we have a set of n hyperplanes

$$H_i = \{ x \in \mathbb{R}^d : a_i \cdot x = b_i \} \quad (i = 1, 2, \ldots, n).$$

The *sign* of H_i with respect to $y \in \mathbb{R}^d$ is defined as $\{-, +, =\}$ depending on

$$a_i \cdot y - b_i \begin{array}{c} < \\ = \\ > \end{array} 0.$$

Geometrically, we wish to determine which side of the hyperplane contains y (including the possibility that y may lie on the hyperplane). We would like to determine the sign of y with respect to all the hyperplanes H_i $(i = 1, 2, \ldots n)$. To do this, we extend our definition to the sign of an *arbitrary* hyperplane in a similar fashion. Megiddo showed that, by determining the signs of a constant number $A(d)$ of carefully chosen hyperplanes, we can determine the sign of a constant fraction $B(d)$ of the H_i's. Here $A(d)$ and $B(d)$ are functions of d only. By repeatedly applying this strategy, one can determine all the signs relatively quickly (as compared to evaluating them individually). Megiddo used an elegant inductive argument to show the existence of $A(d)$ and $B(d)$, starting from the observation that for $d = 1$, $A(1) = 1$ and $B(1) = 1/2$ (by determining the sign of the median half-line). If y is x^*, and the hyperplanes are the constraints of LPd, then determining the sign of all hyperplanes is clearly equivalent to solving LPd. Hereafter, we will be interested in determining the sign of a hyperplane (not necessarily a constraint) with respect to x^*. However, x^* is itself unknown at the outset. Megiddo showed that the sign of an arbitrary hyperplane can

be determined by solving at most three linear programming problems (recursively) in one lower dimension. Using a nontrivial recursive strategy (involving recursion in both n and d), Megiddo constructed an algorithm for LPd with running time linear in n but doubly exponential in d. For convenience, we assume that no constraint hyperplane is parallel to x_d. (This can be achieved by standard perturbation techniques, if necessary.) From here, we focus on the following *hyperplane location* problem. Given a set N of hyperplanes of the form

$$H_i = \left\{ x \in \mathbb{R}^d : x_d = \sum_{j=1}^{d-1} a_{ij} x_j + b_i \right\} \quad (i = 1, 2, \ldots, n),$$

we wish to determine the sign at x^* of all H_i. This is often referred to as the *multidimensional search* problem. We will say that H_i is *located* if we know the sign of H_i with respect to the linear programming optimum x^*. As already noted, a straightforward parallelization of Megiddo's algorithm yields an $O(\log^d n)$ time algorithm with n processors. It is inefficient because, in the later stages of the algorithm when relatively few constraints remain, most of the processors are idle. We now describe a parallelization of multidimensional search which uses processors more efficiently in the later stages, when the number of processors greatly exceeds the number of constraints. The algorithm proceeds in stages, where during each stage, we determine the sign of some hyperplanes. At the beginning of the stage i, we denote the set of hyperplanes by N_i and their number by n_i, and we define processor advantage r_i to be $\max\{2, (p/n_i)^{1/d}\}$, where p is the number of processors. For example, $n_0 = n$ and $r_0 = 2$ if $p \leq n$. Again, for simplicity of presentation, we assume that r_i is an integer (or else take the floor function). Also, in the remaining part of this section we will write N, n, and r instead of N_i, n_i, and r_i since the description is limited to iteration i for some i.

Par_Mul_Search(N, p, d)

1. The set N of hyperplanes is partitioned into r equal sized sets based on their $a_{\ell 1}$ values ($\ell = 1, 2, \ldots, n$). This is done by selecting the $k(n/r)$th ranked elements (denoted by σ_k) from $\{a_{11}, a_{21} \ldots a_{n1}\}$ for $k = 1, 2, \ldots, r$. For convenience, write $\sigma_0 = -\infty$. Denote this partition of N by $\mathcal{P}$, where the kth *class* of $\mathcal{P}$ consists of hyperplanes H_ℓ which satisfy $\sigma_{k-1} < a_{\ell 1} \leq \sigma_k$ ($k = 1, 2, \ldots, r$).
2. For $d = 1$, solve the problem directly and exit. (See below.) Otherwise, partition N into r-sized subsets (*groups*) by picking (for each group) one constraint from each class of $\mathcal{P}$. Consider two hyperplanes H_i and H_j in a group and say $a_{i1} \leq a_{j1}$. Since they come from different classes of $\mathcal{P}$, there are values σ_k, σ_l such that $\sigma_k \in [a_{i1}, a_{j1}]$ and $\sigma_l \notin [a_{i1}, a_{j1}]$.
3. Using the transformation
$$x_1' = x_1 + \sigma_k \cdot x_2 \text{ and } x_2' = x_1 + \sigma_l \cdot x_2,$$
we obtain two hyperplanes H_{ij} and H_{ji}, where H_{ij} (respectively, H_{ji}) is obtained by eliminating x_1' (respectively, x_2') between H_i and H_j. Intuitively, these are planes that pass through the intersection of H_i and H_j and are parallel to the x_1' and x_2' coordinate axes, respectively. There are two such hyperplanes for each pair in the group. From Megiddo's observation (see also Dyer [14]), it follows that if we can locate both H_{ij} and H_{ji} (which are hyperplanes in $\mathbb{R}^{d-1}$), then we can locate at least one of H_i and H_j. Figure 1 illustrates the situation in two dimensions.

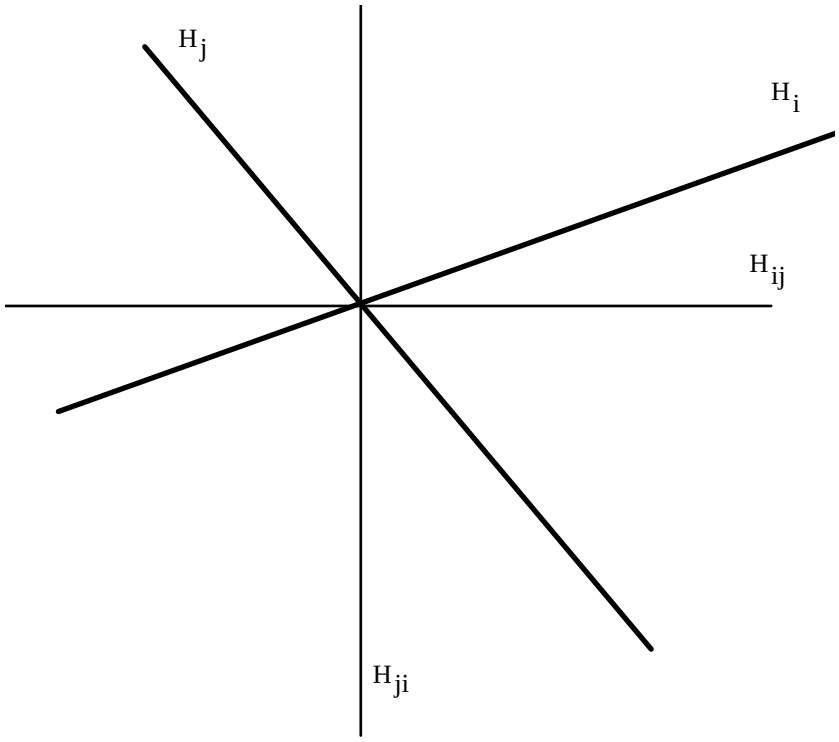

FIG. 1. *Each quadrant is completely contained in a half-plane determined by H_i or H_j. So by determining the signs of both H_{ij} and H_{ji}, we can determine the sign of H_i or H_j. For example, if the optimum lies in the NW quadrant, H_i's sign is determined. (H_{ij} and H_{ji} are not necessarily perpendicular.)*

4. We recursively apply the search algorithm in one lower dimension to all such hyperplanes H_{ij}, H_{ji}. Note that all H_{ij} lie in a subspace corresponding to the absence of $x_1{}'$ but possible presence of $x_2{}'$. Note there are only r different variables of the type $x_1{}'$, one for each of the r different σ_k values. Thus there are only r distinct subspaces for which the algorithm must be called recursively. The algorithm is called in parallel for all the distinct subspaces, allocating processors to the subproblems proportional to their sizes. At the bottom of this recursion on d, we will generate *special* hyperplanes with respect to which we must locate x^*. Location for these special hyperplanes involves recursively solving three $(d-1)$-dimensional linear programming problems. Each such problem is a restriction of the original LPd to a particular hyperplane. (See Megiddo [32] for further details of these lower-dimensional problems.)
5. Repeat the previous step R_d times, where R_d is a function of d that we will determine during the analysis. By repeating this step, we eliminate a fraction of the remaining hyperplanes.
6. The located hyperplanes are now eliminated from consideration, the new processor advantage is determined, and the above procedure is repeated.

The total number of hyperplanes generated in step 2 is $(n/r)r(r-1) < nr$ since every pair of hyperplanes in a group generates two lower-dimensional hyperplanes. Step 4 actually involves a double recursion, one of which we have unfolded (i.e., how to generate the special hyperplanes inductively in $\mathbb{R}^d$) for exposition of the basic

algorithm. This is similar to Megiddo's exposition [32] of the sequential algorithm, where a certain proportion $B(d)$ of hyperplanes is located using $A(d)$ queries, these functions being defined inductively. However, instead of the number of queries, we bound the number of *rounds* of parallel recursive calls. The number R_d will actually be defined according to the following recursive scheme. For the same set of σ_k's and r, we do c rounds of location (where c is some suitable constant) for the H_{ij}' s, where a certain proportion of H_{ij}'s are located recursively. This is done in order to boost the proportion of hyperplanes located in d dimensions for inductive application. This idea has been used before in [4, 14]. The difference here is that we cannot wait for the results of location in one group before we start on the next, as is done in the sequential algorithm. The number of groups r may be large, and so we must operate on them all in parallel. For $d = 1$, the constraints are half-lines, and the linear programs can be solved directly. The problem is equivalent to extremal selection (selection of minimum or maximum), which can be solved in $O(\log n)$ time on an EREW PRAM and $O(\log\log n)$ time on a CRCW PRAM [25]. As constraints are eliminated in each repetition of step 4, data compaction must be done, to ensure efficient processor utilization in the next. The processor requirement is determined by the total size of all problems that have to be solved simultaneously on all levels of the recursion on d. We must show that this remains bounded by the total number of processors. We will show this below and, more significantly, we will show that the recursive procedure in d dimensions takes only $O(\log\log n)$ rounds to eliminate all constraints. This will lead to an overall time bound of $O(\log n \log\log^{d-1} n)$ for LPd on the EREW PRAM.

3. Multidimensional search using approximate computations. To circumvent the $\Omega(\log n/\log\log n)$ lower bound for exact selection in the CRCW PRAM, we will modify step 1 of the previous section. We propose to use approximate splitting in the partitioning step and approximate compaction to do load balancing. As noted previously, extremal selection can be done in $O(\log\log n)$ time in CRCW PRAM. Formally, the problem of *approximate splitting* is defined as follows.

> *Given a set of N of n elements, an integer r, $1 \le r \le n$, and an expansion factor $\theta > 1$, choose a set R of r elements (out of N) such that the maximum number of elements of N in any interval induced by (the sorted order of) R is less than $\theta \cdot n/r$.*

Intuitively, $\theta = 1$ gives even splitting but we will relax that significantly to speed up our algorithm. For approximate splitting on the CRCW model, we use the following result implied by the work of Hagerup and Raman [24] and Goldberg and Zwick [22] (see the appendix for details).

LEMMA 3.1. *For all given integers $n \ge 4$, and $C \le r \le n^{1/4}$, approximate splitting can be done with expansion factor $\sqrt{r}$ in $O(\log\log^2 n)$ time and $O(r \cdot n)$ CRCW processors where C is a sufficiently large constant.*

For smaller r, we partition the a_{i2}'s into two sets by an approximate median which can be found quickly using the following result of Goldberg and Zwick.

LEMMA 3.2. *For a given set X of n elements and any fixed $\epsilon > 0$, an element $x \in X$ whose rank r' satisfies $\frac{n}{2} \le r' \le \frac{n}{2}(1+\epsilon)$ can be found in $O(\log\log n)$ steps using $n/\log\log n$ CRCW processors.*

The problem of *approximate compaction* was defined by Hagerup [23] as follows.

> *Given an n-element set, of which a are* active*, place the active elements in an array of size $(1+\lambda)a$, where λ is the* padding factor.

As one might expect, the running time of fast parallel algorithms for this problem increases as λ decreases. Hagerup described an $O(\log\log^3 n)$ time work-optimal CRCW

algorithm for the above problem for $\lambda = 1/\text{poly}(\log\log n)$. The following improved result was recently obtained by Goldberg and Zwick [22].

LEMMA 3.3. *The approximate compaction problem can be solved on a CRCW PRAM in time* $t \geq \log\log n$, *using* n/t *processors, with a padding factor of* $1/\text{poly}(\log\log n)$.

Suppose we substitute exact compaction by approximate compaction. Then, over the $O(d)$ levels of recursion, there will only be a slowdown in running time by a factor of $(1+\lambda)^{O(d)}$, i.e., a constant. We will also use the following result on *semisorting* to collect the elements of subproblem (i.e., a class or a group) together. The semisorting problem may be defined as follows.

> *Let* $\mathcal{A}$ *be an array of* n *elements such that each element has an integer label* $\ell \in \{1, 2, \ldots, k\}$. *Sort the elements of* $\mathcal{A}$ *into disjoint subarrays* $\mathcal{A}_\ell$ $(\ell = 1, 2, \ldots, k)$ *such that, if there are* n_ℓ *elements with label* ℓ, *the subarray*$\mathcal{A}_\ell$ *must be of size* $O(n_\ell)$.

The following is known about semisorting from [24].

LEMMA 3.4. *Semisorting problems of array size* n *and range size* k *can be solved in* $O(\log\log n)$ *CRCW time using* kn *processors.*

So, if C is the constant for the splitting algorithm above, the modified algorithm is as follows. If $(p/n_i)^{1/d} \geq \beta$, we choose $r_i = (p/n_i)^{1/d}$; otherwise, we choose $r_i = 2$, where $\beta \geq C$ is a constant that we will determine below, and we use the method of Lemma 3.1 to partition the a_{i1}'s, $1 \leq i \leq n$, into classes. Once the splitters are determined, the partitioning can be done by brute force, comparing a_{i1} against all splitters simultaneously in parallel. (There are sufficient processors for this to be done.) We put the hyperplanes in each class in near-contiguous locations by an application of semisorting and approximate compaction. Then we give each hyperplane in a class a group number corresponding to its position in the derived subarray. We now form groups by semisorting on group number, followed by approximate compaction of the group subarray. Thus each group will pick at most one hyperplane from each class, each hyperplane will belong to exactly one group, and each group is held in an array a little longer than its size. There are sufficient processors throughout since each uncompacted array is only a constant factor larger than the group size, by Lemma 3.4. The per-processor overhead caused by arrays not being exactly compacted is a small constant (in fact $o(1)$), and hence we ignore it in the analysis. Note, however, that some groups may have less than r hyperplanes. The number of groups is determined by the size of the largest partition since we take one hyperplane from each partition. Because of the approximate splitting, there could be $n/\sqrt{r}$ groups, rather than the n/r which would result from exact splitting. However, the size of each group is no more than r because the number of classes is only r. We will denote the set of groups by $\mathcal{G}$, and their number by $|\mathcal{G}|$. As indicated in the previous section, we pair hyperplanes from a group and solve the lower dimensional problem recursively a constant number of times, c (to be determined below). Then we start a new iteration by throwing out constraints and compacting the remaining using Lemma 3.3. At the bottom level (when the hyperplanes are points), we choose r splitters, so that the size of the largest partition is at most $n/\sqrt{r}$. Location with respect to the r splitters can be done simultaneously in $O(\log\log n)$ time using extremal selection. We have chosen r so that we will have enough processors at the bottom level.

4. Analysis. First we will prove a slightly weaker result, that our algorithm takes $O(\log\log^{d+1} n)$ in a CRCW PRAM using $p = n$ processors, and subsequently reduce the number of processors. The analysis is generalized to handle approximate

splitting. Therefore, in particular, the bounds that we prove are applicable to the basic algorithm of section 2. For convenience of presentation, we will refer to hyperplanes in $\mathbb{R}^d$ as d-hyperplanes. Our first objective is to bound the number of rounds of hyperplane locations required to eliminate a constant fraction of d-hyperplanes. Let π_d denote the fraction of d-hyperplanes that are located in R_d rounds for a fixed r_i, say r. Since the maximum size of a partition at the bottom level is $n/\sqrt{r}$, $\pi_1 \geq (\sqrt{r}-1)/\sqrt{r}$. The following will be used to write a recurrence for π_d. The groups refer to the groupings of $\mathcal{G}$ as defined in the previous section.

LEMMA 4.1. *The number of $(d-1)$-hyperplanes that have to be located in the recursive call is bounded by $n \cdot (r-1)$.*

Proof. As pointed out in the previous section, although $|\mathcal{G}|$ could be $n/\sqrt{r}$ because of uneven splitting, the number of $(d-1)$-hyperplanes can be bounded by $\sum_{g\in\mathcal{G}} n_g(n_g-1)$, where n_g is the number of d-hyperplanes in group $g \in \mathcal{G}$. Since $n_g \leq r$ and $\sum n_g = n$, the number of $(d-1)$-hyperplanes is bounded by $n/r \cdot r(r-1)$. □

Observation 4.1. Suppose, in a certain group of d-hyperplanes, at most $m(m-1)/2$ of the $(d-1)$-hyperplanes have not been located. Then at most m d-hyperplanes are not located.

Proof. Recall that the $(d-1)$-hyperplanes are obtained by taking all possible pairs in a group and generating two $(d-1)$-hyperplanes from each pair. Suppose there are $m'(>m)$ unlocated d-hyperplanes; consider the $m'(m'-1)/2 > m(m-1)/2$ pairs formed by these. At least one $(d-1)$-hyperplane from each pair has not been located, since locating both $(d-1)$-hyperplanes in a pair would imply that one of the d-hyperplanes is located. This contradicts the antecedent of the observation that at most $m(m-1)/2$ pairs have not been located. □

In order to write a recurrence for π_d, we let $\bar{n}_g$ denote the number of unlocated d-hyperplanes in group g and let u_g denote the number of unlocated $(d-1)$-hyperplanes (among the $n_g(n_g-1)$ generated in g). From the above notations,

$$\pi_d = \frac{1}{n}\left(n - \sum_g \bar{n}_g\right).$$

From Lemma 4.1 and the recursive application (i.e., a fraction π_{d-1} of the $(d-1)$-hyperplanes are located in R_{d-1} rounds),

$$\sum_g u_g \leq (1-\pi_{d-1})^c \cdot n(r-1). \tag{1}$$

From Observation 4.1,

$$u_g \geq \frac{1}{2}\bar{n}_g \cdot (\bar{n}_g - 1),$$

implying

$$2u_g + 1 \geq \bar{n}_g^2 - \bar{n}_g + 1,$$

implying, in turn,

$$2u_g + 1 \geq n_g.$$

Therefore, $\sum_g \bar{n}_g \leq \sum_g (2u_g + 1)$. Substituting in (1), we can write the recurrence for π_d as follows:

$$\pi_d \geq \frac{1}{n}(n - 2(1 - \pi_{d-1})^c n(r-1) - n/\sqrt{r}), \tag{2}$$

where the last term on the right corresponds to $\sum_g 1 = |\mathcal{G}| \leq n/\sqrt{r}$. Simplifying, we obtain

$$\pi_d \geq 1 - 2(1 - \pi_{d-1})^c (r-1) - 1/\sqrt{r}.$$

It is straightforward to verify by induction that, for $d \geq 2$, $\pi_d \geq \frac{\sqrt{r}-2}{\sqrt{r}}$, provided $r \geq 8$ and $c \geq 12$. If $r = 2$, we choose an approximate median with accuracy $1/6$ (i.e., $\epsilon = 1/6$ in Lemma 3.2). Then (2) becomes

$$\pi_d \geq \frac{1}{n}(n - 2(1 - \pi_{d-1})^c \cdot n - 2n/3),$$

since $|\mathcal{G}| \leq n/2 + n/6 = 2n/3$. For $c = 12$ and $\pi_1 \geq 1/3$, $\pi_d \geq 1/4$ by induction. Thus we take $c = 12$ and $\beta = \max\{8, C\}$ in our algorithm description where C is the constant from Lemma 3.1. The total number of rounds R_d for location in dimension d satisfies $R_d = c^{d-1}$, since $R_d = c \cdot R_{d-1}$ and $R_1 = 1$. Hence we can write the recurrence for n_i, the number of surviving constraints at the beginning of iteration i, as

$$n_{i+1} \leq n_i(1 - \pi_d) \leq \begin{cases} \frac{3}{4} n_i & (r_i = 2), \\ \frac{2}{\sqrt{r_i}} n_i & (r_i \geq \beta). \end{cases}$$

After $O(d)$ iterations with $r_i = 2$, we will have $(n/n_i)^{1/d} \geq \beta$. Note that then $n_i/n \leq \frac{1}{8}$. Thereafter,

$$n_{i+1} \leq 2n_i^{1+1/2d}/n^{1/2d}.$$

Letting $\xi_i = n_i/n$, we can rewrite the previous inequality as

$$\xi_i \leq 2\xi_i^{1+1/2d},$$

where $\xi_1 = \frac{1}{8}$. Therefore, $\xi_i = O(1/n)$ (i.e., $n_i = O(1)$) when $i \geq c_1 \log\log n$ for some constant $c_1 = O(d)$. Each iteration involves splitting, compaction, and a constant number of recursive calls to lower dimensional problems. Let $T_d(n)$ be the running time for a d-dimensional problem of size n. Then we can write the recurrence

$$T_d(n) \leq c_1 \log\log n[c^{d-1}(T_{alloc} + T_{split} + 3T_{d-1}(n))], \tag{3}$$

where T_{alloc} and T_{split} denote the times for data compaction and approximate splitting, respectively. From Lemma 3.3, $T_{alloc} = O(\log\log n)$, and from Lemma 3.1, $T_{split} = O(\log\log^2 n)$, respectively. Using $T_1(n) = O(\log\log n)$, $T_d(n)$ is $O(\log \log^{d+1} n)$ for $d \geq 2$. Since $c_1 = O(d)$, the implied constant is $2^{O(d^2)}$, which is of the same form as that in the improvement of Megiddo's algorithm due to Dyer [14] and Clarkson [4]. The processor requirement is bounded by the number of $(d-1)$-dimensional linear programming problems which must be solved simultaneously at the bottom level. Each such problem has n_i constraints per problem. This number is the

total number of hyperplanes that must be located simultaneously. This is bounded by $n_i(r_i-1)^{d-1}$ from Lemma 4.1, since the number of distinct linear programming instances grows by an (r_i-1) factor at each level of the recursion on d. But this is at most n, since either $r_i = 2$ or $r_i = (n/n_i)^{1/d} \geq 8$. We can now state our intermediate result as the following lemma.

LEMMA 4.2. *Linear programming in fixed dimension $d \geq 2$ can be solved in $O(\log \log^{d+1} n)$ CRCW PRAM steps, using n processors .*

Remark. Using a faster approximate splitting algorithm due to Goodrich [19], with $T_{split} = O(\log \log n)$, the running time would decrease to $O(\log \log^d n)$. The previous analysis also holds for the basic algorithm of section 2, and therefore we can analyze the performance of the algorithm on the EREW PRAM simply by substituting bounds for exact selection and compaction. Since then $T_{alloc} = O(\log n)$ and $T_{split} = O(\log n)$, we obtain, similarly to the above, the following result.

LEMMA 4.3. *Linear programming in fixed dimension $d \geq 2$ can be solved in $O(\log n \log \log^{d-1} n)$ steps using n processors in an EREW PRAM.*

To reduce the number of operations to $O(n)$, we use a slow-down technique, applied inductively. We outline our strategy in the case of CRCW PRAM. We have observed that the one-dimensional problem can be solved in $O(\log \log n)$ steps using $n/\log \log n$ processors. Assume that the $(d-1)$-dimensional problem can be solved in $O(\log \log^d n)$ steps optimally. The standard slow-down method implies that, for any time $t > \log \log^d n$, these problems can be solved with optimal work. We start with $p = n/\log \log^{d+1} n$ processors and reduce the number of constraints to $n/\log \log^{d+1} n$ by running the algorithm with $r_i = 2$ for $O(\log \log \log n)$ iterations. Let $t_d = \log \log^{d+1} n$. In each iteration, we apply the work-optimal $(d-1)$-dimensional method. Now iteration i (starting with $i = 0$) takes $\max\{\gamma^i t_d, O(\log \log^d n)\}$ steps. Here $\gamma \leq \frac{3}{4}$ is the fraction of constraints eliminated at each iteration. In each iteration, we use the result of Lemma 3.3 to do load balancing. This takes $O(\max\{\gamma^i t_d, \log \log n\})$ steps. The total time taken to reduce the number of constraints to $n/\log \log^{d+1} n$ by the above method can therefore be bounded by $O(\log \log^{d+1} n + \log \log^d n \cdot \log \log \log n)$. At this stage, we switch to the n-processor algorithm described previously. Therefore, we can state our final result.

THEOREM 4.4. *Linear programming in fixed dimension $d \geq 2$ can be solved in $2^{O(d^2)} \log \log^{d+1} n$ CRCW PRAM steps using $n/\log \log^{d+1} n$ processors.*

Following an identical strategy, but using $t_d = \log n \log \log^{d-1} n$ and $O(\log n)$ for the load balancing time, we obtain an analogous result for the EREW PRAM. However, the running time increases by an $O(\log^* n)$ factor, since the best work-optimal EREW selection algorithm known runs in $O(\log n \log^* n)$ time (Cole [10]).

THEOREM 4.5. *Linear programming in fixed dimension $d \geq 2$ can be solved in $2^{O(d^2)} \log n \log^* n \log \log^{d-1} n$ EREW PRAM steps, using $n/(\log n \log^* n \log \log^{d-1} n)$ processors.*

5. Other applications. Although the search algorithm was described in the context of linear programming, the method extends to problems where prune-and-search methodology has produced linear-time sequential algorithms. We outline two of these applications here, namely, finding *the smallest enclosing circle* (or, more generally, *the Euclidean* 1*-center problem*) and finding *ham-sandwich cuts* of separable point-sets on the plane.

5.1. Smallest enclosing circle. Given a set $N = \{(a_i, b_i), 1 \leq i \leq n\}$ of points in the plane, we wish to determine a circle $\mathcal{C}$ that encloses all the points and

is smallest among all such circles. This has a natural analogue in higher dimension, where we determine the smallest enclosing sphere in the appropriate dimension. Megiddo [31] described a linear-time algorithm for the smallest enclosing circle problem. Dyer [14] extended this to solve the more general *weighted Euclidean* 1-*center* problem in any fixed dimension, using additional tools from convex optimization. The idea of Megiddo's solution is very similar to the linear programming algorithm. The minimum enclosing circle $\mathcal{C}$ is defined by at most three points, so the solution remains unchanged if we eliminate the remaining points. The algorithm proceeds in iterative phases, where in each phase a constant fraction of the input points are eliminated with linear work. The crucial issue is to recognize which points can be eliminated using carefully designed queries. In the following, we follow Megiddo's [31] description with appropriate modifications for the parallel algorithm. We will first solve a restricted version of the problem, where the center of $\mathcal{C}$ is constrained to lie on a given straight line. Without loss of generality, assume this line is the x-axis. Denote the center of $\mathcal{C}$ by x_c. Pair up the points arbitrarily and denote the perpendicular bisector of pair $(a_i, b_i), (a_j, b_j)$ by $\perp_{ij}$. It can be readily seen that there exists a critical value x_{ij} (the intersection of $\perp_{ij}$ with the x-axis), such that depending on $x_c \begin{smallmatrix} < \\ = \\ > \end{smallmatrix} x_{ij}$, one of the points in the pair the one that is closer to x_c, can be eliminated. So if we can determine answers to queries of the form "Is $x \begin{smallmatrix} < \\ = \\ > \end{smallmatrix} x_c$?" for arbitrary x, we can use these to eliminate some of the points. For example, by evaluating the query at x_m, the median value of x_{ij}s, we can eliminate one point from every pair for half the number of pairs, i.e., a quarter of the points. Determining the sign of an arbitrary x ($x \begin{smallmatrix} < \\ = \\ > \end{smallmatrix} x_c$?) is easily done by finding the furthest point (in Euclidean distance) from x. Denote the square of this distance by $g(x)$. Let $I = \{i : (x - a_i)^2 + b_i^2 = g(x)\}$. If $x < a_i$ for every i, then $x < x_c$. If $x > a_i$ for every i, then $x > x_c$, else $x = x_c$. All this can be done in linear time. So, applying the above procedure recursively to the remaining points (at most $3/4n$), x_c can be determined in $O(n)$ steps. More formally, we are solving the following optimization problem (unrestricted case).

$$\min_{x,y} f(x, y) = \max_i \{(x - a_i)^2 + (y - b)^2\}.$$

Note that $f(x, y)$ is a convex function of its arguments. In the preceding paragraph, we described a method to solve the constrained problem when $y = 0$. Given an arbitrary y, the sign of y is defined to be $\{+, =, -\}$ depending on $y \begin{smallmatrix} < \\ = \\ > \end{smallmatrix} y^*$, where (x^*, y^*) is the unconstrained optimum of $g(x, y)$. Because of the convexity, the sign of y can be determined from the sign at (x_c, y), where x_c is the constrained optimum. The sign at (x_c, y) can be determined by an application of linear programming in plane or, alternatively, by a direct method of finding a line separator (see Megiddo [31]). The overall algorithm is very similar to the linear programming algorithm. Here we consider pairs of points instead of pairs of constraints. Each pair of point $(a_{2i-1}, b_{2i-1}), (a_{2i}, b_{2i})$ defines a perpendicular bisector $\perp_i$ such that, if we could determine which half-plane of $\perp_i$ contains (x^*, y^*), we could eliminate one point from the pair. This is similar to determining the sign of $\perp_i$. We pair perpendicular bisectors, $\perp_i$ and $\perp_j$, say, and compute their intersection p_{ij}. Consider the two lines X_{ij} and Y_{ij}, passing through p_{ij}, parallel to the x and y axes, respectively. If the slopes of $\perp_i$ and $\perp_j$ do not have the same signs, then by determining the signs of X_{ij} and Y_{ij}, we can eliminate one of the four points (defining $\perp_i$ and $\perp_j$). Figure 2 illustrates this situation. Determining the sign of X_{ij} or Y_{ij} is essentially a lower dimensional problem (the constrained

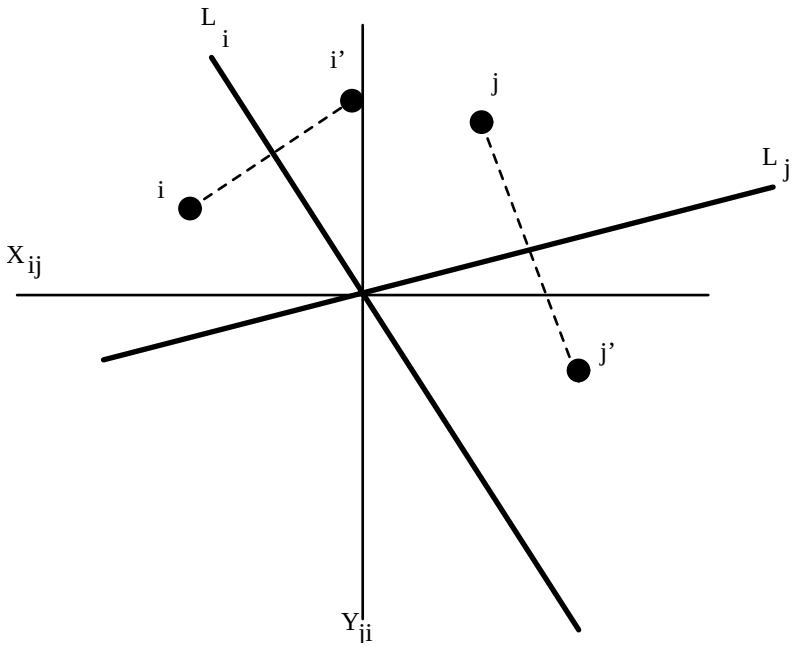

FIG. 2. *If the center of the optimum circle is located in the SW quadrant, clearly point i will be strictly closer than i′ and hence can be eliminated.*

version) that we solved before. So, we have reduced the searching problem to one lower dimension. The strategy is identical to that of computing signs of hyperplanes in section 2. Here the hyperplanes are defined by pairs of points (the perpendicular bisectors). The groupings are done on the basis of slopes and the algorithm is applied recursively to the r different subspaces generated. Here r is processor advantage, which will be defined similarly to the linear programming algorithm. The analysis is carried out in a fashion almost identical to section 4, and we omit further details. Note that computing the sign of a bisector eliminates at least one of the two defining points. Hence we can summarize with the following theorem.

THEOREM 5.1. *The minimum enclosing circle of n points on the plane can be determined in $O(\log\log^3 n)$ CRCW time, using $n/\log\log^3 n$ processors.*

The above algorithm extends to any fixed dimension d. To determine the sign of a hyperplane in dimension $d > 2$, we will use linear programming in dimension d after determining the center of the constrained smallest sphere. (The center lies on the hyperplane.) This is to determine if the center of the constrained sphere is contained within the convex hull of the points I determining the optimum. If it is contained, then we have the global unconstrained optimum. Otherwise, the optimum lies in the direction perpendicular to the hyperplane bounding the d extreme points of I. This additional complication increases the running time by an $O(\log\log n)$ factor compared with the linear programming algorithm.

COROLLARY 5.1.1. *The minimum enclosing sphere of n points in E^d for $d > 2$ can be determined in $O(\log\log^{d+2} n)$ time using $n/\log\log^{d+2} n$ CRCW processors.*

5.2. Ham-sandwich cuts and partitioning a planar point-set. A line l is called the *bisector* of a point set S if each open half-plane defined by the line contains

at most half the points of S. It is known that, given two point sets P and Q, it is possible to bisect them simultaneously using a line l. This line is called a *ham-sandwich* cut of P and Q. In the special case where P and Q are linearly separable, Megiddo [33] described a linear-time algorithm based on prune-and-search. Later, Lo and Steiger [27] described a linear-time algorithm for the general case. Megiddo's algorithm is useful in situations where we need to partition a point set into four quadrants using two lines. We can choose one line to be the median with respect to one of the axes. This partitions the points into two sets S_1 and S_2. Then, using Megiddo's algorithm, we can take the other line to be a ham-sandwich cut of S_1 and S_2. This has numerous applications to divide-and-conquer algorithms. Below we show that our search strategy yields a fast parallel algorithm for this special case of ham-sandwich cuts. However, it must be noted that ham-sandwich cuts can be used to compute an exact median of a set of points on the x-axis. (Simply take this set as P and an arbitrary two-point set in the upper half-plane as Q.) Thus the lower bound on exact median-finding prevents us from attaining poly$(\log\log n)$ performance. Therefore, we will first design an $O(\log n)$ time algorithm for this problem. Then we will show how to obtain *approximate ham-sandwich* cuts in poly$(\log\log n)$ time. An approximate ham-sandwich cut will mean that each of P and Q will be partitioned *approximately* equally. We describe Megiddo's method briefly. (Our version actually follows the description in [17].) The problem is solved in the dual space where a point $p = (a, b)$ is mapped to the line $D(p) : y = 2ax - b$, and a nonvertical line $l : y = \lambda_1 x + \lambda_2$ is mapped to the point $D(l) : (\lambda_1/2, -\lambda_2)$. Thus $D^2 = D$, and it is known, moreover, that D preserves incidence and the below-above relationship. (See [17] for details.) Thus the P and Q are mapped to sets of lines $G = D(P)$ and $H = D(Q)$. Assume, without loss of generality, that the lines of G and H have nonpositive and nonnegative slopes, respectively (by choosing the x-axis as a separating line in the primal plane). In the arrangement $\mathcal{A}(S)$ formed by a set of lines S, a *level* k $(1 \le k \le |S|)$ is the set of points of $\mathcal{A}(S)$ that lie below *exactly* k lines of S. We will write $\mathcal{L}_i(S)$ for the ith level of S. In the arrangements $\mathcal{A}(G)$ and $\mathcal{A}(H)$, the median levels correspond to lines that bisect P and Q in the primal plane. Because of the slope constraints we have imposed, the levels in G and H are monotonically nonincreasing and nondecreasing, respectively. This implies that $\mathcal{L}_i(G)$ and $\mathcal{L}_j(H)$ have a nonempty intersection for all i, j. We wish to determine a point p^* in the intersection of the median levels. Then $D(p^*)$ is a ham-sandwich cut for P and Q. We actually solve a more general problem. We determine a point s in the intersection of the ith level of G and the jth level of H. Let $m = |G|$ and $n = |H|$. The algorithm proceeds in phases, where in the kth phase, we are looking for a point common to the levels g_k of $\mathcal{A}(G^k)$ and h_k of $\mathcal{A}(H^k)$. Here G^k and H^k are the subsets of G and H active during the kth phase. Initially, $k = 0$, $g_0 = i$, $h_0 = j$, $G^0 = G$, and $H^0 = H$. In the kth phase, we eliminate lines from G^k and H^k that cannot contain the common point using line *tests*. A test consists of determining which side of a given line t contains p^*. (The test may also yield a point in the intersection, in which case the algorithm terminates.) Then new sets G^{k+1}, H^{k+1} are calculated after elimination of some lines. New values of g_{k+1} and h_{k+1} are chosen, and we proceed to iteration $k + 1$. A test with respect to a line t is similar to computing the sign in our general search strategy. It can be done in linear time sequentially and involves computing a g_kth and h_kth intersection point of G^k and H^k, respectively, on the line t. There are various cases, and we refer the reader to [17, pp. 339–341] for details. We use the following optimal selection algorithm from Chaudhuri, Hagerup, and Raman [7].

LEMMA 5.2. *For all integers $n \geq 4$, selection problems of size n can be solved in $O(\log n/\log\log n)$ CRCW time using $n\log\log n/\log n$ processors.*

Using this as a subroutine, we can compute the *sign* of a line t in $O(\log n/\log\log n)$ time. Consider the set of lines $L = H \cup G$. Suppose $l_1, l_2 \in L$ have slopes of the opposite sign and $p_{1,2}$ is their common intersection point. Let t_x and t_y be the horizontal and vertical lines through $p_{1,2}$. By determining the signs of t_x and t_y, we can determine at least one of the lines l_1 or l_2 which cannot contain any point s in the intersection of the levels. (Otherwise, we can actually determine such a point s, and the algorithm terminates.) We can therefore apply our search strategy to this situation by partitioning the lines of L using their slopes. Here we can use exact selection using Lemma 5.2 since we have more time at our disposal. The remaining algorithm is very similar to our previous search algorithms, and the analysis follows along similar lines. Since each testing costs us $O(\log n/\log\log n)$ time and the algorithm has $O(\log\log n)$ stages, the total time is $O(\log n)$ using n processors. We may also use exact compaction. Finally, using a technique similar to Theorem 4.4, we can reduce the number of processors to $O(n/\log n)$. Thus, we have the following theorem.

THEOREM 5.3. *A ham-sandwich cut of two linearly separable sets P and Q can be computed in $O(\log n)$ CRCW steps, using $n/\log n$ processors, where $n = |P \cup Q|$.*

An *approximate* ham-sandwich cut of P and Q, with *relative accuracy* λ ($0 < \lambda < 1$), will be defined as follows. The cut is a line l which simultaneously partitions P and Q, so that the partition of P (respectively, Q) does not contain more than $|P|(1+\lambda)/2$ (respectively, $|Q|(1+\lambda)/2$) points. In the context of the dual setting this implies that we have to determine a point s that lies in the intersection of $\mathcal{L}_i(G)$ and $\mathcal{L}_j(H)$, where $(1-\lambda)|G|/2 \leq i \leq (1+\lambda)|G|/2$ and $(1-\lambda)|H|/2 \leq j \leq (1+\lambda)|H|/2$. Ghouse and Goodrich [21] describe a simple algorithm for this problem using random sampling followed by verification. We follow the lines of our previous algorithms, with the modification that testing with respect to a line is done using approximate selection. We use the following algorithm for parallel approximate selection from [7].

LEMMA 5.4. *For all integers $n \geq 4$ and $t \geq \log\log^4 n$, approximate selection with relative accuracy $2^{-t/\log\log^4 n}$ can be achieved in $O(t)$ time, using a CRCW PRAM optimally in $O(n)$ operations. Furthermore, for $q \geq 1$, a relative accuracy of 2^{-q} can be achieved in $O(q + \log\log^4 n)$ time, using $O(qn)$ operations.*

We also use Lemma 3.3 to update the values of g_k, h_k at each iteration. Because of the use of approximate algorithms, testing with respect to a line t returns an answer satisfying the following property. Given g_k, h_k, and a line t, the test returns a half-plane (bounded by t) which contains an intersection point of level $(1 \pm \epsilon)g_k$ of G^k with level $(1 \pm \epsilon)h_k$ of H^k. (Here ϵ is the relative accuracy of our selection algorithm.) Moreover, the updated values of g_k and h_k are accurate within a multiplicative factor $(1 + 1/\text{poly}(\log n))$. Since there are $O(\log\log n)$ iterative phases of the algorithm, the overall accuracy can be bounded by $(1 \pm \epsilon)^{O(\log\log n)}$. From Lemma 5.4, $\epsilon \leq 1/\text{poly}(\log n)$ is achievable in $\text{poly}(\log\log n)$ steps. Hence an overall relative accuracy of $1/\text{poly}(\log n)$ is achievable using this approach. Therefore, we have the following result.

THEOREM 5.5. *An approximate ham-sandwich cut of linearly separable sets P and Q, with relative accuracy $\lambda \leq \log^{-a} n$ for some fixed constant a, can be computed in $O(\log\log^6 n)$ steps, using $O(n)$ operations, where $n = |P \cup Q|$.*

6. Some observations on our method. In this section we offer some insights into the multidimensional search technique relative to other methods, in particular, random-sampling based strategies. The randomized algorithm of Clarkson [5] (later

derandomized by Chazelle and Matoušek [9]) exploits efficient geometric partitioning methods based on ϵ-net constructions (often referred to as *cuttings* in the context of this problem). A $1/r$-*cutting* $\mathcal{C}$, for a set H of hyperplanes in $\mathbb{R}^d$, is a collection of d-dimensional simplices (with disjoint interiors) which covers $\mathbb{R}^d$. Furthermore, no simplex intersects more than $|H|/r$ hyperplanes. The number of simplices in $\mathcal{C}$ is called the *size* of the cutting. The derandomization methods are actually techniques for constructing cuttings whose existence is guaranteed by the probabilistic method. It was shown by Matoušek [29] and Chazelle [8] that $1/r$-cuttings of size $O(r^d)$ can be constructed in time $O(n \cdot r^{d-1})$, using a derandomization technique based on the method of conditional probabilities (known as the *Raghavan–Spencer* technique). It is fairly clear that, given such a cutting, the multidimensional search method becomes easier to implement. We will show that the converse is also true—that the multidimensional search method implies a cutting. This was noted somewhat less explicitly in some previous papers (see [6, 28]). While the size of the cutting is much worse than one obtains from the derandomization methods, it does not involve derandomization and is a direct geometric constructon. The intuition is as follows. The multidimensional search in d dimensions eliminates a fixed fraction $B(d)$ of hyperplanes by location with respect to a set of hyperplanes R of size $A(d)$. Let us denote the arrangement in $\mathbb{R}^d$ induced by the hyperplanes in R by $\mathcal{A}(R)$, and let us denote the region in $\mathcal{A}(R)$ that contains the optimum by Δ^*. Clearly, the number of hyperplanes intersecting Δ^* cannot exceed $|H|(1 - B(d))$, since any plane that has been located cannot intersect Δ^*. However, it is not obvious how many hyperplanes intersect other regions $\Delta \in \mathcal{A}(R)$. If the same bound applies, then we have a $(1 - B(d))$-cutting. This is indeed so, since Megiddo's algorithm selects, at the bottom-most level of recursion, a fixed set of hyperplanes and does the location with respect to these. Irrespective of where the query point lies, the previous bound holds. The size of this cutting is less obvious. We reduce the number of hyperplanes intersecting Δ^* by iterating a fixed number of times c on the lower dimensional problem. This is an adaptive improvement that is local to Δ^*, and it is not clear how it affects other regions. However, modifying (2) from section 4 as follows will give us a bound on the size of a $1/r$-cutting.

$$\pi_d \geq \frac{1}{n}(n - 2(1 - \pi_{d-1}) \cdot n(r - 1) - n/r). \tag{4}$$

We have set the exponent $c = 1$ for the reasons mentioned above, and we have replaced $n/\sqrt{r}$ with n/r since we may do exact splitting in the present context. In (4), it can be verified that $\pi_d \geq 1 - 2/r$ if $\pi_{d-1} \geq 1 - \frac{1}{2r^2}$. Applying this inductively, we find that $\pi_1 \geq 1 - \frac{1}{2^{d-1}r^{2^{d-1}}}$ implies $\pi_d \geq 1 - 2/r$. This implies a $2/r$ cutting in $\mathbb{R}^d$. For any m, a $1/m$-cutting of $\mathbb{R}^1$ has size $(m - 1)$ (by choosing $(m - 1)$ equally spaced values). Thus the overall cutting contains $2^{d-1}r^{2^{d-1}}$ hyperplanes. This is exponentially larger than the cuttings of size $O(r^d)$ obtained from ε-net constructions. However, for small constants r and d, this may be a reasonable alternative to the derandomized schemes for constructing $1/r$-cuttings. We may summarize the discussion of this section as follows.

Observation 6.1. Megiddo's algorithm implies a simple linear-time method (without derandomization) for constructing $1/r$-cuttings of size $(2^{d-1}r^{2^{d-1}})^d$ in $\mathbb{R}^d$, where d is a fixed constant.

7. Concluding remarks. This paper makes two main contributions to parallel fixed-dimensional linear programming. First, we show that an alternative implementation of Megiddo's [32] technique enables efficient processor utilization. Second, we

circumvent the bottleneck of median-finding, found in earlier adaptations of Megiddo's approach, by substituting approximate selection algorithms. (Note that even randomized selection has the same bottleneck.) However, the underlying approximate algorithms have large associated constants, and the algorithms of Goldberg and Zwick [22] use expanders. We can eliminate the need for expanders by settling for a somewhat slower algorithm (by a factor of $O(\log\log^3 n)$), using the method of Hagerup and Raman [24]. On the other hand, the running time of Theorem 5.5 can be improved somewhat by using the selection algorithm of [22]. Finally, we remark that reducing the dependence on d of the running time of our algorithm for LPd is a challenging open problem.

8. Appendix. We give a brief outline of the proof of Lemma 3.1. The ideas are adapted mainly from Hagerup and Raman [24], where the reader can find more detailed proofs. Throughout, we will use $\nu(r)$ to denote a factor of the form $1 + \frac{1}{\text{polylog}(r)}$.

Proof of Lemma 3.1. Hagerup and Raman [24] describe a method for computing r approximate splitters in $O(\log\log^5 n)$ CRCW time, using rn processors. Below we describe how to speed up their method by substituting faster routines for *approximate prefix computation* due to Goldberg and Zwick [22]. The problem *approximate prefix sum* is defined as follows.

A sequence $0 = b_0, b_1, \ldots, b_n$ is said to be an ϵ-approximate prefix sum of a given nonnegative sequence $a_1, \ldots, a_n$ if we have

$$\sum_{j=1}^{i} a_j \le b_i \le (1+\epsilon)\sum_{j=1}^{i} a_j$$

and $b_i - b_{i-1} \ge a_i$ $(1 \le i \le n)$. Lemma 3.3 is actually derived from the following result on approximate prefix sums.

LEMMA 8.1 (see [22]). *For any fixed $\alpha > 0$ and fixed $\delta > 0$, a $1/(\log^\alpha n)$-approximate prefix sum sequence can be computed in $O(1)$ CRCW time, using $n^{1+\delta}$ processors.*

Substituting the previous result in the proof of Lemma 11 of [24], we obtain the following.

LEMMA 8.2. *A set of n keys can be* padded-sorted *with* padding factor $\nu(n)$ *in $O(\log\log n)$ time, using a polynomial number of processors.*

To improve the processor bound in the previous lemma, we apply Lemma 8.1 recursively to a sample-sort algorithm. For this we compute a *group sample* as follows.

Let A be a set of n numbers, let m be an integer, and let $s = \frac{n}{m^2}$. Partition A into s groups $A_1, \ldots, A_s$, each of size m^2. Padded-sort the A_i's into subarrays of size $\nu(n)m^2$, and let B_i be the multiset consisting of the elements with rank $\nu m, 2\nu m \ldots \nu m^2$ in A_i. Then $B = \bigcup_i B_i$ is a group sample of A.

Remark. Computing a group sample of size n/m involves sorting sets of size $O(m^2)$. By choosing a group sample of appropriate size and using its members as splitters in a quicksort-like algorithm (but for only a constant depth of recursion), we obtain the following result, along the same lines as Hagerup and Raman [24].

LEMMA 8.3. *For any fixed $\epsilon > 0$, n keys can be padded-sorted in $O(\log\log n)$ CRCW time, with padding-factor $\nu(n)$, using $n^{1+\epsilon}$ processors.*

An (m, λ)-*sample* of a set A is a subset B such that, for each pair of elements

$x, y \in B$,

$$|\text{rank}_A(x) - \text{rank}_A(y)| \leq \frac{m|A|}{|B|}|\text{rank}_B(x) - \text{rank}_B(y)| + \lambda|A|.$$

By choosing a group sample $B \subseteq A$, using the procedure described previously, we can show the following.

LEMMA 8.4. *B is a $(\nu(m), \nu(m)/m)$-sample of A, computable in $O(\log\log n)$ CRCW time, using mn processors. Moreover, $|B| = n/m$.*

The proof follows by summing $(|rank_{B_i}(x) - rank_{B_i}(y)| + 1)$ over all B_i. From the definition of an (m, λ) sample, the following can easily be verified.

LEMMA 8.5 (see [24]). *Let B be an (r, λ)-sample of A, and let C be an (r', λ') sample of B. Then C is an $(rr', r\lambda' + \lambda)$ sample of A.*

We now describe the algorithm for finding r approximate splitters of a set X of n numbers. We may assume we have nr processors initially. Thus, using Lemma 8.4, we compute a subset $B_1 \subset X$, which is a $(\nu(m), \nu(m)/m)$-sample, where $m = r$. Note that $|B_1| = n/r$, so we now have a processor advantage of r^2. Next we compute B_2, which is a $(\nu(r^2), \nu(r^2)/r^2)$-sample of B_1. At stage i, we will compute a $(\nu(r^{2^i}), \nu(r^{2^i})/r^{2^i})$-sample of B_i. By induction, we can show that $|B_i| = n/r^{2^i-1}$. Now, from Lemma 8.5, we can show that B_i is a $(\prod_i \nu(r^{2^i}), \prod_i \nu(r^{2^i})/r)$-sample of X. We continue this process until $B_j \leq n^{3/4}$ for the first time, and we call this subset D. Clearly, $j < \log\log n$ and from $r \leq n^{1/4}$ it follows that $n^{1/4} \leq |D| \leq n^{3/4}$. Thus we can ensure that D is a $(\prod_i \nu(r^{2^i}), \prod_i \nu(r^{2^i})/r)$-sample of X. Since $(1+x) \leq e^x$, it follows that $\prod_i \left(1 + \frac{1}{2^i}\right) = O(1)$. So D is a $(c', c'/r)$ sample of X for some constant c'. Suppose $|D| = q$, then choose r equally spaced elements from D, and call this set S. We claim that S is a set of r elements which approximately splits X with expansion factor $\sqrt{r}$. To see this, note that between two consecutive elements of S there are q/r elements of D. Since D is a $(c', c'/r)$ sample of X, it follows (from the definition of an (m, λ)-sample) that there are a maximum of $c'(n/q)(q/r) + c'(1/r)n$ elements of X. Substituting $c'' = c'^2$, the number of elements can be bounded by $O(\sqrt{c''}n/r)$. For $r \geq c''$, this is less than $\frac{n}{\sqrt{r}}$. This completes the proof of Lemma 3.1. Note that $C = c''$ in the statement of Lemma 3.1.

Remark. The running time of the above algorithm for finding approximate splitters can be improved to $O(\log\log n)$ time by noting that only the first group sampling step takes $O(\log\log n)$ and $O(1)$ thereafter by exploiting processor advantage carefully. This was pointed out by one of the reviewers.

Acknowledgments. The second author wishes to thank Rajeev Raman for very helpful discussions regarding formulating the present version of Lemma 3.1 and Pankaj Aggarwal for bringing [19] to his attention. The authors also acknowledge several helpful comments of the anonymous reviewers that helped improve the presentation. In particular, one of the reviewers pointed out that a simple modification in the approximate splitting algorithm (described in the appendix) can improve the running time by a factor of $O(\log\log n)$.

ON THE RELATIVE COMPLEXITY OF RESOLUTION REFINEMENTS AND CUTTING PLANES PROOF SYSTEMS*

MARIA LUISA BONET†, JUAN LUIS ESTEBAN†, NICOLA GALESI†, AND JAN JOHANNSEN‡

Abstract. An exponential lower bound for the size of tree-like cutting planes refutations of a certain family of conjunctive normal form (CNF) formulas with polynomial size resolution refutations is proved. This implies an exponential separation between the tree-like versions and the dag-like versions of resolution and cutting planes. In both cases only superpolynomial separations were known [A. Urquhart, *Bull. Symbolic Logic,* 1 (1995), pp. 425–467; J. Johannsen, *Inform. Process. Lett.*, 67 (1998), pp. 37–41; P. Clote and A. Setzer, in *Proof Complexity and Feasible Arithmetics,* Amer. Math. Soc., Providence, RI, 1998, pp. 93–117]. In order to prove these separations, the lower bounds on the depth of monotone circuits of Raz and McKenzie in [*Combinatorica,* 19 (1999), pp. 403–435] are extended to monotone real circuits.

An exponential separation is also proved between tree-like resolution and several refinements of resolution: negative resolution and regular resolution. Actually, this last separation also provides a separation between tree-like resolution and ordered resolution, and thus the corresponding superpolynomial separation of [A. Urquhart, *Bull. Symbolic Logic,* 1 (1995), pp. 425–467] is extended.

Finally, an exponential separation between ordered resolution and unrestricted resolution (also negative resolution) is proved. Only a superpolynomial separation between ordered and unrestricted resolution was previously known [A. Goerdt, *Ann. Math. Artificial Intelligence,* 6 (1992), pp. 169–184].

1. Introduction.

The motivation for research on the proof length of propositional proof systems is double. First, by the work of Cook and Reckhow [10] we know that the claim that *for every propositional proof system there is a class of tautologies that have no polynomial size proofs* is equivalent to $NP \neq co\text{-}NP$. This connection explains the interest in developing combinatorial techniques to prove lower bounds for proof systems. The second motivation comes from the interest in studying efficiency issues in automated theorem proving. The question is which proof systems have efficient algorithms to find proofs. Actually, the proof system most widely used for implementations is resolution or refinements of resolution. Our work is relevant to both motivations. On one hand, all the separation results of this paper improve previously known superpolynomial separations to exponential. On the other hand,

these exponential separations harden the known results showing inefficiency of several widely used strategies for finding proofs, especially for the resolution system.

Haken [16] was the first to prove exponential lower bounds for unrestricted resolution. He showed that the pigeonhole principle requires exponential size resolution refutations. Urquhart [28] found another class of tautologies with the same property. Chvátal and Szemerédi [7] showed that in some sense, almost all classes of tautologies require exponential size resolution proofs (see [2, 3] for simplified proofs of these results). These exponential lower bounds are bad news for automated theorem proving, since they mean that often the time used in finding proofs will be exponentially long in the size of the tautology, just because the shortest proofs are exponentially long in the size of the tautology.

Many strategies for finding resolution proofs are described in the literature (see, e.g., Schöning's textbook [27]). One commonly used type of strategy is to reduce the search space by defining restricted versions of resolution that are still complete. Such restricted forms are commonly referred to as *resolution refinements*. One particularly important resolution refinement is tree-like resolution. Its importance stems from the close relationship between the complexity of tree-like resolution proofs and the runtime of a certain class of satisfiability testing algorithms, the so-called *DLL Algorithms* (cf. [24, 1]). We prove an exponential separation between tree-like resolution and unrestricted resolution (Corollary 4.3), thus showing that finding tree-like resolution proofs is not an efficient strategy for finding resolution proofs. Until now only superpolynomial separations were known [29, 8].

We also consider three more of the most commonly used resolution refinements: negative resolution, regular resolution, and ordered resolution. We show an exponential separation between tree-like resolution and each one of the above restrictions. (See Corollary 4.3 for negative resolution and Corollary 4.6 for both regular and ordered resolution.)

Goerdt [14, 13, 15] gave several superpolynomial separations between unrestricted resolution and some refinements of resolution; in particular, he gave a superpolynomial separation between ordered resolution and unrestricted resolution. In this paper we consider the case of ordered resolution and we improve his separation to exponential. We prove that a certain conjunctive normal form (CNF) formula requires exponential size ordered resolution refutations but can be refuted with a polynomial size negative resolution proof (Corollary 5.7), thus, in particular, showing that unrestricted resolution can have an exponential speed-up over ordered resolution.

The cutting planes proof system, CP from now on, is a refutation system based on manipulating integer linear inequalities. Exponential lower bounds for the size of CP refutations have already been proven. Impagliazzo, Pitassi, and Urquhart [17] proved exponential lower bounds for tree-like CP. Bonet, Pitassi, and Raz [6] proved a lower bound for the subsystem CP*, where the coefficients appearing in the inequalities are polynomially bounded in the size of the formula being refuted. This is a very important result because all known CP refutations fulfill this property. Finally, Pudlák [23] and Cook and Haken [9] gave general circuit complexity results from which exponential lower bounds for CP follow. To this day it is still unknown whether CP is more powerful than CP*, i.e., whether it produces shorter proofs or not.

Since there is an exponential speed-up of CP over resolution, it would be nice to find an efficient algorithm for finding CP proofs and a question to ask is whether trying to find tree-like CP proofs would be an efficient strategy for finding CP proofs.

Johannsen [18] gave a superpolynomial separation, with a lower bound of the form $\Omega(n^{\log n})$, between tree-like CP and dag-like CP. (This was previously known for CP* from [6].) Here we improve that separation to exponential (Corollary 4.3). This shows that searching for tree-like proofs is also not a good strategy for finding proofs in CP.

The separation between tree-like and dag-like versions of resolution and CP is obtained using the technique of the interpolation method introduced by Krajíček [21]. Closely related ideas appeared previously in the mentioned works that gave lower bounds for fragments of CP [17, 6]. The interpolation method applied on CP translates proofs of certain formulas to monotone real circuits (a generalization of boolean circuits). The translation has two important features. First, it preserves the size; that is, the size of the circuit is similar to the size of the proof from which the circuit is built. Second, if the proof is tree-like, the circuit will be also tree-like, i.e., a formula. So we can prove size lower bounds for tree-like CP proofs by proving size lower bounds for monotone real formulas.

In section 3 we prove that a certain boolean function $\textsc{Gen}_n$ requires exponential size monotone real formulas. This is a consequence of extending the result of Raz and McKenzie [25], proving linear depth lower bounds for monotone boolean circuits to the case of monotone real circuits. We use these circuit complexity lower bounds to obtain proof complexity lower bounds using the interpolation method.

2. Preliminaries and outline of the paper. In this section we introduce the notions we use and our main results. We also discuss the structure of the paper and the dependency among our main results.

2.1. Proof systems. We start by giving a short description of the proof systems studied in this paper. Most proof systems can be used in a tree-like or dag-like fashion. In a tree-like proof any line in the proof can be used only once as a premise. Should the same line be used twice, it must be rederived. A proof system that only produces tree-like proofs is called *tree-like*. Otherwise we will call it *dag-like,* or when nothing is said it is understood that the system is dag-like.

2.1.1. Resolution. Resolution is a refutation proof system for CNF formulas, which are represented as sets of *clauses*, i.e., disjunctions of literals. Clauses that contain the same literals are considered equal. The only inference rule is the resolution rule

$$\frac{C \vee x \qquad D \vee \bar{x}}{C \vee D}\,.$$

That is, from clauses $C \vee x$ and $D \vee \bar{x}$ we get clause $C \vee D$, called the *resolvent*. We say that the variable x is *eliminated* in this resolution step. A resolution refutation of a set Σ of clauses is a derivation of the empty clause from Σ using the resolution rule. Resolution is a sound and complete refutation system, i.e., a set of clauses has a resolution refutation if and only if it is unsatisfiable.

Several refinements of the resolution proof system have been proposed. These refinements reduce the search space by restricting the choice of pairs of clauses to which the resolution rule can be applied. In this paper we consider the following three refinements, all of which are still complete.

1. The *regular* resolution system: Viewing the refutations as graph, in any path from the empty clause to any initial clause, no variable is eliminated twice.

2. The *ordered*[1] resolution system: There exists an ordering of the variables in the formula being refuted, such that if a variable x is eliminated before a variable y on any path from an initial clause to the empty clause, then x is before y in the ordering. As no variable is eliminated twice on any path, ordered resolution is a restriction of regular resolution.
3. The *negative* resolution system: To apply the resolution rule, one of the two clauses must consist of negative literals only.

There is an algorithm (see, e.g., Urquhart [29]) that transforms a tree-like resolution proof into a possibly smaller regular tree-like resolution proof; therefore, tree-like resolution proofs of minimal size are regular. This means that from the point of view of proof complexity, tree-like resolution and tree-like regular resolution are equivalent.

2.1.2. Cutting planes. The CP proof system is a refutation system for CNF formulas, as resolution is. It works with linear inequalities. The initial clauses are transformed into linear inequalities. A generic clause

$$\bigvee_{i=1}^{k} p_{j_i} \vee \bigvee_{i=1}^{m} \neg p_{l_i}$$

is transformed into a linear inequality

$$\sum_{i=1}^{k} p_{j_i} + \sum_{i=1}^{m} (1 - p_{l_i}) \geq 1.$$

The CP rules are basic algebraic manipulations, additions of two inequalities, multiplication of an inequality by a positive integer, and the following division rule:

$$\frac{\sum_{i \in I} a_i x_i \geq k}{\sum_{i \in I} \frac{a_i}{b} x_i \geq \left\lceil \frac{k}{b} \right\rceil},$$

where b is a positive integer that evenly divides all a_i, $i \in I$. A CP refutation of a set E of inequalities is a derivation of $0 \geq 1$ from the inequalities in E and the axioms $x \geq 0$ and $-x \geq -1$ for every variable x, using the CP rules. It can be shown that a set of inequalities has a CP refutation iff it has no $\{0,1\}$-solution. Any assignment satisfying the original clauses is actually a $\{0,1\}$-solution of the corresponding inequalities, provided that we assign the numerical value 1 to True and the value 0 to False. It is easy to translate (see [11]) resolution refutations into CP refutations similar in size to the original resolution refutations. Moreover, if the resolution refutation is tree-like, the resulting CP refutation is also tree-like.

2.2. Monotone real circuits. An important part of this paper is concerned with monotone real circuits, which were introduced by Pudlák [23]. A *monotone real circuit* is a circuit of fan-in 2 computing with real numbers where every gate computes a nondecreasing real function. We require that monotone real circuits output 0 or 1 on every input of 0's and 1's only, so that they are a generalization of monotone boolean circuits. The depth and size of a monotone real circuit are defined as for boolean circuits. A *formula* is a circuit in which every gate has at most fan-out 1, i.e., a tree-like circuit.

[1] In Goerdt's paper [13] and in the preliminary version [5] of this paper, this refinement is called the *Davis–Putnam resolution*. In the meantime, we have learned that it is better known as the *ordered* resolution.

Pudlák [23], Cook and Haken [9], and Fu [12] gave lower bounds on the size of monotone real circuits. Rosenbloom [26] showed that they are strictly more powerful than monotone boolean circuits, since every slice function can be computed by a linear-size, logarithmic-depth monotone real circuit, whereas most slice functions require exponential size general boolean circuits. On the other hand, Jukna [19] gives a general lower bound criterion for monotone real circuits, and uses it to show that certain functions in $P/poly$ require exponential size monotone real circuits, and hence the computing power of monotone real circuits and general boolean circuits is incomparable.

For a monotone boolean function f, we denote by $d_{\mathbb{R}}(f)$ the minimal depth of a monotone real circuit computing f, and by $s_{\mathbb{R}}(f)$ the minimal size of a monotone real formula computing f.

2.3. Deterministic and real communication complexity. The use of communication complexity as a tool to prove depth lower bounds for monotone circuits was introduced by Karchmer and Wigderson [20]. They gave an $\Omega(\log^2 n)$ lower bound on the depth of monotone circuits computing st-connectivity.

Krajíček [22] introduced a notion of *real communication complexity*, generalizing ordinary communication complexity, that is suitable to prove depth lower bounds for monotone real circuits. This was used by Johannsen [18] to extend the depth lower bound for st-connectivity to monotone real circuits.

Raz and McKenzie [25] proved an $\Omega(n^\epsilon)$ lower bound on the depth of monotone circuits computing a certain function $\textsc{Gen}_n$, which, on the other hand, can be computed by monotone circuits of polynomial size. This gives a strong separation of the depth and size complexity of monotone circuits. We extend this lower bound to monotone real circuits, again using the notion of real communication complexity.

2.3.1. Communication complexity. Let $R \subseteq X \times Y \times Z$ be a multifunction, i.e., for every pair $(x, y) \in X \times Y$, there is a $z \in Z$ with $(x, y, z) \in R$. We view such a multifunction as a search problem, i.e., given input $(x, y) \in X \times Y$, the goal is to find a $z \in Z$ such that $(x, y, z) \in R$.

A deterministic communication protocol P over $X \times Y \times Z$ specifies the exchange of information bits between two players, I and II, that receive as inputs, respectively, $x \in X$ and $y \in Y$ and finally agree on a value $P(x, y) \in Z$ such that $(x, y, P(x, y)) \in R$. The *deterministic communication complexity* of R, $CC(R)$, is the number of bits communicated between players I and II in an optimal protocol for R.

2.3.2. Real communication complexity. A real communication protocol over $X \times Y \times Z$ is executed by two players I and II who exchange information by simultaneously playing real numbers and then comparing them according to the natural order of $\mathbb{R}$. This generalizes ordinary deterministic communication protocols in the following way: in order to communicate a bit, the sender plays this bit, while the receiver plays a constant between 0 and 1, so that he can determine the value of the bit from the outcome of the comparison.

Formally, such a protocol P is specified by a binary tree, where each internal node v is labeled by two functions $f_v^I : X \to \mathbb{R}$, giving player I's move, and $f_v^{II} : Y \to \mathbb{R}$, giving player II's move, and each leaf is labeled by an element $z \in Z$. On input $(x, y) \in X \times Y$, the players construct a path through the tree according to the following rule:

> At node v, if $f_v^I(x) > f_v^{II}(y)$, then the next node is the left son of v and otherwise the right son of v.

The value $P(x,y)$ computed by P on input (x,y) is the label of the leaf reached by this path.

A real communication protocol P solves a search problem $R \subseteq X \times Y \times Z$ if for every $(x,y) \in X \times Y$, $(x,y,P(x,y)) \in R$ holds. The *real communication complexity* $CC_{\mathbb{R}}(R)$ of a search problem R is the minimal depth of a real communication protocol that solves R.

For a natural number n, let $[n]$ denote the set $\{1,\dots,n\}$. Let $f : \{0,1\}^n \to \{0,1\}$ be a monotone boolean function, let $X := f^{-1}(1)$ and $Y := f^{-1}(0)$, and let the multifunction $R_f \subseteq X \times Y \times [n]$ be defined by

$$(x,y,i) \in R_f \quad \text{iff} \quad x_i = 1 \text{ and } y_i = 0.$$

The Karchmer–Wigderson game for f is defined as follows. Player I receives an input $x \in X$ and player II an input $y \in Y$. They have to agree on a position $i \in [n]$ such that $(x,y,i) \in R_f$. The Karchmer–Wigderson game for a monotone boolean function f is also denoted by R_f. As happens with monotone boolean functions and communication complexity, there is a relation between the real communication complexity of R_f and the depth of monotone real circuits (and the size of a monotone real formulas) computing f.

LEMMA 2.1 (see Krajíček [22]). *Let f be a monotone boolean function. Then*

1. $CC_{\mathbb{R}}(R_f) \le d_{\mathbb{R}}(f)$;
2. $CC_{\mathbb{R}}(R_f) \le \log_{3/2} s_{\mathbb{R}}(f)$.

For a proof see [22] or [18]. Notice that by Lemma 2.1 a linear lower bound for the real communication complexity of R_f gives an exponential lower bound for the size of the smallest monotone real formula computing f.

2.4. DART games and structured protocols. Raz and McKenzie [25] introduced a special kind of communication games, called DART games, and a special class of communication protocols, the *structured protocols*, for solving them.

For $m,k \in \mathbb{N}$, $\mathrm{DART}(m,k)$ is the set of communication games specified by a relation $R \subseteq X \times Y \times Z$ such that the following hold.

- $X = [m]^k$; i.e., the inputs for player I are k-tuples of elements $x_i \in [m]$.
- $Y = (\{0,1\}^m)^k$; i.e., the inputs for player II are k-tuples of binary colorings y_i of $[m]$.
- For all $i = 1,\dots,k$ let $e_i = y_i(x_i) \in \{0,1\}$ (i.e., the x_i-th bit in the m-bits string y_i). The relation $R \subseteq X \times Y \times Z$ defining the game only depends on $e_1,\dots,e_k$ and z, i.e., we can describe $R(x,y,z)$ as $R((e_1,\dots,e_k),z)$.
- $R((e_1,\dots,e_k),z)$ can be expressed as a disjunctive normal form (DNF)-search-problem, i.e., there exists a DNF-tautology F_R defined over the variables $e_1,\dots,e_k$ such that Z is the set of terms of F_R, and $R((e_1,\dots,e_k),z)$ holds iff the term z is satisfied by the assignment $(e_1,\dots,e_k)$.

A *structured protocol* for a DART game is a communication protocol for solving the search problem R, where player I gets input $x \in X$, player II gets input $y \in Y$, and in each round, player I reveals the value x_i for some i, and II replies with $y_i(x_i)$. The structured communication complexity of $R \in \mathrm{DART}(m,k)$, denoted by $SC(R)$, is the minimal number of rounds in a structured protocol solving R. In [25] it was proved that $CC(R) = SC(R) \cdot \Omega(\log m)$ for $R \in \mathrm{DART}(m,k)$. We generalize this result to real communication complexity, proving

$$CC_{\mathbb{R}}(R) = SC(R) \cdot \Omega(\log m).$$

Observe that at each structured round the two players transmit $\lceil \log m \rceil + 1$ bits. The first player transmits a number in $[m]$ and the second answers with a bit. Since both players know the structure of the protocol for the game, at each round they both know the coordinate i of the inputs they are talking about and they have no need to transmit it. So for a DART game R we have $CC_{\mathbb{R}}(R) \leq SC(R) \cdot \Omega(\log m)$.

Proving the opposite inequality, which is one of our main results, is much harder. In Theorem 3.4 we show that for every relation $R \in \text{DART}(m,k)$, where $m \geq k^{14}$, $CC_{\mathbb{R}}(R) \geq SC(R) \cdot \Omega(\log m)$.

2.5. The interpolation method. The separations between tree-like CP (respectively, tree-like resolution) and CP (resolution) are among our main results about proof complexity. The lower bound part of the separation is obtained employing the following theorem which relates the size of CP refutations with size of monotone real circuits.

THEOREM 2.2 (see Pudlák [23]). *Let $\vec{p}, \vec{q}, \vec{r}$ be disjoint vectors of variables, and let $A(\vec{p}, \vec{q})$ and $B(\vec{p}, \vec{r})$ be sets of inequalities in the indicated variables such that the variables $\vec{p}$ either have only nonnegative coefficients in $A(\vec{p}, \vec{q})$ or have only nonpositive coefficients in $B(\vec{p}, \vec{r})$.*

Suppose there is a CP refutation P of $A(\vec{p}, \vec{q}) \cup B(\vec{p}, \vec{r})$. Then there is a monotone real circuit $C(\vec{p})$ of size $O(|P|)$ such that for any vector $\vec{a} \in \{0,1\}^{|\vec{p}|}$

$$\begin{aligned} C(\vec{a}) = 0 \quad &\rightarrow \quad A(\vec{a}, \vec{q}) \text{ is unsatisfiable,} \\ C(\vec{a}) = 1 \quad &\rightarrow \quad B(\vec{a}, \vec{r}) \text{ is unsatisfiable.} \end{aligned}$$

Furthermore, if P is tree-like, then $C(\vec{p})$ is a monotone real formula.

The fact that the interpolant $C(\vec{p})$ is a monotone real formula if the refutation is tree-like is not stated explicitly in [23], but it can be checked easily by analyzing the original proof of Theorem 2.2 in [23].

We use this theorem to get lower bounds for CP refutations from lower bounds for monotone real formulas. Recall that a *minterm* (respectively, a *maxterm*) of a boolean function $f : \{0,1\}^n \to \{0,1\}$ is a set of inputs $x \in \{0,1\}^n$ such that $f(x) = 1$ (respectively, $f(x) = 0$) and for each $y \in \{0,1\}^n$ obtained from x by changing a bit from 1 to 0 (respectively, by changing a bit from 0 to 1) it holds that $f(y) = 0$ (respectively, $f(y) = 1$).

For a certain boolean function f we will apply Theorem 2.2 to a CNF formula $A(\vec{p}, \vec{q}) \cup B(\vec{p}, \vec{r})$ such that $A(\vec{p}, \vec{q})$ will encode that $\vec{p}$ is a minterm of f and $B(\vec{p}, \vec{r})$ will encode that $\vec{p}$ is maxterm of f. Clearly the formula is unsatisfiable. Using the interpolation theorem, from any tree-like CP refutation of $A(\vec{p}, \vec{q}) \cup B(\vec{p}, \vec{r})$ we will get an interpolant which is a monotone real formula computing f. Therefore if we prove exponential lower bounds for the size of the tree-like monotone real circuits computing f, we immediately obtain an exponential lower bound for tree-like CP refutations for $A(\vec{p}, \vec{q}) \cup B(\vec{p}, \vec{r})$. The same result also holds for tree-like resolution.

To get the separation results we need a monotone boolean function with some nice properties, namely,

1. exponential lower bounds for monotone real formulas computing the function, and
2. the corresponding $A(\vec{p}, \vec{q}) \cup B(\vec{p}, \vec{r})$ formula must have polynomial-size resolution (and, therefore, also CP) refutations.

The chosen monotone boolean function f is the function $\text{GEN}_n : \{0,1\}^{n^3} \to \{0,1\}$ considered by Raz and McKenzie [25]. The input bits are called $t_{a,b,c}$ for $a, b, c \in [n]$.

The function is defined as follows: $\text{GEN}_n(t_{111}\cdots t_{nnn}) = 1$ iff $\vdash n$, where for $c \in [n]$, $\vdash c$ (meaning c *is generated*) is defined recursively by

$$\vdash c \quad \text{iff} \quad c = 1 \text{ or there are } a, b \le n \text{ with } \vdash a\ , \vdash b, \text{ and } t_{a,b,c} = 1\ .$$

From now on we will write $a, b \vdash c$ for $t_{a,b,c} = 1$.

To get the exponential separation the task to be done is as follows.

1. Prove exponential lower bounds for the size of monotone real formulas computing GEN_n.
2. Find CNF formulas $A(\vec{p}, \vec{q})$ and $B(\vec{p}, \vec{r})$ expressing, respectively, a minterm and a maxterm of GEN_n.
3. Show polynomial size resolution (and CP) refutations for $A(\vec{p}, \vec{q}) \cup B(\vec{p}, \vec{r})$.

In section 3 we will show, among other things, that $CC_{\mathbb{R}}(R_{\text{GEN}_n}) \ge \Omega(n^\epsilon)$ for some $\epsilon > 0$. From this, it follows by part 2 of Lemma 2.1 that $s_{\mathbb{R}}(\text{GEN}_n) \ge 2^{\Omega(n^\epsilon)}$; thus task 1 is achieved. Tasks 2 and 3 will be developed in section 4.

3. Lower bounds for real communication complexity. In this section we prove an $\Omega(n^\epsilon)$ lower bound for the real communication complexity of the Karchmer–Wigderson game associated to GEN_n, denoted by R_{GEN_n}.

THEOREM 3.1. *For some $\epsilon > 0$ and sufficiently large n*

$$CC_{\mathbb{R}}(R_{\text{GEN}_n}) \ge \Omega(n^\epsilon).$$

To prove Theorem 3.1 we define a DART game $\text{PYRGEN}(m, d)$ in section 3.1 related to the GEN_n function. This game is used with parameters $m = d^{28}$ and $n = \binom{d+1}{2}m + 2$, so that $d \approx n^{1/30}$. Then we will prove the following results from which Theorem 3.1 directly follows:

$$\begin{aligned} SC(\text{PYRGEN}(m,d)) &\ge d && \text{(Lemma 3.2)},\\ CC_{\mathbb{R}}(\text{PYRGEN}(m,d)) &\ge SC(\text{PYRGEN}(m,d))\,\Omega(\log m) && \text{(Theorem 3.4)},\\ CC_{\mathbb{R}}(R_{\text{GEN}_n}) &\ge CC_{\mathbb{R}}(\text{PYRGEN}(m,d)) && \text{(Lemma 3.3)}. \end{aligned}$$

Lemma 3.2 is proved in [25]; therefore, we omit its proof. Theorem 3.4 is proved in section 3.2 for any DART game R. Lemma 3.3 is proved in section 3.1. In section 3.3 we deduce some lower bounds for monotone real circuits from these results.

3.1. The pyramidal generation game. For $d \in \mathbb{N}$, let

$$Pyr_d := \{\, (i,j)\ :\ 1 \le j \le i \le d \,\}\,.$$

Following [25], a communication game in $DART(m, \binom{d+1}{2})$ called $\text{PYRGEN}(m, d)$ is defined as follows. We regard the indices as elements of Pyr_d, so that the inputs for the two players I and II in the $\text{PYRGEN}(m, d)$ game are, respectively, sequences of elements $x_{i,j} \in [m]$ and $y_{i,j} \in \{0,1\}^m$ with $(i,j) \in Pyr_d$, and we picture these as laid out in a pyramidal form with $(1,1)$ at the top and (d,j), $1 \le j \le d$, at the bottom. The goal of the game is to find either an element colored 0 at the top of the pyramid, or an element colored 1 at the bottom of the pyramid, or an element colored 1 with the two elements below it colored 0. That is, we have to find indices (i,j) such that one of the following holds:

1. $i = j = 1$ and $y_{1,1}(x_{1,1}) = 0$, or
2. $y_{i,j}(x_{i,j}) = 1$ and $y_{i+1,j}(x_{i+1,j}) = 0$ and $y_{i+1,j+1}(x_{i+1,j+1}) = 0$, or
3. $i = d$ and $y_{d,j}(x_{d,j}) = 1$.

Observe that, setting $e_{i,j} = y_{i,j}(x_{i,j})$ for $1 \leq j \leq i \leq d$, this search problem can be defined as a DNF-search-problem given by the following DNF-tautology:

$$\bar{e}_{1,1} \vee \bigvee_{1 \leq j \leq i \leq d-1} (e_{i,j} \wedge \bar{e}_{i+1,j} \wedge \bar{e}_{i+1,j+1}) \vee \bigvee_{1 \leq j \leq d} e_{d,j}.$$

Therefore, PyrGen(m,d) is a game in DART$(m, \binom{d+1}{2})$.

A lower bound on the structured communication complexity of PyrGen(m,d) was proved in [25].

Lemma 3.2 (see Raz and McKenzie [25]). *$SC($PyrGen$(m,d)) \geq d$.*

The following reduction shows that the real communication complexity of the game PyrGen(m,d) is bounded by the real communication complexity of the Karchmer–Wigderson game for Gen$_n$ (denoted by R_{Gen_n}) for a suitable n. The proof is taken from [25]. It is included because it can help the reader to understand other parts of this paper.

Lemma 3.3. *Let $d, m \in \mathbb{N}$ and let $n := m \cdot \binom{d+1}{2} + 2$. Then*

$$CC_{\mathbb{R}}(\text{PyrGen}(m,d)) \leq CC_{\mathbb{R}}(R_{\text{Gen}_n}).$$

Proof. We prove that any protocol solving the Karchmer–Wigderson game for Gen$_n$ can be used to solve the PyrGen(m,d) game. Recall that PyrGen(m,d) is a DART$(m, \binom{d+1}{2})$ game, so the two players I and II receive inputs, respectively, of the form $(x_{1,1}, \dots, x_{d,d})$, where $x_{i,j} \in [m]$ for all $(i,j) \in Pyr_d$ and $(y_{1,1}, \dots, y_{d,d})$, where $y_{i,j} \in \{0,1\}^m$ for all $(i,j) \in Pyr_d$.

From their respective inputs for the PyrGen(m,d) game, players I and II compute, respectively, a minterm $t^x_{a,b,c}$ and a maxterm $t^y_{a,b,c}$, for Gen$_n$, and then they play the Karchmer–Wigderson game applying the protocol P.

As in [25] we consider fixed the element 1 as a bottom generator and the element n as the element we want to generate. We interpret the remaining $n-2 = \binom{d+1}{2}m$ elements between 2 and $n-1$ as triples (i,j,k), where $(i,j) \in Pyr_d$ and $k \in [m]$.

Now player I computes from his input $(x_{1,1}, \dots, x_{d,d})$ an input $t^x_{a,b,c}$ for Gen$_n$ such that Gen$_n(t^x_{a,b,c}) = 1$ by setting the following (recall that $a, b \vdash c$ means $t_{a,b,c} = 1$):

$$\begin{aligned} &1, 1 \vdash g_{d,j} && \text{for } 1 \leq j \leq d, \\ &g_{1,1}, g_{1,1} \vdash n, && \\ &g_{i+1,j}, g_{i+1,j+1} \vdash g_{i,j} && \text{for } (i,j) \in Pyr_{d-1}, \end{aligned}$$

where $g_{i,j} := (i,j,x_{i,j}) \in \{2, \dots, n-1\}$ and all the other bits $t^x_{a,b,c} = 0$. This completely determines $t^x_{a,b,c}$, and obviously Gen$_n(t^x_{a,b,c}) = 1$ since we have forced a generation of n (in a pyramidal form).

Likewise, player II computes from his input $(y_{1,1}, \dots, y_{d,d})$ a coloring col of the elements from $[n]$ by setting $col(1) = 0$, $col(n) = 1$, and $col((i,j,k)) = y_{i,j}(k)$ (the kth bit of $y_{(i,j)}$). From this coloring, he computes an input $t^y_{a,b,c}$ by setting $t^y_{a,b,c} = 1$ iff it is not the case that $col(c) = 1$ and $col(a) = col(b) = 0$. Obviously, Gen$_n(t^y_{a,b,c}) = 0$.

Running the protocol for the Karchmer–Wigderson game for Gen$_n$ now yields a triple (a,b,c) such that $t^x_{a,b,c} = 1$ and $t^y_{a,b,c} = 0$. By definition of t^y, this means that $col(a) = col(b) = 0$ and $col(c) = 1$, and by definition of t^x one of the following cases must hold.

- $a = b = 1$ and $c = g_{d,j}$ for some $j \leq d$. By definition of col, $y_{d,j}(x_{d,j}) = 1$.

- $c = n$ and $a = b = g_{1,1}$. In this case, $y_{1,1}(x_{1,1}) = 0$.
- $a = g_{i+1,j}$, $b = g_{i+1,j+1}$, and $c = g_{i,j}$. Then we have $y_{i,j}(x_{i,j}) = 1$, and $y_{i+1,j}(x_{i+1,j}) = y_{i+1,j+1}(x_{i+1,j+1}) = 0$.

In either case, the players have solved PyrGen(m, d) without any additional communication. □

3.2. Relation between structured complexity and real communication complexity. We prove here the following general theorem for DART games.

Theorem 3.4. *Let $m, k \in \mathbb{N}$. For every relation $R \in \mathrm{DART}(m, k)$, where $m \geq k^{14}$,*

$$CC_{\mathbb{R}}(R) \geq SC(R) \cdot \Omega(\log m) .$$

We first need some combinatorial notions from [25] and some lemmas. Let $A \subseteq [m]^k$ and $1 \leq j \leq k$. For $x \in [m]^{k-1}$, let $\deg_j(x, A)$ be the number of $\xi \in [m]$ such that $(x_1, \ldots, x_{j-1}, \xi, x_j, \ldots, x_{k-1}) \in A$. Then we define

$$\begin{aligned} A[j] &:= \left\{ x \in [m]^{k-1} \ : \ \deg_j(x, A) > 0 \right\}, \\ \mathrm{AVDEG}_j(A) &:= \frac{|A|}{|A[j]|}, \\ \mathrm{MINDEG}_j(A) &:= \min_{x \in A[j]} \deg_j(x, A), \\ \mathrm{Thickness}(A) &:= \min_{1 \leq j \leq k} \mathrm{MINDEG}_j(A) . \end{aligned}$$

The following lemmas about these notions were proved in [25].

Lemma 3.5 (see [25]). *For every $A' \subseteq A$ and $1 \leq j \leq k$,*

$$\mathrm{AVDEG}_j(A') \geq \frac{|\mathrm{A}'|}{|\mathrm{A}|} \mathrm{AVDEG}_j(A), \tag{3.1}$$

$$\mathrm{Thickness}(A[j]) \geq \mathrm{Thickness}(A). \tag{3.2}$$

Lemma 3.6 (see [25]). *Let $0 < \delta < 1$ be given. If for every $1 \leq j \leq k$, $\mathrm{AVDEG}_j(A) \geq \delta \mathrm{m}$, then for every $\alpha > 0$ there is $A' \subseteq A$ with $|A'| \geq (1 - \alpha)|A|$ and*

$$\mathrm{Thickness}(A') \geq \frac{\alpha \delta m}{k} .$$

In particular, setting $\alpha = \frac{1}{2}$ and $\delta = 4m^{-\frac{1}{14}}$, we get the following corollary.

Corollary 3.7. *If $m \geq k^{14}$ and for every $1 \leq j \leq k$, $\mathrm{AVDEG}_j(A) \geq 4\mathrm{m}^{\frac{13}{14}}$, then there is $A' \subseteq A$ with $|A'| \geq \frac{1}{2}|A|$ and $\mathrm{Thickness}(A) \geq m^{\frac{11}{14}}$.*

For a relation $R \in \mathrm{DART}(m, k)$, $A \subseteq X$ and $B \subseteq Y$, let $CC_{\mathbb{R}}(R, A, B)$ be the real communication complexity of R restricted to $A \times B$.

Definition 3.8 ((α, β, ℓ)-game). *Let $m \in \mathbb{N}$, $m \geq k^{14}$. Let $A \subseteq X$ and $B \subseteq Y$. A triple (R, A, B) is called an (α, β, ℓ)-game if the following conditions hold:*

1. *$R \in \mathrm{DART}(m, k)$,*
2. *$SC(R) \geq \ell$,*
3. *$|A| \geq 2^{-\alpha}|X|$ and $|B| \geq 2^{-\beta}|Y|$,*
4. *$\mathrm{Thickness}(A) \geq m^{\frac{11}{14}}$.*

The following lemma and its proof are slightly different from the corresponding lemma in [25], because we use the strong notion of real communication complexity

where [25] uses ordinary communication complexity. The modification we apply is analogous to that introduced by Johannsen [18] to improve the result of Karchmer and Wigderson [20] to the case of real communication complexity. This modification will affect the proof of the first point of the next lemma. We include a proof of the second part for completeness.

LEMMA 3.9. *For every $\alpha, \ell \geq 0$ and $0 \leq \beta \leq m^{\frac{1}{7}}$, $m \geq 1000^{14}$, and every (α, β, ℓ)-game (R, A, B),*

1. *if for every $1 \leq j \leq k$, $\mathrm{AVDEG}_j(A) \geq 8\mathrm{m}^{\frac{13}{14}}$, then there is an $(\alpha+2, \beta+1, \ell)$-game (R', A', B') with*

$$CC_{\mathbb{R}}(R', A', B') \leq CC_{\mathbb{R}}(R, A, B) - 1;$$

2. *if $\ell \geq 1$ and for some $1 \leq j \leq k$, $\mathrm{AVDEG}_j(A) < 8\mathrm{m}^{\frac{13}{14}}$, then there is an $(\alpha + 3 - \frac{\log m}{14}, \beta + 1, \ell - 1)$-game (R', A', B') with*

$$CC_{\mathbb{R}}(R', A', B') \leq CC_{\mathbb{R}}(R, A, B) \, .$$

Proof (proof of Lemma 3.9 (part 1)). Let (R, A, B) be an (α, β, ℓ)-game. First we show that $CC_{\mathbb{R}}(R, A, B) \neq 0$. Assume by contradiction that $CC_{\mathbb{R}}(R, A, B) = 0$. Then the players have no need to transmit information to solve R. This means that the answer to the game is implicit in the domain $A \times B$ and, therefore, by requirement (4) of DART games there is a term in the DNF-tautology F_R defining R that is satisfied for every $(x, y) \in A \times B$. Therefore, there is at least a coordinate j, $1 \leq j \leq k$, such that $y_j(x_j)$ is constant (i.e., is always 0 or always 1). If γ denotes the number of possible different values of x_j in elements of A, then this implies that $|B| \leq 2^{mk-\gamma}$. On the other hand, $|B| \geq 2^{mk-\beta}$, and hence it follows that $\beta \geq \gamma$, which is a contradiction since $\beta \leq m^{\frac{1}{7}}$, whereas $\mathrm{AVDEG}_j(A) \geq 8\mathrm{m}^{\frac{13}{14}}$ implies $\gamma \geq 8m^{\frac{13}{14}}$.

Let an optimal real communication protocol solving R restricted to $A \times B$ be given. For $a \in A$ and $b \in B$, let ρ_a and σ_b be the real numbers played by I and II in the first round on input a and b, respectively. Without loss of generality we can assume that these are $|A| + |B|$ pairwise distinct real numbers.

Now consider a $\{0,1\}$-matrix of size $|A| \times |B|$ with columns indexed by the ρ_a and rows indexed by the σ_b, both in increasing order, and where the entry in position (ρ_a, σ_b) is 1 if $\rho_a > \sigma_b$ and 0 if $\rho_a \leq \sigma_b$. Thus this entry determines the outcome of the first round, when these numbers are played. It is now obvious that either the upper right quadrant or the lower left quadrant must form a monochromatic rectangle.

Hence there are $A^\circ \subseteq A$ and $B' \subseteq B$ with $|A^\circ| \geq \frac{1}{2}|A|$ and $|B'| \geq \frac{1}{2}|B|$ such that R restricted to $A^\circ \times B'$ can be solved by a protocol with one round fewer than the original protocol. This means that $CC_{\mathbb{R}}(R, A^\circ, B') \leq CC_{\mathbb{R}}(R, A, B) - 1$. By (3.1) of Lemma 3.5, $\mathrm{AVDEG}_j(A^\circ) \geq 4\mathrm{m}^{\frac{13}{14}}$ for every $1 \leq j \leq k$; hence by Corollary 3.7 there is $A' \subseteq A^\circ$ with $|A'| \geq \frac{1}{2}|A^\circ| \geq \frac{1}{4}|A|$ and $\mathrm{Thickness}(A') \geq m^{\frac{11}{14}}$. Thus (R, A', B') is an $(\alpha + 2, \beta + 1, \ell)$-game; moreover, since $A' \subseteq A^\circ$, we have that $CC_R(R, A', B') \leq CC_R(R, A^\circ, B')$, from which the lemma follows.

(Part 2). We proceed like in the proof of the corresponding lemma of [25], with the numbers slightly adjusted. Assume without loss of generality that k is the coordinate for which $\mathrm{AVDEG}_k(A) < 8\mathrm{m}^{\frac{13}{14}}$. Let R_0 and R_1 be the restrictions of R in which the kth coordinate $e_k = y_k(x_k)$ is fixed to 0 and 1, respectively. Obviously, R_0 and R_1 are $\mathrm{DART}(m, k-1)$ relations, and therefore at least one of $SC(R_0)$ and $SC(R_1)$ is at least $\ell - 1$. Assume without loss of generality that $SC(R_0) \geq \ell - 1$. We will prove that there are two sets $A' \subseteq [m]^{k-1}$ and $B' \subseteq (\{0,1\}^m)^{k-1}$ such that the following

properties hold:

$$|A'| \geq \frac{m^{k-1}}{2^{\alpha+3-\frac{\log m}{14}}}, \tag{3.3}$$

$$|B'| \geq \frac{2^{m(k-1)}}{2^{\beta+1}}, \tag{3.4}$$

$$\text{Thickness}(A') \geq m^{\frac{11}{14}}, \tag{3.5}$$

$$CC_{\mathbb{R}}(R_0, A', B') \leq CC_{\mathbb{R}}(R, A, B). \tag{3.6}$$

This means that there is an $(\alpha + 3 - \frac{\log m}{14}, \beta + 1, \ell - 1)$-game (R_0, A', B') such that $CC_{\mathbb{R}}(R_0, A', B') \leq CC_{\mathbb{R}}(R, A, B)$ and this proves part 2 of Lemma 3.9.

Given any set $U \subset [m]$, consider the sets $A_U \subseteq [m]^{k-1}$ and $B_U \subseteq (\{0,1\}^m)^{k-1}$ associated to the set U by the following definition of [25]:

- $(x_1, \ldots x_{k-1}) \in A_U$ iff there is an $u \in U$ such that $(x_1, \ldots x_{k-1}, u) \in A$;
- $(y_1, \ldots y_{k-1}) \in B_U$ iff there is a $w \in \{0,1\}^m$ such that $w(u) = 0$ for all $u \in U$ and $(y_1, \ldots y_{k-1}, w) \in B$.

The following two claims can be proved exactly as the corresponding claims of [25] and we omit their proof.

CLAIM 3.10. *For a random set U of size $m^{\frac{5}{14}}$, with $m \geq 1000^{14}$, we have that*

$$Prob_U\big[A_U = A[k]\big] \geq \frac{3}{4}\,.$$

CLAIM 3.11. *For a random set U of size $m^{\frac{5}{14}}$, with $m \geq 1000^{14}$, we have that*

$$Prob_U\left[|B_U| \geq \frac{|B|}{2^{m+1}}\right] \geq \frac{3}{4}\,.$$

Moreover, it is immediate to see that the same reduction used in Claim 6.3 of [25] also works for the case of real communication complexity. Therefore, we get the following claim.

CLAIM 3.12. *For every set $U \subset [m]$,*

$$CC_{\mathbb{R}}(R_0, A_U, B_U) \leq CC_{\mathbb{R}}(R, A, B)\,.$$

Take a random set U which, with probability greater than $\frac{1}{2}$, satisfies both the properties of Claim 3.10 and Claim 3.11, and define $A' := A_U$ and $B' := B_U$. This means that with probability at least $\frac{1}{2}$ both $A' = A[k]$ and $|B'| \geq \frac{|B|}{2^{m+1}}$ hold.

Recall that $\frac{|A|}{|A'|} = \frac{|A|}{|A[k]|} = \text{AVDEG}_k(A)$ and that, by hypothesis on part 2 of the lemma $|\text{AVDEG}_k(A)| \leq 8\text{m}^{\frac{13}{14}}$. Therefore, we have that

$$|A'| \geq \frac{|A|}{8m^{\frac{13}{14}}} \geq \frac{m^k}{2^\alpha 8m^{\frac{13}{14}}} = \frac{m^{k-1}}{2^{\alpha+3-\frac{\log m}{14}}}\,.$$

This proves (3.3). For (3.4) observe that by Claim 3.11 we have

$$|B'| \geq \frac{|B|}{2^{m+1}} \geq \frac{2^{mk}}{2^\beta 2^{m+1}} = \frac{2^{m(k-1)}}{2^{\beta+1}}\,.$$

The property (3.5) follows directly from Lemma 3.5 (3.2), and finally (3.6) follows from Claim 3.12. □

3.2.1. Proof of Theorem 3.4.

Proof. Let $k \in \mathbb{N}$, $k \geq 1000$. We prove that for any $\alpha, \beta, \ell, m \geq 0$, with $\beta \leq m^{1/7}$, $\ell \geq 1$, and $m \geq k^{14}$, every (α, β, ℓ)-game (R, A, B) is such that

$$CC_{\mathbb{R}}(R, A, B) \geq \ell \cdot \left(\frac{\log m}{42} - \frac{4}{3}\right) - \frac{\alpha + \beta}{3} . \tag{3.7}$$

Observe that by the definition of an (α, β, ℓ)-game, when $\alpha = \beta = 0$ we have that $A = X$ and $B = Y$. Therefore, $CC_{\mathbb{R}}(R, A, B) = CC_{\mathbb{R}}(R)$. Moreover, the right side of (3.7) reduces to $\ell \cdot \Omega(\log m)$. Since by the same definition $\ell \leq SC(R)$ for $\alpha = \beta = 0$ we get the claim of the theorem:

$$CC_{\mathbb{R}}(R) \geq SC(R) \cdot \Omega(\log m).$$

To prove (3.7), we proceed by induction on $\ell \geq 1$ and $\beta \leq m^{1/7}$. In the base case $\ell < 1$ (that is, $\ell = 0$) and $\beta > m^{\frac{1}{7}}$, the inequality (3.7) is trivial, since the right-hand side gets negative for large m. In the inductive step consider (R, A, B) as an (α, β, ℓ)-game, and assume that (3.7) holds for all (α', β', ℓ')-games with $\ell' \leq \ell$ and $\beta' > \beta$. For the sake of contradiction, suppose that $CC_{\mathbb{R}}(R, A, B) < \ell \cdot (\frac{\log m}{42} - \frac{4}{3}) - \frac{\alpha+\beta}{3}$. Then either for every $1 \leq j \leq k$, $\mathrm{AVDEG}_j(A) \geq 8\mathrm{m}^{\frac{13}{14}}$, and Lemma 3.9 gives an $(\alpha + 2, \beta + 1, \ell)$-game (R', A', B') with

$$\begin{aligned} CC_{\mathbb{R}}(R', A', B') &\leq CC_{\mathbb{R}}(R, A, B) - 1 \\ &< \ell \cdot \left(\frac{\log m}{42} - \frac{4}{3}\right) - \frac{(\alpha + 2) + (\beta + 1)}{3} , \end{aligned}$$

or for some $1 \leq j \leq k$, $\mathrm{AVDEG}_j(A) < 8\mathrm{m}^{\frac{13}{14}}$, and Lemma 3.9 gives an $(\alpha + 3 - \frac{\log m}{14}, \beta + 1, \ell - 1)$-game (R', A', B') with

$$\begin{aligned} CC_{\mathbb{R}}(R', A', B') &< \ell \cdot \left(\frac{\log m}{42} - \frac{4}{3}\right) - \frac{\alpha + \beta}{3} \\ &= (\ell - 1) \cdot \left(\frac{\log m}{42} - \frac{4}{3}\right) - \frac{(\alpha + 3 - \frac{\log m}{14}) + (\beta + 1)}{3} , \end{aligned}$$

both contradicting the assumption. ∎

3.3. Consequences for monotone real circuits. As a first corollary to Theorem 3.4, we observe that for DART games, real communication protocols are no more powerful than deterministic communication protocols.

COROLLARY 3.13. *Let $m, k \in \mathbb{N}$. For $R \in \mathrm{DART}(m, k)$ with $m \geq k^{14}$,*

$$CC_{\mathbb{R}}(R) = \Theta(CC(R)) .$$

Proof. $CC(R) \geq CC_{\mathbb{R}}(R) \geq SC(R) \cdot \Omega(\log m) \geq \Omega(CC(R))$. ∎

From Theorem 3.1 we obtain consequences for monotone real circuits analogous to those obtained in [25] for monotone boolean circuits. An immediate consequence of Theorem 3.1 and Lemma 2.1 is the following theorem.

THEOREM 3.14. *Any tree-like monotone real circuit computing the boolean function GEN_n must have size $2^{\Omega(n^\epsilon)}$ for some $\epsilon > 0$.*

DEFINITION 3.15 (pyramidal generation). *Let $\vec{t}$ be an input to* GEN_n. *We say that n is generated in a depth d pyramidal fashion by $\vec{t}$ if there is a mapping $m : Pyr_d \to [n]$ such that the following hold (recall that $a, b \vdash c$ means $t_{a,b,c} = 1$):*

$$\begin{aligned} &1, 1 \vdash m(d, j) && \text{for every } j \le d, \\ &m(i+1, j), m(i+1, j+1) \vdash m(i, j) && \text{for every } (i, j) \in Pyr_{d-1}, \\ &m(1, 1), m(1, 1) \vdash n. \end{aligned}$$

We can obtain an analogue of Theorem 3.14 also for the simpler case in which the generation is restricted to be only in a pyramidal form.

COROLLARY 3.16. *Every monotone real formula that outputs* 1 *on every input to* GEN_n *for which n is generated in a depth d pyramidal fashion, and outputs* 0 *on all inputs where* GEN_n *is* 0, *has to be of size $\Omega(2^{n^\epsilon})$ for some $\epsilon > 0$.*

Proof. To simplify, let $Pyrgen_n$ be any monotone boolean function that outputs 1 on every input to GEN_n for which n is generated in a depth d pyramidal fashion, and outputs 0 on all inputs where GEN_n is 0. Note that there are many such functions, since the output is not specified in the case where n can be generated, but not in a depth d pyramidal fashion. Observe that in Lemma 3.3, player I builds from his input an input for GEN_n which enforces a depth d pyramidal generation. So the proof of Lemma 3.4 also shows that $CC_{\mathbb{R}}(\text{PYRGEN}(m, d)) \le CC_{\mathbb{R}}(R_{Pyrgen_n})$. Lemma 3.2 and Theorem 3.4 then imply that $CC_{\mathbb{R}}(R_{Pyrgen_n}) \ge \Omega(n^\epsilon)$ for some $\epsilon > 0$. Finally, Lemma 2.1 gives the statement of the corollary. ∎

The other consequences drawn from Theorem 3.4 and Lemma 3.2 in [25] apply to monotone real circuits as well, e.g., we just state without proof the following result.

THEOREM 3.17. *There are constants $0 < \epsilon, \gamma < 1$ such that for every function $d(n) \le n^\epsilon$, there is a family of monotone functions $f_n : \{0,1\}^n \to \{0,1\}$ that can be computed by monotone boolean circuits of size $n^{O(1)}$ and depth $d(n)$, but cannot be computed by monotone real circuits of depth less than $\gamma \cdot d(n)$.*

The method also gives a simpler proof of the lower bounds in [18] in the same way that [25] simplifies the lower bound of [20].

4. Separation between tree-like and dag-like versions of resolution and cutting planes. We will define an unsatisfiable CNF formula $Gen(\vec{p}, \vec{q}) \wedge Col(\vec{p}, \vec{r})$ that fulfills the assumptions of Theorem 2.2, so any CP refutation of it can be transformed into a monotone real circuit, and any tree-like CP refutation into a monotone real formula. This circuit (or formula) is similar in size to the original CP refutation. We will show that it computes a boolean function related to GEN_n: It outputs 1 if n is generated in a pyramidal way, so the exponential size lower bound in Corollary 3.16 implies an exponential size lower bound for tree-like CP refutations of $Gen(\vec{p}, \vec{q}) \wedge Col(\vec{p}, \vec{r})$. Besides, we give a polynomial size resolution refutation of $Gen(\vec{p}, \vec{q}) \wedge Col(\vec{p}, \vec{r})$. As CP polynomially simulates resolution, we get the separation between tree-like CP and CP; in fact, we also get a separation of tree-like resolution from resolution.

Let n and d be natural numbers whose values are to be fixed. Recall that the set Pyr_d is $\{\, (i, j) \,:\, 1 \le j \le i \le d \,\}$. The vector $\vec{p}$, that is, the variables $p_{a,b,c}$ for $a, b, c \in [n]$, represent the input to GEN_n.

The set of clauses $Gen(\vec{p}, \vec{q})$ is designed to be satisfiable if in the input $\vec{p}$, n is generated in a depth d pyramidal fashion. To this end, the variables $q_{i,j,a}$ for $(i, j) \in Pyr_d$ and $a \in [n]$ encode a mapping $m : Pyr_d \to [n]$ as in the definition of pyramidal generation in section 3.15, where $q_{i,j,a}$ is intended to express that $m(i, j) = a$.

On the other hand, the set of clauses $Col(\vec{p},\vec{r})$ is designed to be satisfiable if for the input $\vec{p}$, $\textsc{Gen}_n(\vec{p}) = 0$. To achieve this, the variables r_a for $a \in [n]$ encode a coloring of the elements of $[n]$ such that element 1 is colored 0, element n is colored 1, and the elements colored 0 are closed under generation, i.e., if a and b are colored 0 and $a, b \vdash c$, then c is also colored 0.

The set $Gen(\vec{p},\vec{q})$ is given by (4.1)–(4.4), and $Col(\vec{p},\vec{r})$ by (4.5)–(4.7).

$$\bigvee_{1\le a\le n} q_{i,j,a} \qquad \text{for } (i,j) \in Pyr_d, \tag{4.1}$$

$$\bar{q}_{d,j,a} \vee p_{1,1,a} \qquad \text{for } 1 \le j \le d \text{ and } a \in [n], \tag{4.2}$$

$$\bar{q}_{1,1,a} \vee p_{a,a,n} \qquad \text{for } a \in [n], \tag{4.3}$$

$$\bar{q}_{i+1,j,a} \vee \bar{q}_{i+1,j+1,b} \vee \bar{q}_{i,j,c} \vee p_{a,b,c} \qquad \text{for } (i,j) \in Pyr_{d-1} \text{ and } a,b,c \in [n], \tag{4.4}$$

$$\bar{p}_{1,1,a} \vee \bar{r}_a \qquad \text{for } a \in [n], \tag{4.5}$$

$$\bar{p}_{a,a,n} \vee r_a \qquad \text{for } a \in [n], \tag{4.6}$$

$$r_a \vee r_b \vee \bar{p}_{a,b,c} \vee \bar{r}_c \qquad \text{for } a,b,c \in [n]. \tag{4.7}$$

Obviously, $Gen(\vec{p},\vec{q}) \wedge Col(\vec{p},\vec{r})$ is unsatisfiable. Observe that the variables $\vec{p}$ occur only positively in $Gen(\vec{p},\vec{q})$ and only negatively in $Col(\vec{p},\vec{r})$; thus Theorem 2.2 yields an interpolating monotone real formula $C(\vec{p})$.

Now if, for a assignment $\vec{t}$ to the variables $\vec{p}$, n is generated in a depth d pyramidal fashion, then $Gen(\vec{t},\vec{q})$ is satisfiable by setting the values of the variables $q_{i,j,a}$ according to the mapping m. Therefore, $Col(\vec{t},\vec{r})$ must be unsatisfiable, and thus $C(\vec{t}) = 1$.

If, on the other hand, $\textsc{Gen}_n(\vec{t}) = 0$, then $Col(\vec{t},\vec{r})$ can be satisfied by assigning the color 0 to precisely those elements that can be generated in $\vec{t}$. Therefore, $Gen(\vec{t},\vec{q})$ must be unsatisfiable, and so $C(\vec{t}) = 0$.

Thus $C(\vec{p})$ is a monotone real formula satisfying the assumptions of Corollary 3.16, and therefore it has to be of size $2^{\Omega(n^\epsilon)}$. Note that Theorem 2.2 gives no information about the behavior of $C(\vec{t})$ in the case where $Gen(\vec{t},\vec{q})$ and $Col(\vec{t},\vec{r})$ are both unsatisfiable; thus we need Corollary 3.16 in precisely the general form in which it is stated. From the size bounds in Theorem 2.2 we now obtain the following theorem.

THEOREM 4.1. *Every tree-like CP refutation of the clauses $Gen(\vec{p},\vec{q}) \cup Col(\vec{p},\vec{r})$ has to be of size $2^{\Omega(n^\epsilon)}$ for some $\epsilon > 0$.*

On the other hand, there are polynomial size dag-like resolution refutations of these clauses.

THEOREM 4.2. *There are (dag-like) resolution refutations of size $n^{O(1)}$ of the clauses $Gen(\vec{p},\vec{q}) \cup Col(\vec{p},\vec{r})$.*

Proof. First we resolve clauses (4.2) and (4.5) to get

$$\bar{q}_{d,j,c} \vee \bar{r}_c \tag{4.8}$$

for $1 \le j \le d$ and $1 \le c \le n$.

Now we want to derive $\bar{q}_{i,j,c} \vee \bar{r}_c$ for every $(i,j) \in Pyr_d$ and $1 \le c \le n$, by induction on i downward from d to 1. The induction base is just (4.8).

Now by induction we have

$$\bar{q}_{i+1,j,a} \vee \bar{r}_a \quad \text{and} \quad \bar{q}_{i+1,j+1,b} \vee \bar{r}_b\ .$$

We resolve them against (4.7) to get $\bar{q}_{i+1,j,a} \vee \bar{q}_{i+1,j+1,b} \vee \bar{p}_{a,b,c} \vee \bar{r}_c$ for $1 \le a,b,c \le n$ and then resolve them against (4.4) and get

$$\bar{q}_{i+1,j,a} \vee \bar{q}_{i+1,j+1,b} \vee \bar{q}_{i,j,c} \vee \bar{r}_c$$

for every $1 \le a, b \le n$. All of these are then resolved against two instances of (4.1), and we get the desired $\bar{q}_{i,j,c} \vee \bar{r}_c$ for every $1 \le c \le n$.

Finally, we have, in particular, $\bar{q}_{1,1,a} \vee \bar{r}_a$ for every $1 \le c \le n$. We resolve them with (4.6) and get $\bar{q}_{1,1,a} \vee \bar{p}_{a,a,n}$ for every $1 \le a \le n$. These are resolved with (4.3) to get $\bar{q}_{1,1,a}$ for every $1 \le a \le n$. Finally, this clause is resolved with another instance of (4.3) (the one with $i = j = 1$) to get the empty clause. □

It is easy to check that the above refutation is a negative resolution refutation. The following corollary is an easy consequence of the above theorems and known simulation results.

COROLLARY 4.3. *The clauses $Gen(\vec{p}, \vec{q}) \cup Col(\vec{p}, \vec{r})$ exponentially separate tree-like resolution from dag-like resolution; in fact, they separate tree-like resolution from dag-like negative resolution. They also separate tree-like cutting planes from dag-like cutting planes.*

The resolution refutation of $Gen(\vec{p}, \vec{q}) \cup Col(\vec{p}, \vec{r})$ that appears in the proof of Theorem 4.2 is not regular. We do not know whether $Gen(\vec{p}, \vec{q}) \cup Col(\vec{p}, \vec{r})$ has polynomial size regular resolution refutations. To obtain a separation between tree-like resolution and regular resolution we will modify the clauses $Col(\vec{p}, \vec{r})$.

4.1. Separation of tree-like *cp* from regular resolution. The clauses $Col(\vec{p}, \vec{r})$ are modified (and the modification is called $RCol(\vec{p}, \vec{r})$), so that $Gen(\vec{p}, \vec{q}) \cup RCol(\vec{p}, \vec{r})$ allow small regular resolutions, but in such a way that the lower bound proof still applies. We replace the variables r_a by $r_{a,i,D}$ for $a \in [n]$, $1 \le i \le d$, and $D \in \{L, R\}$, giving the coloring of element a, with auxiliary indices i being a row in the pyramid and D distinguishing whether an element is used as a left or right predecessor in the generation process.

The set $RCol(\vec{p}, \vec{r})$ is defined as follows:

$$\bar{p}_{1,1,a} \vee \bar{r}_{a,d,D} \qquad \text{for } a \in [n] \text{ and } D \in \{L, R\}, \tag{4.9}$$

$$\bar{p}_{a,a,n} \vee r_{a,1,D} \qquad \text{for } a \in [n] \text{ and } D \in \{L, R\}, \tag{4.10}$$

$$r_{a,i+1,L} \vee r_{b,i+1,R} \vee \bar{p}_{a,b,c} \vee \bar{r}_{c,i,D} \qquad \text{for } i < d,\ a, b, c \in [n],\ \text{and } D \in \{L, R\}, \tag{4.11}$$

$$\bar{r}_{a,i,D} \vee r_{a,i,\bar{D}} \qquad \text{for } 1 \le i \le d \text{ and } D \in \{L, R\}, \tag{4.12}$$

$$\bar{r}_{a,i,D} \vee r_{a,j,D} \qquad \text{for } 1 \le i, j \le d \text{ and } D \in \{L, R\}. \tag{4.13}$$

Due to the clauses (4.12) and (4.13), the variables $r_{a,i,D}$ are equivalent for all values of the auxiliary indices i, D. Hence a satisfying assignment for $RCol(\vec{p}, \vec{r})$ still codes a coloring of $[n]$ such that elements a with $1, 1 \vdash a$ are colored 0, the elements b with $b, b \vdash n$ are colored 1, and the 0-colored elements are closed under generation. Hence if $RCol(\vec{t}, \vec{r})$ is satisfiable, then $\text{GEN}(\vec{t}) = 0$.

Hence any interpolant for the clauses $Gen(\vec{p}, \vec{q}) \cup RCol(\vec{p}, \vec{r})$ satisfies the assumptions of Corollary 3.16, and we can conclude the following theorem.

THEOREM 4.4. *Tree-like CP refutations of the clauses $Gen(\vec{p}, \vec{q}) \cup RCol(\vec{p}, \vec{r})$ have to be of size $2^{\Omega(n^\epsilon)}$.*

On the other hand, we have the following upper bound on (dag-like) regular resolution refutations of these clauses.

THEOREM 4.5. *There are (dag-like) regular resolution refutations of the clauses $Gen(\vec{p}, \vec{q}) \cup RCol(\vec{p}, \vec{r})$ of size $n^{O(1)}$.*

Proof. First we resolve clauses (4.2) and (4.9) to get

$$\bar{q}_{d,j,a} \vee \bar{r}_{a,d,D} \tag{4.14}$$

for $1 \le j \le d$, $1 \le a \le n$, and $D \in \{L, R\}$. Next we resolve (4.3) and (4.10) to get

$$\bar{q}_{1,1,a} \vee r_{a,1,D} \tag{4.15}$$

for $1 \le a \le n$, and $D \in \{L, R\}$. Finally, from (4.4) and (4.11) we obtain

$$\bar{q}_{i+1,j,a} \vee \bar{q}_{i+1,j+1,b} \vee \bar{q}_{i,j,c} \vee r_{a,i+1,L} \vee r_{b,i+1,R} \vee \bar{r}_{c,i,D} \tag{4.16}$$

for $1 \le j \le i < d$, $1 \le a, b, c \le n$, and $D \in \{L, R\}$.

Now we want to derive $\bar{q}_{i,j,a} \vee \bar{r}_{a,i,D}$ for every $(i, j) \in Pyr_d$, $1 \le a \le n$, and $D \in \{L, R\}$, by induction on i downward from d to 1. The induction base is just (4.14).

For the inductive step, resolve (4.16) against the clauses

$$\bar{q}_{i+1,j,a} \vee \bar{r}_{a,i+1,L} \quad \text{and} \quad \bar{q}_{i+1,j+1,b} \vee \bar{r}_{b,i+1,R} \,,$$

which we have by induction to give

$$\bar{q}_{i+1,j,a} \vee \bar{q}_{i+1,j+1,b} \vee \bar{q}_{i,j,c} \vee \bar{r}_{c,i,D}$$

for every $1 \le a, b \le n$. All of these are then resolved against two instances of (4.1), and we get the desired $\bar{q}_{i,j,c} \vee \bar{r}_{c,i,D}$.

Finally, we have, in particular, $\bar{q}_{1,1,a} \vee \bar{r}_{a,1,L}$, which we resolve against (4.15) to get $\bar{q}_{1,1,a}$ for every $a \le n$. From these and an instance of (4.1) we get the empty clause. □

Note that the refutation given in the proof of Theorem 4.5 is actually an ordered refutation. It respects the following elimination order:

$$\begin{array}{l} p_{1,1,1} \cdots p_{n,n,n} \\ r_{1,d,L} \;\; r_{1,d,R} \;\; \cdots \;\; r_{n,d,L} \;\; r_{n,d,R} \\ q_{1,d,1} \cdots q_{1,d,n} \cdots q_{d,d,1} \cdots q_{d,d,n} \\ r_{1,d-1,L} \cdots r_{n,d-1,R} \;\; q_{1,d-1,1} \cdots q_{d-1,d-1,n} \\ \vdots \\ r_{1,1,L} \;\; r_{1,1,R} \;\; q_{1,1,1} \cdots q_{1,1,n} \,. \end{array}$$

COROLLARY 4.6. *The clauses $Gen(\vec{p}, \vec{q}) \cup RCol(\vec{p}, \vec{r})$ exponentially separate tree-like resolution from ordered resolution; therefore, they also separate exponentially tree-like resolution from regular resolution.*

5. Lower bound for ordered resolution. Goerdt [13] showed that ordered resolution is strictly weaker than unrestricted resolution by giving a superpolynomial lower bound (of the order $\Omega(n^{\log \log n})$) for ordered resolutions of a certain family of clauses, which, on the other hand, has polynomial size unrestricted resolution refutations. In this section we improve this separation to an exponential one; in fact, we give an exponential separation of ordered resolution from negative resolution.

To simplify the exposition, we apply the method of [13] to a set of clauses $SP_{n,m}$ expressing a combinatorial principle that we call the *string-of-pearls* principle. From a bag of m pearls, which are colored red and blue, n pearls are chosen and placed on a string. The string-of-pearls principle $SP_{n,m}$ says that if the first pearl is red and the last one is blue, then there must be a blue pearl next to a red pearl somewhere on the string.

$SP_{n,m}$ is given by an unsatisfiable set of clauses in variables $p_{i,j}$ and q_j for $i \in [n]$ and $j \in [m]$, where $p_{i,j}$ is intended to say that pearl j is at position i on the string, and q_j means that pearl j is colored blue. The clauses forming $SP_{n,m}$ are

$$\bigvee_{j=1}^{m} p_{i,j}, \qquad i \in [n], \tag{5.1}$$

$$\bar{p}_{i,j} \vee \bar{p}_{i,j'}, \qquad i \in [n],\ j, j' \in [m],\ j \neq j', \tag{5.2}$$

$$\bar{p}_{i,j} \vee \bar{p}_{i',j}, \qquad i, i' \in [n],\ j \in [m],\ i \neq i'. \tag{5.3}$$

These first three sets of clauses express that there is a unique pearl at each position.

$$\bar{p}_{1,j'} \vee \bar{q}_{j'}, \qquad j' \in [m], \tag{5.4}$$

$$\bar{p}_{n,j} \vee q_j, \qquad j \in [m], \tag{5.5}$$

$$\bar{p}_{i,j} \vee \bar{p}_{(i+1),j'} \vee q_j \vee \bar{q}_{j'}, \qquad 1 \leq i < n,\ j, j' \in [m],\ j \neq j'. \tag{5.6}$$

These last three sets of clauses express that the first pearl is red, the last one is blue, and that a pearl sitting next to a red pearl is also colored red. The clauses $SP_{n,m}$ are a modified and simplified version of the clauses related to the *st*-connectivity problem that were introduced by Clote and Setzer [8].

PROPOSITION 5.1. *The clauses $SP_{n,m}$ have negative resolution refutations of size $O(nm^2)$.*

Proof. For every $i \in [n]$, we will derive the clauses $\bar{p}_{i,j} \vee \bar{q}_j$ for $j \in [m]$ from $SP_{n,m}$ by a negative resolution derivation. For $i = 1$, these are the clauses (5.4) from $SP_{n,m}$. Inductively, assume we have derived $\bar{p}_{i,j'} \vee \bar{q}_{j'}$ for $j' \in [m]$, and we want to derive $\bar{p}_{(i+1),j} \vee \bar{q}_j$ from these.

Consider the clauses (5.6) of the form $\bar{p}_{i,j'} \vee \bar{p}_{(i+1),j} \vee q_{j'} \vee \bar{q}_j$ for $j' \in [m]$. Using the inductive assumption, we derive from these the clauses $\bar{p}_{i,j'} \vee \bar{p}_{(i+1),j} \vee \bar{q}_j$ for $j' \in [m]$. Note that these are negative clauses.

By a derivation of length m, we obtain $\bar{p}_{(i+1),j} \vee \bar{q}_j$ from these and the clause $\bigvee_{j' \in [m]} p_{i,j'}$ from $SP_{n,m}$. The whole derivation is of length $O(m)$, and we need m of them, giving a total length of $O(m^2)$ for the induction step.

We end up with a derivation of the clauses $\bar{p}_{n,j} \vee \bar{q}_j$ for $j \in [m]$ of length $O(nm^2)$. In another m steps we resolve these with the initial clauses (5.5), obtaining the singleton clauses $\bar{p}_{n,j}$ for $j \in [m]$. Finally, we derive a contradiction from these and the clauses $\bigvee_{j \in [m]} p_{n,j}$. □

The above refutation of $SP_{n,m}$ is not ordered, since it is not even regular: the variables q_j for every pearl j are eliminated at every stage of the induction. Nevertheless, we are unable to show that there are no short ordered refutations of $SP_{n,m}$. In order to obtain a lower bound for ordered resolution refutations, we shall modify the clauses $SP_{n,m}$. The lower bound is then proved by a bottleneck counting argument similar to that used in [13], which is based on the original argument of Haken [16]. Note that the clauses (5.1)–(5.3) are similar to the clauses expressing the pigeonhole principle, which makes the bottleneck counting technique applicable in our situation.

We call the pearls numbered 1 through $\frac{n}{4}$ (we assume $\frac{n}{4}$ to be an integer, for simplicity) the *special* pearls. The positions 1 to $\frac{n}{2}$ on the string are called the *left half*, and the positions $\frac{n}{2} + 1$ to n are called the *right half* of the string.

For each special pearl j placed on the string, an associated position $\hat{\imath} = \hat{\imath}(j)$ is defined, depending on where on the string j is placed. If j is placed in the left half,

then $\hat{\imath}$ is in the right half; say, $\hat{\imath} = \frac{n}{2} + 2j - 1$ for definiteness, and if j is placed in the right half, then $\hat{\imath}$ is in the left half, say, $\hat{\imath} = 2j$.

The set $SP'_{n,m}$ is obtained from $SP_{n,m}$ by adding additional literals to those clauses that restrict the coloring of the special pearls placed on the string. First, the clauses (5.4) and (5.6) for $1 \leq i < \frac{n}{2}$, where $j' \leq \frac{n}{4}$ is special, are replaced by m clauses each, namely,

$$\bar{p}_{\hat{\imath},\ell} \vee \bar{p}_{1,j'} \vee \bar{q}_{j'}, \tag{5.7}$$

$$\bar{p}_{\hat{\imath},\ell} \vee \bar{p}_{i,j} \vee \bar{p}_{(i+1),j'} \vee q_j \vee \bar{q}_{j'} \tag{5.8}$$

for every $\ell \in [m]$, where $\hat{\imath} := \frac{n}{2} + 2j' - 1$, since j' is placed in the left half. Similarly, the clauses (5.5) and (5.6) for $\frac{n}{2} < i < n$ and special $j \leq \frac{n}{4}$ are replaced by

$$\bar{p}_{\hat{\imath},\ell} \vee \bar{p}_{n,j} \vee q_j, \tag{5.9}$$

$$\bar{p}_{\hat{\imath},\ell} \vee \bar{p}_{i,j} \vee \bar{p}_{(i+1),j'} \vee q_j \vee \bar{q}_{j'} \tag{5.10}$$

for every $\ell \in [m]$, where now $\hat{\imath} := 2j$, since j is placed in the right half. All other clauses remain unchanged. The modified clauses $SP'_{n,m}$ do not have an intuitive combinatorial interpretation different from the meaning of the original clauses $SP_{n,m}$. The added literals only serve to make the clauses hard for ordered refutations. The idea is that for the clauses (5.7)–(5.10) to be used as one would use the original (5.4)–(5.6) in the natural short, inductive proof above, the additional literals $\bar{p}_{\hat{\imath},\ell}$ have to be removed first. The positions $\hat{\imath}$ are chosen in such a way that this cannot be done in a manner consistent with a global ordering of the variables.

THEOREM 5.2. *The clauses $SP'_{n,m}$ have negative resolution refutations of size $O(nm^2)$.*

Proof. We modify the refutation of $SP_{n,m}$ given above for the modified clauses $SP'_{n,m}$. First, note that the original clauses (5.4) can be obtained from (5.7) by a negative derivation of length m.

Next, we modify those places in the inductive step where the clauses (5.6) are used that have been modified. First, we resolve the modified clauses (5.8), respectively, (5.10) with the inductive assumption, yielding the negative clauses

$$\bar{p}_{\hat{\imath},\ell} \vee \bar{p}_{i,j} \vee \bar{p}_{(i+1),j'} \vee \bar{q}_{j'}$$

for $\ell \in [m]$. These are then resolved with the clause $\bigvee_{j=1}^{m} p_{\hat{\imath},j}$, after which we can continue as in the original refutation.

In the places where the clauses (5.5) are used in the original refutation, we first resolve (5.9) with the clauses $\bar{p}_{n,j} \vee \bar{q}_j$, yielding $\bar{p}_{\hat{\imath},\ell} \vee \bar{p}_{n,j}$, which can be resolved with $\bigvee_{j=1}^{m} p_{\hat{\imath},j}$ to get the singleton clauses $\bar{p}_{n,j}$ as in the original refutation. ∎

In particular, there are polynomial size unrestricted resolution refutations of the clauses $SP'_{n,m}$. The next theorem gives a lower bound for ordered resolution refutations of these clauses.

THEOREM 5.3. *For sufficiently large n and $m \geq \frac{9}{8}n$, every ordered resolution refutation of the clauses $SP'_{n,m}$ contains at least $2^{k(\log n - 5)}$ clauses.*

For the sake of simplicity, let n be divisible by 8, say, $n = 8k$. Let $N := nm + m$ be the number of variables, and let an ordering $x_1, x_2, \ldots, x_N$ of the variables be given, i.e., each x_ν is one of the variables $p_{i,j}$ or q_j. Let R be an ordered resolution refutation of $SP'_{n,m}$ respecting this elimination ordering, i.e., on every path through R the variables are eliminated in the prescribed order. We shall show that R contains at least $k!$ different clauses, which is at least $2^{\frac{n}{8}(\log n - 5)}$ for large n.

For a position $i \in [n]$ and $\nu \leq N$, let $S(i,\nu)$ be the set of special pearls $j \leq 2k = \frac{n}{4}$ such that $p_{i,j}$ is among the first ν eliminated variables, i.e.,

$$S(i,\nu) := \{\, j \leq 2k \;:\; p_{i,j} \in \{x_1, \ldots, x_\nu\}\,\} \;.$$

Let ν_0 be the smallest index such that $|S(i,\nu_0)| = k$ for some position i, and call this position i_0. It follows that for all $i \neq i_0$, $|S(i,\nu_0)| < k$. In other words, i_0 is the first position for which k of the variables $p_{i_0,j}$ with $j \leq 2k$ special are eliminated.

Let the elements of $S(i_0,\nu_0)$ be denoted by $j_1, \ldots, j_k$, enumerated in increasing order for definiteness. For each $1 \leq \mu \leq k$, let i_μ be the position $\hat{\imath}(j_\mu)$ associated to j_μ when j_μ is placed on the string at position i_0, i.e.,

$$i_\mu := \begin{cases} \frac{n}{2} + 2j_\mu - 1 & \text{if } i_0 \leq \frac{n}{2}, \\ 2j_\mu & \text{if } i_0 > \frac{n}{2}. \end{cases}$$

Further, we define for the set $R_\mu := [2k] \setminus S(i_\mu,\nu_0)$, i.e., R_μ is the set of special pearls j with the property that on every path in the refutation, the variable $p_{i_\mu,j}$ is eliminated only after all the variables p_{i_0,j_κ} for $1 \leq \kappa \leq k$ have been eliminated. Note that by the definition of ν_0, $|S(i_\mu,\nu_0)| < k$ and therefore $|R_\mu| \geq k$ for all $1 \leq \mu \leq k$.

DEFINITION 5.4. *A* critical assignment *is an assignment that satisfies all the clauses of $SP'_{n,m}$ except for exactly one of the clauses* (5.1)*. From a critical assignment α, we define the following data.*

- *The unique position $i_\alpha \in [n]$ such that no pearl is placed at position i_α by α, i.e., $\alpha(p_{i_\alpha,j}) = 0$ for every $j \in [m]$. We call i_α the* gap *of α.*
- *A* 1-1 *mapping $m_\alpha : [n] \setminus \{i_\alpha\} \to [m]$, where for every $i \neq i_\alpha$, $m_\alpha(i)$ is the pearl placed at position i by α, i.e., the unique $j \in [m]$ such that $\alpha(p_{i,j}) = 1$.*

For every $j \in [m]$, we refer to the value $\alpha(q_j)$ as the color *of j, where we identify the value* 0 *with red and* 1 *with blue.*

A critical assignment α is called 0-critical *if the gap is $i_\alpha = i_0$ and $m_\alpha(i_\mu) \in R_\mu$ for each $1 \leq \mu \leq k$, and, moreover,*

- *if i_0 is in the left half, then $j_1, \ldots, j_k$ are colored blue (i.e., $\alpha(q_{j_1}) = \cdots = \alpha(q_{j_k}) = 1$), and*
- *if i_0 is in the right half, then $j_1, \ldots, j_k$ are colored red (i.e., $\alpha(q_{j_1}) = \cdots = \alpha(q_{j_k}) = 0$).*

Note that the positions $i_0, i_1, \ldots, i_k$ and the pearls $j_1, \ldots, j_k$, and thus the notion of 0-critical assignment, only depend on the elimination order and not on the refutation R.

As in other bottleneck counting arguments, the lower bound will now be proved in two steps. First, we show that there are many 0-critical assignments. Second, we will map each 0-critical assignment α to a certain clause C_α in R, and then show that not too many different assignments α can be mapped to the same clause C_α, and thus that there must be many of the clauses C_α.

The first goal, showing there are many 0-critical assignments, is attained with the following claim.

CLAIM 5.5. *For every choice of pairwise distinct pearls $b_1, \ldots, b_k$ with $b_\mu \in R_\mu$ for $1 \leq \mu \leq k$, there is a 0-critical assignment α with $m_\alpha(i_\mu) = b_\mu$ for $1 \leq \mu \leq k$. In particular, there are at least $k!$ 0-critical assignments that disagree on the values $m_\alpha(i_\mu)$ for $1 \leq \mu \leq k$.*

Proof (proof of Claim 5.5). For those positions i such that $m_\alpha(i)$ is not defined yet, i.e., $i \notin \{i_0, i_1, \ldots, i_k\}$, assign pearls $m_\alpha(i) \in [m] \setminus \{j_1, \ldots, j_k\}$ arbitrarily but

consistently, i.e., choose an arbitrary 1-1 mapping from $[n] \setminus \{i_0, i_1, \dots, i_k\}$ to $[m] \setminus \{b_1, \dots b_k, j_1, \dots, j_k\}$. This is always possible, since by assumption $m \geq 9k$.

Finally, color those pearls that are assigned to positions to the left of the gap red, and those that are assigned to positions to the right of the gap blue, i.e., set $\alpha(q_{m_\alpha(i)}) = 0$ for $i < i_0$ and $\alpha(q_{m_\alpha(i)}) = 1$ for $i > i_0$. The pearls $j_1, \dots, j_k$ are colored according to the requirement in the definition of a 0-critical assignment.

This coloring of the pearls is well defined even if some of the pearls $b_1, \dots b_k$ are among the $j_1, \dots, j_k$, because the positions $i_1, \dots, i_k$ and i_0 are in opposing halves of the string: if i_0 is in the left half, then every i_μ is in the right half, and, in particular, $i_\mu > i_0$. Similarly, if i_0 is in the right half, then $i_\mu < i_0$, so in both cases, the pearls $j_1, \dots, j_k$ get the same color as $b_1, \dots, b_k$. The remaining pearls can be colored arbitrarily. □

Now we map 0-critical assignments to certain clauses in R. For a 0-critical assignment α, let C_α be the first clause in R such that α does not satisfy C_α, and

$$\{\, j \,:\, p_{i_0,j} \text{ occurs in } C_\alpha \,\} = [m] \setminus \{j_1, \dots, j_k\} \,.$$

This clause exists because α determines a path through R from the clause $\bigvee_{j \in [m]} p_{i_0,j}$ to the empty clause, such that α does not satisfy any clause on this path. The variables $p_{i_0,j}$ with $j \leq 2k$ are eliminated along that path, and $p_{i_0,j_1}, \dots p_{i_0,j_k}$ are the first among them in the elimination order.

Claim 5.6. *Let α be a 0-critical assignment. For every $1 \leq \mu \leq k$, the literal $\bar{p}_{i_\mu,\ell_\mu}$, where $\ell_\mu := m_\alpha(i_\mu)$, occurs in C_α.*

Proof (proof of Claim 5.6). Let α' be the assignment defined by $\alpha'(p_{i_0,j_\mu}) := 1$ and $\alpha'(x) := \alpha(x)$ for all other variables x. As p_{i_0,j_μ} does not occur in C_α, α' does not satisfy C_α either.

There is exactly one clause in $SP'_{n,m}$ that is not satisfied by α', depending on where the gap i_0 is; this clause is

$$\begin{aligned}
i_0 = 1 \;:&\quad \bar{p}_{i_\mu,\ell_\mu} \vee \bar{p}_{1,j_\mu} \vee \bar{q}_{j_\mu}, \\
1 < i_0 \leq \frac{n}{2} \;:&\quad \bar{p}_{i_\mu,\ell_\mu} \vee \bar{p}_{i_0-1,h} \vee \bar{p}_{i_0,j_\mu} \vee q_h \vee \bar{q}_{j_\mu}, \qquad \text{where } h = m_\alpha(i_0 - 1), \\
\frac{n}{2} < i_0 < n \;:&\quad \bar{p}_{i_\mu,\ell_\mu} \vee \bar{p}_{i_0,j_\mu} \vee \bar{p}_{i_0+1,h} \vee q_{j_\mu} \vee \bar{q}_h, \qquad \text{where } h = m_\alpha(i_0 + 1), \\
i_0 = n \;:&\quad \bar{p}_{i_\mu,\ell_\mu} \vee \bar{p}_{n,j_\mu} \vee q_{j_\mu}.
\end{aligned}$$

The requirement for the coloring of the j_μ in the definition of a 0-critical assignment entails that these clauses are not satisfied by α' and that all other clauses are satisfied by α'.

In any case, the literal $\bar{p}_{i_\mu,\ell_\mu}$ occurs in this clause, and there is a path through R leading from the clause in question to C_α, such that α' does not satisfy any clause on that path. The variable that is eliminated in the last inference on that path must be one of the p_{i_0,j_κ} for $1 \leq \kappa \leq k$, by the definition of C_α. Since $\ell_\mu \in R_\mu$, the variable p_{i_μ,ℓ_μ} appears after p_{i_0,j_κ} in the elimination order, by the definition of R_μ . Therefore, p_{i_μ,ℓ_μ} cannot have been eliminated on that path, so $\bar{p}_{i_\mu,\ell_\mu}$ still occurs in C_α. □

Finally, we are ready to finish the proof of the theorem. Let α, β be two 0-critical assignments such that $\ell_\mu := m_\alpha(i_\mu) \neq m_\beta(i_\mu)$ for some $1 \leq \mu \leq k$, so that $\beta(p_{i_\mu,\ell_\mu}) = 0$. By Claim 5.6, the literal $\bar{p}_{i_\mu,\ell_\mu}$ occurs in C_α; therefore, β satisfies C_α, and hence $C_\beta \neq C_\alpha$.

By Claim 5.5, there are at least $k!$ 0-critical assignments α that disagree on at least one of the values $m_\alpha(i_\mu)$. Thus R contains at least $k!$ distinct clauses of the form C_α. □

The following corollary is a direct consequence of Theorems 5.3 and 5.2.

COROLLARY 5.7. *The clauses $SP'_{n,m}$ for $m \geq \frac{9}{8}n$ exponentially separate ordered resolution from unrestricted resolution and negative resolution.*

A modification similar to the one that transforms $SP_{n,m}$ into $SP'_{n,m}$ can also be applied to the clauses $Gen(\vec{p}, \vec{q})$, yielding a set $DPGen(\vec{p}, \vec{q})$. Then for the clauses $DPGen(\vec{p}, \vec{q}) \cup Col(\vec{p}, \vec{r})$, an exponential lower bound for ordered resolutions can be proved by the method of Theorem 5.3 (this was presented in the conference version [5] of this paper). Also the negative resolution proofs of Theorem 4.2 can be modified for these clauses. Thus the clauses $DPGen(\vec{p}, \vec{q}) \cup Col(\vec{p}, \vec{r})$ exponentially separate ordered from negative resolution as well.

6. Open problems. We would like to conclude by stating some open problems related to the topics of this paper.

1. For boolean circuits (monotone as well as general), circuit depth and formula size are essentially the same complexity measure, as they are exponentially related by the well-known Brent–Spira theorem. Is there an analogous theorem for monotone real circuits, i.e., is $d_{\mathbb{R}}(f) = \Theta(\log s_{\mathbb{R}}(f))$ for every monotone function f? This would be implied by the converse to Lemma 2.1, i.e., $d_{\mathbb{R}}(f) \leq CC_{\mathbb{R}}(R_f)$. Does this hold for every monotone function f?
2. The separation between tree-like and dag-like resolution was recently improved to a strongly exponential one, with a lower bound of the form $2^{n/\log n}$ [3, 4, 24]. Can we prove the same strong separation between tree-like and dag-like CP?
3. A solution for the previous problem would follow from a strongly exponential separation of monotone real formula size from monotone circuit size. Such a strong separation is not even known for monotone *boolean* circuits.
4. Can the superpolynomial separations of regular and negative resolution from unrestricted resolution [14, 15] be improved to exponential as well? And is there an exponential speed-up of regular over ordered resolution?

Acknowledgments. We would like to thank Ran Raz for reading a previous version of this work and discovering an error, Andreas Goerdt for sending us copies of his papers, Sam Buss for helpful discussions, and, finally, Peter Clote for suggesting to us to work on resolution separations.

RANDOMNESS IS HARD*

HARRY BUHRMAN† AND LEEN TORENVLIET‡

Abstract. We study the set of incompressible strings for various resource bounded versions of Kolmogorov complexity. The resource bounded versions of Kolmogorov complexity we study are polynomial time *CD* complexity defined by Sipser, the nondeterministic variant *CND* due to Buhrman and Fortnow, and the polynomial space bounded Kolmogorov complexity *CS* introduced by Hartmanis. For all of these measures we define the set of random strings R_t^{CD}, R_t^{CND}, and R_t^{CS} as the set of strings x such that $CD^t(x)$, $CND^t(x)$, and $CS^s(x)$ is greater than or equal to the length of x for s and t polynomials. We show the following:

- $\mathrm{MA} \subseteq \mathrm{NP}^{\mathrm{R}_t^{CD}}$, where MA is the class of Merlin–Arthur games defined by Babai.
- $\mathrm{AM} \subseteq \mathrm{NP}^{\mathrm{R}_t^{CND}}$, where AM is the class of Arthur–Merlin games.
- $\mathrm{PSPACE} \subseteq \mathrm{NP}^{\mathrm{cR}_s^{CS}}$.

In the last item cR_s^{CS} is the set of pairs $\langle x, y\rangle$ so that x is random given y. These results show that the set of random strings for various resource bounds is hard for complexity classes under *nondeterministic* reductions.

This paper contrasts the earlier work of Buhrman and Mayordomo where they show that for polynomial time *deterministic* reductions the set of exponential time Kolmogorov random strings is not complete for EXP.

1. Introduction.

The holy grail of complexity theory is the separation of complexity classes like P, NP, and PSPACE. It is well known that all of these classes possess complete sets and that it is thus sufficient for a separation to show that a complete set of one class is not contained in the other. Therefore lots of effort was put into the study of complete sets. (See [11].)

Kolmogorov [19], however, suggested focusing attention on sets which are *not* complete. His intuition was that complete sets possess a lot of "structure" that hinders a possible lower bound proof. He suggested to look at the set of time bounded Kolmogorov random strings. In this paper we will continue this line of research and study variants of this set.

Kolmogorov complexity measures the "amount" of regularity in a string. Informally the Kolmogorov complexity of a string x, denoted as $C(x)$, is the size of the smallest program that prints x and then stops. For any string x, $C(x)$ is less than or equal to the length of x (up to some additive constant). Those strings for which it holds that $C(x)$ is greater than or equal to the length of x are called *incompressible* or *random*. A simple counting argument shows that random strings exist.

In the sixties, when the theory of Kolmogorov complexity was developed, Martin [23] showed that the coRE set of Kolmogorov random strings is complete with respect to (resource unbounded) Turing reductions. Kummer [18] has shown that this can be strengthened to show that this set is also truth-table complete.

The resource bounded version of the set of random strings was first studied by Ko [17]. The *polynomial* time bounded Kolmogorov complexity $C^p(x)$ for p a polynomial is the smallest program that prints x in $p(|x|)$ steps [14]. Ko showed that there exists an oracle such that the set of random strings with respect to this time bounded Kolmogorov complexity is complete for coNP under strong nondeterministic polynomial time reductions. He also constructed an oracle where this set is not complete for coNP under deterministic polynomial time Turing reductions.

Buhrman and Mayordomo [10] considered the *exponential* time Kolmogorov random strings. The exponential time Kolmogorov complexity $C^t(x)$ is the smallest program that prints x in $t(|x|)$ steps for functions $t(n) = 2^{n^k}$. They showed that the set of $t(n)$ random strings is *not* deterministic polynomial time Turing hard for EXP. They showed that the class of sets that reduce to this set has p measure 0 and hence that this set is not even weakly hard for EXP.

The results in this paper contrast those from Buhrman and Mayordomo. We show that the set of random strings is hard for various complexity classes under *nondeterministic* polynomial time reductions.

We consider three well-studied measures of Kolmogorov complexity that lie in between $C^p(x)$ and $C^t(x)$ for p a polynomial and $t(n) = 2^{n^k}$. We consider the distinguishing complexity as introduced by Sipser [25]. The distinguishing complexity, $CD^t(x)$, is the size of the smallest program that runs in time $t(n)$ and accepts x and nothing else. We show that the set of random strings $\mathrm{R}_t^{CD} = \{x \mid CD^t(x) \geq |x|\}$ for t a fixed polynomial is hard for MA under nondeterministic reductions. MA is the class of Merlin–Arthur games introduced by Babai [1]. As an immediate consequence we obtain that BPP and $\mathrm{NP}^{\mathrm{BPP}}$ are in $\mathrm{NP}^{\mathrm{R}_t^{CD}}$.

Next we shift our attention to nondeterministic distinguishing complexity [6], $CND^t(x)$, which is defined as the size of the smallest *nondeterministic* algorithm that runs in time $t(n)$ and accepts only x. We define $\mathrm{R}_t^{CND} = \{x : CND^t(x) \geq |x|\}$ for t a fixed polynomial. We show that $\mathrm{AM} \subseteq \mathrm{NP}^{\mathrm{R}_t^{CND}}$, where AM is the class of Arthur–Merlin games [1]. It follows that the complement of the graph isomorphism problem, $\overline{GI}$, is in $\mathrm{NP}^{\mathrm{R}_t^{CND}}$ and that if for some polynomial t, $\mathrm{R}_t^{CND} \in \mathrm{NP} \cap \mathrm{coNP}$, then $GI \in \mathrm{NP} \cap \mathrm{coNP}$.

The $s(n)$ *space* bounded Kolmogorov complexity $CS^s(x|y)$ is defined as the size of the smallest program that prints x, given y, and uses at most $s(|x| + |y|)$ tape cells [14]. Likewise we define $\mathrm{cR}_s^{CS} = \{\langle x, y\rangle : CS^s(x|y) \geq |x|\}$ for $s(n)$ a polynomial. We show that $\mathrm{PSPACE} \subseteq \mathrm{NP}^{\mathrm{cR}_s^{CS}}$.

For the first two results we use the oblivious sampler construction of Zuckerman [29], a lemma [6] that measures the size of sets in terms of CD complexity, and we prove a lemma that shows that the first bits of a random string are in a sense more random than the whole string. For the last result we make use of the interactive protocol [22, 24] for quantified boolean formulas (QBFs).

To show optimality of our results for relativizing techniques, we construct an oracle world where our first result cannot be improved to deterministic reductions. We show that there is an oracle such that $\mathrm{BPP} \not\subseteq \mathrm{P}^{\mathrm{R}_t^{CD}}$ for any polynomial t. The construction of the oracle is an extension of the techniques developed by Beigel, Buhrman, and Fortnow [4].

2. Definitions and notations. We assume the reader is familiar with standard notions in complexity theory as can be found, e.g., in [2]. Strings are elements of Σ^*, where $\Sigma = \{0,1\}$. For a string s and integers $n, m \leq |s|$ we use the notation $s[n..m]$ for the string consisting of the nth through mth bit of s. We use λ for the empty string. We also need the notion of an *oblivious sampler* from [29].

DEFINITION 2.1. *A universal $(r, d, m, \epsilon, \gamma)$-oblivious sampler is a deterministic algorithm which on input a uniformly random r-bit string outputs a sequence of points $z_1, \ldots, z_d \in \{0,1\}^m$ such that for any collection of d functions $f_1, \ldots, f_d : \{0,1\}^m \mapsto [0,1]$ it is the case that*

$$\Pr\left[\left|\frac{1}{d}\sum_{i=1}^{d}(f_i(z_i) - Ef_i)\right| \leq \epsilon\right] \geq 1 - \gamma$$

(where $Ef_i = 2^{-m}\sum_{z\in\{0,1\}^m} f_i(z)$).

In our application of this definition, we will always use a single function f.

Fix a universal Turing machine U and a nondeterministic universal machine U_{N}. All our results are independent of the particular choice of universal machine. For the definition of Kolmogorov complexity we need the fact that the universal machine can, on input p, y, halt and output a string x. For the definition of distinguishing complexity below we need the fact that the universal machine on input p, x, y can either accept or reject. We also need resource bounded versions of this property.

We define the Kolmogorov complexity function $C(x|y)$ (see [20]) by $C(x|y) = \min\{|p| : U(p,y) = x\}$. We define unconditional Kolmogorov complexity by $C(x) = C(x|\lambda)$. Hartmanis [14] defined a time bounded version of Kolmogorov complexity, but resource bounded versions of Kolmogorov complexity date back as far as [3]. (See also [20].) Sipser [25] defined the distinguishing complexity CD^t.

We will need the following versions of resource bounded Kolmogorov complexity and distinguishing complexity.

- $CS^s(x|y) = \min\left\{|p| : \begin{array}{ll}(1) & U(p,y) = x;\\ (2) & U(p,y) \text{ uses at most } s(|x|+|y|) \text{ tape cells}\end{array}\right\}$.
  (See [14].)
- $CD^t(x|y) = \min\left\{|p| : \begin{array}{ll}(1) & U(p,x,y) \text{ accepts};\\ (2) & (\forall z \neq x)U(p,z,y) \text{ rejects};\\ (3) & (\forall z \in \Sigma^*)U(p,z,y) \text{ runs in at most } t(|u|+|y|) \text{ steps}\end{array}\right\}$.
  (See [25].)
- $CND^t(x|y) = \min\left\{|p| : \begin{array}{ll}(1) & U_{\mathrm{N}}(p,x,y) \text{ accepts};\\ (2) & (\forall z \neq x)U_{\mathrm{N}}(p,z,y) \text{ rejects};\\ (3) & (\forall z \in \Sigma^*)U_{\mathrm{N}}(p,z,y) \text{ runs in at most } t(|z|+|y|) \text{ steps}\end{array}\right\}$.
  (See [6].)

For $0 < \epsilon \leq 1$ we define the following sets of strings of "maximal" CD^p and CND^p complexity.

- $\mathrm{R}^{CD}_{t,\epsilon} = \{x : CD^t(x|\lambda) \geq \epsilon|x|\}$.
- $\mathrm{R}^{CND}_{t,\epsilon} = \{x : CND^t(x|\lambda) \geq \epsilon|x|\}$.

Note that for $\epsilon = 1$ these sets are the sets mentioned in the introduction. In this case we will omit the ϵ and use R^{CD}_t and R^{CND}_t. We also define the set of strings of

maximal space bounded complexity.

$$\mathrm{cR}_s^{CS} = \{\langle x, y\rangle : C\mathrm{S}^s(x|y) \geq |x|\}.$$

The c in the notation is to emphasize that randomness is conditional. Also, cR_s^{CS} technically is a set of pairs rather than a set of strings. The unconditional space bounded random strings would be

$$\mathrm{R}_s^{CS} = \{x : \langle x, \lambda\rangle \in \mathrm{cR}_s^{CS}\}.$$

We have no theorems concerning this set.

The C complexity of a string is always upperbounded by its length plus some constant depending only on the choice of the universal machine. The *CD* and *CND* complexities of a string are always upperbounded by the C complexity of that string plus some constant depending again only on the particular choice of universal machine. All quantifiers used in this paper are polynomially bounded. Often the particular polynomial is not important for what follows, or it is clear from the context and is omitted. Sometimes we need explicit bounds. Then the particular bound is given as a superscript to the quantifier. For example, we use $\exists^m y$ to denote "there exists a y with $|y| \leq m$," or $\forall^{=n} x$ to denote "for all x of length n."

The classes MA and AM are defined as follows.

DEFINITION 2.2. *$L \in \mathrm{MA}$ iff there exists a $|x|^c$ time bounded machine M such that*

1. $x \in L \implies \exists y \Pr[M(x, y, r) = 1] > 2/3$;
2. $x \notin L \implies \forall y \Pr[M(x, y, r) = 1] < 1/3$,

where r is chosen uniformly at random in $\{0,1\}^{|x|^c}$.

$L \in \mathrm{AM}$ iff there exists a $|x|^c$ time bounded machine M such that

1. $x \in L \implies \Pr[\exists y M(x, y, r) = 1] > 2/3$;
2. $x \notin L \implies \Pr[\exists y M(x, y, r) = 1] < 1/3$,

where r is chosen uniformly at random in $\{0,1\}^{|x|^c}$.

It is known that $\mathrm{NP} \cup \mathrm{BPP} \subseteq \mathrm{MA} \subseteq \mathrm{AM} \subseteq \mathrm{PSPACE}$ [1].

Let $\#M(x)$ represent the number of accepting computations of a nondeterministic Turing machine M on input x. A language L is in $\oplus\mathrm{P}$ if there exists a polynomial time bounded nondeterministic Turing machine M such that for all x

- $x \in L \Rightarrow \#M(x)$ is odd;
- $x \notin L \Rightarrow \#M(x)$ is even.

Let g be any function. We say that advice function f is g-bounded if for all n it holds that $|f(n)| \leq g(n)$. In this paper we will be interested only in functions g that are polynomial.

The notation $\leq_T^{sn}$ is used for *strong nondeterministic Turing reductions*, which are defined by $A \leq_T^{sn} B$ iff $A \in \mathrm{NP}^B \cup \mathrm{CoNP}^B$.

3. Distinguishing complexity for derandomization. In this section we prove hardness of R_t^{CD} and R_t^{CND} for AM and MA games, respectively, under NP-reductions.

THEOREM 3.1. *For any t with $t(n) \in \omega(n \log n)$, $\mathrm{MA} \subseteq \mathrm{NP}^{\mathrm{R}_t^{CD}}$.*

THEOREM 3.2. *For any t with $t(n) \in \omega(n)$, $\mathrm{AM} \subseteq \mathrm{NP}^{\mathrm{R}_t^{CND}}$.*

The proof of both theorems is roughly as follows. First guess a string of high CD^{poly} complexity, respectively, CND^{poly} complexity. Next, we use the nondeterministic reductions once more to play the role of Merlin and use the random string to derandomize Arthur. Note that this is not as straightforward as it might look. The

randomness used by Arthur in interactive protocols is used for hiding and cannot in general be substituted by computational randomness.

The idea of using strings of high CD complexity and Zuckerman's sampler derandomization stems from [7, section 8], which is the full version of [6]. Though they do not explicitly define the set R_t^{CD}, they use the same approach to derandomize BPP computations there.

The proof needs a string of high CD^p, respectively, CND^p complexity for p some polynomial. We first show that we can nondeterministically extract such a string from a longer string with high CD^t complexity (respectively, CND^t complexity) for any fixed t with $t(n) \in \omega(n \log n)$.

LEMMA 3.3. *Let f be such that $f(n) < n$, and let t, t', and T be such that $T(n) = (t'(f(n)) + n - f(n))$, $\lim_{n\mapsto\infty} \frac{T(n)\log T(n)}{t(n)} = 0$. Then for all sufficiently large s with $CD^t(s) > |s|$, it holds that $CD^{t'}(s[1..f(|s|)]) \geq f(|s|) - 2\log|f(|s|)| - O(1)$.*

Proof. Suppose for a contradiction that for any constant d_0 and infinitely many s with $CD^t(s) \geq |s|$, it holds that $CD^{t'}(s[1..f(|s|)]) < f(|s|) - 2\log|f(|s|)| - d_0$. Then for any such s there exists a program p_s that runs in $t'(f(|s|))$ and recognizes only $s[1..f(|s|)]$ where $|p_s| < f(|s|) - 2\log|f(|s|)| - d_0$. The following program then recognizes s and no other string.

> Input y.
> Check that the first $f(|s|)$ bits of y equal $s[1..f(|s|)]$, using p_s. (Assume $|f(|s|)|$ is stored in the program for a cost of $\log|f(|s|)|$ bits.)
> Check that the last $|s| - f(|s|)$ bits of y equal $s[f(|s|) + 1..|s|]$. (These bits are also stored in the program.)

This program runs in time $T(|s|) = t'(f(|s|)) + |s| - f(|s|)$. Therefore it takes at most $t(|s|)$ steps on U for all sufficiently large s [16]. We lose the $\log n$ factor here because our algorithm must run on a fixed machine and the simulation is deterministic.

The program's length is $|p_s| + |s| - f(|s|) + \log|f(|s|)| + d_1 < f(|s|) - 2\log|f(|s|)| - d_0 + |s| - f(|s|) + \log|f(|s|)| + d_1$, which is less than $|s|$ for almost all s. Hence $CD^t(s) < |s|$, which contradicts the assumption. □

COROLLARY 3.4. *For every polynomial n^c, $t \in \omega(n \log n)$ and sufficiently large string s with $CD^t(s) \geq |s|$, if $m = |s|^{\frac{1}{c}}$ and $s' = s[1..m]$, then $CD^{n^c}(s') \geq |s'| - 2\log|s'| - O(1)$.*

Proof. Take $t'(n) = n^c$, $f(n) = n^{\frac{1}{c}}$ and apply Lemma 3.3. □

Lemma 3.3 and Corollary 3.4 have the following nondeterministic analogon.

LEMMA 3.5. *For every polynomial n^c, $t \in \omega(n)$ and sufficiently large string s with $CND^t(s) \geq |s|$, if $m = |s|^{\frac{1}{c}}$ and $s' = s[1..m]$, then $CND^{n^c}(s') \geq |s'| - 2\log|s'| - O(1)$.*

Proof. The same proof applies, with a lemma similar to Lemma 3.3. However, in the nondeterministic case the simulation costs only linear time [5]. □

Before we can proceed with the proof of the theorems, we also need some earlier results. We first need the following theorem from Zuckerman.

THEOREM 3.6 (see [29]). *There is a constant c such that for $\gamma = \gamma(m)$, $\epsilon = \epsilon(m)$, and $\alpha = \alpha(m)$ with $m^{-1/2\log^* m} \leq \alpha \leq 1/2$ and $\epsilon \geq \exp(-\alpha^{2\log^* m} m)$, there exists a universal $(r, d, m, \epsilon, \gamma)$-oblivious sampler which runs in polynomial time and uses only $r = (1 + \alpha)(m + \log\gamma^{-1})$ random bits and outputs $d = ((m + log\gamma^{-1})/\epsilon)^{c_\alpha}$ sample points, where $c_\alpha = c(\log\alpha^{-1})/\alpha$.*

We also need the following lemma by Buhrman and Fortnow.

LEMMA 3.7 (see [6]). *Let A be a set in* P. *For each string $x \in A^{=n}$ it holds that $CD^p(x) \leq 2\log(\|A^{=n}\|) + O(\log n)$ for some polynomial p.*

As noted in [6], an analogous lemma holds for CND^p and NP.

LEMMA 3.8 (see [6]). *Let A be a set in* NP. *For each string $x \in A^{=n}$ it holds that $CND^p(x) \leq 2\log(\|A^{=n}\|) + O(\log n)$ for some polynomial p.*

From these results we can prove the theorems. If we want to prove, for Theorem 3.1, that an NP machine oracle with oracle R_t^{CD} can recognize a set A in MA, then the positive side of the proof is easy: If x is in A, then there exists a machine M and a string y such that a 2/3 fraction of the strings r of length $|x|^c$ makes $M(x, y, r)$ accept. So an NP machine can certainly guess one such pair x, y as a "proof" for $x \in A$. The negative side is harder. We will show that if $x \notin A$ and we substitute for r a string of high enough CD complexity (CND complexity for Theorem 3.2), then *no* y can make $M(x, y, r)$ accept.

To grasp the intuition behind the proof let us look at the much simplified example of a BPP machine M having a 1/3 error probability on input x and a string r of maximal unbounded Kolmogorov complexity. There are $2^{|x|^c}$ possible computations on input x, where $|x|^c$ is the runtime of M. Suppose that M must accept x. Then at most a 1/3 fraction, i.e., at most $2^{|x|^c}/3$ of these computations reject x. Each rejecting computation consists of a deterministic part described by M and x and a set of $|x|^c$ coin flips. Identify such a set of coin flips with a binary string and we have that each rejecting computation uniquely identifies a string of length $|x|^c$. Call this set B. We would like to show by contradiction that a random string cannot be a member of this set, and hence that any random string, used as a sequence of coin flips, leads to a correct result. Any string in B is described by M, x, and an index in B, which has length $\log \|B\| \leq |x|^c - \log 3$. So far there are no grounds for a contradiction since a description consisting of these elements can have length greater than $|x|^c$. However, we can *amplify* the computation of M on input x by repetition and taking majority. Suppose we repeat the computation $|x|^2$ times. This will increase the number of incorrect computations to (at most) $(\frac{8}{9})^{|x|^2/2} 2^{|x|^{c+2}}$. An index in this set has length $|x|^{c+2} - (|x|^2/2)\log\frac{9}{8}$. However, $|x| + |x|^{c+2} - (|x|^2/2)\log\frac{9}{8}$ cannot describe a random string of length $|x|^{c+2}$, which is the length of such a computation.

Unfortunately, in our case the situation is a bit more complicated. The factor 2 in Lemma 3.7 renders standard amplifaction of randomized computation useless. Fortunately, Theorem 3.6 allows for a different type of amplification using much less random bits, so that the same type of argument *can* be used. We will now proceed to show how to fit the amplification given by Theorem 3.6 to our situation.

LEMMA 3.9.

1. *Let L be a language in* MA. *For any constant k and any constant $0 < \alpha \leq \frac{1}{2}$, there exists a deterministic polynomial time bounded machine M such that*

(a) $x \in L \implies \exists^m y \Pr[M(x, y, r) = 1] = 1$;

(b) $x \notin L \implies \forall^m y \Pr[M(x, y, r) = 1] < 2^{-km}$,

where $m = |x|^c$ and r is chosen uniformly at random in $\{0,1\}^{(1+\alpha)(1+k)m}$.

2. *Let L be a language in* AM. *For any constant k and any constant $0 < \alpha \leq \frac{1}{2}$, there exists a deterministic polynomial time bounded machine M such that*

(a) $x \in L \implies \Pr[\exists y M(x, y, r) = 1] = 1$;

(b) $x \notin L \implies \Pr[\exists y M(x, y, r) = 1] < 2^{-km}$,

where $m = |x|^c$ and r is chosen uniformly at random in $\{0,1\}^{(1+\alpha)(1+k)m}$.

Proof.

1. Fürer et al. showed that the fraction 2/3 (see Definition 2.2) can be replaced by 1 in [13]. Now let M_L be the deterministic polynomial time machine corresponding to L in Definition 2.2, adapted so that it can accept with probability 1 if $x \in L$. Assume

M_L runs in time n^c (where $n = |x|$). This means that for M_L the $\exists y$ and $\forall y$ in the definition can be assumed to be $\exists^{n^c} y$ and $\forall^{n^c} y$, respectively. Also, the random string may be assumed to be drawn uniformly at random from $\{0,1\}^{n^c}$.

To obtain the value 2^{-km} in the second item, we use Theorem 3.6 with $\gamma = 2^{-km}$, and $\epsilon = 1/6$. For given x and y let f_{xy} be the FP function that on input z computes $M_L(x,y,z)$. If $|y| = |z| = n^c = m$, then $f_{xy} : \{0,1\}^m \mapsto [0,1]$. We use the oblivious sampler to get a good estimate for Ef_{xy}. That is, we feed a random string of length $(1+\alpha)(1+k)m$ in the oblivious sampler and it returns $d = ((1+k)m/\epsilon)^{c_\alpha}$ sample points $z_1, \ldots, z_d$ on which we compute $\frac{1}{d}\sum_{i=1}^{d} f_{xy}(z_i)$. M is the machine that computes this sum on input x, y, and r and accepts iff its value is greater than $1/2$.

If $x \in L$, there is a y such that $\Pr[M_L(x,y,r) = 1] = 1$. This means $\frac{1}{d}\sum_{i=1}^{d} f_{xy}(z_i) = 1$ no matter which sample points are returned by the oblivious sampler. If $x \notin L$, then $(\forall y)[Ef_{xy} < 1/3]$. With probability $1-\gamma$ the sample points returned by the oblivious sampler are such that $|\frac{1}{d}\sum_{i=1}^{d} f_{xy}(z_i) - Ef_{xy}| \leq \epsilon$, so $\frac{1}{d}\sum_{i=1}^{d} f_{xy}(z_i) > \frac{1}{2}$ with probability $\leq 2^{-km}$.

2. The proof is analogous to the proof of part 1. We just explain the differences. For the 1 in the first item of the claim we can again refer to [13]. In this part M_L is the deterministic polynomial time machine corresponding to the AM-language L and we define the function $f_x : \{0,1\}^m \mapsto [0,1]$ as the function that on input z computes $\exists^{n^c} y M_L(x,y,z) = 1$. Now f_x is an $\mathrm{FP}^{\mathrm{NP}}$ computable function. The sample points $z_1, \ldots, z_d$ that are returned in this case have the following properties. If $x \in L$, then $f_x(z_i) = 1$ no matter which string is returned as z_i. That is, for every possible sample point z_i, there is a y_i such that $M_L(x,y_i,z_i) = 1$. So for any set of sample points $z_1, \ldots, z_d$ that the sampler may return, there exists a $y = \langle y_1, \ldots, y_d \rangle$ such that $M_L(x,y_i,z_i) = 1\ \forall i$. If $x \notin L$, then $f_x(z_i) = 1$ for less than half of the sample points with probability $1-\gamma$. That is,

$$\Pr\left[(\exists y = y_1 \ldots y_d)\left[\frac{1}{d}\sum_{i=1}^{d} M_L(x,y_i,z_i) > \frac{1}{2}\right]\right]$$

is less than 2^{-km}. So if we let $M(x,y,r)$ be the deterministic polynomial time machine that uses r to generate d sample points and then interprets y as $\langle y_1, \ldots, y_d \rangle$ and counts the number of accepts of $M_L(x,y_i,z_i)$ and accepts if this number is greater than $\frac{1}{2}d$, we get exactly the desired result. □

In the next lemma we show that a string of high enough CD^{poly} (CND^{poly}) can be used to *derandomize* an MA (AM) protocol.

LEMMA 3.10.

1. *Let L be a language in* MA *and $0 < \epsilon \leq 1$. There exists a deterministic polynomial time bounded machine M, a polynomial q, $\alpha > 0$, and integers k and c such that for almost all n and every r with $|r| = (1+\alpha)(1+k)n^c$ and $CD^q(r) \geq \epsilon|r|$, $\forall^{=n} x[x \in L \iff \exists y M(x,y,r) = 1]$.*

2. *Let L be a language in* AM *and $0 < \epsilon \leq 1$. There exists a deterministic polynomial time bounded machine M a polynomial q, $\alpha > 0$, and integers k and c such that for almost all n and every r with $|r| = (1+\alpha)(1+k)n^c$ and $CND^q(r) \geq \epsilon|r|$, $\forall^{=n} x[x \in L \iff \exists y M(x,y,r) = 1]$.*

Proof.

1. Choose $\alpha < \frac{\epsilon}{2}$ and $k > \frac{6}{\epsilon - 2\alpha}$. Let M be the deterministic polynomial time bounded machine corresponding to L, k, and α of Lemma 3.9(1). The polynomial n^c will be the time bound of the machine witnessing $L \in$ MA of that same lemma. We

will determine q later, but assume for now that r is a string of length $(1+\alpha)(1+k)n^c$ such that $CD^q(r) \geq \epsilon|r|$, and for ease of notation set $m = n^c$.

Suppose $x \in L$. Then it follows that there exists a y such that for all s of length $(1+\alpha)(1+k)n^c$, $M(x,y,s) = 1$. So in particular it holds that $M(x,y,r) = 1$.

Suppose $x \notin L$. We have to show that $(\forall y)[M(x,y,r) = 0]$. Suppose that this is not true and let y_0 be such that $M(x,y_0,r) = 1$. Define

$$A_{x,y_0} = \{s : M(x,y_0,s) = 1\}.$$

It follows that $A_{x,y_0} \in \mathrm{P}$ by essentially a program that simulates M and has x and y_0 hardwired. (Although A_{x,y_0} is finite and therefore trivially in P it is crucial here that the size of the polynomial program is roughly $|M| + |x| + |y_0|$.) Because of the amplification of the MA protocol we have that

$$\|A_{x,y_0}\| \leq 2^{(1+\alpha)(1+k)m - km}.$$

Since $r \in A_{x,y_0}$ it follows by Lemma 3.7 that there is a polynomial p such that

$$\begin{aligned} CD^p(r) &\leq 2[(1+\alpha)(1+k)m - km] + |x| \\ &\quad + |y_0| + O(\log m) \\ &\leq 2\alpha m + 2\alpha km + 5m. \end{aligned}$$

On the other hand, we chose r such that

$$\begin{aligned} CD^q(r) &\geq \epsilon|r| \\ &= (1+\alpha)(1+k)m\epsilon \\ &> 2\alpha m + 2\alpha km + 5m, \end{aligned}$$

which gives a contradiction for $q \geq p$.

2. Choose $\alpha < \frac{\epsilon}{2}$ and $k > \frac{5}{\epsilon - 2\alpha}$. Let M be the deterministic polynomial time bounded machine corresponding to L, α, and k of Lemma 3.9(2). Again, n^c will be the time bound of the machine now witnessing $L \in \mathrm{AM}$, $m = n^c$, and q will be determined later. Assume for now that r is a string of length $(1+\alpha)(1+k)n^c$ such that $CND^q(r) \geq \epsilon|r|$. Suppose $x \in L$. Then it follows that for all s there exists a y such that $M(x,y,s) = 1$. So in particular there is a y_r such that $M(x,y_r,r) = 1$. Suppose $x \notin L$. We have to show that $\forall y M(x,y,r) = 0$. Suppose that this is not true. Define $A_x = \{s : \exists y M(x,y,s) = 1\}$. Then $A_x \in \mathrm{NP}$ by a program that has x hardwired, guesses a y, and simulates M. Because of the amplification of the AM protocol we have that $\|A_x\| \leq 2^{(1+\alpha)(1+k)m - km}$. Since $r \in A_x$ it follows by Lemma 3.8 that there exists a polynomial p such that

$$\begin{aligned} CND^p(r) &\leq 2[(1+\alpha)(1+k)m - km] + |x| + O(\log m) \\ &\leq 2\alpha m + 2\alpha km + 4m. \end{aligned}$$

On the other hand, we chose r such that

$$\begin{aligned} CND^q(r) &\geq \epsilon|r| \\ &= (1+\alpha)(1+k)m\epsilon \\ &> 2\alpha m + 2\alpha km + 4m, \end{aligned}$$

which gives a contradiction whenever $q \geq p$. □

The following corollary shows that a string of high enough CD^{poly} complexity can be used to derandomize a BPP machine (see also [7, Theorem 8.2]).

COROLLARY 3.11. *Let A be a set in* BPP. *For any $\epsilon > 0$ there exists a polynomial time Turing machine M and a polynomial q such that if $CD^q(r) \geq \epsilon|r|$ with $|r| = q(n)$, then for all x of length n it holds that $x \in A \iff M(x, r) = 1$.*

Proof of Theorem 3.1. Let A be a language in MA. Let q, M, and $q'(n) = (1+\alpha)(1+k)q(n)$ be as in Lemma 3.10(1). The nondeterministic reduction behaves as follows on input x of length n. First guess an s of size $q(q'(n))$ and check that $s \in \mathrm{R}_t^{CD}$. Set $r = s[1..q'(n)]$ and accept iff there exists a y such that $M(x, y, r) = 1$. By Corollary 3.4 it follows that $CD^q(r) \geq |r|/2$ and the correctness of the reductions follows directly from Lemma 3.10(1) with $\epsilon = 1/2$. □

Proof of Theorem 3.2. This follows directly from Lemma 3.10(2). The NP-algorithm is analogous to the one above. □

COROLLARY 3.12. *For $t \in \omega(n \log n)$*

1. BPP *and* $\mathrm{NP}^{\mathrm{BPP}}$ *are included in* $\mathrm{NP}^{\mathrm{R}_t^{CD}}$;
2. $\overline{GI} \in \mathrm{NP}^{\mathrm{R}_t^{CND}}$.

It follows that if $\mathrm{R}_t^{CND} \in \mathrm{NP} \cap \mathrm{coNP}$, then the graph isomorphism (GI) problem is in $\mathrm{NP} \cap \mathrm{coNP}$.

4. Limitations. In the previous section we showed that the set R_t^{CD} is hard for MA under NP reductions. One might wonder whether R_t^{CD} is also hard for MA under a stronger reduction like the deterministic polynomial time Turing reduction. In this section we show that, if true, this will need a nonrelativizing proof. We will derive the following theorem.

THEOREM 4.1. *There is a relativized world where for every polynomial t and $0 < \epsilon \leq 1$,* $\mathrm{BPP} \not\subset \mathrm{P}^{\mathrm{R}_{t,\epsilon}^{CD}}$.

The proof of this theorem is given in Lemma 4.2, which says that the statement of Theorem 4.1 is true in any world where $\mathrm{P}^A = \oplus\mathrm{P}^A$ and $\mathrm{EXP}^{\mathrm{NP}^A} \subseteq \mathrm{NP}^A/poly$, and in Theorem 4.3, which precisely shows the existence of such a world.

LEMMA 4.2. *For any oracle A and $0 < \epsilon \leq 1$ it holds that if* $\mathrm{EXP}^{\mathrm{NP}^A} \subseteq \mathrm{NP}^A/poly$ *and* $\oplus\mathrm{P}^A = \mathrm{P}^A$, *then* $\mathrm{BPP}^A \not\subset P^{\mathrm{R}_{t,\epsilon}^{CD\,A}}$.

Proof. Suppose for a contradiction that the lemma is not true. If $\mathrm{EXP}^{\mathrm{NP}} \subseteq \mathrm{NP}/poly$, then $\mathrm{EXP} \subseteq \mathrm{NP}/poly$, so $\mathrm{EXP} \subseteq \mathrm{PH}$ [27]. Furthermore, if $\mathrm{EXP}^{\mathrm{NP}} \subseteq \mathrm{NP}/poly$, then certainly $\mathrm{EXP}^{\mathrm{NP}} \subseteq \mathrm{EXP}/poly$. It then follows from [9] that $\mathrm{EXP}^{\mathrm{NP}} = \mathrm{EXP}$, so $\mathrm{EXP}^{\mathrm{NP}} \subseteq \mathrm{PH}$.

If $\oplus\mathrm{P} = \mathrm{P}$, then unique-SAT (see [8] for a definition) is in P. Then $\mathrm{NP} = \mathrm{R}$ by [26] and so $\mathrm{NP} \subseteq \mathrm{BPP}$ which implies $\mathrm{PH} \subseteq \mathrm{BPP}$ by [28].

Finally, the fact that unique-SAT is in P is equivalent to the following: for all x and y, $C^{poly}(x|y) \leq CD^{poly}(x|y) + O(1)$, as shown in [12]. We can use the proof of [12] to show that unique-SAT in P also implies that $\mathrm{R}_{t,\epsilon}^{CD} \in \mathrm{coNP}$ for a particular universal machine. (Note that we need only contradict the assumption for one particular type of universal machine.) This then in its turn implies by assumption that BPP and hence $\mathrm{EXP}^{\mathrm{NP}}$ are in P^{NP}. This, however, contradicts the hierarchy theorem for relativized Turing machines [15]. As all parts of this proof relativize, we get the result for any oracle. There's one caveat here. Though $\mathrm{R}_{t,\epsilon}^{CD^A}$ clearly has a meaningful interpretation, to talk about $\mathrm{P}^{\mathrm{R}_{t,\epsilon}^{CD\,A}}$ one must of course allow P to have access to the oracle. It is not clear that P can ask any question if the machine can only ask a question about the random strings. Therefore, one might argue that $\mathrm{P}^{\mathrm{R}_{t,\epsilon}^{CD\,A} \oplus A}$ should

actually be in the statement of the lemma. This does not affect the proof.

Our universal machine, say, U_S, is the following. On input p, x, y, U_S uses the Cook–Levin reduction to produce a formula f on $|x|$ variables with the property that x satisfies f iff p accepts x. Then U_S uses the self-reducibility of f and the assumed polynomial time algorithm for unique-SAT to make acceptance of x unique. That is, first if the number of variables is not equal $|y|$, it rejects. Then, using the well-known substitute and reduce algorithm for SAT, it verifies for $i = 1, \ldots, |x|$ and assignments $x_j = v_j$ successively obtained from the algorithm that the algorithm for unique-SAT precisely accepts $f(v_1 \ldots v_i)$ or rejects if this algorithm accepts both $f(v_1 \ldots v_i)$ and $f(v_1 \ldots (1 - v_i))$. Using this universal machine every program accepts at most one string and therefore $\mathrm{R}^{CD}_{t,\epsilon} \in$ coNP via an obvious predicate. As argued above, this gives us our contradiction. □

Now we proceed to construct the oracle.

THEOREM 4.3. *There exists an oracle A such that* $\mathrm{EXP}^{\mathrm{NP}^A} \subset \mathrm{NP}^A/poly \wedge \oplus\mathrm{P}^A = \mathrm{P}^A$.

Proof. The proof parallels the construction from Beigel, Buhrman, and Fortnow [4], who construct an oracle such that $\mathrm{P}^A = \oplus\mathrm{P}^A$ and $\mathrm{NEXP}^A = \mathrm{NP}^A$. We will use a similar setup.

Let M^A be a nondeterministic *linear* time Turing machine such that the language L^A defined by

$$w \in L^A \Leftrightarrow \#M^A(w) \bmod 2 = 1$$

is $\oplus P^A$ complete for every A.

For every oracle A, let K^A be the linear time computable complete set for NP^A. Let N^{K^A} be a deterministic machine that runs in time 2^n and for every A accepts a language H^A that is complete for $\mathrm{EXP}^{\mathrm{NP}^A}$. We will construct A such that there exists a n^2 bounded advice function f such that for all w

$$\begin{array}{lcll} w \in L^A & \Leftrightarrow & \langle 0, w, 1^{|w|^2}\rangle \in A & \text{(Condition 0),} \\ w \in H^A & \Leftrightarrow & \exists v\ |v| = |w|^2 \text{ and} & \\ & & \langle 1, f(|w|), w, v\rangle \in A & \text{(Condition 1).} \end{array}$$

Condition 0 will guarantee that $\mathrm{P} = \oplus\mathrm{P}$, and Condition 1 will guarantee that $\mathrm{EXP}^{\mathrm{NP}} \subset \mathrm{NP/poly}$.

We use the term 0-strings for the strings of the form $\langle 0, w, 1^{|w|^2}\rangle$ and 1-strings for the strings of the form $\langle 1, z, w, v\rangle$ with $|z| = |v| = |w|^2$. All other strings we immediately put in $\overline{A}$.

First we give some intuition for the proof. M is a linear time Turing machine. Therefore setting the 1-strings forces the setting of the 0-strings. Condition 0 will be automatically fulfilled by just describing how we set the 1-strings because they force the 0-strings as defined by Condition 0.

Fulfilling Condition 1 requires a bit more care since $N^{K^A}(x)$ can query exponentially long and *double* exponentially many 0- and 1-strings. We consider each 1-string $\langle 1, z, w, v\rangle$ as a 0-1 valued variable $y_{\langle z,w,v\rangle}$ whose value determines whether $\langle 1, z, w, v\rangle$ is in A. The construction of A will force a 1-1 correspondence between the computation of $N^{K^A}(x)$ and a low-degree polynomial over variables with values in $GF[2]$. To encode the computation properly we use the fact that the OR function has high degree.

We will assign a polynomial p_z over GF[2] to all of the 0-strings and 1-strings z. We ensure that for all z

1. if $p_z = 1$, then z is in A;
2. if $p_z = 0$, then z is not in A.

First for each 1-string $z = \langle 1, z, w, v\rangle$ we let p_z be the single variable polynomial $y_{\langle z,w,v\rangle}$.

We assign polynomials to the 0-strings recursively. Note that $M^A(x)$ can only query 0-strings with $|w| \leq \sqrt{|x|}$. Consider an accepting computation path π of $M(x)$ (assuming the oracle queries are guessed correctly). Let $q_{\pi,1}, \ldots, q_{\pi,m}$ be the queries on this path and $b_{\pi,1}, \ldots, b_{\pi,m}$ be the query answers with $b_{\pi,i} = 1$ if the query was guessed in A, and $b_{\pi,i} = 0$ otherwise. Note that $m \leq n = |x|$.

Let $\mathcal{P}$ be the set of accepting computation paths of $M(x)$. We then define the polynomial p_z for $z = \langle 0, x, 1^{|x|^2}\rangle$ as follows:

$$p_z = \sum_{\pi\in\mathcal{P}} \prod_{1\leq i\leq m} (p_{q_{\pi,i}} + b_{\pi,i} + 1). \tag{1}$$

Remember that we are working over GF[2] so addition is parity.

Setting the variables $y_{\langle z,w,v\rangle}$ (and thus the 1-strings) forces the values of p_z for the 0-strings. We have set things up properly so the following lemma is straightforward.

LEMMA 4.4. *For each* 0*-string* $z = \langle 0, x, 1^{|x|^2}\rangle$ *we have* $p_z = \#M^A(x) \bmod 2$ *and Condition* 0 *can be satisfied. The polynomial* p_z *has degree at most* $|x|^2$.

Proof. The proof is simple by induction on $|x|$. □

The construction will be done in stages. At stage n we will code all the strings of length n of H^A into A setting some of the 1-strings and automatically the 0-strings and thus fulfilling both Conditions 0 and 1 for this stage.

We will need to know the degree of the multivariate multilinear polynomials representing the *OR* and the *AND* function.

LEMMA 4.5. *The representation of the function* $OR(u_1, \ldots, u_m)$ *and the function* $AND(u_1, \ldots, u_m)$ *as multivariate multilinear polynomials over* GF[2] *requires degree exactly* m.

Proof. Every function over GF[2] has a unique representation as a multivariate multilinear polynomial.

Note that *AND* is just the product and by using De Morgan's laws we can write *OR* as

$$OR(u_1, \ldots, u_m) = 1 + \prod_{1\leq i\leq m} (1 + u_i). \qquad \square$$

The construction of the oracle now treats all strings of length n in lexicographic order. First, in a *forcing phase* in which the oracle is set so that all computations of N^{K^A} remain fixed for future extensions of the oracle, and then in a *coding phase* in which first an advice string is picked and then the computations just forced are coded in the oracle in such a way that they can be retrieved by an NP machine with this advice string. Great care has of course to be taken so that the two phases don't disturb each other and do not disturb earlier stages of the construction.

We first describe the *forcing phase*. Without loss of generality, we will assume that machine N queries only strings of the form $q \in K^A$. Note that since N runs in time 2^n it may query exponentially long strings to K^A.

Let x_1 be the first string of length n. When we examine the computation of $N(x_1)$ we encounter the first query q_1 to K^A. We will try to extend the oracle A to $A' \supseteq A$ such that $q_1 \in K^{A'}$. If such an extension does not exist we may assume that q_1 will

never be in K^A no matter how we extend A in the future. We must, however, take care that we will not disturb previous queries that were forced to be in K^A. To this end we will build a set S containing all the previously encountered queries that were forced to be in K^A. We will only extend A such that $\forall q \in S$ it holds that $q \in K^{A'}$. We will call such an extension an *S-consistent* extension of A.

Returning to the computation of $N(x_1)$ and q_1 we ask whether there is an S-consistent extension of A such that $q_1 \in K^{A'}$. If such an extension exists, we will choose the S-consistent extension of A which adds a minimal number of strings to A and puts q_1 in S. Next we continue the computation of $N^{K^A}(x_1)$ with q_1 answered yes, and otherwise we continue with q_1 answered no. The next lemma shows that a minimal extension of A will never add more than 2^{3n} strings to A.

LEMMA 4.6. *Let S be as above and q be any query to K^A and suppose we are in stage n. If there exists an S-consistent extension of A such that $q \in K^{A'}$, then there exists one that adds at most 2^{3n} strings to A.*

Proof. Let M_K be a machine that accepts K^A when given oracle A and consider the computation of machine $M_K^A(q)$. Let $o_1, \ldots, o_l$ be the smallest set of strings such that adding them to A is an S-consistent extension of A such that $M_K^{A'}(q)$ accepts. ($A' = A \cup \{o_1, \ldots, o_l\}$.) Consider the leftmost accepting path of $M_K^{A'}(q)$ and let $q_1, \ldots, q_{2^n}$ be the queries (both 0- and 1-queries) on that path. Moreover let b_i be 1 iff $q_i \in A'$. Define for q the following polynomial:

$$P_q = \prod_{1 \le i \le 2^n} (p_{q_i} + b_i + 1). \tag{2}$$

After adding the strings $o_1, \ldots, o_l$ to A we have that $P_q = 1$. Moreover by Lemma 4.4 the degree of each p_{q_i} is at most 2^{2n} and hence the degree of P_q is at most 2^{3n}. Now consider what happens when we take out any number of the strings $o_1, \ldots, o_l$ of A' resulting in A''. Since this was a minimal extension of A it follows that $M_K^{A''}(q)$ rejects and that $P_q = 0$. So P_q computes the *AND* on the l strings $o_1, \ldots, o_l$. Since by Lemma 4.5 the degree of the unique multivariate multilinear polynomial that computes the *AND* over l variables over GF[2] is l, it follows that $l \le 2^{3n}$. □

After we have dealt with all the queries encountered on $N^{K^A}(x_1)$ we continue this process with the other strings of length n in lexicographic order. Note that since we only extend A S-consistently we will never disturb any computation of N^{K^A} on lexicographic smaller strings. This follows since the queries that are forced to be yes will remain yes, and the queries that could not be forced with an S-consistent extension will never be forced by any S'-consistent extension of A for $S \subset S'$. After we have finished this process we have to code all the computations of N on the strings of length n. It is easy to see that $\|S\| \le 2^{2n}$ and that at this point by Lemma 4.6 at most 2^{5n} strings have been added to A at this stage. Closing the *forcing phase* we can now pick an advice string and proceed to the *coding phase*. A standard counting argument shows that there is a string z of length n^2 such that no strings of the form $\langle 1, z, w, v\rangle$ have been added to A. This string z will be the advice for strings of length n.

Now we have to show that we can code every string x of length n correctly in A to fulfill Condition 1. We will do this in lexicographic order. Suppose we have coded all strings x_j (for $j < i$) correctly and that we want to code x_i. There are two cases.

Case 1. $N^{K^A}(x_i) = 0$. In this case we put all the strings $\langle 1, z, x_i, w\rangle$ in $\overline{A}$ and thus set all these variables to 0. Since this does not change the oracle it is an S-consistent extension.

Case 2. $N^{K^A}(x_i) = 1$. We properly extend A S-consistently adding only strings of the form $\langle 1, z, x_i, w\rangle$ to A. The following lemma shows that this can always be done. A *proper* extension of A is one that adds one or more strings to A.

LEMMA 4.7. *Let* $\|S\| \leq 2^{2n}$ *be as above. Suppose that* $N^{K^A}(x_i) = 1$. *There exists a proper* S*-consistent extension of* A *adding only strings of the form* $\langle 1, z, x_i, w\rangle$ *with* $|w| = n^2$.

Proof. Suppose that no such proper S-consistent extension of A exists. Consider the following polynomial:

$$Q_{x_i} = 1 - \prod_{q \in S}(P_q), \tag{3}$$

where P_q is defined as in Lemma 4.6, equation (2). Initially $Q_{x_i} = 0$ and the degree of $Q_{x_i} \leq 2^{5n}$. Since every extension of A with strings of the form $\langle 1, z, x_i, w\rangle$ is not S-consistent it follows that Q_{x_i} computes the OR of the variables $y_{\langle z, x_i, w\rangle}$. Since there are 2^{n^2} many of those variables we have by Lemma 4.5 a contradiction with the degree of Q_{x_i}. Hence there exists a proper S-consistent extension of A adding only strings of the form $\langle 1, z, x_i, w\rangle$, and x_i is properly coded into A. □

Stage n ends after coding all the strings of length n.

This completes the proof of Theorem 4.3. □

Theorem 4.3 together with the proof of Lemma 4.2 also gives the following corollary.

COROLLARY 4.8. *There exists a relativized world where* $\mathrm{EXP}^{\mathrm{NP}}$ *is in* BPP *and* $\oplus\mathrm{P} = \mathrm{P}$.

Our oracle also extends the oracle of Ko [17] to CD^{poly} complexity as follows.

COROLLARY 4.9. *There exists an oracle such that* $\overline{\mathrm{R}^{CD}_{t,\epsilon}}$ *for any* $t \in \omega(n\log(n))$ *and* $\epsilon > 0$ *is complete for* NP *under strong nondeterministic reductions and* $\mathrm{P}^{\mathrm{NP}} \neq \Sigma^p_2$.

Proof. The relativized world constructed in the proof of Theorem 4.3 is a world where coNP $\subseteq$ BPP and $C^{poly}(x|y) = CD^{poly}(x|y) + O(1)$. Hence it follows that $\overline{\mathrm{R}^{CD}_{t,\epsilon}} \in$ NP. Moreover Corollary 3.12 relativizes so by item 1 we have that BPP $\subseteq \mathrm{NP}^{\overline{\mathrm{R}^{CD}_{t,\epsilon}}}$. □

As a by-product our oracle shows the following.

COROLLARY 4.10. $\exists A$ *unique-SAT* $^A \in \mathrm{P}^A$ *and* $\mathrm{P}^{\mathrm{NP}^A} \neq \Sigma^{p,A}_2$.

This corollary indicates that the current proof that shows that if unique-SAT $\in$ P, then PH $= \Sigma^p_2$ cannot be improved to yield a collapse to P^{NP} using relativizing techniques.

5. PSPACE and cR^{CS}_s. In this section we further study the connection between cR^{CS}_s and interactive proofs. So far we have established that strings that have sufficiently high CND^{poly} complexity can be used to derandomize an IP protocol that has two rounds in such a way that the role of both the prover and the verifier can be played by an NP oracle machine. Here we will see that this is also true for IP itself provided that the random strings have high enough space bounded Kolmogorov complexity. The set of QBFs is defined as the closure of the set of boolean variables x_i and their negations $\overline{x_i}$ under the operations $\wedge$, $\vee$, $\forall x_i$, and $\exists x_i$. A QBF in which all the variables are quantified is called *closed*. Other QBFs are called open. We need the following definitions and theorems from [24].

DEFINITION 5.1 (see [24]). *A QBF B is called* simple *if in the given syntactic representation every occurrence of each variable is separated from its point of quantification by at most one universal quantifier (and arbitrarily many other symbols).*

For technical reasons we also assume that (simple) QBFs can contain negated variables, but no other negations. This is no loss of generality since negations can be pushed all the way down to variables.

DEFINITION 5.2 (see [24]). *The arithmetization of a (simple) QBF B is an arithmetic expression obtained from B by replacing every positive occurrence of x_i by variable z_i, every negated occurrence of x_i by $(1 - z_i)$, every $\wedge$ by $\times$, every $\vee$ by $+$, every $\forall x_i$ by $\prod_{z_i \in \{0,1\}}$, and every $\exists x_i$ by $\sum_{z_i \in \{0,1\}}$.*

It follows that the arithmetization of a (simple) QBF in closed form has an integer value, whereas the arithmetization of an open QBF is equivalent to a (possibly multivariate) function.

DEFINITION 5.3 (see [24]). *The functional form of a simple closed QBF is the univariate function that is obtained by removing from the arithmetization of B either $\sum_{z_i \in \{0,1\}}$ or $\prod_{z_i \in \{0,1\}}$ where i is the least index of a variable for which this is possible.*

Notation. Let B be a (simple) QBF with quantifiers $Q_1, \ldots, Q_k$. For $i \leq k$ we let $*_i = +$ if $Q_i = \exists$ and $*_i = \times$ if $Q_i = \forall$. Let B be a QBF. Let B' be the boolean formula obtained from B by removing all its quantifiers. We denote by $\tilde{B}$ the arithmetization of B'. It is well known that the language of all true QBFs is complete for PSPACE. The restriction of true QBFs to simple QBFs remains complete.

THEOREM 5.4 (see [24]). *The language of all closed simple true QBFs is complete for* PSPACE *(under polynomial time many-one reductions).*

It is straightforward that the arithmetization of a QBF takes on a positive value iff the QBF is true. This fact also holds relative a not-too-large prime.

THEOREM 5.5 (see [24]). *A simple closed QBF B is true iff there exists a prime number P of size polynomial in $|B|$ such that the value of the arithmetization of B is positive modulo P. Moreover if B is false, then the value of the arithmetization of B is* 0 *modulo* any *such prime.*

THEOREM 5.6 (see [24]). *The functional form of every simple QBF can be represented by a univariate polynomial of degree at most* 3.

THEOREM 5.7 (see [24]). *For every simple QBF there exists an interactive protocol with prover P and polynomial time bounded verifier V such that*

1. *when B is true and P is honest, V always accepts the proof;*
2. *when B is false, V accepts the proof with negligible probability.*

The proof of Theorem 5.7 essentially uses Theorem 5.6 to translate a simple QBF to a polynomial in the following way. First, the arithmetization of a simple QBF B in closed form is an integer value V which is positive iff B is true. Then B's functional form F (recall that this is arithmetization of the QBF that is obtained from B by deleting the first quantifier) is a univariate polynomial p_1 of degree at most 3 which has the property that $p_1(0) *_1 p_1(1) = V$. Substituting any value r_1 in p_1 gives a new integer value V_1, which is of course the same value that we get when we substitute r_1 in F. However, $F(r_1)$ can again be converted to a (low-degree) polynomial by deleting its first $\sum$ or $\prod$ sign, and the above game can be repeated. Thus, we obtain a sequence of polynomials. From the first polynomial in this sequence V can be computed. The last polynomial p_n has the property that $p_n(r_1, \ldots, r_n) = \tilde{B}(r_1, \ldots, r_n)$. Two more things are needed: First, if any *other* sequence of polynomials $q_1, \ldots, q_n$ has the property that $q_1(0) *_1 q_1(1) \neq V$, $q_{i+1}(0) *_{i+1} q_{i+1}(1) = q_i(r_i)$, and $q_n(r_n) = \tilde{B}(r_1, \ldots, r_n)$,

then there has to be some i where $q_i(r_i) = p_i(r_i)$, yet $q_i \neq p_i$. That is, r_i is an intersection point of p_i and q_i. Second, all calculations can be done modulo some prime number of polynomial size (Theorem 5.5). We summarize this in the following observation, which is actually a skeleton of the proof of Theorem 5.7.

OBSERVATION 5.8 (see [24, 22]). *Let B be a closed simple QBF wherein the quantifiers are $Q_1, \ldots Q_n$ if read from left to right in its syntactic representation. Let A be its arithmetization, and let V be the value of A. There exist a prime number P of size polynomial in $|B|$ such that for any sequence $r_1, \ldots, r_n$ of numbers taken from $[1..P]$ there is a sequence of polynomials of degree at most 3 and size polynomial in $|B|$ such that*

1. *$p_1(0) *_1 p_1(1) = V$ and $V > 0$ iff B is true;*
2. *$p_{i+1}(0) *_{i+1} p_{i+1}(1) = p_i(r_i)$;*
3. *$p_n(r_n) = \tilde{B}(r_1, \ldots, r_n)$;*
4. *for any sequence of univariate polynomials $q_1, \ldots, q_n$ such that*
   (a) *$p_1(0) *_1 p_1(1) \neq q_1(0) *_1 q_1(1)$ and*
   (b) *$q_{i+1}(0) *_{i+1} q_{i+1}(1) = q_i(r_i)$ and*
   (c) *$q_n(r_n) = \tilde{B}(r_1, \ldots, r_n)$,*
   there is a minimal i such that $p_i \neq q_i$, yet $p_i(r_i) = q_i(r_i)$. That is, r_i is an intersection point of p_i and q_i.

Where all (in)equalities hold modulo P and hold modulo any *prime of polynomial size if B is false. Moreover, p_i can be computed in space $(|B| + |P|)^2$ from B, P, and $r_1, \ldots, r_{i-1}$.*

From this reformulation of Theorem 5.7 we obtain that for any sequence of univariate polynomials $q_1, \ldots, q_n$ and sequence of values $r_1, \ldots, r_n$ that satisfy items 2 and 3 in Observation 5.8 it holds that either $q_1(0) *_1 q_1(1)$ is the true value of the arithmetization of B, or there is some polynomial q_i in this sequence such that r_i is an intersection point of p_i and q_i (where p_i is as in Observation 5.8). As p_i can be computed in quadratic space from B, P, and $r_1, \ldots, r_{i-1}$ it follows that in the latter case r_i cannot have high space bounded Kolmogorov complexity relative to B, P, $q_1, \ldots, q_i$, $r_1, \ldots, r_{i-1}$. Hence, if r_i *does* have high space bounded Kolmogorov complexity, then r_i is *not* an intersection point, so the first case must hold (i.e., the value computed from q_1 is the true value of the arithmetization of B). The following lemma makes this precise.

LEMMA 5.9. *Assume the following for B, P, n, $q_1, \ldots, q_n$, $r_1, \ldots, r_n$, and $y_1, \ldots, y_n$.*

1. *B is a simple* false *closed QBF on n variables.*
2. *P is a prime number $\geq 2^{|B|}$ of size polynomial in $|B|$.*
3. *$q_1 \ldots q_n$ is a sequence of polynomials of degree 3 with coefficients in $[1..P]$.*
4. *$r_1, \ldots, r_n$ are numbers in $[1..P]$.*
5. *$y_1 = B\#P\#q_1\# \ldots \#q_n$ and $y_{i+1} = y_i\#r_i$.*
6. *$CS^{n^2}(r_i \mid y_i) \geq |P|$.*
7. *$(\forall i \geq 2)[q_{i-1}(r_{i-1}) = q_i(0) *_i q_i(1) \mod P]$.*
8. *$\tilde{B}(r_1, \ldots, r_n) = q_n(r_n) \mod P$.*

Then $q_1(0) *_1 q_1(1) = 0 \mod P$.

Proof. Take all calculations modulo P. Suppose $q_1(0) *_1 q_1(1) \neq 0$. It follows from Observation 5.8 that there exists a sequence $p_1, \ldots, p_n$ satisfying items 1 through 3 of that lemma. Furthermore since B is false $p_1(0) *_1 p_1(1) = 0$ modulo *any* prime, so $p_1(0) *_1 p_1(1) \neq q_1(0) *_1 q_1(1)$. It follows that there must be a minimal i such that $p_i \neq q_i$ and r_i is an intersection point of p_i and q_i. However, p_i can be computed in space $(|B|+|P|)^2$ from B, P, and $r_1, \ldots, r_{i-1}$. As both p_i and q_i have degree at most

3, it follows that $CS^{n^2}(r_i \mid y_i)$ is bounded by a constant—a contradiction. □

This suffices for the main theorem of this section. Let s be any polynomial.

THEOREM 5.10. PSPACE $\subseteq \mathrm{NP}^{\mathrm{cR}_s^{CS}}$.

Proof. We prove the lemma for $s(n) = n^2$, but the proof can by padding be extended to any polynomial. There exists an NP oracle machine that accepts the language of all simple closed true QBFs as follows. On input B first check that B is simple. Guess a prime number $P \geq 2^{|B|}$ of size polynomial in $|B|$, a sequence of polynomials $p_1, \ldots, p_n$ of degree at most 3 and with coefficients in $[1..P]$. Finally guess a sequence of numbers $r_1, \ldots, r_n$ all of size $|P|$. Check that

1. $p_1(0) *_1 p_1(1) > 0$ and
2. $p_{i+1}(0) *_{i+1} p_{i+1}(1) = p_i(r_i)$ and
3. $p_n(r_n) = B(r_1, \ldots, r_n)$ and
4. finally that $(\forall i \leq n)[CS^{n^2}(r_i|y_i) \geq |P|]$.

If B is true, Lemma 5.8 guarantees that these items can be guessed such that all tests are passed. If B is false and no other test fails, then Lemma 5.9 guarantees that $p_1(0) *_1 p_1(1) = 0$, so the first check must fail. □

By the fact that PSPACE is closed under complement and the fact that cR_s^{CS} is also in PSPACE Theorem 5.10 gives that cR_s^{CS} is complete for PSPACE under strong nondeterministic reductions [21].

COROLLARY 5.11. cR_s^{CS} *is complete for* PSPACE *under strong nondeterministic reductions.*

Buhrman and Mayordomo [10] showed that for $t(n) = 2^{n^k}$, the set $R_t^C = \{x : C^t(x) \geq |x|\}$ is *not* hard for EXP under deterministic Turing reductions. In Theorem 5.10 we made use of the relativized Kolmogorov complexity (i.e., $CS^s(x|y)$). Using exactly the same proof as in [10] one can prove that the set $\mathrm{cR}_t^C = \{\langle x, y\rangle : C^t(x|y) \geq |x|\}$ is not hard for EXP under Turing reductions. On the other hand the proof of Theorem 5.10 also works for this set: PSPACE $\subseteq \mathrm{NP}^{\mathrm{cR}_t^C}$. We suspect that it is possible to extend this to show that EXP $\subseteq \mathrm{NP}^{\mathrm{cR}_t^C}$. So far, we have been unable to prove this.

Acknowledgments. We thank Paul Vitányi for interesting discussions and providing the title of this paper. We also thank two anonymous referees, who helped with a number of technical issues that cleared up much of the proofs and who pointed us to more correct references. One of the referees also pointed out Corollary 4.8.

ON THE DETERMINIZATION OF WEIGHTED FINITE AUTOMATA*

ADAM L. BUCHSBAUM†, RAFFAELE GIANCARLO‡, AND JEFFERY R. WESTBROOK§

Abstract. We study the problem of constructing the deterministic equivalent of a nondeterministic weighted finite-state automaton (WFA). Determinization of WFAs has important applications in automatic speech recognition (ASR). We provide the first polynomial-time algorithm to test for the *twins* property, which determines if a WFA admits a deterministic equivalent. We also give upper bounds on the size of the deterministic equivalent; the bound is tight in the case of acyclic WFAs. Previously, Mohri presented a superpolynomial-time algorithm to test for the twins property, and he also gave an algorithm to determinize WFAs. He showed that the latter runs in time linear in the size of the output when a deterministic equivalent exists; otherwise, it does not terminate. Our bounds imply an upper bound on the running time of this algorithm.

Given that WFAs can expand exponentially in size when determinized, we explore why those that occur in ASR tend to *shrink* when determinized. According to ASR folklore, this phenomenon is attributable solely to the fact that ASR WFAs have simple topology, in particular, that they are acyclic and layered. We introduce a very simple class of WFAs with this structure, but we show that the expansion under determinization depends on the transition weights: some weightings cause them to shrink, while others, including random weightings, cause them to expand exponentially. We provide experimental evidence that ASR WFAs exhibit this weight dependence. That they shrink when determinized, therefore, is a result of favorable weightings in addition to special topology. These analyses and observations have been used to design a new, approximate WFA determinization algorithm, reported in a separate paper along with experimental results showing that it achieves significant WFA size reduction with negligible impact on ASR performance.

1. Introduction.

Finite-state machines and their relation to rational functions and power series have been extensively studied [2, 3, 13, 19] and widely applied in fields ranging from image compression [10, 11, 12, 17] to natural language processing [20, 21, 22, 28, 30]. A subclass of finite-state machines, the weighted finite-state automata (henceforth simply weighted finite automata (WFAs)), has recently assumed new importance, because WFAs provide powerful method for representing and manipulating models of human language in automatic speech recognition (ASR) systems [23, 24]. This new research direction also raises a number of challenging algorithmic questions [5].

A WFA is a nondeterministic finite automaton (NFA), A, that has both an alpha-

bet symbol and a weight, from some set K, on each transition. Let $R = (K, \oplus, \otimes, \overline{0}, \overline{1})$ be a semiring. Then A together with R generates a partial function from strings to K: the value of an accepted string is the semiring sum over accepting paths of the semiring product of the weights along each accepting path. A partial function that can be generated this way is a *rational power series* [29]. An example important to ASR is the set of WFAs with the *min-sum semiring*, $(\Re^+ \cup \{0, \infty\}, \min, +, \infty, 0)$, which compute for each accepted string the minimum cost accepting path.

In this paper, we study problems related to the determinization of WFAs. A *deterministic*, or *sequential*, WFA has at most one transition with a given input symbol out of each state. Not all rational power series can be generated by deterministic WFAs. A *determinization algorithm* takes as input a WFA and produces a deterministic WFA that generates the same rational power series, if such a deterministic WFA exists. The importance of determinization to ASR is well established [20, 23, 24].

To the best of our knowledge, Mohri [20] presented the first determinization procedure for WFAs, extending the seminal ideas of Choffrut [8, 9] and Weber and Klemm [31] regarding string-to-string transducers. Mohri gives a determinization procedure with three phases. First, A is converted to an equivalent unambiguous, trim WFA A_t, using an algorithm analogous to one for NFAs [13]. (We define *unambiguous* and *trim* below.) Mohri then gives an algorithm, **TT**, that determines if A_t has the *twins property* (also defined below). If A_t does not have the twins property, then there is no deterministic equivalent of A. If A_t has the twins property, a second algorithm of Mohri's, **DTA**, can be applied to A_t to yield A', a deterministic equivalent of A. Algorithm **TT** runs in $O(m^{4n^2})$ time, where m is the number of transitions and n the number of states in A_t. Algorithm **DTA** runs in time linear in the size of A'. In practice, **DTA** is run directly on A, which is assumed to admit a deterministic equivalent; conversion to A_t and testing for twins are theoretical steps needed to make the procedure well defined. Mohri observes that A' can be exponentially larger than A, because WFAs include classical NFAs. He gives no upper bound on the worst-case state-space expansion, however, and because of the weights on transitions, the classical NFA upper bound does not apply. Finally, Mohri gives an algorithm that takes a deterministic WFA and outputs the minimum-size equivalent, deterministic WFA.

We present several results related to the determinization of WFAs. In section 3 we give the first polynomial-time algorithm to test whether an unambiguous, trim WFA satisfies the twins property. It runs in $O(m^2 n^6)$ time. We then provide a worst-case time complexity analysis of **DTA**. The number of states in the output deterministic WFA is at most $2^{n(2\log n + n^2 \log|\Sigma| + 1)}$, where Σ is the input alphabet. If the weights are rational, this bound becomes $2^{n(2\log n + 1 + \min(n^2 \log|\Sigma|, \rho))}$, where ρ is the maximum bit-size of a weight. When the input WFA is acyclic, the bound becomes $2^{n \log|\Sigma|}$. The acyclic bound holds for real weights, and it is tight (up to constant factors) for any alphabet size. It remains open whether there exists a polynomial-time procedure to determine whether an arbitrary WFA admits a deterministic equivalent, because the determinization process above requires converting a WFA to an unambiguous equivalent prior to testing for twins.

In sections 4–6 we study questions motivated by the use of WFA determinization in ASR [23, 24]. Although determinization causes exponential state-space expansion in the worst case, in ASR systems the determinized WFAs are often *smaller* than the input WFAs [20], and they are seldom very large. This is fortunate, because the performance of ASR systems depends directly on WFA size [23, 24]. Folklore within the ASR community credits this phenomenon entirely to the special topology of ASR

WFAs. (The topology of a WFA is its underlying directed graph and labeling by input symbols, ignoring weights.) ASR WFAs tend to be acyclic and layered. Such a WFA always admits a deterministic equivalent. The role that the transition weights might play in controlling expansion under determinization has not been considered.

In section 4 we study the role of topology in expansion under determinization. We exhibit a class of layered, acyclic WFAs whose minimum equivalent deterministic WFAs are exponentially larger regardless of weighting. The languages accepted by these WFAs are quite unnatural, however.

In section 5 we study the role of transition weights in expansion under determinization. We introduce a class of nondeterministic WFAs, RG. Each WFA in this class has an extremely simple multipartite, acyclic topology, accepts a very trivial language, and in the absence of weights (i.e., with all weights set to zero) has a smaller deterministic equivalent. We show, however, that for any $A \in RG$ and any $i \leq n$, there exists an assignment of weights to the transitions of A such that the minimal equivalent deterministic WFA has $\Theta(2^{i \log |\Sigma|})$ states. This gives a lower bound to match the upper bounds of section 3. Using ideas from universal hashing, we also show that similar results hold when the weights are random i-bit numbers.

This motivates us to examine experimentally the effect of varying weights on actual WFAs from ASR applications. In section 6 we give the results of these experiments. We call a WFA *weight-dependent* if its expansion under determinization is strongly determined by its weights. Most of the examples from ASR were weight-dependent. These experimental results together with the theory we develop show that the folklore explanation is insufficient: ASR WFAs shrink under determinization because both the topology and weighting tend to be favorable.

Some of our results help explain the nature of WFAs from the algorithmic point of view, i.e., how weights assigned to the transitions of a WFA can affect the performance of algorithms manipulating it. Others relate directly to the theory of weighted automata. We have used our results to design an approximate variant of Mohri's determinization algorithm. We describe this algorithm separately [6], along with experimental results showing that it achieves size reductions in ASR language models that significantly exceed those of previous methods, with negligible effects on ASR performance (time and accuracy).

2. Definitions and terminology. Given a semiring $(K, \oplus, \otimes, \overline{0}, \overline{1})$, a *WFA* is a tuple $G = (Q, \bar{q}, \Sigma, \delta, Q_f)$. Q is the set of states, $\bar{q} \in Q$ is the initial state, Σ is the set of symbols, $\delta \subseteq Q \times \Sigma \times K \times Q$ is the set of transitions, and $Q_f \subseteq Q$ is the set of final states. We assume that $|\Sigma| > 1$. A *deterministic*, or *sequential*, WFA has at most one transition $t = (q_1, \sigma, \nu, q_2)$ for any pair (q_1, σ); a *nondeterministic* WFA can have multiple transitions on a pair (q_1, σ), differing in target state q_2. The problems examined in this paper are motivated primarily by ASR applications, which work with the *min-sum semiring*, $(\Re^+ \cup \{0, \infty\}, \min, +, \infty, 0)$, and we therefore limit further discussion to the min-sum semiring. (Some of the algorithms considered use subtraction. To be well defined, therefore, they require a skew field. The min-sum semiring is indeed embedded in a skew field [16].)

Let $\vec{t} = (t_1, \ldots, t_\ell)$ be some sequence of transitions, such that $t_i = (q_{i-1}, \sigma_i, \nu_i, q_i)$; $\vec{t}$ *induces* string $w = \sigma_1 \cdots \sigma_\ell$. String w is *accepted by* $\vec{t}$ if $q_0 = \bar{q}$ and $q_\ell \in Q_f$; w is *accepted by* G if some $\vec{t}$ accepts w. Let $c(t_i) = \nu_i$ be the *weight* of t_i. Then the *weight*

of $\vec{t}$ is

$$c(\vec{t}) = \sum_{i=1}^{\ell} c(t_i).$$

Let $T(w)$ be the set of all sequences of transitions that accept string w. Then the *weight of* w is

$$c(w) = \min_{\vec{t} \in T(w)} c(\vec{t}).$$

The *weighted language* of G is the set $L(G) = \{(w, c(w)) \mid w \text{ is accepted by } G\}$; i.e., the weighted strings accepted by G. Intuitively, the weight on a transition of G can be seen as the "confidence" one has in taking that transition. The weights need not, however, satisfy stochastic constraints, as do the probabilistic automata introduced by Rabin [26].

Fix two states q and q' and a string $v \in \Sigma^*$. Let $c(q, v, q')$ be the minimum of $c(\vec{t})$, taken over all transition sequences $\vec{t}$ from q to q' inducing v. We refer to $c(q, v, q')$ as the *optimal cost* of inducing v from q to q'. We generally abuse notation so that $\delta(q, w)$ can represent the set of states reachable from state $q \in Q$ on string $w \in \Sigma^*$. We extend the function δ to strings in the usual way: $q' \in \delta(q, v), v \in \Sigma^+$, means that there is a sequence of transitions from q to q' inducing v.

The *topology* of G is the projection $\pi_{Q \times \Sigma \times Q}(\delta)$; i.e., the transitions of G without respect to the weights. We also refer to the topology of G as the *graph* underlying G.

A WFA is *trim* if every state appears in an accepting path for some string and no transition is weighted $\overline{0}$ (∞ in the min-sum semiring). A WFA is *unambiguous* if there is exactly one accepting path for each accepted string.

Determinization of G is the problem of computing a deterministic WFA G' such that $L(G') = L(G)$, if such a G' exists. We denote the output of algorithm **DTA** by *dta*(G). We denote the minimal deterministic WFA accepting $L(G)$ by *min*(G), if one exists. We say that G *expands* if *dta*(G) has more states and/or transitions than G.

Let $n = |Q|$ and $m = |\delta|$, and let the *size* of G be $|G| = n + m$. We also use $\#G$ to mean $|Q|$, the number of states of G. We assume that each transition is labeled with exactly one symbol, so $|\Sigma| \leq m$. Recall that the weights of G are nonnegative real numbers. Let C be the maximum weight. In the *general case*, weights are incommensurable real numbers, requiring "infinite precision." In the *integer case*, weights can be represented with $\rho = \lceil \lg C \rceil$ bits. We denote the integral range $[a, b]$ by $[a, b]_Z$. The integer case extends to the case in which the weights are rationals requiring ρ bits. We assume that in the integer and rational cases, weights are normalized to remove excess least-significant zero bits.

For our analyses, we use the RAM model of computation as follows. In the general case, we charge constant time for each arithmetic-logic operation involving weights (which are real numbers). We refer to this model as the $\Re$-RAM [25]. The relevant parameters for our analyses are n, m, and $|\Sigma|$. In the integer case, we also use a RAM, except that each arithmetic-logic operation now takes $O(\rho)$ time. We refer to this model as the $\mathcal{CO}$-RAM [1]. The relevant parameters for the analyses are n, m, $|\Sigma|$, and ρ.

3. Determinization of WFAs.

3.1. An algorithm for testing the twins property.

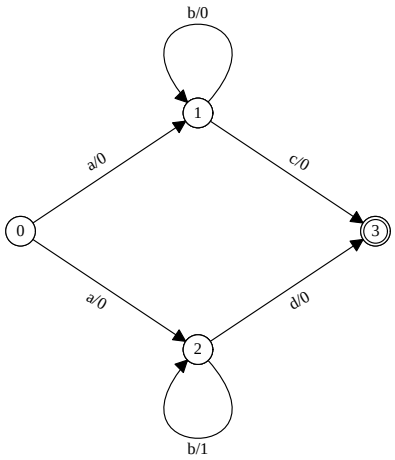

FIG. 1. *A nondeterministic, trim, unambiguous WFA G. Arcs labeled σ/w correspond to transitions labeled σ with weight w. For this and succeeding figures, the start state is the unique source, and final states are denoted by double circles. G accepts the language $\{(ab^n c, 0),\ (ab^n d, n) \mid n \geq 0\}$. States 1 and 2 do not have the twins property: each is reachable from state 0 via string a, yet the costs of the cycles labeled b at each differ. It is easily shown that no deterministic WFA can accept $L(G)$.*

DEFINITION 3.1. *Two states, q and q', of a WFA G are* twins *if $\forall u, v \in \Sigma^*$ such that $q \in \delta(\bar{q}, u)$, $q' \in \delta(\bar{q}, u)$, $q \in \delta(q, v)$, and $q' \in \delta(q', v)$, the following holds: $c(q, v, q) = c(q', v, q')$. G has the* twins property *if all pairs $q, q' \in Q$ are twins.*

That is, if states q and q' are reachable from $\bar{q}$ by a common string, then q and q' are twins only if any string that induces a cycle at each induces cycles of equal optimal cost. Note that two states having no cycle on a common string are twins. Mohri [20, Theorems 11 and 12] proves that any WFA G over the min-sum semiring is determinizable if it has the twins property; furthermore, if G is trim and unambiguous, the twins property becomes a necessary and sufficient condition. For an example of a nondeterminizable WFA, see Figure 1.

The twins property for WFAs is analogous to that defined by Choffrut [8, 9] and (in different terms) by Weber and Klemm [31] to identify necessary and sufficient conditions for a string-to-string transducer to admit a sequential transducer realizing the same rational transduction. In spite of the strong analogy, the proof techniques used for WFAs differ from those used to obtain analogous results for string-to-string transducers. In particular, the efficient algorithm we derive here to test a WFA for twins is not related to the polynomial-time algorithm of Weber and Klemm [31] for testing twins in string-to-string transducers. We reduce the problem of testing the twins property to that of computing shortest paths on some suitably defined graphs, which we introduce next.

Let $T_{\bar{q},\bar{q}}$ be the multipartite acyclic, labeled, weighted graph having $2n^2$ layers and inductively defined as follows. The root vertex $\hat{r}$ is at layer zero and corresponds to $(\bar{q}, \bar{q})$. The vertices at layer one correspond to a subset of $Q \times Q$ obtained as follows: $\hat{r}$ is connected to a vertex u, corresponding to (q_1, q_2), if and only if there are two distinct transitions $t = (\bar{q}, a, c_1, q_1)$ and $t' = (\bar{q}, a, c_2, q_2)$ in G. The arc connecting $\hat{r}$ to u is labeled with $a \in \Sigma$ and has cost $c = c_1 - c_2$. Assume that we have the vertices at layer $i - 1$. The vertices at layer i are obtained as follows. Let u be the vertex

at layer $i-1$ corresponding to $(q_1, q_2) \in Q \times Q$; u is connected to u', corresponding to (q_1', q_2'), at layer i if and only if there are two distinct transitions $t = (q_1, a, c_1, q_1')$ and $t' = (q_2, a, c_2, q_2')$ in G. The arc connecting u to u' is labeled with $a \in \Sigma$ and has cost $c = c_1 - c_2$. This graph has $O(n^4)$ vertices and $O(m^2n^4)$ arcs. Let $(q, q')_i$ denote the vertex corresponding to $(q, q') \in Q \times Q$ at layer i of $T_{\bar{q},\bar{q}}$, if any. Let $RT \subseteq \{(q, q') \mid q \neq q'\}$ be the set of pairs of distinct states of G that are reachable from $(\bar{q}, \bar{q})_0$ in $T_{\bar{q},\bar{q}}$. For each $(q, q') \in RT$, define $T_{q,q'}$ analogously to $T_{\bar{q},\bar{q}}$. Notice that $T_{q,q'}$ has $O(n^4)$ vertices and $O(m^2n^4)$ arcs. We need the following.

LEMMA 3.2. *Fix two distinct states q and q' of G. They can be reached from the initial state $\bar{q}$ of G by the same string $z \in \Sigma^+$ if and only if there exists some string $z' \in \Sigma^i$ for some $1 \leq i \leq 2n^2 - 1$ such that q and q' are both reached from $\bar{q}$ using z'. In that case, there is at least one path in $T_{\bar{q},\bar{q}}$ that goes from $(\bar{q}, \bar{q})_0$ to $(q, q')_i$.*

Proof. Fix a string $z \in \Sigma^+$, and assume that q and q' can be reached from $\bar{q}$ by z. Assume that $|z| > 2n^2 - 1$, or else we are done. Since there are only n^2 distinct pairs of states of G and $|z| > 2n^2 - 1$, there must exist two states q_1 and q_2 and a string $v \in \Sigma^+$ such that (a) $z = xvu$; (b) q_1 (resp., q_2) is on a path from $\bar{q}$ to q (resp., q') inducing z; and (c) $q_1 \in \delta(q_1, v)$ (resp., $q_2 \in \delta(q_2, v)$). But then, $z' = xu$ also reaches both q and q' from $\bar{q}$. If $|z'| \leq 2n^2 - 1$, we are done; otherwise we iterate the argument. The second part of the lemma follows by construction of $T_{\bar{q},\bar{q}}$. □

LEMMA 3.3. *Let G be trim and unambiguous. Fix a string $y \in \Sigma^i$, $1 \leq i \leq 2n^2-1$, and two distinct states q and q' of G. Then $q \in \delta(q, y)$ and $q' \in \delta(q', y)$ if and only if there is exactly one path $\mathbf{p}$ in $T_{q,q'}$ that starts at $(q, q')_0$, ends at $(q, q')_{|y|}$, and induces y. Moreover, the cost of $\mathbf{p}$ is $c(q, y, q') - c(q', y, q')$.*

Proof. We prove the sufficient case; the necessary case should be clear from the construction of $T_{q,q'}$.

First observe that, since G is trim and unambiguous, the following holds: for each string $y \in \Sigma^+$ such that $q \in \delta(q, y)$, there is exactly one cycle starting and ending at q and inducing y.

Let $(q = q_0, q_1, q_2, \ldots, q_{|y|} = q)$ be the unique sequence of states of G originating in q and inducing y in G. Therefore, $c(q, y, q)$ is the sum of the weights on the transitions in that sequence. Similarly define $(q' = q_0', q_1', q_2', \ldots, q_{|y|}' = q')$. By the above construction, there exists a path $\mathbf{p}$ in $T_{q,q'}$, consisting of the vertices $((q, q')_0, (q_1, q_1')_1, \ldots, (q, q')_{|y|})$ and inducing y. This path must be unique, and its cost is $c(q, y, q) - c(q', y, q')$. □

LEMMA 3.4 (see [20, Lemma 2]). *Let G be a trim, unambiguous WFA. G has the twins property if and only if $\forall u, v \in \Sigma^*$, such that $|uv| \leq 2n^2 - 1$, the following holds: when there exist two states q and q' such that* (i) $\{q, q'\} \subseteq \delta(\bar{q}, u)$ *and* (ii) $q \in \delta(q, v)$ *and* $q' \in \delta(q', v)$, *then* (iii) $c(q, v, q) = c(q', v, q')$ *must follow.*

Fix two distinct states q and q' of G. Let $(q, q')_{i_1}, (q, q')_{i_2}, \ldots, (q, q')_{i_s}$, $0 < i_1 < i_2 < \cdots < i_s$, be all the occurrences of (q, q') in $T_{q,q'}$, excluding $(q, q')_0$. This sequence may be empty. A symmetric sequence can be extracted from $T_{q',q}$. We refer to these sequences as the *common cycles sequences* of (q, q'). We say that q and q' satisfy the *local twins property* if and only if (1) their common cycles sequences are empty, or (2) zero is the cost of any shortest path from $(q, q')_0$ to $(q, q')_{i_j}$ in $T_{q,q'}$ and from $(q', q)_0$ to $(q', q)_{i_j}$ in $T_{q'q}$ $\forall\, 1 \leq j \leq s$.

LEMMA 3.5. *Let G be a trim, unambiguous WFA. G satisfies the twins property if and only if* (i) *RT is empty, or* (ii) *all $(q, q') \in RT$ satisfy the local twins property.*

Proof.

⇒) Assume that G satisfies the twins property. If RT is empty, we are done.

Assume then that $RT \neq \emptyset$. The proof is by contradiction. Assume that some $(q, q') \in RT$ does not satisfy the local twins property. The common cycles sequences of (q, q') cannot be empty, or else they would satisfy the local twins property. By assumption, there exists some j for which the cost of some shortest path from $(q, q')_0$ to $(q, q')_{i_j}$ in $T_{q,q'}$ is not zero, while the cost of a shortest path from $(q', q)_0$ to $(q', q)_{i_j}$ in $T_{q'q}$ may be any value, including zero (or vice versa). Fix any such shortest path $\mathbf{p}$ in $T_{q,q'}$. According to Lemma 3.3, $\mathbf{p}$ corresponds to cycles around q and q' that each induce the same string y for some $y \in \Sigma^{i_j}$. Moreover, we must have $c(q, y, q) - c(q', y, q') \neq 0$. By definition of RT, q and q' are each reachable by some string u from the initial state of G. Therefore, G does not satisfy the twins property, which is a contradiction.

$\Leftarrow$) Assume that RT is empty. Then, by Lemma 3.2, no two distinct states q, q' of G can both be reached by some string $z \in \Sigma^+$ from the initial state $\bar{q}$. Therefore, G satisfies the twins property. Assume now that RT is not empty. We have two subcases.

Subcase A. Assume that all states in RT satisfy the local twins property because their common cycles sequences are empty. This implies that all pairs of distinct states reachable from the initial state of G through the same string $z \in \Sigma^+$ do not have any cycles in common inducing identical strings. Thus, G satisfies the twins property.

Subcase B. Assume that some states in RT satisfy the local twins property and their common cycles sequences are not empty. Let RT' be such a set. Assume that G does not satisfy the twins property. We derive a contradiction. Since RT' is not empty, we have that the set of pairs of states for which (i) and (ii) are satisfied in Lemma 3.4 is not empty. But since G does not satisfy the twins property, there must exist two distinct states q and q' and a string $uv \in \Sigma^*$, $|uv| \leq 2n^2 - 1$, such that (i) both q and q' can be reached from the initial state of G through string u; (ii) $q \in \delta(q, v)$ and $q' \in \delta(q', v)$; and (iii) $c(q, v, q) \neq c(q', v, q')$. We now argue that (q, q') must be in RT'. Because $q \neq q'$ and G has only one initial state, we have that $|u| \geq 1$. Thus, $1 \leq |u| \leq 2n^2 - 1$, implying that $(q, q') \in RT$. v cannot be the empty string ϵ because $c(q, \epsilon, q) = c(q', \epsilon, q') = 0$. Since $|uv| \leq 2n^2 - 1$, we have that $1 \leq |v| \leq 2n^2 - 1$. But then, by Lemma 3.3 and (ii) above, we have that $(q, q')_{|v|}$ can be reached from $(q, q')_0$ in $T_{q,q'}$ through the nonempty string v. Therefore, the common cycles sequences of (q, q') cannot be empty, implying that $(q, q') \in RT'$. Without loss of generality, assume that $c(q, v, q) - c(q', v, q') < 0$. Since $1 \leq |v| \leq 2n^2 - 1$, we have by Lemma 3.3 that there is exactly one path $\mathbf{p}$ in $T_{q,q'}$ starting at $(q, q)_0$, ending in $(q, q')_{|v|}$, inducing v, and with cost $c(q, v, q) - c(q', v, q') < 0$. Since $\mathbf{p}$ has negative cost, the cost of the shortest path from $(q, q')_0$ to $(q, q')_{|v|}$ in $T_{q,q'}$ cannot be zero, which contradicts that q and q' satisfy the local twins property and have nonempty common cycles sequences. □

Our algorithm for testing whether a trim, unambiguous WFA has the twins property works as follows. First, compute $T_{\bar{q},\bar{q}}$ and the set RT. Then, for each pair of states $(q, q') \in RT$ that have not been processed yet, compute $T_{q,q'}$ and $T_{q',q}$, extract the common cycles sequences, and compute the single source (from the root) shortest paths to vertices in $T_{q,q'}$ and $T_{q',q}$.

THEOREM 3.6. *Let G be a trim unambiguous WFA. In the general case, whether G satisfies the twins property can be checked in $O(m^2n^6)$ time using the $\Re$-RAM model of computation. In the integer case, the bound becomes $O(\rho m^2 n^6)$ using the $\mathcal{CO}$-RAM model of computation.*

Proof. Lemma 3.5 implies correctness. We now analyze the algorithm, starting with the general case. Recall that each arithmetic-logic operation can be done in

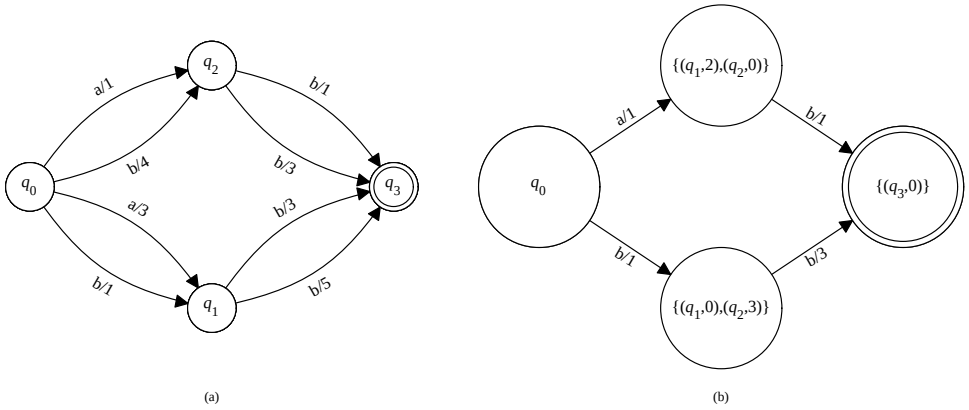

FIG. 2. (a) *A nondeterministic weighted automaton, A. Arcs labeled σ/w correspond to transitions labeled σ with weight w.* (b) *The result of applying* **DTA** *to A. This is derived from Figures* 11 *and* 12 *of Mohri* [20].

constant time. $T_{\bar{q},\bar{q}}$ can be easily obtained in $O(m^2n^4)$ time by visiting the automaton G. Now, visiting $T_{\bar{q},\bar{q}}$, we can obtain the set RT in the same amount of time.

Fix a pair of distinct states q and q' of G. It is sufficient to discuss how to compute shortest paths from the root vertex of $T_{q,q'}$ to the other vertices in the graph. Notice that the edges of $T_{q,q'}$ may have negative cost. However, $T_{q,q'}$ is a multipartite acyclic graph. In that case, it is a simple exercise to show how to perform the required computation in time linear in the size of $T_{q,q'}$, i.e., $O(m^2n^4)$ time. Since $|RT| = O(n^2)$, the total time of the algorithm is $O(m^2n^6)$.

For the integer case, we multiply the above bound by ρ. □

We also mention, omitting the details, that the exponential-time algorithm for testing the twins property originally devised by Mohri [20] can be simplified and implemented to run in pseudopolynomial time in the integer case. The algorithm we devise here is weakly polynomial in the integer case.

3.2. The DTA algorithm. Mohri [20] describes a determinization algorithm for a finite-state automaton with weights drawn from a general semiring. What we refer to as **DTA** is that algorithm restricted to the min-sum semiring. **DTA** is a generalization of the classic power-set construction for finite automata. We describe the algorithm, starting with an example.

Consider the weighted automaton, A, in Figure 2(a). While A is not unambiguous, it has the twins property, and so we can apply **DTA** directly to it, proceeding as follows. From the initial state q_0, we can reach states q_1 and q_2 using the input symbol a. Analogously to the determinization of finite-state automata, we establish a new state $\{q_1, q_2\}$ in A', reachable from q_0 with input symbol a. The transitions to q_1 and q_2, however, have different weights in A. **DTA** selects the smaller weight to be the weight of the transition to $\{q_1, q_2\}$ and records the difference between the two weights in the new state. In the example, the weight of the $q_0 \to q_1$ transition is 3, and that of the $q_0 \to q_2$ transition is 1. Therefore, the new transition to $\{q_1, q_2\}$ gets weight 1, and the difference of $2 = 3 - 1$ is assigned as a *remainder* to component q_1. For completeness, a remainder of $0 = 1 - 1$ is assigned to q_2. The new state is thus encoded as $\{(q_1, 2), (q_2, 0)\}$ in A'. Similarly, from state q_0 in A, we can reach states q_1 and q_2 via symbol b. Again the minimum weight among these transitions is

1, so we assign this weight to the new arc and encode the remainder weights (0 and 3, respectively) in the new state $\{(q_1, 0), (q_2, 3)\}$ in A'.

In general, the states in A' are of the form $\hat{q} = \{(q_{i_1}, r_{i_1}), \ldots, (q_{i_\ell}, r_{i_\ell})\}$. The q_i's are states from A, and the r_i's are called *remainders*. Each such $\hat{q}$ is interpreted as follows. Consider any string $w \in \Sigma^*$ such that there is a (single) path inducing w from the start state, q_0, to $\hat{q}$. As in classical automata determinization, there is at least one path inducing w from q_0 to each q_{i_j} in the nondeterministic input, A. Let c_j be the weight of the minimum weight path inducing w from q_0 to q_{i_j} in A. Let c be the weight of the path from q_0 to $\hat{q}$ in A'. The remainders are constructed so that $r_{i_j} = c_j - c$. In this way, all necessary path length information is encoded into the transition weights and remainders in A'.

Returning to the example, consider state $\{(q_1, 2), (q_2, 0)\}$ in A' and the input symbol b. In A, we can reach state q_3 from both q_1 and q_2. Recalling the above discussion of remainders, we consider the sum of the weight of the transition in A (3 for the $q_1 \to q_3$ transition and 1 for the $q_2 \to q_3$ transition) plus the remainder associated with the original source state encoded in state $\{(q_1, 2), (q_2, 0)\}$ in A'. That is, we consider the sums $3 + 2 = 5$ and $1 + 0 = 1$. We take the minimum among those values, i.e., 1, as the weight of the transition from $\{(q_1, 2), (q_2, 0)\}$ to $\{(q_3, r)\}$ (r to be determined) in A'. Since there is only one destination state (q_3) in A, the remainder r is 0, so we encode the new destination state as $\{(q_3, 0)\}$. Similarly, we construct an arc with weight 3 on symbol b from $\{(q_1, 0), (q_2, 3)\}$ to $\{(q_3, 0)\}$. ($3+0 = 3$, $1+3 = 4$, and we take the minimum, which is 3.) The end result is shown in Figure 2(b).

Generalizing to an arbitrary WFA $G = (Q, \bar{q}, \Sigma, \delta, Q_f)$, the deterministic WFA G' is obtained as follows. The start state of G' is $\{(\bar{q}, 0)\}$, which forms an initial set P. While $P \neq \emptyset$, we remove any state $q = \{(q_1, r_1), \ldots, (q_n, r_n)\}$ from P, where $q_i \in Q$ and $r_i \in \Re^+ \cup \{0, \infty\}$. The remainders encode path length information, as described above. For each $\sigma \in \Sigma$, let $\{q'_1, \ldots, q'_m\}$ be the set of states reachable by σ-transitions out of all the q_i. For $1 \leq j \leq m$, let

$$\rho_j = \min_{1 \leq i \leq n; (q_i, \sigma, \nu, q'_j) \in \delta} \{r_i + \nu\}$$

be the minimum of the weights of σ-transitions into q'_j from the q_i plus the respective r_i. Let $\rho = \min_{1 \leq j \leq m}\{\rho_j\}$. Let $q' = \{(q'_1, s_1), \ldots, (q'_m, s_m)\}$, where $s_j = \rho_j - \rho$ for $1 \leq j \leq m$. If q' is a new state, we add it to P. We add transition (q, σ, ρ, q') to G'. This is the only σ-transition out of state q, so G' is deterministic.

Let $T_G(w)$ be the set of sequences of transitions in G that accept a string $w \in \Sigma^*$; let $\vec{t}_{G'}(w)$ be the (one) sequence of transitions in G' that accepts the same string. Mohri [20] shows that

$$c(\vec{t}_{G'}(w)) = \min_{\vec{t} \in T_G(w)} \{c(\vec{t})\},$$

and thus $L(G') = L(G)$. Moreover, let $T_G(w, q)$ be the set of sequences of transitions in G from state $\bar{q}$ to state q that induce string w. Again, let $\vec{t}_{G'}(w)$ be the (one) sequence of transitions in G' that induces the same string; $\vec{t}_{G'}(w)$ ends at some state $\{(q_1, r_1), \ldots, (q_n, r_n)\}$ in G' such that some $q_i = q$. Mohri [20] shows that

$$c(\vec{t}_{G'}(w)) + r_i = \min_{\vec{t} \in T_G(w,q)} \{c(\vec{t})\}.$$

Thus each remainder r_i encodes the difference between the weight of the shortest path to some state that induces w in A and the weight of the path inducing w in A', as described above. Hence at least one remainder in each state is zero.

3.3. An analysis. We first bound $\#dta(G)$, the number of states in $dta(G)$. The results of section 5 show that our upper bound is tight to within polynomial factors.

LEMMA 3.7. *Assume that G satisfies the twins property. Let $\tilde{R}$ be the set of remainders generated by* **DTA** *when computing $dta(G)$. Let R be the set of remainders r for which the following holds: $\exists w \in \Sigma^*$, $|w| \leq n^2 - 1$, and two states q_1 and q_2, such that $r = |c(\bar{q}, w, q_2) - c(\bar{q}, w, q_1)|$. Then $\tilde{R} \subseteq R$.*

Proof. Let R' be the set of remainders r' such that $\exists w' \in \Sigma^*$ and two states q_1 and q_2 such that $r' = |c(\bar{q}, w', q_2) - c(\bar{q}, w', q_1)|$. Consider a state-remainder tuple in $dta(G)$ reached by w' from the initial state, and assume that q_1 is the optimal state in that tuple, i.e., the one with zero remainder. Then the remainder associated to q_2 is r'. Thus, $\tilde{R} \subseteq R'$. We next show that $R = R'$.

Clearly $R \subseteq R'$. To prove the other inclusion we only need to show that the remainder r generated by any string of length at least n^2 is generated by a string of length at most $n^2 - 1$. Let $\mathbf{p_1}$ and $\mathbf{p_2}$ be the paths of minimum cost in G, starting at $\bar{q}$, ending at q_1 and q_2, respectively, and each inducing u. Because $|u| \geq n^2$ and there are only n^2 distinct pairs of states in G, there exist two (not necessarily distinct) states, q_1' and q_2', in $\mathbf{p_1}$ and $\mathbf{p_2}$, respectively, and a partition of $u = xvz$, $v \in \Sigma^+$, such that $\{q_1', q_2'\} \subseteq \delta(\bar{q}, x)$, $q_1' \in \delta(q_1', v)$ and $q_2' \in \delta(q_2', v)$ (there are cycles at q_1' and q_2' inducing v), and, finally, $q_1 \in \delta(q_1', z)$ and $q_2 \in \delta(q_2', z)$. Since q_1' and q_2' are twins, we have that $|c(\bar{q}, u, q_1) - c(\bar{q}, u, q_2)| = |c(\bar{q}, \bar{u}, q_1) - c(\bar{q}, \bar{u}, q_2)|$, where $\bar{u} = xz$ is in Σ^+ and $|\bar{u}| < |u|$. If $\bar{u}$ is of the required length, we are finished; otherwise, we iterate the argument. □

THEOREM 3.8. *Let G be a WFA satisfying the twins property. In the general case, $\#dta(G) < 2^{n(2\log n + n^2 \log|\Sigma| + 1)}$; in the integer (or rational) case, $\#dta(G) < 2^{n(2\log n + 1 + \min(n^2 \log|\Sigma|, \rho))}$; and if G is acyclic, $\#dta(G) < 2^{n \log|\Sigma|}$ independent of any assumptions on weights. The acyclic bound is tight (up to constant factors) for any alphabet.*

Proof. Let $\tilde{R}$ be the set of remainders in $dta(G)$. Each state in $dta(G)$ is an i-tuple of states from G with a corresponding i-tuple of remainders. In the worst case, each i-state tuple from G will appear in $dta(G)$, and there are $|\tilde{R}|^i$ distinct i-tuples of remainders it can assume. (This over-counts by including tuples without any zero remainders.) Therefore,

$$\#dta(G) \leq \sum_{i=1}^{n} \binom{n}{i} |\tilde{R}|^i \leq (2|\tilde{R}|)^n.$$

Let R be the set of remainders r for which the following holds: $\exists w \in \Sigma^*$, $|w| \leq n^2 - 1$, and two states q_1 and q_2, such that $r = |c(\bar{q}, w, q_2) - c(\bar{q}, w, q_1)|$. By Lemma 3.7, $\tilde{R} \subseteq R$, so we can bound $|\tilde{R}|$ in different settings by bounding $|R|$.

General case. The weights on the transitions of G are incommensurable real numbers, i.e., they require "infinite precision" as binary numbers. Since each string induced by G corresponds to at least one path in G, we have by definition of R that the cardinality of this set is bounded by the number of distinct pairs of paths of length at most $n^2 - 1$. There are at most $\sum_{i=1}^{n^2-1} m^i < m^{n^2}$ such paths, where m is the number of edges in G. Therefore $|R| < m^{2n^2}$. On the other hand, the number of strings of length at most $n^2 - 1$ is bounded by $|\Sigma|^{n^2}$. Since each of those strings can reach a pair of (not necessarily distinct) states in G, we have that $|R| < n^2|\Sigma|^{n^2}$. But $|\Sigma| \leq m$, so $n^2|\Sigma|^{n^2}$ is a tighter bound on $|R|$. Our first estimate follows.

Integer case. The weights are nonnegative integers. Fix a state q and a string w that reaches q from the initial state. Then $c(\bar{q}, w, q)$ is in $[0, (n^2-1)C]_Z$. Therefore, the remainders in R must also be in that range. It follows that $(2|R|)^n < (2n^2C)^n = 2^{n(2\log n+\rho+1)}$. Since the topological bound on $|R|$ we derived for the general case does not depend on the magnitude of weights and it holds also for the case we are considering, we have that $(2|R|)^n < 2^{n(2\log n+1+\min(n^2\log|\Sigma|,\rho))}$. Our second estimate follows. Notice that this result also holds for the case in which the weights are rational numbers represented by ρ bits.

Acyclic case. The graph underlying G is acyclic. Thus, each string induced by G is of length at most $n-1$. There are $|\Sigma|^n = 2^{n\log|\Sigma|}$ such strings. Each of the strings induced by G will reach exactly one state in $dta(G)$ (which is a deterministic automaton). Therefore, the number of states of $dta(G)$ is bounded by $2^{n\log|\Sigma|}$. Tightness follows from Theorem 5.10. □

Processing each tuple of state-remainders generated by **DTA** takes $O(|\Sigma|(n+m))$ time, excluding the cost of arithmetic and min operations involving two weights and/or remainders, yielding the following.

THEOREM 3.9. *Let G be a WFA satisfying the twins property.* **DTA** *takes $O(|\Sigma|(n+m)\cdot \#dta(G))$ time using the $\Re$-RAM and $O(\rho|\Sigma|(n+m)\cdot \#dta(G))$ time using the $\mathcal{CO}$-RAM. For the general case, using the $\Re$-RAM, the time is $O(|\Sigma|(n+m)2^{n(2\log n+n^2\log|\Sigma|+1)})$. For the (rational or) integer case, using the $\mathcal{CO}$-RAM, the time is $O(\rho|\Sigma|(n+m)2^{n(2\log n+1+\min(n^2\log|\Sigma|,\rho))})$. For the acyclic case, the time is $O(|\Sigma|(n+m)2^{n\log|\Sigma|})$ using the $\Re$-RAM and $O(\rho|\Sigma|(n+m)2^{n\log|\Sigma|})$ using the $\mathcal{CO}$-RAM.*

Theorems 3.8 and 3.9 do not require G to be unambiguous. **DTA** terminates within the stated resource bounds on any WFA that has the twins property. Consider in the integer case the interplay between the growth of G when determinized, the time complexity of the algorithm, and the magnitude of the weights.

In the acyclic case first, we have that $\#G \le \mathcal{S} \le 2^{n\log|\Sigma|}$, where $\mathcal{S}$ is the number of distinct strings accepted by G. In some sense, $\mathcal{S}$ gives the "expressive power" of G, i.e., how much information is compactly stored in G with the aid of nondeterminism. For small weights, i.e., $\rho \le n\log|\Sigma|$, the worst-case time complexity of the algorithm is dominated by the number of strings accepted by G. Therefore, we can actually "uncompact" some or all of the information contained in G by eliminating nondeterminism. On the other hand, when $\rho > n\log|\Sigma|$, the bigger weights add no information and actually slow down the algorithm to the point that, for very large weights, the arithmetic and logic operations dominate the cost of the entire algorithm.

For the cyclic case, the situation is analogous, with weights playing an even more prominent role. Let $\rho_{max} = n^2\log|\Sigma|$. For $\rho < \rho_{max}$, the estimate of $\#dta(G)$ depends on ρ, although we do not know how tight that estimate is. For $\rho \gg \rho_{max}$, the expansion of G depends only on its topology, but the large weights slow down the algorithm.

3.4. Computing a worst-case weighting. The results of section 3.3 can be used to generate hard instances for any determinization algorithm. Let G be a WFA. A *reweighting function* (or simply *reweighting*) f is such that, when applied to G, it preserves the topology and labeling of G, but possibly changes the weights on its transitions. We want to determine a reweighting f such that $min(f(G))$ exists and $\#min(f(G))$ is maximized among reweightings for which $min(f(G))$ exists. We restrict attention to the integer case and, without loss of generality, we assume that G is trim and unambiguous.

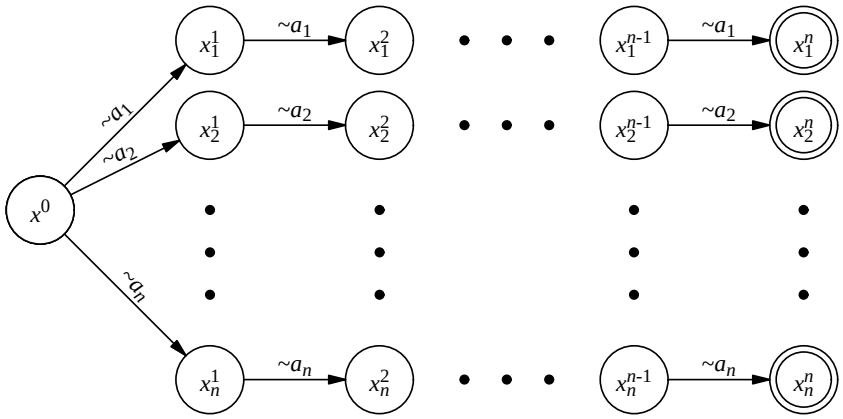

FIG. 3. *A nondeterministic finite-state automaton accepting language* $L = \bigcup_{i=1}^{n} (\Sigma - \{a_i\})^n$. *Arcs labeled* $\tilde{}a_i$ *denote transitions on all symbols in* $\Sigma - \{a_i\}$.

Theorem 3.8 shows that for weights to have an effect on the growth of $dta(G)$, it must be that $\rho \leq n^2 \log |\Sigma|$. Set $\rho_{max} = n^2 \log |\Sigma|$. To find the required reweighting, we simply consider all possible weight assignments to G satisfying the twins property and requiring at most ρ_{max} bits, choosing the one that leads to the minimum deterministic equivalent of maximum size. There are $(2^{\rho_{max}})^m = 2^{m\rho_{max}}$ possible reweightings, and it takes $2^{O(n(2\log n + (n^2 \log |\Sigma|)))}$ time to compute the size expansion or decide that the resulting machine cannot be determinized. The total time is thus bounded by $2^{O(n(2\log n + (n^2 \log |\Sigma|)) + m\rho_{max})}$.

4. Hot automata. This section provides a family of acyclic, multipartite WFAs that are *hot*: when determinized, they expand independently of the weights on their transitions. Given some alphabet $\Sigma = \{a_1, \ldots, a_n\}$, consider the language

$$L = \bigcup_{i=1}^{n} (\Sigma - \{a_i\})^n ;$$

i.e., the set of all n-length strings that do not include all symbols from Σ. It is simple to obtain an acyclic, multipartite NFA H of poly(n) size that accepts L. (See Figure 3.) One can also show that the minimal DFA accepting L has $\Theta(2^{n+\log n})$ states. Furthermore, we can construct H so that these bounds hold for a *binary* alphabet: encode the symbols in Σ as binary strings of length $\log n$, and replace arcs in the above NFA with n-vertex, $(\log n)$-depth trees appropriately. H corresponds to a WFA with all arcs weighted identically. Since acyclic WFAs satisfy the twins property, they can always be determinized. Altering the weights can only increase the expansion.

Continuing, Kintala and Wotschke [18] provide a set of NFAs that produces a hierarchy of expansion factors when determinized. Consider the set of languages

$$L_{h,k} = \{x1y \mid x, y \in \{0,1\}^*; |x| \leq k-1; |y| = k; x \text{ has at most } h \text{ 1's in it}\}$$

for $k \geq 1$, $h < k$. They show that for each $L_{h,k}$, there is an $O(k^2)$-state acyclic (but not multipartite) NFA that accepts $L_{h,k}$, yet any DFA accepting $L_{h,k}$ must have at least $\sum_{i=0}^{2\log h} \binom{k}{i}$ states. These provide additional examples of hot WFAs.

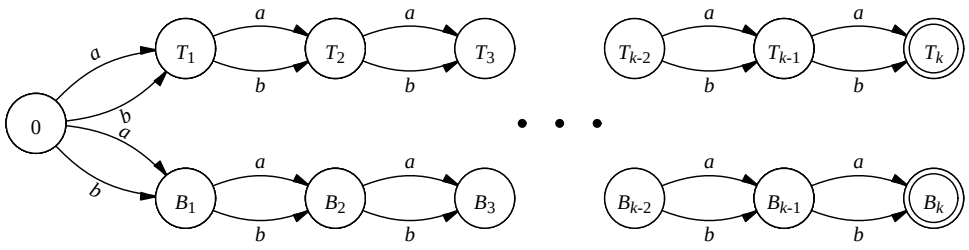

FIG. 4. *Topology of the k-layer rail graph.*

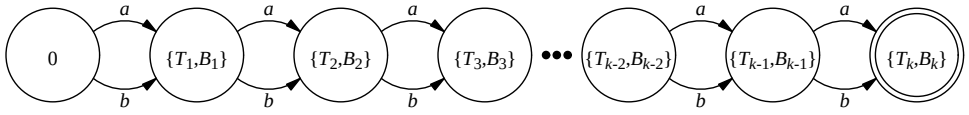

FIG. 5. *The result of determinizing $RG(k)$ when all arc weights are* 0*. In the result, all arcs are again weighted* 0*, and the remainders in the vertices are all* 0*; these values are omitted from the figure.*

5. Weight-dependent automata. In this section we address the effect of weights on the size of the deterministic equivalent of an input WFA. We study a simple family of WFAs with multipartite, acyclic topology. When the arcs are all weighted zero, all WFAs in this family shrink when determinized. We show, however, that even though the topology is by itself very benign, certain weightings can cause exponential increases in size when the WFA is determinized. This study is related in spirit to works that measure amounts of nondeterminism and ambiguity in finite automata [14, 15, 18]. We first discuss the case of a binary alphabet and then generalize to arbitrary alphabets. In this section, we use the terms automaton and graph interchangeably.

5.1. The rail graph. We denote by $RG(k)$ the *k-layer rail graph*. See Figure 4. $RG(k)$ has $2k+1$ vertices, which we denote by $\{0, T_1, B_1, \ldots, T_k, B_k\}$. There are arcs $(0, T_1, a)$, $(0, T_1, b)$, $(0, B_1, a)$, $(0, B_1, b)$, and then, for $1 \leq i < k$, arcs (T_i, T_{i+1}, a), (T_i, T_{i+1}, b), (B_i, B_{i+1}, a), and (B_i, B_{i+1}, b). (It should be clear from Figure 4 that T stands for "top" and B for "bottom.")

Note that $RG(k)$ is $(k+1)$-partite and also has fixed in- and out-degrees. (All vertices have in- and out-degrees 2, except the root, which has in-degree 0 and out-degree 4, and the vertices T_k and B_k, which have out-degree 0.) If we consider the strings induced by paths from 0 to either T_k or B_k, then the language of $RG(k)$ is the set of strings $L_{RG}(k) = \{a, b\}^k$. The only nondeterministic choice is at the state 0, where either the top or bottom rail may be selected. Hence a string w can be accepted by one of two paths: one following the top rail and the other the bottom rail.

Technically, the rail graph is ambiguous. We can easily disambiguate $RG(k)$ by adding transitions from T_k and B_k, each on a distinct symbol, to a new final state. Our results extend to this case. For clarity of presentation, however, we discuss the ambiguous rail graph.

The rail graph is weight-dependent. In section 5.2 we provide weightings such that **DTA** produces a trivial $(k+1)$-vertex series-parallel graph. (See Figure 5 for an example.) On the other hand, in section 5.3 we exhibit weightings for the rail graph such that, when input to **DTA**, we get an exponential increase in the number of states. (See Figures 6 and 7 for an example.) Notice that we cannot get more

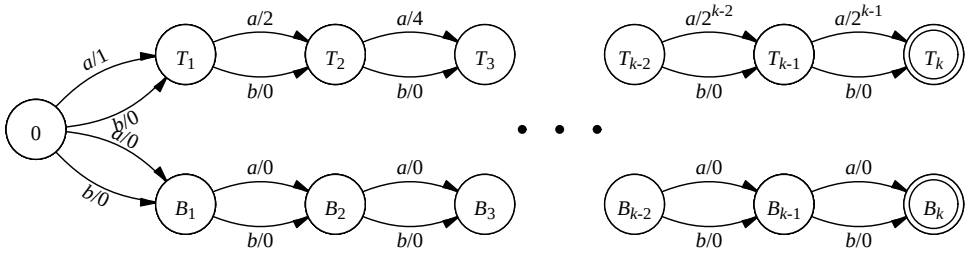

FIG. 6. *"Worst-case" weighting of $RG(k)$. Arc label σ/w means the arc is labeled with symbol σ and has weight w.*

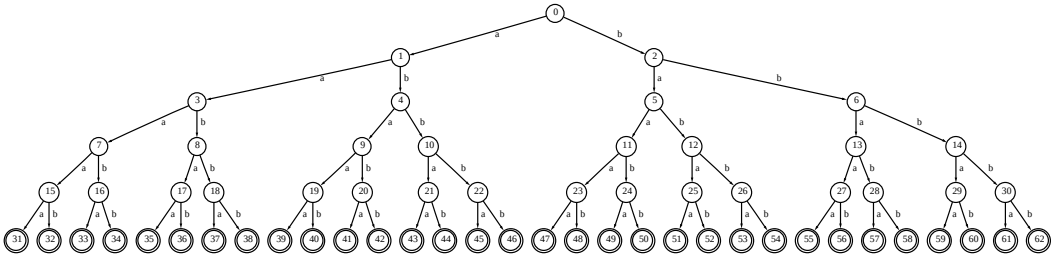

FIG. 7. *Result of determinizing $RG(5)$, weighted as in Figure* 6. *States have been renamed. All arcs are weighted* 0. *The remainders are not shown.*

than 2^k vertices, one per string in $L_{RG}(k)$, in the last layer of the determinized graph, and thus the weighting in Figure 6 is in some sense worst case. In that section we also explore the relationship between the magnitude of the weights and the amount of expansion that is possible. In section 5.4, we show that random weightings induce the behavior of worst-case weightings. We discuss variants of the rail graph in section 5.5, and finally, in section 5.6 we generalize the rail graph to arbitrary alphabets.

5.2. A framework for examining weightings of $RG(k)$. Consider determinizing $RG(k)$ with **DTA**. The set of states reachable on any string $w = \sigma_1 \cdots \sigma_j$ of length $j \leq k$ is $\{T_j, B_j\}$. For a given weighting function c, let $c_T(w)$ denote the cost of accepting string w if the top path is taken; i.e.,

$$c_T(w) = c(0, \sigma_1, T_1) + \sum_{i=1}^{j-1} c(T_i, \sigma_{i+1}, T_{i+1}).$$

Analogously define $c_B(w)$ to be the corresponding cost along the bottom path. Let $R(w)$ be the *remainder vector* for w, which is a pair of the form $(0, c_B(w) - c_T(w))$ or $(c_T(w) - c_B(w), 0)$. A state at layer $0 < i \leq k$ in the determinized WFA is labeled $(\{T_i, B_i\}/R(w))$ for any string w leading to that state; i.e., all strings leading to a particular state induce the same remainder vector. Two strings w_1 and w_2 of identical length lead to distinct states in the determinized version of the rail graph if and only if $R(w_1) \neq R(w_2)$.

It is convenient simply to write $R(w) = c_T(w) - c_B(w)$. The sign of $R(w)$ then determines which of the two forms $(0, x)$ or $(x, 0)$ of the remainder vector occurs.

Suppose that w has length j and can be written $w'\sigma$, where $\sigma \in \{a, b\}$. Let $r_i^T(\sigma)$ denote the weight on the (top) arc labeled σ into vertex T_i and $r_i^B(\sigma)$ denote the weight on the (bottom) arc labeled σ into vertex B_i. Then we can write $R(w) =$

$R(w') + r_j^T(\sigma) - r_j^B(\sigma)$. Abbreviating $r_i^T(\sigma) - r_i^B(\sigma)$ by $\delta_i(\sigma)$, we have

$$R(w) = \sum_{i=1}^{j} \delta_i(\sigma_i).$$

The rail graph with a specific weighting can also be regarded as a function that hashes a k-bit string w into a number $R(w)$. Define symbol a to be 0 and symbol b to be 1, so that a string w can be viewed as a sequence of bits $b_1, \ldots, b_k$. We can write

$$R(b_1, \ldots, b_k) = R(b_1, \ldots, b_{k-1}) + \delta_k(b_k).$$

Also, we can write $\delta_k(b_k) = b_k \cdot \delta_k(1) + (1 - b_k)\delta_k(0)$. Rearranging gives $\delta_k(b_k) = \delta_k(0) + b_k(\delta_k(1) - \delta_k(0))$. Summing over all i gives

$$R(w) = \sum_{i=1}^{k} (\delta_i(0) + b_i(\delta_i(1) - \delta_i(0))).$$

Alternatively,

$$R(w) = R_a + \sum_{i=1}^{k} b_i(\delta_i(1) - \delta_i(0)), \tag{1}$$

where $R_a = \sum_{i=1}^{k} \delta_k(0)$ is fixed for a given weighting function on $RG(k)$.

THEOREM 5.1. *There is a reweighting f such that both dta($f(RG(k))$) and min($f(RG(k))$) realize the topology of the $(k+1)$-vertex trivial series-parallel graph (exemplified in Figure 5).*

Proof. Any weighting in which $\delta_i(a) = \delta_i(b)$ for $i = 1$ to k suffices, since in this case $R(w_1) = R(w_2)$ for all pairs of strings $\{w_1, w_2\}$. In particular, giving zero weights suffices. □

5.3. Worst-case weightings of $RG(k)$. See Figures 6 and 7.

THEOREM 5.2. *For any $j \in [0, k]_Z$ there exists a reweighting f such that dta($f(RG(k))$) has the following form: Layers 0 through j form the complete binary tree on $2^{j+1} - 1$ vertices, and the remaining layers $j+1$ through k consist of trivial series-parallel graphs, each rooted at a leaf of the tree.*

Proof. Choose any weighting such that $\delta_i(a) = 2^{i-1}$ and $\delta_i(b) = 0$ for $1 \le i \le j$, and let $\delta_i(a) = \delta_i(b) = 0$ for $j < i \le k$. Consider a pair of strings w_1, w_2 of identical length that differ in position $i' \le j$. Let $\sigma_i^1 = 1$ if the ith symbol of w_1 is a and $\sigma_i^1 = 0$ otherwise; similarly define σ_i^2 with respect to w_2. Then we can write $R(w_1) = \sum_{i=1}^{j} \sigma_i^1 2^{i-1}$ and $R(w_2) = \sum_{i=1}^{j} \sigma_i^2 2^{i-1}$. Since $\sigma_{i'}^1 \neq \sigma_{i'}^2$, $R(w_1)$ must differ from $R(w_2)$. Hence the two strings must lead to different states. If on the other hand they differ only in positions $i' > j$ they will lead to the same state. There are 2^i strings that differ in positions 1 through i; thus for $i \le j$, there are 2^i distinct vertices in the ith layer of the graph. Since each vertex has out-degree 2, one arc for each symbol, the graph must have the desired form. □

Note that if we set all weights on the bottom rail to zero, and the weights $r_i^T(a) = 2^{i-1}$ and $r_i^T(b) = 0 \; \forall \; 1 \le i \le k$, we get a weighting that yields a complete binary tree of depth k when **DTA** is applied. It is easy to show that the *minimum* deterministic graph preserving shortest paths, however, consists of a trivial series-parallel graph in which all edges have weight zero, corresponding to the lower rail. We can remedy this by choosing weights more judiciously.

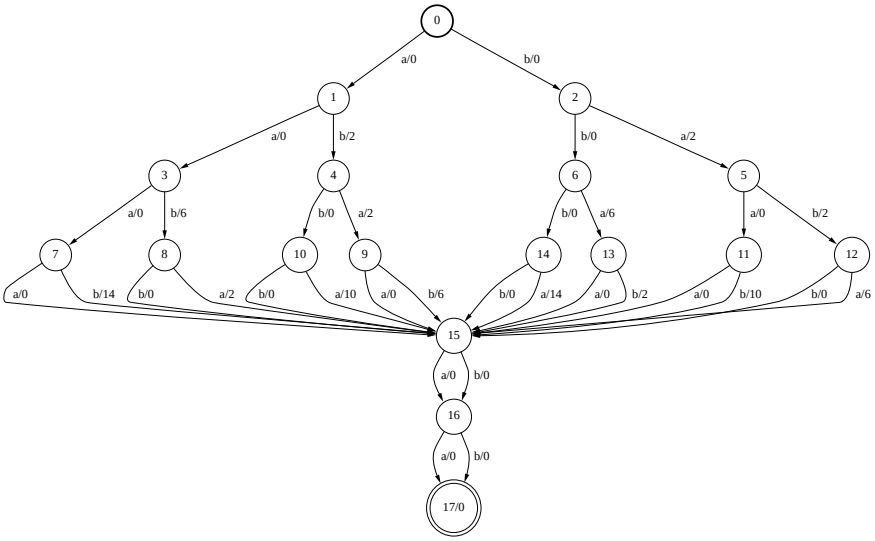

FIG. 8. *Result of minimizing dta*$(RG(6))$*, weighting* $RG(6)$ *as follows:* $r_i^T(a) = r_i^B(b) = 2^i$ *for* $1 \le i \le 4$*; all other weights were* 0*. States have been renamed, and remainders are not shown.*

THEOREM 5.3. *For any* $j \in [0,k]_Z$ *there is a reweighting* f *such that both* $dta(f(RG(k)))$ *and* $min(f(RG(k)))$ *have the following form: Layers* 0 *through* $j-1$ *form the complete binary tree on* $2^j - 1$ *vertices, and the remaining layers* j *through* k *form a trivial series-parallel graph with incoming arcs to the layer-*j *vertex from each vertex at layer* $j-1$.

See Figure 8. Theorem 5.3 is generalized by Theorem 5.10, and therefore we omit its proof here. Theorems 5.2 and 5.3 show that the bound obtained in Theorem 3.8 for the acyclic case is tight for binary alphabets.

We now address the sensitivity of the size expansion to the magnitude of the weights. Note that $RG(k)$ has $2k+1$ vertices and $4k$ arcs, but we use $\Theta(k)$ bits to encode the weight of each arc in the proofs of Theorems 5.2 and 5.3; the input size of the WFA is thus $n = \Theta(k^2)$ bits. The determinized WFA has $2^{k+1} - 1$ states and $2^{k+1} - 2$ transitions. Again we need $\Theta(k)$ bits to encode the weight of each transition, so the bit size of the determinized WFA is $\Theta(k2^k)$, or $2^{\Theta(\sqrt{n})}$ bits. So while the determinized WFA has exponentially more states than the original WFA, the size expansion in bits, while superpolynomial, is not exponential. We argue that exponential state-space expansion requires exponentially big weights for the rail graph.

THEOREM 5.4. *Let* f *be a reweighting. If* $\#dta(f(RG(k))) = \Omega(2^k)$*, then* $\Omega(k^2)$ *bits are required to represent* $f(RG(k))$.

Proof. Consider the $\Omega(2^k)$ vertices at depth k in the determinized graph. Each such state is labeled by a distinct $R(w)$ for some string $w = \sigma_1 \cdots \sigma_k$. Hence if there are $\Omega(2^k)$ states in $dta(f(RG(k)))$, there must be $\Omega(2^k)$ distinct values of $R(w)$. In addition, there must be $\Omega(2^k)$ distinct values of the absolute value of $R(w)$.

Recalling the formulation of $R(w)$ from (1), there can be at most $2^{k'}$ distinct values of $R(w)$, where k' is the number of distinct values of $(\delta_i(1) - \delta_i(0))$. Each value may be included in the sum or not, and at best a choice of inclusions and exclusions will lead to a unique sum. Therefore, the assumption of $\Omega(2^k)$ distinct remainders implies there must be $\Omega(k)$ distinct values of the $(\delta_i(1) - \delta_i(0))$.

Now ignore the $\lfloor \frac{k}{2} \rfloor$ low-order bits of the absolute values of the remainders, and consider only the remaining high-order bits. There must be $\Omega(2^{\lceil \frac{k}{2} \rceil})$ distinct values induced by the high-order bits, or else there cannot be $\Omega(2^k)$ distinct values overall. By the same argument as above, there must be $\Omega(\lceil \frac{k}{2} \rceil)$ distinct values of the $(\delta_i(1) - \delta_i(0))$ that affect the high-order bits of a *large* remainder, i.e., one with one of its high-order $\lceil \frac{k}{2} \rceil$ bits set to 1.

For a particular $(\delta_i(1) - \delta_i(0))$ to affect a high-order bit of a large remainder, $(\delta_i(1) - \delta_i(0))$ must have a nonzero bit at least as high as position $\lceil \frac{k}{2} \rceil - \log k$. This is only true if one of the four arc weights for layer i has a nonzero bit at least that high. Therefore, $\Omega(k)$ arc weights require some nonzero bit at least as high as position $\lceil \frac{k}{2} \rceil - \log k$. Hence $\Omega(k^2)$ bits are required to represent all the arc weights. □

COROLLARY 5.5. *Let f be a reweighting. If $\#min(f(RG(k))) = \Omega(2^k)$, then $\Omega(k^2)$ bits are required to represent $f(RG(k))$.*

Proof. Theorem 5.4 applies, because $\#min(f(RG(k))) = \Omega(2^k)$ implies that $\#dta(f(RG(k))) = \Omega(2^k)$. □

Finally, consider the following analogy between the hot graphs in section 4 and the rail graph. Observe that the hot graphs in section 4 contain some nondeterministic choices that cannot be resolved until the end of the input. This causes the respective deterministic expansions. In those graphs, these choices are part of the strings being accepted. The rail graph manifests this same phenomenon, but in terms of weights rather than strings. The weighted variants of the rail graph that expand when determinized do so because it is not clear until the end of the expansion which rail will provide the shorter path: at any point, the choice of top or bottom rail depends on the symbols that follow. Therefore, the determinization must maintain enough state information to provide for all possible outcomes. Furthermore, in the nonminimizable cases, whereas the language $L_{RG}(k)$ itself could be accepted by a $(k+1)$-state DFA, the weights on $RG(k)$ necessitate an exponential number of states and arcs in any deterministic WFA that induces all the appropriate path lengths.

5.4. Random weightings of $RG(k)$. An *i-bit reweighting function* (or simply *i-bit reweighting*) is a reweighting function f such that the weights on the arcs of $f(G)$ are constrained to be in $[0, 2^i - 1]_Z$. A function f^R is a *random reweighting function* (or simply *random reweighting*) if and only if it chooses the weights to assign to the transitions of G uniformly and independently at random from $\Re^+ \cup \{0, \infty\}$. Finally, let $x \in_R Y$ denote that x is selected uniformly and independently at random from set Y, and let $E[X]$ denote the expected value of some random variable X. We need the following technical claim.

CLAIM 5.6. *Let $X, Y, U, V \in_R [0, 2^k - 1]$. Then*

$$\max_{-2^{k+1}+1 < i < 2^{k+1}-1} \Pr(X - Y - (U - V) = i) \leq \frac{2}{3 \cdot 2^k} + O\left(1/4^k\right).$$

Proof. See Appendix A.1. □

THEOREM 5.7. *Let f^R be a random k-bit reweighting. $E[\#dta(f^R(RG(k)))] = \Theta(2^k)$.*

Proof. As before, let $R(w)$ be the remainder induced by string w of length k; i.e., the difference between the cost of the upper path and the cost of the lower path that respectively induce w. Let $\delta_i(\sigma)$ be the cost of the (top) arc labeled σ into vertex T_i minus the cost of the (bottom) arc labeled σ into vertex B_i. Recall from (1) that the rail graph with a specific weighting can be regarded as a function that hashes a k-bit string $w = \sigma_1 \cdots \sigma_k$ into a number $R(w)$.

Suppose $w_1 \neq w_2$. We can adapt a standard analysis from the theory of universal hash functions [7] to calculate the probability that $R(w_1) = R(w_2)$. Let $w_1 = \alpha_1 \cdots \alpha_k$ and $w_2 = \beta_1 \cdots \beta_k$. Without loss of generality, assume $\alpha_k \neq \beta_k$. (The strings must differ somewhere.) Suppose $R(w_1) = R(w_2)$. Then by definition (with some manipulation)

$$(\alpha_k - \beta_k)(\delta_k(1) - \delta_k(0)) = \sum_{i=1}^{k-1} (\beta_i - \alpha_i)(\delta_i(1) - \delta_i(0)).$$

Fix a set of weights on the arcs in the first $k-1$ layers, so the right-hand side of the equation is a constant. The value $(\alpha_k - \beta_k)$ is either -1 or 1, by assumption. Hence, for the given set of weights on the first $k-1$ layers, there is exactly one value of $(\delta_k(1) - \delta_k(0))$ that makes $R(w_1) = R(w_2)$. If we assign the weights randomly in the kth layer, the probability that $(\delta_k(1) - \delta_k(0))$ has the necessary value is upper-bounded by

$$\max_{-2^{k+1}+1 < C < 2^{k+1}-1} \Pr[X_1 - X_2 - (X_3 - X_4) = C],$$

where the X_is are uniform random variables in the range $[0, 2^k - 1]_Z$. (It is strictly upper-bounded, since the value of $(\delta_k(1) - \delta_k(0))$ lies in $[-2^{k+1} + 2, 2^{k+1} - 2]$, which is in general smaller than the range of values that the right-hand side of the equation can assume.)

By Claim 5.6, therefore, for any fixed assignment of the first $k-1$ values, the probability that $R(w_1) = R(w_2)$ is bounded above by $\frac{2}{3 \cdot 2^k} + O(1/4^k)$. Hence, summing over all possible assignments to the first $k-1$ values, the total probability that $R(w_1) = R(w_2)$ is also bounded above by $\frac{2}{3 \cdot 2^k} + O(1/4^k)$. We will use this result to compute the expected number of vertices at layer k in the determinized graph.

First, we compute the expected number of *collisions*: the number of strings of length k that have the same remainder. Since the number of strings is 2^k, this is simply

$$\sum_{w_1, w_2} \left(\frac{2}{3 \cdot 2^k} + O(1/4^k) \right) = \frac{2}{3} 2^k + O(1).$$

Suppose $x_1, \ldots, x_\ell$ form the set of layer-k vertices in the deterministic graph. Let S_i be the set of strings that map to vertex x_i, and let random variable s_i be $|S_i|$. The expected number of collisions can thus be written as $E[\sum_{i=1}^{\ell} \binom{s_i}{2}]$. Since the expected value is $\frac{2}{3} 2^k + O(1)$, it must be the case that in one-half of the weight assignments, the actual value of the sum is at most $\frac{4}{3} 2^k + O(1)$.

We now consider the minimum number of sets so that there is an assignment of strings to sets that satisfies

$$\sum_{i=1}^{\ell} \binom{s_i}{2} \leq \frac{4}{3} 2^k + O(1)$$

and

$$\sum_{i=1}^{\ell} s_i = 2^k.$$

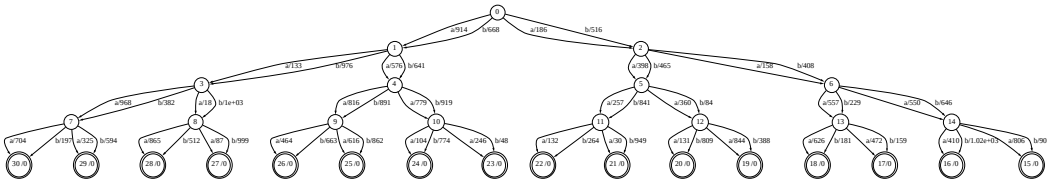

FIG. 9. *A rail tree of depth* 4*, with ten-bit random weights.*

Elementary calculus shows that the binomial sum is minimized when the s_i's are all equal, which implies that the minimal value of ℓ is $\Omega(2^k)$.

Therefore, in at least half the weight assignments, there are $\Omega(2^k)$ distinct remainders and so $\Omega(2^k)$ distinct states in the determinized graph. Hence the expected number of states in the determinized graph is also $\Omega(2^k)$. □

Since the arcs weights of ASR WFAs are (negated) log probabilities, we consider the behavior of determinization when the arcs are weighted with *log-random* numbers, i.e., logarithms of uniform random variables. On the rail graph, we find the same behavior with log-random weights as with random weights, including the increasing expansion as more bits are employed. As the following claim shows, retaining enough bits of the log-random weights drives the collision probability (as discussed in the proof of Theorem 5.7) low enough to ensure this behavior.

CLAIM 5.8. *Let* $X, Y, V, Z \in_R [1, 2^k - 1]$*. Let* $R = \lfloor 2^b \log X \rfloor$*,* $S = \lfloor 2^b \log Y \rfloor$*,* $T = \lfloor 2^b \log V \rfloor$*, and* $U = \lfloor 2^b \log Z \rfloor$ *for some* $b \geq k - O(1)$*. Then*

$$\max_{-k2^{b+1}+1<i<k2^{b+1}-1} \Pr(R - S - (T - U) = i) = \frac{1}{4 \cdot 2^k} + O\left(1/4^k\right).$$

Proof. See Appendix A.2. □

Thus we derive the analogue to Theorem 5.7 for log-random weights.

THEOREM 5.9. *Let* G *be* $RG(k)$ *weighted with logarithms of numbers chosen independently and uniformly at random from* $[1, 2^k - 1]_Z$*. Then* $E[\#dta(G)] = \Theta(2^k)$*.*

Proof. Apply Claim 5.8 instead of Claim 5.6 in the proof of Theorem 5.7, and alter the ensuing discussion appropriately to account for the respective constants. □

5.5. Variations of the rail graph. We remark that all of the above results extend even when we simplify the rail graph as follows.

1. Eliminate the b-arcs out of state 0.
2. Allow the symbols on the arcs at any layer i to differ from a and b. Enforce only that the symbols on the top rail at layer i be the same as those on the bottom rail at layer i.

Using the original definition of $RG(k)$ simplifies the presentation of the theorems and proofs.

Although the rail graph allows us to investigate the relationship between deterministic expansion and weighting in WFAs, the general problem of characterizing this relationship seems difficult. Consider, for example, a *rail tree*, as in Figure 9, in which the rail graph is extended into a tree in a straightforward manner. As shown in Figure 10, when determinized, the resulting tree has the same number of vertices and half the arcs of the original. This is because the language of the original tree contains only 2^4 distinct strings, and so the determinized tree can have only 2^4 leaves. So while many individual rail graphs are embedded in the rail tree, when determinized, it is as if only one expands at the expense of the others.

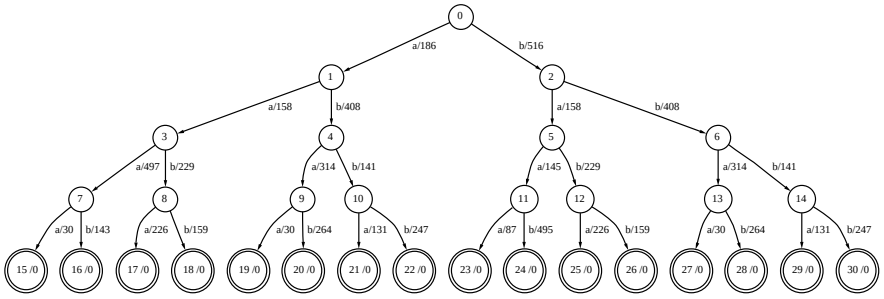

FIG. 10. *The result of determinizing the rail tree of Figure* 10.

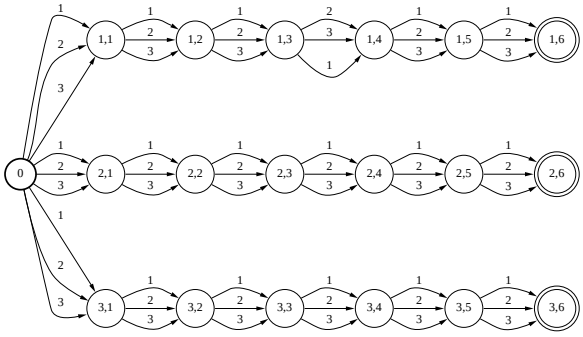

FIG. 11. *Topology of* $RG(3,6)$.

5.6. Extending $RG(k)$ to arbitrary alphabets. We can extend the rail graph to arbitrary alphabets, defining $RG(r,k)$, the *k-layer r-rail graph*, as follows. $RG(r,k)$ has $rk+1$ vertices: vertex 0 and, for $1 \le i \le r$ and $1 \le j \le k$, vertex v_j^i. Assume the alphabet is $\{1,\dots,r\}$. $RG(r,k)$ has arcs $(0, v_1^i, s)\ \forall\ 1 \le i,s \le r$ and also arcs $(v_j^i, v_{j+1}^i, s)\ \forall\ 1 \le i,s \le r$ and $1 \le j < k$. See Figure 11.

The subgraph induced by vertex 0 and vertices v_j^i for some i and $\forall\ 1 \le j \le k$ comprises *rail* i of $RG(r,k)$. The subgraph induced by vertices $v_j^i\ \forall\ 1 \le i \le r$ and some j comprises *layer* j of $RG(r,k)$. Vertex 0 comprises *layer* 0 of $RG(r,k)$. Thus, $RG(2,k)$ is the k-layer rail graph, $RG(k)$, defined in section 5.1.

Denote by $c(i,j,s)$ the weight of the arc labeled s into vertex v_j^i. Theorem 5.3 generalizes to $RG(r,k)$ as follows. (See Figure 12.)

THEOREM 5.10. *For any $j \in [0,k]_Z$ there is an assignment of weights such that the minimal deterministic realization of $RG(r,k)$ has the following form: Layers* 0 *through $j-1$ form the complete r-ary tree on $\frac{r^j-1}{r-1}$ vertices, and the remaining layers j through k form a trivial series-parallel graph with incoming arcs to the layer-j vertex from each vertex at layer $j-1$.*

Proof. Choose the following weighting. Set $c(i,\ell,s) = [(i+s) \mod r] \cdot r^\ell\ \forall\ 1 \le i,s \le r$ and $1 \le \ell \le j$. Set $c(i,\ell,s) = 0\ \forall\ 1 \le i,s \le r$ and $j < \ell \le k$.

We show that there are no two strings of length less than j that lead to the same vertex in *any* deterministic realization of the graph that preserves shortest paths. Hence the number of vertices at layer $\ell < j$ is equal to the number of strings of length

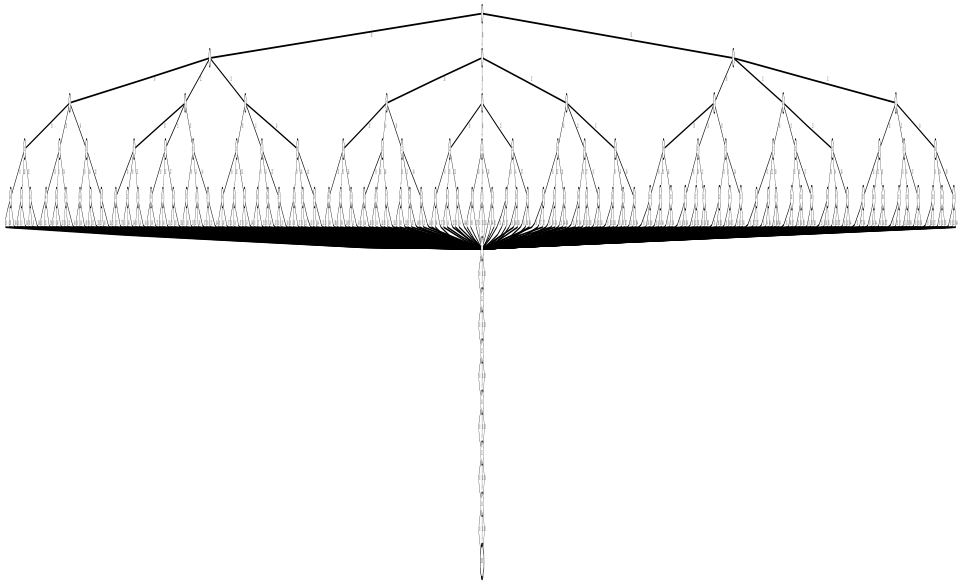

FIG. 12. *Result of minimizing dta($RG(3,10)$), weighting $RG(3,10)$ as follows.* $c(i,\ell,s) = [(i+s) \bmod r] \cdot r^\ell \ \forall\ 1 \le i,s \le 3$ *and* $1 \le \ell \le 4$. $c(i,\ell,s) = 0 \ \forall\ 1 \le i,s \le 3$ *and* $4 < \ell \le 10$. *Only topology is shown.*

ℓ, which is r^ℓ. The proof is by contradiction. Suppose that strings $w_1 \neq w_2$ lead to the same vertex x. Let $\ell < j$ be the length of strings w_1 and w_2. Now consider all strings that have w_1 or w_2 as a prefix. Let $\{w'_1, w'_2, \ldots, w'_m\}$ be the set of possible suffixes, of length $k - \ell$, that can follow any of these prefixes. (In our case, this is simply the set $\{1, \ldots, r\}^{k-\ell}$.)

Let $c(w_1 w'_i)$ and $c(w_2 w'_i)$ denote the costs of strings $w_1 w'_i$ and $w_2 w'_i$, respectively, in the nondeterministic graph, i.e., the sums of the costs of the arcs along the shortest paths inducing the respective strings in $RG(r,k)$. The deterministic graph must satisfy $c(w_1 w'_i) = c_d(w_1) + c_d(w'_i|x)$ and $c(w_2 w'_i) = c_d(w_2) + c_d(w'_i|x)\ \forall\ 1 \le i \le m$, where c_d denotes the cost function in the deterministic graph, and $c_d(w'_i|x)$ denotes the cost of string w'_i starting from vertex x. Hence we have that $\forall\ i$, $c(w_1 w'_i) - c(w_2 w'_i) = c_d(w_1) - c_d(w_2)$. The right-hand side of this equation is a fixed value, say, Δ.

Now consider the pair of suffixes $x\sigma_1 y$ and $x\sigma_2 y$, such that $\sigma_1 \neq \sigma_2$ and, for $i \in \{1,2\}$, $|\sigma_i| = 1$, $|x\sigma_i| = j - \ell$, and $|x\sigma_i y| = k - \ell$; i.e., $x\sigma_i y$ appended to w_1 or w_2 results in a string of length k with σ_i as the jth symbol. We claim that there exists some choice of $\sigma_1, \sigma_2 \in \{1, \ldots, r\}$ such that $c(w_1 x\sigma_1 y) - c(w_2 x\sigma_1 y) \neq c(w_1 x\sigma_2 y) - c(w_2 x\sigma_2 y)$. This contradicts the requirement that both differences should be equal to Δ and hence proves the theorem.

To see the claim, observe that the given weighting on $RG(r,k)$ forces the minimum cost path for any string with some symbol σ in position j to follow rail $(r - \sigma)$. Consider any position $i \le \ell$ in which w_1 and w_2 differ. Denote the ith symbol of w_1 (resp., w_2) by $w_1(i)$ (resp., $w_2(i)$). Then that position contributes $[(w_1(i) + r - \sigma_1) \bmod r - (w_2(i) + r - \sigma_1) \bmod r] \cdot r^i$ to the difference $\Delta_1 = c(w_1 x\sigma_1 y) - c(w_2 x\sigma_1 y)$ and $[(w_1(i) + r - \sigma_2) \bmod r - (w_2(i) + r - \sigma_2) \bmod r] \cdot r^i$ to the difference $\Delta_2 = c(w_1 x\sigma_2 y) - c(w_2 x\sigma_2 y)$. Picking $\sigma_1 = w_1(i)$ and $\sigma_2 = w_2(i)$ implies that position i contributes $\delta_1 = -[(w_2(i) - w_1(i)) \bmod r] \cdot r^i$ to Δ_1 and $\delta_2 = [(w_1(i) - w_2(i))$

mod $r] \cdot r^i$ to Δ_2. Δ_1 and Δ_2 are sums of the form $\sum_{i=1}^{j} c_i r^i$, where $-r < c_i < r$. For some $1 \leq c_1, c_2 < r$, $\delta_1 = -c_1 r^i$ and $\delta_2 = c_2 r^i$ are the only terms involving r^i in Δ_1 and Δ_2, respectively. It follows that $\Delta_1 \neq \Delta_2$, thereby proving the claim. □

We point out that Theorem 5.10 shows that the bounds in Theorem 3.8 for the acyclic case are tight for general alphabets. We also point out that Theorems 5.1 and 5.2 generalize easily to the k-layer r-rail graphs. As for the remaining results stated for binary alphabets in sections 5.3 and 5.4, it would be of some interest to extend them to arbitrary alphabets: while those extensions would not change the "nature" of the lower bound stated in Theorem 5.4, they might shed some more light on the relationship between hashing and **DTA**.

6. Experimental observations on ASR WFAs. In this section, we study whether the WFAs that are generated by ASR systems are weight-dependent. This possibility had not previously been considered by the ASR community, and if true, it suggests that the weights of ASR WFAs, which are generated from training sets with considerable manual intervention, must be carefully monitored to preserve their favorable characteristics.

6.1. Data. We experimented on 100 WFAs generated by the AT&T North American Business speech recognizer [27], using a grammar for the Air Travel Information System (ATIS), a standard 5000-word vocabulary DARPA test bed [4]. Each transition was labeled with a word from the ATIS vocabulary and weighted by the recognizer with the negated log of the probability of realizing that transition out of the source state; we refer to these weights as *speech weights*.

6.2. Method. For each input WFA, we varied the weights on the given topology. We determinized each with its speech weights, with zero weights, and with weights assigned independently and uniformly at random from the integral range $[0, 2^i - 1]$ (for each $0 \leq i \leq 8$). One WFA could not be determinized with speech weights due to computational limitations, and it is omitted from the data. The experiments were run on an SGI R4400 processor with 1 GB of main memory and an SGI R10000 processor with 1.5 GB of main memory.

Figure 13 shows how many WFAs expanded when determinized with different weightings. Figure 14 classifies the 63 WFAs that expanded with at least one weighting. For each WFA, we took the weighting that produced maximal expansion. This was usually the 8-bit random weighting, although due to computational limitations we were unable to determinize some WFAs with large random weightings. The x-axis indicates the open intervals within which the value $\log(|dta(G)|/|G|)$ falls.

Figure 15 provides additional classification of the eighteen WFAs that expanded when determinized with speech weights. The x-axis indicates the open intervals within which the ratio $|dta(G)|/|G|$ falls when G is determinized with its speech weights.

Since the utility of determinization in ASR includes the reduction in size achieved with actual speech weights, we provide some data on how much the WFAs shrink. In our sample, 82 WFAs shrank when determinized. For each of these WFAs, we computed the value $\log(|G|/|dta(G)|)$. In Figure 16, we plot the number of WFAs whose corresponding values fell in various ranges.

Figure 17 demonstrates the relationship between the (log of the) expansion ratio $|dta(G)|/|G|$ and the number of bits used in the random weights for the ten WFAs with highest final expansion value. For reference the functions i^2, $2^{\sqrt{i}}$, and 2^i are plotted, where i is the number of bits. Most of the WFAs exhibit subexponential growth as the number of bits increases, although some, like `q0t063`, have increased

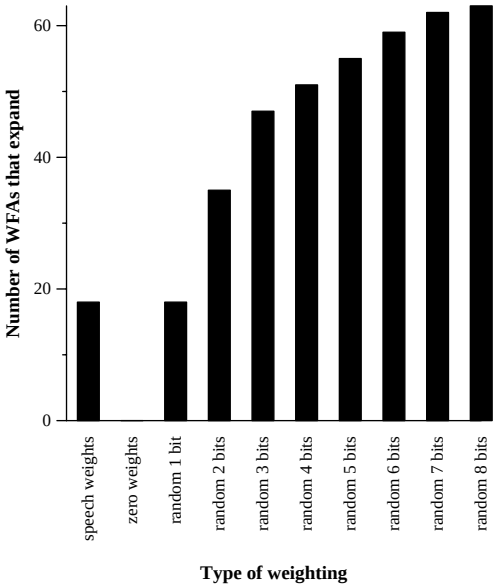

FIG. 13. *Number of WFAs that expanded when determinized with various weightings.*

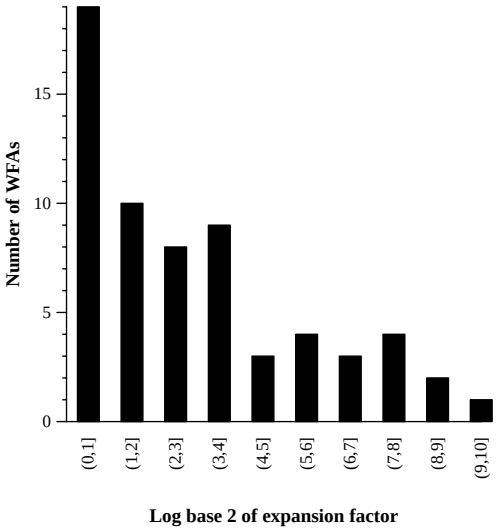

FIG. 14. *Histogram of expansion factors.*

by 128 times even with four random bits.

6.3. Discussion. The WFA that could not be determinized with speech weights was "slightly hot," in that the determinized zero-weighted variant had 2.7% more arcs than the original WFA. The remaining 99 WFAs shrank with zero weights: none was hot. If one expanded, it did so due to weights rather than topology.

Figure 13 indicates that many of the WFAs have some degree of weight-dependence, since 63 expanded when sufficiently large random weights were used. Finally, Figure 17 suggests that random weights are a good way to estimate the degree to which

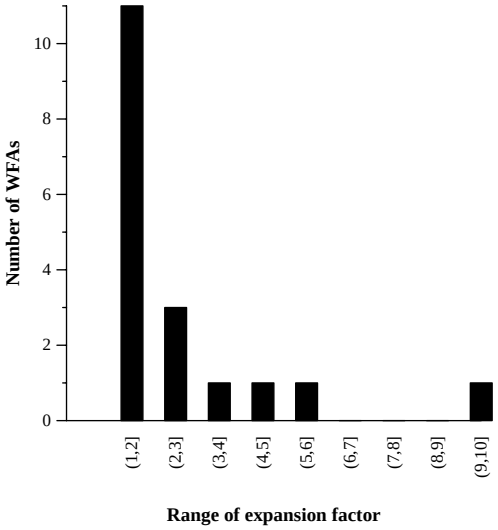

FIG. 15. *Expansion factors for WFAs that expanded when determinized with speech weights.*

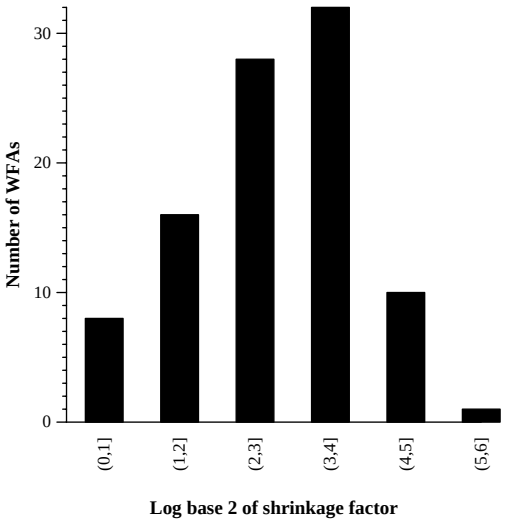

FIG. 16. *Shrinkage factors for WFAs that shrank when determinized with at least one weighting.*

a WFA is weight-dependent. Note that the expansion factor is some superlinear, possibly exponential, function of the number of random bits. This suggests that using large random weights, 32 bits, for example, should cause expansion if anything will. Analogous experiments on the minimized determinized WFAs yield results that are qualitatively the same, although fewer WFAs still expand after minimization. Hence weight-dependence seems to be a fundamental property of these WFAs rather than an artifact of this particular determinization algorithm.

We have used the analyses and experimental observations above to design an *approximate* WFA determinization algorithm: a variant of Mohri's algorithm that unifies state tuples whose remainders differ within a specified relative factor. Using this algorithm, we achieve size reductions in ASR language models that significantly

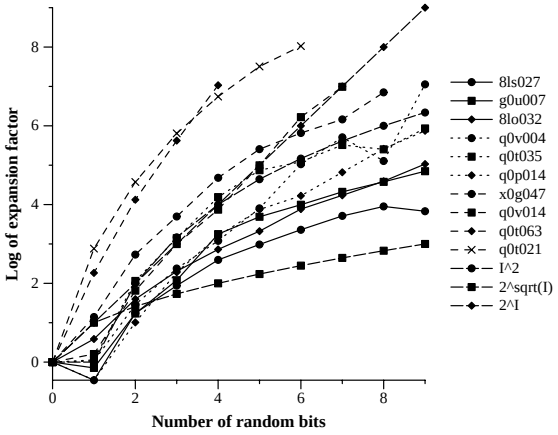

FIG. 17. *Relationship between expansion ratio and number of bits.*

exceed those of previous methods, with negligible effects on ASR performance (time and accuracy). We detail the algorithm and these results separately [6].

The experimental results show that ASR WFAs are generally not hot. This suggests the following open problem: characterize a class of WFAs that are not hot and to which many of the ASR examples belong. Such a characterization might be useful in generating ASR WFAs, so that hot WFAs are guaranteed not to occur.

Appendix. Proofs of claims.

LEMMA A.1. *Let Y_1 and Y_2 be random variables from the same probability distribution. Let X be a random variable such that*

$$\Pr(X = i) = \sum_{j=B+|i|}^{T} \Pr(Y_1 = j) \Pr(Y_2 = j - |i|)$$

for any i and some fixed B and T. Then $\Pr(X = i) \leq \Pr(X = 0)$ for any i.

Proof. Using the fact $ab \leq \frac{1}{2}\left(a^2 + b^2\right)$, we derive

$$\begin{aligned}
\Pr(X = i) &= \sum_{j=B+|i|}^{T} \Pr(Y_1 = j) \Pr(Y_2 = j - |i|) \\
&\leq \frac{1}{2} \sum_{j=B+|i|}^{T} \left(\Pr(Y_1 = j)^2 + \Pr(Y_2 = j - |i|)^2\right) \\
&= \frac{1}{2} \sum_{j=B+|i|}^{T} \Pr(Y_1 = j)^2 + \frac{1}{2} \sum_{j=B+|i|}^{T} \Pr(Y_2 = j - |i|)^2. \qquad (2)
\end{aligned}$$

By definition, $\Pr(X = 0) = \sum_{j=B}^{T} \Pr(Y_1 = j) \Pr(Y_2 = j)$. By symmetry, therefore,

$$\Pr(X = 0) = \sum_{j=B}^{T} \Pr(Y_1 = j)^2 = \sum_{j=B}^{T} \Pr(Y_2 = j)^2,$$

which, combined with (2), completes the proof. □

A.1. Proof of Claim 5.6. It should be clear that, for $-(2^k-1) \le i \le 2^k-1$,

$$\Pr(X-Y=i) = \Pr(U-V=i) = \left(\frac{1}{2^k}\right)^2 \left(2^k - |i|\right).$$

Consider $\Pr(X-Y-(U-V)=i)$ and the following cases.

$$\Pr(X-Y-(U-V)=i \mid i \ge 0) = \sum_{j=-2^k+1+i}^{2^k-1} \Pr(X-Y=j)\Pr(U-V=j-i).$$

$$\Pr(X-Y-(U-V)=i \mid i < 0) = \sum_{j=-2^k+1-i}^{2^k-1} \Pr(X-Y=j+i)\Pr(U-V=j).$$

Unifying the cases and exploiting symmetry yields

$$\Pr(X-Y-(U-V)=i) = \sum_{j=-2^k+1+|i|}^{2^k-1} \Pr\left(X-Y=j\right)\Pr\left(U-V=j-|i|\right).$$

By Lemma A.1, it suffices to solve for $i=0$.

$$\begin{aligned}
\Pr(X-Y-(U-V)=0) &= \sum_{j=-2^k+1}^{2^k-1} \Pr(X-Y=j)\Pr(U-V=j) \\
&= \sum_{j=-2^k+1}^{2^k-1} \left(\frac{1}{2^k}\right)^4 \left(2^k-|j|\right)^2 \\
&= \left(\frac{1}{2^k}\right)^4 \left[\left(2^k\right)^2 + 2\sum_{j=1}^{2^k-1}\left(2^k-j\right)^2\right] \\
&= \left(\frac{1}{2^k}\right)^4 \left[\left(2^k\right)^2 + 2\sum_{j=1}^{2^k-1} j^2\right] \\
&= \left(\frac{1}{2^k}\right)^4 \left[\left(2^k\right)^2 + 2\left(\frac{\left(2^k-1\right)\left(2^k\right)\left(2^{k+1}+1\right)}{6}\right)\right] \\
&\approx \left(\frac{1}{2^k}\right)^4 \left[\left(2^k\right)^2 + \frac{2}{3}\left(2^k\right)^3\right] \\
&= \frac{2}{3\cdot 2^k} + O\left(1/4^k\right). \qquad \square
\end{aligned}$$

A.2. Proof of Claim 5.8. For $0 \le i \le k2^b - 1$, $\Pr(R=i) = \Pr(S=i) = \Pr(T=i) = \Pr(U=i)$, and

$$\begin{aligned}
\Pr(R=i) &= \Pr\left(i \le 2^b \log Z < i+1\right) \\
&= \Pr\left(2^{i/2^b} \le Z < 2^{(i+1)/2^b}\right) \\
&= \frac{1}{2^k-1}\left[2^{i/2^b}\left(2^{1/2^b}-1\right)\right].
\end{aligned}$$

Now consider $\Pr(R - S = i)$ (which equals $\Pr(T - U = i)$). Exploiting symmetry as before, we derive that, for $-k2^b + 1 \le i \le k2^b - 1$,

$$\begin{aligned}
\Pr(R - S = i) &= \sum_{j=|i|}^{k2^b-1} \Pr(R = j) \Pr(S = j - |i|) \\
&= \sum_{j=|i|}^{k2^b-1} \left[\frac{1}{2^k - 1}\left(2^{1/2^b} - 1\right)\right]^2 2^{j/2^b} 2^{(j-|i|)/2^b} \\
&= \left[\frac{1}{2^k - 1}\left(2^{1/2^b} - 1\right)\right]^2 \frac{1}{2^{|i|/2^b}} \sum_{j=|i|}^{k2^b-1} 2^{2j/2^b} \\
&= \left[\frac{1}{2^k - 1}\left(2^{1/2^b} - 1\right)\right]^2 \frac{1}{2^{|i|/2^b}} \left[\frac{\left(2^{2/2^b}\right)^{k2^b} - 1}{2^{2/2^b} - 1} - \frac{\left(2^{2/2^b}\right)^{|i|} - 1}{2^{2/2^b} - 1}\right] \\
&= \left[\frac{1}{2^k - 1}\left(2^{1/2^b} - 1\right)\right]^2 \frac{1}{2^{|i|/2^b}} \left(\frac{2^{2k} - 2^{2|i|/2^b}}{2^{2/2^b} - 1}\right) \\
&= \frac{1}{(2^k - 1)^2} \cdot \frac{2^{2k} - 2^{2|i|/2^b}}{2^{|i|/2^b}} \cdot \frac{2^{1/2^b} - 1}{2^{1/2^b} + 1}.
\end{aligned}$$

By Lemma A.1, $\Pr(R - S = i)$ maximizes at $i = 0$.

$$\Pr(R - S = 0) = \frac{\left(2^k + 1\right)\left(2^{1/2^b} - 1\right)}{\left(2^k - 1\right)\left(2^{1/2^b} + 1\right)}.$$

As k gets large, $\frac{2^k+1}{2^k-1}$ tends to 1. We also have $2 < 2^{1/2^b} + 1 \le 3$. Finally, $2^{1/2^b} - 1 \le 1/2^k$ as long as $b \ge k - O(1)$. Thus,

$$\max_{-k2^b+1 \le i \le k2^b-1} \Pr(R - S = i) \approx \frac{1}{2 \cdot 2^k}.$$

Now consider $\Pr(R - S - (T - U) = i)$. As before, by symmetry we derive that

$$\Pr(R - S - (T - U) = i) = \sum_{j=-k2^b+1+|i|}^{k2^b-1} \Pr(R - S = j) \Pr(T - U = j - |i|)$$

for $-k2^{b+1} + 1 < i < k2^{b+1} - 1$. By Lemma A.1, it suffices to solve for $i = 0$.

$$\Pr(R-S-(T-U)=0)=\left[\frac{2^{1/2^b}-1}{(2^k-1)^2\left(2^{1/2^b}+1\right)}\right]^2\sum_{j=-k2^b+1}^{k2^b-1}\left(\frac{2^{2k}-2^{2|j|/2^b}}{2^{|j|/2^b}}\right)^2$$

$$<\left[\frac{2^{1/2^b}-1}{(2^k-1)^2\left(2^{1/2^b}+1\right)}\right]^2\left[\left(2^{2k}-1\right)^2+2\sum_{j=1}^{k2^b-1}\left(\frac{2^{4k}}{2^{2j/2^b}}+2^{2j/2^b}\right)\right]$$

$$=\frac{\left(2^{1/2^b}-1\right)^2\left(2^{2k}-1\right)^2}{(2^k-1)^4\left(2^{1/2^b}+1\right)^2}+\frac{2\left(2^{1/2^b}-1\right)^2}{(2^k-1)^4\left(2^{1/2^b}+1\right)^2}\left[2^{4k}\sum_{j=1}^{k2^b-1}\frac{1}{2^{2j/2^b}}+\sum_{j=1}^{k2^b-1}2^{2j/2^b}\right].$$

(3)

$$2^{4k}\sum_{j=1}^{k2^b-1}\frac{1}{2^{2j/2^b}}=2^{4k}\left[\frac{\left(\frac{1}{2^{2/2^b}}\right)^{k2^b}-1}{\frac{1}{2^{2/2^b}}-1}-1\right]$$

$$=2^{4k}\left[\frac{1/2^{2k}-1}{\frac{1}{2^{2/2^b}}-1}-1\right]<\frac{2^{4k}}{\left(2^{1/2^b}+1\right)\left(2^{1/2^b}-1\right)}. \tag{4}$$

$$\sum_{j=1}^{k2^b-1}2^{2j/2^b}<\frac{\left(2^{2/2^b}\right)^{k2^b}-1}{2^{2/2^b}-1}$$

$$=\frac{2^{2k}-1}{2^{2/2^b}-1}=\frac{\left(2^k+1\right)\left(2^k-1\right)}{\left(2^{1/2^b}+1\right)\left(2^{1/2^b}-1\right)}. \tag{5}$$

Combining (3)–(5) yields

$$\Pr(R-S-(T-U)=0)<\frac{\left(2^{1/2^b}-1\right)^2\left(2^{2k}-1\right)^2}{(2^k-1)^4\left(2^{1/2^b}+1\right)^2}$$

$$+\frac{2\left(2^{1/2^b}-1\right)^2}{(2^k-1)^4\left(2^{1/2^b}+1\right)^2}\left[\frac{2^{4k}}{\left(2^{1/2^b}+1\right)\left(2^{1/2^b}-1\right)}+\frac{\left(2^k+1\right)\left(2^k-1\right)}{\left(2^{1/2^b}+1\right)\left(2^{1/2^b}-1\right)}\right]$$

$$=\underbrace{\frac{\left(2^{1/2^b}-1\right)^2\left(2^{2k}-1\right)^2}{(2^k-1)^4\left(2^{1/2^b}+1\right)^2}}_{A}+\underbrace{\frac{2\cdot2^{4k}\left(2^{1/2^b}-1\right)}{(2^k-1)^4\left(2^{1/2^b}+1\right)^3}}_{B}+\underbrace{\frac{2\left(2^k+1\right)\left(2^{1/2^b}-1\right)}{(2^k-1)^3\left(2^{1/2^b}+1\right)^3}}_{C}.$$

Recall $2\le 2^{1/2^b}+1<3$ and $2^{1/2^b}-1\le 1/2^k$ as long as $b\ge k-O(1)$. Thus,

$$\max\{A\}\approx\frac{1}{4}\left(\frac{1}{2^k}\right)^2;$$

$$\max\{B\}\approx\frac{1}{4}\cdot\frac{1}{2^k};$$

$$\max\{C\}\approx\frac{1}{4}\left(\frac{1}{2^k}\right)^3. \qquad \square$$

Acknowledgments. We thank Mehryar Mohri, Fernando Pereira, and Antonio Restivo for fruitful discussions. Additionally, Fernando provided us with the WFAs we used in our experiments.

ALGORITHMS FOR THE RELAXED ONLINE BIN-PACKING MODEL*

GIORGIO GAMBOSI†, ALBERTO POSTIGLIONE‡, AND MAURIZIO TALAMO§

Abstract. The typical online bin-packing problem requires the fitting of a sequence of rationals in $(0, 1]$ into a minimum number of bins of unit capacity, by packing the ith input element without any knowledge of the sizes or the number of input elements that follow. Moreover, unlike typical online problems, this one issue does not admit any data reorganization, i.e., no element can be moved from one bin to another.

In this paper, first of all, the "Relaxed" online bin-packing model will be formalized; this model allows a constant number of elements to move from one bin to another, as a consequence of the arrival of a new input element.

Then, in the context of this new model, two online algorithms will be described. The first presents linear time and space complexities with a 1.5 approximation ratio and moves, at most once, only "small" elements; the second, instead, is an $O(n \log n)$ time and linear space algorithm with a $1.33\ldots$ approximation ratio and moves each element a constant number of times. In the worst case, as a result of the arrival of a new input element, the first algorithm moves no more than three elements, while the second moves as many as seven elements. Please note that the number of movements performed is explicitly considered in the complexity analysis.

Both algorithms are below the theoretical $1.536\ldots$ lower bound, effective for the online bin-packing algorithms without the movement of elements. Moreover, our algorithms are "more online" than any other linear space online bin-packing algorithm because, unlike the algorithms already known, they allow the return of a (possibly relevant) fraction of bins before the work is carried out.

Key words. complexity, approximation algorithms, online algorithms, bin packing

1. Introduction.

1.1. The bin-packing problem. The bin-packing problem (see survey in [7] and in [8]) is a major issue in theoretical computer science: it consists of "packing" a set of nonoverlapping objects into a minimum number of well-defined areas. More formally [7], [8], given a positive integer C, it provides for the packing of a set of integer size elements $L = \{a_1, a_2, \ldots, a_n\}$, with $size(a_i) \in (0, C] \cap N_0$, into a minimum number of bins of equal capacity C.

This problem models the variable partitioning storage management in multiprogrammed computer systems and the assignment of commercials to mass media station breaks and truck packing. Bin-packing also models a variant of the scheduling problem in multiprocessors where the objective is to minimize the number of processors in

which all tasks are to be completed within a given deadline. (When the common deadline is the capacity, processors are represented by bins and elements are represented by tasks whose size is given by the execution time.)

An interesting case is when $C = 1$ and $size(a_i) \in (0, 1] \bigcap Q$, which results in a combinatorial optimization problem that is NP-hard in the strong sense[1] since it contains 3-Partition as a special instance [15].

We are interested in searching for approximated fast (polynomial) online bin-packing algorithms that require the packing of the ith element without information on the sizes or the number of the following input elements and whose solution is far from the optimal for a small, fixed, multiplicative constant.

All the known online algorithms share the approach that no element can be moved from the bin it was first inserted in. Moreover, all the $\Theta(n)$-*space* algorithms are offline on output, i.e., no algorithm releases any of the used bins until the end of the input list has been reached, while all the $\Theta(1)$-*space* algorithms release all the bins except for a constant number of them.[2]

As pointed out in [23] a bin-packing algorithm is an algorithm made up of two parts: the first part reorders the list according to a preprocessing rule; the second part generates the packing. An online algorithm has no preprocessing step.

1.2. The relaxed model for the online bin-packing problem. In this paper, we will focus our attention on online algorithms, according to the classical definition [1], which states the following.

DEFINITION 1.1. *The online execution of a sequence of instructions σ requires that the instructions in σ be executed from left to right and that the ith instruction in σ be executed without looking at any of the instructions that follow.*

The above definition corresponds to the definition of online algorithms considered in task systems and server problems (see, for example, [4] and [28]). Please note that the above definition admits internal data reorganization, which is a frequent practice in most online algorithms.

According to these definitions, we introduce a new online bin-packing model, named "Relaxed," which allows a constant number of elements to be moved from one bin to another consequent to the arrival of new input elements. This new model calls for a careful definition of a cost function on the set of the possible item movements, in order to account explicitly for them in the overall algorithm complexity analysis.

Please note that a very limited number of applications of the bin-packing problem cannot be represented by our model. A typical example of such an application is the cutting stock problem, where the more abstract operation "assign an element of size s to a bin" is interpreted in terms of "cut a piece of length s from a stock element."

On the other side there are many real-life situations where the rearrangement of an allocated element is possible and this affects (by lowering) the cost of the resolution process, i.e., packing trucks and multiprocessor memory management strategies. The "Relaxed" model works very well in all situations in which the operation modeled by the assignment of an element to a bin can be "undone" by paying something. Such

[1] Note that, when the number of possible element sizes is a priori bounded, or (it is the same) in the integer formulation C is fixed, the problem can be exactly solved in polynomial time by exhaustive search, although the degree of the polynomial can be very high [7], [8] or it can be exactly solved asymptotically using special linear programming techniques [16], [17]; moreover, the decision problem "Is there a partition of L into disjoints sets $L_1, L_2, \ldots, L_k$ such that $\sum_{a \in L_i} size(a) \leq C$, for each L_i" is NP-complete and solvable in pseudopolynomial time for each fixed $k \geq 2$.

[2] Online algorithms which are not offline on output were considered in [10].

a situation arises, for example, when the input list is not known in advance (it could be infinite, too) and each element (that could arrive with a considerable delay from the previous one) needs to be processed online, while the guaranteed performance needs to be maintained at any time for the set of elements currently involved. In this situation a classical online algorithm (BEST-FIT, $HARMONIC_M$, etc.) or an offline algorithm could be applied in correspondence to each element arrival. In the first case no known algorithm uses, in the worst case, more than 63% of the bin space, while no algorithm can use, in the worst case, more than 65% of the bin space (since 1.53 is the theoretical lower bound). In the second case whenever an element arrives all other elements can be moved out from the bin they are contained in and be assigned to some other bin, according to the new computed solution. In our model only a (known) limited number of element movements is admitted, in correspondence to the arrival of a new element.

In general, this new model is particularly suitable when the elapsed time between two consecutive input elements is $\geq \delta K$, where δ is the maximum cost for each element movement, and K is the maximum number of element movements occurring in correspondence to each input element (so this model permits us to take advantage of the "dead times" between two successive input elements).

In [11] and [13] we informally introduced the "Relaxed" model and gave an $O(n \log n)$-*time* $O(n)$-*space* class of algorithms that, for each prefix of the input sequence, returns a 1.5 asymptotical approximation ratio. This value is below the $1.53\ldots$ theoretical lower bound [5], [26] well grounded for the restricted case and indicates that the relaxation of the classical online bin-packing problem conditions is convenient and theoretically interesting. Some experimental simulations allow us to guess that this class of algorithms has (on the average) very good behavior.

Our paper shows how this result is improved in two different ways by giving two linear space algorithms: the first presents a 1.5 approximation ratio with an $O(n)$ time complexity; the second presents a $1.33\ldots$ approximation ratio with an $O(n \log n)$ time complexity (they fill each bin in the worst case at least for 66% and 75%). Moreover, at the arrival of each input element, in the worst case the first algorithm moves no more than three elements while the second may move up to seven elements.

Last, please note that these algorithms are "more online" than all the other linear space online bin-packing ones because, unlike the known algorithms, they allow the return of a (possibly relevant) fraction of the bins before the work is carried out.

Section 2 gives definitions and a brief summary of the previous results on the online bin-packing problem; section 3 shows the "Relaxed" model, with regard to element movement, small element grouping operations, and definition of movement evaluation function; section 4 introduces the linear algorithm A_1 while section 5 gives an analysis of its performance; the $O(n \log n)$ algorithm A_2 is introduced in section 6 and its performance is analyzed in section 7; section 8 examines some conclusions and open problems.

2. Definitions and previous results.

2.1. Problem definition.

The classical one-dimensional bin-packing problem can be stated [15] as follows.

DEFINITION 2.1. *Given a finite set $L = \{a_1, a_2, \ldots, a_n\}$ of "elements" and a rational "size," $size(a) \in (0, 1]$, for each element $a \in L$, find a partition of L into disjoint subsets $L_1, L_2, \ldots, L_k$ such that the sum of the sizes of the elements in each L_i is no greater than 1 and such that k is as small as possible.*

Since the bin-packing problem contains 3-partition as a special case, it is an NP-hard problem in the strong sense [15], [21]. It is therefore very unlikely that there are fast (polynomial) algorithms for finding the best solution, unless P = NP, even if the magnitude of the numbers involved is bounded by a polynomial in n.

Given an (approximate) algorithm A for the bin-packing problem and a set L of elements, let $A(L)$ be the number of bins used by A to pack L. Therefore

$$OPT(L) \geq \sum_{a_i \in L} size(a_i) \tag{2.1}$$

is a lower bound for the number of bins necessary to pack L.

Now we are able to give some algorithm performance definitions [7], [8].

DEFINITION 2.2. *The performance of A with respect to OPT on the list L is*

$$R_A(L) \equiv \frac{A(L)}{OPT(L)}. \tag{2.2}$$

DEFINITION 2.3. *The absolute performance ratio R_A of the algorithm A is*

$$R_A \equiv \inf\{r \geq 1 | R_A(L) \leq r, \ \forall \ list \ L\}. \tag{2.3}$$

DEFINITION 2.4. *The asymptotic performance ratio R_A^∞ of the algorithm A is*

$$R_A^\infty \equiv \inf\{r \geq 1 | \ for \ some \ N > 0, R_A(L) \leq r, \ \forall \ L \ with \ OPT(L) \geq N\} \tag{2.4}$$

Note that $R_A \geq R_A^\infty$.

2.2. Previous results on the online version. The classical problem presents a variety of cases [7], [8]. In the online version [10] the following definition exists.[3]

DEFINITION 2.5. *"Items are assigned to bins in order $(a_1, \ a_2, \ \ldots)$, with item a_i assigned only according to the size of the previous items and the bins to which they were assigned, without considering the size or number of items that follow."*

The simplest bin-packing algorithm is Next-Fit [7], [8] which is $O(n)$-*time* and $O(1)$-*space*, but whose asymptotical performance, both in the worst and in the average cases, is very poor, respectively, 2.0 and 1.33 [7], [8], [9], [12].

The bin-packing algorithms most extensively used are BEST-FIT and FIRST-FIT [23]. Both algorithms are $O(n \log n)$-*time* and $O(n)$-*space* and present an acceptable asymptotical worst-case performance (i.e., 1.7, [23]) but an optimal asymptotically average performance [2], [3], [12], [32].[4]

Until now, the best online algorithms for the bin-packing problem, without moving elements from the bins they have been assigned to, belonged to the HARMONIC class, first introduced in [25], where an approximated algorithm called $HARMONIC_M$ was introduced; this algorithm is the optimal among all the $O(1)$-*space* algorithms. Such an algorithm has an $O(n)$-*time* complexity and a ratio $R_H^\infty(M) \leq 1.692$ for all $M \geq 12$. Lee and Lee [25], moreover, proved that $R_A^\infty \geq 1.6910$ for all constant space algorithms and that $\lim_{M \to \infty} R_H^\infty(M) = 1.6910$.

[3] More appropriately in such a case, we deal with a sequence of elements to be packed and not with a set.

[4] Note that in [10] it is proved that BEST-FIT obtains its worst-case performance even if a constant ($k \geq 2$) number of bins is maintained online; this reduces the computation time to $O(n \log k)$, that is, $O(n)$ since k is a small constant.

The same authors gave a more complex $O(n)$ algorithm, REFINED HARMONIC, which uses $O(n)$ space and presents a ratio $R^{\infty}_{RH} = \frac{373}{228} = 1.636\ldots$.

Later, the MODIFIED HARMONIC algorithm was introduced in [31], which is $O(n)$ both in time and in space complexity with a ratio $R^{\infty}_{MH} = 1.61(561)^{*}$. The authors also showed how an online algorithm with $R^{\infty}_{A} < 1.59$ can be obtained.

3. The relaxed model.

3.1. Motivations and previous results. All the algorithms mentioned in section 2.2 introduce the additional limit that the solution for $\langle a_1\ a_2\ \ldots\ a_i\rangle$ must derive from the one for $\langle a_1\ a_2\ \ldots\ a_{i-1}\rangle$ without performing any reorganization of the elements in the bins; that is, none of the elements among $a_1, a_2, \ldots, a_{i-1}$ can be moved from the bin it belongs to. In other words, all of these algorithms only search for a suitable bin to which to assign element a_i in order to obtain a good asymptotic approximation of the optimal solution. In this context some interesting lower bounds have been proved, as already pointed out.

A question arising from the above considerations is the following: "What happens if we interpret the online property of bin-packing in a less restricted way, just like the large majority of online models? Is it possible to obtain more efficient performances if a bin-packing algorithm can move the elements a certain number of times from one bin to another?"

In [11] and [13] an affirmative answer to this question is given by presenting a class of online algorithms, $HARMONIC_{REL}(M)$,[5] with time complexity $O(n \log n)$, space complexity $O(n)$, and asymptotic ratio $R^{\infty}_{HREL}(M) \leq 1.5$. In the worst case, the approximation ratio is independent of M, for $M \geq 3$, and the number of movements is limited in an amortized way by a (small) constant (2, for $M = 3$).

3.2. Grouping elements. In this paper we introduce a new operation: the "grouping of elements," i.e., *we assume that a certain number of very small items in the same bin can be collected together and considered as a single unit.* More formally,

Given a constant $0 < c < 1$, we assume that any set of elements smaller than c in the same bin can be collected together in a single group of overall size $\leq c$. This group will be considered as a single unit from now on.

Obviously, the grouping of elements does not modify the approximation ratio of OPT, since OPT is measured as the sum of the elements in the input list. We also assume that there is no kind of movement inside any group.

In the bin-packing problem the grouping operation is possible and convenient. For example, in the truck-packing problem it is useful to fit a collection of very small elements in the same box and then move them as a whole by moving the box. In multiprocessor storage management strategies, the grouping simply consists in collecting a subset of pages.

3.3. Moving elements. In the relaxed model, the critical operation regards moving (part of) the contents from one bin to another.

In the following, i, j are two bins and σ is a subsequence of (not necessarily contiguous) input element(s), all contained in the same bin.

The fundamental operation could therefore be stated as

$$\text{MOVE}(i, j, \sigma), \qquad i \neq j, \tag{3.1}$$

which means that σ is moved from bin i to bin j.

[5] Where REL stands for "Relocation."

This approach is quite natural for all the applications in which we may assume that several small elements can be "carried" from one bin to another in a single step.

3.4. MOVE operation cost. An online algorithm processes the input data one at a time, possibly modifying its internal data structures. Thus the evaluation of the performance of an algorithm is more realistic if it takes into account the number of movements of the elements in its data structures.

In a bin-packing algorithm when the elements move, several kinds of cost functions for the MOVE(i, j, σ) operation could be defined.

DEFINITION 3.1. *The cost of the* MOVE *operation is equal to the total size of all elements moved* ($\sum_{x\in\sigma} size(x)$).

DEFINITION 3.2. *The cost of the* MOVE *operation is equal to the number of elements moved* ($|\sigma|$).

In this paper we will consider a third way to define such a function. In our approach *we assume that each group can be moved at unitary cost.* That is, while moving a "large" element always has a cost equal to 1, we assume that "small" elements can be *grouped* together and moved as a whole, at unit cost. Therefore we have the following.

DEFINITION 3.3. *The cost associated to the* MOVE(i, j, σ) *operation is equal to the number of elements and groups contained in* σ.

If the element moving cost would only be a function of the size of the elements, any reasonable algorithm would tend to move a lot of small elements because the performance is better and there is no cost difference in moving a lot of small elements instead of a few big elements. If the element moving cost would only be a function of the number of the elements moved, there will be no cost difference between an algorithm that moves light elements and another that moves the same number of heavy elements. Therefore, the third cost function is the most likely. It should be clear that for any c, σ this function has a value which is in between the values assumed by the first two cost functions above defined.

3.5. Formal definition of grouping. Let us consider the following nonuniform partition of $(0, 1]$ in $M + 1$ subintervals:

$$(0,1] = \bigcup_{k=0}^{M} I_k,$$

$$I_0 = \left(\frac{3}{4}, 1\right]; \; I_1 = \left(\frac{2}{3}, \frac{3}{4}\right]; \; I_2 = \left(\frac{1}{2}, \frac{2}{3}\right]; \; \ldots; \; I_{M-1} = \left(\frac{1}{M-1}, \frac{1}{M}\right]; I_M = \left(0, \frac{1}{M}\right].$$

Let $c = \frac{1}{M}$ be the *border item size.* The grouping operation consists of collecting a set of elements smaller than c in a single group g (that will be a sort of "superitem"), so that, in each bin B (let $size(g) = \sum_{a\in g} size(a)$),

- for all $g \in B$, $size(g) \le c$;
- there are no pairs of groups $g \in B, h \in B$, such that $size(g) + size(h) \le c$;
- each group $g \in B$, except at most one, has $size(g) \ge \frac{1}{2}c$.

3.6. Grouping primitives.

3.6.1. Create group. This primitive regards the arrival of a new element in $(0, \frac{1}{M}]$ that cannot be merged in any group of the target bin. The operation consists in creating an empty group and in inserting this new element in it. At all times, there will be no more than one I_M-bin open.

3.6.2. Append. This primitive regards the arrival of a new element in $(0, \frac{1}{M}]$ that has to be merged into an existing group.

3.6.3. Primitive performances. Since we are not interested in any kind of arrangement of the elements within the group, a suitable representation (i.e., linked lists) allows all of these operations to be executed in constant time and space. This leads to the "packing" of such elements together, so that they can/must be moved as a whole, in one single step.

3.7. Evaluation function. Below we will show that each bin will contain a constant number of groups. Since the algorithm performance is measured as a function of the space wasted with respect to the sum of the sizes of the elements in the input list, the grouping of the elements does not affect the performance in any manner.

We will not detail the operations involved in inserting and deleting elements to and from bins nor the ones involved in the maintenance of the support data structures, mainly in empty conditions, because they can be easily performed in constant time.

In the following, let

- m be the maximum number of MOVE operations performed upon the arrival of a new element[6];
- r be the asymptotic performance of the algorithm.

Thus, we can assign to an approximation algorithm a pair of numbers, such as

$$A(m, r).$$

For example, the well-known BEST-FIT algorithm is A(1,1.7) since its performance ratio is 1.7. In general, we can say that a classical online bin-packing algorithm is A(1,r) ($r \geq 1.53$) since it does not move the elements already fitted in the bins and 1.53 is the lower bound for this kind of algorithm. Please note that the exact algorithm is A(m,1), for some $m \geq 0$, while our first algorithm, A_1, is A(3,1.5), and A_2 is A(7,1.33).

4. The linear algorithm A_1. A_1 is based on a nonuniform partition of interval $(0, 1]$ into four subintervals (levels):

$$(0, 1] = \bigcup_{k=0}^{3} I_k,$$

$$I_0 = \left(\frac{2}{3}, 1\right]; \quad I_1 = \left(\frac{1}{2}, \frac{2}{3}\right]; \quad I_2 = \left(\frac{1}{3}, \frac{1}{2}\right]; \quad \text{and } I_3 = \left(0, \frac{1}{3}\right].$$

In order to describe it, let us introduce the following points:

- $S = \langle a_1\ a_2\ \ldots\ a_n \ldots \rangle$ is the "input list."
- Let $a_i \in I_k$ $(0 \leq k \leq 2)$ be an element of S. Then a_i is called "I_k-element."
- Let $a_i \in I_3$ be an element of S. Then a_i is called "I_3-group."
- Let B be a bin. Then B is an "I_k-bin (I_3-bin)" $(0 \leq k \leq 2)$ if the first element that was initially assigned to it were an I_k-element (I_3-group).
  By subinterval definition, each I_k-bin $(1 \leq k \leq 2)$ contains no more than k I_k-elements and each I_0-bin contains no more than one I_0-element.

[6] the first insertion of a new element corresponds to a MOVE from outside into a bin

If an I_k-bin ($1 \le k \le 2$) exactly contains k I_k-elements it is *"filled"*; otherwise it is *"unfilled"*. An I_0-bin with an I_0-element is *"filled"* and an I_3-bin is filled only when its gap is $< \frac{1}{3}$.[7]

- For each k ($0 \le k \le 3$) let A_k be the name of the only unfilled I_k-bin.
- "*gap(B)*" is the space available in an I_k-bin, B ($0 \le k \le 2$), to insert I_l-elements (I_3-groups) ($k < l \le 2$). If B is filled, then $gap(B) = 1 - \sum_{a \in B} size(a)$; otherwise we conventionally assume that $gap(B) = 0$.

Algorithm A_1 is reported below (where l denotes the level of the next input element, x). Please note that if $x \in I_1$ is a "small" I_1-element (i.e., $size(x) < \frac{2}{3}$), A_1 tries to insert some I_3-groups in its gap; if this is not possible A_1 will mark this bin for a future I_3-group insertion. Please note that if $x \in I_3$, then A_1 first tries to insert it in the gap of some marked I_1-bin with enough room.

The algorithm uses two stacks of bins, L_1 and L_3, respectively associated with levels 1 and 3. L_1 maintains all the bins whose gap is still "fat" (i.e., $\ge \frac{1}{3}$), while L_3 maintains all the I_3-bins. If there is an unfilled I_3-bin, then it is the first bin in L_3. Please note that in every moment no more than one between L_1 and L_3 can be "not empty."

We do not explicitly consider the management of unfilled bins. For example, we assume that an unfilled bin is automatically generated at the arrival of an element which can be assigned to no other bin available at that time.

Algorithm A_1

For each input element x**:**
if $x \in I_0$ **then** "Insert x in A_0".
if $x \in I_1$ **then**
- "Insert x in A_1";
- **while** ($gap(A_1) \ge \frac{1}{3}$) **AND** ("There still exists an I_3-group", g) **do** "Move g to A_1."
- **if** "There is no more I_3-groups" **AND** ($gap(A_1) \ge \frac{1}{3}$) **then** "Push A_1 in L_1."

if $x \in I_2$ **then**
- "Insert x in A_2";

if $x \in I_3$ **then**
- **if** "There exists an I_1-bin, B, in L_1"
  then "Insert x in B, removing B from L_1 if its gap becomes $< \frac{1}{3}$."
  else "Insert x in A_3"

5. Performance analysis of A_1. In order to analyze the performance of A_1 we must first consider the total number of element movements within the bins at the arrival of a new element. Next, we will consider its asymptotic performance ratio.

5.1. Time, space, and movements.

LEMMA 5.1. *Each filled I_1-bin contains no more than two groups in its gap.*

Proof. Let us assume there are more than two groups in a filled I_1-bin. Let x, y, z be three of them. Since an I_1-bin B has $gap(B) < \frac{1}{2}$, it follows that $size(x) + size(y) + size(z) < \frac{1}{2}$. By definition, we know that in every bin all the groups except for one (at most) are $\ge \frac{1}{6}$ in size. Without loss of generality (w.l.o.g.) let us assume that $size(x) \ge \frac{1}{6}$. Therefore

$$\frac{1}{2} > size(x) + size(y) + size(z) \ge \frac{1}{6} + size(y) + size(z) \Rightarrow size(y) + size(z) < \frac{1}{3},$$

which is a contradiction, since every pair of groups in each bin has a total size $> \frac{1}{3}$. □

[7] Note that we distinguish among "I_k-filled bins" (that is, bins no more able to receive all possible items of their class, but still active) and "I_k-full bins" (that is, bins whose gap is empty or that are never used afterwards).

Please note that this bound is tight. It is easy to show that two groups can be fitted together in the gap of this bin. An example is the following: $(\frac{1}{2}+\epsilon), (\frac{1}{6}-2\epsilon), (\frac{1}{6}+3\epsilon)$.

COROLLARY 5.2. *No more than three movements will be performed at each insertion.*

Proof. The above lemma proves how the movements only occur at the arrival of I_1-elements with $size < 2/3$. However, the algorithm performs no more than three movements since each I_1-bin has a $gap < \frac{1}{2}$ and each pair of groups has $size > \frac{1}{3}$. This implies that, in the worst case, it is sufficient to move one group from A_3 and two groups from another bin in L_3. □

THEOREM 5.3. *Algorithm A_1 has space complexity $O(n)$ and time complexity $\Theta(n)$.*

Proof. The space complexity easily derives from the observation that each element is represented no more than once in L_1 and L_3.

As far as time complexity, according to the above lemma we know that the maximum number of element insertions in a bin is bounded by $3n$. Each insertion can be performed in $O(1)$ time. Moreover, the movement of an existing element is performed in $O(1)$ time since this movement uses the first element in the first bin on the list, accessed in constant time. Therefore, the time complexity is easily derived. □

5.2. Performance ratio. In order to derive the approximation ratio for A_1, the following lemmas are needed.

LEMMA 5.4. *If, after all elements have been considered, L_3 is not empty, then $R^{\infty}_{A_1} < \frac{3}{2}$.*

Proof. The gaps of I_0-bin and I_k-bin ($k \geq 2$) are $< \frac{1}{3}$, by definition.

As far as I_1-bins please note that there is at least one element in L_3 whose size is $\leq \frac{1}{3}$, which has not been moved to the gap of any I_1-bin; this implies that all the gaps of I_1-bins have size $\leq \frac{1}{3}$.

In conclusion, the maximum gap in each bin is $< \frac{1}{3}$ and, consequently,

$$R^{\infty}_{A_1} < \frac{3}{2}. \qquad \square$$

LEMMA 5.5. *If, after all the elements have been considered, L_3 is empty and in the input sequence $L = \{a_1, a_2, \ldots, a_n\}$ there was no pair of a_i, a_j, so that $a_i \in I_1$ and $a_j \in I_2$, then $R^{\infty}_{A_1} = 1$.*

Proof. In this case A_1 uses $N_0 + N_1$ or $N_0 + \frac{N_2}{2}$ bins, where N_j is the number of I_j-elements in the input set, since no I_1-elements or I_2-elements could be inserted in any bin which already has an I_0-element and 2 I_2-elements are inserted in the same I_2-bin. Since OPT cannot use fewer bins, then

$$R^{\infty}_{A_1} = 1. \qquad \square$$

LEMMA 5.6. *If, after all the elements have been considered, L_3 is empty and in the input sequence $L = \{a_1, a_2, \ldots, a_n\}$ there was at least one pair a_i, a_j, so that $a_i \in I_1$ and $a_j \in I_2$, then $R^{\infty}_{A_1} \leq \frac{3}{2}$.*

Proof. Let B_i be the number of bins of level i used by OPT. We can derive the maximum number of bins used by A_1 as a function of the B_i's.

By definition,

$$OPT = B_0 + B_1 + B_2.$$

Since in each I_1-bin OPT could have inserted no more than one I_2-element, the extra bins for A_1 are no more than $\frac{B_1}{2}$. Thus,

$$A_1 \leq B_0 + B_1 + B_2 + \frac{B_1}{2} \leq \frac{3}{2}(B_0 + B_1 + B_2) = \frac{3}{2}\text{OPT}. \qquad \square$$

THEOREM 5.7. *Algorithm A_1 has a ratio $R^{\infty}_{A_1} \leq \frac{3}{2}$.*

Proof. The proof derives directly from the previous three lemmas. $\square$

THEOREM 5.8. *Algorithm A_1 is $A(3, 1.5)$.*

Proof. The proof derives directly from Corollary 5.2 and Theorem 5.7. $\square$

6. The $O(n \log n)$ Algorithm A_2.

6.1. Main features. A_2 is based on a nonuniform partition of the interval $(0, 1]$ into six subintervals (levels):

$$(0, 1] = \bigcup_{k=0}^{5} I_k, \tag{6.1}$$

$$I_0 = \left(\frac{3}{4}, 1\right]; I_1 = \left(\frac{2}{3}, \frac{3}{4}\right]; I_2 = \left(\frac{1}{2}, \frac{2}{3}\right]; I_3 = \left(\frac{1}{3}, \frac{1}{2}\right]; I_4 = \left(\frac{1}{4}, \frac{1}{3}\right]; I_5 = \left(0, \frac{1}{4}\right]. \tag{6.2}$$

The definitions of I_k-element, I_k-bin, A_k-bin, "filled" bin, and gap are similar to the ones given for Algorithm A_1, while the definition of I_5-group is similar to the definition of I_3-group given for Algorithm A_1. Please note that an I_5-group B is "filled" if $gap(B) < \frac{1}{4}$. Thus, A_2 considers I_5-elements as "little" elements which can be collected in groups g_i and moved together. As pointed out in section 3.6, all the grouping primitives are constant in time and space.

6.2. Packing strategy. The algorithm operates as reported in Algorithm A_2, where l denotes the level of the next input element, x. When the input element is a "big" one (i.e., $size(x) > \frac{1}{2}$), A_2 inserts it in a new bin and tries to "fill" its gap with smaller elements from some other bin(s). If the input element is a "small" one (i.e., $size(x) \leq \frac{1}{2}$), the algorithm first tries to insert it in the gap of a filled bin which already exists; only if there is no room for x in any other existing bin, the algorithm inserts it in a new bin. During its execution, A_2 refers to an unfilled bin for each level.[8] The guidelines of the algorithm are the following:

- A_2 encourages the pairing of elements x, y, where $(x \in I_1, y \in I_4)$ or $(x \in I_2, y \in I_3)$.
- A_2 tries to fill the gap of I_1-, I_2-, I_3-filled bins with smaller elements (I_4-elements or I_5-groups) since there are no more I_5-groups or no bin B has $gap(B) > \frac{1}{4}$.

Both of these guidelines may imply the move of a few elements from one bin to another. Bins may be emptied as an effect of element moving: in this case, the emptied bins are considered as automatically disregarded. Finally, please note that the algorithm may return some of the used bins as output before the end of the input list.

[8] As for Algorithm A_1, we do not explicitly consider the management of unfilled bins.

6.3. Data structures. The algorithm requires the use of

- one stack S, containing all the I_5-bins; the unfilled bin is the top one;
- three dictionaries, D_2, D_3, and D_4, maintaining all the I_k-elements contained exclusively in I_k-bins (not necessarily filled), for $k = 2, 3, 4$.
- three dictionaries (tournaments), G_1, G_2, and G_3, maintaining the size of the gap of all the I_1-, I_2-, I_3-filled bins.

We will not give details of the operations involved in inserting and deleting elements to and from the bins and the ones involved in the lists and in I_5-groups maintenance, since they can be easily performed in constant time. Moreover, we will not give details of the operations regarding the tree data structures since they are well known and they may be executed in $O(\log n)$ time. G_1, G_2, and G_3 can be implemented as binary trees of depth $\lceil \log_2 n \rceil$ with n leaves corresponding to the n bins in sequence from left to right. Each internal node is labeled with the largest label among the labels of its sons and each leaf is labeled with the current gap of the bin it represents. Please note that bins containing pairs $x \in I_1$ and $y \in I_4$ or $x \in I_2$ and $y \in I_3$ are immediately returned as output by the algorithm, hence they are not represented in these directories. The tree representation chosen is similar to the one Johnson used to implement the FIRST-FIT algorithm [23]. Last, we will not refer to the possible output of any bin (e.g., either all the I_0-bins or all the bins containing an I_2-element and an I_3-element could be sent to the output).

6.4. Algorithm primitives.

6.4.1. Insert(b,A). This primitive inserts object b, which could be either an item or a group, into bin A and updates, if necessary, one or two of the dictionaries.

Insert (b,A)

- "**Insert** b in A."
- **if** $b \in I_5$ **then** "**Append** b to an existing group or **Create a new group** with only b."
- "**Update**, if necessary, D_2, D_3 or D_4 and G_1, G_2 or G_3"

The updating operation is an $O(\log n)$-time operation and will be carried out only if

- both $(b \in I_k)$ and $(A \in I_k)$ $(k = 2, 3, 4)$ ("enter b in D_k");
- both $(b \in I_k)$ and $(A \in I_k)$ $(k = 1, 2, 3)$ AND A is filled as a consequence of this new element insertion ("enter A in G_k");
- $(A \in I_k)$ and $(b \notin I_k)$ $(k = 1, 2, 3)$ ("Update the size of the gap of A in G_k"). This case occurs only if A is filled and b has to be inserted in its gap.

In conclusion, the Insert operation is $O(\log n)$ worst case time.

6.4.2. Extract(b,A). This primitive extracts object b, which could be either an item or a group, from bin A and updates, if necessary, one or two of the dictionaries.

Extract (b,A)

- "Pop b from A"
- "Update, if necessary, D_2, D_3 or D_4 and G_1, G_2 or G_3"

The updating operation is an $O(\log n)$-time operation and will be carried out only if

- both $(b \in I_k)$ and $(A \in I_k)$ $(k = 2, 3, 4)$ ("extract b from D_k");
- both $(b \in I_k)$ and $(A \in I_k)$ $(k = 1, 2, 3)$, AND A becomes "unfilled" as a consequence of this element extraction ("extract A from G_k");
- $(A \in I_k)$ and $(b \notin I_k)$ $(k = 1, 2, 3)$ ("Update the size of the gap of A in G_k). This case occurs only if A is filled and b has to be extracted from its gap.

In conclusion, the Extract operation is $O(\log n)$ worst case time.

6.4.3. Move(b,B,A). This primitive moves object b from bin B to bin A. It is a composition of Extract(b,B) and Insert (b,A), so it is $O(\log n)$ worst case time.

6.4.4. Fill(C). This primitive fills the gap of the "filled" bin $C \in I_k (1 \le k \le 3)$ with smaller elements since there is no room in C (i.e., $gap(C) < \frac{1}{4}$) or there are no more of these little elements. This operation easily is $O(\log n)$ worst case time.

Fill (C)
if "there exists an I_4-bin B containing an element $b \in D_4$ such that $size(b) \le gap(C)$" **then** Move(b,B,C)
if $B \neq A_4$ **then** Move(x,A_4,B), "for whatever element $x \in A_4$"
else while "there exists $g \in A_5$ such that $size(g) \le gap(C)$ **AND** $gap(C) \ge \frac{1}{4}$" **do** Move(g,A_5, C)

6.4.5. MoveTheGap(C). This primitive moves all the objects (I_5-groups and eventually the only I_4-element) from the gap of bin C and distributes them among all the other bins. This operation easily is $O(\log n)$ worst case time.

MoveTheGap(C)
if "C contains an I_4-element, b" **then** Move(b,C,A)(where A is, in the sequence of checks, an I_1-bin, an I_2-bin, an I_3-bin or the A_4-bin)
for "every group $g \in C$" **do if** "there exists some I_1, I_2, I_3-bin C' with $size(g) \le gap(C')$" **then** Move (g,C,C') **else** Move(g,C,A_5)

6.5. The algorithm.

Algorithm A_2
For each element x:
if $x \in I_0$ **then**
- Insert(x,A), where A is a new I_0-bin;

if $x \in I_1$ **then**
- Insert(x,A), where A is a new I_1-bin;
- Fill(A);

if $x \in I_2$ **then**
- Insert(x,A), where A is a new I_2-bin;
- **If** there is a $b \in I_3$ in some I_3-bin B, so that $size(b) + size(x) \le 1$,
  then * Move (b,B,A); MoveTheGap (B);
  * **if** $B \neq A_3$ **then** "Move(b,A_3,B) for whatever element $b \in A_3$; Fill(B)"
  else * **Fill**(A);

if $x \in I_3$ **then**
- **If** there is a $b \in I_2$ in some I_2-bin B so that $size(b) + size(x) \le 1$
  then * **If** $size(x) > gap(B)$ **then** MoveTheGap (B);
  * Insert(x,B);
  else * Insert(x,A_3); **if** A_3 becomes filled, **then** Fill(A_3);

if $x \in I_4$ **then**
- **If** there is an I_1-bin B so that $size(x) \le gap(B)$, **then** Insert(x,B);
- **else** Insert (b,A) (where A is, in the sequence of checks, an I_2-bin, an I_3-bin or, at last, the A_4-bin).

if $x \in I_5$ **then**
- Create a group g containing only x;
- **If** there is an I_1, I_2, I_3-bin B such that $size(g) \le gap(B)$ **then** Insert(g,B) **else** Insert(g,A_5)

7. Performance analysis of A_2. In order to analyze the performance of the algorithm we must first consider the number of element movements caused by the arrival of a new input element and then its asymptotic performance ratio.

7.1. Time, space, and movements.

LEMMA 7.1. *Each filled I_1-bin may contain, in its gap, no more than two I_5-groups.*

Proof. If we assume there are more than two I_5-groups in a filled I_1-bin and let x, y, z be three of them, by definition it follows that

$$x \le \frac{1}{4}, \quad y \le \frac{1}{4}, \quad z \le \frac{1}{4}; \qquad x+y > \frac{1}{4}, \quad x+z > \frac{1}{4}, \quad y+z > \frac{1}{4}.$$

Moreover, an I_1-bin B, has $gap(B) < \frac{1}{3}$, thus $x+y+z < \frac{1}{3}$. Hence

$$\frac{1}{3} > x+y+z > \frac{1}{4} + z \Rightarrow z < \frac{1}{12}.$$

Therefore

$$x > \frac{1}{4} - z > \frac{1}{6}; \qquad y > \frac{1}{4} - z > \frac{1}{6}; \qquad x+y+z > \frac{1}{3},$$

which is a contradiction. □

LEMMA 7.2. *Each filled I_2-bin may contain no more than three I_5-groups or one I_4-element plus one I_5-group in its gap.*

Proof. Let us assume there are more than three I_5-groups in a filled I_2-bin. Let x, y, z, w be four of them. By definition of *group* we have that

$$x \le \frac{1}{4}, \quad y \le \frac{1}{4}, \quad z \le \frac{1}{4}, \quad w \le \frac{1}{4}, \quad x+y > \frac{1}{4}, \quad x+z > \frac{1}{4},$$
$$x+w > \frac{1}{4}, \quad y+z > \frac{1}{4}, \quad y+w > \frac{1}{4}, \quad z+w > \frac{1}{4}.$$

By construction, an I_2-bin, B, has $gap(B) < \frac{1}{2}$, so $x+y+z+w < \frac{1}{2}$.

Therefore

$$\frac{1}{2} > x+y+z+w > \frac{1}{4} + z + w \Rightarrow z+w < \frac{1}{4},$$

which is a contradiction.

Similarly, let us assume that the group contains one I_4-element together with two I_5-groups. Let x be the I_4-element and let y, z be the I_5-groups. By definition, we have that $x \ge \frac{1}{4}$, $y+z \ge \frac{1}{4}$.

By construction, an I_2-bin, B, has $gap(B) < \frac{1}{2}$, so $x+y+z < \frac{1}{2}$.

Therefore

$$\frac{1}{2} > x+y+z > \frac{1}{4} + y + z \Rightarrow y+z < \frac{1}{4},$$

which is a contradiction. □

LEMMA 7.3. *Each filled I_3-bin may contain no more than two I_5-groups or one I_4-element plus one I_5-group in its gap.*

Proof. The first bound is proved as in Lemma 7.1.

To prove the second bound let us assume that the group contains one I_4-element and one I_5-group. Let x be the I_4-element and let y, z be the I_5-groups. By definition, we have that $x \ge \frac{1}{4}$, $y+z \ge \frac{1}{4}$.

By construction, an I_3-bin, B, has $gap(B) < \frac{1}{3}$, so $x+y+z < \frac{1}{3}$.

Therefore

$$\frac{1}{3} > x+y+z > \frac{1}{4} + y + z \Rightarrow y+z < \frac{1}{12},$$

which is a contradiction. □

LEMMA 7.4. *Each I_5-bin may contain no more than seven I_5-groups.*

Proof. It follows from the definition of I_5-group. □

The bound of the previous lemma is tight. The sequence matching this bound is $\frac{1}{8}, \frac{1}{8}, \frac{1}{8}, \frac{1}{8}, \frac{1}{8}, \frac{1}{8}, \frac{1}{8}, \frac{1}{8} + \epsilon$, when no one of the these elements has to be fitted in any of the I_k-bins ($0 \leq k \leq 3$) and there is no (unfilled) I_5-bin at the arrival of the first element of the subsequence.

THEOREM 7.5. *In every moment, Algorithm A_2 maintains at most a constant number of I_5-groups and I_4-elements, and no other different level element, in the gap of each bin.*

Proof. It derives from Lemmas 7.1, 7.2, 7.3, and 7.4 and by the fact that I_0-bins contain only I_0-elements and I_4-bins contain only I_4-elements.

The remaining part of the theorem is proved by observing that no I_3-element can be fitted in the gap of any I_0-, I_1-, I_4-, I_5-bin while those fitted in the gap of I_2-bins are immediately returned as output. Note that, for the same reason, no I_4-element is maintained in the gap of any I_1-bin. □

LEMMA 7.6. *When procedure* **Fill** *is called to "fill" an I_k-bin ($1 \leq k \leq 3$) it performs no more than two I_4-element movements or three I_5-group movements.*

Proof. The first bound is simply inferred from the algorithm structure.

The second one is easily obtained by considering that, in every moment, there is only one "unfilled" I_5-bin, named A_5. If $SIZE(A_5) > \frac{1}{4}$ procedure **Fill** moves no more than two groups from it since, whatever is the I_5-bin, any pair of groups has a total size $\geq \frac{1}{4}$, each filled bin has a gap $< \frac{1}{2}$, and the loop ends when $gap(A) < \frac{1}{4}$. If $SIZE(A_5) \leq \frac{1}{4}$ then it contains only one group. Let ϵ be its size. If $SIZE(A) + \epsilon < \frac{3}{4}$ and there is another I_5-bin (that is necessarily filled) the situation is the same as the above. Thus, the total number of group movements is three. □

The bound of the previous lemma is tight. In fact let us suppose that the input sequence starts with the following elements: $\frac{1}{8}, \frac{1}{8}, \frac{1}{8}, \frac{1}{8}, \frac{1}{8}, \frac{1}{8}, \frac{1}{8} + \epsilon, \epsilon, \frac{1}{2} + \epsilon$; in this case the first seven elements will be fitted in one I_5-bin, the eighth will be fitted in another I_5-bin and the last will be fitted in an I_2-bin. The **Fill** procedure will move ϵ, then $\frac{1}{8} + \epsilon$, and at last $\frac{1}{8}$ to the gap of the I_2-bin.

THEOREM 7.7. *In correspondence to each insertion, a constant number of element or group movements is performed.*

Proof. Let x be the current input element to be fitted in any bin. Then the algorithm makes

- $x \in I_0$
  - 0 movements
- $x \in I_1$
  - no more than three movements (Lemma 7.6) as a consequence of
    - (two I_4-element movements) OR (three I_5-group movements)
- $x \in I_2$
  - no more than seven movements[9] as a consequence of
    - one I_3-element movement
    - two movements (Lemma 7.3) as a consequence of
      - (one I_4-element and one I_5-group movement) OR (two I_5-group movements)
    - one I_3-element movement
    - no more than three movements (Lemma 7.6) as a consequence of
      - (two I_4-element movements) OR (three I_5-group movements)

    OR, alternatively,
  - no more than three movements (Lemma 7.6) as a consequence of

[9] If there exists a $b \in I_3$ such that $size(x) + size(b) \leq 1$.

(two I_4-element movements) OR (3 I_5-group movements)

$x \in I_3$ • no more than three movements[10] (Lemma 7.2) as a consequence of
(one I_4-element and one I_5-group movements) OR (three I_5-group movements)
OR, alternatively,
• no more than three movements (Lemma 7.6) as a consequence of
(two I_4-element movements) OR (three I_5-group movements)

$x \in I_4$ • 0 movements.

$x \in I_5$ • 0 movements.

Therefore, in each case, the total number of element (or group) movements is constant. □

COROLLARY 7.8. *No more than seven element movements occur at the arrival of a new input element when A_2 is applied to a list of n elements.*

Proof. The proof is easily derived from Theorem 7.7. □

THEOREM 7.9. *Algorithm A_2 has space complexity $O(n)$.*

Proof. The theorem is easily proved when observing that each element is represented no more than once in the list S or in the data structures involved and that the maximum number of gaps is n. □

THEOREM 7.10. *Algorithm A_2 has time complexity $O(n \log n)$.*

Proof. According to Theorem 7.7, the time complexity is bounded by n times the cost of an element insertion or movement. Each insertion and each movement of an element already in the structure is performed at most in $O(\log n)$ time, when the tree data structures are involved. In fact the directory representation for the gaps of I_1-, I_2-, I_3-bins allows the finding of the right element in no more than $\lceil \log_2 n \rceil$ binary comparisons and the update operations may be performed by using no more than $\lceil \log_2 n \rceil$ comparisons [23]. This same principle is valid for the heaps maintaining the I_3-and I_4-elements [33]. □

7.2. Performance ratio. In the following items we assume that

- N_j is the total number of I_j-elements in the input list L.
- H is the size of the best matching between I_2-and I_3-elements, that is, the maximum number of pairs $x_2 \in I_2$, $x_3 \in I_3$ which can be coupled. Note that this corresponds to the maximum matching in a bipartite graph $G = (N_2 \cup N_3, E)$ so that
  - $N_2 = \{x \in I_2\}$,
  - $N_3 = \{x \in I_3\}$,
  - $E = \{(x, y) | x \in N_2, y \in N_3, size(x) + size(y) \leq 1\}$.
- K is the size of the best matching between I_1-and I_4-elements, that is, the maximum number of pairs $x_1 \in I_1$, $x_4 \in I_4$ which can be coupled. Please note that this corresponds to the maximum matching in a bipartite graph $G = (N_1 \cup N_4, E)$ so that
  - $N_1 = \{x \in I_1\}$,
  - $N_4 = \{x \in I_4\}$,
  - $E = \{(x, y) | x \in N_1, y \in N_4, size(x) + size(y) \leq 1\}$.

LEMMA 7.11. *If S is not empty after all the elements have been considered, then $R_{A_2} < \frac{4}{3}$.*

Proof. By hypothesis, since there is at least one group with size $\leq \frac{1}{4}$ which cannot be moved to a different gap, all of the I_0-, I_1-, I_2-, I_3-bins have a gap $< \frac{1}{4}$.

[10] If there exists a $b \in I_2$ such that $size(x) + size(b) \leq 1$.

Moreover, each I_k-bin ($k \geq 4$) has a gap $< \frac{1}{4}$.
Consequently, the maximum gap in each bin is $< \frac{1}{4}$, and

$$R_{A_2} < \frac{4}{3}. \qquad \square$$

LEMMA 7.12. *If $H = 0$ and S is empty after all the elements have been considered, then $R_{A_2} \leq \frac{4}{3}$.*

Proof. We can observe two different situations:

- In the input list there is no I_4-element.
  In this case A_2 uses no more than $N_0 + N_1 + N_2 + \frac{N_3}{2}$ bins, since no I_2-element or I_3-element could be inserted in any bin already containing an I_1-element or an I_0-element and no more than two I_3-elements may be inserted in any other bin. OPT cannot use fewer bins, since $H = 0$ implies that no bin can contain both an I_2-element and an I_3-element. Therefore

$$R_{A_2} = 1.$$

- In the input list there were some I_4-elements.
  Let $\alpha = N_1 + N_2 + \frac{N_3}{2}$. In this case we can still obtain two situations:
  $N_4 \leq \alpha$ then
  - OPT uses at least $\alpha + N_0$ bins.
  - A_2 uses no more than $N_0 + \alpha + \frac{N_4}{3}$ bins, in case it does not insert any I_4-element into some other bin. Then $A_2 \leq N_0 + \alpha + \frac{\alpha}{3} = N_0 + \frac{4}{3}\alpha$ and so

$$R_{A_2} \leq \frac{\frac{4}{3}\alpha + N_0}{\alpha + N_0} < \frac{4}{3}.$$

  $N_4 > \alpha$ then let $\beta = N_4 - \alpha$.
  - OPT cannot use fewer than $N_0 + \alpha + \frac{\beta}{3}$ bins, since no more than one I_4-element can fit into an I_1-, I_2-, or I_3-bin.
  - A_2 uses no more than $N_0 + \alpha + \frac{N_4}{3}$ bins. Then $A_2 \leq N_0 + \alpha + \frac{\alpha+\beta}{3} = N_0 + \frac{4}{3}\alpha + \frac{\beta}{3}$. Therefore we have

$$\frac{A_2}{OPT} \leq \frac{\frac{4}{3}\alpha + \frac{\beta}{3} + N_0}{\alpha + \frac{\beta}{3} + N_0} < \frac{4}{3}. \qquad \square$$

LEMMA 7.13. *If $H \neq 0$ and in the input sequence $L = \{a_1, a_2, \ldots, a_n\}$ there are no I_k-elements ($k \geq 4$), then $R_{A_2} < \frac{5}{4}$.*

Proof. OPT uses at least
N_0 bins to pack all the I_0-elements;
N_1 bins to pack all the I_1-elements;
N_2 bins to pack all the I_2-elements;
$\frac{N_3 - H}{2}$ bins to pack all the I_3-elements, since H of them are inserted in the gap of the H I_2-elements.
Hence,

$$OPT \geq N_0 + N_1 + N_2 + \frac{N_3}{2} - \frac{H}{2}.$$

A_2 uses no more than

N_0 bins to pack all the I_0-elements;
N_1 bins to pack all the I_1-elements;
N_2 bins to pack all the I_2-elements;
$\frac{N_3-\frac{H}{2}}{2}$ bins to pack all the I_3-elements, since $\frac{H}{2}$ of them are necessarily packed with a corresponding I_2-element [22].

Hence

$$A_2 \leq N_0 + N_1 + N_2 + \frac{N_3}{2} - \frac{H}{4}.$$

In conclusion, since $H \leq N_3$ and $H \leq N_2$, it follows that

$$\frac{A_2}{OPT} \leq \frac{4N_0 + 4N_1 + 4N_2 + 2N_3 - H}{4N_0 + 4N_1 + 4N_2 + 2N_3 - 2H} \leq \frac{4N_0 + 4N_1 + 5N_2 + 2N_3 - 2H}{4N_0 + 4N_1 + 4N_2 + 2N_3 - 2H} < \frac{5}{4}. \qquad \square$$

LEMMA 7.14. *If $H \neq 0$ and in the input sequence $L = \{a_1, a_2, \ldots, a_n\}$ there are some I_k-elements ($k \geq 4$), and S is empty after all elements have been considered, then $R_{A_2} \leq \frac{4}{3}$.*

Proof. Let B_i be the number of bins of level i used by OPT and let B'_i be the number of bins of level i used by A_2. We calculate the maximum number of bins used by A_2 as a function of the B_i's.

We can obtain two different situations:

- In the case that no I_4-bins are returned as output, since in such a case there are no I_5- and I_4-bins, we can say that $OPT = B_0 + B_1 + B_2 + B_3$:
  $B'_0 = B_0$;
  $B'_1 = B_1$;
  $B'_2 = B_2$;
  $B'_3 \leq B_3 + \frac{\frac{H}{2}}{2}$;
  Therefore, since $H \leq B_2$,

$$A_2 \leq B_0 + B_1 + \frac{5}{4}B_2 + \frac{5}{4}B_3 \leq \frac{5}{4}\text{OPT}.$$

- In the case that some I_4-bins are returned as output, since in such a case there are no I_5-bins, we can say that $OPT = B_0 + B_1 + B_2 + B_3 + B_4$:
  $B'_0 = B_0$;
  $B'_1 = B_1$;
  $B'_2 = B_2$;
  $B'_3 \leq B_3 + \frac{\frac{H}{2}}{2}$;
  $B'_4 = B_4 + [K + (B_2 - H) + B_3]\frac{1}{3} = \frac{B_2}{3} + \frac{B_3}{3} + B_4 + \frac{K}{3} - \frac{H}{3}$.
  Therefore, since $K \leq B_1$ and $H \geq 0$,

$$\begin{aligned} A_2 &\leq B_0 + B_1 + \tfrac{4}{3}B_2 + \tfrac{4}{3}B_3 + B_4 + \tfrac{k}{3} - \tfrac{H}{12} \\ &\leq B_0 + \tfrac{4}{3}B_1 + \tfrac{4}{3}B_2 + \tfrac{4}{3}B_3 + B_4 \leq \tfrac{4}{3}\ \text{OPT}. \end{aligned} \qquad \square$$

THEOREM 7.15. *Algorithm A_2 has a ratio of $R_{A_2} \leq \frac{4}{3}$.*

Proof. The proof is easily given by the previous lemmas. $\square$

THEOREM 7.16. *Algorithm A_2 is $A\ (7, 1.33)$.*

Proof. The proof is given by Corollary 7.8 and Theorem 7.15. $\square$

8. Conclusions and open problems. This paper focuses its attention on the possibility of maintaining a guaranteed approximation of the optimal solution for the online bin-packing problem in terms of time computation and element movements and with a limited reorganization of the previous solutions.

The problem is equivalent to the one considered in the more general bin-packing model where the elements can move (for a limited number of times) from the bin they are currently assigned to. Please note that this model still fits the general definition of online algorithms.

It would be interesting to see if these algorithms frequently touch any particular element and move it many times: it is also possible to demonstrate that the first algorithm (A_1) moves an element no more than once.

Contrarily to the offline model, the requests arriving to this model reach it online and the bins are always ready to be closed with no additional effort. This model is suitable in many different fields (for example in multiprocessor storage management and in packing trucks).

In the environment of this less restricted model, we have presented two new algorithms with the best approximation ratio available at this time, respectively, for linear and $O(n \log n)$ algorithms.

These algorithms are also "more" online than all the other linear space online bin-packing algorithms, because they allow the return of a fraction of the bins before the end of the execution.

There are still a lot of problems which remain to be solved in this area. First, it would be interesting to check if algorithms more efficient than A_2 can be found (as far as approximation ratio and/or time complexity are concerned). Generally speaking, it would also be interesting to define the lower bounds of the approximation ratio of the $O(n \log n)$ algorithms that allow the element to freely move between the bins.

It would also be interesting to verify if there is some kind of relation between the (amortized) number of movements allowed at the arrival of each input element and the asymptotic performance ratio. In other words: is there an algorithm that for each ϵ constant is $A(\frac{1}{\epsilon}, f(\epsilon))$?

It would also be useful to gain more knowledge about whether the approximation ratio can be maintained and if it is possible to send output the bins containing "enough" of the elements contained therein (e.g., what happens when all the bins with gap less than $\frac{k}{3}$ ($k \leq 1$) are send output?).

Other interesting questions concern the capacity of deleting elements from the bins maintaining the guaranteed algorithm performance (the target is to minimize the space wasted considering the actual element involved) and the analytical evaluation of the average performance of this algorithm compared to the ones characterized in [27], [30], [29], [32]. It would be very interesting to study the performances of the algorithm as a function of the number of movements admitted.

Acknowledgments. We are grateful to two anonymous referees for their useful remarks and to Giuseppe Alesio and Gennaro Gravina for useful discussions.

We also wish to thank Lucio Bianco of CNR IASI, Rome, for suggesting the transportation applications.

TIGHT BOUNDS FOR SEARCHING A SORTED ARRAY OF STRINGS*

ARNE ANDERSSON†, TORBEN HAGERUP‡, JOHAN HÅSTAD§, AND OLA PETERSSON¶

Abstract. Given a k-character query string and an array of n strings arranged in lexicographical order, computing the rank of the query string among the n strings or deciding whether it occurs in the array requires the inspection of

$$\Theta\left(\frac{k\log\log n}{\log\log(4+\frac{k\log\log n}{\log n})}+k+\log n\right)$$

characters in the worst case.

Key words. string searching, character comparisons, dictionaries, potential functions, lower bounds

1. Introduction.

Given n strings, each of k characters, arranged in lexicographical order (i.e., a string precedes a string from which it differs if it has the smaller character in the first position in which the two strings differ), how many characters must we inspect to determine whether a k-character query string is present? We assume that the n strings are given in a $k \times n$ array and that no extra information is available. If k is a constant, we can solve the problem with $\Theta(\log n)$ character inspections by means of binary search, and this is optimal; but what happens for larger values of k? In the presence of preprocessing and extra storage, there are efficient methods, such as using a tree, each node of which can be implemented as a weighted tree as suggested by Mehlhorn [7, Sect. III.6.3], or the suffix array of Manber and Myers [6]; but what if we are given just the sorted strings?

The question is a basic one; we are simply asking for the complexity of searching a dictionary for a string, where the common assumption that entire strings can be compared in constant time is replaced by the assumption that only single characters can be compared in constant time. For sufficiently long strings, the latter assumption seems more realistic. At first glance the problem may appear easy—some kind of

generalized binary search should do the trick. However, closer acquaintance with the problem reveals an unexpected intricacy.

Given the relevance of this problem, surprisingly few results have been reported. Hirschberg [4] indicated a lower bound of $\Omega(k+\log n)$ and upper bounds of $O(k \log n)$ and $O(k+n)$ and combined the upper bounds to derive a bound of $O(k \log(2+n/k))$, all of which is straightforward. A later publication by the same author [3] mentions a first nontrivial upper bound of $O(k \log n/\log k)$. Kosaraju [5] gave an algorithm with a running time of $O(k\sqrt{\log n} + \log n)$. The only nontrivial lower bound deals with constant factors: Kosaraju [5] showed that at least roughly $\log n + \frac{1}{2}\sqrt{k \log n} = O(k + \log n)$ characters need to be inspected. We determine the exact complexity of the problem, up to a constant factor.

Before formulating our result, we describe two relevant computational problems more formally. For all integers $k, n \geq 1$ and all ordered sets Σ, an instance of the *string-ranking problem* of size $k \times n$ over the alphabet Σ is given by a list $s, s_1, \ldots, s_n$ of $n+1$ strings, each consisting of k characters drawn from Σ, such that $s_1 \preceq \cdots \preceq s_n$, where $\preceq$ denotes the lexicographical order derived from the order on Σ. The task is to compute $|\{j : 1 \leq j \leq n \text{ and } s_j \preceq s\}|$, i.e., the rank of s in the multiset $\{s_1, \ldots, s_n\}$. An instance of the *string-membership problem* of size $k \times n$ over Σ is given by a list of the same form, and the task is to output "yes" if $s = s_j$ for some $j \in \{1, \ldots, n\}$, and "no" otherwise.

The string-membership problem clearly is no harder than the string-ranking problem in the sense that after solving the latter, we can solve the former after inspecting at most k additional characters. An algorithm for the string-ranking problem also allows us to determine the indices of the first and last occurrences, if any, of the query string. As implied by our result, stated below, these problems in fact all have the same deterministic complexity, up to a constant factor. The logarithm function to base 2 is denoted by "log."

THEOREM 1.1. *For all integers $k \geq 1$ and $n \geq 4$ and all ordered sets Σ of at least two elements, the solution of instances of size $k \times n$ of the string-ranking problem and of the string-membership problem over the alphabet Σ requires the inspection of*

$$\Theta\left(\frac{k \log\log n}{\log\log\left(4 + \frac{k \log\log n}{\log n}\right)} + k + \log n\right)$$

characters in the worst case.

As a curiosity we note that for the special case $k = \Theta(\log n)$, natural in view of the lower bound of $\Omega(k + \log n)$, we get a tight bound of

$$\Theta\left(\frac{\log n \log\log n}{\log\log\log\log n}\right),$$

which would have been hard to guess in advance.

This paper is based on the two conference presentations [1] and [2]. The proofs given here are significantly shorter and simpler due to the use of potential functions. All four authors contributed equally to both upper-bound and lower-bound parts of the paper.

After introducing notation and terminology in section 2, we provide intuition in section 3, and we prove the upper bound in section 4 and the lower bound in section 5. Sections 3, 4, and 5 can be read independently of each other.

2. Preliminaries.

2.1. The leftmost-all-1 problem. To simplify the presentation, we introduce a simplified searching problem called the *leftmost-all*-1 problem and demonstrate the upper bound first for this problem. For all integers $k, n \geq 1$, the leftmost-all-1 problem of size $k \times n$ is the special case of the string-ranking problem of size $k \times n$ obtained by fixing the alphabet to be $\{0, 1\}$ and the query string to be $1^{k-1}0$ (i.e., $k-1$ 1's followed by one 0). We assume an instance of the leftmost-all-1 problem of size $k \times n$ to be given in a $k \times n$ matrix I in the following way: for $i = 1, \ldots, k$ and $j = 1, \ldots, n$, $I[i, j]$ is the ith character of the jth string; i.e., each string is written vertically from top to bottom, and the strings are ordered from left to right. The rows and columns of I are numbered from top to bottom and from left to right, respectively, the number of a row or column also being called its *index*. The task is to determine the number of columns in I that contain at least one 0. An alternative formulation, which gives the problem its name, is that the task is to compute one less than the index of the leftmost column in I containing the string 1^k, or n if there is no such column. An algorithm for the leftmost-all-1 problem is said to perform a *probe* when it examines an entry in I, and we charge the algorithm according to how many probes it performs.

2.2. Surface and fence algorithms. In this subsection we introduce terminology convenient for discussing solutions to the leftmost-all-1 problem. The terminology is illustrated in Figures 2.1 and 2.2.

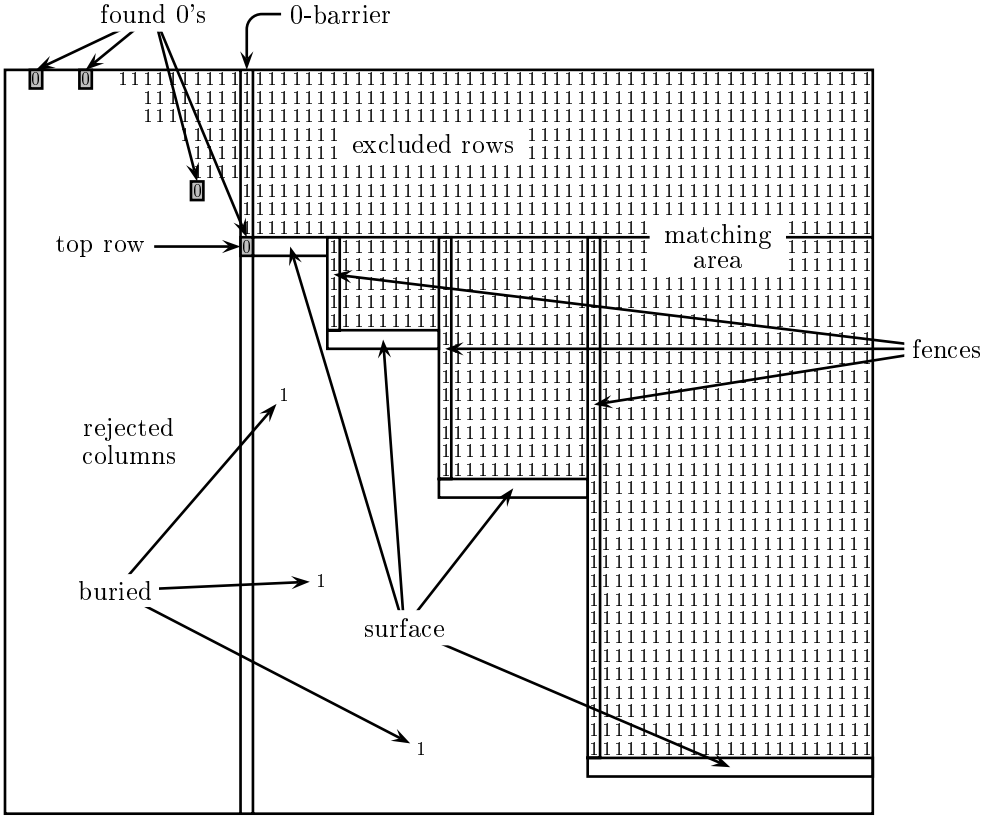

FIG. 2.1. *Terminology related to surface algorithms.*

Consider an algorithm for the leftmost-all-1 problem that inspects entries in a $k \times n$ input matrix I one by one. Once the algorithm has established that certain positions in I contain 1's, it may be able to deduce from the sortedness of I and without actual probes that certain other positions in I must also contain 1's. Specifically, let $1 \leq r \leq k$ and $1 \leq c \leq n$, and suppose that the algorithm has already established that $I[i, c] = 1$ for $i = 1, \ldots, r$. Then, clearly, we also have $I[i, j] = 1$ for $i = 1, \ldots, r$ and $j = c + 1, \ldots, n$. We say that these additional occurrences of 1 in I are deduced by 1-*extension*.

If a column in I is known to contain at least one 0 because a 0 was found in the column itself or in a column to its right, the column and all positions in the column are said to be *rejected*; such a column cannot be the leftmost column containing the string 1^k. The rightmost rejected column is called the 0-*barrier*; initially, before any columns have been rejected, we take the 0-barrier to be an imaginary column of index 0. The remaining positions are classified as follows. If a nonrejected position is known to contain a 1, either because it was explicitly probed or by way of 1-extension, it belongs to the *matching area*—the entries in this area are known to match those of the string 1^k. A nonrejected position outside of the matching area is a *surface position* if all positions above it belong to the matching area, and a *buried position* otherwise. Of course, each column contains at most one surface position.

For $r = 1, \ldots, k$, row r is said to be *excluded* if none of the rows $1, \ldots, r$ contains a surface position. The part of an excluded row outside of the rejected columns is known to contain only 1's. If and when an algorithm for the leftmost-all-1 problem manages to exclude the last row, it can therefore output the number of rejected columns as its result. As long as at least one row is not excluded, we define the *top row* to be the topmost nonexcluded row. Initially, no columns are rejected and no rows are excluded, row 1 is the top row, all positions in the top row are surface positions, and all other positions are buried positions.

A *surface probe* is a probe that inspects the entry in a surface position, and a *surface algorithm* is an algorithm all of whose probes are surface probes. We call a surface probe *successful* if it returns a 1 (the string probed still matches the string 1^k) and *unsuccessful* if it returns a 0. The following observations are helpful.

Whenever a surface algorithm finds a 1 in some position, that position and all positions above it and to its right subsequently are part of the matching area. If the position containing the 1 is in the column next to the 0-barrier, the row containing the 1 is excluded and the top row moves down by one position.

Whenever a surface algorithm finds a 0 in a particular column, the 0-barrier moves to that column, and that column and all nonrejected columns to its left are rejected. Since the newly rejected columns may have contained all surface positions of some rows, this may also cause the top row to move downwards. The new top row will be either the row in which the 0 was found or a row below it; the latter happens when the position immediately to the right of the 0 belongs to the matching area.

It can be seen that at all times during the execution of a surface algorithm, a position above or to the right of a position in the matching area also belongs to the matching area—we express this by saying that the matching area is *monotonic*—so that the boundary between the matching area and the remaining positions forms a "staircase" going down and to the right. The part of a column contained in the matching area but outside of the excluded rows is called a *fence* if at least one position immediately to its left is not part of the matching area (i.e., a fence resides in a column where the matching area becomes "deeper"). A *fence algorithm* is a surface algorithm

each of whose probes is a *top-row probe*, i.e., a probe in the (current) top row, or an *extending probe*, i.e., a probe of an entry immediately below an existing fence.

The height of a fence F, denoted $|F|$, is defined as the number of positions contained in F. It is obvious that every fence is strictly higher than every fence to its left. When a fence algorithm executes a probe below a fence F, we will say that it attempts to *extend* F. If the extension is successful, the height of F usually increases by 1, i.e., the position probed and the positions belonging to F before the probe form a fence that we identify with F; two exceptions are noted below. If the extension is unsuccessful, F and all fences to the left of F (equivalently, shorter than F) are *excluded*, since they are now completely contained in the excluded rows (and in the rejected columns), while the height of every other fence decreases by the number of rows excluded.

An exceptional case of a successful extension of a fence F or of a successful top-row probe that creates F occurs if, before the probe, some fence F' to the right of F had the same height as F after the probe; i.e., a "stair" of the "staircase" vanishes. In this case we will say that F and F' *merge* to create a new fence. We shall frequently need to distinguish between new fences that result from merges and new fences that result from successful top-row probes (without a merge or before a merge triggered by the probe); we shall say that the latter fences are created *from scratch*.

Another exceptional situation happens when a fence algorithm finds a 1 in the column next to the 0-barrier or a 0 in the column immediately to the left of some fence. In either case, no new fence is created, no merge takes place, one or more rows are excluded, and one or more fences may be excluded. We call a probe *excluding* if it causes one or more rows to be excluded.

The *gap* of a fence F is defined as its distance from the 0-barrier, i.e., as $c_F - c_Z$, where c_F and c_Z are the indices of the column containing F and of the 0-barrier, respectively. Observe that the gap of every fence is at least 2. The *index* of a fence is one more than the number of fences strictly to its right; in other words, the fences are numbered from right to left. The proofs of both the upper bound and the lower bound associate with each fence F an integer *weight*, denoted $\|F\|$. We define the *cumulative weight* of a fence as the sum of its own weight and the weights of all fences of strictly smaller index; i.e., if the weights are summed from right to left, the partial sum obtained for each fence is its cumulative weight.

We will denote by $\mathcal{F}$ the (current) list of fences, ordered from left to right. For example, if $\mathcal{F} = (F_N, \ldots, F_1)$, then F_N and F_1 are the leftmost and rightmost fences, respectively, and $1 \le |F_N| < \cdots < |F_1|$. For $i = 2, \ldots, N$, we call F_i the *left neighbor* of F_{i-1} and F_{i-1} the *right neighbor* of F_i.

Figure 2.2 illustrates the various possibilities for a surface probe. Rejected columns and excluded rows are separated from the remaining positions by double vertical and horizontal lines, respectively, the matching area is filled with 1's, and unknown entries that are still of interest are represented by dark squares. Consider the situation in (a), in which we have two fences: F_1 of height 3 in column 10 and F_2 of height 2 in column 7. The six situations in (b)–(g) show possible results of performing one probe, starting from (a). The contents of the probed position are circled. (b) shows a successful top-row probe, creating a new fence of height 1 from scratch in column 5. (c) shows an unsuccessful top-row probe in column 5. (d) shows a successful extension of F_2, leading to a merge of F_1 and F_2. (e) shows an unsuccessful attempt to extend F_2. (f) shows a successful top-row probe in the column next to the 0-barrier; no new fence is created, but one row is excluded. (g) shows an unsuccessful top-row probe

in the column next to the leftmost fence F_2; F_2 and the rows that it spans are excluded. Finally, starting from the situation in (b), (h) shows a successful top-row probe performed when the leftmost fence is of height 1; the new fence immediately merges with its right neighbor to form a new leftmost fence.

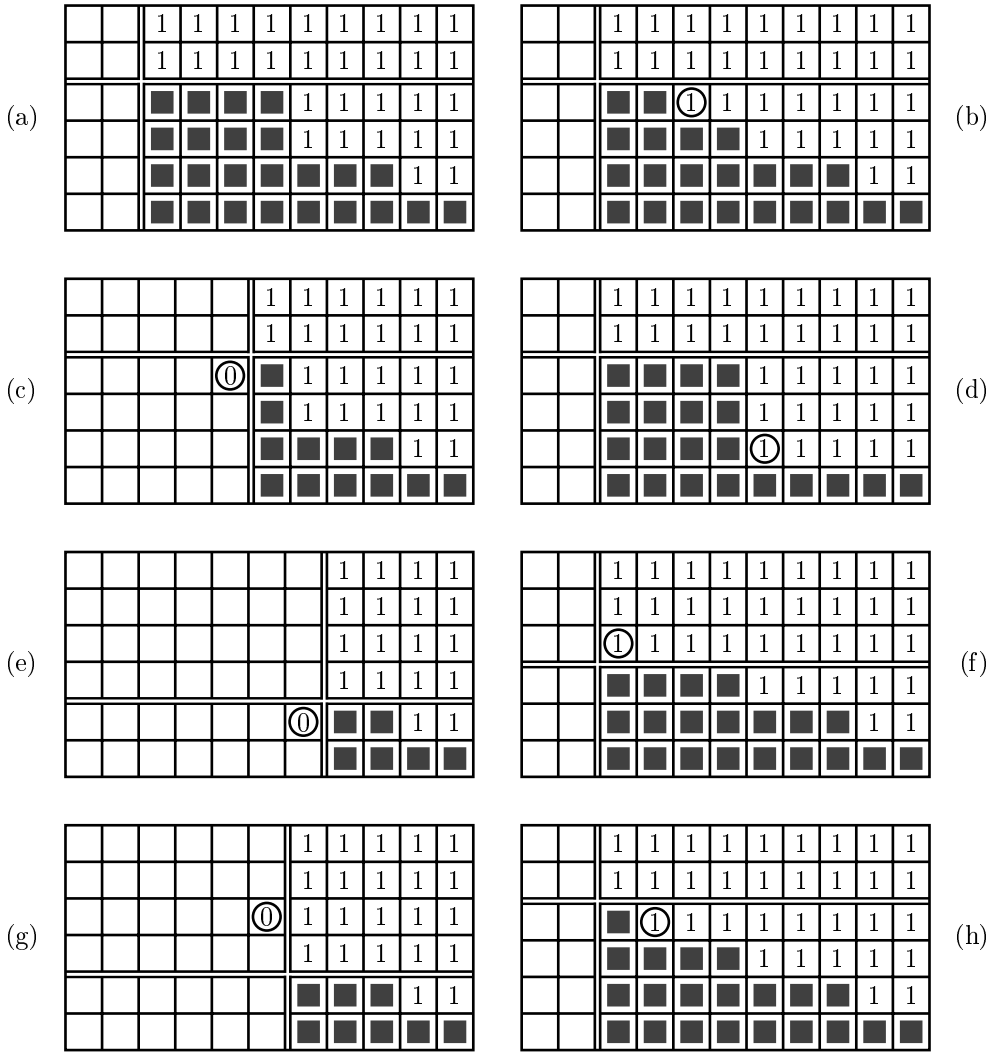

FIG. 2.2. *Possible outcomes of a surface probe.*

3. Intuitive sketch. Before delving into the formal arguments, let us try to provide intuition behind some important parameters used in the proofs of the upper and lower bounds. The reader should keep in mind that we do not claim to *prove* anything in this section, but merely to show how one may arrive at the parameter values of the proofs through plausible reasoning. Exact values of the parameters and rigorous proofs are given in the remainder of the paper. This section can be skipped without loss of continuity.

First, fence algorithms do come naturally—and one conclusion of our work is that they are optimal, up to a constant factor—so let us concentrate on fence algorithms.

Since the goal of a fence algorithm can be viewed as that of excluding all k rows, a natural measure of its progress is the number of rows that it has managed to exclude so far. Excluding a row comes at a certain price, however, since, in some sense, all probes of positions in a row become worthless when the row is excluded. Our main concern, therefore, will be not to perform too many probes per row, at least in an amortized sense. A symmetric argument could be made concerning rejected columns instead of excluded rows, but this appears to offer less useful insights.

Important properties of a fence algorithm are the number of fences, their spatial distribution, and their heights. Suppose that we aim for a bound of the form kt for some value of t. That is, we wish to spend an average of t probes per row. We must analyze what happens when we fail to extend a fence. One the one hand, we gain one or more rows, i.e., they are excluded, but on the other hand we lose probes. We identify two kinds of losses.

1. All fences contained in the excluded rows disappear, and thus all probes spent to create these short fences are now useless.
2. If N fences remain after the row exclusions, N probes per row used in building these fences are now useless. This suggests that we should keep the number of fences bounded by t.

Let us define some quantities needed to analyze losses of the first kind. When creating a new fence from scratch, it is natural to probe the middle entry of the unknown part of the top row, that is, to make one step of a binary search for locating the rightmost 0 in that row. Suppose that we perform more such probes, all of which find 1's. In effect, the new fence moves leftward and away from its neighboring fence, while still being of height 1. It is intuitively clear that as the new fence F moves to the left, it becomes more and more valuable to the fence algorithm. In order to quantify this, we count the number of binary-search steps used to move F to its current position and call this number the *weight* of F, denoted $\|F\|$. When two fences merge, we define the weight of the resulting fence to be the sum of the weights of the two fences from which it is formed. It can be seen that with this rule, the total weight of all fences can grow to around $\log n$, but not beyond that.

A second important quantity associated with a fence F is the total number of probes spent to construct F. We call this the *investment* in F and denote it by $\mathit{Invest}(F)$. Investments also add up when fences merge. Investments differ from weights in that vertical extensions of fences are counted in the former, but not in the latter. As a consequence, $\mathit{Invest}(F) \geq \|F\|$ for every fence F.

As observed above, we want at most t fences, and a natural way to spread the fences is to make sure that, going from left to right, they are of exponentially increasing weights. If weights increase by a factor of a from each fence to the next, then we should have $a^t = \log n$ or, equivalently,

$$\log a = \frac{\log \log n}{t}, \tag{3.1}$$

since the maximum weight of any fence is around $\log n$.

Consider a loss of the first kind. As stated above, we choose the weights of the existing fences to be exponentially increasing from left to right, and it turns out that the same will be true for the investments in the fences. Hence a constant fraction of the loss is due to the disappearance of the tallest excluded fence; for simplicity, we assume that this is the only loss.

We want the height of a fence to be a function simply of its weight, and we denote the relevant function by T. Now consider the situation when we fail to extend a fence

F. We gain $T(\|F\|)$ rows and lose the investment $\mathit{Invest}(F)$. To keep the cost of t probes per row, this means that we need

$$T(\|F\|) \geq \mathit{Invest}(F)/t \geq \|F\|/t. \tag{3.2}$$

It is natural to assume that it is optimal for the first inequality to hold with equality. Under this assumption, let us analyze the key operation of merging two fences.

Consider two fences F and F' that merge, with F' to the left of F. The merge is caused by a number of probes that extend F'. Assume that before these probes are made, F and F' are of heights $T(\|F\|)$ and $T(\|F'\|)$, respectively, and that $tT(\|F\|)$ and $tT(\|F'\|)$ probes, respectively, have been invested in them. Furthermore, since the weight of the new fence is the sum of the weights of the old fences, assume that after its creation it is extended to height $T(\|F\| + \|F'\|)$. The extension needs $T(\|F\| + \|F'\|) - T(\|F\|)$ probes, so that afterwards the investment in the new fence will be

$$t(T(\|F\|) + T(\|F'\|)) + T(\|F\| + \|F'\|) - T(\|F'\|).$$

If we disregard the last term (which turns out to be insignificant) and observe that T grows at least linearly, by (3.2) we see that this expression is at least $(t+1)(T(\|F\|)+ T(\|F'\|))$. As the investment in the new fence should be at most $tT(\|F\| + \|F'\|)$, we obtain the relation

$$(t+1)(T(\|F\|) + T(\|F'\|)) \leq tT(\|F\| + \|F'\|).$$

Combining this with the relation

$$\|F\| + \|F'\| = (1 + 1/a)\|F\|,$$

which expresses the intended meaning of the parameter a, yields

$$(t+1)T(\|F\|) \leq tT((1 + 1/a)\|F\|)$$

or

$$(1 + 1/t)T(\|F\|) \leq T((1 + 1/a)\|F\|).$$

Setting $T(x) = dx^p$ for arbitrary constants $d > 0$ and $p \geq 1 + a/t$ is sufficient to satisfy this requirement, and choosing

$$T(x) = \frac{x^{1+a/t}}{t}$$

also takes care of the condition of (3.2).

Finally, the biggest possible weight of a fence (namely, $\log n$) should correspond to the biggest possible height of a fence (namely, k), i.e.,

$$T(\log n) = \frac{(\log n)^{1+a/t}}{t} = k.$$

Together with (3.1), this implies $a \log a = \log(kt/\log n)$. After some simplification, this and (3.1) yield suitable values for a and t.

Essentially, the algorithm can be derived from this discussion by defining everything precisely and adjusting a few constants. This is done in the next section.

The lower bound is proved by means of an adversary that keeps track of the investments made by an algorithm. Whenever the algorithm has not protected its investment by erecting tall enough fences, the adversary reveals information that makes the algorithm lose part of its investment at too high a cost. The adversary's actions basically force the algorithm to behave as the algorithm in the proof of the upper bound, or it will do worse.

4. The upper bound. In this section we first describe a fence algorithm that solves the leftmost-all-1 problem using a number of probes that is within the upper bound of Theorem 1.1. Later, in section 4.4, we extend the methods to solve the original string-ranking problem using at most twice as many probes, where a probe, in the case of the string-ranking and string-membership problems, is the inspection of a character in the sorted sequence of input strings.

Consider an input I of size $k \times n$, where $k \geq 1$ and $n \geq 4$ (the condition $n \geq 4$ simply ensures that $\log\log n$ is well defined and at least 1). We begin by defining a number of parameters in terms of k and n. First,

$$a = \sqrt{\max\left\{\log\left(\frac{k\log\log n}{\log n}\right), 4\right\}} \qquad \text{and} \qquad t = \left\lceil \frac{\log\log n}{\log a} \right\rceil + 2.$$

Second, for all real $x \geq 0$, take

$$T(x) = \frac{x^{1+ea/t}}{t},$$

where $e = 2.718\ldots$ is the base of the natural logarithm function. T maps the set of nonnegative real numbers to itself, and its derivative T' satisfies $T'(x) \geq 1/t$ for all $x \geq 1$. The only other properties of T of relevance to us are expressed in the two lemmas below.

LEMMA 4.1. $T(2\log n) = O(k + \log n/\log\log n)$.

Proof.

$$\begin{aligned} T(2\log n) = \frac{(2\log n)^{1+ea/t}}{t} &\leq \frac{(2\log n)^{1+ea\log a/\log\log n}\cdot \log a}{\log\log n} \\ &\leq 2^{1+2ea\log a}\cdot \log a \cdot \frac{\log n}{\log\log n} = O\left(2^{a^2}\cdot\frac{\log n}{\log\log n}\right). \end{aligned}$$

Since $2^{a^2}\cdot \log n/\log\log n = k$ if $a > 2$, the lemma follows. □

LEMMA 4.2. *Let x, y, and ϵ be nonnegative real numbers with $0 \leq \epsilon \leq 1$ and $y \geq x \geq \epsilon y$. Then*

$$T(x+y) \geq (1+\epsilon a/t)(T(x)+T(y)).$$

Proof. By the mean-value theorem, $e^{\epsilon/e} \leq 1+\epsilon$, and therefore

$$x + y \geq (1+\epsilon)y \geq e^{\epsilon/e}\cdot y$$

and

$$\begin{aligned} tT(x+y) &= (x+y)^{1+ea/t} \\ &\geq (e^{\epsilon/e} \cdot y)^{ea/t}(x+y) \\ &= e^{\epsilon a/t} \cdot y^{ea/t}(x+y) \\ &\geq (1+\epsilon a/t)y^{ea/t}(x+y) \\ &\geq (1+\epsilon a/t)(x^{1+ea/t} + y^{1+ea/t}) \\ &= (1+\epsilon a/t)t(T(x)+T(y)). \qquad \square \end{aligned}$$

Using the lemma with $x = y$ and $\epsilon = 0$, we obtain the following.

COROLLARY 4.3. *For all* $x \geq 0$, $T(2x) \geq 2T(x)$.

4.1. The algorithm. Whenever the fence algorithm to be described performs a top-row probe, it probes in the middle of the surface part of the top row. More precisely, if the leftmost and rightmost surface positions in the top row are in columns c_{L} and c_{R}, respectively, the top-row probe is performed in column $\lfloor (c_{\mathrm{L}} + c_{\mathrm{R}})/2 \rfloor$ or in column $\lceil (c_{\mathrm{L}} + c_{\mathrm{R}})/2 \rceil$. (If $c_{\mathrm{L}} + c_{\mathrm{R}}$ is odd, either choice is acceptable.) It will be convenient to allow probes below the actual input, i.e., in "row r" for $r > k$. By convention, such probes always return 1.

As mentioned earlier, the algorithm associates with each fence F a positive integer, called the *weight* of F and denoted by $\|F\|$. The *target height* of F is defined as $H(F) = \lceil T(\|F\|) \rceil$. We say that F is *of target height* if $|F| = H(F)$ and *below target height* if $|F| < H(F)$.

The algorithm repeatedly performs one probe using the procedure Probe, specified below, until all k rows have been excluded and then outputs the number of rejected columns, which is easily seen to be the correct answer even if fictitious probes below row k were performed. Upon entry to the procedure, the notation is assumed to be fixed so that $\mathcal{F} = (F_N, \ldots, F_1)$. (Recall that $\mathcal{F}$ is the list of all fences in the order from left to right.)

Probe:
  if some fence is below target height
  then perform an extending probe below the rightmost such fence
  else
    if $N \geq 2$ **and** $\|F_N\| > \|F_{N-1}\|/a$
    then perform an extending probe below F_N
    else perform a top-row probe.

In the interest of succinctness, the description given above does not specify the manipulation of fence weights. When a new fence is created from scratch, it is given weight 1. When two fences F and F' merge, the resulting fence acquires $\|F\| + \|F'\|$ as its weight. Finally, when a nonexcluding top-row probe encounters a 0 and $N \geq 1$, the weight of the leftmost fence is increased by 1. No other weight changes take place. In particular, only the leftmost fence ever changes its weight.

It may be helpful to visualize how a second fence is created by the algorithm. As long as there is only one fence and this fence is of height 1, the new fence created by a top-row probe that encounters a 1 immediately merges with the old fence. Informally, the net effect can be viewed as the old fence moving to the left and increasing its weight by 1. When the weight of the single fence has increased sufficiently for its target height to reach 2, the fence may be extended beyond height 1, after which a second fence can be created.

4.2. Properties of the algorithm.

LEMMA 4.4. *Suppose that $\mathcal{F} = (F_N, \ldots, F_1)$ before a probe that extends a fence F_i such that $2 \le i \le N$ and $\|F_i\| \le \|F_{i-1}\|/a$ before the probe. Then the probe will not cause F_i and F_{i-1} to merge.*

Proof. Consider the situation before the probe. F_i is below target height, whereas F_{i-1} is not, since otherwise F_i would not be extended. In particular, $T(\|F_i\|) \ge 1$. Since $a \ge 2$ and $T(x) \ge 2T(x/2)$ for all $x \ge 0$ (Corollary 4.3), $T(\|F_{i-1}\|) \ge 2T(\|F_i\|) \ge T(\|F_i\|) + 1$ and therefore $H(F_{i-1}) > H(F_i)$. The lemma follows. ∎

The following two lemmas are proved together by induction on the number of probes executed.

LEMMA 4.5. *At all times, with $\mathcal{F} = (F_N, \ldots, F_1)$, $\|F_i\| \le \|F_{i-1}\|/a \le \|F_{i-1}\|/2$ for $2 \le i < N$.*

LEMMA 4.6. *Every merge combines the two leftmost fences.*

Proof. Lemma 4.4 states that if $2 \le i < N$ and $\|F_i\| \le \|F_{i-1}\|/a$ before an extension of F_i, then the extension will not cause a merge. Conversely, if the condition of Lemma 4.5 holds before a merge that involves the leftmost fence, it will clearly hold afterwards. Since the condition of Lemma 4.5 is vacuously satisfied initially, while no fence is ever created from scratch unless $N \le 1$ or the claim holds even for $i = N$, it can be seen that the condition must hold at all times. ∎

LEMMA 4.7. *At all times, if $\mathcal{F} = (F_N, \ldots, F_1)$ and $1 \le i \le j < N$, then $\|F_j\| \le a^{i-j}\|F_i\|$ and $T(\|F_j\|) \le 2^{i-j}T(\|F_i\|)$.*

Proof. The first part of the lemma is obtained by $j - i$ applications of Lemma 4.5. Since $x \le y/2$ implies $T(x) \le T(y)/2$ for all $x, y \ge 0$ (Corollary 4.3), the second part can be proved in a similar way. ∎

LEMMA 4.8. *At all times, if $\mathcal{F} = (F_N, \ldots, F_1)$ and $N \ge 2$, then $\|F_N\| \le \|F_{N-1}\|$.*

Proof. Initially, the claim is vacuously satisfied. We show that if it holds immediately before a probe, then it holds immediately after the probe. Let $\mathcal{F} = (F_N, \ldots, F_1)$ before the probe.

When a fence is created from scratch, it is given weight 1, and the claim is clearly satisfied. An unsuccessful top-row probe may increase $\|F_N\|$ by 1 but is not performed unless $N \le 1$ or $\|F_{N-1}\| \ge a\|F_N\| \ge \|F_N\| + 1$, so that the claim also holds after the probe. Lemma 4.6 states that every merge combines the two leftmost fences. By induction and Lemma 4.5, their combined weight is bounded by the weight of the right neighbor, if any, of the resulting fence. In symbols: $\|F_N\| + \|F_{N-1}\| \le 2\|F_{N-1}\| \le \|F_{N-2}\|$. Finally, and again using Lemma 4.5, the claim is easily seen to hold after the exclusion of one or more fences. ∎

LEMMA 4.9. *At all times, with $\mathcal{F} = (F_N, \ldots, F_1)$, $\sum_{j=i}^{N} T(\|F_j\|) \le 2T(\|F_i\|)$ for $i = 1, \ldots, N$.*

Proof. Assume that $i < N$, since otherwise the claim is trivial. By Lemmas 4.7 and 4.8, $T(\|F_j\|) \le 2^{i-j}T(\|F_i\|)$ for $j = i, \ldots, N-1$ and $T(\|F_N\|) \le T(\|F_{N-1}\|)$. Thus

$$\sum_{j=i}^{N} T(\|F_j\|) \le \left(\sum_{j=i}^{N-1} 2^{i-j} + 2^{i-N+1} \right) \cdot T(\|F_i\|) = 2T(\|F_i\|). \qquad \blacksquare$$

LEMMA 4.10. *At all times, with $\mathcal{F} = (F_N, \ldots, F_1)$, $H(F_i)/2 \le |F_i| \le H(F_i)$ for $i = 1, \ldots, N-1$.*

Proof. Initially, the claim is vacuously satisfied. We show that if it holds immediately before a probe, then it holds immediately after the probe. Let $\mathcal{F} = (F_N, \ldots, F_1)$ before the probe.

Consider first the upper bound of the lemma, i.e., the claim that only the leftmost fence can have a height exceeding its target height. By induction and since the weight of a fence never decreases, when a fence becomes the leftmost fence, because of row exclusions or a merge or because the fence was just created from scratch, its height will not exceed its target height. Moreover, once the algorithm starts extending a fence beyond its target height, the fence must be the leftmost fence, and the algorithm will continue to extend it until an extension is unsuccessful, a merge takes place, or the algorithm terminates. In all cases, the offending fence disappears before it can acquire a left neighbor.

The other inequality of the lemma states that only the leftmost fence can have a height below half its target height. Since no other fence is below target height when a new fence is created from scratch, while only the leftmost fence can increase its weight, this could be invalidated only by row exclusions, which decrease fence heights. Before a top-row probe is performed, no fence is below target height, so that even if the probe excludes one row, the height of every surviving fence after the probe will still be at least half its target height. Consider, therefore, a probe that excludes fences $F_N, \ldots, F_i$, and let j be arbitrary with $1 \le j < i-1$. Before the probe, F_{i-1} and F_j are both of target height, by the upper bound established above, so that at this time, by Corollary 4.3 and Lemma 4.5,

$$\begin{aligned} |F_j| = H(F_j) &\ge T(\|F_j\|) \ge T(2\|F_{i-1}\|) \\ &\ge 2T(\|F_{i-1}\|) \ge 2(H(F_{i-1}) - 1) = 2(|F_{i-1}| - 1). \end{aligned}$$

Hence, before the probe, $|F_i| \le |F_{i-1}| - 1 \le |F_j|/2$, so that after the probe we still have $|F_j| \ge H(F_j)/2$. This holds for all j with $1 \le j < i-1$; i.e., the lower bound of the lemma is satisfied. ∎

The following consequence of the previous lemma and its proof will be useful later.

COROLLARY 4.11. *Immediately before the algorithm performs a probe, every fence strictly to the right of the position probed is of target height.*

LEMMA 4.12. *At all times, if $\mathcal{F} = (F_N, \ldots, F_1)$, then for $i = 1, \ldots, N$, the gap of F_i is at most $2^{\lceil \log n \rceil + 1 - w_i}$, where $w_i = \sum_{j=1}^{i} \|F_j\|$ is the cumulative weight of F_i.*

Proof. The proof is by induction on the number of probes performed. Since the gap of a fence never increases, the proof amounts to a simple inspection of the cases in which a fence is created or its cumulative weight increases.

Consider first the case in which a fence F is created from scratch. If F is created without a right neighbor (i.e., it is the only fence), it has a cumulative weight of 1, and its gap is bounded by n, so the claim is satisfied. Immediately after the creation from scratch of a fence F with a right neighbor F', the cumulative weight w of F is one more than the cumulative weight w' of F', and by the policy of placing new fences created from scratch in the middle of the surface part of the top row, the gap of F is at most $1/2$ plus half the gap of F'. By induction, therefore, the gap of F is at most $\lfloor 2^{\lceil \log n \rceil + 1 - w'}/2 + 1/2 \rfloor = 2^{\lceil \log n \rceil + 1 - w}$ (recall that the gap of F' is at least 2), and the claim continues to hold.

When two fences merge, the cumulative weight of every fence after the merge is the same as the cumulative weight of the fence residing in the same column before the merge. Finally, an unsuccessful top-row probe that increases the weight of the

leftmost fence by 1 also reduces its gap to at most 1/2 plus half the old gap, and the claim continues to hold as above. □

COROLLARY 4.13. *No weight of a fence ever exceeds* $\lceil \log n \rceil + 1 < 2 \log n$.

LEMMA 4.14. *The number of fences never exceeds* t.

Proof. If at some point more than t fences exist, we can apply Lemma 4.7 with $i = 1$ and $j = t$ and derive the following contradiction from the previous corollary:

$$1 \leq \|F_t\| \leq a^{1-t} \cdot \|F_1\| < a^{-\log\log n/\log a - 1} \cdot 2 \log n = 2/a. \qquad \square$$

4.3. Analysis of the number of probes. In this subsection we complete the analysis of the algorithm by showing the number of probes performed to be $O(kt + \log n)$. The approach is simple: we define a potential function Φ of the state of the algorithm, initially zero, show that every probe increases Φ by at least one, and bound the maximum value of Φ.

Consider a point in time during the execution of the algorithm at which $\mathcal{F} = (F_N, \ldots, F_1)$, and let X_{C} and X_{R} be the numbers of rejected columns and of excluded rows, respectively. The potential function Φ has the form $\Phi = \Phi_1 + \Phi_2 + \Phi_3 + \Phi_4$, where $\Phi_1 = \log(n/(n - X_{\mathrm{C}}))$ measures the ratio of original columns to remaining columns, $\Phi_2 = 13tX_{\mathrm{R}}$ is proportional to the number of excluded rows, $\Phi_3 = \sum_{i=1}^{N} |F_i|$ is the total height of all fences, and

$$\Phi_4 = 2t \cdot \left(\min\{T(\|F_N\|), 3|F_N|\} + \sum_{i=1}^{N-1} T(\|F_i\|) \right),$$

taken to be zero if no fences exist. Φ_3 and Φ_4 decompose naturally into contributions by the individual fences. The contribution of a fence F_i to Φ_3 is its height $|F_i|$, and the contribution of F_i to Φ_4 is essentially $2t$ times $T(\|F_i\|)$. An exception concerns the leftmost fence F_N. If the height of F_N is less than one third of $T(\|F_N\|)$, the contribution of F_N to Φ_4 instead is $6t$ times its height. If and when column n is rejected, Φ_1 becomes undefined; since this also causes the algorithm to terminate without additional probes, it is of no concern to the proof.

LEMMA 4.15. *Every nonexcluding successful top-row probe increases* Φ *by at least* 1.

Proof. The probe leaves Φ_1 and Φ_2 unchanged. If it does not cause a merge, it increases Φ_3 by 1 and does not decrease Φ_4. If the probe causes a merge, it leaves Φ_3 unchanged and increases Φ_4 by replacing the leftmost fence by a fence of the same height whose weight is greater by 1. Since the leftmost fence was of target height before the probe (Corollary 4.11) and $T'(x) \geq 1/t$ for all $x \geq 1$, the increase in Φ_4 is at least 2. In either case, the net increase in Φ is at least 1. □

LEMMA 4.16. *Every successful extending probe increases* Φ *by at least* 1.

Proof. Even if the probe causes a merge, consider an imagined intermediate situation in which the fence in question has been extended, but no merge has yet taken place. Until this point, the probe leaves Φ_1 and Φ_2 unchanged, increases Φ_3 by 1, and does not decrease Φ_4. Overall, Φ increases by at least 1, and we are done if no merge happens.

In the rest of the proof we assume that a merge happens and prove that it does not decrease Φ. Φ_1 and Φ_2 are not affected by the merge. Let $\mathcal{F} = (F_N, \ldots, F_1)$ immediately before the merge. By Lemma 4.6, the fences that merge are the leftmost ones, i.e., F_N and F_{N-1}. By Corollary 4.11 and Lemma 4.8, the fences that merge as well as the resulting fence are all of height $|F_N| = H(F_{N-1}) \geq T(\|F_{N-1}\|) \geq T(\|F_N\|)$.

The contribution to $\Phi_3 + \Phi_4$ of F_N and F_{N-1} before the merge is at most

$$2|F_N| + 2t(T(\|F_N\|) + T(\|F_{N-1}\|)) \le 6t|F_N|,$$

the contribution to $\Phi_3 + \Phi_4$ of the fence resulting from the merge is

$$|F_N| + 2t \cdot \min\{T(\|F_N\| + \|F_{N-1}\|), 3|F_N|\},$$

and no other fence changes its contribution.

If $3|F_N| < T(\|F_N\| + \|F_{N-1}\|)$, the merge clearly increases $\Phi_3 + \Phi_4$. Otherwise the increase in Φ caused by the merge is at least

$$2t[T(\|F_N\| + \|F_{N-1}\|) - (T(\|F_N\|) + T(\|F_{N-1}\|))] - |F_N|.$$

By Lemmas 4.4 and 4.8, we must have $\|F_{N-1}\| \ge \|F_N\| > \|F_{N-1}\|/a$. We can therefore apply Lemma 4.2 with $\epsilon = 1/a$, which shows that Φ increases by at least

$$\frac{2t}{t}[T(\|F_N\|) + T(\|F_{N-1}\|)] - |F_N|.$$

To see that this is nonnegative, observe that $T(\|F_{N-1}\|) > 1$ (since $|F_{N-1}| \ge 2$) and therefore $|F_N| = \lceil T(\|F_{N-1}\|) \rceil \le 2T(\|F_{N-1}\|)$. □

LEMMA 4.17. *Every nonexcluding unsuccessful probe increases Φ by at least 1.*

Proof. The probe is a top-row probe and leaves $\Phi_2 + \Phi_3$ unchanged. If no fences are present when the probe is performed, at least half of the remaining columns are rejected, causing Φ_1 to increase by at least 1 while Φ_4 remains zero. If one or more fences are present at the time of the probe, the weight of the leftmost fence increases by 1. Since the fence was of target height before the probe, by Corollary 4.11, an argument as in the proof of Lemma 4.15 shows that this increases Φ_4 by at least 2, while Φ_1 does not decrease. □

LEMMA 4.18. *Every excluding probe causes all nonrejected columns to be rejected or increases Φ by at least 1.*

Proof. Let $\mathcal{F} = (F_N, \ldots, F_1)$ immediately before the probe under consideration. Suppose that the probe leads to the exclusion of m rows but not to the rejection of all nonrejected columns. Then the probe does not decrease Φ_1, increases Φ_2 by $13tm$, and, since there are at most t fences (Lemma 4.14), decreases Φ_3 by at most tm.

If no fences are excluded and $N \ge 1$, $|F_N|$ decreases by m and $\|F_i\|$ is unchanged for $i = 1, \ldots, N$, so that Φ_4 decreases by at most $6tm$.

If at least one fence is excluded, let the excluded fences be $F_N, \ldots, F_i$. By Lemmas 4.9 and 4.10, the contribution to Φ_4 of the excluded fences $F_N, \ldots, F_i$ before the probe was at most $4tT(\|F_i\|) \le 8t|F_i|$ if $i < N$ and at most $6t|F_i|$ if $i = N$, so that their exclusion decreases Φ_4 by at most $8t|F_i| \le 8tm$. If $i > 1$, the contribution of F_{i-1} to Φ_4 may also decrease because F_{i-1} becomes the new leftmost fence. Since F_{i-1} was of target height before the probe under consideration, however (Corollary 4.11), this happens only if F_{i-1} loses more than two thirds of its height, in which case its contribution to Φ_4 before the probe was $2tT(\|F_{i-1}\|) \le 2t|F_{i-1}| \le 3tm$. Altogether, therefore, Φ_4 decreases by at most $8tm + 3tm = 11tm$.

In either case Φ_4 decreases by at most $11tm$, yielding a net increase in Φ of at least $13tm - tm - 11tm = tm \ge 1$. □

LEMMA 4.19. *As long as at least one column has not been rejected, $\Phi = O(kt + \log n)$.*

Proof. As long as at least one column has not been rejected, $\Phi_1 \leq \log n$, and $\Phi_2 \leq 13kt$. By Corollary 4.13, the weight of every fence remains bounded by $2 \log n$. Coupled with the facts that $\sum_{i=1}^{N} T(\|F_i\|) \leq 2T(\|F_1\|)$ if $N \geq 1$ (Lemma 4.9), that $T(2 \log n) = O(k + \log n / \log \log n)$ (Lemma 4.1), and that $t = O(\log \log n)$, this shows that $\Phi_4 = O(kt + \log n)$. In order to complete the proof by demonstrating that $\Phi_3 = O(kt + \log n)$, it suffices, since there are at most t fences (Lemma 4.14), to show that no fence is ever of height more than $\lceil T(2 \log n) \rceil$. Since only the leftmost fence can have a height exceeding its target height (Lemma 4.10), this follows immediately from Corollary 4.13 for all other fences. As for the leftmost fence F, its height is bounded by 1 or by the height of a nonleftmost fence (that may disappear at the creation of F) when F is created and whenever it is not the only fence. We finally observe that the algorithm never extends a fence whose height is no smaller than its target height if it is the only fence, and we conclude that even the leftmost fence can never acquire a height of more than $\lceil T(2 \log n) \rceil$. □

LEMMA 4.20. *The total number of probes performed by the algorithm is* $O(kt + \log n)$.

Proof. Since $\Phi = 0$ initially, the claim follows immediately from Lemmas 4.15–4.19. □

We can conclude the following theorem.

THEOREM 4.21. *For all integers* $k \geq 1$ *and* $n \geq 4$, *leftmost-all-*1 *problems of size* $k \times n$ *can be solved by a fence algorithm using*

$$O\left(\frac{k \log \log n}{\log \log (4 + \frac{k \log \log n}{\log n})} + k + \log n\right)$$

probes in the worst case.

4.4. String ranking. In this subsection we extend the algorithm for the leftmost-all-1 problem to solve the original string-ranking problem using at most twice as many probes. The upper bound of our main result, Theorem 1.1, follows from Theorem 4.21 and Lemma 4.22 below.

LEMMA 4.22. *For all integers* $k, n, m \geq 1$, *if there is a surface algorithm that solves instances of size* $k \times n$ *of the leftmost-all-*1 *problem using at most* m *probes, then there is an algorithm that solves instances of size* $k \times n$ *of the string-ranking problem using at most* $2m$ *probes.*

Proof. Let I and s be the input matrix and the query string, respectively, and denote by s_i the ith character of s for $i = 1, \ldots, k$. We derive a $k \times n$ matrix I' from I as follows. First, for each column of I that coincides with s, the corresponding column of I' contains 1's in every position. Now assume that $1 \leq c \leq n$ and that column c of I differs from s in at least one position, and let r be the smallest row index with $I[r, c] \neq s_r$. Then we set $I'[r, c] = 0$ if $I[r, c] < s_r$ and $I'[r, c] = 2$ if $I[r, c] > s_r$, and all other entries in column c of I' are set to 1. It can be seen that I' is sorted and that the task is to compute the number of columns in I' that do not contain a 2.

With the understanding that each occurrence of 2 is to be considered equivalent to a 1, a convention that again preserves sortedness, we can run a process $\mathcal{A}_{\mathrm{L}}$ that executes the given surface algorithm for the leftmost-all-1 problem on the input I'. This computes the number of columns containing a 0, which is not what we want. On the other hand, we can instead run a "mirrored" process $\mathcal{A}_{\mathrm{R}}$ that also executes the given surface algorithm but interchanges the roles of left and right, $<$ and $>$, and 0 and 2. (In particular, $\mathcal{A}_{\mathrm{R}}$ considers 0 to be equivalent to 1.) This process will indeed

compute the number of columns that do not contain a 2 or, rather, n minus that number.

There is a catch, however, namely, that it is not clear how to produce the input I' before starting $\mathcal{A}_{\mathrm{R}}$ without using too many probes. Instead, $\mathcal{A}_{\mathrm{R}}$ must be able to convert the outcome of each of its probes in I to the corresponding entry in I' without performing additional probes. This takes a little care and requires us to execute both $\mathcal{A}_{\mathrm{L}}$ and $\mathcal{A}_{\mathrm{R}}$ in an interleaved fashion.

Let us consider the situation from the perspective of $\mathcal{A}_{\mathrm{L}}$. Since $\mathcal{A}_{\mathrm{L}}$ is a surface algorithm, initially it has no difficulty converting the entries read in I to the corresponding entries in I', the reason being that in each column, it probes from the top towards the bottom. When about to exclude one or more rows, however, $\mathcal{A}_{\mathrm{L}}$ runs into a problem. Outside of the rejected columns, the rows of I' to be excluded are known to contain only characters that $\mathcal{A}_{\mathrm{L}}$ considers to be equivalent to 1, namely, 1's and 2's, and $\mathcal{A}_{\mathrm{L}}$ will assume that all such characters are in fact 1's. However, any occurrence of a 2 changes the interpretation of a 0 that may later be discovered further down in the same column, and therefore $\mathcal{A}_{\mathrm{L}}$ may later convert entries of I incorrectly to ones of I' if it excludes a row containing 2's. Whenever $\mathcal{A}_{\mathrm{L}}$ is about to exclude a row, it therefore needs help. In complete symmetry, $\mathcal{A}_{\mathrm{R}}$ can run until it is about to exclude one or more rows, at which point, since the rows of I' to be excluded might contain 0's, $\mathcal{A}_{\mathrm{R}}$ needs help.

Now consider a situation in which both $\mathcal{A}_{\mathrm{L}}$ and $\mathcal{A}_{\mathrm{R}}$ are blocked and waiting for help, and let r_{L} and r_{R} be the indices of the topmost rows about to be excluded by $\mathcal{A}_{\mathrm{L}}$ and $\mathcal{A}_{\mathrm{R}}$, respectively. Also let z_{L} and z_{R} be the indices of the 0-barriers of $\mathcal{A}_{\mathrm{L}}$ and $\mathcal{A}_{\mathrm{R}}$, respectively. Assume inductively that up to the present point, neither of the two processes has ever excluded a row of I' with a position containing an entry different from 1 and rejected by neither $\mathcal{A}_{\mathrm{L}}$ nor $\mathcal{A}_{\mathrm{R}}$. Also assume that $\mathcal{A}_{\mathrm{L}}$ and $\mathcal{A}_{\mathrm{R}}$ are modified so that whenever one of the processes wants to query a position that has been rejected by the other process, it receives a 1 as the answer to its query without consulting I. By the inductive hypothesis, the column of I' of index z_{L} is known to contain a string smaller than 1^k and therefore must be to the left of the column of I' of index z_{R}, which is known to contain a string larger than 1^k. In other words, $z_{\mathrm{L}} < z_{\mathrm{R}}$. Moreover, for all c with $z_{\mathrm{L}} < c < z_{\mathrm{R}}$, every position of the form $I[\min\{r_{\mathrm{L}}, r_{\mathrm{R}}\}, c]$ is known to contain an entry that is both ≥ 1 and ≤ 1 and thus equals 1. It follows that if $r_{\mathrm{L}} \leq r_{\mathrm{R}}$, then $\mathcal{A}_{\mathrm{L}}$ can proceed and exclude row r_{L} without falsifying the inductive property, while if $r_{\mathrm{R}} \leq r_{\mathrm{L}}$, $\mathcal{A}_{\mathrm{R}}$ can resume operation.

Thus $\mathcal{A}_{\mathrm{L}}$ and $\mathcal{A}_{\mathrm{R}}$ are never simultaneously blocked. Moreover, once one of the processes terminates, the other process can finish without being suspended again. Since the two processes $\mathcal{A}_{\mathrm{L}}$ and $\mathcal{A}_{\mathrm{R}}$ are copies of the given surface algorithm, except that sometimes they wait and that some answers are given to them for free, the total number of probes performed is bounded by $2m$. □

Although the upper bounds of Theorems 1.1 and 4.21 specify only the number of probes performed, we note that the algorithms realizing the upper bounds can be executed in a total time that is within the bound on the number of probes, each probe being followed by exactly one (three-way) comparison between two characters. The only nontrivial observation needed is that during an execution of the algorithm described in section 4.1, whenever a fence that is not the leftmost fence is of target height, it remains of target height until the next row exclusion, at which point we can afford to step through a list of all fences.

5. The lower bound. The aim of this section is to prove the following theorem, which implies the lower-bound part of Theorem 1.1.

THEOREM 5.1. *For all integers $k \geq 1$ and $n \geq 4$, every deterministic algorithm for the string-membership problem or the leftmost-all-1 problem performs*

$$\Omega\left(\frac{k \log\log n}{\log\log(4 + \frac{k \log\log n}{\log n})} + k + \log n\right)$$

probes on some input of size $k \times n$.

We prove Theorem 5.1 by exhibiting an adversary that forces every deterministic algorithm $\mathcal{A}$ for either problem to spend as many probes as stated in the theorem before announcing its answer. In the case of the string-membership problem, the lower bound is proved for a special case: the alphabet Σ and the string s whose presence is to be tested are fixed to be $\{0, 1\}$ and $1^{k-1}0$, respectively.

The adversary fixes entries of a legal input I online in response to the queries made by $\mathcal{A}$. Whenever $\mathcal{A}$ poses a query (r, c), i.e., asks for the value of $I[r, c]$, the adversary executes a call $\mathsf{Process}(r, c)$, where $\mathsf{Process}$ is described in the next subsection, that fixes zero or more entries of I. Subsequently, $I[r, c]$ will have been fixed to either 0 or 1, and the value to which it was fixed is returned to $\mathcal{A}$ as the answer to its query.

We formally define a *position* to be an element of $\{1, \ldots, k\} \times \{1, \ldots, n\}$. The adversary maintains information about the part of I already fixed in a $k \times n$ array J with entries drawn from $\{0, 1,$ "tentative-1," "?"$\}$ and a set P of *pending positions*. For $r = 1, \ldots, k$ and $c = 1, \ldots, n$, by definition, if $(r, c) \in P$, then $I[r, c]$ has been fixed to 1; if $(r, c) \notin P$, then $I[r, c]$ has been fixed to the value $b \in \{0, 1\}$ exactly if $J[r, c] = b$.

Although the adversary is not a fence algorithm probing the input I, it will be very convenient for the proof to reuse the terminology introduced for fence algorithms in section 2.2. In order to make this possible, it suffices to define the rejected positions and the matching area, since all other relevant concepts (fences, surface positions, the 0-barrier, etc.) were derived from these basic notions. But this is easy: a position (r, c) is rejected exactly if $J[i, j] = 0$ for some position (i, j) with $j \geq c$, and a nonrejected position (r, c) belongs to the matching area exactly if $J[r, c] \in \{1,$ "tentative-1"$\}$. The adversary will carry out explicit 1-extension (or, rather, "tentative-1-extension") to ensure that the matching area remains monotonic. Thus entries of 0 in J correspond to probes answered 0, and entries of 1 or "tentative-1" correspond to probes answered 1. The difference between 1 and "tentative-1" is that a 1 is permanent, as is a 0, while a "tentative-1" may later be changed to 0 or 1. If $J[r, c] =$ "?" for some position (r, c), the adversary has not yet decided upon the value of $I[r, c]$ (unless $(r, c) \in P$, in which case $I[r, c] = 1$).

To a first approximation, the adversary fixes only those entries of I that were queried by $\mathcal{A}$ or whose values can be deduced from such entries by 1-extension. In order to simplify the book-keeping, however, we let the adversary sometimes fix additional entries of I. Informally, this allows us to assume that $\mathcal{A}$ operates largely as the algorithm analyzed in the previous section. The lower bound holds even if the additional information about I volunteered by the adversary in this manner is made known to $\mathcal{A}$. It is therefore not necessary to distinguish between the information available to $\mathcal{A}$ and that available to the adversary—this is obvious anyway, since the adversary operates according to a fixed, deterministic strategy.

5.1. The adversary's strategy. The adversary's strategy is formulated in terms of a number of parameters that we introduce next. It will be convenient to

use the natural logarithm function "ln" to base e instead of the logarithm function to base 2 employed in the previous section. First, let

$$a = \ln\left(\frac{k \ln\ln n}{\ln n}\right) \qquad \text{and} \qquad v = 3a + 1.$$

For $k = O(\log n/\log\log n)$, the bound of Theorem 5.1 reduces to a trivial bound of $\Omega(k + \log n)$. This allows us to assume a to be larger than any convenient constant. In particular, we will assume that $a \geq 4$ and hence

$$v \leq a^2. \tag{5.1}$$

Next, we take

$$t = \left\lfloor \frac{\ln\ln n}{8 \ln a} \right\rfloor.$$

Similarly as before, the bound of Theorem 5.1 reduces to the trivial bound of $\Omega(k + \log n)$ for $t = O(1)$ and hence for $a = (\log n)^{\Omega(1)}$, for which reason we will assume that $t \geq 2$ and that the following relations hold:

$$e^{1/(3t)} \leq 1 + 1/(2t), \tag{5.2}$$

$$4at \leq \sqrt{\ln n}, \tag{5.3}$$

$$kt + 1 \leq n^{1/4}. \tag{5.4}$$

The parameters a and t have essentially the same meaning as in the proof of the upper bound. In particular, the goal of the adversary is to force $\mathcal{A}$ to spend $\Omega(t)$ probes per row. We associate with each fence F (as implied by J) a weight, $\|F\|$, which is maintained, with one exception, as in the proof of the upper bound. Every new fence created from scratch has weight 1, and when two fences F and F' merge to form a new fence, the new fence is given weight $\|F\| + \|F'\|$. The difference to the proof of the upper bound is that these two rules are the only ones that govern the weights of fences. In particular, the rejection of a number of columns does not change the weight of any surviving fence.

For each integer i and all $x \geq 0$, take

$$\phi_i(x) = \frac{x}{t}\left(\frac{x}{v^{t-i}}\right)^{a/t} \ln\left(\frac{x}{v^{t-i}} + e\right) \geq 0,$$

and note for later use that the derivative

$$\phi_i'(x) = \frac{1}{t}\left(\frac{x}{v^{t-i}}\right)^{a/t}\left[\left(1 + \frac{a}{t}\right)\ln\left(\frac{x}{v^{t-i}} + e\right) + \frac{1}{1 + e \cdot v^{t-i}/x}\right]$$

of ϕ_i is a strictly increasing function. Recall that the *index* of a fence F is one more than the number of fences to the right of F. We define the *value* (to $\mathcal{A}$) of a fence F of index i as

$$\Phi(F) = |F| + \|F\| + \phi_i(\|F\|).$$

The fence will be called *dense* if $\Phi(F) \geq t|F|$. A fence is *critical* if it is dense or if its index is t. The following technical lemma is needed later.

LEMMA 5.2. *If a fence F of index i is not dense, then*

$$|F| \geq \frac{\|F\|}{at} \cdot z^{a/t},$$

where $z = \|F\|/v^{t-i}$.

Proof. Since F is not dense,

$$|F| \geq \frac{\Phi(F)}{t} \geq \frac{\|F\|}{t} + \frac{\|F\|}{t^2} \cdot z^{a/t} \ln(z+e).$$

If $z \leq a^{t/a}$, then

$$|F| \geq \frac{\|F\|}{t} \geq \frac{\|F\|}{t} \cdot \frac{z^{a/t}}{a},$$

as desired. If $z > a^{t/a} \geq e^{t/a}$, on the other hand, then

$$|F| \geq \frac{\|F\|}{t^2} \cdot z^{a/t}(t/a) = \frac{\|F\|}{at} \cdot z^{a/t}. \qquad \square$$

The adversary exercises tight control over the horizontal placement of fences. As an aid in describing this mechanism, we introduce a set L of "legal fence-column indices" and a corresponding set of "legal fence columns." Suppose that $\mathcal{F} = (F_N, \ldots, F_1)$, that F_i is in column c_i for $i = 1, \ldots, N$, and that the 0-barrier is in column c_Z. Then $L = \{c^*, c_N, c_{N-1}, \ldots, c_1\}$, where $c^* = c_Z + \max\{\lfloor e^{-a} \cdot (c_N - c_Z) \rfloor, 1\}$, with c_N taken to be $n+1$ if $N = 0$. A legal fence column is a column whose index belongs to L. Thus every column that already contains a fence is a legal fence column, and there is one more legal fence column to the left of the leftmost fence, about e^{-a} of the way from the 0-barrier to that fence. The adversary rejects the column of every probe to the left of the leftmost legal fence column and translates every other probe to the nearest legal fence column to the left of or in the column of the position probed and in this way allows fences to grow only in legal fence columns. Note that since $e^{-a} \leq 1/2$, this implies that no two fences will ever reside in adjacent columns.

We now describe the strategy of the adversary precisely by giving the procedure Process and two subroutines PutZero and OneProbe that it employs. Before the first call of Process, every entry of J is initialized to "?," and the set P of pending positions is set to $\emptyset$. For the sake of a succinct description of PutZero, we take $\min \emptyset$ to be ∞, i.e., distinct from every integer.

PutZero(c):
  for $(i,j) \in \{1, \ldots, k\} \times \{1, \ldots, c\}$ **do**
    $J[i,j] := \begin{cases} 0, & \text{if } i = \min\{\ell \mid 1 \leq \ell \leq k \text{ and } J[\ell, j] \neq 1\}, \\ 1, & \text{otherwise.} \end{cases}$

OneProbe(r, c):
  if $c < \min L$ **then** PutZero(c) **else**
    $c' := \max\{j \in L \mid j \leq c\}$;
    for $j \in \{c', \ldots, n\}$ **do if** $J[r,j] =$ "?" **then** $J[r,j] :=$ "tentative-1";
    if column c' contains a critical fence **then** PutZero(c').

Process(r, c):
  if (r,c) is buried **then** insert (r,c) in P and return 1 **else**

if $J[r, c] =$ "?" **then**
  OneProbe(r, c);
  while P contains a surface position **do**
    Let (r', c') be a surface position in P;
    OneProbe(r', c');
    Remove from P all positions $(i, j) \in P$ with $J[i, j] \neq$ "?";
  for $(i, j) \in \{1, \ldots, k\} \times \{1, \ldots, n\}$ **do**
    if $J[i, j] =$ "tentative-1" **then** $J[i, j] := 1$;
Return $J[r, c]$.

We illustrate the adversary's strategy through an extensive example worked in Figure 5.1. The symbols "0," "1," and "T" denote positions in J containing the values 0, 1 and "tentative-1," respectively. Each "P" denotes a position $(i, j) \in P$ with $J[i, j] =$ "?," while other occurrences of "?" in J are not shown explicitly. The matching area is separated from the remaining positions by a staircase line, and surface positions are shown shaded.

Assume that Process$(6, 7)$ is called when the situation is as shown in (a). Since $(6, 7)$ is a surface position, a call OneProbe$(6, 7)$ is executed. The argument $(6, 7)$ of OneProbe is indicated by a circle in (a), and the effect of the call OneProbe$(6, 7)$ is shown in (b). The position $(6, 7)$ is "moved" left until it hits a legal fence column, the fence F in that column is extended by one position containing the value "tentative-1," and "tentative-1-extension" is carried out from the new fence position. The latter causes several formerly buried positions in P to become part of the surface, and the call of Process proceeds to execute OneProbe(r', c') for one such position (r', c'). This second extension of F, the result of which is shown in (c), causes F to merge with its right neighbor. The transition from (c) to (d) gives rise to yet another merge. We assume that the fence in column 6 resulting from the merge is dense, so that PutZero(6) is executed. The outcome is shown in (e): four columns were rejected, and six rows were excluded. Each excluded column contains a 0 in the position that belonged to the surface in situation (a) and 1's in all other positions. In situation (e), the surface still contains elements of P, so another call of OneProbe is executed. Let us assume that the argument of this call is the leftmost eligible surface position, $(9, 8)$, and that the condition $c < \min L$ is satisfied. Then the call PutZero(8) leads to the situation in (f). The effect of three more calls of OneProbe, none of which is assumed to call PutZero, is shown in (g). Since the surface in (g) contains no elements of P, no further calls of OneProbe are initiated. The call Process$(6, 7)$ finally converts all occurrences of "tentative-1" to 1—we call this step, shown in the transition from (g) to (h), the *consolidation*—and returns the value of $J[6, 7]$, which is 0.

5.2. Properties of the strategy. We first show in a series of lemmas that the answers provided by the adversary are consistent with a fixed input I, by which we mean that each query (r, c) is answered by $I[r, c]$. We also argue (Lemma 5.8) that I can be chosen to be sorted, i.e., as a legal input to the string-membership and leftmost-all-1 problems.

LEMMA 5.3. *For all* $(r, c) \in \{1, \ldots, k\} \times \{1, \ldots, n\}$*, the value of* $J[r, c]$ *can change only according to the transitions indicated in Figure* 5.2*. Moreover, no occurrences of "tentative-*1*" are present in* J *at the start or end of a call of* Process*, and no call of* Process *returns the value "tentative-*1*."*

Proof. The claim concerning "tentative-1" is a consequence of the consolidation. It is clear from a simple inspection of the code that, following the initialization, no "?" is stored in J and that no occurrence of 1 is replaced by a different value. Moreover, an

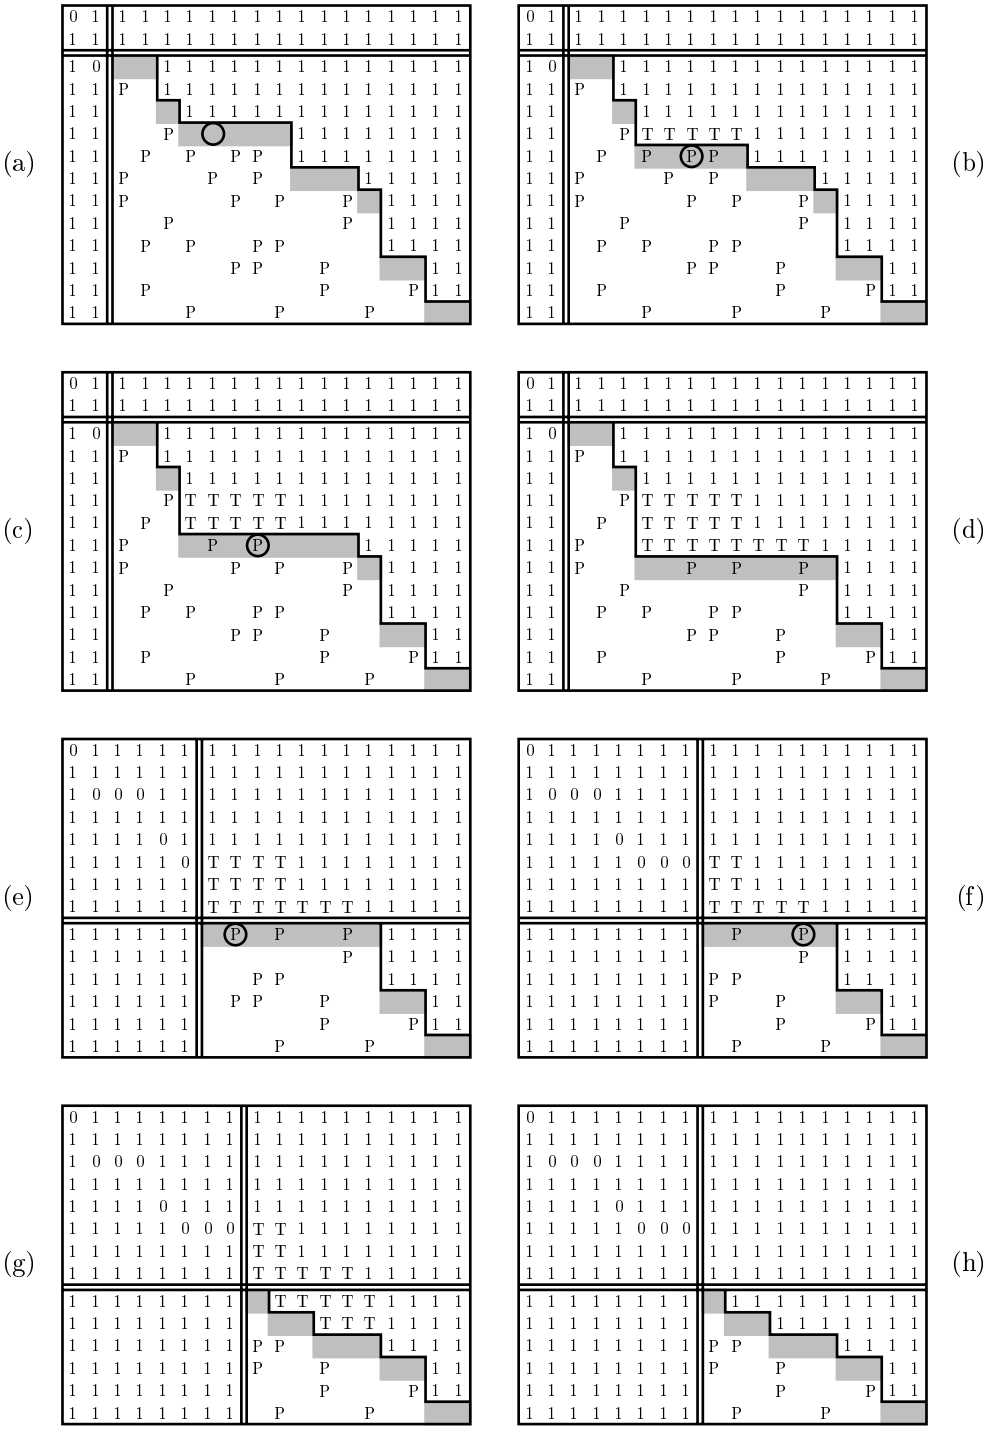

FIG. 5.1. *An example execution of* Process.

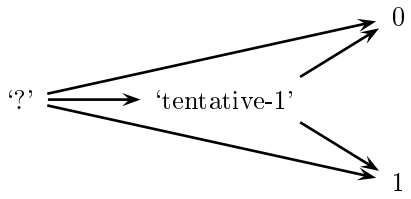

FIG. 5.2. *The possible transitions of an entry in J.*

occurrence of 0 could be changed only in a call of PutZero. What remains, therefore, is to show that no 0 in a column rejected in a call of PutZero is changed by a subsequent call of PutZero. But this is obvious. □

LEMMA 5.4. *Every call* Process(r, c) *returns a value in* $\{0, 1\}$.

Proof. By Lemma 5.3, the claim is obvious if (r, c) is buried or $J[r, c] \neq$ "?" at the start of the call. But otherwise, a call OneProbe(r, c) is executed, which can easily be seen to store a value different from "?" in $J[r, c]$. The lemma now follows by a second appeal to Lemma 5.3. □

LEMMA 5.5. *All positions whose entries are set to* 0 *during a call of* Process *were surface positions at the start of the call of* Process.

Proof. The only occasions on which a 1 is stored in a position in J are when the column containing the position is rejected and during the final consolidation. By this observation and Lemma 5.3, immediately before a call of Process causes a column to be rejected, the topmost position in the column that contains a value different from 1 is the same as it was at the start of the call of Process, at which time it was a surface position. □

LEMMA 5.6. *The matching area at all times is monotonic.*

Proof. The matching area initially is empty and hence monotonic. It is changed through only two types of operations: the removal of a number of leftmost (rejected) columns and the inclusion of a surface position and all positions to its right that do not already belong to the matching area. Both operations preserve monotonicity. □

LEMMA 5.7. *No column of J is ever rejected while it contains the string* 1^k.

Proof. Suppose that $1 \leq c \leq n$ and that column c of J is rejected while containing 1^k. Then column c must contain 1^k already at the start of the call of Process that rejects it. At that time, by Lemmas 5.3 and 5.6, all columns to the right of column c also contain 1^k, in which case column c cannot be rejected. □

LEMMA 5.8. *The answers provided by the adversary are consistent with a sorted input.*

Proof. Let I be the input obtained from the final value of J by changing to 1 all entries that are not 0. We prove that each query (r, c) is answered by $I[r, c]$ and that I is sorted.

A query (r, c) is answered by 0 only if $J[r, c] = 0$ at the time of the answer and thus, by Lemma 5.3, only if $I[r, c] = 0$. The same argument applies to answers of 1, except that, because of the probes of buried positions, we must additionally show that no entry in J of a position that belongs to P at some time is ever set to 0. Assume, to the contrary, that such an entry is set to 0 in some call of Process. By Lemma 5.3, the value of the entry must have been "?" at the start of the call of Process; i.e., the corresponding position still belonged to P at that time. But given that P contained

no surface positions at that time, due to the termination condition of the **while** loop in Process, this contradicts Lemma 5.5.

We now show that I is sorted and begin by observing that no column of I contains more than one 0. Let $1 \le c < c' \le n$ and $1 \le r' \le k$ and suppose that $I[r', c'] = 0$. By Lemmas 5.3 and 5.7, we must have $I[r, c] = 0$ for some $r \in \{1, \ldots, k\}$. In order to complete the demonstration that I is sorted, it suffices to show that $r \le r'$.

By Lemma 5.5, (r, c) belongs to the surface at some time τ, and (r', c') belongs to the surface at the same or some later time (since column c' is rejected simultaneously with or later than column c). If $(\bar{r}, c')$ is the surface position in column c' at time τ, we have $r \le \bar{r}$ by the monotonicity of the matching area at time τ (Lemma 5.6) and $\bar{r} \le r'$ because, as long as a column contains a surface position, the row index of its surface position never decreases. (This is a consequence of Lemma 5.3.) Thus indeed $r \le r'$. □

LEMMA 5.9. *When $\mathcal{A}$ terminates, either all rows except at most one have been excluded, or all entries in the last row outside of the rejected columns have been fixed to* 1.

Proof. Assume that $\mathcal{A}$ terminates while the entry of some position (k, c) in the last row is still unfixed. We complete the tableau J to two inputs I_0 and I_1: I_1 is obtained simply by fixing all remaining unfixed entries of I to 1. I_0 is obtained as follows. If $c > 1$, first PutZero$(c-1)$ is executed. Then the entry in position (k, c) is fixed to 0, and all remaining unfixed entries of I are fixed to 1.

The inputs I_0 and I_1 are both consistent with all answers obtained by $\mathcal{A}$. It was already argued in the preceding proof that I_1 is sorted, and, using essentially the same argument, it can be seen that I_0 is sorted as well, so that I_0 and I_1 are both legal inputs. Moreover, column c of I_0 contains the string $1^{k-1}0$, column c of I_1 contains 1^k, and if two or more rows had not been excluded when $\mathcal{A}$ terminated, no column of I_1 contains $1^{k-1}0$. But in that case, whether $\mathcal{A}$ is an algorithm for the string-membership problem with query string $1^{k-1}0$ or for the leftmost-all-1 problem, I_0 and I_1 are not associated with a common correct output. Thus $\mathcal{A}$ cannot produce its answer, which is a contradiction. □

Recall that the *gap* of a fence is its distance from the 0-barrier and that its *cumulative weight* is the sum of its own weight and the weights of all fences to its right. We define the *bias* of a fence F of gap g and cumulative weight w as the quantity

$$Bias(F) = \frac{\ln(n+1) - \ln g - 2aw}{-\ln(1 - e^{-a})}.$$

We apply this definition even to an imaginary fence F_0 in column $n+1$ and of cumulative weight 0 and define the *maximum bias* B as $\max_{i=0}^{N} Bias(F_i)$, where $\mathcal{F} = (F_N, \ldots, F_1)$.

LEMMA 5.10. *$B = 0$ initially, $B \ge 0$ always, and a call of* PutZero *or* OneProbe *increases B by at most* 1.

Proof. The first two claims are obvious, the second one because $Bias(F_0) \ge 0$. It is not difficult to see from the definition of the set of legal fence-column indices that after the rejection of one or more columns, the gap of every surviving fence is at least $1 - e^{-a}$ times what it was before the rejection—every potential new 0-barrier is at most a fraction of e^{-a} of the way from the current 0-barrier to the fence. A call of PutZero or OneProbe that causes columns to be rejected therefore increases B by at most 1.

If a new fence F is created from scratch at a time when the previous leftmost fence F' (F_0 if there are no fences) has gap g, we have $e^{-a}g \geq 2$, so that the gap of F is at least $e^{-a}g - 1 \geq e^{-2a}g$. Since the cumulative weight of F is one more than that of F', we will have $Bias(F) \leq Bias(F')$. Thus a call of OneProbe that does not cause columns to be rejected also does not increase B. □

Note that since a critical fence is excluded immediately after its creation, the number of fences never exceeds t.

5.3. Analysis of the number of probes. The number of probes needed is bounded from below using the potential function

$$\Phi = \Phi_1 + \Phi_2 + \Phi_3 + \Phi_4,$$

where $\Phi_1 = \sum_{F \in \mathcal{F}} \Phi(F)$ is the total value of all fences, $\Phi_2 = tX_{\mathrm{R}}$ is t times the number of excluded rows, $\Phi_3 = 4|P|$ is four times the number of pending positions, and $\Phi_4 = B$ is the maximum bias.

LEMMA 5.11. *If $\Phi \leq kt$, then the gap of every fence, including the imaginary fence F_0, is greater than $n^{1/4}$.*

Proof. Assume that $\Phi \leq kt$ and that the gap g of some fence F (possibly F_0) is at most $n^{1/4}$, and let w be the cumulative weight of F. By the mean-value theorem, $\ln(1-x) \geq -2x$ for $0 \leq x \leq 1/2$. Using this with $x = e^{-a} = \ln n/(k \ln\ln n)$ and assuming that $Bias(F) \geq 0$, we obtain

$$\begin{aligned} Bias(F) &= \frac{\ln(n+1) - \ln g - 2aw}{-\ln(1-e^{-a})} \\ &\geq (\ln(n+1) - \ln g - 2aw) \cdot \frac{k \ln\ln n}{2 \ln n} \geq \left(\frac{3}{4} - \frac{2aw}{\ln n}\right) \cdot 4kt. \end{aligned}$$

Since $Bias(F) \leq kt$, we must have $2aw/\ln n \geq 1/2$. This relation holds also if $Bias(F) < 0$. In either case, (5.3) therefore implies that $w \geq t\sqrt{\ln n}$. In particular, $F \neq F_0$. Let $\mathcal{F} = (F_N, \ldots, F_1)$. Then $1 \leq N \leq t$, and, therefore, by (5.1),

$$\frac{w/N}{v^{t-1}} \geq \frac{w/N}{a^{2t}} \geq e^{\ln(w/t) - 2t\ln a} \geq e^{\ln(\sqrt{\ln n}) - (\ln\ln n)/4} = e^{(\ln\ln n)/4}.$$

Now, by the convexity of ϕ_1,

$$\begin{aligned} \Phi &\geq \sum_{i=1}^{N} \phi_i(\|F_i\|) \geq \sum_{i=1}^{N} \phi_1(\|F_i\|) \geq N\phi_1\left(\frac{1}{N}\sum_{i=1}^{N}\|F_i\|\right) \\ &\geq N\phi_1(w/N) \geq \frac{w}{t}\left(\frac{w/N}{v^{t-1}}\right)^{a/t} \ln\left(\frac{w/N}{v^{t-1}}\right) \\ &\geq \frac{\ln n}{4at} \cdot e^{(\ln\ln n)/4 \cdot a/t} \cdot \frac{\ln\ln n}{4} \geq \frac{\ln n}{2a} \cdot e^{2a\ln a} \cdot \ln a \geq e^a \ln n = k \ln\ln n > kt, \end{aligned}$$

which is a contradiction. □

LEMMA 5.12. *During the execution of $\mathcal{A}$, Φ increases by at least $(k-1)t$.*

Proof. $\Phi = 0$ initially, so let us consider the situation when $\mathcal{A}$ terminates and show that $\Phi \geq (k-1)t$. This is obvious if all except at most one row have been excluded, so assume that this is not the case and that $\Phi \leq kt$. Let g be the gap of an arbitrary fence, or of F_0 if no fence exists. By Lemma 5.9, we have $|P| \geq g - 1$ and hence, by (5.4), $g \leq kt + 1 \leq n^{1/4}$. Lemma 5.11 now shows that $\Phi > kt$, which is a contradiction. □

LEMMA 5.13. *Every call of* PutZero *increases* Φ *by at most* 1.

Proof. The call increases neither Φ_1 nor Φ_3. By Lemma 5.10, Φ_4 increases by at most 1. If the call causes the exclusion of $m > 0$ rows, some fence of height m was critical—here we use the fact that no two fences are ever in adjacent columns—so the corresponding increase in Φ_2 of tm is compensated by a decrease in Φ_1 of at least tm caused by the exclusion of a dense fence of height m or by a reduction by m in the height of each of t fences. □

LEMMA 5.14. *If* $\Phi \le kt$ *before a call of* OneProbe*, the call increases* Φ *by at most* 4.

Proof. Unless a call of OneProbe simply executes a call of PutZero, which increases Φ by at most 1 according to the previous lemma, it begins by extending a fence F' by one position or creating a new fence F' from scratch. Extending an existing fence by one position increases its value by 1, and the value of a fence of height and weight 1 is bounded by 3; we here use the fact that there are never more than t fences, so that we never employ ϕ_i for $i > t$. Until this point, therefore, Φ has increased by at most 3.

Subsequently to the operation on the fence F', it may disappear through exclusion because it is in the column next to the 0-barrier, as part of the execution of a call of PutZero, or through merging with its right neighbor. The first case is ruled out by Lemma 5.11 in conjunction with (5.3), which shows that $e^{-a} \cdot n^{1/4} \ge n^{1/4-1/(4t)} \ge n^{1/8} \ge 2$, where the last inequality follows from the assumption $t \ge 2$. The second case increases Φ by another at most 1, according to Lemma 5.13, for a total increase in Φ of at most 4. What remains, therefore, is to assume that F' merges with its right neighbor F and to show that this does not increase Φ.

Let the indices of F and F' be i and $i+1$, respectively. The new fence resulting from the merge has index i, and the remaining fences are affected by the merge only insofar as some of them decrease their index by 1; since this decreases Φ, we need not account for it here. What is to be shown, hence, is that the value of the new fence resulting from the merge is no larger than the combined value of the two fences from which it is formed.

All three fences of interest have the same height $|F|$. Let us write $\|F'\| = u\|F\|$, where $u > 0$ is a suitable real number. Then the weight of the new fence is $(1+u)\|F\|$, so that the relation to be shown is

$$\begin{aligned}(|F| + \|F\| + \phi_i(\|F\|)) + (|F| + u\|F\| + \phi_{i+1}(u\|F\|)) \\ - (|F| + (1+u)\|F\| + \phi_i((1+u)\|F\|)) \ge 0\end{aligned}$$

or, equivalently,

$$|F| + \phi_i(\|F\|) + \frac{\phi_i(uv\|F\|)}{v} - \phi_i((1+u)\|F\|) \ge 0.$$

The derivative of the left-hand side above with respect to u is

$$\|F\|\phi_i'(uv\|F\|) - \|F\|\phi_i'((1+u)\|F\|).$$

Recall that ϕ_i' is a strictly increasing function. This implies that the original left-hand side has a unique minimum that occurs for the value of u satisfying $uv = 1 + u$, i.e., $u = 1/(v-1)$. It therefore suffices to prove the original claim for this value of u, i.e., to show that

$$|F| + \phi_i(\|F\|) + \frac{1}{v}\phi_i\left(\frac{v}{v-1}\|F\|\right) - \phi_i\left(\frac{v}{v-1}\|F\|\right) \ge 0$$

or, equivalently, that

$$\frac{1}{q}\phi_i(q\|F\|) - \phi_i(\|F\|) \le |F|,$$

where we introduced the abbreviation $q = v/(v-1)$. Note that $q = 1 + 1/(3a)$ and hence

$$q^{a/t} = \left(1 + \frac{1}{3a}\right)^{a/t} \le e^{1/(3t)}.$$

Take $z = \|F_i\|/v^{t-i}$. Then

$$\begin{aligned}
\frac{1}{q}\phi_i(q\|F\|) - \phi_i(\|F\|) &= \frac{\|F\|}{t}(qz)^{a/t}\ln(qz+e) - \frac{\|F\|}{t}z^{a/t}\ln(z+e) \\
&\le \frac{\|F\|}{t}z^{a/t}[q^{a/t}(\ln q + \ln(z+e)) - \ln(z+e)] \\
&= \frac{\|F\|}{t}z^{a/t}[(q^{a/t}-1)\ln(z+e) + q^{a/t}\ln q] \\
&\le \frac{\|F\|}{t}z^{a/t}\left[(e^{1/(3t)}-1)\ln(z+e) + e^{1/(3t)}\frac{1}{3a}\right].
\end{aligned}$$

By (5.2), we can bound the right-hand side above by

$$\frac{\|F\|}{2t^2}\cdot z^{a/t}\ln(z+e) + \frac{\|F\|}{2at}\cdot z^{a/t} = \frac{\phi_i(\|F\|)}{2t} + \frac{\|F\|}{2at}\cdot z^{a/t}.$$

Since critical fences are excluded as soon as they arise, F is not dense at the time of the merge. Thus the first term of the right-hand side above is bounded by $|F|/2$, and Lemma 5.2 shows that the same is true of the second term. This completes the proof of the lemma. □

LEMMA 5.15. *If $\Phi \le kt - 4$ before a call of* Process*, the call increases Φ by at most* 4.

Proof. Consider a call Process(r, c). If (r, c) is buried, the call increases $|P|$ by at most 1 and Φ by at most 4. Otherwise, the call executes a call of OneProbe and, subsequently, zero or more times, executes a call of OneProbe and decreases $|P|$ by at least 1 and hence Φ by at least 4. By a simple induction based on Lemma 5.14, $\Phi \le kt$ at the start of each call of OneProbe, and Φ altogether increases by at most 4. The final consolidation does not affect Φ. □

Theorem 5.1 follows from Lemmas 5.8, 5.12, and 5.15.

6. Conclusions. We have given tight bounds for a fundamental searching problem. The problem is natural and easy to formulate, yet the solution—the bound achieved as well as its proof—is surprisingly complicated.

As mentioned in the introduction, the problem becomes much easier if preprocessing and extra space are allowed. It should be noted that our lower bound imposes no restrictions on the model of computation other than the absence of preprocessing; a search algorithm is allowed to use extra memory and arbitrary data structures during its execution.

Acknowledgment. We thank Jyrki Katajainen for bringing the papers by Hirschberg [3, 4] to our attention.

MINIMUM NETWORKS IN UNIFORM ORIENTATION METRICS*

M. BRAZIL†, D. A. THOMAS†, AND J. F. WENG†

Abstract. In this paper we use the variational method to systematically study properties of minimum networks connecting any given set of points (called terminals) in a λ-plane, in which all lines are in λ uniform orientations $i\pi/\lambda$ $(0 \le i < \lambda)$. We prove a number of angle conditions for Steiner minimum λ-trees, which are similar to the ones in the Euclidean case. In particular, we show that there exists a Steiner minimum λ-tree whose minimum angles at Steiner points are $\lfloor 2\lambda/3 \rfloor \pi/\lambda$ and whose maximum angles are $\lceil 2\lambda/3 \rceil \pi/\lambda$. We also investigate the assignment of nonstraight edges and unequal angles in Steiner minimum λ-trees, and we prove that there exists a Steiner minimum λ-tree in which every full component has at most one nonstraight edge. From these properties we are able to devise a number of finite methods for constructing Steiner minimum λ-trees. One of these methods is based on using algorithms for finding graphical Steiner minimum trees, and the other uses a generalization of the method of Melzak for Euclidean Steiner trees.

1. Introduction.

Given λ orientations $i\omega\,(i = 1, 2, \ldots, \lambda)$ in the Euclidean plane, where $\lambda(\ge 2)$ is an integer and $\omega = \pi/\lambda$ is a unit angle, we represent the orientations by the angles with the x-axis of corresponding straight lines. For a given λ, a line or line segment with one of these orientations is said to be in a *legal direction*. Define the distance between two points p and q to be the length of the shortest path joining p and q with all edges in legal directions. This definition of distance induces a metric, called the λ-*metric*, in the Euclidean plane. The plane in which a λ-metric is defined is called λ-*oriented*, or a λ-*plane*. Note that a λ-plane is a Minkowski plane in which the unit disc is a regular 2λ-gon with the x-axis being a diagonal direction. A network (or tree) in the plane, composed of line segments in legal directions, is called a λ-*network* (respectively, λ-*tree*). Such objects are said to belong to a λ-*geometry*.

Let N be a set of n points in a λ-plane. The Steiner problem in a λ-plane asks for a shortest λ-network interconnecting the given points possibly incorporating some additional nodes to shorten the network. The network T, which must be a λ-tree, is called the *Steiner minimum* λ-*tree* for N. The given points are referred to as *terminals*, and the additional points are referred to as *Steiner points*.

The study of Steiner minimum λ-trees is of both theoretical and practical interest. Note that the λ-metric is the rectilinear metric when $\lambda = 2$, the hexagonal metric when $\lambda = 3$, and the Euclidean metric when $\lambda = \infty$ [11]. Hence it represents an important generalization of some of the key areas of research on this problem. The study of the hexagonal metric formed part of the basis of the solution of the Steiner ratio conjecture for the Euclidean Steiner problem [2]. Rectilinear Steiner minimum trees (Steiner minimum λ-trees for $\lambda = 2$) have been employed in the design of printed circuit boards and VLSI chips for a long time. Recent developments in VLSI fabrication

technology are beginning to make it possible to design chips with wires running in more than two directions. In particular, the λ-metric for $\lambda = 4$ is already being introduced into VLSI design. The literature to date on λ-metrics includes the papers [14],[3],[11],[7], and [15].

A Steiner minimum λ-tree is called *full* if all terminals are of degree 1. Moreover, as in the rectilinear Steiner problem, a λ-tree is called *fulsome* if the number of full components is maximized. Hence, for any N there is a Steiner minimum λ-tree that is fulsome. By the topology of a network we mean its graph structure. The topology of a (full) Steiner tree is called a (full) Steiner topology. Unlike Euclidean Steiner trees, not all edges in a Steiner minimum λ-tree are necessarily straight, and not all angles at degree 3 Steiner points must equal 120°. Therefore, a λ-tree is not uniquely determined by its Steiner topology but also depends on a knowledge of the assignments of nonstraight edges and unequal angles.

In this paper we use the variational argument [10] to make a systematic study of the Steiner λ-tree problem. Our methods provide a powerful theoretical framework from which we can easily derive the known basic properties of Steiner minimum λ-trees [11] and prove a number of significant new results. The paper is organized as follows. In section 2 we prove angle conditions for Steiner minimum λ-trees, which are similar to those that apply in the Euclidean case. In particular, we show that there exists a Steiner minimum λ-tree whose minimum angles at Steiner points are $\lfloor 2\lambda/3 \rfloor \pi/\lambda$ and whose maximum angles are $\lceil 2\lambda/3 \rceil \pi/\lambda$. It follows that degree 4 Steiner points exist only for $\lambda = 2$, 3, 4, or 6. In section 3 we investigate the assignment of nonstraight edges and unequal angles in Steiner minimum λ-trees. We prove that there exists a Steiner minimum λ-tree in which every full component has at most one nonstraight edge. Consequently, there exists a Steiner minimum λ-tree such that all its Steiner points are grid points of $GG_{n-2}(N)$, a grid point set defined recursively from the terminal set N. This implies that algorithms for constructing graphical Steiner minimum trees can be applied to Steiner minimum λ-trees. Moreover, we also prove some restrictions on angle assignments in Steiner minimum λ-trees. Finally, in section 4 the Melzak method for Euclidean Steiner trees [9] is generalized to Steiner λ-trees. It follows that a Steiner λ-tree with a specified assignment of nonstraight edges and unequal angles can be constructed in linear time, independently of λ.

2. Angle conditions. The basic elements in a geometry are line segments between points and angles between lines. Let p, q be distinct points in the plane. Let $|pq|$ and $|pq|_\lambda$ denote the length of pq in the Euclidean geometry and λ-geometry, respectively. Recall that $\omega = \pi/\lambda$, the smallest positive angle between line segments in λ-geometry. If the Euclidean line segment pq lies in a legal direction, then pq is a straight edge in λ-geometry and $|pq|_\lambda = |pq|$. Otherwise, there is an infinite number of shortest paths joining p, q in λ-geometry. The union of all these paths forms a parallelogram $prqr'$ whose interior angles at r and r' are $\pi - \omega$ (see Figure 2.1(b)) [14],[11]. In this case the edge pq in λ-geometry is a *nonstraight edge*, which can be represented by either of the two *critical paths* prq and $pr'q$. Therefore, $|pq|_\lambda = |pr| + |rq| = |pr'| + |r'q|$. As in the rectilinear metric, the points r, r' are referred to as *corner points*. The following lemma follows immediately from the above discussion.

LEMMA 2.1. *Any angle in λ-geometry is a multiple of ω. Furthermore, the angle at any corner point is $(\lambda - 1)\omega$.*

Given three distinct points p, q, p', let $\angle qpp'$ and $\angle_\lambda qpp'$ denote the angle at p in Euclidean geometry and λ-geometry, respectively. If both pq and pp' are straight

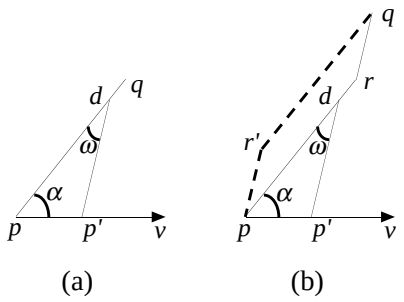

FIG. 2.1. *A one-point variation for a straight edge* (a) *and a nonstraight edge* (b).

edges, then $\angle_\lambda qpp' = \angle qpp'$; otherwise, $\angle_\lambda qpp'$ depends on the positions of the corner points. To most easily accommodate our variational methods, it is convenient to define $\angle_\lambda qpp'$ to be the smallest angle between the shortest paths of pq and pp' (see Figure 2.1(b)).

Let p, q be distinct points in the plane. Suppose q is fixed and p is perturbed to p' in a given legal direction. Let $\alpha = \angle_\lambda qpp'$. By the above definition of angles, if pq is a straight edge, then $\alpha = \angle qpp'$ (Figure 2.1(a)), whereas if pq is a nonstraight edge, then $\alpha = \angle rpp'$, where r is the corner point lying on the same side of the straight line pq as p' (Figure 2.1(b)). Assume the perturbation is sufficiently small that there exists a point d on pq (or pr) such that $\angle p'dp = \omega$. Then dp' is in a legal direction and $|qp'|_\lambda = |qd|_\lambda + |dp'|$. Let $l = |pq|_\lambda, v = |pp'|$. We have

$$\begin{aligned} \dot{l} = \frac{d}{dv}|pq|_\lambda &= \lim_{v\to 0}\frac{|qp'|_\lambda - |qp|_\lambda}{v} = \lim_{v\to 0}\frac{|dp'| - |dp|}{v} \\ &= \lim_{v\to 0}\frac{v\sin\alpha - v\sin(\alpha+\omega)}{v\sin\omega} \\ &= -\frac{\cos(\alpha+\omega/2)}{\cos(\omega/2)}. \end{aligned} \tag{2.1}$$

Remark 2.1. When λ goes to infinity, ω goes to 0 and $\dot{l}$ approaches $-\cos\alpha$, which corresponds to the derivative of l in the Euclidean plane [10].

Remark 2.2. Although we have assumed above that p is perturbed in a legal direction, it is easy to see that formula (2.1) still holds if pp' is not in a legal direction. Note, however, that in that case α is no longer a multiple of ω.

LEMMA 2.2. *Define*

$$f(k) = -\frac{\cos(k+1/2)\omega}{\cos(\omega/2)}.$$

Then, for any fixed λ, f *is an increasing function for all positive* $k \le \lambda - 1/2$, *and*

$$f(m-1) < -1/2, \quad f(2m-1) < 1/2 \text{ if } \lambda = 3m, \tag{2.2}$$

$$f(m-1) + f(m) < -1, \quad f(2m) < 1/2 \text{ if } \lambda = 3m+1, \tag{2.3}$$

$$f(m) < -1/2, \quad f(2m) + f(2m+1) < 1 \text{ if } \lambda = 3m+2. \tag{2.4}$$

Proof. The first statement follows immediately from a consideration of the derivative of f.

The three sets of inequalities have similar proofs to each other. We prove inequalities (2.3) as an example. When $\lambda = 3m+1$,

$$\begin{aligned} f(m-1) + f(m) &= -\frac{\cos((m-1/2)\omega) + \cos((m+1/2)\,\omega)}{\cos(\omega/2)} \\ &= -2\cos(m\omega) = -2\cos\left(\frac{m\pi}{3m+1}\right) < -1, \end{aligned}$$

and

$$f(2m) = -\frac{\cos((2m+1/2)\omega)}{\cos(\omega/2)} < 1/2$$

because $\frac{df(2m)}{dm} > 0$ and $\lim_{m\to\infty} f(2m) = 1/2$. □

It is well known that any angle in a Euclidean Steiner minimum tree is at least $2\pi/3$, and hence there are exactly three angles at each Steiner point, each of which is $2\pi/3$ [6]. We will show that in the λ-plane, there are similar angle conditions. Let $\lambda = 3m+i,\ i = 0, 1, 2$. Note that $2\pi/3 \geq \lfloor 2\lambda/3 \rfloor \omega$.

For a given value of λ, define $\phi_{\min}$ to be the minimum angle that can occur in any Steiner minimum λ-tree.

LEMMA 2.3. *For every (finite) λ, $\phi_{\min} < 2\pi/3$.*

Proof. Since the sum of the angles at a Steiner point of degree 3 is 2π, it immediately follows that $\phi_{\min} \leq 2\pi/3$. It remains to show that $\phi_{\min} \neq 2\pi/3$ when $\lambda = 3m$. Let T be the unique Steiner minimum λ-tree (with $\lambda = 3m$) for the vertices of an equilateral triangle with horizontal axis. This tree contains three straight edges meeting at a single Steiner point. By perturbing one of the terminals at right angles to the incident edge, the resulting Steiner minimum λ-tree will, by continuity, contain a nonstraight edge incident to the Steiner point. One of the choices of a critical path for this nonstraight edge must result in an angle at the Steiner point being strictly less than $2\pi/3$. □

THEOREM 2.4. 1. *Let $\lambda = 3m+i$. Then*

$$\phi_{\min} = \begin{cases} (\lfloor 2\lambda/3 \rfloor - 1)\omega & = (2m-1)\omega & \text{if } i = 0, \\ \lfloor 2\lambda/3 \rfloor \omega & = (2m)\omega & \text{if } i = 1, \\ \lfloor 2\lambda/3 \rfloor \omega & = (2m+1)\omega & \text{if } i = 2. \end{cases}$$

2. *If $\lambda = 3m$, then for any terminal set N there exists a Steiner minimum λ-tree T' such that the minimum angle in T' is at least $\lfloor 2\lambda/3 \rfloor \omega = 2\pi/3$.*

Proof. Let T be a Steiner minimum λ-tree, and let $\angle qpr$ be an angle between two straight line segments in a Steiner minimum λ-tree T. We begin by proving statement 1 for the case where $i = 0$.

So assume $\lambda = 3m$. By Lemma 2.1 the largest legal angle less than $(\lfloor 2\lambda/3 \rfloor - 1)\omega$ is $2(m-1)\omega$. Suppose, contrary to the theorem, that $\angle qpr \leq 2(m-1)\omega$. We regard p as being a (possibly degenerate) Steiner point, so that all variations on p result in a point of degree 3 connected to p, q, and r. Then we can choose a variation of p to p' in a legal direction between the two legs of the angle such that $\angle qpp' \leq (m-1)\omega$

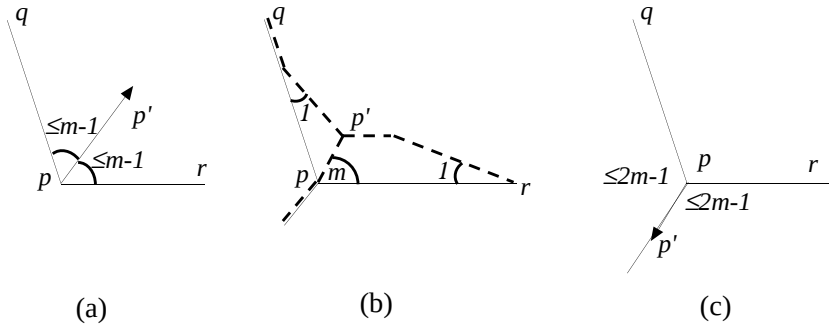

FIG. 2.2. *Variations for $\phi_{\min}$ and $\phi_{\max}$. The labels at angles represent multiples of ω.*

and $\angle p'pr \le (m-1)\omega$ (Figure 2.2(a)). It follows from Lemma 2.2 that, under this perturbation,

$$\dot{T} = \frac{d|pq|_\lambda}{dv} + \frac{d|pr|_\lambda}{dv} + \frac{d|pp'|_\lambda}{dv} \le 2f(m-1) + 1 < 0,$$

contradicting the minimality of T. This shows $\phi_{\min} \ge (\lfloor 2\lambda/3 \rfloor - 1)\omega$, and equality immediately follows from Lemma 2.3. The other two cases, $i = 1$ and $i = 2$, follow by a similar argument.

To prove statement 2, suppose $\angle qpr = (2m-1)\omega$. Consider the variation of p to p' such that $\angle qpp' = (m-1)\omega$ and $\angle p'pr = m\omega$ (Figure 2.2(a)). Note that, under this perturbation,

$$\dot{T} = f(m-1) + f(m) + 1 = -2\cos(m\omega) + 1 = 0,$$

and hence the length of T remains unchanged. Now choose critical paths for the nonstraight edges qp' and rp' such that the corner point of qp' lies on qp but the corner point of rp' does not lie on rp (as in Figure 2.2(b)). Then it follows that the angles at p' all equal $2m\omega = 2\pi/3$. In this way we can transform T into an equally long Steiner λ-tree T' in which any angle is at least equal to $2\pi/3$. □

COROLLARY 2.5. *Any Steiner point in a Steiner minimum λ-tree has degree* 3 *or* 4. *Degree* 4 *Steiner points exist only if $\lambda =$* 2, 4, *or* 6. *If $\lambda =$* 2, 4, *or* 6, *then the angles at degree* 4 *Steiner points are all equal to $\pi/2$.*

For any given value of λ, we define $\phi_{\max}$ to be the maximum angle that can occur at a Steiner point in any Steiner minimum λ-tree.

THEOREM 2.6. 1. *Let $\lambda = 3m + i$. Then*

$$\phi_{\max} = \begin{cases} (\lceil 2\lambda/3 \rceil + 1)\omega & = (2m+1)\omega \quad \text{if } i = 0, \\ \lceil 2\lambda/3 \rceil \omega & = (2m+1)\omega \quad \text{if } i = 1, \\ \lceil 2\lambda/3 \rceil \omega & = (2m+2)\omega \quad \text{if } i = 2. \end{cases}$$

2. *If $\lambda = 3m$, then for any terminal set N there exists a Steiner minimum λ-tree T' such that the maximum angle in T' at a Steiner point is $\lceil 2\lambda/3 \rceil \omega = 2\pi/3$.*

Proof. Clearly, this theorem is symmetric to Theorem 2.4. Hence, it holds by symmetry and by using the second inequalities in formulae (2.2)–(2.4) (Figure 2.2(c)). □

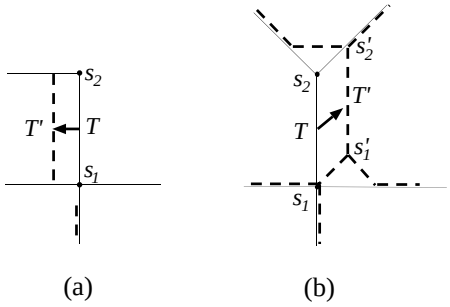

FIG. 3.1. *Two variations for a degree* 4 *Steiner point* s_1 *and its neighboring Steiner point* s_2.

If the angles at a degree 3 Steiner point are α, β, γ, and $\alpha \leq \beta \leq \gamma$, then we define the *angle set* at this point to be the triple (α, β, γ). Combining Theorems 2.4 and 2.6, we have the following corollary.

COROLLARY 2.7. *The only possible angle sets at a degree* 3 *Steiner point in a Steiner minimum* λ*-tree are*

1. $(2m-1, 2m, 2m+1)\omega$ *and* $(2m, 2m, 2m)\omega$ *if* $\lambda = 3m$,
2. $(2m, 2m+1, 2m+1)\omega$ *if* $\lambda = 3m+1$,
3. $(2m+1, 2m+1, 2m+2)\omega$ *if* $\lambda = 3m+2$.

There are also extra restrictions on which angles can appear next to a given nonstraight edge.

COROLLARY 2.8. *Let* ps *be a nonstraight edge in a Steiner minimum* λ*-tree, such that* s *is a Steiner point. Let* c *be the corner point of* ps*, and let* q *and* r *be the other two vertices or corner points immediately adjacent to* s*. If* c *lies on the same side of* ps *as* q *(that is,* $\angle_\lambda psq = \angle csq$*), then* $\angle csq \neq \phi_{\max}$ *and* $\angle csr \neq \phi_{\min}$.

3. Possible structures of Steiner minimum λ-trees. First, we prove a theorem involving degree 4 Steiner points.

THEOREM 3.1. *For any* N *there exists a Steiner minimum* λ*-tree on* N *such that the vertices adjacent to degree* 4 *Steiner points are all terminals.*

Proof. By Corollary 2.5, $\lambda = 2$, 3, 4, or 6. This theorem is well known for $\lambda = 2$ (see, for example, [6]) and follows from statement 2 of Theorem 2.4 when $\lambda = 3$ or 6. So let $\lambda = 4$, and let T be a Steiner minimum λ-tree. By Corollary 2.7, the angle set at any degree 3 Steiner point of T is $(\pi/2, 3\pi/4, 3\pi/4)$.

Assume that s_1 is a degree 4 Steiner point in T. Suppose one of the adjacent vertices of s_1, say s_2, is not a terminal. Clearly, $s_1 s_2$ must be a straight edge, since otherwise the other choice of corner point for that edge would give a contradiction to Corollary 2.4. There are two cases to consider. If s_2 is Steiner point with a $\pi/2$ angle sharing $s_1 s_2$ (Figure 3.1(a)), then we can slide $s_1 s_2$ between two parallel line segments without changing the length of T. This results in a degree 3 Steiner point whose angle set contradicts Corollary 2.7. If a $\pi/2$ angle does not share $s_1 s_2$, then s_2 is a degree 3 Steiner point as in Figure 3.1(b). In this case we can transform T into an equally long Steiner λ-tree T' (shown in dotted lines in the figure) by moving s_2 along one of the legs of this angle and moving s_1 an equal distance in the same

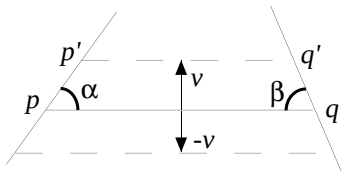

FIG. 3.2. *A parallel shift.*

direction. In this way the degree 4 Steiner point s_1 is eliminated since it has been split into two degree 3 Steiner points s_1, s_1'. □

This theorem means we can often restrict our attention to full Steiner minimum λ-trees with degree 3 Steiner points. Hence it can help reduce the number of tree topologies that need to be considered for a given set of terminals. Unlike the Euclidean case, however, there may be many Steiner minimum λ-trees with the same topology but with different assignments of nonstraight edges and unequal angles. Using the variational argument, we can significantly reduce the number of possible assignments.

We first consider how to minimize the number of nonstraight edges when $\lambda = 3$. (See [3] for details of the case when $\lambda = 3$.) Note that the process of removing degree 4 Steiner points (as illustrated in Figure 3.1(b)) may create extra bent edges. Hence it is still necessary to consider Steiner trees with degree 4 Steiner points when $\lambda = 4$ or 6.

Define a *shift* v of a straight edge pq to be a move of p to p' and a simultaneous move of q to q' such that $p'q' \| pq$ (Figure 3.2). Note that the rate of change in the length of pq under a shift, $d|pq|/dv$, is independent of $|pq|$ but depends only on the angles $\angle p'pq$ and $\angle pqq'$. Clearly, the concept of a shift can be generalized to a path P composed of straight line segments and is well defined once one has specified the directions in which the endpoints of line segments are permitted to move. A variation is said to be *reversible* if $\dot{P}_v = -\dot{P}_{-v}$. It is easy to see that a shift is reversible if each endpoint of a line segment of P is restricted to moving along the same line through that point for both shifts.

LEMMA 3.2. *Let $\lambda = 4$ or 6. Let T be a Steiner minimum λ-tree containing at least two nonstraight edges. If the path, P, between the two nonstraight edges contains a Steiner point s of degree 4, then the angle between the two edges of P incident with s is π.*

Proof. Clearly we can choose the path P in T such that ps_1 and s_kq are nonstraight edges in T and such that all other edges on the path $P = ps_1s_2 \dots s_kq$ are straight.

Suppose, for the moment, that, for any Steiner point on P with degree 4 in T, the two incident edges in P meet at an angle of π. For each s_i on P, let r_i be a vertex or corner point adjacent to s_i not lying on P. Let the corner points on ps_1 and s_kq be c and d, respectively. Let v be the variation of shifting $cs_1s_2 \dots s_kd$ to one side of the path such that c moves towards p, each point s_i moves along the line through s_ir_i, and d moves along the line through dq. This is illustrated in Figure 3.3. In this case the variation is clearly reversible, that is, $\dot{T}_v = -\dot{T}_{-v}$.

Now suppose, contrary to the lemma, that P contains a Steiner point s with

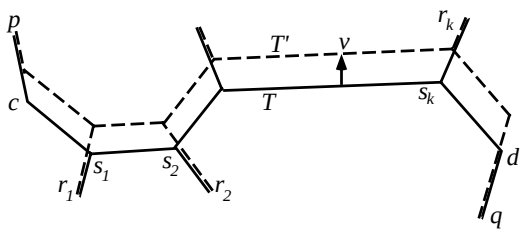

FIG. 3.3. *Shifting a path in T to reduce the number of corner points.*

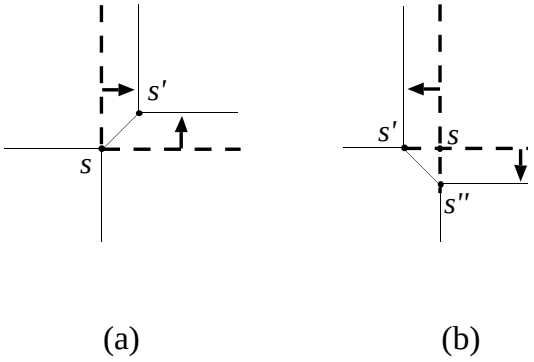

FIG. 3.4. *Two variations for a degree* 4 *Steiner point s and two of its incident edges.*

degree 4 in T such that the two incident edges in P meet at an angle of $\pi/2$. By Figure 3.4 there exist two perturbations on s and its two incident edges in P such that these perturbations have the following properties.

(1) They each split s into two Steiner points (s and s' in Figure 3.4(a), and s' and s'' in Figure 3.4(b)).

(2) One perturbation shifts the two incident edges to one side of P, while the other shifts them to the opposite side of P.

(3) In each case they reduce the length of T in the vicinity of s.

By property (2) we can incorporate these perturbations into the shift variations v and $-v$ described above. It then follows, by property (3), that $\dot{T}_v < 0$ or $\dot{T}_{-v} < 0$, contradicting the minimality of T. □

THEOREM 3.3. *For any N there exists a fulsome Steiner minimum λ-tree on N such that in each component at most one edge is nonstraight.*

Proof. Assume that $\lambda > 3$, and suppose that T is a full component of a fulsome Steiner minimum λ-tree on N containing more than one nonstraight edge. We begin with a similar construction to the previous lemma. There exists a pair of nonstraight edges ps_1 and s_kq in T such that all other edges on the path $P = ps_1s_2 \dots s_kq$ are straight. For each s_i on P let r_i be a vertex or corner point adjacent to s_i not lying

on P. Let the corner points on ps_1 and s_kq be c and d, respectively. Let v be the variation of shifting $cs_1s_2 \ldots s_kd$ to one side of the path such that c moves towards p, each point s_i moves along the line through s_ir_i, and d moves along the line through dq. By Lemma 3.2, v is well defined and is reversible, that is, $\dot{T}_v = -\dot{T}_{-v}$.

It follows that $\dot{T}_v = 0$ since T is minimal. Therefore, such a shift does not change the length of T. We can continue to perform this shift without changing the length of T until one of the following occurs.

(1) Two points s_i and s_{i+1} coincide, or a point s_i coincides with a Steiner point r_i.

(2) A point s_i coincides with a terminal r_i.

(3) A point s_i coincides with a corner point r_i, or c or d coincides with a terminal or Steiner point.

If (1) occurs and $\lambda \neq 4$ or 6, then we have a contradiction to the fact that T is minimum. If (1) occurs and $\lambda = 4$ or 6, then by Lemma 3.2 the two edges in P incident to this point must meet at an angle of π, and hence we can continue to perform the shift. If (2) occurs, we have a contradiction to the fact that T is fulsome. Hence, one of the possibilities in (3) must eventually occur, reducing the number of nonstraight edges. In this way T can be transformed into a λ-tree of equal length containing at most one nonstraight edge. □

Remark 3.1. We conjecture that Theorems 3.1 and 3.3 can always hold simultaneously; that is, if $\lambda = 4$ or 6, there exists for any terminal set a Steiner minimum tree such that each full component contains at most one nonstraight edge, and each degree 4 Steiner point is adjacent to four terminals. In light of Theorem 3.1 and this conjecture, it will be convenient for the remainder of this paper to use the term "Steiner topology" to refer to a tree topology in which all nonterminals have degree no more than 3.

Suppose N is a set of n terminals. Let $GG_0(N) = N$, and recursively define $GG_i(N)$ to be the set of grid points that are intersections of the legal lines through all points in $GG_{i-1}(N)$. The so-called multilevel grid theorem in [8] is now a simple corollary of the above theorem.

COROLLARY 3.4. *For each set N of n terminals, there exists a Steiner minimum λ-tree T for N such that all Steiner points in T are grid points of $GG_{n-2}(N)$.*

Proof. If all edges of T are straight edges, then each Steiner point adjacent to two terminals lies on $GG_1(N)$, and each Steiner point adjacent to two vertices of T on $GG_{i-1}(N)$ lies on $GG_i(N)$. Since we can assume, in general, that T contains at most one nonstraight edge, it follows that all Steiner points in the two connected components of T minus that nonstraight edge lie on $GG_{n-2}(N)$. □

The shift technique also helps us to reduce the number of feasible angle assignments. Consider again the shift of pq shown in Figure 3.2. Let $\alpha = \angle p'pq$, $\beta = \angle pqq'$, and $l = |pq|$. Then we have

$$\frac{d}{dv}|pq| = \dot{l}(v) = -\cos\alpha - \cos\beta.$$

Now assume all edges are in λ-geometry and hence $\alpha = k_1\omega, \beta = k_2\omega$. Define a function $g(k_1, k_2)$ as follows:

$$g(k_1, k_2) = -\cos(k_1\omega) - \cos(k_2\omega).$$

This is similar to $f(k)$ which expresses the variation of moving a point, except that g expresses the variation of shifting a straight edge. Just as for the inequalities in Lemma 2.2, it is easy to show that the following inequalities hold.

1. If $\lambda = 3m$, then

$$2f(m-1) + g(m,m) < -2, \tag{3.1}$$

$$2f(2m) + g(2m-1, 2m-1) < 2, \tag{3.2}$$

$$2f(2m-1) + g(2m, 2m) < 2, \tag{3.3}$$

$$f(2m) + f(2m-1) + g(2m, 2m-1) < 2. \tag{3.4}$$

2. If $\lambda = 3m+1$, then

$$2f(m) + g(m,m) < -2. \tag{3.5}$$

3. If $\lambda = 3m+2$, then

$$2f(2m+1) + g(2m+1, 2m+1) < 2. \tag{3.6}$$

Suppose that s_1s_2 is a straight edge joining two Steiner points. The angles at s_1, s_2, sharing s_1s_2 and lying on the same side of s_1s_2, are referred to as *neighboring angles*. Some restrictions occur on neighboring angles when they are either both $\phi_{\min}$ or both $\phi_{\max}$.

THEOREM 3.5. *In a Steiner minimum λ-tree T two neighboring angles cannot both be*

1. $\phi_{\min}$ *or both be* $\phi_{\max}$ *if* $\lambda = 3m$,
2. $\phi_{\min}$ *if* $\lambda = 3m+1$,
3. $\phi_{\max}$ *if* $\lambda = 3m+2$.

Proof. Consider the case of $\lambda = 3m$. First, suppose, to the contrary, that there are two neighboring angles $\angle ps_1s_2 = \angle s_1s_2q = \phi_{\min} = 2m-1$ in T. Then perform a variation by shifting s_1s_2 so that s_1 and s_2 each move at an angle of $m\omega$ to s_1s_2, as shown in Figure 3.5(a). We have $\dot{T} \le 2f(m-1) + g(m,m) + 2 < 0$ by inequality (3.1). Next, if $\angle ps_1s_2 = \angle s_1s_2q = \phi_{\max} = 2m+1$, then there are 3 cases as shown in Figures 3.5(b)–3.5(d) corresponding to the different assignments of angles around s_1 and s_2. In each case, we perform the shift by shrinking the third edges at s_1 and s_2, effectively stretching s_1s_2. Then $\dot{T} < 0$ by inequalities (3.2)–(3.4). The other two statements of the theorem can be proved similarly by inequalities (3.5) and (3.6) using the shifts illustrated in Figures 3.5(e) and 3.5(f). □

Remark 3.2. The above proof demonstrates that in order to show $\dot{T} < 0$ for the given cases it suffices to shrink s_1s_2 for two neighboring angles $\phi_{\min}$ and to stretch s_1s_2 for two neighboring angles $\phi_{\max}$. Note, however, that there are other possible shifts we could have chosen in the proof. For example, in the case shown in Figure 3.5(b), the nonminimality of T can be derived from the fact that it is covered by Figure 3.5(a).

Remark 3.3. Theorem 3.5 does not exhaust all possibilities for assignments of angles that cannot occur at two neighboring Steiner points in a Steiner minimum λ-tree. There is one remaining infeasible configuration, which occurs for $\lambda = 3m$. In this case the neighboring angles at s_1, s_2 are, respectively, $(2m-1)\omega$, $2m\omega$ on one side of s_1s_2 and $2m\omega$, $(2m+1)\omega$ on the other, as shown in Figure 3.6. Now perform a shift variation as shown in the figure, where s_1 and s_2 both move in the same direction and the critical paths are chosen so that the new corner points p' and

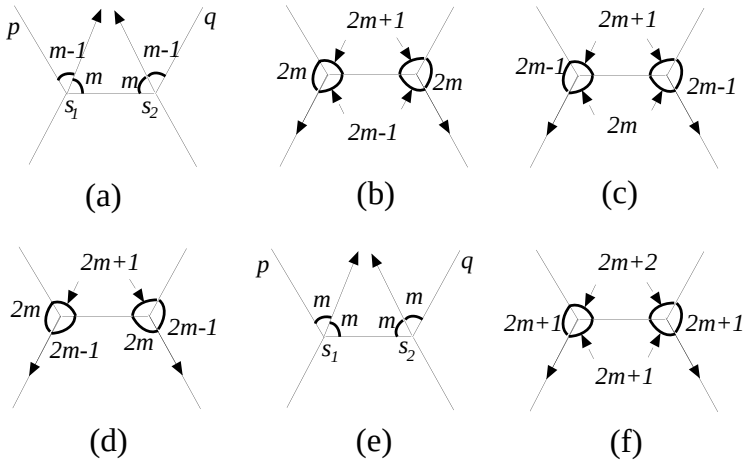

FIG. 3.5. *Infeasible pairs of neighboring angles, both of which are $\phi_{\min}$ or $\phi_{\max}$. The labels at angles represent multiples of ω.*

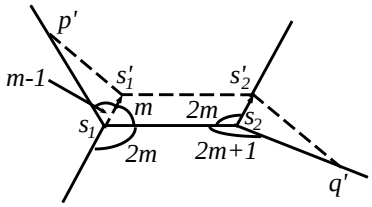

FIG. 3.6. *Another infeasible angle configuration for $\lambda = 3m$.*

q' both lie on edges of the original λ-tree. Then $|p's_1| + |s_2q'| > |p's_1'| + |s_2'q'|$ because $p's_1' \parallel s_2'q'$. Hence, the original tree is not minimal.

The λ-metric for $\lambda = 3$ (hexagonal metric) is a special metric in λ-metrics because $\omega = \phi_{\min} = \pi - \phi_{\max}$. When $\lambda = 3$, for any point set N in the λ-plane there is a Steiner minimum λ-tree such that all Steiner points are vertices of $GG_{\lceil (n-2)/2 \rceil}$ [15], which is a significant improvement on Corollary 3.4. It is not difficult, however, to see that this result cannot be generalized to larger values of λ. Moreover, it has been proved in [12] that for any set N and any given Steiner topology there exists a Steiner λ-tree (with $\lambda = 3$) such that the unique nonstraight edge in each full component is incident to a terminal, and that all angles at Steiner points are $2\pi/3$. Therefore, it directly follows that Melzak's construction for Euclidean Steiner trees [9] can also be used to construct Steiner λ-trees for $\lambda = 3$. An algebraic algorithm, which is equivalent to Melzak's construction but much more suitable for computer implementation, was developed [13],[5]. In the next section we show that in a certain sense Melzak's construction can apply to λ-trees for any λ.

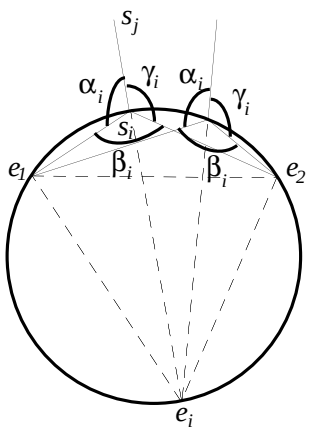

FIG. 4.1. *Merging two terminals.*

4. Steiner trees with fixed angles. To generalize Melzak's construction for Euclidean Steiner trees, which is a geometric construction using only ruler and compass, to Steiner λ-trees, we first give a brief description of the method in the Euclidean setting. Suppose the topology of a Steiner tree T spanning a terminal set N in the Euclidean plane is given. Since each full component is constructed independently, we can assume T is full. Melzak's construction is divided into two stages. The basic operation at the first stage (orientation stage) is as follows. Suppose a Steiner point s_i in T is adjacent to two terminals e_1, e_2, and suppose the third adjacent vertex is s_j. Let e_i be the third vertex of the equilateral triangle $e_1e_ie_2$ that lies on the side of e_1e_2 opposite to s_i. (The correct side can be determined by the other terminals, as shown in [4].) Without loss of generality, assume e_1, e_i, e_2 are in counterclockwise order. An easy trigonometric argument shows that s_i must lie on the minor arc $\overset{\frown}{e_1e_2}$ of the circle circumscribing e_1, e_2, and e_i, and that the point e_i lies on the major arc $\overset{\frown}{e_1e_2}$ (Figure 4.1) and satisfies the properties

(P1) e_i lies on the extension of s_js_i, and

(P2) $|e_1s_i| + |e_2s_i| = |e_is_i|$.

From these properties it follows that we can replace e_1, e_2 with e_i. (Hence, e_i is referred to as a *merging point*.) Repeat this operation until only two points are left. Then the line segment joining the two points, called a *Simpson line* of T, gives

1. the orientation of an edge of T by (P1), and
2. the length of T, which equals the length of the Simpson line, by (P2).

Once the Simpson line is determined, all Steiner points can be determined by backtracking at the second stage (reconstruction stage).

Related to this method, a notation describing a full Steiner topology was proposed [1]. Since e_1, e_2 are replaced by a merging point in this construction, the association of e_1, e_2 can be denoted as (e_1e_2). In this way, the topology of T can be represented by a sequence of terminals that are bracketed in pairs according to the order of the association of terminals. For example, the topology in Figure 4.2(b) can be represented as $(a(bc))(de)$.

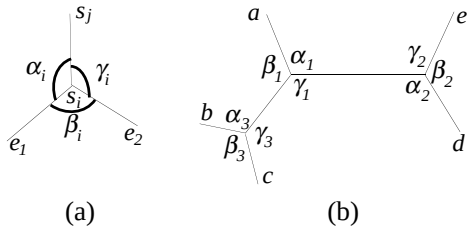

FIG. 4.2. *Steiner patterns.*

Property (P1) is very much the core of Melzak's construction, whereas property (P2), though useful, is not essential. Without using (P2), we can still find the length of T since it is the sum of all edge lengths. These edge lengths can be computed after the Steiner points are determined at the reconstruction stage. Thus, Melzak's construction can be generalized to a wide range of Steiner trees in which all angles at Steiner points are fixed.

A full Steiner topology accompanied by information about the size of all angles at Steiner points will be referred to as a *Steiner pattern*. A suitable notation for Steiner patterns can be developed by generalizing the notation for a Steiner topology. As before, suppose s_i is a Steiner point adjacent to two terminals e_1, e_2, and the third adjacent vertex is s_j. Suppose the angles at s_i are $\angle e_1 s_i s_j = \alpha_i$, $\angle e_2 s_i e_1 = \beta_i$, and $\angle s_j s_i e_2 = \gamma_i$ (Figure 4.2(a)). Then, the association of e_1, e_2 is denoted as $(\alpha_i(e_1 \beta_i e_2)\gamma_i)$. In this way the pattern in Figure 4.2(b) can be represented as

$$(\alpha_1(a\beta_1(\alpha_3(b\beta_3 c)\gamma_3))\gamma_1)(\alpha_2(d\beta_2 e)\gamma_2).$$

It is easy to see that this pattern can be simplified by removing all brackets because the insertion of angles makes it possible to find the order of association of terminals. For example, the above pattern can be easily retrieved from the *simplified pattern*

$$\alpha_1 a \beta_1 \alpha_3 b \beta_3 c \gamma_3 \gamma_1 \alpha_2 d \beta_2 e \gamma_2.$$

In fact, this pattern is the sequence of terminals and angles occurring in turn in a counterclockwise tour of the topology.

Suppose T is a full Steiner tree with a given pattern. Then the basic operation in constructing the tree can be modified as follows. Let e_i be the third vertex of the triangle $e_1 e_i e_2$ in which $\angle e_2 e_1 e_i = \pi - \gamma_i, \angle e_i e_2 e_1 = \pi - \alpha_i$. Clearly, e_1, e_i, e_2, s_i lie on a circle (as in Figure 4.1). Since the angles at s_i are fixed, property (P1) holds: that is, the extension of $s_j s_i$ must go through e_i no matter where s_i lies on $\overset{\frown}{e_1 e_2}$. Hence we still can find the orientation of an edge of T, and we can construct T by backtracking. However, (P2) does not hold unless all angles at each s_i equal $2\pi/3$. Otherwise, the length of the tree can be computed after all Steiner points are determined, as mentioned above.

We can now generalize the Steiner pattern and Melzak's construction to Steiner λ-trees. Suppose T is a full Steiner λ-tree in which $s_1 s_2$ is the unique nonstraight edge by Theorem 3.3. Then the angles at all Steiner points other than s_1, s_2 are fixed.

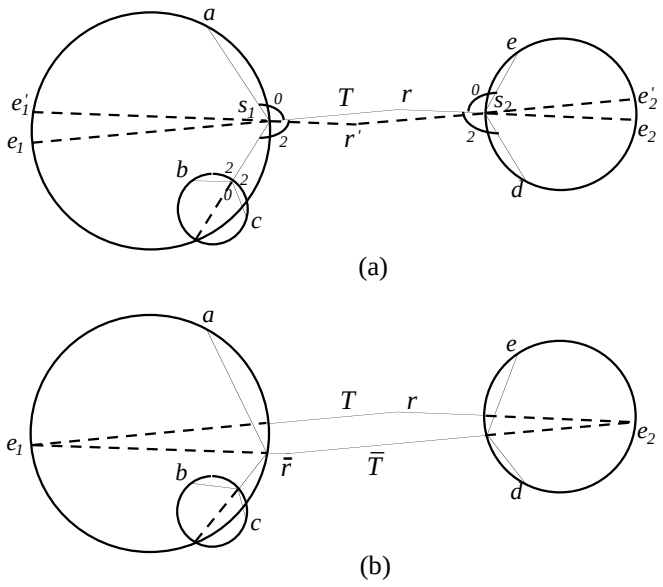

FIG. 4.3. *Melzak's construction and Steiner patterns in the λ-plane.*

If one of the critical paths of s_1s_2, say, s_1rs_2, is chosen as the nonstraight edge, then the angles at s_1, s_2 are also fixed. Thus T can be regarded as the union of two full subtrees T_1, T_2 joined at the corner point r. Let w_1, w_2 be the patterns of the subtrees T_1, T_2, respectively. Then we define $w_1 \frown w_2$ to be the pattern of the λ-tree T. Note that all edges in T_1, T_2 are straight and that all angles correspond to the possibilities given in Corollary 2.7. In the simplified pattern of λ-trees, let $\phi_{\min}$ be denoted by 0, let $\phi_{\max}$ be denoted by 2, and let the angle $2m$ for $\lambda = 3m$, which is between $\phi_{\min}$ and $\phi_{\max}$, be denoted by 1. Then, for example, the pattern of the λ-tree in Figure 4.3(a), whose topology is the same as the tree in Figure 4.2(b), is

$$0a22b0c22 \frown 2d2e0.$$

Remark 4.1. If the other critical path $s_1r's_2$ is chosen as the nonstraight edge, then the pattern becomes $2a22b0c20 \frown 0d2e2$ (Figure 4.3(a)). Although the merging points are different for the two patterns, as shown in the figure, the Steiner points s_1, s_2 are the same. Therefore, the two patterns can be regarded as equivalent.

Because both T_1, T_2 are full Steiner trees with fixed angles, they can be constructed by Melzak's method as stated above. Hence, as shown in Figure 4.3, we can find merging points e_1, e_2 after merging all terminals in T_1, T_2, respectively. Now there may exist two choices of the nonstraight edge e_1e_2 as shown in Figure 4.3(b), and two λ-trees $T, \overline{T}$ can be constructed. Because (P2) does not hold, $|T|_\lambda$ may not equal $|\overline{T}|_\lambda$ though two paths of e_1e_2 (e_1re_2 and $e_1\bar{r}e_2$) are equally long. Only by comparing the lengths of T and $\overline{T}$ are we able to determine which one is shorter.

5. Concluding remarks. Sections 3 and 4 essentially give two finite exact algorithms for solving the Steiner problem in a λ-plane. The strategy suggested by

Corollary 3.3 is to treat the problem as a graphical Steiner tree problem on the grid $GG_{n-2}(N)$, and then use standard techniques for Steiner trees on graphs (see, for example, [6]). Unfortunately, the number of grid points in $GG_{n-2}(N)$ has order $O(n^{2^{n-2}})$, making such an approach impractical for large n. The alternative algorithm suggested by section 4 is to run through all possible patterns for a Steiner minimum λ-tree. The modified version of Melzak's theorem then allows the minimum λ-tree for each pattern to be constructed in linear time (independently of λ). The practical disadvantage of this approach lies in the fact that the number of Steiner topologies increases at an exponential rate as n increases. Furthermore, for each Steiner topology the number of different patterns that needs to be considered is potentially also an exponential function of n. Noting that a Steiner minimum λ-tree can be found in linear time for a given Steiner topology if $\lambda = 2, 3$, or ∞, we have the following tantalizing but apparently difficult open question.

Open question. Given $\lambda > 3$ and a terminal set N, does there exist a polynomial-time algorithm for finding a Steiner minimum λ-tree for any given Steiner topology on N?

We will consider a number of issues connected with this question in a forthcoming paper, in which we will also develop a more practical exact algorithm for solving the Steiner minimum problem in the λ-plane.

GENERAL DYNAMIC ROUTING WITH PER-PACKET DELAY GUARANTEES OF O(DISTANCE + 1/SESSION RATE)*

MATTHEW ANDREWS†, ANTONIO FERNÁNDEZ‡, MOR HARCHOL-BALTER§, TOM LEIGHTON¶, AND LISA ZHANG†

Abstract. A central issue in the design of modern communication networks is that of providing performance guarantees. This issue is particularly important if the networks support real-time traffic such as voice and video. The most critical performance parameter to bound is the delay experienced by a packet as it travels from its source to its destination.

We study dynamic routing in a connection-oriented packet-switching network. We consider a network with arbitrary topology on which a set of sessions is defined. For each session i, packets are injected at a rate r_i to follow a predetermined path of length d_i. Due to limited bandwidth, only one packet at a time may advance on an edge (link). Session paths may overlap subject to the constraint that the total rate of sessions using any particular edge is at most $1-\varepsilon$ for any constant $\varepsilon \in (0,1)$.

We address the problem of scheduling the sessions at each switch, so as to minimize worst-case packet delay and queue buildup at the switches. We show the existence of a periodic schedule that achieves a delay bound of $O(1/r_i + d_i)$ with only constant-size queues at the switches. This bound is asymptotically optimal for periodic schedules.

A consequence of this result is an asymptotically optimal schedule for the static routing problem, wherein all packets are present at the outset. We obtain a delay bound of $O(c_i + d_i)$ for packets on path P_i, where d_i is the number of edges in P_i and c_i is the maximum congestion along edges in P_i. This improves upon the previous known bound of $O(c+d)$, where $d = \max_i d_i$ and $c = \max_i c_i$.

We also present a simple distributed algorithm that, with high probability, delivers every session-i packet to its destination within $O(1/r_i + d_i \log(m/r_{\min}))$ steps of its injection, where $r_{\min}$ is the minimum session rate and m is the number of edges in the network. Our results can be generalized to (leaky-bucket constrained) bursty traffic, where session i tolerates a burst size of b_i. In this case, our delay bounds become $O(b_i/r_i + d_i)$ and $O(b_i/r_i + d_i \log(m/r_{\min}))$, respectively.

Key words. communication networks, packet routing, scheduling, delay bounds

1. Introduction.

1.1. Motivation.

Motivated by the need for quality-of-service guarantees, network designers today offer *connection-oriented* service in many networks, e.g., ATM (asynchronous transfer mode) networks. In this medium, a user requests a particular share of the bandwidth and injects a stream of packets along one particular session at the agreed-upon rate. An important consequence of the user's predictability is that the network can, in return, guarantee the user an *end-to-end delay bound*, i.e.,

an upper bound on the time that any packet takes to move from its source to its destination. In order to provide this delay guarantee, the network must determine how to schedule the packets that contend for the same edge simultaneously. Apart from delay bounds, it is also important to guarantee small queues at each switch due to limited buffer size. In this paper we show how to design schedules that guarantee asymptotically optimal per-session delay bounds as well as small queues.

1.2. Model and problem. Consider a network $\mathcal{N}$ of arbitrary topology and a set of sessions defined on this network. A session i is associated with a source node, a destination node, and a simple path from the source to the destination. (A path is *simple* if it uses each edge at most once.) Packets are injected to the network $\mathcal{N}$ in sessions. A packet injected in session i enters the system at the source node of i, traverses the path associated with i, and then is absorbed at its destination. The length d_i is the number of edges on the path from the source to the destination of session i.

Each session i has an associated injection rate r_i. This rate constrains the injection of new packets from the session so that, during any interval of t consecutive steps, at most $tr_i + 1$ packets can be injected in session i for any t.

We assume that all packets have the same size and all edges have the same bandwidth. We also assume a synchronized store-and-forward routing, where at each step at most one packet can traverse each edge. When two packets simultaneously contend for the same edge, one packet has to wait in a queue. During the routing, packets wait in two different kinds of queues. After a packet has been injected but before it leaves its source, the packet is stored in an *initial queue*. Once the packet has left its source, during any time it is waiting to traverse an edge, the packet is stored in an *edge queue*. The *end-to-end delay* (delay for short) for a packet is the total time from the packet injection until it reaches its destination. This includes the total time the packet spends waiting in both types of queues, plus the time it spends traversing edges.

Our goal is to minimize both the end-to-end delay for each packet and the length of all edge queues. In order to achieve delay guarantees and bounded queue sizes, it is necessary to require that, for all edges e, the sum of the rates of the sessions that use edge e is at most 1. Throughout, we shall assume that the sum of the rates of the sessions using any edge e is at most $1 - \varepsilon$ for a constant $\varepsilon \in (0, 1)$. This constant ε will appear throughout our subsequent bounds.

Our paper focuses on the problem of timing the movements of the packets along their paths. A *schedule* specifies which packets move and which packets wait in queues at each time step. Most of the schedules obtained in this paper are *template-based*. The schedule defines a fixed *template* for each edge in advance. A template of size M is a wheel with M slots, each of which contains at most one token. Each token is affiliated with some session. The wheel spins at the speed of one slot per time step. A session-i packet can traverse the edge if and only if a session-i token appears. For each session-i token, the session-i packet that uses it will be the one that has been waiting to cross the edge for the longest amount of time, i.e., the session-i packets use the session-i tokens in a first-come-first-served manner. The template size and associated tokens do not change over time.

We show that per-session delay bounds that are asymptotically optimal for template-based schedules can be achieved. Meanwhile, constant-size edge queues can be achieved as well.

1.3. Lower bounds. We observe that d_i is always a lower bound on the delay for session i, since every session-i packet has to cross d_i edges. It is also easy to see that $\Omega(1/r_i)$ is an existential lower bound. For instance, consider n sessions, all of which have the same rate $r = (1-\varepsilon)/n$ and the same initial edge e. If a packet is injected in each session simultaneously, one of the packets requires $n = \Omega(1/r)$ steps to cross e.

Furthermore, for *any* given set of sessions, $\Omega(1/r_i)$ is a lower bound for some session i in template-based schedules. Consider the template for an edge e where $\sum_e r_i = 1-\varepsilon$. By the pigeon-hole principle, the tokens for some session i can occupy at most an $r_i/(1-\varepsilon)$ fraction of the slots on the template. Hence, there exist two session-i tokens that are separated by at least $(1-\varepsilon)/r_i$ slots. As a result, an adversary can make sure a session-i packet arrives just after the first token has passed, thereby forcing the packet to wait $\Omega(1/r_i)$ steps.

If the schedule is not restricted to being template-based, the scheduler is more powerful. The scheduler does not have to decide on a fixed schedule in advance, but rather can make a new decision at each step, based on seeing the adversary's injections. In this case it is unknown if for *any* given set of sessions $\Omega(1/r_i)$ is a lower bound.

1.4. Previous work. The problem of dynamic packet routing in the above setting is well studied. Until recently, the best delay bound known was $O(d_i/r_i)$ for packets of session i. It is tempting to believe that this is the best possible delay bound, since a session-i packet may need to wait $\Omega(1/r_i)$ steps to cross each of the d_i edges on its route. However, this upper bound of $O(d_i/r_i)$ can be much improved.

In 1990, Demers, Keshav, and Shenker [8] proposed a widely studied routing algorithm called Weighted Fair Queueing (WFQ). WFQ is a packetized approximation of the idealized fluid model algorithm Generalized Processor Sharing (GPS). WFQ is simple and distributed. This same algorithm was proposed independently by Parekh and Gallager [14, 15] in 1992 under the name of Packet-by-Packet Generalized Processor Sharing (PGPS). Parekh and Gallager prove that the algorithm has an end-to-end delay guarantee of $2d_i/r_i$ [15, p. 148] in the case when all packets have the same size.

In their 1996 paper, Rabani and Tardos [16] produce an algorithm that routes every packet to its destination with probability $1-p$ in time

$$O(1/r_{\min}) + (\log^* p^{-1})^{O(\log^* p^{-1})} d_{\max} + poly(\log p^{-1}),$$

where $r_{\min} = \min_i r_i$ and $d_{\max} = \max_i d_i$. Ostrovsky and Rabani improve the bound to $O(1/r_{\min} + d_{\max} + \log^{1+\varepsilon} p^{-1})$ [13]. These bounds are not session-based, meaning that if one session has a small rate or a long path, then the delay bounds for all sessions will suffer. The algorithms of [13, 16] are distributed, where knowledge of the entire network is not assumed, but each packet carries some information.

The main technique of [13, 16] is based on "delay-insertion." The intuition here is that if each packet receives a large random initial delay, then the packets are sufficiently spread out to ensure that they only need to wait $O(1)$ steps at each successive edge rather than $\Omega(1/r_i)$ steps. This delay-insertion technique is used extensively by Leighton et al. in [10, 11] in the context of static routing. (In the *static* routing problem, all packets are present in the network initially.) Since our main result employs many techniques from [10], we give a detailed summary of [10] in section 4.1.

A contrasting model, the *connectionless adversarial queueing model*, is also much studied, e.g., [4, 1]. Here the paths on which packets are injected can change over

time, giving the adversary more power. In the adversarial queueing model the best delay bound known is polynomial in the maximum path length [1].

1.5. Our results. We first provide a randomized, distributed scheduler that achieves a delay bound for session-i packets of $O(1/r_i + d_i \log(m/r_{\min}))$ and a bound on the queue size of $O(\log(m/r_{\min}))$, where m is the number of edges in the network and $r_{\min} = \min_i r_i$. While this bound is not optimal, it nevertheless conveys some intuition for our main result.

The main contribution of this paper is an asymptotically optimal template-based schedule. We prove that a schedule exists for the dynamic routing problem such that the end-to-end delay of each session-i packet is bounded by $O(1/r_i + d_i)$.[1] Our result improves upon previous work in several aspects.

- We provide a session-based delay guarantee. That is, packets from sessions with short paths and high injection rates reach their destinations quickly. This is a big improvement over the previous bounds, which are stated in terms of $r_{\min} = \min_i r_i$ and $d_{\max} = \max_i d_i$. We also guarantee that every packet always reaches its destination within the delay bound, without dropping any packets.
- We guarantee constant-size edge queues. This is interesting because edge queues are much more expensive than initial queues in practice.
- A consequence of our result is a packet-based bound, which improves upon the $O(c + d)$ bound in [10] for the static problem. (See section 4.1 for the problem and parameter definitions.) We show that if packet p_i follows a route P_i, then p_i can be routed to its destination within $O(c_i + d_i)$ steps, where c_i is the maximum congestion along P_i and d_i is the number of edges on P_i. This result trivially follows from our result by creating a different session i for each packet p_i, and defining $r_i = (1-\varepsilon)/c_i$, where ε is a positive constant used to ensure that the load on any edge is under 1.

For a template-based schedule, even if the computation of the schedule is time-consuming, it needs to be done only once. Packets can then be scheduled indefinitely as long as the sessions do not change.

Leaky-bucket injection model. Our results above can be generalized to bursty traffic streams that are *leaky-bucket regulated*. Here, each session i has a maximum burst size (or bucket size) of $b_i \geq 1$ and an average arrival rate of r_i. During any t consecutive time steps at most $r_i t + b_i$ session-i packets are injected. Leaky-bucket regulated traffic is widely used in the literature, e.g., [6, 7, 9, 14, 15, 18].

Leaky-bucket regulated injections allow traffic shaping. When session-i packets are injected, they first enter the session-i bucket at the source. These packets then leave the bucket one at a time at the rate of r_i. In this way, the end-to-end delay is separated into two components: delay in the bucket and delay in the network. Since delay in the bucket is at most b_i/r_i, the end-to-end delay is increased by at most b_i/r_i steps, and the size of the edge queues is unchanged.

The rest of the paper is divided into sections as follows. We first give some definitions and preliminary results in section 2. Then, in section 3, we describe a simple distributed scheduler that has a delay bound of $O(1/r_i + d_i \log(m/r_{\min}))$. In section 4, we overview the major techniques employed to achieve the main result: a bound of $O(1/r_i + d_i)$ and constant-size edge queues. In section 5 we define a set of

[1] In this paper, we concentrate on proving the existence of such a schedule. However, the proof can be made constructive using ideas of Leighton, Maggs, and Richa [11] that are based on Beck's algorithm [3]. For details, see [19].

parameters used in the proof of the main result, and in section 6 we provide a detailed proof of the main result.

2. Preliminaries. In this section we present some preliminary results. Section 2.1 proves a generic fact about "token sequences" for template-based schedules. Section 2.2 presents two lemmas for probabilistic analysis that will be used extensively throughout the paper.

2.1. Token sequences. Throughout the paper we define template-based schedules in terms of *token sequences*. A token sequence for session i consists of d_i session-i tokens, $\mathcal{K}_1$, ..., $\mathcal{K}_{d_i}$, one from each template along the session-i path, where $\mathcal{K}_{j+1}$ appears $x_j > 0$ steps after $\mathcal{K}_j$. Then x_j is the *token lag* for these two tokens and $\sum_{j=1}^{d_i-1} x_j$ is the end-to-end delay for this token sequence. Two token sequences cannot have tokens in common.

In the following, we show that in any template-based schedule, bounding the delay for token sequences is sufficient to bound the packet delays and that bounding the token lag is sufficient to bound the edge queues. Our proof relies on Lemma 2.1. A vector $\vec{v} = [v_1, v_2, \ldots, v_n]$ is *sorted* if $v_1 \le v_2 \le \cdots \le v_n$. We define $perm(\vec{v})$ to be a sorted vector whose components form a permutation of the components of $\vec{v}$. We also use the notation $\vec{u} < \vec{v}$ to indicate that the jth component of $\vec{u}$ is smaller than the jth component of $\vec{v}$ for each j.

LEMMA 2.1. *Let $\vec{u} = [u_1, u_2, \ldots, u_n]$ and $\vec{v} = [v_1, v_2, \ldots, v_n]$ be two vectors, each of which consists of n distinct numbers. Suppose $\vec{u}$ is sorted, i.e., $perm(\vec{u}) = \vec{u}$, and suppose $\vec{u} < \vec{v}$. Then, the following hold.*

1. *$perm(\vec{u}) < perm(\vec{v})$.*
2. *If $\vec{v} < \vec{u} + \vec{z}$, then $perm(\vec{v}) < perm(\vec{u}) + \vec{z}$, where $\vec{z} = [z, \ldots, z]$ is a vector of n z's for a scalar z.*
3. *Let $|\vec{v}|$ represent the maximum component of $\vec{v}$; then $|perm(\vec{v}) - perm(\vec{u})| \le |\vec{v} - \vec{u}|$.*

Proof. Let $perm(\vec{v}) = [v_{\sigma(1)}, \ldots, v_{\sigma(n)}]$, where σ represents the sorted permutation of $\vec{v}$.

1. Let us compare u_j and $v_{\sigma(j)}$. There are two cases to consider. If $j \le \sigma(j)$, then $u_j \le u_{\sigma(j)} < v_{\sigma(j)}$. These inequalities hold since $\vec{u}$ is sorted by assumption and $\vec{u} < \vec{v}$. If $j > \sigma(j)$, then there exists $j' \ge j$ such that $v_{j'} \le v_{\sigma(j)}$. (Otherwise, for all $j' \ge j$, $v_{j'} > v_{\sigma(j)}$. However, only $n - j$ components of $\vec{v}$ can be greater than $v_{\sigma(j)}$.) Combining the fact that $\vec{u}$ is sorted and $\vec{u} < \vec{v}$, we have $u_j \le u_{j'} < v_{j'} \le v_{\sigma(j)}$. Therefore, $perm(\vec{u}) < perm(\vec{v})$ in both cases.
2. Since $perm(\vec{u} + \vec{z}) = perm(\vec{u}) + \vec{z}$ for $\vec{z} = [z, \ldots, z]$, property 1 implies $perm(\vec{v}) < perm(\vec{u} + \vec{z}) = perm(\vec{u}) + \vec{z}$.
3. Suppose $|perm(\vec{v}) - perm(\vec{u})| = v_{\sigma(j)} - u_j$. There are two cases to consider. If $v_{\sigma(j)} \le v_j$, then $v_{\sigma(j)} - u_j \le v_j - u_j$, which implies $|perm(\vec{v}) - perm(\vec{u})| \le |\vec{v} - \vec{u}|$. If $v_{\sigma(j)} > v_j$, then there exists $j' < j$ such that $v_{\sigma(j)} \le v_{j'}$. (Otherwise, for all $j' \le j$, $v_{\sigma(j)} > v_{j'}$. However, only $j - 1$ components of $\vec{v}$ can be smaller than $v_{\sigma(j)}$.) Since $u_{j'} < u_j$ by the assumption that $\vec{u}$ is sorted, we have $v_{\sigma(j)} - u_j \le v_{j'} - u_{j'}$, which implies $|perm(\vec{v}) - perm(\vec{u})| \le |\vec{v} - \vec{u}|$. Property 3 follows. ∎

We are ready to transform a token-sequence-based bound into a packet-based bound. Although it might seem straightforward, the difficulty is that a packet is unable to identify a token sequence. This means if a session-i token appears, then the session-i packet that has been waiting the longest has to move. The first token in a

token sequence is called an *initial token.*

THEOREM 2.2. *Consider any template-based schedule. If the end-to-end delay for each session-i token sequence is bounded by X, then each session-i packet reaches its destination within X steps after it obtains an initial token. If the token lag is bounded by x for* all *token sequences for* all *sessions, then the edge queue size is also bounded x.*

Proof. It suffices to show the following. For any $y \geq 1$, consider the first y session-i packets injected. After obtaining its initial token, each of these y packets reaches the destination within X steps, and it waits at most x steps to advance each edge.

Let T_{k1} be the time that the kth packet catches an initial token $\mathcal{K}_k$ and advances its first edge. Let T_{kj} be the time that the kth packet would cross the jth edge if it followed the token sequence initiated at $\mathcal{K}_k$. Note that T_{kj} is not necessarily the time that the kth packet crosses the jth edge in a template-based schedule. However, T_{kj} does represent the time that a token would appear on the jth edge. We have $T_{11} < T_{21} < \cdots < T_{y1}$, and $T_{k1} < T_{k2} < \cdots < T_{kd_1}$ for $1 \leq k \leq y$.

We first apply property 1 of Lemma 2.1 to show that packets 1 through y are able to cross the jth edge by times $perm(T_{1j}, T_{2j}, \ldots, T_{yj})$ for $1 \leq j \leq d_i$. Take an example of the second edge. Let $perm(T_{12}, T_{22}, \ldots, T_{y2}) = [T_{\sigma(1),2}, T_{\sigma(2),2}, \ldots, T_{\sigma(y),2}]$, where σ represents the sorted permutation. Property 1 of Lemma 2.1 implies

$$[T_{11}, T_{21}, \ldots, T_{y1}] < [T_{\sigma(1),2}, T_{\sigma(2),2}, \ldots, T_{\sigma(y),2}].$$

Since packet 1 has left its first edge by time T_{11} and an unused token for the second edge appears by $T_{\sigma(1),2}$, packet 1 is able to advance its second edge by $T_{\sigma(1),2}$. Since packet 1 has left by $T_{\sigma(1),2}$, packet 2 is able to obtain an unused token by $T_{\sigma(2),2}$ and advance its second edge. Similar reasoning applies to packets 3 through y for the second edge. Inductively, packets 1 through y are able to advance their last edge by $perm(T_{1d_i}, T_{2d_i}, \ldots, T_{yd_i})$. This quantity is bounded by $[T_{11}+X, T_{21}+X, \ldots, T_{y1}+X]$ by property 2 of Lemma 2.1. Hence, all the session-i packets reach their destination within X steps after they obtain the initial tokens.

Let us bound the queue size now. Consider the jth edge, where $1 \leq j \leq d_i$. Suppose packet k, for $1 \leq k \leq y$, uses token $\mathcal{K}_{kj}$ to cross its jth edge at time t_{kj}. Let $\mathcal{K}_{k,j+1}$ be the $(j+1)$st token on the same token sequence as $\mathcal{K}_{kj}$, and let $t_{k,j+1}$ be the time that $\mathcal{K}_{k,j+1}$ appears. (Note that $\mathcal{K}_{kj}$ is not necessarily on the same token sequence as the initial token that packet k used to cross its first edge, and that $\mathcal{K}_{k,j+1}$ is not necessarily the token that packet k would use to cross the $(j+1)$st edge.) Since $t_{kj} < t_{k,j+1}$, property 1 of Lemma 2.1 and our argument for the delay bound above imply that packets 1 through y are able to cross the $(j+1)$st edge by $perm(t_{1,j+1}, t_{2,j+1}, \ldots, t_{y,j+1})$. Property 3 of Lemma 2.1 shows that $|perm(t_{1,j+1}, t_{2,j+1}, \ldots, t_{y,j+1}) - [t_{1j}, t_{2j}, \ldots, t_{yj}]|$ is bounded by x, the token lag. Hence, a packet waits at most x steps to advance each edge once it obtains an initial token. □

2.2. Lemmas for probabilistic analysis. Throughout the construction of our schedules, we use the Lovász local lemma [17, pp. 57–58] and a Chernoff bound [5] for probabilistic analysis. We include them here for easy reference.

Lovász local lemma. *Let $E_1, \ldots, E_n$ be a set of "bad events," each occurring with probability at most p and with dependence at most d (i.e., every bad event is*

mutually independent of some set of $n-d$ other bad events). If $4pd < 1$, then

$$\Pr\left[\bigcap_{i=1}^{n} \bar{E}_i\right] > 0.$$

In other words, no bad event occurs with a nonzero probability.

Chernoff bound. *Let X_i be n independent Bernoulli random variables with probability of success p_i. Let $X = \sum_{i=1}^{n} X_i$, and let the expectation $\mu = \sum_{i=1}^{n} p_i$. Then for $0 < \delta < 1$, we have*

$$\Pr[\ X > (1+\delta)\mu\ ] \le e^{-\delta^2\mu/3}.$$

We also prove a variation of the Chernoff bound.

LEMMA 2.3. *Let X_i be n independent Bernoulli random variables with probability of success p_i. Let $X = \sum_i^n X_i$ and the expectation $E[X] = \sum_i^n p_i$. Then for $u \ge E[X]$ and $0 < \delta < 1$, we have*

$$\Pr[\ X > (1+\delta)u\ ] \le e^{-\delta^2 u/3}.$$

Proof. We prove the lemma by amplifying the success probabilities. If $u \ge n$, then $\Pr[\ X \ge (1+\delta)u\ ] = 0$ and we are done. Otherwise, let p_i' be a value such that $p_i \le p_i' \le 1$ and $\sum_i^n p_i' = u$. We have

$$\begin{aligned}&\Pr[\ X > (1+\delta)u \mid \text{success probabilities } p_1, \ldots, p_n\ ]\\ &\le \Pr[\ X > (1+\delta)u \mid \text{success probabilities } p_1', \ldots, p_n'\ ].\end{aligned}$$

The Chernoff bound implies that the above probability is bounded by $e^{-\delta^2 u/3}$. ∎

3. Suboptimal schedules. We present in this section a simple randomized distributed scheduler that, with high probability, produces a delay bound of

$$O\left(\frac{1}{r_i} + d_i \log \frac{m}{r_{\min}}\right)$$

and edge queues of size $O(\log \frac{m}{r_{\min}})$, where m is the number of edges and $r_{\min} = \min_i r_i$. This preliminary result is substantially simpler to prove than the optimal result of $O(1/r_i + d_i)$ because of the relaxed bounds. Nevertheless, it illustrates the basic ideas necessary to prove the main result. We begin with a *centralized* scheme in section 3.1 that achieves these bounds, and then we convert it to a *distributed* scheme in section 3.2.

3.1. A simple centralized scheduler. As stated above, we now present a centralized scheduler that achieves the desired delay bound of $O(\frac{1}{r_i} + d_i \log \frac{m}{r_{\min}})$ with edge queues of size $O(\log \frac{m}{r_{\min}})$.

The structure of the proof is as follows. Each session-i packet must traverse d_i edges. We prove that the time the packet spends waiting for a token at each edge along the path (after the first edge) is $O(\log \frac{m}{r_{\min}})$. Hence the time to traverse all edges (but the first) is $O(d_i \log \frac{m}{r_{\min}})$. It turns out that the time spent waiting to receive the very first token (what we refer to as *initial* waiting time) is $O(\frac{1}{r_i} + d_i \log \frac{m}{r_{\min}})$. Hence the result follows.

The difficulty is to come up with a placement of tokens that achieves the above bounds. To do this, we will first come up with an *illegal* placement of tokens, where we place more than one token in some slots and zero tokens in other slots. We will prove delay bounds on the illegal placement. We will then apply a *smoothing* procedure which "smooths" out the bumps in the illegal placement, making it legal. We will prove that the smoothing process does not change the bounds very much.

Template size. We first decide the template size $\mathcal{T}$. Roughly speaking, $\mathcal{T}$ needs to be sufficiently large so that enough tokens can be placed to accommodate arrivals from all sessions every $\mathcal{T}$ steps. We express the injection rate for session i in terms of $\hat{r}_i = s_i/\ell_i$, a fraction slightly larger than r_i. If $\mathcal{T}$ is the least common multiple of ℓ_i for all i, then we can place s_i session-i tokens every ℓ_i consecutive slots on each template along the path of session i. The quantities of ℓ_i and s_i are defined as follows:

$$\ell_i = 2^{\lceil \log \frac{2}{\varepsilon r_i} \rceil}, \tag{3.1}$$

$$s_i = \lfloor \ell_i r_i (1 + \varepsilon/2) \rfloor, \tag{3.2}$$

$$\hat{r}_i = s_i/\ell_i, \tag{3.3}$$

where ε is a constant to ensure that the sum of the rates of the sessions using any edge is less than 1. In other words, ℓ_i is the smallest power of 2 that is larger than or equal to $2/(\varepsilon r_i)$, and s_i is the largest integer that is less than or equal to $\ell_i r_i(1+\varepsilon/2)$. The template size $\mathcal{T}$ is the least common multiple of ℓ_i. Since all the ℓ_i's are powers of 2, $\mathcal{T} = O(1/r_{\min})$.

LEMMA 3.1. *We have the following properties for $\hat{r}_i$.*

1. *$r_i \le \hat{r}_i \le r_i(1+\varepsilon/2)$ for each session i.*
2. *$\sum_{i \in S_e} \hat{r}_i \le 1 - \varepsilon/2$ for each edge e, where S_e is the set of sessions that cross edge e.*

Proof. Property 1 is equivalent to

$$\ell_i r_i \le s_i \le \ell_i r_i (1 + \varepsilon/2).$$

The difference between the lower bound and the upper bound is $\ell_i r_i \varepsilon/2$, which is at least 1 by the definition of ℓ_i. Therefore, there exists an integer in the range of $[\ell_i r_i, \ell_i r_i(1+\varepsilon/2)]$, and s_i is such an integer by definition. Property 1 follows.

Given $\sum_{i \in S_e} r_i \le 1 - \varepsilon$, we have $\sum_{i \in S_e} \hat{r}_i \le (1-\varepsilon)(1+\varepsilon/2) < 1 - \varepsilon/2$. Property 2 follows. ∎

We now define the template size $\mathcal{T}$ to be $\max_i \ell_i$, which is $\Theta(\frac{1}{r_{\min}})$. Since all the ℓ_i's are powers of 2, $\mathcal{T}$ is also the least common multiple of the ℓ_i's.

Token placement. We describe a procedure to place the tokens for all sessions. We start with an *illegal placement* of tokens. For each session i, we first place s_i *initial tokens* in one slot every ℓ_i slots on the template that corresponds to the first edge of session i. We then delay each initial token of session i by an amount chosen uniformly and independently at random from $[L+1, L+\ell_i]$, where

$$L = 2^{\lceil \log\left(\frac{\alpha}{2} \log(m\mathcal{T})\right) \rceil} \tag{3.4}$$

for a constant α. In other words, L is a power of 2 that is greater than or equal to $\frac{\alpha}{2}\log(m\mathcal{T})$. As we shall see, this is enough randomness to spread out the tokens. For every session-i token a placed on the template corresponding to the jth edge, we place a session-i token b on the template corresponding to the $(j+1)$st edge such that b appears exactly $2L$ steps after a. In this way, we have partitioned all the session-i tokens into $\mathcal{T}\hat{r}_i$ sequences, where each token sequence has d_i tokens and two neighboring tokens in each sequence are $2L$ apart. In the following we show that the tokens cannot be too clustered.

LEMMA 3.2. *At most L tokens appear in any consecutive L slots on any template with probability at least $1 - 1/(m\mathcal{T})$, where L is defined in* (3.4) *for a sufficiently large constant α.*

Proof. Since s_i initial tokens for session i are placed in one slot every ℓ_i slots and each is delayed by an amount chosen independently and uniformly at random from $[L+1, L+\ell_i]$, the expected number of session-i tokens in a single slot is s_i/ℓ_i, which is $\hat{r}_i$. Hence by linearity of expectations and property 2 of Lemma 3.1, the expected number of tokens over all sessions in L consecutive slots is $\sum_i \hat{r}_i L \le (1-\varepsilon/2)L$. For a particular interval of L consecutive slots on a particular template, let the random variable X be the number of tokens in these slots. Whether or not a token lands in these L slots is a Bernoulli event. Since the delays to the initial tokens are chosen independently and all session paths are simple, these Bernoulli events are independent. Since $E[X] \le (1-\varepsilon/2)L$, we have the following by Lemma 2.3.

$$\Pr[\ X > L\ ] \le \Pr[\ X > (1+\varepsilon/2)(1-\varepsilon/2)L\ ] \le e^{-\varepsilon^2(1-\varepsilon/2)L/12}.$$

In m templates there are at most $m\mathcal{T}$ intervals of L consecutive slots. Therefore, by a union bound the probability that more than L tokens appear in *any* L consecutive slots is bounded by

$$m\mathcal{T} \Pr[\ X > L\ ] \le m\mathcal{T} e^{-\varepsilon^2(1-\varepsilon/2)L/12} = m\mathcal{T} e^{-\varepsilon^2(1-\varepsilon/2)\alpha \log(m\mathcal{T})/24}.$$

By choosing a sufficiently large constant α, we can bound the above probability by $1/(m\mathcal{T})$. □

If the first pass of the delay insertion does not produce a token assignment that satisfies the condition of at most L tokens every L slots, we simply try another pass until the condition is met.

Smoothing. In order to guarantee one token per slot, we carry out a *smoothing process*. Since there are at most L tokens in any consecutive L slots, we partition each template into intervals of L consecutive slots and arbitrarily place at most one token in each slot within each interval. (Note the template size $\mathcal{T}$ is a multiple of L since $\mathcal{T}$ and L are both powers of 2.) Recall we have defined a token sequence for each session in the token placement process.

LEMMA 3.3. *Let $\mathcal{K}_1, \ldots, \mathcal{K}_{d_i}$ be any token sequence for session i; then, after the smoothing process, we have the following.*

1. *Token $\mathcal{K}_j$ appears after $\mathcal{K}_{j-1}$ for $1 < j \le d_i$.*
2. *The end-to-end delay of the token sequence is bounded by $2d_iL + 2L$, and the token lag is bounded by $4L$.*

Proof. Before the smoothing, $\mathcal{K}_j$ appears exactly $2L$ steps after $\mathcal{K}_{j-1}$ for $1 < j \le d_i$, i.e., the token lag is $2L$. Since the smoothing process shifts each token by at most $L-1$ slots, $\mathcal{K}_j$ still appears after $\mathcal{K}_{j-1}$ after the smoothing. The token lag therefore increases to at most $4L$. The end-to-end delay for the token sequence increases from $2d_iL$ to at most $2d_iL + 2L$ due to the shift of the first and the last tokens. □

THEOREM 3.4. *With high probability, the above randomized centralized scheme generates a template-based schedule that produces a delay bound of $O(\frac{1}{r_i} + d_i \log \frac{m}{r_{\min}})$ and edge queues of size $O(\log \frac{m}{r_{\min}})$.*

Proof. We first show that each session-i packet, p, is able to catch an initial token within $2L + 2\ell_i$ steps of its injection. Before the initial session-i tokens are delayed, we have exactly s_i tokens every ℓ_i slots. Since at most s_i session-i packets can be injected during ℓ_i steps, packet p would be able to obtain an initial token, say $\mathcal{K}$, in fewer than ℓ_i steps if the tokens were not delayed or shifted. Let p be injected at time t, and let $\mathcal{K}$ appear at T before $\mathcal{K}$ is delayed and shifted; then $t \le T < t + \ell_i$. Each initial token is delayed by an amount in the range of $[L+1, L+\ell_i]$ during the token

placement process and is shifted by at most $L-1$ slots during the smoothing process. Therefore, after the smoothing process, $\mathcal{K}$ appears after t but before $t+2L+2\ell_i$.

By Theorem 2.2 and Lemma 3.3, any session-i packet p is able to reach its destination within $2d_iL+2L$ steps after it obtains its initial token. Therefore, the end-to-end delay for session-i packets is $(2L+2\ell_i)+(2d_iL+2L)$, which is $O(\frac{1}{r_i}+d_i\log\frac{m}{r_{\min}})$. The edge queue size is bounded by the token lag $4L$, which is $O(\log\frac{m}{r_{\min}})$. □

3.2. A simple distributed scheduler. The above scheme is centralized since the session-i tokens on one template are dependent on the previous template. However, it suggests the following simple *distributed* scheme for scheduling packets so as to achieve small delay. As in section 3.1, we place initial tokens on the first edge of session i; however, this time we delay each initial token by an amount chosen independently and uniformly at random from $[1,\ell_i]$, where ℓ_i is defined in (3.1). (Note that the delay is from $[L+1,L+\ell_i]$ in the centralized scheme.) Suppose that a session-i packet p now obtains its initial token at time T. Then for the jth edge on the session-i path, p is given a deadline of $T+2L(j-1)+L$, where L is defined in (3.4). Whenever two or more packets contend for the same edge simultaneously, the packet with the earliest deadline moves. Ties are broken arbitrarily. We call this scheme Earliest-Deadline-First (EDF). Note that EDF is no longer template based. We show in Lemma 3.5 that the deadlines do not cluster together with high probability, and we show in Lemma 3.6 that every packet meets its deadlines.

Lemma 3.5. *For any edge, at most L deadlines appear in any consecutive L time steps with probability at least $1-1/(m\mathcal{T})$, where L is defined in* (3.4) *for a sufficiently large constant α.*

Proof. The deadlines for a packet p are $T+L$, $T+3L$, $T+5L$, ..., which correspond to the times that the tokens in a sequence appear. Hence, the proof is identical to that of Lemma 3.2. □

Lemma 3.6. *If for any edge at most L deadlines appear in any consecutive L time steps, then each packet crosses every edge by its deadline by* EDF.

Proof. For the purpose of contradiction, let D be the first deadline that is missed. This implies all deadlines earlier than D are met. Let p be the packet that misses deadline D for edge e. Since packet p makes its previous deadlines, p must have crossed its previous edge by time $D-2L$, or else e must be p's first edge and p must have obtained its initial token at time $D-L$. Hence, at every time step from time $D-L+1$ to D, packet p is held up by another packet with a deadline no later than D. Furthermore, these deadlines must be later than $D-L$ since all deadlines earlier than D are met. Therefore, at least $L+1$ packets have deadlines for edge e from time $D-L+1$ to D. Our lemma follows from the contradiction. □

By an argument similar to that in Theorem 3.4, a session-i packet obtains its initial token within $2\ell_i$ steps of its injection. Combined with Lemmas 3.5 and 3.6, we have the following theorem.

Theorem 3.7. *With high probability, the randomized distributed scheme* EDF *generates a schedule that produces an end-to-end delay bound of $O(\frac{1}{r_i}+d_i\log\frac{m}{r_{\min}})$.*

In [2], simulations were carried out to compare the end-to-end delays produced by our EDF scheme against those produced by WFQ. The former outperformed the latter in a range of simulations.

4. Overview of the main result. Our main result for the dynamic routing problem parallels an earlier result on static routing. In section 4.1 we review the method used for solving the static case, and in section 4.2 we give an overview of the additional complexities that need to be addressed in the dynamic case.

TABLE 4.1
Frame-refinement for static routing in [10].

Schedule	Frame size	Relative congestion
$\mathcal{S}^{(q)}$	$I^{(q)}$	$c^{(q)}$
Refinement	$\log^5 I^{(q)}$	$(1+o(1))c^{(q)}$
$\mathcal{S}^{(q+1)}$	$I^{(q+1)}$	$c^{(q+1)}$

4.1. A bound of $O(c+d)$ for static routing. Leighton, Maggs, and Rao consider the static routing problem for arbitrary networks in [10]. For static routing, all packets are present in the network initially. Each packet is associated with a source, a destination, and a route. The *congestion* on each edge is the total number of routes that require that edge, and the *dilation* of a route is the number of edges on the route. Leighton, Maggs, and Rao show that for any set of routes with maximum congestion c (over all edges) and maximum dilation d (over all routes), there is a schedule of length $O(c+d)$ and edge queue size $O(1)$. In this schedule, at most one packet traverses each edge at each time step. A packet waits $O(c+d)$ steps initially before leaving its source, and it waits $O(1)$ steps to cross each edge thereafter.

We summarize here the techniques in [10]. The strategy for constructing an efficient schedule is to make a succession of *refinements* to an initial schedule $\mathcal{S}^{(0)}$. In $\mathcal{S}^{(0)}$, each packet moves at every step until it reaches its destination. This schedule has length d, but as many as c packets may traverse the same edge at the same step. Each refinement brings the schedule closer and closer to the requirement that at most one packet uses one edge per time step.

A *T-frame* is a time interval of length T. The *frame congestion*, C, in a T-frame is the largest number of packets that use any edge during the frame. The *relative congestion* in a T-frame is the ratio C/T. The frame congestion (resp., relative congestion) on an edge e during a T-frame is defined to be the frame congestion (resp., relative congestion) associated with edge e.

It is obvious that the initial schedule $\mathcal{S}^{(0)}$ has relative congestion at most 1 for any c-frame. A *refinement* transforms a schedule $\mathcal{S}^{(q)}$ with relative congestion at most $c^{(q)}$ in any frame of size $I^{(q)}$ or larger into a schedule $\mathcal{S}^{(q+1)}$ with relative congestion at most $c^{(q+1)}$ in any frame of size $I^{(q+1)}$ or larger. The resulting frame size $I^{(q+1)}$ is much smaller than $I^{(q)}$, whereas the relative congestion $c^{(q+1)}$ is only slightly bigger than $c^{(q)}$. In particular, $I^{(q+1)} = \log^5 I^{(q)}$ and $c^{(q+1)} = (1+o(1))c^{(q)}$. After a series of $O(\log^* c)$ refinements, a schedule $\mathcal{S}^{(\zeta)}$ is obtained, where the relative congestion is $O(1)$ for any $O(1)$-frame. A final schedule, in which at most one packet at a time crosses each edge, can be constructed by replacing each step of $\mathcal{S}^{(\zeta)}$ by a constant number of steps. Each refinement is achieved by inserting delays to the packets. It is the central issue in [10] to show that a set of delays always exists satisfying the criteria in Table 4.1.

4.2. A bound of $O(1/r_i + d_i)$ for dynamic routing. Our result for the dynamic routing problem is parallel to that in [10]. For an arbitrary network where paths (sessions) are defined, we show that there is a schedule such that every session-i packet reaches its destination within $O(1/r_i + d_i)$ steps of its injection, where r_i and d_i are the injection rate and path length for session i, respectively. A session-i packet waits $O(1/r_i + d_i)$ steps initially before leaving its source, and it waits $O(1)$ steps to cross each edge afterwards.

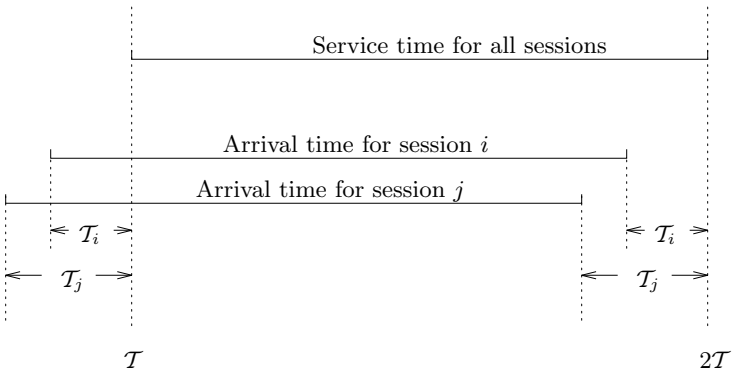

FIG. 4.1. *All the session-i packets that arrive during* $[k\mathcal{T}-\mathcal{T}_i,(k+1)\mathcal{T}-\mathcal{T}_i)$ *are serviced during* $[k\mathcal{T},(k+1)\mathcal{T})$. *In this figure,* $k=1$.

To achieve a session-based, end-to-end delay bound of $O(1/r_i+d_i)$ for our dynamic routing problem, we adopt the general approach in [10]. However, there are three major problems in transforming the solution for the static problem into a solution for the dynamic problem. In the remainder of this section we present these three problems and their solutions.

In the remainder of the paper we use the language of "scheduling packets" rather than "placing tokens." At the end of the presentation we show how to transform the packet schedule into a template-based schedule. Although the actual packet arrivals are not be periodic, the times at which the packets cross the first edge *are* periodic. This is the key to the transformation.

Problem 1: Infinite time. In [10] all the packets to be scheduled are present initially. In the dynamic model, packets are injected over an infinite time line. We would like to partition the infinite time line into finite time intervals which can be scheduled independently of each other. We divide time into intervals of length $\mathcal{T}$, where $\mathcal{T}=\Theta(1/r_{\min}+d_{\max})$. We then independently schedule the time intervals $[0,\mathcal{T})$, $[\mathcal{T},2\mathcal{T})$, $[2\mathcal{T},3\mathcal{T})$, etc.

We associate each session i with a quantity $\mathcal{T}_i=\Theta(1/r_i+d_i)$. For any integer $k\geq 0$ consider all the session-i packets that are injected during interval $[k\mathcal{T}-\mathcal{T}_i,(k+1)\mathcal{T}-\mathcal{T}_i)$. We provide a schedule in which all these packets leave their sources no earlier than time $k\mathcal{T}$ and reach their destinations before time $(k+1)\mathcal{T}$. (See Figure 4.1.) From now on, we concentrate on scheduling the arrivals that would be serviced during interval $[\mathcal{T},2\mathcal{T})$.

The quantity $\mathcal{T}$ will also serve as the size of all templates in the template-based schedule.

Problem 2: Session-based delay guarantees. Once we restrict ourselves to the interval $[\mathcal{T},2\mathcal{T})$, it seems that the dynamic routing problem is similar to the static problem. However, we cannot simply proceed with the successive refinements as in section 4.1, since some sessions need tighter delay bounds than others. Session-i packets can only tolerate a delay proportional to $1/r_i+d_i$. We group sessions according to their associated $1/r_i+d_i$ value. We start by inserting delays to sessions having large values of $1/r_i+d_i$, reducing the frame size, and bounding the relative congestion. When the frame size becomes small enough, sessions with smaller $1/r_i+d_i$ join in.

TABLE 4.2
Refinement and conversion for dynamic routing.

Schedule	Integral sessions	Frame size	Relative congestion
$\mathcal{S}^{(q)}$	$A^{(q)}$	$I^{(q)}$	$c^{(q)}$
Refinement	$A^{(q)}$	$\log^5 I^{(q)}$	$(1+o(1))c^{(q)}$
Conversion	$A^{(q)} \cup B^{(q+1)}$	$\log^5 I^{(q)}$	$(1+o(1))^2 c^{(q)}$
$\mathcal{S}^{(q+1)}$	$A^{(q+1)}$	$I^{(q+1)}$	$c^{(q+1)}$

More precisely, we introduce the concept of *integral* and *fractional* sessions. When session i is *integral*, packets of size 1 are injected at rate r_i. When session i is *fractional*, a packet of size $\hat{r}_i$ is injected at every time step, where $\hat{r}_i$ is a value slightly larger than r_i. A packet from a fractional session always crosses one edge at a time, whether or not other packets are crossing the edge at the same time. Therefore, a fractional packet from session i always contributes exactly $\hat{r}_i$ to the congestion. Integral sessions are those to which we can afford to insert delays in order to bound the congestion. Fractional sessions are those to which we cannot insert delays. However, congestion due to a fractional session i is only $\hat{r}_i$, which is small.

As before, $\mathcal{S}^{(q)}$ represents the schedule in the qth iteration. The set of integral sessions for $\mathcal{S}^{(q)}$ is denoted by $A^{(q)}$. For the initial schedule $\mathcal{S}^{(0)}$, all the sessions are fractional and we show that the relative congestion is less than 1. For schedule $\mathcal{S}^{(q)}$ we inductively assume that the relative congestion due to the current integral and fractional sessions is at most $c^{(q)}$ for any frame of size $I^{(q)}$ or larger. To create a schedule $\mathcal{S}^{(q+1)}$ from schedule $\mathcal{S}^{(q)}$ we carry out a frame-refinement step and a conversion step.

The frame-refinement step reduces the frame size from $I^{(q)}$ to $I^{(q+1)} = \log^5 I^{(q)}$, while slightly increasing the relative congestion from $c^{(q)}$ to $(1+o(1))c^{(q)}$. This step is achieved by delaying the integral packets by up to $\Theta\left((I^{(q)})^2\right)$ steps. We make sure that if session i is in $A^{(q)}$, then $1/r_i + d_i \geq (I^{(q)})^2$, and therefore the delays inserted can be tolerated. The conversion step converts some sessions from fractional to integral, while maintaining the frame size of $I^{(q+1)}$ and slightly increasing the relative congestion to $c^{(q+1)} = (1+o(1))^2 c^{(q)}$. These newly-converted sessions form a set $B^{(q+1)}$ and have associated values $1/r_i + d_i \geq (I^{(q+1)})^2$. This bound is chosen so that the sessions in $A^{(q+1)}$, which is $A^{(q)} \cup B^{(q+1)}$, will be able to tolerate the delays inserted during the next iteration of frame refinement. During the conversion step we delay the packets in $B^{(q+1)}$ by up to $\Theta(1/r_i + d_i)$ steps. We are able to show the existence of "good" delays for both frame refinement and conversion steps. Table 4.2 summarizes our approach.

At the termination of our algorithm we have a schedule $\mathcal{S}^{(\zeta)}$ in which every session is integral and the relative congestion is at most 1 for all frames of size larger than a certain constant. In $\mathcal{S}^{(\zeta)}$ all session-i arrivals during $[\mathcal{T} - \mathcal{T}_i, 2\mathcal{T} - \mathcal{T}_i)$ are serviced during $[\mathcal{T}, 2\mathcal{T})$. Furthermore, all session-i packets reach their destination within $O(\mathcal{T}_i)$ steps of their injections.

Problem 3: Constant-factor stretching in the final schedule. As discussed above, we repeat the process of refinement and conversion until we have a schedule, $\mathcal{S}^{(\zeta)}$, in which all sessions are integral and in which the relative congestion is 1 for all frames of size larger than a certain constant w. In the static problem, a final schedule can easily be obtained by stretching $\mathcal{S}^{(\zeta)}$ by a constant factor. However, we cannot

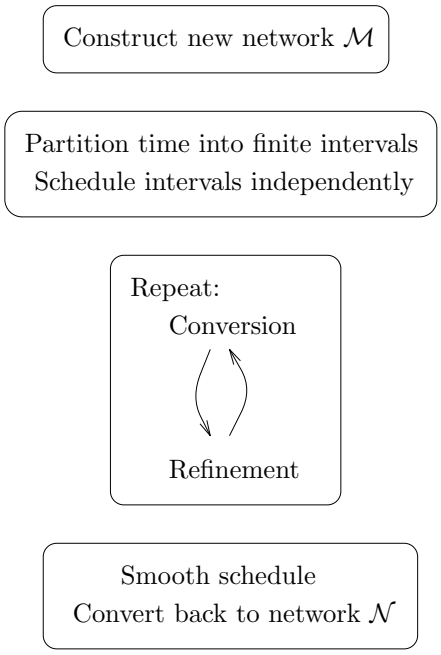

FIG. 4.2. *An overview of our approach for the dynamic routing problem.*

afford to have a constant blowup in our final schedule for the dynamic problem. This is because we need to independently schedule all time intervals $[0, \mathcal{T})$, $[\mathcal{T}, 2\mathcal{T})$, etc., and a constant blowup would make these time intervals overlap.

To overcome this problem, we first devise a schedule for a new network $\mathcal{M}$ that is constructed from the original network $\mathcal{N}$ as follows. Each edge e of $\mathcal{N}$ is replaced by $2w$ consecutive edges $e_1, \ldots, e_{2w}$, where w is the constant introduced above. The rates and routes of the sessions are unaffected. In $\mathcal{M}$, session i has length $D_i = 2wd_i = O(d_i)$.

All the techniques described earlier are applied to the network $\mathcal{M}$. We carry out successive conversion and refinement steps for $\mathcal{M}$ and obtain a schedule $\mathcal{S}^{(\zeta)}$, where the relative congestion is 1 for any frame whose size is larger than w. We then "smooth" $\mathcal{S}^{(\zeta)}$ and convert it to a schedule for $\mathcal{N}$ where only one packet at a time traverses any edge.

The idea behind the smoothing process is as follows. In $\mathcal{S}^{(\zeta)}$, more than one packet may require some edge of $\mathcal{M}$ during a given time step, but at most w packets can require any given edge f in $\mathcal{M}$ within w time steps. This means we can shuffle each packet that requires edge f by at most w time steps, so that exactly one packet traverses f at any step. Unfortunately, this shuffling in time can lead to an illegal schedule for $\mathcal{M}$, in which a packet can be scheduled to traverse the edges on its path out of order (timewise). However, one can prove that if we consider the schedule with respect to the packets traversing edge e_{2w} for all e, then this schedule *is* legal, i.e., the packets cross *these* edges in order. Hence, we schedule edge e in $\mathcal{N}$ in exactly the same way that the corresponding edge e_{2w} is scheduled in $\mathcal{M}$.

Figure 4.2 is a schematic picture of our overall approach.

5. Parameter definitions.

Interval length $\mathcal{T}$ and $\mathcal{T}_i$. As discussed in section 4.2, we independently schedule intervals $[0, \mathcal{T})$, $[\mathcal{T}, 2\mathcal{T})$, etc. Our proof will concentrate on the interval $[\mathcal{T}, 2\mathcal{T})$. All the session-$i$ packets that arrive during $[\mathcal{T} - \mathcal{T}_i, 2\mathcal{T} - \mathcal{T}_i)$ are serviced during $[\mathcal{T}, 2\mathcal{T})$. We define $\mathcal{T}$ and $\mathcal{T}_i$ for session i as follows. Recall $D_i = 2wd_i$, where w is a constant defined at the end of this section.

$$\mathcal{T}_i = 4D_i + 2 + (8/\varepsilon + 2)/r_i,$$
$$\mathcal{T} = \left\lceil \frac{(1 + 4/\varepsilon) \max_i \mathcal{T}_i}{w} \right\rceil w.$$

In other words, $\mathcal{T}$ is the smallest multiple of w that is greater than or equal to $(1 + 4/\varepsilon) \max_i \mathcal{T}_i$. Clearly $\mathcal{T}_i = O(1/r_i + D_i) = O(1/r_i + d_i)$.

In the template-based schedule, all template sizes will be $\mathcal{T}$.

Packet size for a fractional session. In this section we define $\hat{r}_i$, the packet size for a fractional session i. For reasons that will become clear in the conversion step of section 6.3, we need $\hat{r}_i$, to be slightly larger than r_i, and we shall need to express $\hat{r}_i$ as the ratio of two integers. Let

$$\ell_i = \lceil 8/(\varepsilon r_i) \rceil,$$
$$s_i = \lfloor \ell_i r_i (1 + \varepsilon/2) \rfloor,$$
$$\hat{r}_i = s_i/\ell_i.$$

The following lemma is analogous to Lemma 3.1.

LEMMA 5.1. *We have the following properties for $\hat{r}_i$.*

1. *$r_i(1 + \varepsilon/4) \le \hat{r}_i \le r_i(1 + \varepsilon/2)$ for each session i.*
2. *$\sum_{i \in S_e} \hat{r}_i \le 1 - \varepsilon/2$ for each edge e, where S_e is the set of sessions that cross edge e.*

Note that the definition of ℓ_i and property 1 of Lemma 5.1 are different from the ones in section 3.1. We need this stronger lower bound on $\hat{r}_i$ to handle the extra complexity in the conversion step. In particular, $\hat{r}_i$ is also used to indicate the rate at which the initial tokens for session i appear. During the conversion step, the initial tokens for session i are placed in the interval $[\mathcal{T}, 2\mathcal{T} - \mathcal{T}_i)$. Since these tokens are to accommodate all the session-i arrivals during $[\mathcal{T}, 2\mathcal{T})$, we need $\hat{r}_i(\mathcal{T} - \mathcal{T}_i) \ge r_i\mathcal{T}$. This condition is guaranteed by the choices of $\mathcal{T}$ and $\mathcal{T}_i$ and property 1 of Lemma 5.1. (See Lemma 6.8.)

Parameters for schedule $\mathcal{S}^{(q)}$. We shall show later that, in schedule $\mathcal{S}^{(q)}$, the relative congestion, due to all integral and fractional sessions, is at most $c^{(q)}$ for any frame of size $I^{(q)}$ or larger. For $\mathcal{S}^{(q)}$, the set $A^{(q)}$ consists of all the integral sessions. As we construct schedule $\mathcal{S}^{(q+1)}$ from $\mathcal{S}^{(q)}$, sessions in $B^{(q+1)}$ become integral and join $A^{(q)}$. The schedule at the end of the refinement and the conversion is $\mathcal{S}^{(\zeta)}$. The parameters $I^{(q)}$, $c^{(q)}$, $A^{(q)}$, and $B^{(q+1)}$ are defined by the following recurrences. Let $X_i = D_i + 1/r_i$ for session i, and let $X_{\max} = \max_i X_i$.

$$I^{(0)} = e^{\log^{2/5} X_{\max}},$$
$$I^{(q+1)} = \log^5 I^{(q)},$$
$$c^{(0)} = 1 - \varepsilon/2,$$
$$c^{(q+1)} = (1 + \delta^{(q)})^2 c^{(q)},$$
$$\delta^{(q)} = \beta/\sqrt{\log I^{(q)}},$$

$$
\begin{aligned}
A^{(0)} &= \emptyset, \\
A^{(q+1)} &= A^{(q)} \cup B^{(q+1)}, \\
B^{(q+1)} &= \left\{ i \notin A^{(q)} : \left(I^{(q+1)}\right)^2 \le X_i \le e^{\sqrt{I^{(q+1)}}} \right\} \qquad \text{for } q \neq \zeta - 1, \\
B^{(q+1)} &= \left\{ i \notin A^{(q)} : X_i \le e^{\sqrt{I^{(q+1)}}} \right\} \qquad \text{for } q = \zeta - 1.
\end{aligned}
$$

The parameter β is a sufficiently large positive constant. Note that $I^{(q)}$ decreases polylogarithmically and $c^{(q)}$ increases by a factor of $1+o(1)$. One can verify that $B^{(q)}$ forms a partition of all the sessions and that sessions with large X_i values become integral first. We make use of the bound $X_i \ge \left(I^{(q+1)}\right)^2$ in the frame refinement step, and we use the bound $\log^2 X_i \le I^{(q+1)}$ in the conversion step.

Definition of w. We define a constant w that has two purposes. First, the process of refinement and conversion terminates when the frame size becomes smaller than or equal to w. Second, the intermediate network $\mathcal{M}$ is constructed from the original network $\mathcal{N}$ by replacing each edge in $\mathcal{N}$ with $2w$ edges. We define w to be a constant that satisfies the following two bounds:

1. $w \ge x$, where x satisfies $(1 - \frac{\alpha}{\sqrt{\log x}})^2 = 1 - \varepsilon/2$, i.e., $x = e^{\alpha^2(1-\sqrt{1-\varepsilon/2})^{-2}}$,
2. $w \ge 2\log^{15} w + 2\log^{10} w - \log^5 w$.

The first bound ensures that the relative congestion $c^{(\zeta)}$ is at most 1. (See Lemma 6.11.) The second bound is to maintain an invariant throughout the frame refinement steps. (See section 6.2.)

6. An asymptotically optimal schedule. In this section we show the existence of an asymptotically optimal schedule. Sections 6.1 through 6.4 concentrate on problem 2 of section 4.2. We begin with an initial schedule $\mathcal{S}^{(0)}$ and transform it to schedule $\mathcal{S}^{(\zeta)}$ through a process of refinement and conversion. All these schedules are designed for the intermediate network $\mathcal{M}$. Section 6.5 concentrates on problem 3 of section 4.2. We describe how to obtain an optimal schedule $\mathcal{S}_{\mathcal{N}}$ for the original network $\mathcal{N}$ from $\mathcal{S}^{(\zeta)}$.

We first define or recall several basic concepts. Given some schedule $\mathcal{S}$, a *region* R of the schedule is some interval of contiguous time steps in the schedule. A *T-frame* is a region of length T. The *congestion* C in a T-frame is the maximum number of packets that cross any edge in that interval, and the *relative congestion* is the ratio C/T. A fractional packet from session i always contributes exactly $\hat{r}_i$ to the relative congestion of any frame.

6.1. An initial schedule $\mathcal{S}^{(0)}$. In $\mathcal{S}^{(0)}$, all sessions are fractional, i.e., $A^{(0)} = \emptyset$. Each packet (of a fractional size) crosses one edge per time step whether or not other packets are using the same edge at the same time. Since the relative congestion is entirely due to fractional sessions, the relative congestion is at most $\sum \hat{r}_i < 1 - \varepsilon/2 = c^{(0)}$ on any edge e. (See Lemma 5.1.)

Note that the above relative congestion holds for any frame size. We choose the initial frame size $I^{(0)} = e^{\log^{2/5} X_{\max}}$, so that $I^{(1)} = \log^2 X_{\max}$, which implies $X_{\max} = e^{\sqrt{I^{(1)}}}$. This allows the sessions with the largest X_i value to be converted in the first iteration of the algorithm (see definition of $B^{(1)}$).

6.2. Frame refinement for schedule $\mathcal{S}^{(q)}$. In this section we describe the frame-refinement process. For each schedule, a frame refinement delays the packets

from integral sessions in a way that dramatically reduces the frame size but does not increase the relative congestion and the length of the schedule by much.

To be more precise, for schedule $\mathcal{S}^{(q)}$, we inductively assume that the relative congestion is at most $c^{(q)}$ for frames of size $I^{(q)}$ or larger and that each integral packet waits at most once every $I^{(q-1)}$ steps after leaving its source. In this frame refinement step we show that there is a way to delay (by an amount related to the frame size) the packets from $A^{(q)}$ so that, in the resulting schedule $\mathcal{S}^{(q+\frac{1}{2})}$, the relative congestion is at most $(1+\delta^{(q)})c^{(q)}$ for any frame of size $I^{(q+1)} = \log^5 I^{(q)}$ or larger, where $\delta^{(q)} = \beta/\sqrt{\log I^{(q)}}$, and each integral packet waits at most once every $I^{(q)}$ steps.

The base case of the initial schedule $\mathcal{S}^{(0)}$ is described in section 6.1. Since there are no integral sessions, no delays are inserted in this step. Trivially, the resulting relative congestion is at most $(1+\delta^{(0)})c^{(0)}$ for any frame of size $I^{(1)}$ or larger at the end of this step, and no packet ever waits.

Let us now consider refining schedule $\mathcal{S}^{(q)}$ for $q > 0$. The refinement is divided into two steps. In the first refinement step we divide the current schedule into blocks of length $2(I^{(q)})^3 + 2(I^{(q)})^2 - I^{(q)}$, and we insert delays into each block so that its length increases to $2(I^{(q)})^3 + 2(I^{(q)})^2$. We show that these delays can be introduced in such a way that in the central $2(I^{(q)})^3$ steps of each block the relative congestion of frames of at least length $I^{(q+1)}$ is only a little larger than $c^{(q)}$. (See Figure 6.1.) At the beginning and end of each block there are "fuzzy" regions of length $(I^{(q)})^2$ each. In the second step we move the block boundaries so that the fuzzy regions at the end and beginning of adjacent blocks are at the center of the new blocks of $2(I^{(q)})^3 + 2(I^{(q)})^2$ steps. Again, we insert delays into each block, increasing the size of the block by $(I^{(q)})^2$ steps. We show that there is a way to insert these delays so that the final conditions for refining $\mathcal{S}^{(q)}$ are indeed satisfied. (See Figure 6.2.)

In the following we present Lemma 6.2, which will be used extensively in both steps of the refinement. We continue by presenting both steps in detail.

A useful lemma. The following lemma is used to prove Lemma 6.2.

LEMMA 6.1. *Let X and Y be independent random variables. Let Y be binomially distributed with mean μ_y, and let σ_1, σ_2, and v be values such that $\sigma_2 = \sigma_1 - 1/v$. Then,*

$$\Pr[\, X + \mu_y > (1+\sigma_1)v \,] \le 2\Pr[\, X + Y > (1+\sigma_2)v \,].$$

Proof. Let $z = (1+\sigma_1)v - \mu_y$. We have

$$\Pr[\, X + \mu_y > (1+\sigma_1)v \,] = \Pr[\, X > z \,], \tag{6.1}$$

$$\Pr[\, X + Y > (1+\sigma_2)v \,] = \Pr[\, X + Y > \mu_y + z - 1 \,]. \tag{6.2}$$

Note also that

$$\begin{aligned}\Pr[\, X + Y > \mu_y + z - 1 \,] &\ge \Pr[\, X > \mu_y + z - 1 - \lfloor \mu_y \rfloor \text{ and } Y \ge \lfloor \mu_y \rfloor \,] \\ &= \Pr[\, X > z - 1 + \mu_y - \lfloor \mu_y \rfloor \,] \Pr[\, Y \ge \lfloor \mu_y \rfloor \,].\end{aligned}$$

This last equality follows from the independence of X and Y. Theorem B.1 in [12] shows that $\Pr[\, Y \ge \lfloor \mu_y \rfloor \,] \ge 1/2$. Since $\mu_y - \lfloor \mu_y \rfloor < 1$, we have

$$\Pr[\, X + Y > \mu_y + z - 1 \,] \ge \frac{1}{2}\Pr[\, X > z \,].$$

Our lemma follows from equalities (6.1) and (6.2) and the above inequality. ∎

We say that a packet is *active* during some region of a schedule if the packet belongs to some integral session and it traverses at least one edge during the region. Since we maintain the invariant that a packet waits at most once every $I^{(q-1)}$ steps after leaving its source, an *inactive* packet is either at its source or its destination during the entire region. Lemma 6.2 below is a stepping stone that allows us to reduce the frame size from $I^{(q)}$ to $poly \log I^{(q)}$. We invoke this lemma for various values of s, t, r, and R.

LEMMA 6.2. *Consider some region R of a schedule where the relative congestion is at most $r = \Theta(1)$ for frames of length s or more, where $\log^3 I^{(q)} \le s \le (I^{(q)})^2$. Consider any edge e and any t-frame, where $\log^2 I^{(q)} \le t \le 2\log^2 I^{(q)}$. Assume each active packet in the region is delayed between the beginning of R and the beginning of the t-frame by a number of steps randomly, independently, and uniformly chosen from $[1, s]$. Then, for any constant k there is some value $\gamma = \Theta(1)/\sqrt{\log I^{(q)}}$ such that the probability of having a relative congestion larger than $r(1+\gamma)$ on e during the t-frame is at most $(I^{(q)})^{-k}$.*

Proof. Let the random variable X be the frame congestion on e during the t-frame due to the active packets after they are delayed. If the relative congestion due to fractional sessions is r_f, the frame congestion due to fractional sessions in the t-frame is exactly $r_f t$. Since the active packets are the only integral-session packets that can cross e during the region, the frame congestion on e during the t-frame is $X + r_f t$ after the delay.

Consider now a binomial random variable Y with parameters $(r_f s, t/s)$ and mean $E[Y] = r_f t$. From Lemma 6.1, the probability p that the congestion in the t-frame is larger than $(1+\gamma)rt$ after the packets have been delayed is

$$p = \Pr[\, X + r_f t > (1+\gamma)rt \,] \le 2\Pr[\, X + Y > (1+\sigma)rt \,],$$

where $\sigma = \gamma - 1/rt$. Since $t \ge \log^2 I^{(q)}$ and $r = \Theta(1)$, $\gamma = \Theta(1)/\sqrt{\log I^{(q)}}$ if and only if $\sigma = \Theta(1)/\sqrt{\log I^{(q)}}$. Let $\sigma = v/\sqrt{\log I^{(q)}}$, where v is a constant. We shall choose an appropriate value v so that the lemma is satisfied.

We first concentrate on X. Since the active packets are delayed up to s steps, an active packet that crosses e in the t-frame after the delay could cross e in an interval of $t + s$ steps before the delay. The relative congestion due to active packets is at most $r - r_f$ in that interval before the delay. Hence, at most $(t+s)(r-r_f)$ active packets can cross e in the t-frame after the delay, and each of them has a probability of at most t/s of doing so.

Recall that Y is a binomial random variable with parameters $(r_f s, t/s)$. We define Z to be a binomial random variable with parameters $(n, t/s)$, where $n = r(t+s) > (r - r_f)(t+s) + r_f s$. It is easy to see that

$$p \le 2\Pr[\, X + Y > (1+\sigma)rt \,] \le 2\Pr[\, Z > (1+\sigma)rt \,].$$

Therefore, we bound the probability p as follows:

$$p \le 2 \sum_{i=(1+\sigma)rt}^{r(t+s)} \binom{r(t+s)}{i} (t/s)^i (1 - t/s)^{r(t+s)-i}.$$

We bound the sum by observing that $(1+\sigma)rt$ is larger than $E[Z] = (t+s)rt/s$, since $t/s \le 2/\log I^{(q)}$. Thus, the first term of the sum is the largest. Hence, from the fact

that there are at most $r(t+s)$ terms in the sum, we have

$$p \le 2r(s+t)\binom{r(t+s)}{(1+\sigma)rt}(t/s)^{(1+\sigma)rt}(1-t/s)^{r(t+s)-(1+\sigma)rt}.$$

By applying the inequality $\binom{a}{b} \le (ae/b)^b$ for $0 < b < a$, we get

$$p \le 2r(s+t)\left(\frac{(t+s)e}{(1+\sigma)t}\right)^{(1+\sigma)rt}(t/s)^{(1+\sigma)rt}(1-t/s)^{r(t+s)-(1+\sigma)rt}.$$

Now applying the inequality $\ln(1+x) \ge x - x^2/2$ for $0 \le x \le 1$, for the case $x = \sigma$,

$$p \le 2r(s+t)\left((1+t/s)e^{1-\sigma+\sigma^2/2}\right)^{(1+\sigma)rt}(1-t/s)^{r(t+s)-(1+\sigma)rt}.$$

Finally, by applying the inequality $(1+x) \le e^x$ for $1+x = 1+t/s$ in one case and for $1+x = 1-t/s$ in the other, we obtain

$$p \le 2r(t+s)e^{-rt\sigma^2(1/2-\sigma/2-t/\sigma^2 s-2t/\sigma s)}.$$

The bounds on s and t and the definitions of r and σ imply that we can choose a constant v large enough so that $p < (I^{(q)})^{-k}$ for any constant $k > 0$. □

The first refinement step for schedule $\mathcal{S}^{(q)}$. We first divide the interval $[\mathcal{T}, \mathcal{T}+|\mathcal{S}^{(q)}|)$ into blocks of length $2(I^{(q)})^3 + 2(I^{(q)})^2 - I^{(q)}$. We shall reschedule each block B independently. During a block B we only delay active packets.

For each block B, each active packet in B is assigned a delay randomly, uniformly, and independently chosen from $[1, I^{(q)}]$. An active packet p, whose assigned delay is x, is delayed in the first $xI^{(q)}$ steps of B once every $I^{(q)}$ steps. In order to independently reschedule the next block, packet p is also delayed in the last $(I^{(q)} - x)I^{(q)}$ steps of B once every $I^{(q)}$ steps. Therefore, a rescheduled block has length $2(I^{(q)})^3 + 2(I^{(q)})^2$.

Before the delays are inserted to reschedule block B, an active packet p is delayed at most once within the block, provided that $2(I^{(q)})^3 + 2(I^{(q)})^2 - I^{(q)} < I^{(q-1)}$, which holds as long as $I^{(q)}$ is larger than some constant. Prior to inserting any new delay to a block, we check if it is within $I^{(q)}$ steps of the single old delay. If the new delay would be too close to the old delay, then it is simply not inserted. The loss of one delay in a block has a negligible effect on the probability analysis that follows.

Lemma 6.4 shows that with the insertion of delays we can dramatically reduce the frame size in the center of the block and increase the relative congestion only slightly. In order to prove Lemma 6.4, we need the following fact.

LEMMA 6.3. *If the relative congestion in every frame of size T to $2T-1$ is at most r, then the relative congestion in any frame of size T or greater is at most r.*

Proof. Consider a frame of size T', where $T' > 2T-1$. The first $\lfloor T'/T \rfloor T - T$ steps of the frame can be broken into T-frames, each with relative congestion r. The remainder of the T'-frame consists of a single frame of size between T and $2T-1$ steps in which the relative congestion is also at most r. □

LEMMA 6.4. *There exists a way of choosing delays so that in between the first and last $(I^{(q)})^2$ steps of block B, the relative congestion of any frame of size $\log^2 I^{(q)}$ or larger is at most $(1+\gamma_1)c^{(q)}$ for some $\gamma_1 = \Theta(1)/\sqrt{\log I^{(q)}}$.*

Proof. With each edge e, we associate a bad event. A bad event on e happens when the frame congestion on edge e is more than $(1+\gamma_1)c^{(q)}I$ during *any* I-frame

of size $\log^2 I^{(q)}$ or larger. Due to Lemma 6.3, it is sufficient to prove the statement for all frames of size between $\log^2 I^{(q)}$ and $2\log^2 I^{(q)}$. We shall use the Lovász local lemma to show that the probability that no bad event occurs is nonzero.

We first bound the dependence, d, of bad events. Two bad events on two edges are dependent only if a packet from a session $i \in A^{(q)}$ can use both edges. At most $c^{(q)}(2(I^{(q)})^3 + 2(I^{(q)})^2 - I^{(q)})$ packets (from sessions in $A^{(q)}$) can cross the same edge in block B, and each packet crosses at most $2(I^{(q)})^3 + 2(I^{(q)})^2 - I^{(q)}$ edges in B. As we shall show later, $c^{(q)} \leq 1$. Therefore, a bad event can be dependent on at most $O((I^{(q)})^6)$ other bad events.

We now bound the probability, p, that a bad event happens on e. Consider a particular I-frame, where $\log^2 I^{(q)} \leq I \leq 2\log^2 I^{(q)}$, that lies completely between the first and last $(I^{(q)})^2$ steps of B. By setting $R = B$, $r = c^{(q)}$, $s = I^{(q)}$, and $t = I$, we apply Lemma 6.2 to show that for any constant k_1 there is some value $\gamma_1 = \Theta(1)/\sqrt{\log I^{(q)}}$ such that the probability p_1 of a bad event happening on e in the I-frame is smaller than $(I^{(q)})^{-k_1}$.

Since there are $O((I^{(q)})^3 \log^2 I^{(q)})$ possible I-frames in B, the probability that a bad event happens on e during any I-frame is $p < p_1 O((I^{(q)})^3 \log^2 I^{(q)})$. We can set the value k_1 appropriately so that this probability is upper bounded by $O((I^{(q)})^{-7})$.

Therefore, we have $4pd < 1$, and our lemma follows from the Lovász local lemma. □

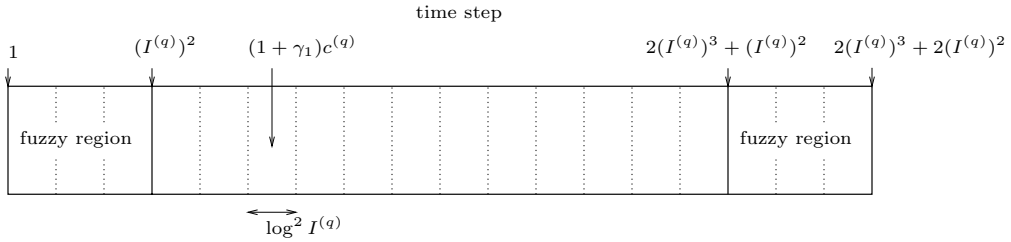

FIG. 6.1. *Situation after the first refinement step.*

At the end of the first refinement step, the center of each block has small relative congestion for small frame sizes. However there are regions of $(I^{(q)})^2$ steps at the beginning and end of each block that may have very large relative congestion. We call these "fuzzy" regions, and we deal with them in the second refinement step.

The second refinement step for schedule $\mathcal{S}^{(q)}$. We start the second step of the refinement by relocating the block boundaries so that blocks still have $2(I^{(q)})^3 + 2(I^{(q)})^2$ steps, but now the fuzzy regions that were at the beginning and end of adjacent blocks are in the center of new blocks. Then, a new block has two "clean" regions of $(I^{(q)})^3$ steps each at the beginning and the end, and a fuzzy region of length $2(I^{(q)})^2$ steps in the center.

As in the first step of the refinement we now concentrate on individual blocks. We first show that the relative congestion is not very large for frames of size $(I^{(q)})^2$ or larger (even in the fuzzy region).

LEMMA 6.5. *For any choice of delays in the first step of the refinement, the relative congestion in any frame of size* $(I^{(q)})^2$ *or larger is at most* $(1 + 2/I^{(q)})c^{(q)}$.

Proof. Without loss of generality we shall assume that all the sessions are integral. Consider an I-frame with I_1 steps before the center of the block and I_2 steps after the center. ($I = I_1 + I_2$, and either I_1 or I_2 could be zero.) A packet crosses some edge e in

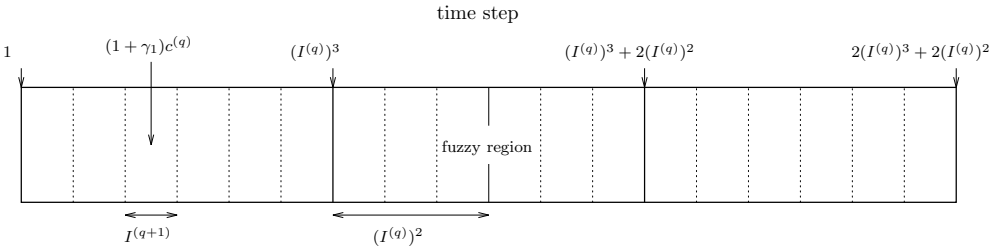

FIG. 6.2. *Situation after relocating block boundaries.*

the I_1-frame only if it did so in some frame of length $I_1 + I^{(q)}$ before the delays where inserted. Therefore, at most $(I_1 + I^{(q)})c^{(q)}$ packets can cross edge e in the I_1-frame. Similarly, at most $(I_2 + I^{(q)})c^{(q)}$ packets can cross edge e in the I_2-frame. Therefore, the congestion in the I-frame can be at most $(I_1 + I_2 + 2I^{(q)})c^{(q)} = (I + 2I^{(q)})c^{(q)}$, and for $I \geq (I^{(q)})^2$ the relative congestion is at most $(1 + 2/I^{(q)})c^{(q)}$. □

Now, in order to reduce the frame size in the fuzzy region, we consider only the active packets in each block B, and we assign a delay randomly, independently, and uniformly chosen from $[1, (I^{(q)})^2]$ to each active packet. A packet p with delay x waits once every $(I^{(q)})^3/x$ at the beginning of the block and once every $(I^{(q)})^3/((I^{(q)})^2 - x)$ at the end. As in the first step a delay is not inserted if it is going to be within $I^{(q)}$ steps of an existing delay for a moving packet.

The block length after the delay insertion is $2(I^{(q)})^3 + 3(I^{(q)})^2$, and the fuzzy region can be $(I^{(q)})^2$ steps longer, spanning steps $(I^{(q)})^3$ to $(I^{(q)})^3 + 3(I^{(q)})^2$.

The next lemma shows that there is some way of inserting delays so that the frame size in the fuzzy region is reduced, and the frame size and relative congestion in the rest of the block are increased by only a small amount.

LEMMA 6.6. *In a block B, there exists a way of choosing delays so that in the fuzzy region (i.e., interval $[(I^{(q)})^3, (I^{(q)})^3 + 3(I^{(q)})^2]$) the relative congestion of any frame of size $\log^2 I^{(q)}$ or larger is at most $(1 + \gamma_2)c^{(q)}$ for some $\gamma_2 = \Theta(1)/\sqrt{\log I^{(q)}}$, and so that in the intervals $[I^{(q)} \log^3 I^{(q)}, (I^{(q)})^3]$ and $[(I^{(q)})^3 + 3(I^{(q)})^2, 2(I^{(q)})^3 + 3(I^{(q)})^2 - I^{(q)} \log^3 I^{(q)}]$ the congestion of any frame of size $\log^2 I^{(q)}$ or larger is at most $(1 + \gamma_3)c^{(q)}$ for some $\gamma_3 = \Theta(1)/\sqrt{\log I^{(q)}}$.*

Proof. As in Lemma 6.4, we will use the Lovász local lemma to prove the claim. We associate a bad event with every edge e, so that a bad event happens on e if, for any $I \geq \log^2 I^{(q)}$,

- more than $(1 + \gamma_2)c^{(q)}I$ packets cross e in any I-frame in $[(I^{(q)})^3, (I^{(q)})^3 + 3(I^{(q)})^2]$ (the fuzzy region), or
- more than $(1+\gamma_3)c^{(q)}I$ packets cross e in any I-frame in $[I^{(q)} \log^3 I^{(q)}, (I^{(q)})^3]$ or $[(I^{(q)})^3 + 3(I^{(q)})^2, 2(I^{(q)})^3 + 3(I^{(q)})^2 - I^{(q)} \log^3 I^{(q)}]$.

The dependency, d, of the bad events is bounded as in Lemma 6.4. Two bad events on two edges are dependent if packets from some session $i \in A^{(q)}$ can use both edges. At most $O((I^{(q)})^3)$ packets cross any edge in a block, and each of them can cross at most $O((I^{(q)})^3)$ other edges. Therefore, $d = O((I^{(q)})^6)$.

Now, to bound the probability p of a bad event happening on some edge e, we consider the three intervals separately and sum their respective probabilities. From Lemma 6.3 we only consider frames of length I such that $\log^2 I^{(q)} \leq I \leq 2 \log^2 I^{(q)}$.

Take first some I-frame in $[(I^{(q)})^3, (I^{(q)})^3 + 3(I^{(q)})^2]$ (the fuzzy region). From Lemma 6.5 we know that the relative congestion for frames of size $(I^{(q)})^2$ or longer

is at most $(1+2/I^{(q)})c^{(q)} = \Theta(1)$. Then, by choosing $R = B$, $r = (1+2/I^{(q)})c^{(q)}$, $s = (I^{(q)})^2$, and $t = I$, we can use Lemma 6.2 to show that, for any constant k_2, there is some $\sigma_2 = \Theta(1)/\sqrt{\log I^{(q)}}$ such that the probability p_1 of having relative congestion on e in the I-frame larger than $c^{(q)}(1+2/I^{(q)})(1+\sigma_2) = c^{(q)}(1+\gamma_2)$ is smaller than $(I^{(q)})^{-k_2}$. Note that $\gamma_2 = \Theta(1)/\sqrt{\log I^{(q)}}$.

Take now some I-frame in $[I^{(q)}\log^3 I^{(q)}, (I^{(q)})^3]$ which starts at step j. Given the way delays are inserted, by the jth step an active packet with delay x has been delayed $jx/(I^{(q)})^3$ steps. Thus, the delay of an active packet at the jth step is essentially a random value uniformly chosen from $[1, j/I^{(q)}]$. For $j \geq I^{(q)}\log^3 I^{(q)}$ the value $j/I^{(q)} \geq \log^3 I^{(q)}$.

Note that before inserting delays, from Lemma 6.4 the relative congestion in any frame of length $\log^2 I^{(q)}$ or larger in the interval $[1, (I^{(q)})^3]$ was at most $(1+\gamma_1)c^{(q)}$. Then, we can make $R = [1, (I^{(q)})^3]$, $r = (1+\gamma_1)c^{(q)}$, $s = \log^3 I^{(q)}$, and $t = I$, and we use Lemma 6.2 to show, for any constant k_3, the existence of some $\sigma_3 = \Theta(1)/\sqrt{\log I^{(q)}}$ such that the probability p_2 of having relative congestion larger than $(1+\sigma_3)(1+\gamma_1)c^{(q)} = (1+\gamma_3)c^{(q)}$ on e in the I-frame is smaller than $(I^{(q)})^{-k_3}$. Again, $\gamma_3 = \Theta(1)/\sqrt{\log I^{(q)}}$.

By symmetry, the same value γ_3 makes the probability of a bad event happening on e in some I-frame in $[(I^{(q)})^3 + 3(I^{(q)})^2, 2(I^{(q)})^3 + 3(I^{(q)})^2 - I^{(q)}\log^3 I^{(q)}]$ smaller than $(I^{(q)})^{-k_3}$.

There are $O((I^{(q)})^3 \log^2 I^{(q)})$ possible I-frames as described in total. Hence, we can choose values for k_2 and k_3 such that the probability of a bad event is bounded as $p \leq (p_1 + 2p_2)O((I^{(q)})^3 \log I^{(q)}) < O((I^{(q)})^7)$. Therefore, we can guarantee $4pd < 1$ and invoke the Lovász local lemma to prove the claim. □

Finally, we bound the frame size and the relative congestion in the remaining intervals of the block in the following lemma.

LEMMA 6.7. *The relative congestion in any frame of size* $\log^4 I^{(q)}$ *or larger in the intervals* $[1, I^{(q)}\log^3 I^{(q)}]$ *and* $[2(I^{(q)})^3 + 3(I^{(q)})^2 - I^{(q)}\log^3 I^{(q)}, 2(I^{(q)})^3 + 3(I^{(q)})^2]$ *is at most*

$$(1+\gamma_1)(1+1/\log I^{(q)})c^{(q)} = (1+\gamma_4)c^{(q)}.$$

Proof. Let us first consider some I-frame in $[1, I^{(q)}\log^3 I^{(q)}]$. Recall that, before inserting delays, the relative congestion for frames of size $\log^2 I^{(q)}$ or more was at most $(1+\gamma_1)c^{(q)}$. In the interval no packet is delayed more than $\log^3 I^{(q)}$ steps. Therefore, the packets crossing some edge e in the I-frame could have crossed e in some interval of at most $I + \log^3 I^{(q)}$ steps, and the congestion in the I-frame can be of at most $(I + \log^3 I^{(q)})(1+\gamma_1)c^{(q)}$. For $I \geq \log^4 I^{(q)}$ the claim follows. The proof for interval $[2(I^{(q)})^3 + 3(I^{(q)})^2 - I^{(q)}\log^3 I^{(q)}, 2(I^{(q)})^3 + 3(I^{(q)})^2]$ is similar. □

From the above two lemmas we have that any frame of length at least $\log^4 I^{(q)}$ in each of the different intervals has at most a relative congestion $(1+\gamma)c^{(q)}$, where $\gamma = \max(\gamma_2, \gamma_3, \gamma_4)$ and $\gamma = O(1)/\sqrt{\log I^{(q)}}$. We need to be careful now with the relative congestion in frames that overlap several intervals or several blocks. We can safely say that for any frame of size $I^{(q+1)} = \log^5 I^{(q)}$ or larger in the schedule $\mathcal{S}^{(q+\frac{1}{2})}$ obtained after the frame refinement, the relative congestion is at most $(1+\delta^{(q)})c^{(q)}$ for some $\delta^{(q)} = \beta/\sqrt{\log I^{(q)}}$ large enough.

6.3. Conversion for schedule $\mathcal{S}^{(q)}$. In the conversion process we transform the schedule $\mathcal{S}^{(q+\frac{1}{2})}$, obtained from the frame refinement step, into a new schedule $\mathcal{S}^{(q+1)}$. In this new schedule, all the sessions in $B^{(q+1)}$ which were fractional in $\mathcal{S}^{(q)}$

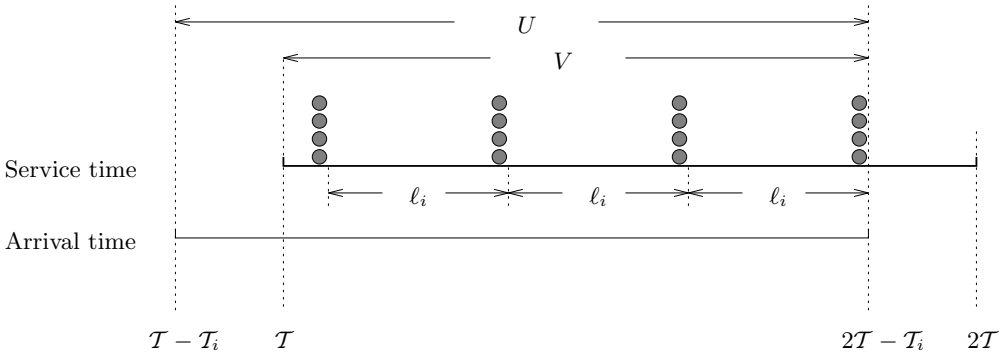

FIG. 6.3. *Session-i packets that are injected in interval U are assigned initial tokens in interval V. The interval V is divided into consecutive intervals of length ℓ_i, each of which has s_i initial tokens. The initial tokens are shown in solid dots.*

have been made integral, and the relative congestion of frames of size $I^{(q+1)}$ or larger is at most $c^{(q+1)} = (1 + \delta^{(q)})^2 c^{(q)}$.

At the beginning of this step, we inductively assume that the relative congestion is at most $(1 + \delta^{(q)})c^{(q)}$ for any frame of size $I^{(q+1)}$ or larger, where $\delta^{(q)} = \beta/\sqrt{\log I^{(q)}}$. If the set $B^{(q+1)}$ is empty, then we skip this conversion step; clearly, the relative congestion is at most $c^{(q+1)}$ for any frame of size $I^{(q+1)}$, and we are done.

On the other hand, if the set $B^{(q+1)}$ is not empty, then for each session $i \in B^{(q+1)}$ we apply the following two processes. (a) In the discretization process we convert the schedule for fractional session-i packets into a schedule for integral packets in which no packet has to wait too long before it starts moving. (b) In the delay-insertion process we delay the time at which packets start moving (i.e., we insert *initial delays*) in such a way that the relative congestion requirements are satisfied.

Discretization. We first show how to transform a fractional session in $B^{(q+1)}$ into an integral session. Consider a session i in $B^{(q+1)}$. When session i is fractional, a packet of size $\hat{r}_i = s_i/\ell_i$ is injected at every time step, where ℓ_i and s_i are integer constants defined in section 5. A fractional packet marches to its destination one edge at a time with no delay.

We want to replace these fractional packets by integral packets. An integral packet waits at its source until it finds an unused *initial token*. Then, it crosses one edge every time step until it reaches its destination. The number of initial tokens and their distribution have to be carefully chosen so that no packet waits at its source for too long.

To transform session i, we consider the two intervals shown in Figure 6.3, $U = [\mathcal{T} - \mathcal{T}_i, 2\mathcal{T} - \mathcal{T}_i)$ and $V = [\mathcal{T}, 2\mathcal{T} - \mathcal{T}_i)$. When session i is converted, we distribute enough *initial tokens* in the interval V to accommodate all the session-i arrivals during U. Integral packets arrive at a rate r_i during U, and initial tokens will appear at a rate roughly equal to $\hat{r}_i$ during V. Recall from section 5 that $\hat{r}_i$ is slightly larger than r_i. By choosing the interval U long enough (i.e., $\mathcal{T}$ large enough), we guarantee that there are more initial tokens than arrivals.

Let $|V| = \mathcal{T} - \mathcal{T}_i$ be the length of interval V. We divide V into consecutive intervals of length ℓ_i (starting from the end), and we put s_i initial tokens in the last slot of each ℓ_i-interval. Note that if $|V|$ is not an integer multiple of ℓ_i, then the first ℓ_i-interval is "incomplete." (See Figure 6.3.) We show that there are enough initial

tokens and that no packet waits too long for an unused one.

LEMMA 6.8. *For a converted session $i \in B^{(q+1)}$, every session-i packet that is injected during U finds an unused initial token in V within $\mathcal{T}_i + \ell_i = O(1/r_i + D_i)$ steps of its injection.*

Proof. Let $x = \mathcal{T}/(\mathcal{T} - \mathcal{T}_i)$ be the ratio of the length of interval U to the length of interval V. It suffices to show that s_i, the number of initial tokens in an ℓ_i-interval (shown in Figure 6.3), is as large as the number of session-i arrivals during an interval of length $x\ell_i$. At most $n = x\ell_i r_i + 1$ packets can arrive during $x\ell_i$ steps. Since $\mathcal{T} \geq (1 + 4/\varepsilon) \max_i \mathcal{T}_i$ by definition, we have $x \leq 1 + \varepsilon/4$ and $n \leq \ell_i r_i (1 + \varepsilon/4) + 1$. By the left-hand side of property 1 of Lemma 5.1, we have $n \leq s_i$. Therefore, we have enough initial tokens. Since the initial tokens are at the end of an ℓ_i-interval, each packet can use an initial token that appears after the packet arrival time. It is also easy to verify that an unused initial token appears within $\mathcal{T}_i + \ell_i = O(\mathcal{T}_i)$ steps of the packet injection. ∎

Delay insertion. Before any delay is inserted for a packet from session $i \in B^{(q+1)}$, the packet leaves its source at the time of its initial token and marches to its destination with no more waiting. Now we insert an initial delay for each session-i packet, which has the effect of deferring the start time of the packet. We choose the delays uniformly from $[1, \ell_i]$. After the initial delay each packet travels to its destination without further delay.

LEMMA 6.9. *Consider a particular edge e and a particular t-frame during interval $[\mathcal{T}, 2\mathcal{T})$. Suppose session i requires edge e; then the expected number of session-i packets that use e in the t-frame is at most $ts_i/\ell_i = t\hat{r}_i$.*

Proof. Let us assume first that delays have not been inserted yet. Due to the way initial tokens are distributed, session-i packets cross edge e in a very synchronous manner: a batch of at most s_i packets crosses every ℓ_i steps. Since we want an upper bound on the expectation, we assume that exactly s_i packets cross e every ℓ_i steps.

Let us now partition time in ℓ_i-intervals, so that each interval ends with a step in which packets cross e (i.e., all packets cross e in the last step of the intervals). Observe that, once delayed, all the packets that crossed e in the last step of some ℓ_i-interval will cross it in the following interval. Then, the total number of packets crossing e in an ℓ_i-interval after the delay insertion is exactly s_i. Also, after the insertion of delays, the expected number of packets crossing e in some subinterval of length ℓ of an ℓ_i-interval is exactly $\ell s_i/\ell_i$.

Take now the t-frame, and consider the incomplete ℓ_i-intervals it contains. There can be at most one at the beginning and one at the end. Assume they have lengths t_1 and t_2, respectively. From the above observations, the expected number of packets crossing e in the t_1 (resp., t_2) subinterval is $t_1 s_i/\ell_i$ (resp., $t_2 s_i/\ell_i$). In the remainder of the t-frame the number of packets crossing is exactly $(t - t_1 - t_2)s_i/\ell_i$. Hence, the expected number of packets crossing e in the t-frame is $(t - t_1 - t_2)s_i/\ell_i + t_1 s_i/\ell_i + t_2 s_i/\ell_i = ts_i/\ell_i$. ∎

We now use a Chernoff bound and the Lovász local lemma to show the following.

LEMMA 6.10. *There exists a way of choosing the initial delays for sessions in $B^{(q+1)}$ such that the relative congestion in any frame of size $I^{(q+1)}$ or bigger is at most $c^{(q+1)}$ after the delays are inserted.*

Proof. Due to Lemma 6.3, it is sufficient to prove the result for all frames of size $I^{(q+1)}$ to $2I^{(q+1)}$. We associate a bad event with each edge e and each I-frame, where $I^{(q+1)} \leq I \leq 2I^{(q+1)}$. A bad event $E_{\{e,I\}}$ happens when more than $Ic^{(q+1)}$ packets use e during frame I. We use the Lovász local lemma to show that with nonzero

probability no bad event occurs. Let $D_{\max} = \max_{i \in B^{(q+1)}} D_i$, $r_{\min} = \min_{i \in B^{(q+1)}} r_i$, $X = \max_{i \in B^{(q+1)}} D_i + 1/r_i$, and $\ell_{\max} = \max_{i \in B^{(q+1)}} \ell_i$.

We first bound the dependency d of bad events. Note that the probability space is given by the delays assigned to packets from sessions in $B^{(q+1)}$. Hence, a bad event $E_{\{e,I\}}$ is dependent on another bad event $E_{\{e',I'\}}$ only if there is a packet p from a session $i \in B^{(q+1)}$ such that there is a nonzero probability that p uses e during the I-frame and there is a nonzero probability that p uses e' during the I'-frame.

There are at most $1/r_{\min}$ sessions in $B^{(q+1)}$, each of which is at most $D_{\max}$ long. Therefore, $E_{\{e,I\}}$ depends on $E_{\{e',I'\}}$ for at most $D_{\max}/r_{\min} = O(X^2)$ choices of e'. Furthermore, intervals I and I' cannot be more than $D_{\max} + \ell_{\max}$ steps apart. (Otherwise any session-i packet either has probability 0 of crossing edge e during I or probability 0 of crossing e' during I'.) Therefore, the starting point of I' is limited to $2D_{\max} + 2\ell_{\max} + 4I^{(q+1)}$ locations, and the total possible choices for I' is at most $(2D_{\max} + 2\ell_{\max} + 4I^{(q+1)})I^{(q+1)} = O(X(I^{(q+1)})^2)$. We conclude that the dependency d is $O(X^3(I^{(q+1)})^2)$.

We now bound the probability p that a bad event $E_{\{e,I\}}$ happens. By our inductive assumption, the frame congestion on edge e during the I-frame is at most $(1 + \delta^{(q)})c^{(q)}I$ before the conversion. Let S be the set of sessions in $B^{(q+1)}$ that use edge e. When sessions in $B^{(q+1)}$ are fractional, they contribute exactly $I \sum_{i \in S} \hat{r}_i$ to the frame congestion. Lemma 6.9 implies that the expected frame congestion due to the sessions in $B^{(q+1)}$ is at most $I \sum_{i \in S} \hat{r}_i$ after the initial delays are inserted. The congestion due to sessions not in $B^{(q+1)}$ does not change during the conversion. Hence, the expected frame congestion on edge e during the I-frame is at most $(1 + \delta^{(q)})c^{(q)}I = \mu$. We bound the probability of $E_{\{e,I\}}$ as follows.

$$\begin{aligned}
p &= \Pr\left[\text{ Frame congestion on } e \text{ in } I > c^{(q+1)}I \right] \\
&= \Pr\left[\text{ Frame congestion on } e \text{ in } I > (1+\delta^{(q)})\mu \right] \\
&\le e^{-(\delta^{(q)})^2\mu/3} \\
&\le e^{-(1-\varepsilon)\beta^2 I^{(q+1)}/(3\log I^{(q)})} \\
&\le e^{-(1-\varepsilon)\frac{\beta^2}{3}(I^{(q+1)})^{1/5}(I^{(q+1)})^{3/5}} \\
&\le e^{-(1-\varepsilon)\frac{\beta^2}{3}(I^{(q+1)})^{1/5}\log^{6/5} X}.
\end{aligned}$$

The first inequality follows from Lemma 2.3. The second inequality holds since $\mu > (1-\varepsilon)I \ge (1-\varepsilon)I^{(q+1)}$ and from the definition of $\delta^{(q)}$. The third inequality follows from the recurrence for $I^{(q+1)}$. The last inequality follows from the fact that $\log^2 X \le I^{(q+1)}$. (This explains the need for $\log^2 X_i \le I^{(q+1)}$ in the definition of $B^{(q+1)}$.)

When β is a sufficiently large constant, we have $4dp < 1$. Hence, the Lovász local lemma implies that with nonzero probability no bad events occur. That is, there exists a way to choose the initial delays for sessions in $B^{(q+1)}$ such that for all frames of size $I^{(q+1)}$ or larger the relative congestion is at most $c^{(q+1)}$.

Note that in the proof of this lemma we associate a bad event with each edge e and each interval I. Why couldn't we associate a bad event with each edge e only and then use a union bound on the number of intervals, as in Lemma 6.4? This is because we are considering all the session-i packets during an interval of length $\mathcal{T}$, which can be much bigger than $1/r_i + D_i$ for some sessions i. □

6.4. Termination at schedule $\mathcal{S}^{(\zeta)}$. The succession of refinement and conversion terminates at schedule $\mathcal{S}^{(\zeta)}$ when the frame size $I^{(\zeta)}$ becomes smaller than

or equal to w, a constant defined in section 5. The following lemma shows that the relative congestion of $\mathcal{S}^{(\zeta)}$ is small.

LEMMA 6.11. *In the schedule $\mathcal{S}^{(\zeta)}$ all sessions are integral and the relative congestion is at most $c^{(\zeta)} < 1$ for any frame of size $I^{(\zeta)}$ or larger.*

Proof. One can verify that $B^{(q+1)}$ forms a partition of all the sessions. Therefore, all the sessions are integral in the schedule $\mathcal{S}^{(\zeta)}$. By our induction, the relative congestion is at most $c^{(\zeta)}$ for all frames of size $I^{(\zeta)}$ or larger. Hence, we only need to show that $c^{(\zeta)} < 1$.

Due to the termination conditions, $x \le I^{(\zeta-1)}$, where x is defined in section 5. Let $\Delta = \beta/\sqrt{\log x}$, and observe that $\delta^{(\zeta-1)} \le \Delta < 1$. By the recursive definition of $c^{(\zeta)}$, we have

$$\begin{aligned}
c^{(\zeta)} &= (1+\delta^{(\zeta-1)})^2(1+\delta^{(\zeta-2)})^2 \dots (1+\delta^{(0)})^2 c^{(0)} \\
&< (1+\Delta)^2(1+\Delta^2)^2(1+\Delta^4)^2(1+\Delta^8)^2 \dots c^{(0)} \\
&\le (1-\Delta)^{-2}\left\{(1-\Delta)^2(1+\Delta)^2(1+\Delta^2)^2(1+\Delta^4)^2(1+\Delta^8)^2 \dots\right\} c^{(0)} \\
&\le (1-\Delta)^{-2} c^{(0)} \\
&= \left(1-\beta/\sqrt{\log x}\right)^{-2} c^{(0)} \\
&= \frac{1-\varepsilon/2}{1-\varepsilon/2} \\
&= 1.
\end{aligned}$$

The first inequality holds since $\delta^{(q)} < (\delta^{(q+1)})^2$ for all q by the recurrence defined in section 5. The third inequality holds since $\Delta < 1$, and therefore the "telescope product" in the braces is less than 1. The last equality holds by the above choice of x and the definition of $c^{(0)}$ in section 5. ∎

Now, we have to make sure that in the resulting schedule $\mathcal{S}^{(\zeta)}$ no packet waits too long. The conversion step guarantees that when a session i becomes integral, no packet waits more than $O(D_i + 1/r_i)$ steps before it starts moving, and it does not wait anymore. The last frame refinement step also guarantees that a moving packet never waits more than once every $I^{(\zeta-1)}$ steps. However, all the frame refinement steps that an integral packet has to go through can, in fact, delay the time it starts moving. The following lemma shows that this delay does not add up to a large amount, and therefore that a session-i packet reaches its destination in at most $O(D_i + 1/r_i)$ steps in the schedule $\mathcal{S}^{(\zeta)}$.

LEMMA 6.12. *During frame-refinement a session-i packet is delayed by at most $2(D_i + 1/r_i)$ steps before it starts moving.*

Proof. Suppose session i first becomes integral in schedule $\mathcal{S}^{(q')}$. Consider a session-i packet p. For schedule $\mathcal{S}^{(q)}$, where $q \le q'-1$, p is never delayed during frame refinement. For schedule $\mathcal{S}^{(q)}$, where $q \ge q'$, p is delayed by at most $I^{(q)} + (I^{(q)})^2$ steps before it starts moving. Therefore, the total delay inserted during all the frame refinement steps is at most $\sum_{q \ge q'} I^{(q)} + (I^{(q)})^2$. Since session i becomes integral for schedule $\mathcal{S}^{(q')}$, we must have $i \in B^{(q')}$. By the definition of $B^{(q')}$, $D_i + 1/r_i \ge (I^{(q')})^2$. Since $I^{(q)}$ decreases polylogarithmically, a session-i packet is delayed during frame refinement by at most $2(D_i + 1/r_i)$ steps before it starts moving. ∎

We proceed to prove that $\mathcal{S}^{(\zeta)}$ has all the properties.

THEOREM 6.13. *Given network $\mathcal{M}$ and a set of sessions as defined in section 1.2, there is a schedule $\mathcal{S}^{(\zeta)}$ such that the following hold.*

1. *The relative congestion is at most* 1 *for any frame of size larger than a certain constant.*
2. *After leaving its source, each packet waits at most once every* $O(1)$ *steps, which implies that all edge queues in* $\mathcal{M}$ *have size* $O(1)$.
3. *For all sessions* i*, any session-*i *packet reaches its destination within* $O(1/r_i + D_i)$ *steps of its injection.*
4. *All session-*i *arrivals during* $[\mathcal{T} - \mathcal{T}_i, 2\mathcal{T} - \mathcal{T}_i)$ *are serviced during* $[\mathcal{T}, 2\mathcal{T})$*, i.e., all packets leave their source no earlier than* $\mathcal{T}$ *and reach their destination before* $2\mathcal{T}$.

Proof.

1. By Lemma 6.11, the relative congestion is at most 1 for any frame of size $I^{(\zeta)}$ or larger. Due to the termination conditions $I^{(\zeta)}$ is a constant.
2. By the invariant maintained throughout the frame refinement steps, a packet waits at most once every $I^{(\zeta-1)}$ steps once it leaves its source. In addition, by property 1 above, at most $I^{(\zeta)}$ packets cross an edge during any time step. Therefore, the edge queues have size at most $2I^{(\zeta)}$.
3. We first show that a session-i packet reaches its destination within $\mathcal{T}_i$ steps after it obtains an initial token. After the initial token, a session-i packet is deferred by an initial delay during the conversion step and other delays during the frame refinement step before it could leave its source. The initial delay is at most $\ell_i < 1 + 8/(\varepsilon r_i)$, and the delay during the refinement is at most $2(D_i + 1/r_i)$ by Lemma 6.12. Once the packet starts moving, it reaches its destination in at most $2D_i$ steps by property 2. Therefore, a session-i packet reaches its destination within $4D_i + 1 + (8/\varepsilon + 2)/r_i < \mathcal{T}_i$ steps after obtaining its initial token.

   Since any session-i packet obtains an initial token within $\mathcal{T}_i + \ell_i$ steps of its injection by Lemma 6.8, the packet reaches its destination within $2\mathcal{T}_i + \ell_i = O(1/r_i + D_i)$ steps of its injection.
4. For all session-i arrivals during $[\mathcal{T} - \mathcal{T}_i, 2\mathcal{T} - \mathcal{T}_i)$, the initial tokens are in $[\mathcal{T}, 2\mathcal{T} - \mathcal{T}_i)$. From the discussion of property 3, a session-i packet reaches its destination within $\mathcal{T}_i$ steps after it obtains an initial token. Therefore, all packets leave their sources no earlier than $\mathcal{T}$ and reach their destinations before $2\mathcal{T}$. ∎

6.5. The final schedule for the original network $\mathcal{N}$. We now describe how to create a schedule $\mathcal{S}_{\mathcal{N}}$ for network $\mathcal{N}$ from $\mathcal{S}^{(\zeta)}$. In $\mathcal{S}_{\mathcal{N}}$ at most one packet at a time crosses each edge in $\mathcal{N}$. Recall that in the construction of $\mathcal{M}$ from $\mathcal{N}$, each edge e in $\mathcal{N}$ is replaced by $2w$ consecutive edges $e_1, \ldots, e_{2w}$, where w is a constant defined in section 5.

We first partition the time interval $[\mathcal{T}, 2\mathcal{T})$ into consecutive intervals of length w (recall that by definition $\mathcal{T}$ is a multiple of w). For each w-interval and each edge f in $\mathcal{M}$, as many as w packets, $p_1, p_2, \ldots, p_w$, can cross f during the w-interval by schedule $\mathcal{S}^{(\zeta)}$. We *smooth out* $\mathcal{S}^{(\zeta)}$ so that p_j is the jth packet to cross f in the w-interval, where $p_1, \ldots, p_w$ represents an arbitrary ordering. After smoothing, a packet may not be scheduled to cross the edges on its route in order. For example, a packet may be scheduled to cross edge f before g, whereas f follows g on the route in $\mathcal{M}$. A packet may also be scheduled to leave its source before its injection time. However, $\mathcal{S}^{(\zeta)}$ after smoothing does have the property that at most one packet at a time crosses each edge. We define $\mathcal{S}_{\mathcal{N}}$ as follows. $\mathcal{S}_{\mathcal{N}}$ schedules a packet p to cross e in $\mathcal{N}$ at time t if and only if $\mathcal{S}^{(\zeta)}$ after smoothing schedules p to cross e_{2w} in $\mathcal{M}$ at time t.

LEMMA 6.14. *In $\mathcal{S}_{\mathcal{N}}$, each packet is scheduled to leave its source after its injection and is scheduled to cross the edges on its route in order.*

Proof. We first show that each packet crosses the edges on its route in order. Consider a packet p. Let e and $\hat{e}$ be two edges on p's route in $\mathcal{N}$, where $\hat{e}$ follows e. Let t and $\hat{t}$ be the times that p crosses e and $\hat{e}$ in schedule $\mathcal{S}_{\mathcal{N}}$. We shall show that $t < \hat{t}$.

Let e_{2w} and $\hat{e}_{2w}$ be the edges in $\mathcal{M}$ that correspond to e and $\hat{e}$. Let τ and $\hat{\tau}$ be the times that p crosses e_{2w} and $\hat{e}_{2w}$ in the schedule $\mathcal{S}^{(\zeta)}$ *before* smoothing. Since p crosses the edges in $\mathcal{M}$ in order before smoothing, we have

$$\tau + 2w \leq \hat{\tau}. \tag{6.3}$$

In schedule $\mathcal{S}_{\mathcal{N}}$, packet p crosses e at time t, which is shifted by at most $w-1$ steps from τ. Similarly, $\hat{t}$ is shifted by at most $w-1$ steps from $\hat{\tau}$. Hence we have

$$\begin{array}{rcccl} \tau - (w-1) & \leq & t & \leq & \tau + (w-1), \\ \hat{\tau} - (w-1) & \leq & \hat{t} & \leq & \hat{\tau} + (w-1). \end{array}$$

From (6.3) and the above inequalities, we have $t < \hat{t}$. Therefore, p crosses the edges on its route in order.

The proof that packet p leaves its source after its injection time is similar. Suppose that p is injected into the network at time s. Let edge e be the first edge on the route of p in network $\mathcal{N}$, and let t be the time that p crosses e in $\mathcal{S}_{\mathcal{N}}$. Also, let e_{2w} be the corresponding edge in $\mathcal{M}$, and let τ be the time that p crosses e_{2w} in $\mathcal{S}^{(\zeta)}$ before smoothing. Since in $\mathcal{S}^{(\zeta)}$ before smoothing p crosses the edges in order and leaves its source after its injection, we have

$$s + 2w \leq \tau.$$

In schedule $\mathcal{S}_{\mathcal{N}}$, packet p crosses e at time t, which is shifted by at most $w-1$ steps from τ. Hence we have

$$\tau - (w-1) \quad \leq \quad t \quad \leq \quad \tau + (w-1).$$

Therefore, $s < t$ and packet p leaves its sources in $\mathcal{N}$ after the injection time. □

We summarize the properties of $\mathcal{S}_{\mathcal{N}}$.

THEOREM 6.15. *Schedule $\mathcal{S}_{\mathcal{N}}$ satisfies the following properties.*

1. *At most one packet at a time crosses each edge in $\mathcal{N}$.*
2. *After leaving its source, each packet waits a constant number of steps to cross an edge, which implies all the edge queues in $\mathcal{N}$ have a constant size.*
3. *For all sessions i, any session-i packet reaches its destination within $O(1/r_i + d_i)$ steps of its injection.*
4. *All session-i arrivals during $[\mathcal{T} - \mathcal{T}_i, 2\mathcal{T} - \mathcal{T}_i)$ are serviced during $[\mathcal{T}, 2\mathcal{T})$, i.e., all packets leave their source no earlier than $\mathcal{T}$ and reach their destination before $2\mathcal{T}$.*

Proof. The smoothing process guarantees property 1. Properties 2 and 3 come from properties 2 and 3 of $\mathcal{S}^{(\zeta)}$ given in Theorem 6.13, the construction of $\mathcal{M}$ from $\mathcal{N}$, and the fact that each packet is scheduled to reach its destination in $\mathcal{S}_{\mathcal{N}}$ at most w steps later than in $\mathcal{S}^{(\zeta)}$.

To see property 4, recall that the interval $[\mathcal{T}, 2\mathcal{T})$ is partitioned into intervals of size w (with one interval possibly longer than w), and that schedule $\mathcal{S}^{(\zeta)}$ is smoothed

out within each w-interval. Therefore, if a packet is scheduled to cross an edge e during $[\mathcal{T}, 2\mathcal{T})$ according to $\mathcal{S}^{(\zeta)}$, the packet must also be scheduled to cross e during $[\mathcal{T}, 2\mathcal{T})$ according to $\mathcal{S}_{\mathcal{N}}$. Property 4 follows. Property 4 of the above theorem implies that all intervals of $[0, \mathcal{T})$, $[\mathcal{T}, 2\mathcal{T})$, etc. can be scheduled independently. □

6.6. Derivation of the templates. We now describe how to transform $\mathcal{S}_{\mathcal{N}}$ into a template-based schedule. Property 4 of Theorem 6.15 says that all packets considered in schedule $\mathcal{S}_{\mathcal{N}}$ (those injected in interval $[\mathcal{T} - \mathcal{T}_i, 2\mathcal{T} - \mathcal{T}_i)$ for each session i) move from their sources to their destination during interval $[\mathcal{T}, 2\mathcal{T})$. For this reason, we choose $\mathcal{T}$ as the size of each template. Recall that in the conversion step of section 6.3, the placement of the initial tokens is *independent* of the actual packet arrival times. The placement is simply a result of randomization added onto the fixed configuration shown in Figure 6.3. As we have shown, even if each session-i initial token is owned by a session-i packet, we can schedule these packets by schedule $\mathcal{S}_{\mathcal{N}}$. Then, if we place a session-i token in the template of edge e whenever a session-i packet crosses e in $\mathcal{S}_{\mathcal{N}}$, the movement of each packet determines a token sequence, and these token sequences define the locations of all the tokens. We emphasize that the placement of these tokens is fixed as the initial tokens are.

Obviously, the token lag is $O(1)$ for all sequences and the end-to-end delay is $O(1/r_i + d_i)$ for all session-i token sequences. Since each session-i packet is able to obtain an initial token within $O(1/r_i + d_i)$ steps of its injection, Theorem 2.2 implies that the template-based schedule defined by the token sequences achieves a delay bound of $O(1/r_i + d_i)$ and constant-edge queues. Combined with Theorem 2.2, we have a template-based schedule with desired delay bounds and constant-edge queues. In summary, we have the following theorem.

THEOREM 6.16. *Consider an arbitrary network in which sessions are defined. Each session i is associated with an injection rate r_i and path length d_i. Packets are injected into the network along these sessions subject to the injection rates. If the total rate on each edge is at most $1 - \varepsilon$ for a constant $\varepsilon \in (0, 1)$, then there exists a template-based schedule such that each session-i packet reaches its destination within $O(1/r_i + d_i)$ steps of its injection and at most one packet crosses an edge at each time step. This schedule also maintains constant-edge queues.*

Acknowledgments. The authors wish to thank Bruce Maggs, Greg Plaxton, and Salil Vadhan for many helpful comments.

A DECOMPOSITION THEOREM FOR TASK SYSTEMS AND BOUNDS FOR RANDOMIZED SERVER PROBLEMS*

AVRIM BLUM†, HOWARD KARLOFF‡, YUVAL RABANI§, AND MICHAEL SAKS¶

Abstract. A lower bound of $\Omega(\sqrt{\log k/\log\log k})$ is proved for the competitive ratio of randomized algorithms for the k-server problem against an oblivious adversary. The bound holds for arbitrary metric spaces (having at least $k+1$ points) and provides a new lower bound for the metrical task system problem as well. This improves the previous best lower bound of $\Omega(\log\log k)$ for arbitrary metric spaces [H.J. Karloff, Y. Rabani, and Y. Ravid, *SIAM J. Comput.*, 23 (1994), pp. 293–312] and more closely approaches the conjectured lower bound of $\Omega(\log k)$. For the server problem on $k+1$ equally spaced points on a line, which corresponds to a natural motion-planning problem, a lower bound of $\Omega(\frac{\log k}{\log\log k})$ is obtained.

The results are deduced from a general decomposition theorem for a simpler version of both the k-server and the metrical task system problems, called the "pursuit-evasion game." It is shown that if a metric space $\mathcal{M}$ can be decomposed into two spaces $\mathcal{M}_{\mathcal{L}}$ and $\mathcal{M}_{\mathcal{R}}$ such that the distance between them is sufficiently large compared to their diameter, then the competitive ratio for this game on $\mathcal{M}$ can be expressed nearly exactly in terms of the ratios on each of the two subspaces. This yields a divide-and-conquer approach to bounding the competitive ratio of a space.

1. Introduction and main results.

On-line computation is a setting in which randomization has been shown to have a provable advantage over determinism (see, e.g., [BE]). An on-line computation problem typically involves responding to a sequence of requests in order to minimize some cost function. The standard measure of success is the *competitive ratio* [ST, KMRS], which is, roughly, the maximum over all request sequences of the ratio of the cost charged to the algorithm on a request sequence, to the optimal off-line cost of servicing that sequence. It is useful and customary to view the request sequence as chosen by an adversary who knows the algorithm being used and seeks to force this ratio to be large. Against a deterministic algorithm, the adversary can completely predict the responses of the algorithm, and

this gives it great power for forcing the algorithm to perform badly. Against a randomized algorithm the adversary knows the algorithm but not the random choices of the algorithm. Intuitively, this can be interpreted by saying that after each successive request, the adversary "knows" only a probability distribution over states of the algorithm rather than the precise state. This restriction on the adversary provides the potential advantage of randomization. (Note that here and throughout this paper we are discussing a version of the adversary known as an "oblivious" adversary [BBKTW, RS]. There are other, more powerful, adversaries that are less vulnerable to randomization.)

In the well-known k-server problem, an algorithm controls k servers, each of which occupies some point in a metric space $\mathcal{M}$. At each time step the algorithm is given a *request*, which is a point in $\mathcal{M}$, and must serve it by moving a server to that point if none is there already. The algorithm is charged a cost equal to the total distance moved. It has been shown that for any metric space having at least $k+1$ points no deterministic on-line algorithm can achieve a competitive ratio less than k [MMS]. (Note that the problem is nontrivial only if there are at least $k+1$ points.) The well-known k-server conjecture [MMS] says that for any metric space, there is a deterministic on-line algorithm that can achieve a competitive ratio of k. In other words, if we define the competitive ratio of a metric space to be the minimum ratio achievable by any algorithm, then the conjecture is that for the k-server problem, the deterministic competitive ratio of any metric space on at least $k+1$ points is exactly k. A breakthrough result [KP] provided a deterministic algorithm with competitive ratio $2k-1$, improving on the previous exponential upper bounds [FRR, Gro].

The power of randomization in this setting was first demonstrated for the *uniform* metric space on $k+1$ points, $\mathcal{U}(k+1)$, in which all pairs of distinct points are equidistant. For this space there is an $O(\log k)$-competitive algorithm, and indeed this is a lower bound.

THEOREM 1.1 (see [FKLMSY, MS, BLS]). *The k-server problem for $\mathcal{U}(k+1)$ has a randomized competitive ratio exactly $1+\frac{1}{2}+\frac{1}{3}+\cdots+\frac{1}{k} \sim \ln k$.* In fact, these bounds hold for uniform metric spaces of any size greater than k. Various people have speculated on the following conjecture.

CONJECTURE 1.1. *For any k and any metric space $\mathcal{M}$ on more than k points, the randomized competitive ratio of the k-server problem on $\mathcal{M}$ is $\Theta(\log k)$.*

Unlike the deterministic case, where the lower bound is relatively easy and only the upper bound seems difficult, neither bound has been proved in the randomized case. For the lower bound, the previous best result is the following.

THEOREM 1.2 (see [KRR]). *Let k be a positive integer, and let $\mathcal{M}$ be a metric space with at least $k+1$ points. Then the k-server problem on $\mathcal{M}$ has randomized competitive ratio $\Omega(\min\{\log k, \log\log|\mathcal{M}|\})$.*

If $\mathcal{M}$ is sufficiently large (exponential in k), then the lower bound in Conjecture 1.1 holds. For arbitrary spaces, in particular those whose size is polynomial in k, the lower bound is $\Omega(\log\log k)$. One of the main results of this paper is to improve this lower bound.

THEOREM 1.3. *For any metric space $\mathcal{M}$ with at least $k+1$ points, the k-server problem on $\mathcal{M}$ has randomized competitive ratio $\Omega(\sqrt{\frac{\log k}{\log\log k}})$.*

The competitive ratio of the k-server problem for $\mathcal{M}$ is at least as large as the ratio for a subspace of $\mathcal{M}$, as the adversary can restrict its requests to that subspace. Thus a lower bound on the competitive ratio of the k-server problem for the case that the space has exactly $k+1$ points implies the same lower bound for every metric space.

One way to view this special case is to think of the algorithm as occupying a single point of the space (corresponding to the unique location where there is no server) and to think of the adversary as probing points of this space. When the adversary probes the point on which the algorithm stands, the algorithm must move to a different location. We call this the *pursuit-evasion (PE) game* and call the adversary the pursuer and the algorithm the evader. This paper is about this game. It should be noted that the PE game bears a superficial resemblance to the cat-and-mouse game of [CDRS], but that game models the case of randomized algorithms against a more powerful adversary.

The PE game also models a problem in robotics. Imagine a robot walking down a long hallway of some width n (e.g., if $n = 3$, then the robot may walk either down the left side, the center, or the right side of the hallway). The hallway contains rectangular obstacles, and when the robot meets an obstacle, it must go left or right around it. Any algorithm at all must travel the length of the hallway, so we will not charge for that. Instead we look at the left/right motion of the robot and compare it to the least possible left/right motion by an algorithm that knew the placement of the obstacles in advance. If the hallway has width n, then this is the PE game for the metric space of n equally spaced points on the real line, a metric space we call $\mathcal{L}(n)$. The above lower bound of $\Omega(\sqrt{\frac{\log(n-1)}{\log\log(n-1)}})$ applies, of course, but for this case we have a better lower bound.

THEOREM 1.4. *The PE game on $\mathcal{L}(n)$ has randomized competitive ratio $\Omega(\frac{\log n}{\log\log n})$. Thus if $n > k$, the k-server problem on $\mathcal{L}(n)$ has competitive ratio $\Omega(\frac{\log k}{\log\log k})$.*

This nearly matches the conjectured bounds.

For general spaces $\mathcal{M}$, the special case of Conjecture 1.1 with $k = |\mathcal{M}| - 1$ can be stated as the following conjecture.

CONJECTURE 1.2. *For any metric space $\mathcal{M}$ on n points, the randomized competitive ratio of the PE game on $\mathcal{M}$ is $\Theta(\log n)$.*

As noted, the lower bounds of Conjectures 1.2 and 1.1 are equivalent. On the other hand, an upper bound for the PE game does not have immediate application to the upper bound conjecture for the general k-server problem. (In fact, there is some evidence that for $k = 2$ the competitive ratio might be worse for metric spaces with more than 3 points; see [LR].) In any case, we believe that a solution to the PE game would be a major step towards the solution of the more general problem and would also be interesting in its own right. (Since the appearance of a preliminary version of the present work, significant progress on this problem has been made. Bartal et al. [BBBT] gave a polylog(n) algorithm for the PE game, and more generally for any metrical task system.)

Previously, Conjecture 1.2 was known to be true only for the case of uniform (or nearly uniform) spaces mentioned earlier. Here, we establish Conjecture 1.2 for a dual situation. If $C > 1$, a metric space is *C-unbalanced* if for any three distinct points, the ratio of the largest distance to the smallest nonzero distance is at least C. For example, the metric space consisting of four points in a rectangle with side lengths 1 and C is C-unbalanced.

THEOREM 1.5. *There is a polynomial $p(n)$ such that for all n, the PE problem on any $p(n)$-unbalanced metric space with n points has randomized competitive ratio between $\ln n$ and $3 \ln n$.*

It is worth mentioning that bounds on the competitive ratio of the PE game carry over to the *task system* model of [BLS]. In particular, Theorems 1.3, 1.4, and 1.5 hold if we replace "the PE game on $\mathcal{M}$" by "the task system on $\mathcal{M}$."

1.1. Overview of the method. Theorems 1.3, 1.4, and 1.5 are proved as a consequence of a *decomposition theorem* for the competitive ratio of the PE game. (Henceforth, when we say "competitive ratio" we will mean the "randomized competitive ratio.") The theorem concerns metric spaces that can be split into two subspaces, where the diameter of each subspace is small relative to the overall diameter, and it asserts that the competitive ratio of the PE game on the whole space can be expressed almost exactly in terms of the competitive ratios of the games on the two subspaces.

To state this result, we need some notation. For a finite metric space $\mathcal{M}$, $\delta(\mathcal{M})$ denotes its diameter and $\lambda(\mathcal{M})$ denotes the competitive ratio of the associated PE game. We use the convention that the competitive ratio of a one point space is 0. A subspace $\mathcal{N}$ of $\mathcal{M}$ is said to be γ-*small* in $\mathcal{M}$ for $\gamma < 1$ if $\delta(\mathcal{N}) < \gamma\delta(\mathcal{M})$. We say that $\mathcal{M}$ is *bipartite* if it can be split into two subspaces $\mathcal{M}_L$ and $\mathcal{M}_R$ (called, respectively, the left space and the right space) such that the diameters of $\mathcal{M}_L$ and $\mathcal{M}_R$ are each less than $\delta(\mathcal{M})/2$. We call $(\mathcal{M}_L, \mathcal{M}_R)$ a *bipartition* of $\mathcal{M}$. It is easy to see that if a bipartition exists, then it is unique. If $\mathcal{M}$ is bipartite, then we say that it is γ-*bipartite* for $\gamma < 1/2$ if $\delta(\mathcal{M}_L)$ and $\delta(\mathcal{M}_R)$ are each γ-small in $\mathcal{M}$, and we call $(\mathcal{M}_L, \mathcal{M}_R)$ a γ-*bipartition* of $\mathcal{M}$.

The precise statement of our result is a bit long and is given as Theorem 1.7. We begin with a simpler version, useful when $\mathcal{M}_L$ and $\mathcal{M}_R$ have nearly the same competitive ratio.

THEOREM 1.6. *For any $\epsilon > 0$, there exists a polynomial p such that the following holds. Let $\mathcal{M}$ be a metric space with bipartition $(\mathcal{M}_L, \mathcal{M}_R)$. If $\lambda_{\min}$ and $\lambda_{\max}$ are real numbers such that $\lambda_{\min} \le \lambda(\mathcal{M}_R), \lambda(\mathcal{M}_L) \le \lambda_{\max}$, and each part is $\frac{1}{p(\lambda_{\max})}$-small in $\mathcal{M}$, then*

$$\lambda_{\min} + 1 - \epsilon \le \lambda(\mathcal{M}) \le \lambda_{\max} + 1 + \epsilon.$$

In other words, if $\mathcal{M}_R$ and $\mathcal{M}_L$ both have a competitive ratio close to λ, then the competitive ratio of $\mathcal{M}$ is close to $1 + \lambda$.

The decomposition theorem can be used to estimate the competitive ratio of the PE game on a space by partitioning it into smaller spaces and applying induction. The lower bound of the theorem can be applied to nonbipartite spaces by applying it to a bipartite subspace $\mathcal{N}$ and using $\lambda(\mathcal{N}) \le \lambda(\mathcal{M})$. For example, Theorem 1.4 can be derived as follows. Let $\epsilon = 1/2$ and let $p()$ be the increasing polynomial whose existence is given by Theorem 1.6. Let t be the greatest integer such that $\lceil p(\log n)\rceil^t \le n$ and let $n' = \lceil p(\log n)\rceil^t$. Note that $t = \Omega(\frac{\log n}{\log\log n})$. Let $j = n'/\lceil p(\log n)\rceil = \lceil p(\log n)\rceil^{t-1}$ and let $\mathcal{M}_L$ and $\mathcal{M}_R$ be the leftmost j points and rightmost j points of $\mathcal{M} = \mathcal{L}(n')$, respectively. By choice of j, either $\lambda(\mathcal{M}_L) > \log n$ and we are done, or else the condition on δ of Theorem 1.6 is satisfied. So $\lambda(\mathcal{L}(n)) \ge \lambda(\mathcal{L}(n')) \ge \lambda(\mathcal{M}_L \cup \mathcal{M}_R) \ge \lambda(\mathcal{M}_L) + 1/2$. We can continue on $\mathcal{M}_L$, letting $j' = j/\lceil p(\log n)\rceil$ and so forth until after t steps we have run out of points. The competitive ratio of $\mathcal{L}(n)$ is thus at least $t/2$, which is $\Omega(\frac{\log n}{\log\log n})$.

The full decomposition theorem provides sharp bounds on $\lambda(\mathcal{M})$ even if $\mathcal{M}_L$ and $\mathcal{M}_R$ have different competitive ratios. Define the function $Z(x)$ on nonnegative reals by $Z(x) = x/(e^x - 1)$ if $x > 0$ and $Z(0) = 1$. The theorem says that $\lambda(\mathcal{M})$ is well approximated by $\max\{\lambda(\mathcal{M}_L), \lambda(\mathcal{M}_R)\} + Z(|\lambda(\mathcal{M}_L) - \lambda(\mathcal{M}_R)|)$.

THEOREM 1.7. *Let $\mathcal{M}$ be a metric space with at least three points, having bipartition $(\mathcal{M}_R, \mathcal{M}_L)$. Let $\alpha_R, \alpha_L \ge 0$ and set $\alpha_{\max} = \max\{\alpha_R, \alpha_L\}$ and $\alpha_{\text{diff}} = |\alpha_R - \alpha_L|$. Let $\delta = \delta(\mathcal{M})$ and $\delta_{\max} = \max\{\delta(\mathcal{M}_L), \delta(\mathcal{M}_R)\}$. Suppose that $\alpha_{\max} \ge 1$ and that each part is $1/\max\{324\alpha_{\max}, \alpha_{\max}^3\}$-small in $\mathcal{M}$. Then*

1. *if* $\alpha_L \geq \lambda(\mathcal{M}_L)$ *and* $\alpha_R \geq \lambda(\mathcal{M}_R)$, *then* $\lambda \leq \alpha_{\max} + Z(\alpha_{\text{diff}})(1+\zeta)$, *and*

2. *if* $\alpha_L \leq \lambda(\mathcal{M}_L)$ *and* $\alpha_R \leq \lambda(\mathcal{M}_R)$, *then* $\lambda \geq \alpha_{\max} + Z(\alpha_{\text{diff}})(1-\zeta)$, *where* $\zeta = 23e^{\alpha_{\text{diff}}}\sqrt{\frac{\delta_{\max}}{\delta}\alpha_{\max}^3}$.

The proof of Theorem 1.7 consists of two parts. We introduce and completely analyze a new game, called the *walker-jumper* game, which abstracts the essential elements of the analysis of a decomposed problem. Then we formally demonstrate that the competitive ratio of a decomposed problem can be tightly bounded by the competitive ratio of an associated walker-jumper game.

Theorem 1.6 follows easily by applying the first part of Theorem 1.7 with $\alpha_L = \alpha_R = \lambda_{\max}$ and the second part of the Theorem with $\alpha_L = \alpha_R = \lambda_{\min}$.

Theorem 1.7 is combined with a Ramsey-type theorem for metric spaces to prove Theorem 1.3. The cases of Theorem 1.7 needed are the case where $\mathcal{M}_L$ and $\mathcal{M}_R$ have nearly the same competitive ratio, and the "highly unbalanced" case where $\mathcal{M}_L$ is large and $\mathcal{M}_R$ is a single point. The Ramsey-type theorem, which can be viewed as an extension of a theorem from [KRR], says, roughly, that any metric space of n points must contain at least one of the following *three* objects: (a) a roughly uniform space of around $2^{\sqrt{\log n/\log\log n}}$ points, (b) two highly separated spaces with small diameter, each having around $n/2^{\sqrt{\log n \log\log n}}$ points, or (c) one point very far from a small diameter subspace containing nearly all the rest (around $n - n/2^{\sqrt{\log n/\log\log n}}$ points). (For other Ramsey-like theorems for metric spaces, see [Mat].)

In section 3, we present an informal discussion of the proof to motivate the connection with the walker-jumper game. In section 4 we define the walker-jumper game and state a theorem which gives its exact competitive ratio, and we describe and prove the optimal strategies for each of the two players. The precise statement and proof of the lemma connecting the walker-jumper game to the decomposition theorem is given in section 5. The applications of the decomposition theorem needed to prove Theorems 1.3 and 1.5 are given in section 6, which can be read independently of the previous ones. It requires only the statement of the main decomposition theorem.

Section 5 is long and technical, although the underlying idea as sketched in section 3 is fairly intuitive. Two technical lemmas stated in that section, Lemmas 5.2 and 5.3, provide quantitative bounds on the additive constant that occurs in the definition of competitive ratio, and may be of independent interest. The proofs of these lemmas are deferred to the last section.

2. On-line games: Definitions and preliminary results.

2.1. Notation. As usual, $\mathbb{R}$ and $\mathbb{N}$ denote, respectively, the sets of real numbers and the set of nonnegative integers. The set $\{x \in \mathbb{R} : x \geq 0\} \cup \{\infty\}$ is denoted by $\mathbb{R}_\infty$.

We will need the following notation for sequences. Let X be a set. We denote by X^n the set of sequences consisting of n terms from X and $X^* = \bigcup_{n\geq 1} X^n$. An element of X^* is denoted in boldface as $\mathbf{x} = (x_1, x_2, \ldots, x_t)$; sequences are indexed from 1 unless otherwise noted. The number t of terms is called the *term length* of x and is denoted $|\mathbf{x}|$. If $j \leq t$, then we use $\mathbf{x}^j$ to denote the sequence consisting of the first j terms of $\mathbf{x}$. If $\mathbf{x}$ and $\mathbf{y}$ are sequences such that $\mathbf{x}^j = \mathbf{y}$ for some integer j, then we say that $\mathbf{y}$ is a *prefix* of $\mathbf{x}$ and that $\mathbf{x}$ is an *extension* of $\mathbf{y}$. If $\mathbf{x}$ and $\mathbf{y}$ are sequences, then $\mathbf{xy}$ denotes their concatenation.

If $\mathbf{x}$ is a sequence of real numbers of term length n, then $\mathbf{\Delta x}$ denotes the sequence of differences: $\Delta x_1 = x_1$ and for $2 \leq j \leq n$, $\Delta x_j = x_j - x_{j-1}$.

A metric space $\mathcal{M}$ consists of a set of points P and a symmetric nonnegative valued distance function defined on $P \times P$ that satisfies the triangle inequality and is zero only on the diagonal. We abuse notation and use $\mathcal{M}$ to denote both the metric space and the underlying set of points P. The associated metric is denoted by $d = d_{\mathcal{M}}$. $\mathcal{M}$ is assumed to be a finite set unless otherwise noted. The diameter of the space, $\delta = \delta(\mathcal{M})$, is the maximum distance between any pair of points.

A sequence of points in a metric space is referred to as a *walk* in the space. The domain of the distance function can be viewed as the set of walks of term length 2. We extend the domain of d to the set of all walks by defining $d(\mathbf{x})$ to be the sum of the distances between successive pairs of points. We refer to this as the *metric length* of the walk.

2.2. Two-player zero-sum games. The on-line algorithmic problems considered in this paper can be viewed as two-person zero-sum games. We recall some basic definitions and results about such games. A two-player zero-sum game G with players MAX and MIN is a triple $(S_{\mathrm{MAX}}, S_{\mathrm{MIN}}, C)$, where S_{MAX} and S_{MIN} are sets, and a *cost* function $C = C^G$, where $C : S_{\mathrm{MIN}} \times S_{\mathrm{MAX}} \to \mathbb{R}_\infty$. An element of S_{MAX} (resp., S_{MIN}) is called a *pure strategy* of MAX (resp., MIN). The game is *finite* if S_{MAX} and S_{MIN} are finite sets. It will be convenient to use an asymmetric notation: $C_q(r)$ denotes the value of this function for strategies $q \in S_{\mathrm{MIN}}$ and $r \in S_{\mathrm{MAX}}$. The value $C_q(r)$ is intuitively the cost to MIN given these two strategies.

In a *randomized instance* of the game, each player selects a probability distribution over its strategy set; such a distribution is called a *mixed strategy*. The set of mixed strategies for player X is denoted by $\tilde{S_X}$. Similarly, we denote a mixed strategy by a letter with a $\sim$ over it.

The cost of two mixed strategies $\tilde{q} \in \tilde{S}_{\mathrm{MIN}}$ and $\tilde{r} \in \tilde{S}_{\mathrm{MAX}}$, denoted by $C_{\tilde{q}}(\tilde{r})$, is the expected value of $C_q(r)$ with respect to the product distribution of the two strategies. The *value* of a mixed strategy $\tilde{r} \in \tilde{S}_{\mathrm{MAX}}$, denoted by $V_{\mathrm{MAX}}(\tilde{r})$, is the infimum of $C_{\tilde{q}'}(\tilde{r})$ over all $\tilde{q}' \in \tilde{S}_{\mathrm{MIN}}$ (which may be 0.) Similarly, for $\tilde{q} \in \tilde{S}_{\mathrm{MIN}}$, $V_{\mathrm{MIN}}(\tilde{q})$ is the supremum of $C_{\tilde{q}}(\tilde{r}')$ over all $\tilde{r}' \in \tilde{S}_{\mathrm{MAX}}$ (which may be $+\infty$.)

It is well known (and easy to show) that the value of a mixed strategy is determined by its cost with respect to pure strategies for the other player.

LEMMA 2.1. *Let G be a two-player zero-sum game.*

1. *For any mixed strategy $\tilde{r}$ for MAX, $V_{\mathrm{MAX}}(\tilde{r})$ is equal to the infimum of $C_q(\tilde{r})$ over all pure strategies $q \in S_{\mathrm{MIN}}$.*
2. *For any mixed strategy $\tilde{q}$ for* MIN*, $V_{\mathrm{MIN}}(\tilde{q})$ is equal to the supremum of $C_{\tilde{q}}(r)$ over all pure strategies $r \in S_{\mathrm{MAX}}$.*

The supremum of $V_{\mathrm{MAX}}(\tilde{r})$ over all $\tilde{r} \in \tilde{S}_{\mathrm{MAX}}$ is called the MAX-value of game G, and is denoted by $V_{\mathrm{MAX}}(G)$. A strategy $\tilde{r}$ that attains this supremum is called an *optimal* strategy for MAX. Similarly, the infimum of $V_{\mathrm{MIN}}(\tilde{q})$ over all $\tilde{q} \in \tilde{S}_{\mathrm{MIN}}$ is called the MIN-value of game G, and is denoted by $V_{\mathrm{MIN}}(G)$, and a strategy $\tilde{q}$ that attains this infimum is called an *optimal* strategy for MIN. In general, optimal strategies may exist for one, both, or neither player.

The following elementary result is easily proved.

LEMMA 2.2. *For any game G, $V_{\mathrm{MAX}}(G) \le V_{\mathrm{MIN}}(G)$.*

A game G is said to have the *min-max property* if (i) $V_{\mathrm{MAX}}(G) = V_{\mathrm{MIN}}(G)$ and (ii) both players have an optimal strategy. For such a game, the common value is denoted $V(G)$ and is called the *value* of the game. The following fundamental theorem of two-person games, known as the min-max theorem, was proved by von Neumann (see, e.g., [vNM]).

THEOREM 2.2.1. *Any finite two-player zero-sum game has the min-max property.*

A *subgame* of the game $G = (S_{\text{MAX}}, S_{\text{MIN}}, C)$ is a game $G' = (T_{\text{MAX}}, T_{\text{MIN}}, C)$, where $T_{\text{MAX}} \subseteq S_{\text{MAX}}$ and $T_{\text{MIN}} \subseteq S_{\text{MIN}}$. We say that G' is *equivalent* to G if (i) $V_{\text{MAX}}(G') = V_{\text{MAX}}(G)$, (ii) $V_{\text{MIN}}(G') = V_{\text{MIN}}(G)$, and (iii) MAX (resp., MIN) has an optimal strategy in G' if and only if MAX (resp., MIN) has an optimal strategy in G.

A subset $T_{\text{MAX}} \subseteq S_{\text{MAX}}$ *dominates* S_{MAX} with respect to the game G if for any strategy $r \in S_{\text{MAX}}$, there is a strategy $r' \in T_{\text{MAX}}$ such that $C_q(r') \geq C_q(r)$ for all $q \in S_{\text{MIN}}$. Similarly, a subset $T_{\text{MIN}} \subseteq S_{\text{MIN}}$ dominates S_{MIN} with respect to G if for any strategy $q \in S_{\text{MIN}}$, there is a strategy $q' \in T_{\text{MIN}}$ such that $C_{q'}(r) \leq C_q(r)$ for all $r \in S_{\text{MAX}}$. We have the following proposition.

PROPOSITION 2.1. *Let $G = (S_{\text{MAX}}, S_{MIN}, C)$ be a game, let $T_{\text{MAX}} \subseteq S_{\text{MAX}}$, and let $T_{\text{MIN}} \subseteq S_{\text{MIN}}$.*

1. *If T_{MAX} dominates S_{MAX} relative to G, then the subgame $(T_{\text{MAX}}, S_{\text{MIN}}, C)$ is equivalent to the game G.*
2. *If T_{MIN} dominates S_{MIN} relative to G, then the subgame $(S_{\text{MAX}}, T_{\text{MIN}}, C)$ is equivalent to the game G.*

Finally, we define the notion of the *competitive ratio* of a two-person game. Let G be a game whose payoff function is nonnegative. A *base-cost* function C_{BASE} for the game G is an $\mathbb{R}_\infty$-valued function defined on S_{MAX}. We say that the mixed strategy $\tilde{q}$ for MIN is *κ-competitive with respect to* C_{BASE} if there exists a constant K such that for any strategy r for MAX,

$$C_{\tilde{q}}(r) \leq \kappa C_{\text{BASE}}(r) + K.$$

The *competitive ratio* $\lambda = \lambda(G)$, with respect to C_{BASE}, is the infimum over all κ for which there is a κ-competitive algorithm, with respect to C_{BASE}.

A natural choice for a base-cost function is the *optimal cost function*, $C_{\text{OPT}}(r)$, which is defined as the infimum of $C_q(r)$ over all MIN-strategies q. (Notice that $C_{\text{OPT}}(r) = V_{\text{MAX}}(r)$.) In the context of on-line algorithms, the competitive ratio with base-cost $C_{\text{OPT}}(r)$ corresponds to the standard notion of the *randomized competitive ratio* of the associated on-line problem. We call C_{OPT} the *standard* base-cost function. In this paper, we will also have need to refer to nonstandard base-costs.

The following result gives a criterion for upper bounding the competitive ratio (which is slightly more general than the definition).

PROPOSITION 2.2. *Let G be a game with base-cost function C_{BASE}. Let $\kappa > 0$ and $f : \mathbb{R} \longrightarrow \mathbb{R}$ be a function such that $\lim_{x\to\infty} \frac{f(x)}{x} = \kappa$. Suppose that $\tilde{q}$ is a strategy for* MIN *such that for any strategy r for* MAX*,*

$$C_{\tilde{q}}(r) \leq f(C_{\text{BASE}}(r)).$$

Then $\lambda(G) \leq \kappa$.

Proof. It is easy to check that the hypothesis of the proposition implies that $\tilde{q}$ is $\kappa + \epsilon$ competitive for any positive ϵ, which implies that $\lambda \leq \kappa$. □

The following result gives a criterion for lower bounding the competitive ratio.

PROPOSITION 2.3. *Let G be a game with base-cost function C_{BASE}. Let $\kappa > 0$ and $f : \mathbb{R} \longrightarrow \mathbb{R}$ be a function such that $\lim_{x\to\infty} \frac{f(x)}{x} = \kappa$. Suppose that $\{\tilde{r_i} : i \in \mathbb{N}\}$ is a sequence of mixed strategies for* MAX *and $\{u_i : i \in \mathbb{N}\}$ is a sequence of real numbers tending to ∞, such that for each i, $C_{\text{BASE}}(\tilde{r_i}) \leq u_i$, and for each pure* MIN*-strategy q,*

$$C_q(\tilde{r_i}) \geq f(u_i).$$

Then $\lambda(G) \geq \kappa$.

Proof. It suffices to show that if $\epsilon > 0$, there is no $(\kappa - \epsilon)$-competitive algorithm $\tilde{q}$. Suppose, to the contrary, that $\tilde{q}$ is $(\kappa - \epsilon)$-competitive. Then there is a constant K such that for any pure strategy r

$$C_{\tilde{q}}(r) \leq (\kappa - \epsilon) C_{\mathrm{BASE}}(r) + K.$$

Now by taking expectation with respect to the distribution $\tilde{r}_i$, we get

$$\begin{aligned} C_{\tilde{q}}(\tilde{r}_i) &\leq (\kappa - \epsilon) C_{\mathrm{BASE}}(\tilde{r}_i) + K \\ &\leq (\kappa - \epsilon) u_i + K. \end{aligned}$$

For each i, there is a deterministic strategy q_i such that $C_{q_i}(\tilde{r}_i) \leq C_{\tilde{q}}(\tilde{r}_i)$. For that strategy we have $C_{q_i}(\tilde{r}_i) \leq (\kappa - \epsilon) u_i + K$. Thus by the hypothesis of the proposition, $f(u_i) \leq (\kappa - \epsilon) u_i + K$ for every i. This contradicts the hypothesis that $\lim_{x \to \infty} \frac{f(x)}{x} = \kappa$. □

Taking $u_i = C_{\mathrm{BASE}}(\tilde{r}_i)$ in the above Proposition yields the following corollary.

COROLLARY 2.3. *Let G be a game with base-cost function C_{BASE}. Let $\kappa > 0$ and $f : \mathbb{R} \longrightarrow \mathbb{R}$ be a function such that $\lim_{x \to \infty} \frac{f(x)}{x} = \kappa$. Suppose that $\{\tilde{r}_i : i \in \mathbb{N}\}$ is a sequence of mixed strategies for* MAX *such that $C_{\mathrm{BASE}}(\tilde{r}_i)$ tends to ∞ and such that for each i and for each pure* MIN*-strategy q*

$$C_q(\tilde{r}_i) \geq f(C_{\mathrm{BASE}}(\tilde{r}_i)).$$

Then $\lambda(G) \geq \kappa$.

2.3. The PE game: Definitions and preliminary results. The PE game for a metric space $\mathcal{M}$, denoted PE($\mathcal{M}$), is a two-person zero-sum game between two players, the pursuer (the MAX player) and the evader (the MIN player). Intuitively, the game is played as a sequence of rounds. At all times the evader is located at some point of the space. In each round, the pursuer probes some point of the metric space. If she picks the point containing the evader, then the evader must move to some other point; otherwise, the evader may stay where he is. The cost to the evader in responding to a sequence of probes is the total distance he travels.

In the language of two-player zero-sum games, the set of pure strategies of the pursuer is the set $\mathcal{M}^*$ of all finite sequences from the metric space. Such sequences are referred to as *probe* sequences. A sequence σ is said to be a *response sequence* for the probe sequence ρ if it has the same term length as ρ and $\sigma_i \neq \rho_i$ for all i. The point σ_i represents the location of the evader at time i. The pure strategies for the evader are called *deterministic response algorithms* or, simply, *deterministic algorithms*. A response algorithm A maps each probe sequence ρ to a response sequence $A(\rho)$ subject to the following consistency requirement: for any probe sequence ρ and point a, $A(\rho a)$ extends $A(\rho)$. The consistency requirement formalizes the intuition that the algorithm determines the response sequence of the evader in an on-line manner, i.e., the ith response depends only on the first i probes.

The cost function $C_A(\rho)$ is defined to be $d(A(\rho))$, the metric length of the response sequence generated by the algorithm A on input ρ. $C_{\mathrm{OPT}}(\rho)$ denotes the minimum of $C_A(\rho)$ over all algorithms A. It is easy to see that this is the same as the minimum metric length of a response sequence for ρ. (Note that in our definition, the evader is allowed to choose his own starting point σ_1 at no cost. Other authors specify a starting point σ_0 and charge the evader an additional $d(\sigma_0, \sigma_1)$. This is a matter of convention that does not affect the results.)

A mixed strategy for the pursuer is a probability distribution $\tilde{\rho}$ over probe sequences. A mixed strategy for the evader, called a *randomized response algorithm*, is a probability distribution $\tilde{A}$ over response algorithms. Since the set of pure strategies for the evader is uncountable, a probability distribution cannot be specified simply by assigning a probability value to each strategy. The general approach to mixed strategies on infinite strategy spaces requires measure theory; in our case the measure theoretic definition can be restated in algorithmic terms: in a randomized algorithm the sth move of the evader is chosen according to some probability distribution on $\mathcal{M}$, where the probability distribution may depend on the first s moves by the pursuer and the first $s-1$ responses of the evader.

We can define a randomized response algorithm formally via *decision trees*. Let $T = T_{\mathcal{M}}$ denote the infinite rooted tree of degree $|\mathcal{M}|$ where the edges from each node are in one-to-one correspondence with the points of $\mathcal{M}$ and the nodes are labeled as follows. The root is labeled P (for pursuer), the children of the root are labeled E (for evader), and the remaining nodes are labeled inductively P or E so that labels alternate along each path from the root. We can represent a (randomized) on-line response algorithm $\tilde{A}$ by assigning to each E-node v a probability distribution on $\mathcal{M}$, i.e., a nonnegative function p_v on $\mathcal{M}$ whose values sum to 1. On probe sequence $\rho_1, \rho_2, \ldots, \rho_k$, the algorithm follows the branch labeled ρ_1 from the root. It chooses its response according to the probability distribution p_v for its node, and it follows the corresponding branch from v to the next P node. It then processes each successive probe in the same way, following down the tree to depth $2k$.

As in section 2.2, we extend the definition of the cost function C to randomized strategies by defining $C_{\tilde{A}}(\tilde{\rho})$ to be the expectation of $C_A(\rho)$ with respect to the product distribution of $\tilde{A}$ and $\tilde{\rho}$. Also, $C_{\mathrm{OPT}}(\tilde{\rho})$ is the expectation of $C_{\mathrm{OPT}}(\rho)$ with respect to the distribution $\tilde{\rho}$. (It is important here to emphasize $C_{\mathrm{OPT}}(\tilde{\rho})$ is *not* the same as the minimum of $C_A(\tilde{\rho})$ over all A. In computing the former, we choose the best algorithm for each deterministic ρ and average the cost with respect to $\tilde{\rho}$, while in the latter we choose the one algorithm that minimizes the average cost with respect to $\tilde{\rho}$.)

For $s > 0$, an *s-block* of $\mathcal{M}$ is a prefix-minimal probe sequence whose optimal cost is at least $s-\delta$. In other words, ρ is an s-block if $C_{\mathrm{OPT}}(\rho) \geq s-\delta$, but $C_{\mathrm{OPT}}(\tau) < s-\delta$ for any proper prefix τ of ρ. In the nondegenerate case that $\mathcal{M}$ has at least two points, an s-block ρ satisfies $s - \delta \leq C_{\mathrm{OPT}}(\rho) < s$ since the last step can increase C_{OPT} by at most δ. In the degenerate case that $\mathcal{M}$ consists of a single point p, we define an s-block to be the singleton sequence.

Any probe sequence ρ can be parsed uniquely into subsequences $\rho_{\mathbf{1}}\rho_{\mathbf{2}}\ldots\rho_{\mathbf{k}}$ where each successive $\rho_{\mathbf{i}}$ except possibly the last is an s-block. We refer to this as the *s-block partition* of ρ.

The competitive ratio of $PE(\mathcal{M})$ is defined in terms of the standard base-function C_{OPT} and is denoted by $\lambda(\mathcal{M})$. For brevity, we often refer to this as the *competitive ratio of* $\mathcal{M}$. It is trivial that the competitive ratio of a two-point space is 1. From the previously noted result of [MMS] (which was proved for the deterministic competitive ratio), we have the following lemma.

LEMMA 2.4. *For any* $\mathcal{M}$, $\lambda(\mathcal{M}) \leq |\mathcal{M}| - 1$.

The PE game on a one-point space does not really make sense. However, it will be convenient to adopt the convention that the competitive ratio of a one-point space is 0. With that definition, the main decomposition theorem will hold when one or both spaces is a one-point space.

The following fact is both well known and easy to prove.

PROPOSITION 2.4. *For any metric space $\mathcal{M}$ and subspace $\mathcal{N}$, $\lambda(\mathcal{M}) \geq \lambda(\mathcal{N})$.*

3. An overview of the decomposition theorem. We are working in a space $\mathcal{M}$ with bipartition $(\mathcal{M}_L, \mathcal{M}_R)$, which we call the *left* space and the *right* space. In the present discussion, we assume that each space has at least two points; the degenerate case that one of the spaces consists of a single point will require special treatment, which we delay until later. The assumptions of the theorem imply that the distances within each subspace are small relative to distances between the two subspaces.

We want to express the competitive ratio of the big space in terms of the competitive ratio of each of the two subspaces. The key idea is to abstract the behaviors of the pursuer and the evader so as to focus on their movements *between* the spaces, treating their movements within each space as a "black box." This idea leads to the formulation of a new game, called the walker-jumper game, which abstracts the PE game for such a partitioned space. This game is defined and analyzed in the next section, and the proof of the decomposition theorem is then completed in the following section.

The proof is technical, but the underlying idea is natural. In this section, we provide intuition for the proof with an informal discussion that leads naturally to the definition of the walker-jumper game. Throughout the section we make various plausible but unjustified assumptions and approximations, which will be cleaned up in the proof.

At each point in the game, the evader is either "on the left" or "on the right." While the pursuer probes the opposite space, the evader need do nothing. While the pursuer probes the subspace occupied by the evader, it seems apparent that either the evader should follow his optimal randomized response algorithm for that space (achieving, over that interval of moves, a competitive ratio equal to that for that space) or he should move to the other space. By randomizing his choice of when to switch between spaces, he can hope to "fool" the pursuer as to his location.

We view the probe sequence of the pursuer as a sequence of left phases and right phases, where a left (resp., right) phase consists of moves in the left (resp., right) space. When the evader uses a randomized strategy, the pursuer will only have a probability distribution on the location of the evader. In order to maximize the competitive ratio, the pursuer wants to construct a probe sequence that (i) has a good chance of catching the evader often, and (ii) has a low off-line cost. For the first goal, it would seem that she should always probe on the side with higher probability of containing the evader, while for the second goal, it would seem that she would do well to avoid switching between spaces too often (this will make it easier for an off-line algorithm to "hide" safely in one space for long intervals of moves) and thus should tend to make each phase long.

For $s > 0$, we defined an s-block to be a prefix-minimal probe sequence of cost at least $s - \delta$, and we observed that its cost is at most s. For some large integer D (to be specified later) we define $s = \delta/D$, where δ is the diameter of $\mathcal{M}$, and define a *left block* (resp., *right block*) to be a probe sequence which is an s-block with respect to the space $\mathcal{M}_L$ (resp., $\mathcal{M}_R$). Note that an s-block for $\mathcal{M}_L$ or $\mathcal{M}_R$ is not an s-block with respect to the entire space; indeed, any such block has 0 optimal cost with respect to the entire space since an off-line evader will respond by staying at one location on the opposite space.

Recall that the s-block partition provides a canonical way to parse every probe sequence from a space as a concatenation of sequences, each of which, except possibly the last, is an s-block. For a given probe sequence of $\mathcal{M}$, parse each left phase

according to its s-block partition with respect to $\mathcal{M}_L$ and parse each right phase similarly. It is reasonable to expect that if s is small relative to the typical cost of a phase, then we may ignore the "remainder" block of the phase and simply assume that each left (resp., right) phase is a concatenation of left (resp., right) blocks.

With this assumption, we view the entire probe sequence as a sequence of left and right blocks. If the pursuer chooses to add a right block, it would seem natural that she select the right block so that, assuming the evader is on the right, the expected cost to the evader is maximized. This expected cost cannot exceed $s\lambda_R$ (by much) since the evader can follow his λ_R-competitive strategy for the space $\mathcal{M}_R$. On the other hand, the pursuer can force an evader who stays on the right to incur nearly this much (in expectation) by selecting her right block according to her optimal randomized s-block strategy $\tilde{\rho}_{\mathbf{s}} = \tilde{\rho}_{\mathbf{s}}(\mathcal{M}_R)$. Similarly, when the pursuer picks a left block, she can force an evader who stays on the left to pay roughly $s\lambda_L$.

To summarize, when the pursuer adds a block, if the evader is on the opposite side, he pays nothing. If the evader is on the same side, he either moves to the other side immediately, paying roughly δ, or he stays on the original side and incurs an expected cost of $s\lambda_R$ or $s\lambda_L$ depending on the side. We assume that δ is much larger than both $s\lambda_R$ and $s\lambda_L$ so that it would not pay for him to move to the opposite side at the beginning and back at the end of the block.

Thus we have a good approximation to the cost of each block to the evader, depending only on (i) the side from which each block is chosen by the pursuer, and (ii) the side on which the evader finishes responding to each block.

We would like to get a similar estimate for the off-line cost. For each probe sequence ρ, define $C_L(\rho)$ to be the minimum cost of a response sequence σ whose last point is on the left and $C_R(\rho)$ in the analogous way. We refer to these, respectively, as the left-optimal and right-optimal cost of ρ. The optimal cost of ρ is just the minimum of these. Since they clearly differ by at most the diameter δ of $\mathcal{M}$, we may take $C_R(\rho)$ as a good estimate of $C_{\mathrm{OPT}}(\rho)$. We want to understand how C_L and C_R change when the pursuer adds a left block or a right block. So let ρ be the sequence constructed so far and consider adding a right block β. It is easy to see that $C_L(\rho\beta) = C_L(\rho)$, as $C_L(\rho\beta) = \min\{C_L(\rho), C_R(\rho)+\delta\}$ and $C_L(\rho) \le C_R(\rho)+\delta$. On the other hand, we can estimate $C_R(\rho\beta) \approx \min\{C_L(\rho)+\delta, C_R(\rho)+s\}$, where the two terms correspond to the two choices of the off-line evader: either finish the previous block on the left and move right only at the end of β or finish the previous block on the right and respond to β on the right.

Let us summarize this discussion by considering the evolution of the parameter $w = (C_R - C_L)/s$. Note that w is always between $-D$ and D. Each right block increases w by (roughly) 1, subject to $w \le D$ and, similarly, each left block decreases w by 1, subject to $w \ge -D$. It is useful to visualize the evolution of w as a walk on the integer points between $-D$ and D. A right step corresponds to w being increased by 1, and C_R being increased by s. Similarly, a left step corresponds to w being decreased by 1, and C_L being decreased by s.

Notice that if the pursuer adds a right block that causes w to reach D, then the pursuer may add an arbitrary number of right blocks without affecting C_L, C_R, or w. Let us assume that she does this, i.e., a right step from $D-1$ to D corresponds to a huge number of right blocks. The effect of this on the evader is clear: on such a step he must move to the left space (if he is not there already) or incur a huge cost. (Note that the evader can compute C_R, C_L, and w on-line and thus recognize this situation). Similarly, we may assume that a left step from $1-D$ to $-D$ corresponds

to a huge number of left blocks and the evader must move to the right space.

Having associated the pursuer's probe sequence to a walk on the integer line, we now can make the following estimates of the off-line cost and the evader's cost. The off-line cost is estimated by s times the number of steps to the right. The evader's cost is 0 on any step that is taken in the direction opposite the space he occupies. On a step taken in the direction of the space that he occupies, his cost is sD if he chooses to move to the other space and is $s\lambda_R$ or $s\lambda_L$ (depending on his space) if he chooses to stay in his space. Whenever a right (resp., left) step is taken that reaches D (resp.,$-D$), the evader must move to the left (resp., right) space.

This idealization suggests that we can model our problem by a game between two players, the *walker* who walks on the line (and corresponds to the pursuer) and the *jumper* who jumps between the left and right side (and corresponds to the evader). In the next section we define this game precisely and analyze it. In the succeeding section, we then formally show how to use the analysis of this game to establish the decomposition theorem.

4. Walker-jumper games. The walker-jumper game $WJ[D, \alpha_R, \alpha_L]$ has parameters D, a positive integer, and nonnegative real numbers α_R and α_L. The players are referred to as the walker (Wendy) and the jumper (Jack). The game "board" is the set $I_D = \{-D, -D+1, \ldots, D-1, D\}$. At each integer time $t \geq 0$, the position of the game is the ordered pair (w_t, j_t), where $w_t \in I_D$ is Wendy's position and $j_t \in \{-D, D\}$ is Jack's location. The initial position for Wendy is $w_0 = 0$, and Jack can choose either $j_0 = -D$ or $j_0 = D$.

At each time t, a legal move for Wendy consists of one step either to the left ($w_t = w_{t-1} - 1$) or to the right ($w_t = w_{t-1} + 1$). If $|w_t| = D$, Wendy has only one legal move. Thus the sequence $\mathbf{\Delta w}$ defined by $(\Delta w)_i = w_i - w_{i-1}$ has entries in the set $\{-1, 1\}$. We refer to Δw_i as the *direction* of move i. A move of -1 (resp., $+1$) will be referred to as a left move (resp., right move). Also, for convenience of notation, we sometimes use α_{-1}, α_1 in place of α_L, α_R.

Jack's answer to request w_t is either to stay where he is ($j_t = j_{t-1}$) or to *jump* to his other allowed position ($j_t = -j_{t-1}$). Jack's moves are subject to the constraint that $j_t \neq w_t$, i.e., if Wendy arrives at Jack's location ($w_t = j_{t-1}$), then Jack must jump ($j_t = -w_t$).

If $j_t = (\Delta w)_t D$, i.e., Wendy's move at time t brought her closer to the location that Jack occupies *after* his move, then we say that Wendy *hit* Jack; it is a *left hit* or a *right hit* depending on the direction of Wendy's move.

Formally, a (pure) strategy for Wendy (a request sequence) is given by a sequence $\mathbf{w} = (w_0 = 0, w_1, w_2, \ldots)$ having entries in I_D and satisfying $|w_t - w_{t-1}| = 1$ for each $t > 0$. A pure strategy for Jack is a function (algorithm) A that maps each finite request sequence $\mathbf{w} = (0, w_1, \ldots, w_s)$ to a sequence $(j_0, j_1, j_2, \ldots j_s)$ in $\{-D, D\}^{s+1}$. The map satisfies the constraint $A(\mathbf{w})_i \neq w_i$ for each i, and it also satisfies the consistency constraint that if $\mathbf{w}$ is an extension of $\mathbf{v}$, then $A(\mathbf{w})$ is an extension of $A(\mathbf{v})$; this constraint means that A is an on-line algorithm. As usual, we also consider randomized strategies for both players. A randomized strategy for Wendy is a probability distribution $\tilde{\mathbf{w}}$ on request sequences and a randomized strategy for Jack is a probability distribution $\tilde{A}$ on algorithms.

The cost function for algorithm A on request sequence $\mathbf{w}$, $C_A(\mathbf{w})$ (representing the cost to Jack), is given as follows.

1. Each jump by Jack costs him D.
2. Each right hit by Wendy costs Jack α_R.

3. Each left hit by Wendy costs Jack α_L.

Thus the cost of step t to Jack, $(\Delta C_A(\mathbf{w}))_t = C_A(\mathbf{w^t}) - C_A(\mathbf{w^{t-1}})$, can be written as

$$(\Delta C_A(\mathbf{w}))_t = D\chi(j_t = -j_{t-1}) + \alpha_{((\Delta w)_t)}\chi(j_t = (\Delta w)_t D),$$

where for the predicate P, $\chi(P) = 1$ if P is true and 0 otherwise.

As usual, if $\tilde{A}$ and $\tilde{\mathbf{w}}$ are randomized strategies, then $C_{\tilde{A}}(\tilde{\mathbf{w}})$ is defined to be the expectation of $C_A(\mathbf{w})$ with respect to the distributions.

We are interested in the competitive ratio $\lambda = \lambda(WJ[D, \alpha_R, \alpha_L])$ of this game with respect to a nonstandard base-cost function: $C_{\mathrm{BASE}}(\mathbf{w})$ is the total number of steps to the right. Note that $C_{\mathrm{BASE}}(\mathbf{w})$ is within $\pm D$ of $|\mathbf{w}|/2$. Applying Proposition 2.2, we obtain the following criterion for upper bounding λ.

COROLLARY 4.1. *Let $\tilde{A}$ be an algorithm for Jack. Suppose that b is a positive real such that for all $j \in \mathbb{N}$ and sequences $\mathbf{w}$ of term length j*

$$C_{\tilde{A}}(\mathbf{w}) \le j(b + g(j)),$$

where $g(j)$ is a function that tends to 0 as j tends to ∞. Then $\lambda \le 2b$.

Proof. Let $g'(x) = \max_{\{d:-D\le d\le D\}} g(x+d)$. The hypothesis implies that for any $\mathbf{w}$, $C_{\tilde{A}}(\mathbf{w}) \le (C_{\mathrm{BASE}}(\mathbf{w}) + D/2)(b + g'(C_{\mathrm{BASE}}(\mathbf{w})))$. So the corollary follows if we take $f(x) = (x + D/2)(b + g'(x))$, and $c = 2b$ in Proposition 2.2. □

Similarly, we get a criterion for lower bounding λ from Corollary 2.3. Recall that $\mathbf{w^j}$ denotes the prefix of $\mathbf{w}$ up to w_j.

COROLLARY 4.2. *Let $g(j) \to 0$ as $j \to \infty$. Let $\tilde{\mathbf{w}}$ be a distribution over infinite sequences for Wendy. Suppose that b is a positive real such that for any algorithm A for Jack and $j \in \mathbb{N}$,*

$$C_A(\tilde{\mathbf{w}}^{\mathbf{j}}) \ge j(b - g(j)).$$

Then $\lambda \ge 2b$.

An algorithm A for Jack is called *lazy* if Jack never jumps when Wendy moves away from him, i.e., if $(\Delta w)_t \ne j_{t-1}/D$, then $j_t = j_{t-1}$. It is easy to show that any nonlazy strategy is dominated by some lazy one in the sense that the lazy strategy performs at least as well on any request sequence by Wendy. Thus we may assume that Jack is restricted to lazy strategies.

We consider only the case that D is at least $\alpha_{\max} = \max\{\alpha_R, \alpha_L\}$. To develop some intuition for this game, let us first show that $\alpha_{\max} \le \lambda \le \alpha_L + \alpha_R + 1$.

To see the lower bound assume, without loss of generality, that $\alpha_L \ge \alpha_R$ and consider the following pure strategy for Wendy: move right D times to position D, and then, alternately, move between $D-1$ and D. Each time Wendy moves from D to $D-1$, Jack must start at $-D$ and pays $\alpha_{\max}$ (if he doesn't move) or D (if he does). After j steps by Wendy, Jack's cost is at least $\alpha\frac{j-D}{2} = j(\frac{\alpha_{\max}}{2} - \frac{D\alpha_{\max}}{2j})$. Applying Corollary 4.2 yields a lower bound of $\alpha_{\max}$ on the competitive ratio.

To see the upper bound of $\alpha_L + \alpha_R + 1$, consider the following pure strategy for Jack: never jump unless a jump is required (because Wendy arrives at the same location). On any j step sequence, Wendy takes at most $j/2 + D$ steps in each direction (since the number of left steps differs from the number of right steps by at most D) and Jack jumps at most $j/(2D)$ times (since he jumps at most once every $2D$ steps). Thus Jack's cost can be bounded above by $(\alpha_R + \alpha_L)(j/2 + D) + j/2$.

Applying Corollary 4.1 implies an upper bound of $\alpha_R + \alpha_L + 1$ on the competitive ratio.

As we shall see, the trivial lower bound above is much closer to the truth than the trivial upper bound. The main result of this section is an exact expression for the competitive ratio $\lambda(WJ[D, \alpha_R, \alpha_L])$. Define $\beta_R = 1 - \alpha_R/2D$ and $\beta_L = 1 - \alpha_L/2D$.

THEOREM 4.2.1. *For nonnegative real numbers α_R and α_L and positive integer $D \geq max\{\alpha_L, \alpha_R\}$, the competitive ratio λ of the game $WJ[D, \alpha_R, \alpha_L]$ is given by*

$$\lambda = \begin{cases} \alpha_R + \beta_R & \text{if } \alpha_R = \alpha_L, \\ \frac{\alpha_R \beta_L^{2D} - \alpha_L \beta_R^{2D}}{\beta_L^{2D} - \beta_R^{2D}} & \text{if } \alpha_R \neq \alpha_L. \end{cases}$$

Using elementary estimates and recalling that we defined $Z(x) = x/(e^x - 1)$ for $x > 0$ and $Z(0) = 1$, we obtain the following corollary.

COROLLARY 4.3. *For nonnegative real numbers α_R and α_L, define $\alpha_{\max} = \max\{\alpha_R, \alpha_L\}$ and $\alpha_{\text{diff}} = |\alpha_R - \alpha_L|$. Suppose that $\alpha_{\max} \geq 1$. Let $D \geq \alpha_{\max}^2$ be a positive integer. Then the competitive ratio λ of $WJ[D, \alpha_R, \alpha_L]$ satisfies*

$$\alpha_{\max} + Z(\alpha_{\text{diff}})(1 - \epsilon) \leq \lambda \leq \alpha_{\max} + Z(\alpha_{\text{diff}})(1 + \epsilon),$$

where $\epsilon = \frac{4\alpha_{\max}^2}{D}$.

We first deduce the corollary from the theorem.

Proof of Corollary 4.3. The case $\alpha_R = \alpha_L$ is trivial since $Z(0) = 1$. So assume $\alpha_R \neq \alpha_L$. From the theorem and simple algebraic manipulation, we get

$$\lambda = \frac{\alpha_R \beta_L^{2D} - \alpha_L \beta_R^{2D}}{\beta_L^{2D} - \beta_R^{2D}} = \alpha_{\max} + \frac{\alpha_{\text{diff}}}{(1 + \frac{\alpha_{\text{diff}}}{2D - \alpha_{\max}})^{2D} - 1}.$$

To prove the corollary, we need to show that for $\epsilon = 4\alpha_{\max}^2/D$

$$\left| \frac{1}{(1 + \frac{\alpha_{\text{diff}}}{2D - \alpha_{\max}})^{2D} - 1} - \frac{1}{e^{\alpha_{\text{diff}}} - 1} \right| \leq \frac{\epsilon}{e^{\alpha_{\text{diff}}} - 1},$$

or, equivalently,

$$\left| \frac{(1 + \frac{\alpha_{\text{diff}}}{2D - \alpha_{\max}})^{2D} - e^{\alpha_{\text{diff}}}}{(1 + \frac{\alpha_{\text{diff}}}{2D - \alpha_{\max}})^{2D} - 1} \right| \leq \epsilon.$$

Note that $(1 + \frac{\alpha_{\text{diff}}}{2D - \alpha_{\max}})^{2D} \geq e^{\alpha_{\text{diff}}}$ by taking $x = (2D - \alpha_{\text{diff}})/\alpha_{\text{diff}}$ in the inequality $(1 + 1/x)^{x+1} \geq e$, which holds for all positive x. Thus we may remove the absolute value from the inequality to be proved. Replacing the denominator by a smaller quantity, it now suffices to show that

$$\frac{(1 + \frac{\alpha_{\text{diff}}}{2D - \alpha_{\max}})^{2D} - e^{\alpha_{\text{diff}}}}{e^{\alpha_{\text{diff}}} - 1} \leq \epsilon.$$

Next we upper bound $(1 + \frac{\alpha_{\text{diff}}}{2D - \alpha_{\max}})^{2D}$:

$$\begin{aligned} \left(1 + \frac{\alpha_{\text{diff}}}{2D - \alpha_{\max}}\right)^{2D} &= e^{2D \ln(1 + \frac{\alpha_{\text{diff}}}{2D - \alpha_{\max}})} \leq e^{\frac{2D\alpha_{\text{diff}}}{2D - \alpha_{\max}}} \leq e^{\alpha_{\text{diff}}} e^{\frac{\alpha_{\text{diff}}\alpha_{\max}}{2D - \alpha_{\max}}} \\ &\leq e^{\alpha_{\text{diff}}} e^{\frac{\alpha_{\text{diff}}\alpha_{\max}}{D}} \leq e^{\alpha_{\text{diff}}} \left(1 + \frac{2\alpha_{\text{diff}}\alpha_{\max}}{D}\right). \end{aligned}$$

(The last inequality uses the assumption $\alpha_{\max}^2 \le D$.) Thus it suffices to show

$$\frac{e^{\alpha_{\text{diff}}} 2\alpha_{\text{diff}}\alpha_{\max}/D}{e^{\alpha_{\text{diff}}}-1} \le \epsilon.$$

If $e^{\alpha_{\text{diff}}} \le 2$, then since the denominator is at least α_{diff}, the expression on the left is at most $4\alpha_{\max}/D$. If $e^{\alpha_{\text{diff}}} > 2$, then $e^{\alpha_{\text{diff}}}/(e^{\alpha_{\text{diff}}}-1) < 2$, and the expression is at most $4\alpha_{\text{diff}}\alpha_{\max}/D \le 4\alpha_{\max}^2/D$. □

We now return to the proof of Theorem 4.2.1. This is proved in two parts.

1. We analyze a specific randomized algorithm for Jack and use Corollary 4.1 to obtain an upper bound on λ.
2. We analyze a specific randomized strategy for Wendy (a probability distribution on request sequences) and use Corollary 4.2 to obtain a lower bound on λ.

4.1. The upper bound: A strategy for the jumper. We begin with an explicit description of a randomized strategy for Jack. The strategy is simple but not particularly intuitive; we will motivate it as we analyze it.

Jumper strategy.

1. The strategy is defined in terms of $2D+1$ parameters $0 = p_{-D} < p_{-D+1} < p_{-D+2} < \cdots < p_{D-1} < p_D = 1$, which are specified below. Initially, Jack chooses his initial position to be $-D$ with probability p_0. At round $t+1$, if Wendy moves in the direction away from j_t, Jack does not move. If $j_t = D$ and Wendy moves rightward from $w_t = j-1$ to $w_{t+1} = j$, then Jack moves to $-D$ with probability $\frac{p_j - p_{j-1}}{1-p_{j-1}}$. The probability of jumping from D to $-D$ is chosen so that if Jack occupied $-D$ with probability p_{j-1}, then Jack is now at $-D$ with probability $p_{j-1} + (1-p_{j-1})\frac{p_j - p_{j-1}}{1-p_{j-1}} = p_j$. If $j_t = -D$ and Wendy moves leftward from $w_t = j+1$ to $w_{t+1} = j$, then Jack moves to D with probability $\frac{p_{j+1}-p_j}{p_{j+1}}$. Here, the probability of jumping from $-D$ to D is chosen so that if Jack occupied $-D$ with probability p_{j+1}, then Jack is now at $-D$ with probability $p_{j+1}(1 - \frac{p_{j+1}-p_j}{p_{j+1}}) = p_j$.
   Notice that this strategy ensures that at all times t, Jack is at $-D$ with probability p_{w_t}: at the start, Wendy is at location 0 and Jack is at $-D$ with probability p_0; and, as noted above, this property is maintained inductively.
2. The parameters p_i that are used are given by

$$p_i = \begin{cases} \frac{1}{2} + \frac{i}{2D} & \text{if } \alpha_R = \alpha_L, \\ \frac{\beta_L^i \beta_R^{2D-i} - \beta_R^{2D}}{\beta_L^{2D} - \beta_R^{2D}} & \text{if } \alpha_R \ne \alpha_L. \end{cases}$$

For a given sequence $\mathbf{w}$ for Wendy, let $N_{j,j'} = N_{j,j'}(\mathbf{w})$ be the total number of steps that Wendy takes from j to j' (which can be nonzero only if $j' \in \{j-1, j+1\}$). Recall that each right hit costs Jack α_R, each left hit costs Jack α_L, and each jump costs Jack D. So each time Wendy takes a step from j to $j+1$, Jack pays α_R with probability $1-p_{j+1}$ (the probability Jack is at D after the step is taken) and pays D with probability $p_{j+1} - p_j$. Similarly, each time Wendy moves from $j+1$ to j, Jack's expected cost is $p_j\alpha_L + (p_{j+1} - p_j)D$. Therefore, we can express the expected cost to Jack of the sequence $\mathbf{w}$ as

$$C_{\tilde{A}}(\mathbf{w}) = \sum_{j=-D}^{D-1} N_{j,j+1}((1-p_{j+1})\alpha_R + (p_{j+1}-p_j)D) + N_{j+1,j}(p_j\alpha_L + (p_{j+1}-p_j)D)$$
$$\leq \sum_{j=-D}^{D-1} (N_{j,j+1}+1)((1-p_{j+1})\alpha_R + p_j\alpha_L + 2(p_{j+1}-p_j)D).$$

The inequality follows from the fact that $N_{j,j+1}+1 \geq N_{j+1,j}$.

The expression $r_j = (1-p_{j+1})\alpha_R + p_j\alpha_L + 2(p_{j+1}-p_j)D$ that multiplies $N_{j,j+1}$ can be interpreted as the expected cost to Jack if Wendy makes a "round trip" from j to $j+1$. The specific definition of p_j given in Jack's strategy was chosen so that r_j is the same for all j. These values can be determined by introducing a parameter K, setting the $r_j = K$ for each j, solving the resulting linear recurrence relation for p_j, and then using $\sum p_j = 1$ to determine K. As is easily verified, this yields

$$K = \begin{cases} \alpha_R + \beta_R & \text{if } \alpha_R = \alpha_L, \\ \frac{\alpha_R\beta_L^{2D} - \alpha_L\beta_R^{2D}}{\beta_L^{2D} - \beta_R^{2D}} & \text{if } \alpha_R \neq \alpha_L. \end{cases}$$

As noted, $\sum_{j=-D}^{D-1} N_{j,j+1} \leq \frac{1}{2}|\mathbf{w}| + D$. This leads to

$$C_{\tilde{A}}(\mathbf{w}) \leq \sum_{j=-D}^{D-1} (N_{j,j+1}+1)r_j$$
$$\leq K \sum_{j=-D}^{D-1} (N_{j,j+1}+1)$$
$$\leq \frac{1}{2}|\mathbf{w}|K + 3DK.$$

Applying Corollary 4.1 yields $\lambda \leq K$, as desired.

4.2. The lower bound: A strategy for the walker. We now prove a matching lower bound by describing and analyzing a randomized strategy for Wendy. As for the upper bound, the strategy is simple; we describe it first and motivate it as we analyze it. Essentially, Wendy's strategy is to follow a biased random walk on the line, where the bias to the left or right depends on the direction taken in the previous step.

Walker strategy.

1. The strategy is defined in terms of two parameters σ_R and σ_L, which are real numbers between 0 and 1. If $w_t = D$ or $w_t = -D$, then w_{t+1} is forced. Otherwise, $|w_t| < D$ and Wendy moves as follows. If move t was to the right ($w_t = w_{t-1}+1$), then Wendy goes left at step $t+1$ with probability σ_L and to the right with probability $1-\sigma_L$. Similarly, if move t was to the left ($w_t = w_{t-1}-1$), then Wendy goes right at step $t+1$ with probability σ_R and to the left with probability $1-\sigma_R$.
2. The parameters σ_R and σ_L are defined by $\sigma_R = \alpha_L/2D = 1-\beta_L$ and $\sigma_L = \alpha_R/2D = 1-\beta_R$.

The intuition behind this strategy is the following. We want to choose a strategy for Wendy that guarantees that the ratio of Jack's cost to the base-cost is at least a certain value, regardless of what Jack's algorithm is. This suggests that we seek a strategy that has the property that the expected cost to Jack is essentially independent of what Jack does. This was the guiding principle in designing this strategy.

Fix a lazy deterministic strategy A for Jack and define $C(\mathbf{w}) = C_A(\mathbf{w})$. We are interested in lower bounding the expectation of $C(\mathbf{w})$ with respect to the above distribution for Wendy. It will be convenient to introduce a modified cost function, $C^*(\mathbf{w}) = C(\mathbf{w}) + \psi(\mathbf{w})$, where the correction ψ depends only on the final step: if the last step by Wendy scored a hit on Jack (precisely, $j_s = D(w_s - w_{s-1})$), then $\psi(\mathbf{w}) = D - \alpha_R$ if the hit was to the right and $D - \alpha_L$ if the hit was to the left. Otherwise, $\psi(\mathbf{w}) = 0$. Thus $C(\mathbf{w}) \geq C^*(\mathbf{w}) - D$.

The purpose of introducing this modified cost is that with respect to this cost measure, the cost to Jack of any given step does not depend on what Jack does at that step. More precisely, define Jack's *modified cost at step* t to be $(\Delta C^*)_t(\mathbf{w}) = C^*(\mathbf{w^t}) - C^*(\mathbf{w^{t-1}})$. Since we are assuming that Jack is following a lazy strategy, Jack has an option to move only if $j_{t-1} = (\Delta w)_t D$. In this case, if he does not jump, then his true cost increases by $\alpha_{(\Delta w)_t}$, while his modified cost increases by $\alpha_{(\Delta w)_t} + \psi(\mathbf{w^t}) - \psi(\mathbf{w^{t-1}}) = D - \psi(\mathbf{w^{t-1}})$. If he jumps at time t, then his true cost goes up by D, but his modified cost goes up by $D + \psi(\mathbf{w^t}) - \psi(\mathbf{w^{t-1}}) = D - \psi(\mathbf{w^{t-1}})$, which is the same as if he did not jump. The reader can now check the following lemma.

LEMMA 4.4. *For any fixed lazy strategy A for Jack, the change $(\Delta C^*)_t(\mathbf{w})$ in the modified cost at time t is given by the following table.*

$(\Delta w)_t$	$(\Delta w)_{t-1}$	j_{t-1}	$(\Delta C^*)_t(\mathbf{w})$
$+1$	$+1$	$+D$	α_R
$+1$	$+1$	$-D$	0
-1	$+1$	$+D$	$\alpha_R - D$
-1	$+1$	$-D$	D
-1	-1	$-D$	α_L
-1	-1	$+D$	0
$+1$	-1	$-D$	$\alpha_L - D$
$+1$	-1	$+D$	D

Recall that if $|w_{t-1}| = D$, then by the rules of the game, it must be the case that $j_{t-1} = -w_{t-1}$, $(\Delta w)_{t-1} = w_{t-1}/D$, and $(\Delta w)_t = j_{t-1}/D$. Thus in this case, $(\Delta C^*)_t(\mathbf{w}) = D$.

If $|w_{t-1}| < D$, then when Wendy moves at time t, her move can depend on $(\Delta w)_{t-1}$, the direction of her last move, but not on j_{t-1}, which she does not know. So we try a strategy for Wendy in which her probability of moving in each direction depends on the direction of her last move. This motivates condition 1 in the definition of the strategy. So consider a strategy satisfying this condition, with σ_R and σ_L as yet unspecified. We now can write down an expression in terms of w_{t-1} and j_{t-1} for the expectation (with respect to this randomized strategy) in the change of the modified cost at time t for the case $|w_{t-1}| < D$.

$$(\Delta C^*)_t(\tilde{\mathbf{w}}) = \begin{cases} \alpha_R - D\sigma_L & \text{if } ((\Delta w)_{t-1}, j_{t-1}) = (+1, +D), \\ D\sigma_L & = (+1, -D), \\ \alpha_L - D\sigma_R & = (-1, -D), \\ D\sigma_R & = (-1, +D). \end{cases}$$

By selecting σ_L and σ_R so that this expectation is independent of j_{t-1}, we obtain condition 2 of the strategy.

Having motivated Wendy's strategy, we now continue with its analysis. The change in the expected modified cost at time t can now be written as

$$(\Delta C^*)_t(\tilde{\mathbf{w}}) = \begin{cases} D & \text{if } |w_{t-1}| = D, \\ \alpha_R/2 & \text{if } |w_{t-1}| < D \text{ and } (\Delta w)_{t-1} = +1, \\ \alpha_L/2 & \text{if } |w_{t-1}| < D \text{ and } (\Delta w)_{t-1} = -1. \end{cases}$$

To apply Corollary 4.2, we need to lower bound Jack's expected cost against the sequence $\mathbf{w}^j$ generated by the first j steps of Wendy's strategy.

Wendy's strategy can be described by a Markov chain with state space $\{L_i : -D \le i < D\} \bigcup \{R_i : -D < i \le D\}$, where Wendy is in state L_i at time $t-1$ if $w_{t-1} = i$ and $(\Delta_w)_{t-1} = -1$ (she is at point i and her last move was to the left) and Wendy is in state R_i at time $t-1$ if $w_{t-1} = i$ and $(\Delta_w)_{t-1} = +1$ (she is at point i and her last move was to the right). For state U, let $N_j(U)$ denote the expected number of visits to state U during the first j steps by Wendy. Also, let $p(U)$ denote the steady state probability for state U. For large j, $N_j(U) = p(U)j(1 + o(1))$. Thus for a sequence $\tilde{\mathbf{w}}$ of j steps chosen according to Wendy's strategy,

$$\begin{aligned} C^*(\tilde{\mathbf{w}}) &= D[N_j(L_{-D}) + N_j(R_D)] + \frac{1}{2} \sum_{i=1-D}^{D-1} [N_j(L_i)\alpha_L + N_j(R_i)\alpha_R] \\ &= j(1 + o(1)) \left[D(p(L_{-D}) + p(R_D)) + \frac{1}{2} \sum_{i=1-D}^{D-1} (p(L_i)\alpha_L + p(R_i)\alpha_R) \right]. \end{aligned}$$

Applying Corollary 4.2, we obtain

$$\lambda \ge 2 \left[D(p(L_{-D}) + p(R_D)) + \frac{1}{2} \sum_{i=1-D}^{D-1} (p(L_i)\alpha_L + p(R_i)\alpha_R) \right].$$

We proceed to determine the steady state probabilities of the Markov chain. The transition matrix of the chain yields the following equations for the steady state probabilities:

$$\begin{aligned} p(L_i) &= (1 - \sigma_R)p(L_{i+1}) + \sigma_L p(R_{i+1}) \quad \text{if } -D \le i < D-1, \\ p(L_{D-1}) &= p(R_D), \\ p(R_i) &= (1 - \sigma_L)p(R_{i-1}) + \sigma_R p(L_{i-1}) \quad \text{if } 1-D < i \le D, \\ p(R_{1-D}) &= p(L_{-D}). \end{aligned}$$

Solving this system and recalling that $\beta_R = 1 - \alpha_R/2D = 1 - \sigma_L$ and $\beta_L = 1 - \alpha_R/2D = 1 - \sigma_R$, we get the following solution (which can be easily checked against the defining equations):

$$p(L_i) = \frac{J}{4D} \left(\frac{\beta_R}{\beta_L} \right)^i, \tag{4.1}$$

$$p(R_i) = \frac{J}{4D} \left(\frac{\beta_R}{\beta_L} \right)^{i-1}, \tag{4.2}$$

where

$$J = \begin{cases} 1 & \text{if } \alpha_R = \alpha_L, \\ \frac{(\alpha_R - \alpha_L)(\beta_L \beta_R)^D}{\beta_L(\beta_L^{2D} - \beta_R^{2D})} & \text{if } \alpha_R \ne \alpha_L \end{cases}$$

is chosen so that the sum of the probabilities is 1. Notice that $p(L_i) = p(R_{i+1})$ for all i and therefore $\sum_i p(L_i) = \sum_i p(R_{i+1}) = 1/2$. Thus we can rewrite the lower bound on λ as

$$\begin{aligned}\lambda &= 2\left[D(p(L_{-D}) + p(R_D)) + \left(\frac{1}{2} - p(L_{-D})\right)\frac{\alpha_L}{2} + \left(\frac{1}{2} - p(R_D)\right)\frac{\alpha_R}{2}\right] \\ &= 2\left[D(\beta_L p(L_{-D}) + \beta_R p(R_D)) + \frac{\alpha_L + \alpha_R}{4}\right] \\ &= \frac{1}{2}\left[\left(\frac{J(\beta_L^{2D} + \beta_R^{2D})}{(\beta_L^{D-1}\beta_R^D)}\right) + \alpha_L + \alpha_R\right].\end{aligned}$$

A routine calculation shows that this simplifies to the expression in the theorem. ∎

5. Proof of the decomposition theorem. This section is devoted to the proof of Theorem 1.7. Recall the notation of the theorem: $\mathcal{M}$ is a metric space partitioned into subspaces $\mathcal{M}_L$ and $\mathcal{M}_R$. Their respective diameters and competitive ratios are denoted $\delta, \delta_L, \delta_R$ and $\lambda, \lambda_L, \lambda_R$. Also $\delta_{\max} = \max\{\delta_L, \delta_R\}$, $\lambda_{\max} = \max\{\lambda_L, \lambda_R\}$, and $\lambda_{\text{diff}} = |\lambda_L - \lambda_R|$.

The overview of the proof in section 3 developed the walker-jumper game as a rough model for the PE game on a partitioned space. We now make this connection precise.

LEMMA 5.1. *Let $\mathcal{M}_L, \mathcal{M}_R$ be a partition of $\mathcal{M}$ such that $\frac{\delta}{\delta_{\max}}$ is at least 32. Let α_R and α_L be nonnegative numbers and $\alpha_{\max}$ be their maximum. Let D be an integer satisfying* $\max\{2\lambda_{\max} + 2, \sqrt{\frac{\delta}{\delta_{\max}}}\} \le D \le \frac{\delta}{4\delta_{\max}}$.

1. *If $\alpha_L \ge \lambda_L$ and $\alpha_R \ge \lambda_R$, then*

$$\lambda \le \lambda(WJ[D, \alpha_R, \alpha_L])(1 + \eta).$$

2. *If $\alpha_L \le \lambda_L$ and $\alpha_R \le \lambda_R$, then*

$$\lambda \ge \lambda(WJ[D, \alpha_R, \alpha_L])(1 - \eta),$$

where

$$\eta \le 6\frac{\delta_{\max} D}{\delta}.$$

Given Lemma 5.1 and the analysis of the walker-jumper game, the decomposition Theorem 1.7 is easily proved.

Proof of Theorem 1.7. For the first part, we need to show

$$\frac{\lambda - \alpha_{\max}}{Z(\alpha_{\text{diff}})} - 1 \le 23e^{\alpha_{\text{diff}}}\sqrt{\frac{\delta_{\max}}{\delta}\alpha_{\max}^3}.$$

Leaving D unspecified for now, let us abbreviate $\lambda(WJ[D, \alpha_R, \alpha_L])$ by $\lambda(WJ)$. Then the left-hand side may be written and upper bounded as follows:

$$\frac{\lambda - \lambda(WJ)}{Z(\alpha_{\text{diff}})} + \frac{\lambda(WJ) - \alpha_{\max}}{Z(\alpha_{\text{diff}})} - 1 \le \left|\frac{\lambda - \lambda(WJ)}{Z(\alpha_{\text{diff}})}\right| + \left|\frac{\lambda(WJ) - \alpha_{\max}}{Z(\alpha_{\text{diff}})} - 1\right|.$$

We bound the two terms in the sum separately. Corollary 4.3 implies that, as long as D is chosen larger than $\alpha_{\max}^2$, the second term is at most $4\alpha_{\max}^2/D$. The first term

is bounded using Lemma 5.1, the trivial upper bound $\lambda(WJ) \le 2\alpha_{\max} + 1 \le 3\alpha_{\max}$ observed early in section 4, and the fact that $Z(x) \ge e^{-x}$ for all nonnegative x:

$$\begin{aligned}\left|\frac{\lambda - \lambda(WJ)}{Z(\alpha_{\text{diff}})}\right| &\le \frac{3\alpha_{\max}\eta}{Z(\alpha_{\text{diff}})} \\ &\le \frac{3\alpha_{\max}\cdot 6\cdot \delta_{\max} D}{Z(\alpha_{\text{diff}})\delta} \\ &\le \frac{18\alpha_{\max}\delta_{\max} D e^{\alpha_{\text{diff}}}}{\delta}.\end{aligned}$$

Now set D to be an integer satisfying $\sqrt{\delta\alpha_{\max}/\delta_{\max}} \le D \le \frac{19}{18}\sqrt{\delta\alpha_{\max}/\delta_{\max}}$. This is possible because the hypothesis of the theorem implies that $\sqrt{\delta\alpha_{\max}/\delta_{\max}} \ge 18$. It is easily verified that, under the hypothesis of Theorem 1.7, the resulting D satisfies both the hypothesis $D \ge \alpha_{\max}^2$ of Corollary 4.3 and the conditions in Lemma 5.1. Summing the upper bounds on the two terms using this value of D yields an upper bound of

$$19e^{\alpha_{\text{diff}}}\sqrt{\frac{\alpha_{\max}^3\delta_{\max}}{\delta}} + 4\sqrt{\frac{\alpha_{\max}^3\delta_{\max}}{\delta}} \le 23e^{\alpha_{\text{diff}}}\sqrt{\frac{\alpha_{\max}^3\delta_{\max}}{\delta}},$$

as required for the first part of the theorem.

For the second part of the theorem, either $\lambda_{\max} \ge \alpha_{\max} + Z(\alpha_{\text{diff}})(1-\zeta)$ or else we must prove

$$\frac{\alpha_{\max} - \lambda}{Z(\alpha_{\text{diff}})} + 1 \le \ 23e^{\alpha_{\text{diff}}}\sqrt{\frac{\delta_{\max}}{\delta}\alpha_{\max}^3}.$$

The proof is similar to that of the first part. □

Thus it remains to prove Lemma 5.1. The proof of this follows the outline in section 3 but needs a lot of technical work which is divided into three subsections. First, we state two technical results that bound the constants occurring in the definition of the competitive ratio; the proofs of these lemmas are deferred until the end of the paper. Then we prove the upper and lower bounds of the lemma.

5.1. Two technical lemmas. In the proof overview, we related a step to the left (resp., right) by the walker in the walker-jumper game, to the addition of an s-block for some appropriately chosen s by the pursuer in the PE game. In sketching how this works, we approximated the cost of such a left block to the evader by $s\lambda_R$. When we formalize this argument one of the things we will have to do is to bound the error in this approximation. For this, we will need two lemmas concerning the existence of "good" strategies for the pursuer and the evader in the PE game.

The competitive ratio for a two-person game was defined, in general, as an infimum over κ for which there is a κ-competitive algorithm. In general, this infimum need not be attained, i.e., if the competitive ratio is λ, there need not be a λ competitive strategy for MIN. However, as we will see in the next lemma, for the PE game there is always a randomized evader strategy that attains the competitive ratio. Furthermore, we can also upper bound the constant K that occurs in the definition of the competitive ratio.

LEMMA 5.2. *Let $\mathcal{M}$ be a metric space of diameter δ, and let λ denote the competitive ratio of its PE problem. Then there exists an algorithm $\tilde{A}$ such that for any probe sequence ρ*

$$C_{\tilde{A}}(\rho) \le \lambda C_{\text{OPT}}(\rho) + \delta\lambda.$$

Corollary 2.3 provides a criterion for lower bounding the competitive ratio of any game. The sequence of strategies $\tilde{r}_i$ in the hypothesis of the corollary can be viewed as a *witness* to the fact that the competitive ratio is at least κ. To prove tight lower bounds on the competitive ratio, we would like to be able to find such a witness sequence in the case $c = \lambda$.

LEMMA 5.3. *Let $\mathcal{M}$ be a metric space and λ the competitive ratio of its PE game. For any $s > 0$, there is a distribution $\tilde{\rho}_{\mathbf{s}}$ on s-blocks such that for any response algorithm A,*

$$C_A(\tilde{\rho}_{\mathbf{s}}) \geq \lambda(s - \delta) - \delta.$$

The proofs require a somewhat tedious technical formulation, after which the results follow from elementary analysis. So as not to distract from the flow of the main argument, we defer the proof to the last section of the paper.

5.2. The upper bound (proof of Lemma 5.1, part 1). We now proceed with the proof of Lemma 5.1. We assume for now that both the left and right space have at least two points. In the case that one or both of them is degenerate (has only one point), the proof is similar but requires some technical modifications which we indicate at the end of the subsection.

The upper bound is proved by associating for each jumper strategy $\tilde{J}$ for $WJ[D, \alpha_R, \alpha_L]$ an evader algorithm $\tilde{A}(\tilde{J})$ for $PE(\mathcal{M})$ that satisfies that if $\tilde{J}$ is κ-competitive, then $\tilde{A}(\tilde{J})$ is $\kappa(1+\eta)$-competitive. The evader algorithm $\tilde{A}(\tilde{J})$ must specify an on-line rule for responding to a probe sequence. The idea will be to associate the incoming probe sequence to a walker sequence, apply $\tilde{J}$ to that walker sequence, and then translate the jumper's moves into moves for the evader.

We first describe a rule for associating a probe sequence ρ for $\mathcal{M}$ to a walker sequence $\mathbf{w} = \mathbf{w}(\rho)$. View ρ as the interleaving of two probe sequences, one for $\mathcal{M}_R$ (the *right* subsequence) and one for $\mathcal{M}_L$ (the *left* subsequence). Define the parameter $s_2 = (\delta - 2\delta_{\max})/D$. (The reader should think of this as approximating δ/D.) Parse each of these subsequences separately into its s_2-block partition, as defined in section 2.3. Now build $\mathbf{w}$ in the following on-line manner. Each time a right (resp., left) block of ρ is completed, a right (resp., left) walker step is added to $\mathbf{w}$ unless that step will take the walker outside the bounds $[-D, D]$. Let $\rho^{\mathbf{i}}$ denote the prefix corresponding to the steps up to w_i. Let $k = |\mathbf{w}|$ and let μ be the portion of ρ coming after the last s_2-block of either subsequence; thus $\rho = \rho^{\mathbf{k}}\mu$.

Given the jumper strategy $\tilde{J}$, the algorithm $\tilde{A}(\tilde{J})$ responds to the probe sequence ρ as follows. As the sequence ρ is received, the evader constructs $\mathbf{w}(\rho)$ and simulates the response of $\tilde{J}$ to this sequence. The evader uses the position (left or right) of the simulated jumper to determine which space to be in; the response by $\tilde{J}$ to a step of $\mathbf{w}$ determines whether the evader continues in the same space or moves to the other. The times at which the evader switches spaces delimits a sequence of *left* and *right* intervals. During a right (resp., left) interval, the evader ignores probes on the other side and responds to the subsequence of right (resp., left) probes by applying the algorithm $\tilde{A}_R$ (resp., $\tilde{A}_L$), where $\tilde{A}_R$ (resp., $\tilde{A}_L$) is the evader strategy for $PE(\mathcal{M}_R)$ (resp., $PE(\mathcal{M}_L)$) that satisfies the conclusion of Lemma 5.2.

Now, supposing that $\tilde{J}$ is κ-competitive, we need to verify that $\tilde{A}(\tilde{J})$ is $\kappa(1+\eta)$-competitive. We will deduce this from the following lemma.

LEMMA 5.4. *Let $\tilde{J}$ be a jumper strategy for $WJ[D, \alpha_R, \alpha_L]$. Then for any probe sequence ρ for $PE(\mathcal{M})$,*

1. $C_{\mathrm{OPT}}(\rho) \geq (s_2 - \delta_{\max})C_{\mathrm{BASE}}(\mathbf{w}(\rho)) - \delta$,
2. $C_{\tilde{A}(\tilde{J})}(\rho) \leq (s_2 + 2\delta_{\max})C_{\tilde{J}}(\mathbf{w}(\rho)) + K$ *for some constant* K *independent of* ρ.

Using this lemma and the assumption that $\tilde{J}$ is κ-competitive, we obtain that for some constants H and H' independent of ρ

$$\begin{aligned} C_{\tilde{A}(\tilde{J})}(\rho) &\leq (s_2 + 2\delta_{\max})C_{\tilde{J}}(\mathbf{w}(\rho)) + K \\ &\leq (s_2 + 2\delta_{\max})\kappa C_{\mathrm{BASE}}(\mathbf{w}(\rho)) + H \\ &\leq \frac{s_2 + 2\delta_{\max}}{s_2 - \delta_{\max}}\kappa C_{\mathrm{OPT}}(\rho) + H' \\ &\leq \left(1 + \frac{3D\delta_{\max}}{\delta - (D+2)\delta_{\max}}\right)\kappa C_{\mathrm{OPT}}(\rho) + H' \\ &\leq \left(1 + \frac{6D\delta_{\max}}{\delta}\right)\kappa C_{\mathrm{OPT}}(\rho) + H', \end{aligned}$$

where the last inequality follows from $\delta \geq 2(D+2)\delta_{\max}$ which is an easy consequence of the hypotheses of the lemma. This implies that $\tilde{A}(\tilde{J})$ is $(1+\eta)\kappa$-competitive, as required to prove the upper bound.

So it remains to prove Lemma 5.4.

Proof of Lemma 5.4. Define $C_L(i)$ (resp., $C_R(i)$), for $1 \leq i \leq k$, to be the minimum cost of a response sequence to $\rho^{\mathbf{i}}$ whose last point is in $\mathcal{M}_L$ (resp., $\mathcal{M}_R$). Note that $C_{\mathrm{OPT}}(\rho) \geq C_{\mathrm{OPT}}(\rho^{\mathbf{k}}) = \min\{C_R(k), C_L(k)\}$. Since $|C_L(i) - C_R(i)| \leq \delta$, we have $C_{\mathrm{OPT}}(\rho) \geq C_R(k) - \delta$.

LEMMA 5.5. $C_R(i) \geq (s_2 - \delta_{\max})(i + w_i)/2$ *and* $C_L(i) \geq (s_2 - \delta_{\max})(i - w_i)/2$.

Since $C_{\mathrm{BASE}}(\mathbf{w}) = (k + w_k)/2$, the first part of Lemma 5.4 follows.

Proof. We prove this by induction on i; the basis $i = 0$ is trivial. Suppose $i > 0$. Assume that $(\Delta w)_i = +1$; the case $(\Delta w)_i = -1$ is proved analogously. Thus $\rho^{\mathbf{i}}$ marks the end of a right block.

The induction step for $C_L(i)$ follows from $C_L(i) \geq C_L(i-1)$. For $C_R(i)$, let $j < i$ be the least index such that $(\Delta w)_h = -1$ for $j < h < i$. Thus either $j = 0$ and w_i is the first step to the right, or w_j is the last step to the right prior to w_i. It is easy to see that this implies that $i + w_i = j + w_j + 2$, and hence $j \geq i + w_i - D - 2$.

We need to show that any response sequence for $\rho^{\mathbf{i}}$ that ends on the right costs at least $(s_2 - \delta_{\max})(w_i + i)/2$. Consider such a response sequence, written as $\sigma\tau$, where σ is the portion that is a response sequence to $\rho^{\mathbf{j}}$.

Note that $d(\sigma)$ must be at least the minimum of $C_L(j)$ and $C_R(j)$, which, by induction and the above expression for j, is at least $(s_2 - \delta_{\max})(j - D)/2 \geq (s_2 - \delta_{\max})(i + w_i - 2D - 2)/2$. Any move between the two spaces costs at least $\delta - 2\delta_{\max} = Ds_2$, which can be shown to be larger than $(s_2 - \delta_{\max})(D+1)$ using the hypotheses $D \geq \sqrt{\delta/\delta_{\max}}$ of the theorem. Thus it follows that if there is any move between spaces subsequent to σ, then the total cost of the response sequence is at least $(s_2 - \delta_{\max})(w_i + i)/2$, as required.

So assume that after σ there is no move between spaces. Then σ ends on the right and all steps of τ are on the right. Since the portion of ρ between $\rho^{\mathbf{j}}$ and $\rho^{\mathbf{i}}$ contains a right s_2-block, it follows that τ has optimal cost at least $s_2 - \delta_{\max}$. Thus

$$\begin{aligned} d(\sigma\tau) &\geq (s_2 - \delta_{\max})(w_j + j)/2 + s_2 - \delta_{\max} \\ &= (s_2 - \delta_{\max})(w_j + j + 2)/2 \\ &= (s_2 - \delta_{\max})(w_i + i)/2, \end{aligned}$$

as required. □

We now turn to the proof of the second part of Lemma 5.4. For this we want to upper bound the expected cost incurred by $\tilde{A}(\tilde{J})$ on ρ, in terms of the expected cost of $\tilde{J}$ on $\mathbf{w}(\rho)$. Consider the cost incurred by the evader during each interval that begins after a move into one space and ends with the move out of that space, or, in the case of the last such interval, with the end of the sequence ρ. We will compare the evader's cost to the cost of the jumper during the corresponding interval. Without loss of generality, assume that the evader is on the right during this interval and thus the jumper is at $+D$. This implies that the simulated walker cannot be at $+D$ at any step (except possibly the last one) during this interval.

First, consider the case that the interval is not the last such interval. The evader responds only to the probes that occur on the right during that interval. In the definition of the algorithm, the subsequence of right probes was partitioned into right s_2-blocks. Let m be the number of s_2-blocks that end during this interval. By the definition of $\mathbf{w}$ and the fact that the walker is not at $+D$ at any time during the interval, it follows that the walker took m right steps during the interval. Thus the cost to the simulated jumper is $m\alpha_R$ for those steps, plus D for the final jump.

Now consider the cost to the evader corresponding to the interval. Since the evader is on the right, he responds only to the right probes that occur during the interval. The subsequence of right probes has optimal cost (with respect to the right space) at most $m(s_2 + \delta_R)$ since it is the concatenation of m sequences, each with optimal cost at most s_2. Since the evader uses algorithm $\tilde{A}_R$ to respond, the expected cost of responding is at most $\alpha_R m(s_2 + \delta_R) + \lambda_R \delta_R \le \alpha_R m(s_2 + 2\delta_R)$. Adding the cost of the final move to the left space, which is at most δ, we obtain an upper bound on the evader's cost for the interval of

$$\begin{aligned}\alpha_R m(s_2 + 2\delta_R) + \delta &= \alpha_R m(s_2 + 2\delta_R) + Ds_2 + 2\delta_{\max} \\ &\le \alpha_R m(s_2 + 2\delta_R) + D(s_2 + 2\delta_{\max}) \\ &\le (\alpha_R m + D)(s_2 + 2\delta_{\max}).\end{aligned}$$

Thus the evader's cost on every interval except the last is at most $(s_2 + 2\delta_{\max})$ times the simulated jumper's cost on the interval.

For the last interval, the cost to the jumper is $\alpha_R m$. To bound the expected cost to the evader we must include the portion μ of ρ which occurs after the last step by the simulated walker. This could increase the optimal cost (with respect to the right space) of the subsequence of right probes in this interval to $(m+1)(s_2+\delta_R)$. Thus the expected cost to the evader within the interval is bounded above by $\alpha_R(m+1)(s_2 + \delta_R) + \alpha_R\delta_R$, which is in turn bounded above $(s_2 + 2\delta_R)$ times the simulated jumper's cost of $m\alpha_R$ plus a constant that does not depend on ρ. □

We now indicate how to modify the proof in the case that one or both of the spaces has exactly one point. First, we have to modify the definition of the walker sequence $\mathbf{w}(\rho)$ associated to a probe sequence. As before, we view ρ as the interleaving of a right and a left subsequence, and we parse each of these sequences into their s_2-block partitions. Recall that for one-point spaces, we defined an s_2-block partition to be the partition into singleton blocks. As before, at the completion of a left or right block, the next step of the walker is generated. For a block corresponding to a nondegenerate subspace, the walker step is generated as before. A block corresponding to a degenerate subsequence will correspond to not one but a sequence of walker steps that take the walker all the way to the corresponding endpoint ($-D$ for a left block and D for a right block). If this is the ith completed block, then we abuse notation

by setting $w_i = D$ for a right block and $w_i = -D$ for a left block; thus we compress all of the walker steps corresponding to a degenerate block into one step.

Lemma 5.4 can be extended to hold in this case. The definitions of $C_L(i)$ and $C_R(i)$ need to be modified in Lemma 5.7: if the left (resp., right) space is degenerate and $\rho^{(\mathbf{i})}$ ends with a left (resp., right) block, then the definition of $C_L(i)$ (resp., $C_R(i)$) does not make sense and we modify it by defining $C_L(i) = C_R(i) + \delta$ (resp., $C_R(i) = C_L(i) + \delta$). The proof of Lemma 5.7 is then routine.

In the proof of the second part of Lemma 5.4 we analyze intervals defined by moves of the evader from one space to the other. The case of an interval in which the evader occupies a degenerate space is different than those analyzed but is actually easier since during the interval there are no requests inside the degenerate space and the cost to the evader is the cost of the move to the other space at the end of the interval which is bounded above by δ. The cost to the jumper during the same interval is just D.

5.3. The lower bound (proof of Lemma 5.1, part 2). As with the upper bound, we prove the lower bound in the case that $\mathcal{M}_L$ and $\mathcal{M}_R$ each have size at least two. Afterwards, we indicate how to modify the proof to handle the degenerate case that one or both spaces has only one point.

The strategy of the lower bound is the "mirror image" of the upper bound proof. That is, we will define a function which maps each evader algorithm $\tilde{A}$ for $PE(\mathcal{M})$ to a jumper algorithm $\tilde{J}(\tilde{A})$ for $WJ[D, \alpha_R, \alpha_L]$ and has the following property: if $\tilde{A}$ is a κ-competitive algorithm for the $PE(\mathcal{M})$, then $\tilde{J}(\tilde{A})$ is a $\frac{\kappa}{1-\eta}$-competitive algorithm for $WJ[D, \alpha_R, \alpha_L]$, where $\eta \le 6\frac{\delta_{\max} D}{\delta}$. This immediately implies the lower bound of the lemma.

There are two main steps. Define the parameter $s_1 = \delta/D$.

1. For each walker strategy $\mathbf{w}$ for the game $WJ[D, \alpha_R, \alpha_L]$, we define a distribution $\tilde{\mu}(\mathbf{w})$ on probe sequences for the pursuer in the PE game on $\mathcal{M}$ such that

$$C_{\mathrm{BASE}}(\mathbf{w})(s_1 + \delta_{\max}) \ge C_{\mathrm{OPT}}(\tilde{\mu}(\mathbf{w})). \tag{5.1}$$

2. For each (randomized) evader algorithm $\tilde{A}$ we define a jumper algorithm $\tilde{J}(\tilde{A})$ for $WJ[D, \alpha_R, \alpha_L]$ and show that for all evader algorithms $\tilde{A}$ and walker strategies $\mathbf{w}$

$$C_{\tilde{A}}(\tilde{\mu}(\mathbf{w})) \ge C_{\tilde{J}(\tilde{A})}(\mathbf{w})(s_1 - 2\delta_{\max}) \tag{5.2}$$

(where the first cost function is with respect to $PE(\mathcal{M})$ and the second is with respect to $WJ[D, \alpha_R, \alpha_L]$).

It follows immediately from these two steps that if $\tilde{A}$ is κ-competitive, then there is a real number K such that for any walker sequence $\mathbf{w}$

$$(1 - 2\delta_{\max} D/\delta)(1 - \delta_{\max} D/\delta) C_{\tilde{J}(\tilde{A})} \le \kappa C_{\mathrm{BASE}}(\mathbf{w}) + K,$$

and thus $\tilde{J}(\tilde{A})$ is $\frac{\kappa}{(1-3\delta_{\max} D/\delta)}$-competitive, which will complete the proof.

For this proof, we define a *left block* (resp., *right block*) to be an s_1-block of the space $\mathcal{M}_L$ (resp., $\mathcal{M}_R$). For a walker sequence $\mathbf{w} = (w_0 = 0, w_1, \ldots, w_k)$ in the game $WJ[D, \alpha_R, \alpha_L]$ we say that probe sequence ν for $\mathcal{M}$ is *compatible* with $\mathbf{w}$ if ν is the concatenation of k probe sequences $\nu_{\mathbf{1}}\nu_{\mathbf{2}} \ldots \nu_{\mathbf{k}}$ satisfying the following.

1. For each i such that $|w_i| \neq D$, $\nu_{\mathbf{i}}$ is a single right block if $(\Delta_w)_i = 1$ and is a single left block if $(\Delta_w)_i = -1$.
2. Let N be a large integer parameter to be specified later. If $|w_i| = D$, then $\nu_{\mathbf{i}}$ is the concatenation of N right blocks if $(\Delta_w)_i = 1$ and is the concatenation of N left blocks if $(\Delta_w)_i = -1$.

The sequences $\nu_{\mathbf{i}}$ are referred to as *segments* and are designated as left or right segments depending on whether they are from $\mathcal{M}_R$ or $\mathcal{M}_L$. A segment consisting of a single block is called a *small* segment, and one consisting of N blocks is called a *large* segment.

The distribution $\tilde{\mu}(\mathbf{w})$ will be a distribution over probe sequences compatible with $\mathbf{w}$. To define this distribution, we first need the following special case (actually, a slight weakening) of Lemma 5.3.

COROLLARY 5.6. *There exists a distribution $\tilde{\rho}_L$ on the set of left s_1-blocks and a distribution $\tilde{\rho}_R$ on the set of right s_1-blocks such that the following hold.*

1. *For any response algorithm A for $\mathcal{M}_L$, $C_A(\tilde{\rho}_L) \geq \alpha_L(s_1 - 2\delta_L)$.*
2. *For any response algorithm A for $\mathcal{M}_R$, $C_A(\tilde{\rho}_R) \geq \alpha_R(s_1 - 2\delta_R)$.*

The distribution $\tilde{\mu}(\mathbf{w})$ is now defined to be the distribution over probe sequences compatible with $\mathbf{w}$ in which each left block is chosen independently from the distribution $\tilde{\rho}_L$ and each right block is chosen independently from the distribution $\tilde{\rho}_R$.

Next, we relate the base-cost of $\mathbf{w}$ to the expected optimal cost $\tilde{\mu}(\mathbf{w})$. The base-cost of $\mathbf{w}$ equals the number of right steps, which is equal to $(k+w_k)/2$, where $k = |\mathbf{w}|$. We will show that for any probe sequence ν compatible with $\mathbf{w}$, its optimal cost is at most $(s_1 + \delta_{max})(k + w_k)/2$. Since $\tilde{\mu}(\mathbf{w})$ is a distribution over such sequences, this will imply inequality (5.1).

So fix ν compatible with $\mathbf{w}$. Denote by $C_L(i)$ (resp., $C_R(i)$) the minimum cost of a response sequence for the first i segments of ν whose last point is in $\mathcal{M}_L$ (resp., $\mathcal{M}_R$). Note that $|C_L(i) - C_R(i)| \leq \delta$. Then $C_{\mathrm{OPT}}(\nu)$ is equal to the minimum of $C_L(k)$ and $C_R(k)$, and thus the desired upper bound on $C_{\mathrm{OPT}}(\nu)$ is an immediate consequence of the following lemma.

LEMMA 5.7. *$C_R(i) \leq (s_1 + \delta_{\max})(i + w_i)/2$ and $C_L(i) \leq (s_1 + \delta_{\max})(i - w_i)/2$.*

Proof. We prove this by induction on i; the basis case $i = 0$ is trivial. Now suppose that $i > 0$ and that the result holds for $i - 1$.

We assume $(\Delta w)_i = +1$; the case $(\Delta w)_i = -1$ is proved analogously. Thus ν_i consists of one or N s_1-blocks from $\mathcal{M}_R$.

To prove the induction step for $C_L(i)$ it suffices to observe that $C_L(i) = C_L(i-1)$, which is obvious since the definition of $C_L(i-1)$ implies that there is a response sequence for $\nu_{\mathbf{1}} \ldots \nu_{\mathbf{i-1}}$ that ends at some point $y \in \mathcal{M}_L$ that costs $C_L(i-1)$. This sequence can be extended by remaining at y through $\nu_{\mathbf{i}}$ and the cost does not increase.

Next we prove the induction step for $C_R(i)$. In the case that segment ν_i consists of a single right block, then by the definition of $C_R(i-1)$ there is a response sequence σ for $\nu_{\mathbf{1}} \ldots \nu_{\mathbf{i-1}}$ ending at some point $y \in \mathcal{M}_R$ that costs at most $C_R(i-1)$. Since ν_i is an s_1-block for $\mathcal{M}_R$, there is a response sequence τ for $\nu_{\mathbf{i}}$ that costs at most s_1 and ends in $\mathcal{M}_R$. Then the sequence $\sigma\tau$ costs at most $C_R(i-1)+s_1+d(y,\tau_1) \leq C_R(i-1)+s_1+\delta_{\max}$ which is bounded by $(s_1 + \delta_{\max})(i + w_i)/2$ by the induction hypothesis.

In the case that the segment ν_i consists of N right blocks, we must have $w_i = D$. Then we use the fact that $C_R(i) \leq C_L(i)+\delta$ to obtain $C_R(i) \leq (s_1+\delta_{\max})(i-D)/2+ s_1 D \leq (s_1 + \delta_{\max})(i + D)/2$ as required. ∎

Now we turn to the second and final step: the definition of $\tilde{J}(\tilde{A})$ and the verification of inequality (5.2). Given an evader strategy $\tilde{A}$, the jumper strategy $\tilde{J}(\tilde{A})$ will

be defined as follows. On being presented walker sequence $\mathbf{w}$, J generates a probe sequence according to the distribution $\tilde{\mu}(\mathbf{w})$. Note that this generation can be done on-line with segment i being generated given w_i. At the same time, he simulates the algorithm A on the sequence $\tilde{\mu}(\mathbf{w})$. At step i, the jumper responds to w_i as follows.

1. If $|w_i| = D$, then $j_i = -w_i$ (which is forced by the rules of the game).
2. If $|w_i| < D$ and $\mathbf{w}_i$ is in the direction opposite to j_{i-1} (i.e., they have opposite signs), then the jumper does not move, i.e., $j_i = j_{i-1}$.
3. If $|w_i| < D$ and $\mathbf{w}_i$ is in the direction towards j_{i-1}, then $j_i = D$ if $\tilde{A}$ is in $\mathcal{M}_R$ at the end of segment i and $j_i = -D$ otherwise.

It remains to verify inequality (5.2) and it suffices to verify this inequality for deterministic algorithms A; the result for randomized algorithms will follow by taking expectation with respect to the distribution over algorithms. So fix a deterministic algorithm A.

We will say that the simulated evader and the jumper are *synchronized at step i* if after the ith step of the jumper the jumper is at $+D$ and the evader is either in the left space or the jumper is at $-D$ and the evader is in the right space.

For technical reasons, it will be useful to modify the cost to the jumper by adding D to his cost if at the last step he is not synchronized with the evader. Obviously, this modified cost is an upper bound on the true cost, so it suffices to work with this modified cost. What we will show is that the expected change in the cost incurred by the evader during segment i is at least $(s_1 - 2\delta_{\max})$ times the expected change in the modified cost incurred by the jumper at step i. We assume that the jumper is on the right, $j_{i-1} = D$; the other case is handled similarly.

If step i of the walker is to the left, then the change in the jumper's actual cost will be 0. His modified cost will go up by D if and only if the evader was in $\mathcal{M}_R$ and moved to $\mathcal{M}_L$ during segment i. In this case, the evader's cost increased by at least $\delta - 2\delta_{\max}$ which is at least $(s_1 - 2\delta_{\max})D$.

Now consider the case that the ith step of the walker is to the right. If the jumper and evader were not synchronized at step $i-1$, then at the end of step i, there are three possibilities: they both end on the left, they both end on the right, or they switch places. (This can happen only if $w_i = D$ so that the jumper is forced to jump.) In the first two cases, the expected change in the modified cost of the jumper is less than or equal to 0, while the evader always incurs a nonnegative cost, and the desired inequality is trivial. In the third case, the jumper's modified cost increases by D, while the evader's cost increases by at least $\delta - 2\delta_{\max}$ which is at least $(s_1 - 2\delta_{\max})D$.

So we may assume that the jumper and evader are both on the right after step $i-1$ and the next step is to the right. As the evader is following a lazy algorithm, we may assume that if the evader moves left during the block, he does not move again during the block.

We consider separately the cases that $w_i < D$ and $w_i = D$. In the case that $w_i < D$, then by the definition of the jumper's strategy, they will still be synchronized at step i. So either they both stayed on the right, or they both moved to the left. If they both end on the left, then the jumper's modified cost increases by D and the evader's cost increases by at least $\delta - 2\delta_{\max}$ which we have already noted is good for us. If they both stay on the right, then the jumper incurs a cost of α_R and we'd like to say that the evader incurs an expected cost of at least $(s_1 - 2\delta_R)\alpha_R$. This would seem to be true: the pursuer chooses her s_1-block from the distribution $\tilde{\rho}_{\mathbf{R}}$, and we know from Corollary 5.6 that any algorithm B incurs expected cost at least $(s_1 - 2\delta_R)\alpha_R$ against this distribution.

However, there is a subtle flaw in this reasoning. The algorithm A does not have to decide whether to move to the left at the beginning of the s_1-block; it can start on the right and at some point decide to move left. For example, suppose A stays on the right as long as the cost he has incurred during that block is less than some value V. The conditional expectation of the cost incurred given that the algorithm finishes the block on the right is at most V. Since V can be chosen less than $(s_1 - 2\delta_R)\alpha_R$, this demonstrates that the above argument is fallacious.

To argue correctly, we must consider that, conditioned on the probe sequence up to the beginning of the current block, there is a probability p that A stays on the right for the entire block. Thus the expected increase in the jumper's modified cost is $p\alpha_R + (1-p)D$. We need to show that the expected increase in the evader's cost is at least $(s_1 - 2\delta_R)$ times this. The expected increase in the evader's cost is $(1-p)(\delta - 2\delta_{\max})$ plus the expected cost incurred in responding to probes while on the right. Now the key point is that when computing this expected cost, not only must we consider the cost incurred when the evader finishes on the right, but also, in the case that the evader finishes on the left, we must consider the cost incurred by the evader before moving to the left.

So let us consider the behavior of the algorithm A from the beginning of this s_1-block until the point that it jumps to the left. We can think of this algorithm as one for the game $PE(\mathcal{M}_R)$ which has the additional option of *stopping* the game in the middle. Let us call such an algorithm a *stopping algorithm*.

LEMMA 5.8. *Let B be a stopping algorithm for $PE(\mathcal{M}_R)$. Let p be the probability that B does not stop on input distribution $\tilde{\rho}_R$. Let q denote the expected cost incurred by B before it stops. Then $q \geq p\alpha_R(s_1 - 2\delta_R) - (1-p)\delta_R(3\lambda_R + 1)$.*

Proof. Define the (nonstopping) algorithm $\tilde{B}'$ for $PE(\mathcal{M}_R)$ as follows: respond using B until B stops. Then switch to using the algorithm $\tilde{A}_R$, the algorithm that satisfies the conclusion of Lemma 5.2.

Now we upper bound $C_{\tilde{B}'}(\tilde{\rho}_{\mathbf{R}})$. This cost is at most q plus the cost incurred after switching to $\tilde{A}_R$. The probability of ever switching to $\tilde{A}_R$ is $1-p$, and conditioned on switching, $\tilde{A}_R$ incurs a cost of at most δ_R for its first move and an expected cost of at most $\lambda_R(s_1 + \delta_R)$ for the rest of its moves since it is responding to an s_1 block (or a subsequence of it). Thus $C_{\tilde{B}'}(\tilde{\rho}_R) \leq q + (1-p)(\lambda_R(s_1 + \delta_R) + \delta_R)$. On the other hand, by Corollary 5.6, $C_{\tilde{B}'}(\tilde{\rho}_R) \geq \alpha_R(s_1 - 2\delta_R)$. We conclude, therefore, that $q \geq p\alpha_R(s_1 - 2\delta_R) - (1-p)(3\lambda_R + 1)(\delta_R)$. ∎

With Lemma 5.8 in hand, we now can lower bound the expected cost to the evader in responding to the s_1-block by

$$\begin{aligned} &p\alpha_R(s_1 - 2\delta_R) - (1-p)\delta_R(3\lambda_R + 1) + (1-p)(\delta - 2\delta_{\max}) \\ &\quad \geq p\alpha_R(s_1 - 2\delta_R) + (1-p)(\delta - (3\lambda_R + 3)\delta_{\max}) \\ &\quad \geq (s_1 - 2\delta_{\max})(p\alpha_R) + (1-p)D(s_1 - 2\delta_{\max}), \end{aligned}$$

where the last inequality is obtained by applying the hypotheses about D and s_1. The final term is $(s_1 - 2\delta_{\max})$ times the change in the jumper's modified cost, as needed.

Finally, we consider the case that both the jumper and evader begin on the right, $w_{i-1} = D - 1$, and the step by the walker is to the right. As before, since the evader is following a lazy algorithm, either he stays on the right or he moves to the left at some time and stays there. Let p be the probability that the evader stays on the right. The idea is that since the segment corresponding to the last step of the walker consists of N right blocks, where N is a large integer, we want to conclude that either p is extremely small, or the evader incurs a very large cost. For $1 \leq j \leq N$, define p_j to

be the probability that the evader is still on the right after j of the s_1-blocks; thus for all j, $p_j \geq p_N = p$. Note that the conditional probability that he is on the right after block j given that he is on the right after block $j-1$ is p_{j+1}/p_j. Then by Lemma 5.8, the expected cost incurred due to responding to requests on the right during block j is at least $p_j(\alpha_R(s_1 - 2\delta_R)) - (p_{j-1} - p_j)\delta_R(3\lambda_R + 1)$.

Summing this over j, we find that the expected cost incurred due to responses on the right is at least $pN\alpha_R(s_1 - 2\delta_R) - (1-p)\delta_R(3\lambda_R + 1)$. Adding in the expected cost of the final move to the left, and simplifying we get a lower bound on the evader's cost of the form $(1-p)D(s_1 - 2\delta_{\max}) + pNT$, where T is a positive real number. We need this to be at least $(s_1 - 2\delta_{\max})$ times the expected change in the jumper's modified cost, which is $D + pD$ since he must move to the left. For this we need pNT to be at least $2pD(s_1 - 2\delta_{\max})$ and this will hold as long as N was chosen large enough. □

Finally, let us indicate how the above proof changes if one of the spaces, say $\mathcal{M}_R$, has exactly one point p. The only change in the definitions of $\mathbf{w}(\rho)$ and $\tilde{J}(\tilde{A})$ comes from a change in the definition of compatibility. The modification is that for a step to the right $(\Delta w)_i = 1$, the segment $\nu_{\mathbf{i}}$ is defined to be empty if $w_i < D$ and is equal to the single point p if $w_i = D$. The analysis of this strategy involves similar considerations to the given proof and is left to the reader.

6. Applications of the decomposition theorem. In this section, we use Theorem 1.7 to prove Theorems 1.3 and 1.5. (Theorem 1.4 was already proved in the introduction.)

Recall that a subspace $\mathcal{N}$ of space $\mathcal{M}$ is ϵ-small relative to $\mathcal{M}$ if $\delta(\mathcal{N}) \leq \epsilon\delta(\mathcal{M})$. We also say that $\mathcal{M}$ is *ϵ-uniform* if the distance between any two points in $\mathcal{M}$ is at least $\epsilon\delta(\mathcal{M})$. The following easy consequence of Theorem 1.1 is left to the reader (see also [KRR]).

LEMMA 6.1. *The competitive ratio of an* ϵ-uniform *space on n points is between $\epsilon \ln n$ and $(2/\epsilon)\ln n$.*

It will be convenient to state three special cases of Theorem 1.7.

COROLLARY 6.2. *Let $\mathcal{M}$ be a metric space of at least three points and let $\mathcal{M}_R, \mathcal{M}_L$ be a partition. Let α_R and α_L be nonnegative numbers with $\alpha_{\max}$ their maximum and α_{diff} their absolute difference. Suppose that $\alpha_{\max} \geq 1$ and that both spaces are $(e^{2\alpha_{\text{diff}}}\alpha_{\max}^3 2200)^{-1}$-small in $\mathcal{M}$.*

1. *If $\alpha_L \geq \lambda_L$ and $\alpha_R \geq \lambda_R$, then $\lambda \leq \alpha_{\max} + 3Z(\alpha_{\text{diff}})/2$.*
2. *If $\alpha_L \leq \lambda_L$ and $\alpha_R \leq \lambda_R$, then $\lambda \geq \alpha_{\max} + Z(\alpha_{\text{diff}})/2$.*

Proof. Apply the bounds of Theorem 1.7, noting that the hypothesis of the Corollary guarantees $\zeta \leq 1/2$. □

The special case where $\alpha_R = \alpha_L$ is worth noting.

COROLLARY 6.3. *Let $\mathcal{M}$ be a metric space and let $\mathcal{M}_R, \mathcal{M}_L$ be a partition into two subspaces of size at least 2. Let $\beta \geq 1$ be a lower bound on both λ_R and λ_L and suppose that both spaces $\mathcal{M}_R$ and $\mathcal{M}_L$ are $(2200\beta^3)^{-1}$-small. Then $\lambda \geq \beta + 1/2$.*

We also have the following corollary.

COROLLARY 6.4. *Let $\mathcal{M}$ be a metric space of at least three points and let $\mathcal{N}$ be a subspace. Let $\beta \geq 1$ be a lower bound on $\lambda(\mathcal{N})$ and suppose that $\mathcal{N}$ is $(27000e^{3\beta})^{-1}$-small. Then $\lambda(\mathcal{M}) \geq \beta + e^{-2\beta}$.*

Proof. Let x, y be points of $\mathcal{M}$ of distance δ. Then by the triangle inequality, one of the spaces obtained by adding exactly one of x and y to $\mathcal{N}$ has diameter at least $\delta/2$. Assume x is the point and let $\mathcal{K}$ be the union of $\mathcal{K}_R = \mathcal{N}$ and $\mathcal{K}_L = \{x\}$. The hypothesis of the corollary guarantees that the ratio of $\delta(\mathcal{N})$ to $\delta(\mathcal{K})$ is at most $\frac{2e^{-3\beta}}{27000}$ which is less than or equal to $\frac{\beta^{-3}e^{-2\beta}}{2200}$ for any $\beta \geq 1$. Thus we may apply Theorem 1.7

to the space $\mathcal{K}$ with $\alpha_R = \beta$ and $\alpha_L = 0$. We obtain a lower bound on the competitive ratio of $\mathcal{K}$ of $\beta + Z(\beta)(1-\zeta)$. Finally, note that $Z(\beta) \geq 2e^{-2\beta}$ for $\beta \geq 1$ and that the hypothesis of the corollary guarantees that $\zeta \leq 1/2$. □

6.1. Tight bounds for highly unbalanced spaces.

Proof of Theorem 1.5. We want to show that for some polynomial $p(n)$, any $p(n)$-unbalanced metric space has competitive ratio between $\ln n$ and $3 \ln n$. We prove only the upper bound here; the lower bound proof is very similar. For $n = 1, 2$ the result is trivial. Let $n > 2$ and let $\mathcal{M}$ be a $p(n)$-unbalanced metric space on n points. Let x and y be two points of distance δ, the diameter of the space. Then by the imbalance property, every other point z is close to exactly one of the points x or y, i.e., its distance to one of them is at most $\frac{\delta}{p(n)}$. This yields a $\frac{2}{p(n)}$-bipartition $(\mathcal{M}_L, \mathcal{M}_R)$. Let $n_L = |\mathcal{M}_L|$ and $n_R = |\mathcal{M}_R|$ and assume $n_L \geq n_R$. By induction, $\lambda(\mathcal{M}_L) \leq 3\ln(n_L)$ and $\lambda(\mathcal{M}_R) \leq 3\ln(n_R)$. Calling these upper bounds α_L and α_R, we have $\alpha_{\max} = 3\ln(n_L)$ and $\alpha_{\text{diff}} = 3\ln(n_L/n_R)$. By choosing $p(n)$ to be a sufficiently large polynomial, the conditions of Corollary 6.2 apply, and $\lambda \leq 3\ln(n_L) + (3/2)Z(3\ln(n_L/n_R))$. Thus it suffices to show

$$3\ln n \geq 3\ln(n_L) + \frac{3}{2} Z(3ln(n_L/n_R)).$$

For $n_L = n_R$, this reduces to $\ln 2 \geq 1/2$. For $n_L > n_R$, let $\rho = n_L/n_R - 1$, so that $\rho > 0$. Rewriting the desired inequality in terms of ρ, we need

$$\ln\left(1 + \frac{1}{1+\rho}\right) \geq \frac{3\ln(1+\rho)}{6\rho + 6\rho^2 + 2\rho^3}.$$

Using $x \geq \ln(1+x) \geq x - x^2/2$ to lower bound the left-hand side and upper bound the right-hand side, it is enough to show

$$\frac{1+2\rho}{2(1+\rho)^2} \geq \frac{3}{6 + 6\rho + 2\rho^2},$$

which is easily checked by cross-multiplying. □

6.2. A lower bound for all metric spaces. In order to prove Theorem 1.3 we will need a structure lemma for finite metric spaces, which says roughly that every finite metric space contains at least one of the following: (1) a small set of points whose removal reduces the diameter by a large fraction, (2) a roughly uniform subspace of large size, or (3) a bipartite subspace in which both parts are large and have small diameter relative to their union.

LEMMA 6.5. *Let $k \geq 0$ be an integer and $s \geq 1$. Every finite metric space $\mathcal{M}$ has a subspace satisfying at least one of the following conditions:*

1. *a 2^{1-s}-small subspace of size at least $(1 - \frac{1}{s})|\mathcal{M}|$,*
2. *a $\frac{1}{4}$-uniform subspace of size at least s,*
3. *a 2^{1-k}-bipartite subspace, each of whose parts has size at least $\frac{|\mathcal{M}|}{2s^{k+2}}$.*

Proof. The first step in the proof is given by the following proposition.

PROPOSITION 6.1. *Let $k \geq 0$ be an integer and $s \geq 1$ be real. Any finite metric space $\mathcal{M}$ that has no $\frac{1}{4}$-uniform subspace of size at least s has a 2^{-k}-small subspace of size at least $\frac{|\mathcal{M}|}{s^k}$.*

We proceed by induction on k; the basis $k = 0$ is trivial. Suppose $k > 0$ and that $\mathcal{M}$ has no $\frac{1}{4}$-uniform subspace of size at least s. By the induction hypothesis there

is a subspace $\mathcal{N}$ of size at least $\frac{|\mathcal{M}|}{s^{k-1}}$ and diameter at most $\delta 2^{1-k}$. Let $x_1, x_2, \ldots, x_t$ be a maximal sequence of points in $\mathcal{N}$ such that $d(x_i, x_j) \geq \delta(\mathcal{N})/4$ for $i \neq j$. For each $i \in \{1, \ldots, t\}$ let $X_i = \{y \in \mathcal{N} : d(y, x_i) < \delta(\mathcal{N})/4\}$. By the maximality of t, $\cup_i X_i = \mathcal{N}$. The largest X_i has size at least $|\mathcal{N}|/t \geq |\mathcal{M}|/s^k$ and has diameter at most $\delta(\mathcal{N})/2 \leq \delta(\mathcal{M})/2^k$. □

PROPOSITION 6.2. *Let $k \geq 0$ be an integer, $s \geq 1$, and $\gamma \in (0, 1)$. Any finite metric space $\mathcal{M}$ has at least one of the following:*

1. *a 1/2-small subspace of size at least $(1-\gamma)|\mathcal{M}|$,*
2. *a 1/4-uniform subspace of size at least s,*
3. *a 2^{1-k}-bipartite subspace, each of whose parts has size at least $\frac{\gamma}{s^k}|\mathcal{M}|$.*

Proof. Assume that $\mathcal{M}$ has no 1/4-uniform subspace of size at least s. Define sequences $\mathcal{M}_0, \mathcal{M}_1, \ldots, \mathcal{M}_u$ and $\mathcal{N}_1, \ldots, \mathcal{N}_u$ as follows. $\mathcal{M}_0 = \mathcal{M}$. Having constructed $\mathcal{M}_i$, if $|\mathcal{M}_i| < \gamma|\mathcal{M}|$, then stop and set $u = i$. Otherwise, the previous proposition implies that $\mathcal{M}_i$ has a 2^{-k}-small subspace of size at least $\frac{|\mathcal{M}_i|}{s^k} \geq \frac{\gamma}{s^k}|\mathcal{M}|$. Let $\mathcal{N}_{i+1}$ be such a subspace and let $\mathcal{M}_{i+1} = \mathcal{M}_i - \mathcal{N}_{i+1}$.

The union $\mathcal{N}$ of the $\mathcal{N}_i$ has size at least $(1-\gamma)|\mathcal{M}|$. If it is 1/2-small, then we have a space satisfying the first condition. Otherwise, there exist $x, y \in \mathcal{N}$ with $d(x, y) \geq \delta/2$. If $\mathcal{N}_i$ and $\mathcal{N}_j$ are the parts containing x and y, respectively, then their union is a space satisfying the third condition. □

To complete the proof of Lemma 6.5, fix k, s as hypothesized. Let $\mathcal{M}$ be given and assume that $\mathcal{M}$ has no $\frac{1}{4}$-uniform subspace of size at least s and no 2^{1-k}-bipartite subspace in which each part has size at least $\frac{1}{2s^{k+2}}|\mathcal{M}|$. We show that $\mathcal{M}$ has a 2^{1-s}-small subset of size at least $(1-\frac{1}{s})|\mathcal{M}|$. This is trivial if $s = 1$, so assume $s > 1$ and set $\gamma = 1/s^2$. We define a sequence of metric spaces $\mathcal{M}_0, \mathcal{M}_1, \mathcal{M}_2, \ldots, \mathcal{M}_{\lfloor s \rfloor}$, where $\mathcal{M}_i$ has size at least $(1 - i\gamma)|\mathcal{M}|$ and has diameter at most $\delta 2^{-i}$. Then $\mathcal{M}_{\lfloor s \rfloor}$ has the desired properties.

To define the sequence, let $\mathcal{M}_0 = \mathcal{M}$. For $0 < i < \lfloor s \rfloor$, having defined $\mathcal{M}_i$, apply Proposition 6.2 to it. Our assumption about $\mathcal{M}$ implies that neither conclusion (2) nor conclusion (3) of Proposition 6.2 hold for $\mathcal{M}_i$. (For this we need to observe that since $i \leq \lfloor s \rfloor$, $|\mathcal{M}_i| \geq |\mathcal{M}|/2$.) $\mathcal{M}_i$ has a $\frac{1}{2}$-small subspace of size at least $(1-\gamma)|\mathcal{M}_i| \geq (1-(i+1)\gamma)|\mathcal{M}|$, which we take to be $\mathcal{M}_{i+1}$. □

Proof of Theorem 1.3. Let $g(n)$ denote the minimum competitive ratio over all n point spaces. Because of the uniform space, $g(n) \leq 2 \ln n$. We derive a recurrence inequality for $g(n)$. Let $\mathcal{M}$ be an n point space. Fix $s = s(n)$ and an integer $k = k(n)$ to be specified later and apply Lemma 6.5. If the second conclusion holds, then Lemma 6.1 implies that $\lambda(\mathcal{M}) \geq \frac{1}{4} + \ln s$. If the third conclusion of Lemma 6.5 holds, we want to apply Corollary 6.3 with $\beta = g(\lceil \frac{n}{2s^{k+2}} \rceil)$ to conclude that $\lambda(\mathcal{M}) \geq g(\lceil \frac{n}{2s^{k+2}} \rceil) + 1/2$. To apply Corollary 6.3 it suffices that $2^{-k} \leq 1/(2200(2 \ln n)^3)$ (using the fact that $g(n) \leq 2 \ln n$)). So we choose $k = \lceil 20 + 3 \log \ln n \rceil \leq 20 + 6 \log \log n$. Finally, if the first conclusion of Lemma 6.5 holds, then we want to apply Corollary 6.4 with $\beta = g(\lceil n(1-\frac{1}{s}) \rceil)$ to conclude $\lambda(\mathcal{M}) \geq g(\lceil n(1-\frac{1}{s}) \rceil) + e^{-2g(\lceil n(1-\frac{1}{s}) \rceil)}$. To apply Corollary 6.4 it suffices that $2^{1-s} \leq 1/(27000 e^{6 \ln n})$ which holds if $s \geq 6 \log n + 20$. Thus under this assumption on s,

$$g(n) \geq \min \left\{ \frac{\log s}{4}, g\left(\left\lceil n\left(1 - \frac{1}{s}\right) \right\rceil \right) + e^{-2g(\lceil n(1-\frac{1}{s}) \rceil)}, g\left(\left\lceil \frac{n}{2s^{6 \log \log n + 22}} \right\rceil \right) + \frac{1}{2} \right\}. \tag{6.1}$$

It now suffices to choose $s(n)$ satisfying the above condition, guess a function that lower bounds $g(n)$, and use the recurrence to verify the lower bound.

We choose $s(n) = 2^{C_0\sqrt{\log n/\log\log n}}$, where $C_0 > 0$ is a small constant to be chosen later. We choose $n_0 = n_0(C_0)$ so that for $n \geq n_0$, $s(n) \geq 6\log n + 20$. Finally set $h(n) = C_1 \log s(n)$, where $C_1 > 0$ is chosen to be at most $1/4$ and also small enough so that for $3 \leq n \leq n_0$, $h(n) \leq 1$.

We claim that $g(n) \geq h(n)$ for all $n \geq 3$, which suffices to prove the theorem. We proceed by induction on n.

For $n \leq n_0$, the result is trivial since $g(n) \geq 1$. So assume $n > n_0$. Applying the recurrence (6.1) and the induction hypothesis, we get

$$g(n) \geq \min\left\{\frac{\log s}{4}, h\left(\left\lceil n\left(1-\frac{1}{s}\right)\right\rceil\right) + e^{-2h(\lceil n(1-\frac{1}{s})\rceil)}, h\left(\left\lceil \frac{n}{2s^{6\log\log n+22}}\right\rceil\right) + \frac{1}{2}\right\}. \tag{6.2}$$

In substituting h for g in the second term, we observe that $x + e^{-2x}$ increases with x for $x \geq \frac{\ln 2}{2}$ and is at most 1 for $x \in [0, \frac{\ln 2}{2}]$. Next, since h increases with n, we can drop the $\lceil\cdot\rceil$:

$$g(n) \geq \min\left\{\frac{\log s}{4}, h\left(n\left(1-\frac{1}{s}\right)\right) + e^{-2h(n(1-\frac{1}{s}))}, h\left(\frac{n}{2s^{6\log\log n+22}}\right) + \frac{1}{2}\right\}. \tag{6.3}$$

Now it suffices to show that each of the terms in the minimum is at least $h(n)$. This is true for the first term since $C_1 \leq 1/4$. For the second and third terms, we bound $h(n) - h(n/B)$ for $B > 1$ by the following chain of inequalities:

$$\begin{aligned} h(n) - h(n/B) &= C_1C_0\sqrt{\frac{\log n}{\log\log n}} - C_1C_0\sqrt{\frac{\log(n/B)}{\log\log(n/B)}} \\ &\leq C_1C_0\sqrt{\frac{\log n}{\log\log n}}\left(1 - \sqrt{1-\frac{\log B}{\log n}}\right) \\ &\leq C_1C_0\sqrt{\frac{\log n}{\log\log n}}\frac{\log B}{\log n} \\ &= C_1C_0\frac{\log B}{\sqrt{\log n\log\log n}}. \end{aligned}$$

To show that the second term in (6.3) is at least $h(n)$ we take $B = s/(s-1)$ in the above inequality. The final expression is then at most $C_1C_0\frac{1}{s\sqrt{\log n\log\log n}}$. We need to show that this is at most $e^{-2h(n(1-1/s))}$. This is true, as $C_1C_0\frac{1}{s\sqrt{\log n\log\log n}} \leq 1/s \leq 1/s^{2C_1/\ln 2} = e^{-2h(n)} \leq e^{-2h(n(1-1/s))}$, where the second inequality uses $C_1 \leq 1/4$.

To show that the third term in (6.3) is at least $h(n)$ take $B = 2s^{6\log\log n+22}$ in the above inequality. The final expression in the inequality is then at most $C_1C_0^2(6\log\log n + 22)/\log\log n$, which is at most $1/2$ for sufficiently small C_0. ∎

7. Proof of technical lemmas. In this section, we present the proofs of Lemmas 5.2 and 5.3. Throughout this section, $\mathcal{M}$ is a fixed finite metric space with distance function d and diameter δ. The minimum distance between (distinct) points in $\mathcal{M}$ is denoted $\delta_{\min}$.

We begin with some facts about the topological structure of the set of randomized

evader algorithms.[1] Recall from section 2.3 that an algorithm can be defined as a function that labels each E-node of $T_{\mathcal{M}}$ by a probability distribution on $\mathcal{M}$. The set $P(\mathcal{M})$ of probability distributions on $\mathcal{M}$ can be viewed as a topological subspace of Euclidean space $\mathbf{R}^{\mathcal{M}}$, and so the set of randomized algorithms can be viewed as a product of copies of this space (where the product is indexed by the E-nodes of $T_{\mathcal{M}}$).

The topological facts we need are summarized in the following proposition.

PROPOSITION 7.1.

1. *Any sequence of randomized evader algorithms has a subsequence that converges.*
2. *Suppose that the sequence $\tilde{A}_1, \tilde{A}_2, \ldots$ of algorithms converges to algorithm $\tilde{A}$ in the product topology. If ρ is any probe sequence, then the sequence of real numbers $\tilde{A}_1(\rho), \tilde{A}_2(\rho), \ldots$ converges to $\tilde{A}(\rho)$.*

Proof. The topological space of algorithms is equivalent to the product of a countable number of spaces isomorphic to $P(\mathcal{M})$. Notice that $P(\mathcal{M})$ is metrizable and compact. By Tychonoff's theorem (see [Kel, pp. 143–144]), the product of compact topological spaces is compact with respect to the product topology. Moreover, the product of a countable number of metrizable topological spaces is metrizable (see [Kel, p. 122]). The first part follows from the fact that every sequence in a compact metrizable topological space has a subsequence that converges to a point in the space (see [Kel, pp. 138–139]). For the second part, we note that for a probe sequence ρ, the mapping from the set of randomized algorithms to the reals, defined by $\tilde{A} \longrightarrow \tilde{A}(\rho)$ is continuous. □

We need a modification of the PE game. Fix the metric space $\mathcal{M}$ and let λ denote the competitive ratio of the PE game. We define the *modified game* for $\mathcal{M}$ to be a game whose strategy sets are the same as for the PE game but whose cost function is $f_A(\rho) = C_A(\rho) - \lambda C_{\mathrm{OPT}}(\rho)$. For $s > 0$, let G_s (resp., H_s) denote the game obtained from the modified game by restricting the strategies of the pursuer to be probe sequences ρ satisfying $C_{\mathrm{OPT}}(\rho) \leq s$ (resp., satisfying $s - \delta \leq C_{\mathrm{OPT}}(\rho) \leq s$). We will prove the following lemma.

LEMMA 7.1. *For every $s > 0$,*

1. *the games G_s and H_s have the min-max property, and*
2. *the values of G_s and H_s satisfy*

$$-\delta \leq V(H_s) \leq V(G_s) \leq \lambda\delta.$$

Assuming this lemma, it is easy to prove the two main technical lemmas.

Proof of Lemma 5.2. For $s > 0$, let $\tilde{A}_s$ denote an optimal strategy for G_s. By the first part of Proposition 7.1, there is a an infinite sequence $i_1 < i_2 < \cdots$ of positive integers such that the sequence $\tilde{A}_{i_j}$ converges to a limit algorithm $\tilde{A}$. If ρ is any probe sequence and j is chosen such that $i_j \geq C_{\mathrm{OPT}}(\rho)$, the second part of

[1] In the following discussion, we use the following concepts from point set topology (see, e.g., [Kel]): A set system $\mathcal{F}$ is a *topology* if and only if the union of any number of elements of $\mathcal{F}$ is in $\mathcal{F}$ and the intersection of a finite number of elements of $\mathcal{F}$ is in $\mathcal{F}$. The pair $(X, \mathcal{F})$, where $X = \cup F \in \mathcal{F}$, is called a *topological space*. The elements of $\mathcal{F}$ are called *open sets*. If $Y \subset X$, then $(Y, \mathcal{G})$, where $\mathcal{G} = \{F \cap Y;\ F \in \mathcal{F}\}$, is a *topological subspace* of $(X, \mathcal{F})$. (Notice that a topological subspace is a topological space.) For a metric space $\mathcal{M} = (X, d)$, the associated *metric topology* $\mathcal{F}$ is derived by putting $\mathcal{F}$ to be the set of all the unions of open balls in $\mathcal{M}$. A topological space that can be derived this way is *metrizable*. Any subset of $\mathcal{F}$ whose union equals X is an *open cover* of the topological space $(X, \mathcal{F})$. A topological space is *compact* if and only if every open cover has a finite subset that is also an open cover. If $(X, \mathcal{F})$ and $(Y, \mathcal{G})$ are topological spaces, then a function $f : X \to Y$ is *continuous* if and only if for every $G \in \mathcal{G}$, $f^{-1}(G) \in \mathcal{F}$.

Lemma 7.1 implies $C_{\tilde{A}_{i_j}}(\rho) - \lambda C_{\mathrm{OPT}}(\rho) \le V(G_{i_j}) \le \lambda\delta$. Letting i_j tend to ∞ yields $C_{\tilde{A}}(\rho) - \lambda C_{\mathrm{OPT}}(\rho) \le \lambda\delta$, as required. □

Proof of Lemma 5.3. Fix $s > 0$ and let $\tilde{\rho}_s$ denote an optimal strategy for the pursuer for the game H_s. Then for any evader algorithm $\tilde{A}$, we have $C_{\tilde{A}}(\rho_s) - \lambda C_{\mathrm{OPT}}(\rho) \ge -\delta$, or $C_{\tilde{A}}(\rho_s) \ge \lambda(s-\delta) - \delta$, as required. □

The remainder of the section proves Lemma 7.1. To prove the first part of the lemma, it would be enough, by Theorem 2.2.1, to show that the set of pure strategies is finite. Unfortunately, it is not, in general, true that the set of pure strategies is finite. However, we will reduce these games to an analysis of games with finite strategy sets. More precisely, we will define the notion of a *standard* probe sequence and a *standard* evader algorithm and show that the restrictions of the games G_s and H_s to these sets are essentially finite games and that the the analysis of G_s and H_s can be reduced to that of the restricted game.

As a preliminary restriction, we say that an evader algorithm A is *lazy* if it does not move unless it has to; i.e., the evader moves from its current location only if the pursuer probes the location he occupies. It is easy to show and well known (see [BE]) that the set of lazy algorithms dominates the set of all algorithms in the sense of section 2.2. (Actually, the versions of this result that appear in the literature prove the dominance with respect to the cost function $C_A(\rho)$ rather than $f_A(\rho)$, but it is easy to show that the one result implies the other). Thus, applying Lemma 2.1 (2.1), it suffices to restrict the evader to lazy algorithms, which we do from now on.

By the definition of a lazy algorithm, if the evader is at point a after probe sequence ρ, the evader will move only if the next probe is to a. Thus for a lazy deterministic algorithm A, each probe sequence ρ induces a *transition function* $A[\rho]$ mapping the metric space to itself where $A[\rho](a)$ is the point the evader moves to if it is at a after ρ and the next probe is to a.

Before we can define the notion of standard algorithm and standard probe sequence, we need to review some basic facts about the PE game and the function C_{OPT}. For the PE game, C_{OPT} can be expressed as follows. For probe sequence ρ and point $p \in M$, let $C_A(\rho; p)$ denote the cost incurred by A in responding to ρ and then moving to point p; this is $C_A(\rho) + d(a, p)$, where a is the final point of $A(\rho)$. Let $C_{OPT}(\rho; p)$ denote the minimum of $C_A(\rho; p)$ over all algorithms A. Then $C_{\mathrm{OPT}}(\rho) = \min\{C_{\mathrm{OPT}}(\rho; p) : p \in \mathcal{M}\}$. For ρ equal to the empty string, we have $C_{\mathrm{OPT}}(\rho; p) = 0$. For any ρ and any points a, p, we have

$$C_{\mathrm{OPT}}(\rho a; p) = \begin{cases} C_{\mathrm{OPT}}(\rho; p) & \text{if } a \neq p, \\ \min_{q \neq p} C_{\mathrm{OPT}}(\rho; q) + d(q, a) & \text{if } a = p. \end{cases}$$

For each ρ, $C_{\mathrm{OPT}}(\rho; p)$ is a function mapping $p \in \mathcal{M}$ to the nonnegative reals. This is the well known *work function* associated with this game (see, e.g., [BE]) and will be denoted $WF[\rho]$.

It is easy to check that if τ is an extension of ρ, then $WF[\tau] \ge WF[\rho]$, where the inequality of work functions is defined pointwise. τ is a *null extension* of ρ if they have the same work function. A point a is said to be *null* with respect to a sequence ρ if ρa is a null extension of ρ. Let $N(\rho)$ denote the set of points that are null with respect to ρ.

We state a few easy facts without proof.

PROPOSITION 7.2. *Let $\rho = (\rho_1, \ldots, \rho_k)$ be an arbitrary probe sequence.*

1. *$\rho_k \in N(\rho)$.*
2. *If τ has the same work function as ρ, then $N(\rho) = N(\tau)$. In particular, if $a \in N(\rho)$, then $N(\rho a) = N(\rho)$.*
3. *If a is any point that minimizes $WF[\rho](\cdot)$, then $a \notin N(\rho)$. In particular, there is at least one point that is not null with respect to ρ.*

A sequence $\rho = (\rho_1, \ldots, \rho_k)$ is said to be *standard* if the work functions associated to its prefixes are all different; equivalently, for each i between 2 and k $\rho_i \notin N(\rho_1, \ldots, \rho_{i-1})$.

A *standard* algorithm A is a lazy algorithm that ignores null points. More precisely, a standard algorithm never moves to a point that is null with respect to the current sequence, and ignores requests to null points in the sense that its present and future behavior is unaffected by such requests.

Let G'_s (resp., H'_s) denote the game obtained from G_s (resp., H_s) by restricting to standard probe sequences and standard evader algorithms.

PROPOSITION 7.3. *For each $s > 0$ there is an integer $t(s)$ with the property that any standard probe sequence of optimal cost at most s has term length at most $t(s)$.*

Proof. Let $\rho = (\rho_1, \ldots, \rho_t)$ be a standard probe sequence. Let w^i denote the work function associated to the prefix ρ^i. For each i, $w^i(p) = w^{i-1}(p)$ if $p \neq \rho_i$ and $w^i(\rho_i) > w^{i-1}(\rho_{i-1})$. Let $\Delta_i = w^i(\rho_i) - w^{i-1}(\rho_{i-1})$. Induction on s yields $\sum_p w^s(p) = \sum_{i=1}^s \Delta_i$. Since the maximum and minimum work function values associated to any probe sequence differ by at most δ, $w^i(p) \geq \frac{1}{n}(\sum_{i=1}^s \Delta_i) - \delta$. Recall that $\delta_{\min}$ is the minimum distance between two distinct points in the metric space. We will show the following.

CLAIM. *In any subsequence of n^n consecutive indices there is an i such that $\Delta_i \geq \delta_{\min}$.*

This implies that for any ρ of length t, $w^i(\rho) \geq \lfloor \frac{t}{n^n} \rfloor \delta_{\min}$ and so for any $s > 0$ we can choose $t(s)$ so that for $|\rho| \geq t(s)$, the minimum work function value is at least s.

So we prove the claim. Fix an arbitrary ordering $<$ on $\mathcal{M}$. For each i, let $p_1^i, \ldots, p_n^i$ denote the sequence of points ordered so that $w^i(p_r^i) \leq w^i(p_{r+1}^i)$ with ties broken according to the ordering $<$. Let Γ_i denote the directed graph on vertex set $\mathcal{M}$, with arcs $p \longrightarrow_i q$ if $w^i(q) = w^i(p) + d(p, q)$. (Note that a point p is null with respect to ρ^i precisely if its in-degree in Γ_i is positive.) Define $\mathbf{d}^i = (d_1^i, \ldots, d_n^i)$ with d_r^i equal to the outdegree of p_r^i in Γ_i. We will show that for each i, if $\Delta_i < \delta_{\min}$, then the sequence $\mathbf{d}^i$ is lexicographically greater than $\mathbf{d}^{i-1}$. Since there are at most n^n distinct out-degree sequences, this will prove the claim and the proposition.

Γ_i differs from Γ_{i-1} only on the arcs incident on ρ_i. The in-degree of ρ_i in Γ_{i-1} is 0 since ρ_i is nonnull with respect to ρ^{i-1} and is positive in Γ_i since ρ_i is null with respect to ρ^i. Let h be an index such that $p_h^{i-1} \longrightarrow_i \rho_i$ and let j be the index such that $\rho_i = p_j^{i-1}$. By definition of Γ_i, $w^i(\rho_i) = w^i(p_h^{i-1}) + d(p_h^{i-1}, \rho_i) \geq w^{i-1}(p_h^{i-1}) + \delta_{\min}$.

If $h > j$, then $w^{i-1}(\rho_i) \leq w^{i-1}(p_h^{i-1})$ and we conclude $w^i(\rho_i) - w^{i-1}(\rho_i) \geq \delta_{\min}$.

So suppose that $h < j$. For $r < j$, $p_r^i = p_r^{i-1}$ and all edges out of p_r^{i-1} in Γ_{i-1} are present in Γ_i. Thus $d_r^i \geq d_r^{i-1}$. For $r = h$, we have strict inequality since $d_h^i \longrightarrow_i \rho_i$. This implies that $\mathbf{d}^i$ is lexicographically greater than $\mathbf{d}^{i-1}$. □

An immediate consequence of Proposition 7.3 is that the number of standard probe sequences of cost at most s is finite. Also, although the number of deterministic evader algorithms is infinite, if we call two algorithms equivalent if they respond identically to any probe sequence of term length at most $t(s)$, then the number of equivalence classes is finite. Hence G'_s (resp., H'_s) is essentially a finite game, and

thus by Theorem 2.2.1 it has the min-max property. We will show that the game G_s (resp., H_s) is "essentially" the same as G'_s (resp., H'_s), to prove the first part of Lemma 7.1. For ease of notation, we refer only to G_s in this argument. The argument holds as well if we replace G_s by H_s and G'_s by H'_s.

For an evader algorithm $\tilde{A}$, we write $V_{\mathrm{MIN}}(\tilde{A})$ for the value of $\tilde{A}$ in the game G_s, i.e., the supremum over all probe sequences ρ of optimal cost at most s of $f_{\bar{A}}(\rho)$. We write $V'_{\mathrm{MIN}}(\tilde{A})$ for the value of $\tilde{A}$ in the game G'_s. Similarly, for a randomized probe sequence $\tilde{\rho}$, we write $V_{\mathrm{MAX}}(\tilde{\rho})$ and $V'_{\mathrm{MAX}}(\tilde{\rho})$, respectively, for the value of $\tilde{\rho}$ with respect to the games G_s and G'_s.

PROPOSITION 7.4. *For any randomized standard evader algorithm $\tilde{A}$, $V_{\mathrm{MIN}}(\tilde{A}) = V'_{\mathrm{MIN}}(\tilde{A})$.*

Proof. Let $\rho = (\rho_1, \ldots, \rho_k)$ be an arbitrary probe sequence. Write w^i for the work function associated to the prefix ρ^i. We observed earlier that $w^1 \leq w^2 \leq \cdots \leq w^k$ (where the inequality is pointwise). Define the sequence of indices $i_1 < i_2 < \cdots < i_j$, where $i_1 = 1$, i_2 is the least i such that $w^{i_2} \neq w^{i_1}$ and, in general, i_h is the least i such that $w^{i_h} \neq w^{i_{h-1}}$. It is easy to see that the sequence $\hat{\rho} = \rho_{i_1}\rho_{i_2}\ldots\rho_{i_j}$ is standard and has the same work function as ρ.

Now let $\tilde{A}$ be a randomized standard algorithm. Since $\tilde{A}$ ignores all probes to null points, it behaves the same on ρ as it does on $\hat{\rho}$. More precisely, the probability that $\tilde{A}$ responds to $\hat{\rho}$ with the sequence $\sigma_1\sigma_2\ldots\sigma_j$ is equal to the probability that it responds to ρ with $\sigma_1^{i_2-1}\sigma_2^{i_3-i_2}\ldots\sigma_{j-1}^{i_j-i_{j-1}}\sigma_j^{n+1-i_j}$, which has the same cost as $\sigma_1\ldots\sigma_j$. □

Given an analogous result for pursuer strategies, the first part of Lemma 7.1 would follow immediately. However, such a result is not true: if $\tilde{\rho}$ is a randomized standard pursuer strategy, then since the pursuer never probes null points, a nonstandard algorithm might be able to avoid the pursuer by moving to null points.

So we need to prove something a little subtler about pursuer strategies. The key property of a null point is that the pursuer can probe a null point without increasing the work function, and thus probes to a null point are "free" to the pursuer. Thus we can modify any standard pursuer strategy so that it probes null points often enough to ensure that it does not benefit the evader to ever visit a null point. If we modify the optimal standard pursuer strategy in this way, we will get a strategy whose value in the game G_s is the same as that of the optimal standard strategy in the game G'_s.

We now make this argument precise. Let $\rho = (\rho_1, \ldots, \rho_k)$ be a probe sequence. For i between 1 and k, Let $\eta_{\mathbf{i}}$ be some fixed ordering on $N(\rho^i)$, the set of points that are null with respect to ρ^i. For a nonnegative integer j, we define the *j-fold inflation of ρ* to be the sequence $\rho_1{\eta_{\mathbf{1}}}^j\rho_2{\eta_{\mathbf{2}}}^j\ldots\rho_k{\eta_{\mathbf{k}}}^j$. It is trivial that the work functions associated with a sequence and its j-fold inflation are identical.

If $\tilde{\rho}$ is a randomized pursuer strategy, i.e., a probability distribution over probe sequences, then the j-fold inflation of $\tilde{\rho}$ is the distribution obtained by selecting a sequence according to $\tilde{\rho}$ and applying j-fold inflation to it.

PROPOSITION 7.5. *For j a sufficiently large integer (depending on $\mathcal{M}$ and s) the following holds. For any deterministic lazy evader algorithm A there is a deterministic standard algorithm $\bar{A}$ such that for any randomized pursuer strategy $\tilde{\rho}$ in the game G_s, if $\tilde{\sigma}$ is the j-fold inflation of ρ, then $C_{\bar{A}}(\tilde{\rho}) \leq C_A(\tilde{\sigma})$. Consequently, $V'_{\mathrm{MAX}}(\tilde{\rho}) \leq V_{\mathrm{MAX}}(\tilde{\sigma})$.*

Before proving the proposition, let us see that it implies the first part of Lemma 7.1. Let $\tilde{A}^*$ and $\tilde{\rho}^*$ be the optimal strategies of evader and pursuer in the game G'_s, and let $\tilde{\sigma}^*$ be the j-fold inflation of $\tilde{\rho}^*$ (where j is large enough for Proposition 7.5). From Proposition 7.4, $V_{\mathrm{MIN}}(\tilde{A}^*) = V'_{\mathrm{MIN}}(\tilde{A}^*)$. From Proposition 7.5, $V'_{\mathrm{MAX}}(\tilde{\rho}^*) \leq$

$V_{\mathrm{MAX}}(\tilde{\sigma}^*)$. Since G'_s has the min-max property, we have that $V'_{\mathrm{MIN}}(\tilde{A}^*) = V'_{\mathrm{MAX}}(\tilde{\rho}^*)$. Hence $V_{\mathrm{MIN}}(\tilde{A}^*) \leq V_{\mathrm{MAX}}(\tilde{\sigma}^*)$, and combining this with Lemma 2.2, we conclude that $V_{\mathrm{MIN}}(\tilde{A}^*) = V_{\mathrm{MAX}}(\tilde{\sigma}^*)$, i.e., G_s has the min-max property.

Proof of Proposition 7.5. Fix j sufficiently large. Given A, we need to define $\bar{A}$. The behavior of A on a probe sequence $\rho = (\rho_1, \ldots, \rho_k)$ is defined using an on-line simulation of A applied to the j-fold inflation $\sigma = \rho_1 \eta_{\mathbf{1}}{}^j \ldots \rho_k \eta_{\mathbf{k}}{}^j$ of ρ. Prior to the ith request, $\bar{A}$ will have processed $\rho_1, \ldots, \rho_{i-1}$ and responded with $\sigma_1 \sigma_2 \ldots \sigma_{i-1}$. It will also have simulated A on the j-fold inflation of $\rho_1, \ldots, \rho_{i-1}$. Upon receipt of ρ_i, it continues the simulation by giving A the sequence $\rho_i \eta_{\mathbf{i}}{}^j$. Let τ_i denote the final point A occupies after processing that sequence.

$\bar{A}$ then chooses its response σ_i according to the following rule. If $\sigma_{i-1} \neq \rho_i$, then $\sigma_i = \sigma_{i-1}$ (following laziness). Otherwise, if τ_i is not null with respect to $\rho_1 \ldots \rho_i$, then $\sigma_i = \tau_i$, else $\bar{A}$ moves to any nonnull point (say, the least one under some predetermined ordering).

It is immediate that $\bar{A}$ is a standard algorithm. We claim that $C_{\bar{A}}(\rho) \leq C_A(\sigma)$. This then extends by linearity to the case of randomized pursuer strategies.

We say that A is *well behaved* on $\rho_1, \rho_2, \ldots, \rho_k$ provided that for each i, the point τ_i is not null with respect to $\rho_1 \ldots \rho_i$. By the definition of $\bar{A}$ (and the fact that A itself is lazy), if A is well behaved, then the response sequence $\sigma_1, \ldots, \sigma_k$ of $\bar{A}$ is just $\tau_1, \tau_2, \ldots, \tau_k$ and is thus a subsequence of A's response sequence. Hence $C_{\bar{A}}(\rho) \leq C_A(\sigma)$.

If A is not well behaved, then for some i, τ_i is null with respect to $\rho_1 \ldots \rho_i$. Consider the responses of A to $\rho_i \eta_i^j$. If A ever responded with a point that is not null with respect to $\rho_1 \ldots \rho_i$, then since A is lazy and all requests appearing in η_i are null, A would have ended in a nonnull point. So it must be that each of A's responses to this subsequence was a null point. Now since η_i contains each null point once, A was forced to move at least j times. Thus $c_A(\sigma) \geq j\delta_{\min}$. Taking j large enough (depending on $\mathcal{M}$ and s) ensures that this is at least $C_{\bar{A}}(\rho)$. □

This completes the proof of the first part of Lemma 7.1. We proceed to the proof of the second part. We state without proof a routine fact concerning the function C_{OPT}.

LEMMA 7.2. *Let $\mathcal{M}$ be a metric space of diameter δ, and let $\rho_{\mathbf{1}}, \rho_{\mathbf{2}}, \ldots, \rho_{\mathbf{w}}$ be probe sequences. Then*

$$\sum_{i=1}^{w} C_{\mathrm{OPT}}(\rho_{\mathbf{i}}) \leq C_{\mathrm{OPT}}(\rho_{\mathbf{1}} \rho_{\mathbf{2}} \ldots \rho_{\mathbf{w}}) \leq \sum_{i=1}^{w} C_{\mathrm{OPT}}(\rho_{\mathbf{i}}) + (w-1)\delta.$$

Furthermore, the inequalities extend to the case that the ρ_i are replaced by randomized probe sequences $\tilde{\rho}_{\mathbf{i}}$.

(Recall that the definition of C_{OPT} allows the evader to choose its own starting point. So if each $\rho_{\mathbf{i}}$ misses some point in $\mathcal{M}$, then $\sum_{i=1}^{w} C_{\mathrm{OPT}}(\rho_{\mathbf{i}}) = 0$, and if all $\rho_{\mathbf{i}}$ miss the *same* point in $\mathcal{M}$, then $C_{\mathrm{OPT}}(\rho_{\mathbf{1}} \rho_{\mathbf{2}} \ldots \rho_{\mathbf{w}}) = 0$.)

We now prove the second part of Lemma 7.1. The middle inequality is trivial since the only difference between G_s and H_s is that the pursuer strategy set in H_s is a subset of that in G_s.

Consider the first inequality and suppose for contradiction that there is an $s > 0$ and an $\epsilon > 0$ such that $V(H_s) = -\delta - \epsilon$. Let $\tilde{B}_s$ denote an optimal evader algorithm for H_s. We define an evader algorithm $\tilde{B}$ for the original PE game as follows: for probe sequence τ determine its s-block partition, $\tau_{\mathbf{1}} \tau_{\mathbf{2}} \ldots \tau_{\mathbf{r}}$, which can be parsed on-line. The algorithm $\tilde{B}$ is performed by applying $\tilde{B}_s$ to each $\tau_{\mathbf{i}}$. We obtain a contradiction

by showing that $\tilde{B}$ is λ'-competitive for some $\lambda' < \lambda$. There is some absolute upper bound K on the cost incurred by $\tilde{B}_s$ on a sequence of optimal cost at most s. We have

$$\begin{aligned} C_{\tilde{B}}(\tau) &\le \sum_{i=1}^{r-1} (C_{\tilde{B}_s}(\tau_{\mathbf{i}}) + \delta) + C_{\tilde{B}_s}(\tau_{\mathbf{r}}) \\ &\le \sum_{i=1}^{r-1} (\lambda C_{\mathrm{OPT}}(\tau_{\mathbf{i}}) - \epsilon) + K \\ &\le \sum_{i=1}^{r-1} \left(\lambda - \frac{\epsilon}{s}\right) C_{\mathrm{OPT}}(\tau_{\mathbf{i}}) + K \\ &\le \left(\lambda - \frac{\epsilon}{s}\right) C_{\mathrm{OPT}}(\tau) + K, \end{aligned}$$

where the first and last inequalities follow from Lemma 7.2, the second inequality follows from the optimality of $\tilde{B}_s$ for H_s, and the third inequality follows from the fact that each τ_i has optimal cost at most s. We conclude that $\tilde{B}$ is $(\lambda - \frac{\epsilon}{s})$-competitive, a contradiction that completes the proof of the first inequality.

Turning to the third inequality, we suppose for contradiction that there is an $s > 0$ and an $\epsilon > 0$ such that $V(G_s) \ge \lambda\delta + \epsilon$. Let $\tilde{\rho}_s$ be the optimal pursuer strategy for G_s. Then for any algorithm $\tilde{B}$, $C_{\tilde{B}}(\tilde{\rho}_s) \ge \lambda(C_{\mathrm{OPT}}(\tilde{\rho}_s) + \delta) + \epsilon$. For each $j \in \mathbb{N}$, define the distribution $\tilde{\tau}_{\mathbf{j}}$ on probe sequences obtained by concatenating j sequences generated independently from $\tilde{\rho}_s$. Then by Lemma 7.2, $C_{\mathrm{OPT}}(\tilde{\tau}_{\mathbf{j}})$ is bounded above by $u_j = j(C_{\mathrm{OPT}}(\tilde{\rho}_{\mathbf{s}}) + \delta)$. We will obtain a contradiction by showing that there exists a real number $\gamma > 0$ such that for any deterministic algorithm A, $C_A(\tilde{\tau}_{\mathbf{j}}) \ge u_j(\lambda + \gamma)$, which by Proposition 2.3 would imply that the competitive ratio is greater than $\lambda + \gamma$.

Let A be a deterministic algorithm and consider the cost of A on $\tilde{\tau}_{\mathbf{j}}$. By Lemma 7.2, we can lower bound this cost by the sum of costs that are incurred in responding to each of the j blocks. Note that the way that A responds to the ith block depends on the previous $i-1$ blocks, and we can view A's behavior on the ith block as a randomized algorithm $\tilde{B}_i$, where the randomization comes from the previous $i-1$ blocks. Thus

$$\begin{aligned} C_A(\tilde{\tau}_{\mathbf{j}}) &\ge \sum_{i=1}^{j} C_{\tilde{B}_i}(\tilde{\rho}_{\mathbf{s}}) \\ &\ge j[\lambda(C_{\mathrm{OPT}}(\tilde{\rho}_{\mathbf{s}}) + \delta) + \epsilon] \\ &= u_j \left(\lambda + \frac{\epsilon}{C_{\mathrm{OPT}}(\tilde{\rho}_{\mathbf{s}}) + \delta}\right), \end{aligned}$$

where the second inequality follows from the optimality of $\tilde{\rho}_s$. Thus we have the desired contradiction, which establishes the claim and the lemma.

Acknowledgments. We would like to thank the anonymous referees for the many useful comments in their reports, which helped improve the presentation of our results.

LINEAR TIME ALGORITHMS FOR HAMILTONIAN PROBLEMS ON (CLAW,NET)-FREE GRAPHS*

ANDREAS BRANDSTÄDT†, FEODOR F. DRAGAN‡, AND EKKEHARD KÖHLER§

Abstract. We prove that claw-free graphs, containing an induced dominating path, have a Hamiltonian path, and that 2-connected claw-free graphs, containing an induced doubly dominating cycle or a pair of vertices such that there exist two internally disjoint induced dominating paths connecting them, have a Hamiltonian cycle. As a consequence, we obtain linear time algorithms for both problems if the input is restricted to (claw,net)-free graphs. These graphs enjoy those interesting structural properties.

Key words. claw-free graphs, (claw,net)-free graphs, Hamiltonian path, Hamiltonian cycle, dominating pair, dominating path, linear time algorithms

1. Introduction.

Hamiltonian properties of claw-free graphs have been studied extensively in the last couple of years. Different approaches have been made, and a couple of interesting properties of claw-free graphs have been established (see [1, 2, 3, 5, 6, 13, 14, 15, 16, 19, 22, 23, 25, 26]). The purpose of this work is to consider the algorithmic problem of finding a Hamiltonian path or a Hamiltonian cycle efficiently. It is not hard to show that both the Hamiltonian path problem and the Hamiltonian cycle problem are NP-complete, even when restricted to line graphs [28]. Hence, it is quite reasonable to ask whether one can find interesting subclasses of claw-free graphs for which efficient algorithms for the above problems exist.

Already in the eighties, Duffus, Jacobson, and Gould [12] defined the class of (claw,net)-free (CN-free) graphs, i.e., graphs that contain neither an induced claw nor an induced net (see Figure 1.1). Although this definition seems to be rather restrictive, the family of CN-free graphs contains a couple of graph families that are of interest in their own right. Examples of those families are unit interval graphs, claw-free asteroidal triple-free (AT-free) graphs, and proper circular arc graphs. In their paper [12], Duffus, Jacobson, and Gould showed that this class of graphs has the nice property that every connected CN-free graph contains a Hamiltonian path and every 2-connected CN-free graph contains a Hamiltonian cycle. Later, Shepherd [27] proved that there is an $O(n^6)$ algorithm for finding such a Hamiltonian path/cycle in CN-free graphs. Note also that CN-free graphs are exactly the Hamiltonian-hereditary

graphs [10], i.e., the graphs for which every connected induced subgraph contains a Hamiltonian path.

In this paper we give a constructive existence proof and present linear time algorithms for the Hamiltonian path and Hamiltonian cycle problems on CN-free graphs. The important structural property that we exploit for this is the existence of an induced *dominating path* in every connected CN-free graph (Theorem 2.3). The concept of a dominating path was first used by Corneil, Olariu, and Stewart [8] in the context of AT-free graphs. They also developed a simple linear time algorithm for finding such a path in every AT-free graph [7]. As we show in Theorem 2.3, for the class of CN-free graphs, a linear time algorithm for finding an induced dominating path exists as well. This property is of interest for our considerations since we prove that all claw-free graphs that contain an induced dominating path have a Hamiltonian path (Theorem 3.1). The proof implies that, given a dominating path, one can construct a Hamiltonian path for a claw-free graph in linear time.

For 2-connected claw-free graphs, we show that the existence of a dominating pair is sufficient for the existence of a Hamiltonian cycle. (A *dominating pair* is a pair of vertices such that every induced path connecting them is a dominating path.) Again, given a dominating pair, one can construct a Hamiltonian cycle in linear time (Theorem 5.6). This already implies, for example, a linear time algorithm for finding a Hamiltonian cycle in claw-free AT-free graphs, since every AT-free graph contains a dominating pair and it can be found in linear time [9]. Unfortunately, CN-free graphs do not always have a dominating pair. For example, an induced cycle with more than six vertices is CN-free but does not have such a pair of vertices. Nevertheless, 2-connected CN-free graphs have another nice property: they have a good pair or an induced doubly dominating cycle. An *induced doubly dominating cycle* is an induced cycle such that every vertex of the graph is adjacent to at least two vertices of the cycle. A *good pair* is a pair of vertices, such that there exist two internally disjoint induced dominating paths connecting these vertices. We prove that the existence of an induced doubly dominating cycle or a good pair in a claw-free graph is sufficient for the existence of a Hamiltonian cycle (Theorems 5.1 and 5.5). Moreover, given an induced doubly dominating cycle or a good pair of a claw-free graph, a Hamiltonian cycle can be constructed in linear time. In section 4 we present an $O(m+n)$ time algorithm which, for a given 2-connected CN-free graph, finds either a good pair or an induced doubly dominating cycle.

For terms not defined here, we refer to [11, 17]. In this paper we consider finite connected undirected graphs $G = (V, E)$ without loops and multiple edges. The cardinality of the vertex set is denoted by n, whereas the cardinality of the edge set is denoted by m.

A *path* is a sequence of vertices $(v_0, \ldots, v_l)$ such that all v_i are distinct and $v_i v_{i+1} \in E$ for $i = 0, \ldots, l-1$; its *length* is l. An *induced path* is a path where $v_i v_j \in E$ if and only if $i = j-1$ and $j = 1, \ldots, l$. A *cycle* (*k-cycle*) is a path $(v_0, \ldots, v_k)$ $(k \geq 3)$ such that $v_0 = v_k$; its *length* is k. An *induced cycle* is a cycle where $v_i v_j \in E$ if and only if $|i-j| = 1$ (modulo k). A *hole* H_k is an induced cycle of length $k \geq 5$.

The *distance* $dist(v, u)$ between vertices v and u is the smallest number of edges in a path joining v and u. The *eccentricity* $ecc(v)$ of a vertex v is the maximum distance from v to any vertex in G. The *diameter* $diam(G)$ of G is the maximum eccentricity of a vertex in G. A pair v, u of vertices of G with $dist(v, u) = diam(G)$ is called a *diametral pair*.

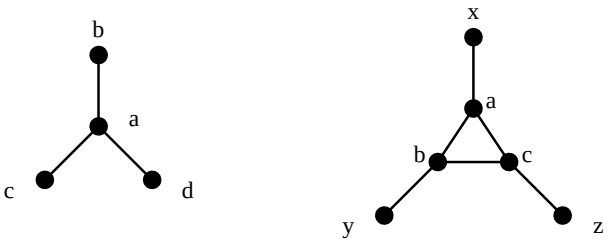

FIG. 1.1. *The claw* $K(\mathrm{a};\mathrm{b},\mathrm{c},\mathrm{d})$ *and the net* $N(\mathrm{a},\mathrm{b},\mathrm{c};\mathrm{x},\mathrm{y},\mathrm{z})$.

For every vertex we denote by $\mathrm{N}(v)$ the set of all neighbors of v, $\mathrm{N}(v) = \{u \in V : dist(u,v) = 1\}$. The *closed neighborhood* of v is defined by $\mathrm{N}[v] = \mathrm{N}(v) \cup \{v\}$. For a vertex v and a set of vertices $S \subseteq V$, the minimum distance between v and vertices of S is denoted by $dist(v,S)$. The *closed neighborhood* $\mathrm{N}[S]$ of a set $S \subseteq V$ is defined by $\mathrm{N}[S] = \{v \in V : dist(v,S) \leq 1\}$.

We say that a set $S \subseteq V$ *dominates* G if $\mathrm{N}[S] = V$, and S *doubly dominates* G if every vertex of G has at least two neighbors in S. An induced path of G which dominates G is called an *induced dominating path*. A shortest path of G which dominates G is called a *dominating shortest path*. Analogously one can define an *induced dominating cycle* of G. A *dominating pair* of G is a pair of vertices $v, u \in V$, such that every induced path between v and u dominates G. A *good pair* of G is a pair of vertices $v, u \in V$, such that there exist two internally disjoint induced dominating paths connecting v and u.

The *claw* is the induced complete bipartite graph $K_{1,3}$, and for simplicity, we refer to it by $K(a;b,c,d)$ (see Figure 1.1). The *net* is the induced six-vertex graph $N(a,b,c;x,y,z)$ shown in Figure 1.1. A graph is called *CN-free* or, equivalently, *(claw, net)-free* if it contains neither an induced claw nor an induced net. An *asteroidal triple* of G is a triple of pairwise nonadjacent vertices, such that for each pair of them there exists a path in G that does not contain any vertex in the neighborhood of the third one. A graph is called *AT-free* if it does not contain an asteroidal triple. Finally, a *Hamiltonian path* or *Hamiltonian cycle* of G is a path or cycle, respectively, containing all vertices of G.

2. Induced dominating path. In this section we give a constructive proof for the property that every connected CN-free graph contains an induced dominating path. In fact, we show that there is an algorithm that finds such a path in linear time. To prove the main theorem of this section we will need the following two lemmas.

LEMMA 2.1 (see [12]). *Let $P = (x_1, \ldots, x_k)$ be an induced path of a CN-free graph G, and let v be a vertex of G such that $dist(v,P) = 2$. Then any neighbor y of v with $dist(y,P) = 1$ is adjacent to x_1 or to x_k.*

LEMMA 2.2. *Let P be an induced path connecting vertices v and u of a CN-free graph G. Let also s be a vertex of G such that $s \notin \mathrm{N}[P]$ and $dist(v,s) \leq dist(v,u)$. Then*

1. *for every shortest path P' connecting v and s, $P' \bigcap P = \{v\}$ holds, and*
2. *if there is an edge xy of G such that $x \in P \setminus \{v\}$ and $y \in P' \setminus \{v\}$, then both x and y are neighbors of v.*

Proof. Let y be the vertex of $P' \setminus \{v\}$ which is closest to s and has a neighbor x on $P \setminus \{v\}$; clearly, $y \neq s$. Let s', v' be the neighbors of y on the subpaths of P' connecting y with s and y with v, respectively. Since $s' \notin \mathrm{N}[P]$, by Lemma 2.1, vertex

y must be adjacent to v or to u. If $yu \in E$, then $v'u \in E$, too (otherwise, we have a claw $K(y; s', v', u)$). But now $dist(v, u) \leq dist(v, v') + 1 = dist(v, y) < dist(v, s) \leq dist(v, u)$, and a contradiction arises. Therefore, y is adjacent to v, and since $y \notin P$, the paths P and P' have only the vertex v in common. Moreover, to avoid a claw $K(y; s', v, x)$, vertex x has to be adjacent to v. □

THEOREM 2.3. *Every connected CN-free graph G has an induced dominating path, and such a path can be found in $O(n + m)$ time.*

Proof. Let G be a connected CN-free graph. One can construct an induced dominating path in G as follows. Take an arbitrary vertex v of G. Using breadth first search (BFS), find a vertex u with the largest distance from v and a shortest path P connecting u with v. Check whether this path P dominates G. If so, we are done. Now, assume that the set $S = V \setminus \mathrm{N}[P]$ is not empty. Again, using BFS, find a vertex s in S with largest distance from v and a shortest path P' connecting v with s. Create a new path P^* by joining P and P' in the following way: $P^* = (P \setminus \{v\}, P' \setminus \{v\})$ if there is a chord xy between the paths P and P' (see Lemma 2.2), and $P^* = (P \setminus \{v\}, P')$, otherwise. By Lemma 2.2, the path P^* is induced. It remains to show that this path dominates G.

Assume there exists a vertex $t \in V \setminus \mathrm{N}[P^*]$. First, we claim that t is dominated neither by P nor by P'. Indeed, if $t \in (\mathrm{N}[P] \bigcup \mathrm{N}[P']) \setminus \mathrm{N}[P^*]$, then necessarily $tv \in E$ and $v \notin P^*$, i.e., neighbors $x \in P$ and $y \in P'$ of v are adjacent. Therefore, we get a net $N(v, y, x; t, s', u')$, where s' and u' are the vertices at distance two from v on paths P' and P, respectively. Note that vertices s', u' exist because $dist(v, s) \geq 2$.

Thus, t is dominated neither by P nor by P'. Moreover, from the choice of u and s we have $2 \leq dist(v, t) \leq dist(v, s) \leq dist(v, u)$. Now let P'' be a shortest path, connecting t with v, and let z be a neighbor of v on this path. Applying Lemma 2.2 twice (to P, P'' and to P', P''), we obtain a subgraph of G depicted in Figure 2.1. We have three shortest paths P, P', P'', each of length at least 2 and with only one common vertex v. These paths can have only chords of type zx, zy, xy. Any combination of them leads to a forbidden claw or net. This contradiction completes the proof of the theorem. Evidently, the method described above can be implemented to run in linear time. □

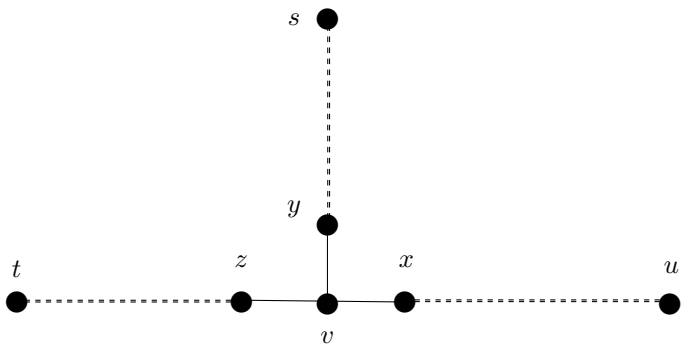

FIG. 2.1.

It is not clear whether CN-free graphs can be recognized efficiently. But, to apply our method for finding an induced dominating path in these graphs, we do not need to know in advance that a given graph G is CN-free. Actually, our method can be

applied to any graph G. It either finds an induced dominating path or returns either a claw or a net of G, showing that G is not CN-free.

COROLLARY 2.4. *There is a linear time algorithm that for a given (arbitrary) connected graph G either finds an induced dominating path or outputs an induced claw or an induced net of G.*

Proof. Let G be a graph. For an arbitrary vertex v of G, we find a vertex u with the largest distance from v and a shortest path P connecting u with v. If P dominates G, then we are done. Else, we find a vertex $s \in V \setminus \mathrm{N}[P]$ with the largest distance from v and a shortest path P' connecting v with s. If there are vertices in $P' \setminus \{v\}$ which have a neighbor on $P \setminus \{v\}$, we take the vertex y that is closest to s and check whether y is adjacent to v and u. If it is adjacent neither to u nor to v, then G has a net or a claw (see the proof of Lemma 2.1). If $yu \in E$ or $yv \in E$ and a neighbor x of y on $P \setminus \{v\}$ is not adjacent to v, then G has a claw (see Lemma 2.2). Now, if we did not yet find a forbidden subgraph, then the only possible chord between the paths P and P' is xy with $xv, yv \in E$, and we can create an induced path P^* as described in the proof of Theorem 2.3. Hence, it remains to check whether P^* dominates G. If there exists a vertex $t \in V \setminus \mathrm{N}[P^*]$, then again we will find a net or a claw in G (see Theorem 2.3). It is easy to see that the total time bound of all these operations is linear. □

3. Hamiltonian path. In what follows we show that for claw-free graphs the existence of an induced dominating path is a sufficient condition for the existence of a Hamiltonian path. The proof for this result is constructive, implying that, given an induced dominating path, one can find a Hamiltonian path efficiently.

THEOREM 3.1. *Every connected claw-free graph G containing an induced dominating path has a Hamiltonian path. Moreover, given an induced dominating path, a Hamiltonian path of G can be constructed in linear time.*

Proof. Let $G = (V, E)$ be a connected claw-free graph and let $P = (x_1, \ldots, x_k)$ ($k \geq 1$) be an induced dominating path of G. If $k = 1$, vertex x_1 dominates G and, since G is claw-free, there are no three independent vertices in $G - \{x_1\}$. (By $G - \{x_1\}$ we denote a subgraph of G induced by vertices $V \setminus \{x_1\}$.) If $G - \{x_1\}$ is not connected, then, again because G is claw-free, it consists of two cliques C_0, C_1 and a Hamiltonian path of G can easily be constructed. If $G - \{x_1\}$ is connected, we can construct a Hamiltonian path as follows. First, we construct a maximal path $P_1 = (y_1, \ldots, y_l)$, i.e., all vertices that are not in P_1 are neither connected to y_1 nor to y_l. Let R be the set of all remaining vertices. If $R = \emptyset$, we are done. If there is any vertex in R, it follows that $y_1 y_l \in E$ since otherwise there are three independent vertices in $G - \{x_1\}$. Furthermore, any two vertices of R are joined by an edge, since otherwise they would form an independent triple with y_1 (and with y_l as well). Hence, R induces a clique. Since $G - \{x_1\}$ is connected, there has to be an edge from a vertex $v_R \in R$ to some vertex $y_i \in P_1$ ($1 < i < l$). Now we can construct a Hamiltonian path P of G: $P = (x_1, y_{i+1}, y_{i+2}, \ldots, y_l, y_1, y_2, \ldots, y_i, v_R, \tilde{R})$, where $\tilde{R}$ stands for an arbitrary permutation of the vertices of $R \setminus \{v_R\}$.

For $k \geq 2$ we first construct a Hamiltonian path P_2 for $G' = G(\mathrm{N}[x_1] \setminus \{x_2\})$ as described above, using x_1 as the dominating vertex. At least one endpoint of P_2 is adjacent to x_2 since if $G' - \{x_1\}$ is not connected, x_2 has to be adjacent to all vertices of either C_0 or C_1 (otherwise, there is a claw in G), and if $G' - \{x_1\}$ is connected, the construction gives a path ending in x_1 which is, of course, adjacent to x_2. To construct a Hamiltonian path for the rest of the graph we define for each vertex x_i ($i \geq 2$) of P a set of vertices $C_i = \mathrm{N}(x_i) \setminus \bigcup_{j=1}^{i-1} \mathrm{N}[x_j]$. Each set C_i forms a clique of G since if two

vertices $u, v \in C_i$ are not adjacent, then the set u, v, x_i, x_{i-1} induces a claw. Hence we can construct a path $P^* = (P_2, x_2, P_2^C, x_3, P_3^C, x_4, \ldots, x_{k-1}, P_{k-1}^C, x_k, P_k^C)$, where P_i^C stands for an arbitrary permutation of the vertices of $C_i \setminus \{x_{i+1}\}$. This path P^* is a Hamiltonian path of G because it obviously is a path, and, since P is a dominating path, each vertex of G has to be either on P, P_2, or in one of the sets C_i.

For the case $k = 1$ both finding the connected components of $G - \{x_1\}$ and constructing the path P_1 can easily be done in linear time. For $k \geq 2$ we just have to make sure that the construction of the sets C_i can be done in $O(n+m)$, and this can be realized easily within the required time bound. □

THEOREM 3.2. *Every connected CN-free graph G has a Hamiltonian path, and such a path can be found in $O(n+m)$ time.*

Proof. By Theorem 2.3, every connected CN-free graph has an induced dominating path P, and it can be found in linear time. Using the path P, by Theorem 3.1, one can construct a Hamiltonian path of G in linear time. □

Analogously to Corollary 2.4, we can state the following.

COROLLARY 3.3. *There is a linear time algorithm that for a given (arbitrary) connected graph G either finds a Hamiltonian path or outputs an induced claw or an induced net of G.*

Proof. The proof follows from Corollary 2.4 and the proof of Theorem 3.1. □

4. Induced dominating cycle, dominating shortest path, or good pair. In this section we show that every 2-connected CN-free graph G has an induced doubly dominating cycle or a good pair. Moreover, we present an efficient algorithm that, for a given 2-connected CN-free graph G, finds either a good pair or an induced doubly dominating cycle.

LEMMA 4.1. *Every hole of a connected CN-free graph G dominates G.*

COROLLARY 4.2. *Let H be a hole of a connected CN-free graph G. Every vertex of $V \setminus H$ is adjacent to at least two vertices of H.*

A *subgraph G' of G (doubly) dominates* G if the vertex set of G' (doubly) dominates G.

LEMMA 4.3. *Every induced subgraph of a connected CN-free graph G which is isomorphic to S_3 or S_3^- (see Figure 4.1) dominates G.*

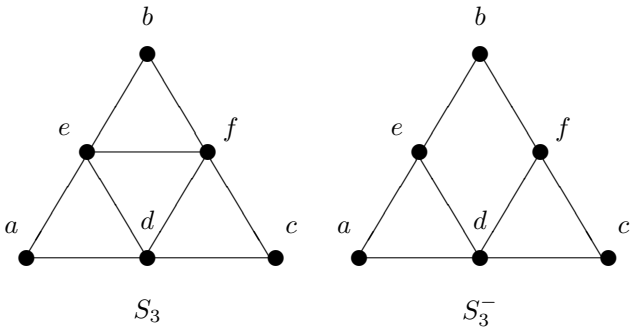

FIG. 4.1.

Proof. Let G contain an induced subgraph isomorphic to S_3^-, and assume that it does not dominate G. Then, there must be a vertex s such that $dist(s, S_3^-) = 2$. Let x be a neighbor of s from $N[S_3^-]$. If x is adjacent neither to a, nor to b, nor to c (see Figure 4.1), then G contains a claw (e.g., if $xf \in E$, then a claw $K(f; b, c, x)$ arises). Thus, without loss of generality, x has to be adjacent to a or b.

If $xa \in E$, then x is adjacent neither to b nor to c, since otherwise we will get a claw ($K(x; a, b, s)$ or $K(x; a, c, s)$). To avoid a net $N(a, e, d; x, b, c)$ vertex x must be adjacent to e or d. But, if $ex \in E$, then $xd \in E$ too. (Otherwise, we will have a claw $K(e; b, d, x)$.) Analogously, if $xd \in E$, then also $xe \in E$. Hence, x is adjacent to both e and d, and a net $N(x, e, d; s, b, c)$ arises.

Now, we may assume that x is adjacent to b and not to a, c. To avoid a claw $K(b; x, e, f)$, x must be adjacent to e or f. But again, $xe \in E$ if and only if $xf \in E$. (Otherwise, we get a net $N(x, b, e; s, f, a)$ or $N(x, b, f; s, e, c)$.) Hence x is adjacent to both e and f and a claw $K(x; s, e, f)$ arises.

Consequently, S_3^- dominates G. Similarly, every induced S_3 (if it exists) dominates G. □

LEMMA 4.4. *Let P be an induced path connecting vertices v and u of a connected CN-free graph G. Let s be a vertex of G such that $s \notin \mathrm{N}[P]$ and $dist(v, s) \leq dist(v, u)$, $dist(u, s) \leq dist(v, u)$. Then G has an induced doubly dominating cycle, and such a cycle can be found in linear time.*

Proof. Let P_v and P_u be shortest paths connecting vertex s with v and u, respectively. Both these paths as well as the path P have lengths at least 2. Since $dist(v, s) \leq dist(v, u)$ and $dist(u, s) \leq dist(u, v)$, by Lemma 2.2, we have $P \bigcap P_v = \{v\}$ and $P \bigcap P_u = \{u\}$. Moreover, if there is a chord between P and P_v, then it is unique and both its endvertices are adjacent to v. The same holds for P and P_u; both endvertices of the chord (if it exists) are adjacent to u.

Now, without loss of generality, we suppose that $dist(s, u) \leq dist(s, v)$. Then, from $u \notin \mathrm{N}[P_v]$ and Lemma 2.2 we deduce that $P_u \bigcap P_v = \{s\}$ and between paths P_v and P_u at most one chord is possible, namely, the one with both endvertices adjacent to s. Consequently, we have constructed an induced subgraph of G shown in Figure 4.2 (only chords $s's'', v'v''$ and $u'u''$ are possible).

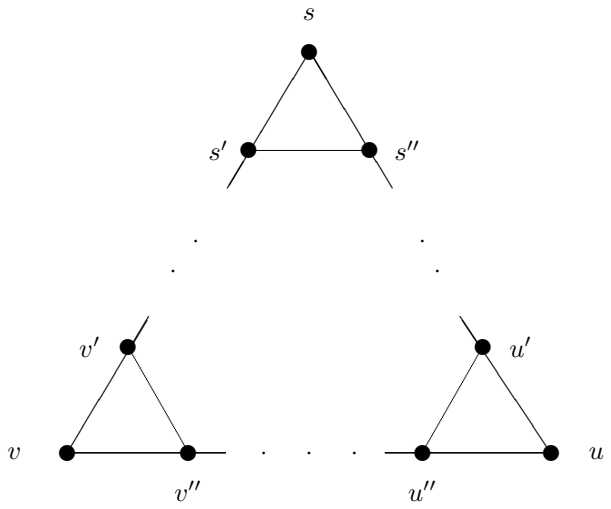

FIG. 4.2.

If the lengths of all three paths P, P_v, P_u are at least 3, then it is easy to see that G has a hole H_k ($k \geq 6$). Furthermore, if at least one of these paths has length greater than or equal to 4, or two of them have lengths 3, then G must contain a hole H_k ($k \geq 5$). It remains to consider two cases: lengths of both P_v and P_u are 2 and

the length of P is 3 or 2. Clearly, in both of these cases the graph G contains either a hole H_k ($k \in \{5, 6, 7\}$) or an induced subgraph isomorphic to S_3^- or S_3. By Corollary 4.2, every hole of G doubly dominates G.

Let G contain an S_3^- with vertex labeling shown in Figure 4.1. We claim that the induced cycle (e, b, f, d, e) dominates G or G contains a hole H_6. Indeed, if a vertex s of G does not belong to S_3^-, then, by Lemma 4.3, it is adjacent to a vertex of S_3^-. Suppose that s is adjacent to none of e, b, f, d. Then, without loss of generality, $sa \in E$, and we obtain an induced subgraph of G isomorphic either to a net $N(e, a, d; b, s, c)$ or to $H_6 = (s, a, e, b, f, c, s)$, depending on whether vertices s and c are adjacent. Hence, we may assume that (e, b, f, d, e) dominates G, and since G is claw-free, this cycle is doubly dominating.

Now let G contain an S_3 with vertex labeling shown in Figure 4.1. We will show that every vertex of G is adjacent to at least two vertices of the cycle (e, f, d, e) or G contains a hole H_5. Suppose vertex s of G is adjacent to none of e, d. Then, by Lemma 4.3, s is adjacent to at least one of a, b, c, f. Let $sf \in E$. To avoid a claw, vertex s is adjacent to both b and c. But then a hole $H_5 = (s, b, e, d, c, s)$ arises. Assume that $sf \notin E$ and, without loss of generality, $sa \in E$. To avoid a net $N(a, e, d; s, b, c)$, s must be adjacent to b or c. In both cases a hole H_5 occurs.

Clearly, the construction of an induced doubly dominating cycle of G given above takes linear time. □

THEOREM 4.5. *There is a linear time algorithm that, for a given connected CN-free graph G, either finds an induced doubly dominating cycle or gives a dominating shortest path of G.*

Proof. Let G be a connected CN-free graph. One can construct an induced doubly dominating cycle or a dominating shortest path of G as follows (compare with the proof of Theorem 2.3). Take an arbitrary vertex v of G. Find a vertex u with the largest distance from v and a shortest path P connecting u with v. Check whether P dominates G. If so, we are done; P is a dominating shortest path of G. Assume now that the set $S = V \setminus \mathrm{N}[P]$ is not empty. Find a vertex s in S with the largest distance from v and a shortest path P_v connecting v with s. Create again a new path P^* by "joining" shortest paths P and P_v as in the proof of Theorem 2.3. We have proven there that P^* dominates G. Now let P_u be a shortest path between s and u. If $dist(s, u) \leq dist(v, u)$ or both $dist(s, u) > dist(v, u)$ and $v \notin \mathrm{N}[P_u]$, then Lemma 4.4 can be applied to get an induced doubly dominating cycle of G in linear time. Therefore, we may assume that $dist(s, u) > dist(v, u) \geq dist(v, s)$ and $v \in \mathrm{N}[P_u]$. Now we show that the shortest path P_u dominates G. If v lies on the path P_u, then $P^* = P_u$ and we are done. Otherwise, let x be a neighbor of v in P_u. Note that $dist(v, s) > 1$ and so $x \neq s, u$. Since G is claw-free, v is adjacent to a neighbor $y \in P_u$ of x. Assume, without loss of generality, that x is closer to s than y. If we show that $dist(v, s) = 1 + dist(x, s)$ and $dist(v, u) = 1 + dist(y, u)$, then again, by the proof of Theorem 2.3, the path P_u will dominate G (as a path obtained by "joining" two shortest paths that connect v with u and v with s, respectively). By the triangle condition, we have $dist(u, s) < dist(v, u) + dist(v, s)$ (strict inequality because $v \notin P_u$) and $dist(v, s) \leq 1 + dist(x, s)$, $dist(u, v) \leq 1 + dist(y, u)$. Consequently, $dist(v, u) + dist(v, s) > dist(u, s) = dist(u, y) + 1 + dist(x, s) \geq dist(v, u) - 1 + 1 + dist(v, s) - 1 = dist(v, u) + dist(v, s) - 1$. That is, $dist(u, s) = dist(v, u) + dist(v, s) - 1$ and $dist(v, s) = 1 + dist(x, s)$, $dist(u, v) = 1 + dist(y, u)$. □

Since all our proofs were constructive, we can conclude the following.

COROLLARY 4.6. *There is a linear time algorithm that, for a given (arbitrary) connected graph G, either finds an induced doubly dominating cycle, or gives a dominating shortest path, or outputs an induced claw or an induced net of G.*

LEMMA 4.7. *Let $P = (v, x_2, \ldots, x_{k-1}, u)$ be a dominating shortest path of a graph G. Then* $\max\{ecc(v), ecc(u)\} \geq diam(G) - 1$.

Proof. Let x, y be a diametral pair of vertices of G; that is, $diam(G) = dist(x, y)$. If both x and y are on P, then necessarily $\{x, y\} = \{v, u\}$ and therefore $dist(v, u) = diam(G) = ecc(v) = ecc(u)$. If $x \in P$ and $y \in N[P] \setminus P$, then either $x \neq v, u$ and $diam(G) = dist(x, y) = dist(v, u)$ holds or, without loss of generality, $v = x$ and $ecc(v) = diam(G)$. Finally, if both x and y are in $N[P] \setminus P$ and $dist(v, u) < dist(x, y)$, then we may assume that at least one of x, y belongs to $N(v)$, say, x. Hence, $dist(x, y) \leq 1 + dist(v, y) \leq 1 + ecc(v)$; that is, $ecc(v) \geq diam(G) - 1$. □

A pair of vertices u, v of G with $dist(u, v) = ecc(u) = ecc(v)$ is called a *pair of mutually furthest vertices.*

COROLLARY 4.8. *For a graph G with a given dominating shortest path, a pair of mutually furthest vertices can be found in linear time.*

Proof. Let $P = (v, x_2, \ldots, x_{k-1}, u)$ be a dominating shortest path of G with $ecc(v) \geq ecc(u)$. Then, by Lemma 4.7, $ecc(v) \geq diam(G) - 1$ holds. Denote by x a vertex of G such that $dist(v, x) = ecc(v)$. Note that both the eccentricity of v and a vertex furthest from v can be found in linear time by BFS. Now, if $ecc(x) = ecc(v)$, then v, x are mutually furthest vertices of G. Else, $ecc(x) > ecc(v) \geq diam(G) - 1$ must hold and vertices x and y, where y is a vertex with $dist(x, y) = ecc(x)$, form a diametral pair of G; $dist(x, y) = ecc(x) = ecc(y) = diam(G)$. □

In what follows we will use the fact that in a 2-connected graph every pair of vertices is joined by two internally disjoint paths. In order to actually find such a pair of paths, one can use Tarjan's linear time depth first search- (DFS)-algorithm for finding the blocks of a given graph. For the proof of Lemma 4.9, we refer to [21].

LEMMA 4.9. *Let G be a 2-connected graph, and let x, y be two different nonadjacent vertices of G. Then one can construct in linear time two induced, internally disjoint paths, both joining x and y.*

THEOREM 4.10. *There is a linear time algorithm that, for a given 2-connected CN-free graph G, either finds an induced doubly dominating cycle or gives a good pair of G.*

Proof. By Theorem 4.5, we get either an induced doubly dominating cycle or a dominating shortest path of G in linear time. We show that, having a dominating shortest path of a 2-connected graph G, one can find in linear time a good pair or an induced doubly dominating cycle. By Corollary 4.8, we may assume that a pair x, y of mutually furthest vertices of G is given. Let also P_1, P_2 be two induced internally disjoint paths connecting x and y in G. They exist and can be found in linear time by Lemma 4.9 (clearly, we may assume that $xy \notin E$, because otherwise $N[x] = V = N[y]$ and x, y together with a vertex $z \in V \setminus \{x, y\}$ will form a doubly dominating triangle). If one of these paths, say, P_1, is not dominating, then there must be a vertex $s \in V \setminus N[P_1]$. Since x, y are mutually furthest vertices of G, we have $dist(s, x) \leq dist(x, y)$, $dist(s, y) \leq dist(x, y)$. Hence, we are in the conditions of Lemma 4.4 and can find an induced doubly dominating cycle of G in linear time. □

COROLLARY 4.11. *There is a linear time algorithm that, for a given (arbitrary) 2-connected graph G, either finds an induced doubly dominating cycle, or gives a good pair, or outputs an induced claw or an induced net of G.*

5. Hamiltonian cycle. In this section we prove that, for claw-free graphs, the existence of an induced doubly dominating cycle or a good pair is sufficient for the existence of a Hamiltonian cycle. The proofs are also constructive and imply linear time algorithms for finding a Hamiltonian cycle.

THEOREM 5.1. *Every claw-free graph G that contains an induced doubly dominating cycle has a Hamiltonian cycle. Moreover, given an induced doubly dominating cycle, a Hamiltonian cycle of G can be constructed in linear time.*

Proof. Let $DC = (x_1, \ldots, x_k, x_1)$ $(k \geq 3)$ be an induced doubly dominating cycle of G. As before, we define $C_i = \mathrm{N}(x_i) \setminus \bigcup_{j=1}^{i-1} \mathrm{N}[x_j]$ $(2 \leq i \leq k)$. Each set C_i forms a clique of G; otherwise, we would have a claw. Furthermore, $C_k = \emptyset$ holds, and the sets $\mathrm{N}[x_1], C_2, \ldots, C_{k-1}$ form a partition of the vertex set of G. Note that any vertex adjacent to x_k and not to x_j $(1 < j < k)$ belongs to $\mathrm{N}[x_1]$, since the cycle DC is doubly dominating. Let $G' = G(\mathrm{N}[x_1] \setminus \{x_2, x_k\})$ be the subgraph of G induced by $\mathrm{N}[x_1] \setminus \{x_2, x_k\}$. If we show that there is a Hamiltonian path P in G' starting at a neighbor of x_k and ending at a neighbor of x_2, then we are done; the cycle $(x_k, P, x_2, P_2^C, x_3, P_3^C, x_4, \ldots, x_{k-1}, P_{k-1}^C, x_k)$, is a Hamiltonian cycle of G (recall that P_i^C stands for an arbitrary permutation of the vertices of $C_i \setminus \{x_{i+1}\}$).

Since G' is a connected graph, by Theorem 3.1, there exists a Hamiltonian path $P' = (s, y_1, \ldots, y_l, t)$ of G'. Assume that $x_k s, x_k t \notin E$. Then, to avoid a claw $K(x_1; x_k, s, t)$, vertices s and t have to be adjacent, giving a new Hamiltonian path P'' of G' starting at x_1 and ending at a vertex y. If y is adjacent neither to x_k nor to x_2, then a claw $K(x_1; x_k, x_2, y)$ occurs. (Note that in case $k = 3$, i.e., $x_k x_2 \in E$, y is adjacent to at least one of x_k, x_2 because the cycle $DC = (x_1, x_2, x_3, x_1)$ is doubly dominating.) Without loss of generality, $y x_2 \in E$ and the path P'' is a desired path of G'.

So, we may assume that x_k is adjacent to t or s. Analogously, x_2 is adjacent to one of t, s. If x_k, x_2 are adjacent to different vertices, then we are done; the path P' starts at a neighbor of x_k and ends at a neighbor of x_2. Otherwise, let both x_k and x_2 be adjacent to t and not to s. Then a claw $K(x_1; x_k, x_2, s)$ arises when $k > 3$, or we get a contradiction with the property of $DC = (x_1, x_2, x_3, x_1)$ to be a doubly dominating cycle. □

COROLLARY 5.2. *Every claw-free graph, containing an induced dominating cycle of length at least 4, has a Hamiltonian cycle, and, given that induced dominating cycle, one can construct a Hamiltonian cycle in linear time.*

Let $G = (V, E)$ be a graph, and let $P = (x_1, \ldots, x_k)$ be an induced dominating path of G. P is called an *enlargeable* path if there is some vertex v in $V \setminus P$ that is either adjacent to x_1 or to x_k but not to both of them and, additionally, to no other vertex in P. Consequently, an induced dominating path P is called *nonenlargeable* if such a vertex does not exist. Obviously, every graph G that has an induced dominating path has a nonenlargeable induced dominating path as well. Furthermore, given an induced dominating path P, one can find in linear time a nonenlargeable induced dominating path P' by simply scanning the neighborhood of both x_1 and x_k. For the next theorem we will need an auxiliary result.

LEMMA 5.3. *Let G be a claw-free graph, and let $P = (x_1, x_2, \ldots, x_k)$ $(k > 2)$ be an induced nonenlargeable dominating path of G such that there is no vertex y in G with $\mathrm{N}(y) \cap P = \{x_1, x_k\}$. Then there is a Hamiltonian path in G that starts in x_1 and ends in x_k and, given the path P, one can construct this Hamiltonian path in linear time.*

Proof. Let $C_i = \mathrm{N}(x_i) \setminus \bigcup_{j=1}^{i-1} \mathrm{N}[x_j]$ $(i \geq 2)$. Since P is nonenlargeable, C_k is empty. Using the method described in the proof of Theorem 3.1, we can easily construct a path, starting in x_1 and ending in x_k, that contains all vertices of $C_2, \ldots, C_{k-1}$. This implies that we have to worry only about how to insert the vertices of the neighborhood of x_1 into this path. We have to consider two cases.

Case 1. $H = G(\mathrm{N}(x_1) \setminus \{x_2\})$ consists of two connected components C_0, C_1.

Since G is claw-free, both C_0 and C_1 induce cliques in G. Furthermore, x_2 is adjacent to all vertices of at least one of C_0 and C_1, say, C_1, because otherwise we have a claw in G.

Let y be an arbitrary vertex of C_0. Since P is nonenlargeable, y has at least one neighbor on $P \setminus \{x_1\}$, and let x_j be the one with smallest index. By the preconditions of our lemma, $j \neq k$. If $j > 2$, then y has to be adjacent to x_{j+1} as well, since otherwise $K(x_j; y, x_{j-1}, x_{j+1})$ is a claw. Furthermore, y is adjacent to all vertices $c_j \in C_j$, since otherwise $K(x_j; y, x_{j-1}, c_j)$ is a claw. Hence, when constructing the Hamiltonian path, we can simply add y to C_j.

Now we consider the set Y of all vertices y of C_0 with $yx_2 \in E$. Suppose there is a vertex c_2 in C_2 with $c_2 \neq x_3$. If there is a vertex $c_1 \in C_1$ that is nonadjacent to vertex c_2, then there is an edge from every vertex $c_0 \in Y$ to c_2; otherwise, $K(x_2; c_0, c_1, c_2)$ is a claw of G. This implies that we can construct a Hamiltonian path with the required properties. If, on the other hand, all vertices of C_1 are adjacent to all vertices of C_2, we can construct such a path by starting in x_1, traversing through Y, x_2, C_1, C_2, and proceeding as before. Now suppose that there is no vertex $c_2 \in C_2$ with $c_2 \neq x_3$. In this case either all vertices $c_0 \in Y$ or all vertices $c_1 \in C_1$ have to be adjacent to x_3, because otherwise $K(x_2; c_0, c_1, x_3)$ is a claw. Suppose, without loss of generality, that all vertices of Y are adjacent to x_3. Then we construct the path by starting in x_1, traversing through C_1, x_2, Y, x_3, and proceeding as before.

Case 2. $H = G(\mathrm{N}(x_1) \setminus \{x_2\})$ induces a connected graph.

If x_2 is not adjacent to any of the vertices in H, then H has to be a clique and we can apply the method described in case 1.

Suppose now that x_2 is adjacent to some vertex in H. First, we construct a Hamiltonian path $P' = (y_1, \ldots, y_l)$ in H, which is done as in the proof of Theorem 3.1, since there is no independent triple in H. Now we claim that either x_2 is adjacent to one of y_1 or y_l, or P' does in fact induce a Hamiltonian cycle of H implying again the existence of a path with an end-vertex adjacent to x_2. Indeed, suppose x_2 is not adjacent to any of the endvertices of P'. Then, since G is claw-free, y_1 has to be adjacent to y_l, because otherwise $K(x_1; y_1, y_l, x_2)$ would induce a claw in G. Hence P' induces a Hamiltonian cycle in H.

Using P', we can easily construct a Hamiltonian path in $\mathrm{N}[x_1]$ starting in x_1 and ending in x_2. The rest of the Hamiltonian path of G can be constructed as before. □

In fact, we can prove a slightly stronger result. Let $A = \mathrm{N}(x_1) \setminus \bigcup_{j=2}^{k} \mathrm{N}[x_j]$, $B = \mathrm{N}(x_k) \setminus \bigcup_{j=1}^{k-1} \mathrm{N}[x_j]$, and, as usual, $C_i = \mathrm{N}(x_i) \setminus \bigcup_{j=1}^{i-1} \mathrm{N}[x_j]$ $(i \geq 2)$. Each of these sets forms a clique of G.

LEMMA 5.4. *Let G be a claw-free graph, and let $P = (x_1, x_2, \ldots, x_k)$ $(k > 2)$ be an induced dominating path of G such that there is no vertex y in G with $\mathrm{N}(y) \cap P = \{x_1, x_k\}$. Let also P be enlargeable but only to one end, e.g., $A = \emptyset$, $B \neq \emptyset$, and assume that there exists an edge zb with $z \in C_{k-1} \setminus \{x_k\}$ and $b \in B$. Then there is a Hamiltonian path in G that starts in x_1 and ends in x_k and, given the path P, one can construct this Hamiltonian path in linear time.*

Proof. First, we can easily construct a path, starting in x_1 and ending in x_{k-1}, that contains all vertices of $C_2, \ldots, C_{k-2}$. Then we attach to this path a path which starts at x_{k-1}, goes through C_{k-1}, B using all their vertices, and ends in x_k. Finally, we insert the vertices of the neighborhood of x_1 into the obtained path as we have done in the proof of Lemma 5.3. □

THEOREM 5.5. *Let G be a 2-connected claw-free graph with a good pair u, v. Then G has a Hamiltonian cycle and, given the corresponding induced dominating paths, one can construct a Hamiltonian cycle in linear time.*

Proof. Let $P_1 = (u = x_1, \ldots, v = x_k)$, $P_2 = (u = y_1, \ldots, v = y_l)$ be the induced dominating paths, corresponding to the good pair u, v. By the definition of a good pair both k and l are greater than 2. We may also assume that, for any induced dominating path $P = (a_1, \ldots, a_s)$ of G with $s > 2$, no vertex $y \in V \setminus P$ exists such that $\mathrm{N}(y) \bigcap P = \{a_1, a_s\}$. Otherwise, P together with y would form an induced dominating cycle of length at least 4, and we can apply Corollary 5.2 to construct a Hamiltonian cycle of G in linear time.

Let A_1 be the set of vertices a_1 that are adjacent to x_1 but to no other vertex of P_1; let B_1 be the set of vertices b_1 that are adjacent to x_k but to no other vertex of P_1. A_2 and B_2 are defined accordingly for P_2. Of course, each of the sets A_1, A_2, B_1, B_2 forms a clique of G.

First we assume that one of these paths, say, P_1, is nonenlargeable, i.e., $A_1 = \emptyset$, $B_1 = \emptyset$. In this case we do the following. We remove the inner vertices of P_2 from G and get the graph $G - (P_2)$, where (P_2) denotes the inner vertices of P_2. Then, using P_1, we create a Hamiltonian path in $G - (P_2)$ that starts at u and ends at v (Lemma 5.3), and we add (P_2) to this path to create a Hamiltonian cycle of G.

We can use this method for creating a Hamiltonian cycle of G whenever we have two internally disjoint paths P, P' of G both connecting u with v such that one of them is an induced dominating and nonenlargeable path of the graph obtained from G by removing the inner vertices of the other path.

Now we suppose that both paths P_1, P_2 are enlargeable. Because of symmetry we have to consider the following three cases.

Case 1. There exist a vertex $a_1 \in A_1 \setminus A_2$ and a vertex $b_1 \in B_1 \setminus B_2$.

In this case there must be edges from a_1, b_1 to inner vertices y_i, y_j of P_2. Consequently, we can form a new path P_2' by starting in u and traversing through A_1, $y_i, \ldots, y_j$, B_1, v, where $(y_i, \ldots, y_j)$ is the subpath of P_2 between y_i and y_j. Evidently, P_2' contains all vertices of B_1, A_1 and is internally disjoint from P_1, which is nonenlargeable in $G - (P_2')$.

Case 2. $B_1 = B_2$ and either $A_1 = A_2$ or there exists a vertex $a_1 \in A_1 \setminus A_2$.

In this case none of the vertices of $B := B_1 = B_2$ (if $B \neq \emptyset$) has a neighbor in $P_1 \bigcup P_2$ other than v. As G is 2-connected, for some vertex $b \in B$ there has to be a vertex $z \in V \setminus (P_1 \bigcup P_2 \bigcup B)$ with $zb \in E$. Since P_2 dominates G and $z \notin B$, vertex z must be adjacent to a vertex $y \in P_2 \setminus \{v\}$. If z is only adjacent to $y_1 = u$ but to no other vertex of P_2, then z necessarily belongs to A_2 and we can form a new path P_1' by starting in u, using all vertices of A_2, B and ending in v. Again, P_1' is internally disjoint from P_2 and P_2 is nonenlargeable in $G - (P_1')$. If $\mathrm{N}(z) \bigcap P_2 = \{u, v\}$, then we can apply Corollary 5.2.

Therefore, we may assume that z is adjacent to an inner vertex y of P_2. Now, if there exists a vertex $a_1 \in A_1 \setminus A_2$, then a_1 is adjacent to some vertex y' of (P_2) and we can construct a new path P_2' by using u, A_1, y', $\ldots$, y, z, B, v. (If B was empty, then P_2' ends at $\ldots, y', \ldots, y_{l-1}, v$.) This path is internally disjoint from P_1, which

is nonenlargeable in $G-(P_2')$. If $A_1 = A_2$, then from the discussion above we may assume that either $A := A_1 = A_2$ is empty or there is a vertex $z' \in V \setminus (P_1 \bigcup P_2 \bigcup A)$ which is adjacent to a vertex of A and has a neighbor y' in (P_2). Hence, we can construct a path P_2' by using u, A, z', y', $\ldots$, y, z, B, v, which is internally disjoint from P_1. (If $z' = z$, then P_2' is constructed by using u, A, z, B, v.)

Case 3. A_2 is strictly contained in A_1, and B_1 is strictly contained in B_2.

Consider vertices $b \in B_1$, $z \in B_2 \setminus B_1$, and $z' \in A_1 \setminus A_2$ and cliques $C_i = \mathrm{N}(x_i) \setminus \bigcup_{j=1}^{i-1} \mathrm{N}[x_j]$ $(i \geq 2)$. If $zz' \in E$, then we can construct a new path P_2' by using u, A_1, z, B_1, v. This path is internally disjoint from P_1, which is nonenlargeable in $G-(P_2')$.

Since $z' \notin A_2$, there must be a neighbor $y' \in (P_2)$ of z'. If vertex b is adjacent to some vertex in $C_{k-1} \setminus \{v\}$, then we construct a new path P_2' by using $u, A_1, y', \ldots, v$. It will be internally disjoint from P_1, which is enlargeable only to one end (at $x_k = v$) in $G-(P_2')$. We are now in the conditions of Lemma 5.4 and can construct a Hamiltonian path of $G-(P_2')$ that starts in u and ends in v. Adding (P_2') to this path, we obtain a Hamiltonian cycle of G.

So, we may assume that $zz' \notin E$ for any vertex $z' \in A_1 \setminus A_2$ and that vertex b is not adjacent to any vertex of $C_{k-1} \setminus \{v\}$. From this we conclude also that $z \notin C_{k-1}$. But since $z \notin B_1$, there must be a neighbor $x_j \in (P_1)$ of z. We choose vertex $x_j \in (P_1)$ with the smallest j. Clearly, $1 < j < k-1$ and $z \in C_j$.

First we define a new induced path $P_1' := (P_1 \setminus \{x_{j+1}, \ldots x_{k-1}\}) \cup \{z\}$ and cliques $A_1' := \mathrm{N}(u) \setminus \bigcup_{x \in P_1' \setminus \{u\}} \mathrm{N}[x]$, $B_1' := \mathrm{N}(v) \setminus \bigcup_{x \in P_1' \setminus \{v\}} \mathrm{N}[x]$. We have $z' \in A_1'$, since otherwise from the construction of P_1', z' would be adjacent to z, and that is impossible.

Note that vertex x_{j+1} is dominated by the path P_2. If it is adjacent to only vertex v from P_2, then $j+1 = k-1$ and a claw $K(v; x_{k-1}, y_{l-1}, b)$ arises. Therefore, x_{j+1} must be adjacent to an inner vertex y of P_2. Now we define a new path P_2' by using $u, A_1', y', \ldots, y, x_{j+1}, C_{j+1}, x_{j+2}, \ldots, C_{k-1}, v$. It is internally disjoint from P_1' and contains all vertices of A_1' and C_i $(j+1 \leq i \leq k-1)$. It is clear from the construction that the path P_1' dominates the graph $G-(P_2')$. (Every vertex which was not dominated by the path P_1' in G belongs to some set C_i $(j+1 \leq i \leq k-2)$.)

It remains to show that the path P_1' is nonenlargeable in $G-(P_2')$. Assume by way of contradiction that it is enlargeable. Since $A_1' \subset (P_2')$, this is possible only if $B_1' \neq \emptyset$. Let p be a vertex of B_1'. Then p does not belong to B_1, since otherwise it should be adjacent to z, which is contained in (P_1'). (Recall that B_1, B_2 are cliques, $B_1 \subset B_2$, and $z \in B_2 \setminus B_1$.) Now, from $p \in B_1' \setminus B_1$ we conclude that the neighbors of p in $P_1 \setminus \{v\}$ are only vertices from $\{x_{j+1}, \ldots, x_{k-1}\}$, i.e., p belongs to a set C_s for some $s \geq j+1$. Consequently, a contradiction to $C_s \subset (P_2')$ arises.

It is not hard to see that the above method can be implemented to run in linear time. □

THEOREM 5.6. *Every 2-connected claw-free graph G that contains a dominating pair has a Hamiltonian cycle, and, given a dominating pair, a Hamiltonian cycle can be constructed in linear time.*

Proof. Let v, u be a dominating pair of a 2-connected graph G. If $vu \notin E$, then by Lemma 4.9, there exist two internally disjoint induced paths connecting v and u. Both these paths dominate G, and, therefore, u, v is a good pair of G. Thus, the statement holds by Theorem 5.5.

Now let $vu \in E$. Define sets $A := \mathrm{N}(u) \setminus \mathrm{N}[v]$, $B := \mathrm{N}(v) \setminus \mathrm{N}[u]$, and $S := \mathrm{N}(v) \bigcap \mathrm{N}(u)$. Since G is claw-free, the sets A and B are cliques of G. Notice also that

sets A, B, S, and $\{v, u\}$ form a partition of the vertex set of G.

If there is an edge ab in G such that $a \in A$ and $b \in B$, then vertices a, u, v, b induce a 4-cycle which dominates G. Hence, we can apply Corollary 5.2 to get a Hamiltonian cycle of G. Therefore, assume that no such edge exists. But since G is 2-connected, there must be edges ax, by with $x, y \in S$, $a \in A$, and $b \in B$. We distinguish between two cases. Let G_S denote the subgraph of G induced by S.

Case 1. G_S is disconnected.

Then, it consists of two cliques S_1 and S_2. Now, if vertices x, y are in different components of G_S, say, $x \in S_1$ and $y \in S_2$, then $(u, P^{A\setminus\{a\}}, a, x, P^{S_1\setminus\{x\}}, v, P^{B\setminus\{b\}}, b, y, P^{S_2\setminus\{y\}}, u)$ is a Hamiltonian cycle of G. (P^M stands for an arbitrary permutation of the vertices of a set M.) If x, y are in one component, say, S_1, then $(u, P^{A\setminus\{a\}}, a, x, P^{S_1\setminus\{x,y\}}, y, b, P^{B\setminus\{b\}}, v, P^{S_2}, u)$ is a Hamiltonian cycle of G.

Case 2. G_S is connected.

Then, by Theorem 3.1, there exists a Hamiltonian path $P = (s, y_1, \ldots, y_l, t)$ of G_S. Assume that $as, at \notin E$. Then, to avoid a claw $K(u; a, s, t)$, vertices s and t have to be adjacent, giving a Hamiltonian cycle $HC := (s, y_1, \ldots, y_l, t, s)$ of G_S. Vertices x and y split this cycle into two paths $P_1 = (x, \ldots, y)$ and $P_2 = HC \setminus P_1$. Hence, a cycle $(u, P^{A\setminus\{a\}}, a, P_1, b, P^{B\setminus\{b\}}, v, P_2, u)$ is a Hamiltonian cycle of G.

Now, we may assume that a is adjacent to s or t. Analogously, b is adjacent to one of t, s. If a, b are adjacent to different vertices, say, $as, bt \in E$, then $(u, P^{A\setminus\{a\}}, a, P, b, P^{B\setminus\{b\}}, v, u)$ is a Hamiltonian cycle of G. Finally, if a, b are adjacent only to s (similarly, to t), then $(u, P \setminus \{s\}, v, P^{B\setminus\{b\}}, b, s, a, P^{A\setminus\{a\}}, u)$ is a Hamiltonian cycle of G. □

THEOREM 5.7. *Every* 2*-connected CN-free graph* G *has a Hamiltonian cycle, and such a cycle can be found in* $O(n + m)$ *time.*

Proof. The proof follows from Theorems 4.10, 5.1, and 5.5. □

COROLLARY 5.8. *There is a linear time algorithm that for a given (arbitrary)* 2*-connected graph* G *either finds a Hamiltonian cycle or outputs an induced claw or an induced net of* G.

COROLLARY 5.9. *A Hamiltonian cycle of a* 2*-connected (claw,AT)-free graph can be found in* $O(n + m)$ *time.*

Remark. Corollary 5.8 implies that every 2-connected unit interval graph has a Hamiltonian cycle, which is, of course, well known (see [24, 20]). The interesting difference of the above algorithm compared to the existing algorithms for this problem on unit interval graphs is that it does not require the creation of an interval model. It also follows from Corollaries 3.3 and 5.8 that both the Hamiltonian path problem and the Hamiltonian cycle problem are linear time solvable on proper circular arc graphs. Note that previously known algorithms for these problems had time bounds $O(m + nlogn)$ [18].

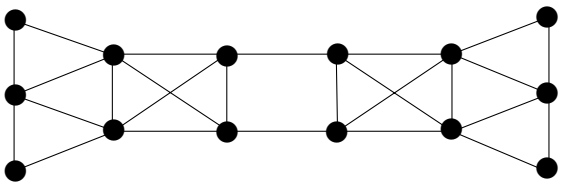

FIG. 5.1. *Claw-free graph, containing a dominating pair and a net.*

It should also be mentioned that Theorems 3.1 and 5.5 do cover a class of graphs that is not contained in the class of CN-free graphs. Figure 5.1 shows a graph that is claw-free, does contain a dominating/good pair and, consequently, a dominating path, but, obviously, it is neither AT-free nor net-free.

SQUARISH k-d TREES*

LUC DEVROYE†, JEAN JABBOUR†, AND CARLOS ZAMORA-CURA†

Abstract. We modify the k-d tree on $[0,1]^d$ by always cutting the longest edge instead of rotating through the coordinates. This modification makes the expected time behavior of lower-dimensional partial match queries behave as perfectly balanced complete k-d trees on n nodes. This is in contrast to a result of Flajolet and Puech [*J. Assoc. Comput. Mach.*, 33 (1986), pp. 371–407], who proved that for (standard) random k-d trees with cuts that rotate among the coordinate axes, the expected time behavior is much worse than for balanced complete k-d trees. We also provide results for range searching and nearest neighbor search for our trees.

Key words. k-d trees, partial match query, range search, expected time, probabilistic analysis of algorithms, data structures

1. Introduction.

The k-d tree, or k-dimensional binary search tree, was proposed by Bentley (1975). In this paper, we propose a modification, the squarish k-d tree, and analyze its expected time performance for partial match queries, orthogonal range searching, and nearest neighbor search under the standard random model for the input (n points independently and uniformly distributed on the unit hypercube). We point out its superiority over the standard k-d tree for this model.

Bentley's k-d tree is a binary search tree that generalizes the 1-d tree or ordinary binary search tree to $\mathbb{R}^k$. A partition of space into hyperrectangles is obtained by splitting alternating coordinate axes by hyperplanes through data points. Figure 1 shows the partition and the corresponding k-d tree. Insertion and search are implemented as for the standard binary search tree algorithms. These trees are used for a variety of other operations, including orthogonal range searching (report all points within a given rectangle), partial match queries (report all points whose values match a given k-dimensional vector with possibly a number of wild cards, e.g., we may search for all points with values $(a_1, *, *, a_4, a_5, *)$, where $*$ denotes a wild card). Additionally, nearest neighbor searching is greatly facilitated by k-d trees. For orthogonal range searching, a host of particular data structures have been developed, such as the range tree and variations or improvements of it (for surveys, see Bentley and Friedman (1979); Bentley (1979); Yao (1990); Samet (1990a), (1990b); and Agarwal (1997)). However, the k-d tree offers several advantages: it takes $O(kn)$ space for n data points, it is easily updated and maintained, it is simple to implement and comprehend, and it is useful for other operations besides orthogonal range search.

Bentley's orthogonal range search algorithm simply visits recursively all subtrees of the root that have a nonempty intersection with the query rectangle. In Figure 1, for example, the left and right subtrees of the root are visited. Note that each node in the tree represents both a point of the data and a rectangle in the partition, namely,

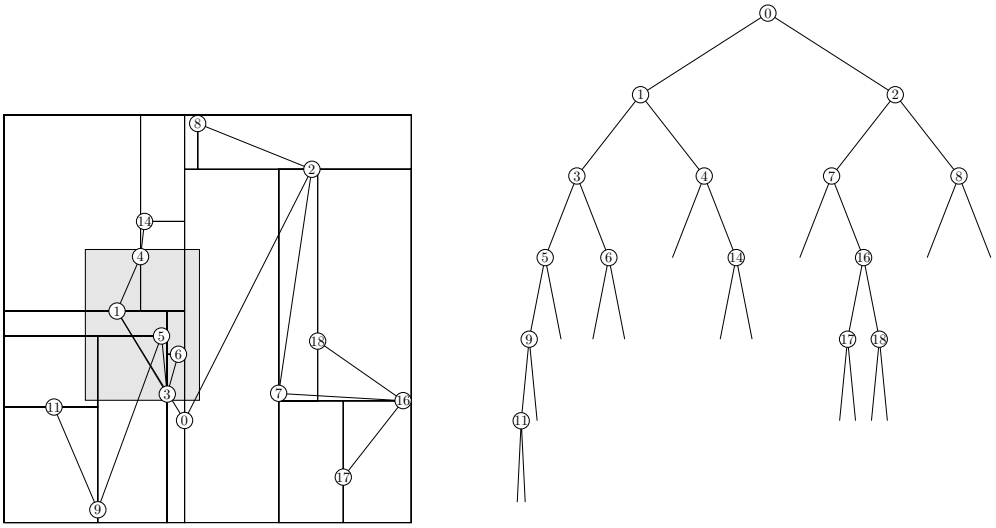

FIG. 1. *The query rectangle is shaded.*

the rectangle split by that point. Leaf regions thus have no points strictly in their interior. The query time for orthogonal search depends upon many factors, such as the location of the query rectangle and the distribution of the points. One may construct a median k-d tree off-line by splitting each time about the median, thus obtaining a perfectly balanced binary tree, in which ordinary point search takes $\Theta(\log n)$ worst-case time, and a partial match query with s coordinates specified takes worst-case time $O(n^{1-s/k}+N)$, where N is the number of points returned (see, for example, Lee and Wong (1977)).

For on-line insertion, balancing is notoriously difficult. If we assume that the data are independent and have a common distribution, then the expected query time is clearly of interest. For standard random binary search trees, it is known (Knuth (1997); Pittel (1984); Devroye (1986), (1987); Mahmoud (1992)) that most properties of balanced search trees are inherited: the expected depth of a randomly selected node is about $2\log n$ and the expected height is $O(\log n)$. One would hope that the random k-d tree, constructed by consecutive insertion of n data points, would also have a performance close to that of the median (off-line) k-d tree. Assuming that the data points are drawn from the uniform distribution on the unit k-cube, Flajolet and Puech (1986) showed that a random partial match query (carried out with s values also drawn uniformly and independently on $[0,1]$ so there are $k-s$ wild cards) has expected time performance $\Theta(n^{1-s/k+\theta(s/k)})$, where $\theta(u)$ is a strictly positive function of $u\in(0,1)$, with maximum not exceeding 0.07. Thus, random k-d trees behave a bit worse than their balanced counterparts, the median k-d trees. Surveys of related known probabilistic results are provided by Vitter and Flajolet (1990) and Gonnet and Baeza-Yates (1991).

We propose a minor modification of the insertion procedure, namely, each time a rectangle is split by a newly inserted leaf point, the longest side of its rectangle is cut, that is, the cut is a $(k-1)$-dimensional hyperplane through the new point perpendicular to the longest edge of the rectangle. It was shown by Chanzy, Devroye, and Zamora-Cura (1999) that elongated rectangles explain the poor performance of random k-d trees. In this paper, we show to what extent the proposed k-d trees have

more squarish-looking rectangles, and we will therefore call these trees *squarish k-d trees*. For the probabilistic model of Flajolet and Puech, it will be shown that the expected time for a partial match query is $\Theta(n^{1-s/k})$, just as for random median k-d trees. Furthermore, the expected complexity of any orthogonal range search in median k-d trees is asymptotically equivalent to that for the simple squarish k-d trees proposed here.

In the last part of the paper, we deal with orthogonal range search in general when the query rectangles may have dimensions that depend upon n in an arbitrary fashion. The proofs are probabilistic, rather than analytical, and do not offer explicit constants for expected times but only $\Theta(\cdot)$ results. However, they are short and explain many of the phenomena at work. Interestingly, very little probability beyond Hölder's inequality is needed. We conclude the paper by showing that a natural nearest neighbor search (with a randomly selected probe point) takes $O(\log n \log\log n)$ expected time in any dimension.

We should note that there are indeed more sophisticated data structures for some of the subproblems dealt with here. For example, if one is just interested in partial match queries, then one could just make j-d trees for each of the $2^k - 1$ nonempty subsets of size j of the k coordinates separately, so that search in the proper tree is just a point search, taking expected worst-case time $O(\log n)$, while the space used is still $O(n2^k)$. However, these would not be helpful for general orthogonal, simplex, or convex range searches. For an analysis of range search based on multiattribute trees see Gardy, Flajolet, and Puech (1989).

2. The random processes. In this section, we will try to explain the differences between alternating cuts and longest-edge cuts in sequences of randomly cut rectangles. To explain the processes at work, we consider the following simplification of our problem: in $\mathbb{R}^2$, start with a rectangle with one vertex permanently pegged at the origin and the opposite one at $(1,1)$, and let (U_n, V_n) denote the coordinates of the top right vertex after n iterations, with $(U_0, V_0) = (1,1)$. The rectangle will be reduced in size, first by alternating uniform cuts, that is, if $Z_1, Z_2, \ldots$ are independently and identically distributed (i.i.d.) uniform $[0,1]$ random variables, then we set

$$(U_n, V_n) = \begin{cases} (Z_n U_{n-1}, V_{n-1}) & \text{if } n \text{ is odd;} \\ (U_{n-1}, Z_n V_{n-1}) & \text{if } n \text{ is even.} \end{cases}$$

If we denote by $\stackrel{\mathcal{L}}{=}$ equality in distribution, clearly, at time $2n$, we have

$$U_{2n} \stackrel{\mathcal{L}}{=} V_{2n} \stackrel{\mathcal{L}}{=} \prod_{i=1}^{n} Z_i \stackrel{\mathcal{L}}{=} e^{-\sum_{i=1}^{n} E_i} \stackrel{\mathcal{L}}{=} e^{-G_n},$$

where the E_i are independent exponential random variables, and G_n denotes a gamma random variable with parameter n. As U_k and V_j are independent of each other for all k, j, we see that the ratio

$$\frac{U_{2n}}{V_{2n}} \stackrel{\mathcal{L}}{=} e^{G_n - G'_n},$$

where G_n, G'_n are i.i.d. gamma random variables. By the central limit theorem, it is easy to see that

$$\frac{1}{\sqrt{n}} \log\left(\frac{U_{2n}}{V_{2n}}\right) \stackrel{\mathcal{L}}{\to} \mathcal{N} - \mathcal{N}',$$

FIG. 2. *Two random k-d tree partitions clearly show the elongated rectangles.*

a difference of two independent standard normal random variables. Thus, the raw ratio behaves asymptotically like $\exp(\sqrt{n}(\mathcal{N}-\mathcal{N}'))$, and thus exhibits wide swings. In fact, if we stop at a large value for n, the rectangle will look very skinny indeed (see Figure 2).

Since we would like to preserve squarish rectangles, we may opt instead to always cut the longest side of the rectangle. More formally, with notation as above, $(U_0, V_0) = (1, 1)$, we have

$$(U_n, V_n) = \begin{cases} (Z_n U_{n-1}, V_{n-1}) & \text{if } U_{n-1} > V_{n-1}; \\ (U_{n-1}, Z_n V_{n-1}) & \text{if } U_{n-1} < V_{n-1}. \end{cases}$$

In case of equality $U_{n-1} = V_{n-1}$, which only occurs at $n = 1$, we flip a perfect coin and pick an edge to cut at random.

LEMMA 1. *With the longest-edge cutting method, the sequence U_n/V_n, $n \geq 1$, is identically distributed. The common distribution is that of Z_1/Z_2, the ratio of two independent uniform $[0, 1]$ random variables.*

Proof. Clearly, U_1/V_1 is distributed as Z_1 with probability $1/2$ and as $1/Z_1$ otherwise. It is easy to verify that this has the required density $1/(2\max(z, 1))^2$, $z > 0$. By induction, we need to show that if Z_1, Z_2, Z are i.i.d. uniform $[0, 1]$ random variables, then the random variable $ZZ_1/Z_2 I_{Z_1 > Z_2} + Z_1/(ZZ_2) I_{Z_1 < Z_2}$ is in turn distributed as Z_1/Z_2. This can be done by standard calculations, or even the method of characteristic functions. However, by far the quickest way to see this is by embedding. We note that Z_1/Z_2 is distributed as the random variable Z_4^S where $S = 1$ and $S = -1$ with equal probability, and Z_4 is another uniform $[0, 1]$ random variable. The case $Z_1 > Z_2$ corresponds to $S = -1$, and thus we see that $ZZ_1/Z_2 I_{Z_1 > Z_2} + Z_1/(ZZ_2) I_{Z_1 < Z_2}$ is distributed as $(Z_4/Z)^S$, which was to be shown, as S is independent of Z and Z_4. □

Lemma 1 shows that cutting the longest edge is extremely stabilizing. Nevertheless, as U_n/V_n has Cauchy-like tails, its mean does not exist, and we will often see skinny rectangles, although by and large the rectangles will be rather squarish (see Figures 3 and 4). The above observations explain why the squarish k-d trees are useful. Our analysis is of course more involved, as rectangles participate in an evolv-

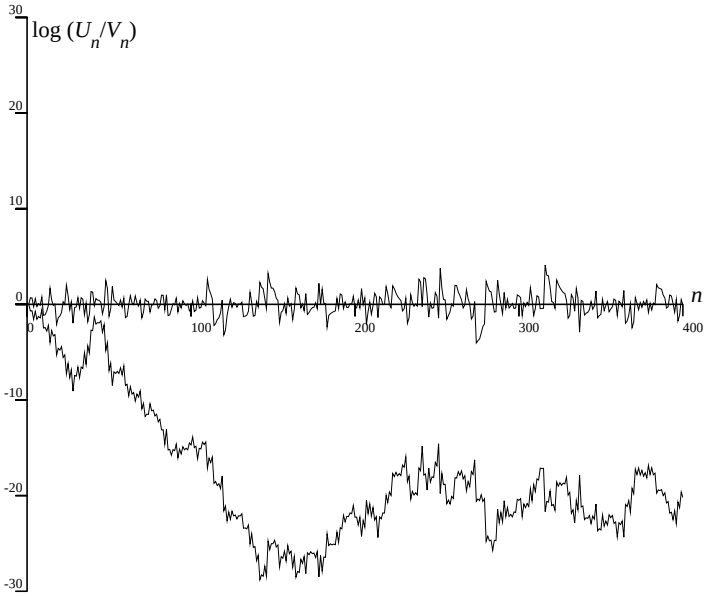

FIG. 3. *For the two processes above,* $\log(U_n/V_n)$ *is plotted versus* n*. The alternating cuts process wanders off just as a random walk. The largest edge cut strategy induces a sequence* U_n/V_n *that hovers near one and remains stationary.*

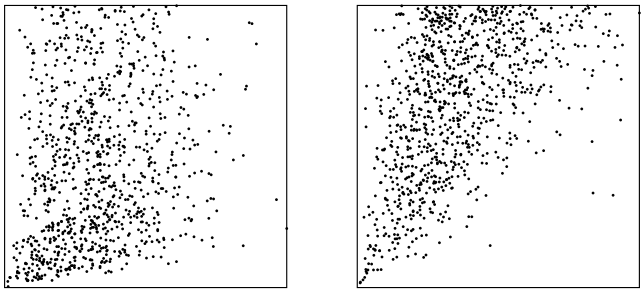

FIG. 4. *For the two processes above, let* L_n *and* S_n *be the long and short dimensions of a leaf rectangle in the* 2*-d partition. The values* $\sqrt{L_n/S_n}$ *are plotted versus* $\sqrt{L_n S_n}$ *(normalized so that the largest value is one) for the two k-d trees. For squarish k-d trees (on the right), there are many more rectangles in which* L_n *and* S_n *are close. And nearly all big rectangles are squarish. For the ordinary random* 2*-d tree (on the left) most rectangles have very small edge ratios.*

ing collection of rectangles, with very intricate dependencies. As soon as a rectangle becomes too small, it is unlikely to be picked again soon, and thus, the ratio of the sides of the rectangles must be considered in conjunction with the sizes. For this, we introduce a few new analysis methods.

3. Notation and preliminaries. In k-d trees, nodes represent rectangular regions. Bentley's algorithm for orthogonal range search and partial match queries starts at the root of a k-d tree and recursively visits all subtrees that have a nonempty overlap with the rectangular regions of the children, and reports all points that fall in the search region. Let $u_1, u_2, \ldots, u_n$, $n \geq 1$, denote the nodes in the k-d tree, and let $U_1, \ldots, U_n$ denote the data points, which are i.i.d. and uniformly distributed on

$[0,1]^k$. Thus, U_i is the data point corresponding to u_i. The rectangle split by u_i is R_i. Thus, $R_1 = [0,1]^k$. Let $|R_i|$ denote the volume of rectangle i. The $n+1$ leaf rectangles (the dangling edges in Figure 1) are also denoted R_i, with the index i now running from $n+1$ to $2n+1$. The collection of rectangles is denoted by $\mathcal{R}_n$. The collection of the indices of the $n+1$ final rectangles is $\mathcal{F}_n$. We will denote by T the k-d tree constructed by inserting successively $u_1, u_2, \ldots, u_n$ into an initially empty k-d tree. Given a node u in T, we will denote by T_u the subtree of T rooted at u. With rotating coordinate cuts, such a tree is called a *random k-d tree*. With our method of cutting the longest edges, it will be called a *random squarish k-d tree*.

The dimensions of rectangle R_i are $X_{ij}, 1 \le j \le k$. For 2-d trees, we will use the lighter notation X_i, Y_i for the x and y dimensions of R_i. The query rectangle Q is $Z + [-m_1, m_1] \times \cdots \times [-m_k, m_k]$, $m_i \ge 0$ for all i, where the m_i's are fixed (that is, they may depend upon n only) and Z is uniformly distributed on $[0,1]^k$ and independent of $(U_1, \ldots, U_n)$. Bentley's range search applied to Q is called a *random orthogonal range search*. Note that a node u_i is visited by the range search algorithm if and only if the query rectangle Q intersects R_i. Any rectangle R_i is visited if and only if it intersects Q. Let N_n be the time complexity of Bentley's orthogonal range search. Then,

$$N_n = \sum_{i=1}^{2n+1} \mathbf{1}_{[R_i \cap Q \neq \emptyset]},$$

where $\mathbf{1}_{[A]}$ is the characteristic function of the event A. This quantity will be analyzed further on for random squarish k-d trees.

In a *random partial match query*, we specify a subset of s dimensions, $j_1, \ldots, j_s$, and perform an orthogonal range query with the ith interval in the rectangle either $\{Z_i\}$ (a uniform random number on $[0,1]$) if $i \in \{j_1, \ldots, j_s\}$, or $(-\infty, \infty)$ otherwise. It is assumed that the Z_i's are independent, and independent of $(U_1, \ldots, U_n)$. In this paper, we first study random partial match queries for random squarish k-d trees and obtain results that should be compared against the following result for random k-d trees.

THEOREM 1 (Flajolet and Puech (1986)). *For a random k-d tree and a random partial match query, in which s of the k fields are specified with $k > s \ge 0$, let $N_n^{(s)}$ be the number of comparisons that Bentley's orthogonal range search performs. Define*

$$\alpha(u) = \max_{0 \le t \le 1} \left\{ t + 2 \left(\frac{1-t}{1-u} \right)^{1-u} \left(\frac{t}{u} \right)^{u} - 2 \right\}, \ 0 < u < 1,$$

and note in particular that α is decreasing on $(0,1)$, $\alpha(0) = 1$, and that $1 - u < \alpha(u) < 1.07 - u$, $0 < u < 1$. Then, the expected value of $N_n^{(s)}$ is such that

$$\mathbf{E}\left\{ N_n^{(s)} \right\} = (c + o(1)) n^{\alpha(s/k)},$$

where c is a constant depending on the indices of the s fixed coordinates.

The following proposition is useful in relating partial random partial match queries to the range search problem.

PROPOSITION 1. *Given is a random k-d tree based on i.i.d. random variables $U_1, \ldots, U_n$, distributed uniformly on $[0,1]^k$. Consider a random partial match query, in which $s \ge 0$ of the k fields are specified. Let $N_n^{(s)}$ be the number of comparisons that*

Bentley's orthogonal range search performs. Let S be the set of specified coordinates. Then

$$\mathbf{E}\left\{N_n^{(s)}\right\} = \mathbf{E}\left\{\sum_{i=1}^{2n+1}\prod_{j\in S} X_{ij}\right\},$$

where $X_{ij}, 1 \le j \le k$, are the lengths of the sides of rectangle R_i in $\mathcal{R}_n$.

Proof. Let Q be the query rectangle. Note that $\mathbf{P}\{Q \cap R_i \neq \emptyset \,|\, U_1, \ldots, U_n\} = \prod_{j\in S} X_{ij}$. Thus we have

$$\mathbf{E}\left\{N_n^{(s)}\right\} = \mathbf{E}\left\{\sum_{i=1}^{2n+1} \mathbf{1}_{[Q\cap R_i\neq\emptyset]}\right\} = \sum_{i=1}^{2n+1}\mathbf{P}\{Q\cap R_i\neq\emptyset\} = \mathbf{E}\left\{\sum_{i=1}^{2n+1}\prod_{j\in S} X_{ij}\right\}. \qquad \square$$

The next observation is important. It follows immediately by considering the random growth of our k-d trees, and, of course, it implies that the joint distribution of the ordered volumes of the $n+1$ leaf rectangles is identical for both random k-d trees considered here!

LEMMA 2. *Consider a random k-d tree or a random squarish k-d tree. Then, the volumes of the rectangles in $\mathcal{F}_n$ are distributed as the set $\mathcal{V}_n$ of the consecutive spacings between the order statistics of n i.i.d. random variables, uniformly distributed on $[0,1]$.*

4. Random partial match queries with squarish 2-d trees. In a vertical random partial match query on a 2-d tree, we take a uniformly distributed value Z and visit all nodes in the tree whose rectangle cuts the vertical line at Z. Horizontal partial match queries on 2-d trees are defined in an analogous manner. The probability of hitting a rectangle with dimensions $X_i \times Y_i$ is of course X_i, so that the expected number of nodes visited, and hence the expected time for a partial match query, is simply $\mathbf{E}\{\sum_{i=1}^{2n+1} X_i\}$, where the sum is taken over all $2n+1$ rectangles in the partition. A similar formula holds, of course, for horizontal partial match queries. In this section, we prove that a random partial match query in a random squarish 2-d tree takes expected time $\Theta(\sqrt{n})$ as opposed to $\Theta(n^{0.5616})$ for random 2-d trees (see Theorem 1).

THEOREM 2. *For random squarish 2-d trees,*

$$\frac{\sqrt{\pi n}}{3} \le \mathbf{E}\left\{\sum_{i=1}^{2n+1} Y_i\right\} \le 180\sqrt{n}.$$

The same result holds for $\mathbf{E}\{\sum_{i=1}^{2n+1} X_i\}$. Hence, the expected time for a random partial match query is $\Theta(\sqrt{n})$.

Of course, no attempt was made to optimize the constants. A few technical results will be needed in what follows. In particular, the next lemma is valid for squarish k-d trees in arbitrary dimension.

LEMMA 3. *For random squarish k-d trees, let $p \ge 0, n \ge 1$; then*

$$\left(\frac{1}{1+p}\right)^{\lfloor p\rfloor+1}\frac{\Gamma(p+1)}{n^{p-1}} \le \mathbf{E}\left\{\sum_{i\in\mathcal{F}_n}|R_i|^p\right\} \le \frac{4\Gamma(p+1)}{n^{p-1}}$$

for all n.

Proof. Let $V_1, \ldots, V_{n+1}$ be the spacings induced by n independent uniformly distributed random variables on $[0,1]$. It is known that $V_i \stackrel{\mathcal{L}}{=} \text{Beta}(1,n)$. Thus, by Lemma 2, with $\text{B}(s,t) = \frac{\Gamma(s)\Gamma(t)}{\Gamma(s+t)}$,

$$\begin{aligned}\mathbf{E}\left\{\sum_{i\in\mathcal{F}_n}|R_i|^p\right\} &= \mathbf{E}\left\{\sum_{i=1}^{n+1}V_i^p\right\} = \sum_{i=1}^{n+1}\int_0^1 v^p\frac{(1-v)^{n-1}}{\text{B}(1,n)}dv \\ &= (n+1)\frac{\text{B}(p+1,n)}{\text{B}(1,n)} = \Gamma(p+1)\frac{\Gamma(n+2)}{\Gamma(p+n+1)}\ .\end{aligned}$$

Now, $\Gamma(x+1) = x\Gamma(x)$ for any $x > 0$, and for any natural number n and any $s \in [0,1]$, $n^{1-s} \le \Gamma(n+1)/\Gamma(n+s) \le (n+1)^{1-s}$ (see Mitrinović (1970)). Thus,

$$\begin{aligned}\mathbf{E}\left\{\sum_{i\in\mathcal{F}_n}|R_i|^p\right\} &= \Gamma(p+1)(n+1)\frac{\Gamma(n+1)}{(n+p)\cdots(n+p-\lfloor p\rfloor)\Gamma(n+p-\lfloor p\rfloor)} \\ &\le \frac{\Gamma(p+1)(n+1)^{2-p+\lfloor p\rfloor}}{n^{\lfloor p\rfloor+1}} \\ &= \frac{\Gamma(p+1)}{n^{p-1}}\left(\frac{n+1}{n}\right)^{2+\lfloor p\rfloor-p} \\ &\le \frac{4\Gamma(p+1)}{n^{p-1}},\end{aligned}$$

as $2 + \lfloor p\rfloor - p \le 2$. Now, for the lower bound, note that

$$\begin{aligned}\mathbf{E}\left\{\sum_{i\in\mathcal{F}_n}|R_i|^p\right\} &= \Gamma(p+1)(n+1)\frac{\Gamma(n+1)}{(n+p)\cdots(n+p-\lfloor p\rfloor)\Gamma(n+p-\lfloor p\rfloor)} \\ &\ge \frac{\Gamma(p+1)}{n^{p-1}}\frac{n^{\lfloor p\rfloor+1}}{(n+p)\cdots(n+p-\lfloor p\rfloor)} \\ &\ge \frac{\Gamma(p+1)}{n^{p-1}}\left(\frac{n}{n+p}\right)^{\lfloor p\rfloor+1} \\ &\ge \frac{\Gamma(p+1)}{n^{p-1}}\left(\frac{1}{1+p}\right)^{\lfloor p\rfloor+1}.\end{aligned}$$ □

LEMMA 4. *In a random squarish 2-d tree constructed from the insertion of $U_1, \ldots, U_n$ independent and uniformly distributed random vectors on $[0,1]^2$ we have that for every $q \ge 1$,*

$$\mathbf{E}\left\{\sum_{i\in\mathcal{F}_n}Y_i^q\right\} \le \begin{cases}\frac{8}{1-q/2}n^{1-q/2} & \text{for } q\in[1,2);\\ 8e\log n & \text{for } 2-\frac{2}{\log n}\le q\le 2;\\ \frac{5\Gamma(q/2+1)}{q/2-1}\left(\frac{q}{2}-\frac{1}{n^{q/2-1}}\right) & \text{for } q>2,\end{cases}$$

and for $q \in [1,2)$,

$$\mathbf{E}\left\{\sum_{i\in\mathcal{F}_n}Y_i^q\right\} \ge \left(\frac{1}{q/2+1}\right)^{\lfloor q/2\rfloor+1}\Gamma(q/2+1)n^{1-q/2}.$$

The same result holds for $\mathbf{E}\left\{\sum_{i\in\mathcal{F}_n}X_i^q\right\}$.

Proof. Let $r > 1$, and define $S_r^{(q)} = \sum_{i\in\mathcal{F}_r} Y_i^q$. Note that, given $U_1,\dots,U_r$, $S_{r+1}^{(q)} - S_r^{(q)}$ is distributed as Y^q when $X > Y$ and as $Y^q(U^q + (1-U)^q - 1)$ when $X \le Y$, where U is a uniform $[0,1]$ random variable, and (X,Y) are the dimensions of the rectangle split when U_{r+1} is added. Thus,

$$\mathbf{E}\left\{S_{r+1}^{(q)} - S_r^{(q)}\right\} = \mathbf{E}\left\{\sum_{i\in\mathcal{F}_r} X_iY_i\left(\mathbf{1}_{[X_i>Y_i]}Y_i^q + \mathbf{1}_{[X_i<Y_i]}Y_i^q\left(U^q + (1-U)^q - 1\right)\right)\right\}.$$

Notice that $U^q + (1-U)^q - 1 \le 0$ for $q \ge 1$, and as $\min\{a,b\} \le \sqrt{ab}$, for $a,b \ge 0$, then by Lemma 3,

$$\begin{aligned}\mathbf{E}\left\{S_{r+1}^{(q)} - S_r^{(q)}\right\} &\le \mathbf{E}\left\{\sum_{i\in\mathcal{F}_r} X_iY_i\left(\mathbf{1}_{[X_i>Y_i]}Y_i^q\right)\right\}\\ &\le \mathbf{E}\left\{\sum_{i\in\mathcal{F}_r}(X_iY_i)^{q/2+1}\right\} \le \frac{4\Gamma(q/2+2)}{r^{q/2}}.\end{aligned}$$

By summing the differences, we get

$$\begin{aligned}\mathbf{E}\left\{S_n^{(q)}\right\} &= \mathbf{E}\left\{\sum_{r=1}^{n-1}\left(S_{r+1}^{(q)} - S_r^{(q)}\right) + S_1^{(q)}\right\}\\ &\le \sum_{r=1}^{n-1}\frac{4\Gamma(q/2+2)}{r^{q/2}} + 2\\ &\le 2 + 4\Gamma(q/2+2)\left(1 + \int_1^{n-1}\frac{1}{x^{q/2}}dx\right)\\ &\le \begin{cases} 10 + \frac{4\Gamma(q/2+2)}{1-q/2}(n^{1-q/2} - 1) & (q\in[1,2)),\\ 5\Gamma(q/2+2) + \frac{4\Gamma(q/2+2)}{q/2-1}(1-n^{1-q/2}) & (q>2)\end{cases}\\ &\le \begin{cases} \frac{8}{1-q/2}n^{1-q/2} & (q\in[1,2)),\\ \frac{5\Gamma(q/2+2)}{q/2-1}\left(\frac{q}{2} - n^{1-q/2}\right) & (q>2).\end{cases}\end{aligned}$$

Because $\frac{8}{1-q/2}n^{1-q/2}$, as a function of q, reaches its minimum at $q_0 = 2(1-1/\log n)$, and $\mathbf{E}\{S_n^{(q)}\}$ is a decreasing function of q, we have that $\mathbf{E}\{S_n^{(q)}\} \le 8e\log n$, for $q_0 \le q \le 2$. The result for $\mathbf{E}\left\{\sum_{i\in\mathcal{F}_n} X_i^q\right\}$ can be obtained similarly just by replacing the y-lengths for the x-lengths in the appropriate places.

Now, for the lower bound, note that as the X_i's and the Y_i's are identically distributed,

$$\begin{aligned}\mathbf{E}\left\{\sum_{i\in\mathcal{F}_n} Y_i^q\right\} &= \frac{1}{2}\,\mathbf{E}\left\{\sum_{i\in\mathcal{F}_n}(Y_i^q + X_i^q)\right\}\\ &\ge \mathbf{E}\left\{\sum_{i\in\mathcal{F}_n}(Y_iX_i)^{q/2}\right\}\\ &\ge \left(\frac{1}{q/2+1}\right)^{\lfloor q/2\rfloor+1}\frac{\Gamma(q/2+1)}{n^{q/2-1}},\end{aligned}$$

by Lemma 3, for $q \in [1,2)$. ∎

Proof of Theorem 2. Note that the lower bound follows from Lemma 4, as $\mathbf{E}\left\{\sum_{i\in\mathcal{F}_n} Y_i\right\}$ is less than $\mathbf{E}\{\sum_{i=1}^{2n+1} Y_i\}$. For the upper bound we will use the same technique as in the proof of Lemma 4. Let $S_n = \sum_{i=1}^{2n+1} Y_i$. Note that as the sum is over all the rectangles generated by $U_1, \ldots, U_n$, we have now that for $r \geq 1$, as X_i and Y_i are identically distributed,

$$\begin{aligned}\mathbf{E}\left\{S_{r+1} - S_r\right\} &= \mathbf{E}\left\{\sum_{i\in\mathcal{F}_r} X_i Y_i \left(\mathbf{1}_{[X_i>Y_i]} 2Y_i + \mathbf{1}_{[X_i<Y_i]}(Y_i U + Y_i(1-U))\right)\right\} \\ &\leq 3\,\mathbf{E}\left\{\sum_{i\in\mathcal{F}_r} X_i Y_i^2\right\},\end{aligned}$$

where $U \stackrel{\mathcal{L}}{=} \text{Uniform}[0,1]$, and independent of all $U_1, \ldots, U_n$. Let $q \in (1,2)$ and $p > 1$ such that $\frac{1}{p} + \frac{1}{q} = 1$, then by Hölder's inequality used twice,

$$\begin{aligned}\mathbf{E}\left\{\sum_{i\in\mathcal{F}_r} X_i Y_i^2\right\} &\leq \mathbf{E}\left\{\sum_{i\in\mathcal{F}_r} (X_i Y_i)^p\right\}^{1/p} \mathbf{E}\left\{\sum_{i\in\mathcal{F}_r} Y_i^q\right\}^{1/q} \\ &\leq \left(\frac{4\Gamma(p+1)}{r^{p-1}}\right)^{1/p} \left(\frac{8}{1-q/2}\frac{1}{r^{q/2-1}}\right)^{1/q}\end{aligned}$$

by Lemmas 3 and 4. Take $p = 3$, $q = 3/2$, and verify that the upper bound is not more than $24^{1/3}32^{2/3}/\sqrt{r} < 30/\sqrt{r}$. By summing the differences we finally obtain

$$\mathbf{E}\left\{\sum_{i=1}^{2n+1} Y_i\right\} \leq \frac{5}{2} + 90\sum_{r=1}^{n-1}\frac{1}{\sqrt{r}} \leq \frac{5}{2} + 90(2\sqrt{n-1} - 1) \leq 180\sqrt{n}.$$

The result for $\mathbf{E}\{\sum_{i=1}^{2n+1} X_i\}$ can be obtained similarly just by replacing the y-lengths for the x-lengths in the appropriate places. □

5. The *k*-dimensional case. In this section, we obtain the k-dimensional generalization of the results in the previous section by induction. Given $U_1, \ldots, U_n$, we define for each $R_i \in \mathcal{R}_n$, $X_i^* = \max_{j=1,\ldots,k} X_{ij}$ and j_i^* as the index $j \in \{1, \ldots, n\}$ for which $X_{ij} = X_i^*$. Note that j_i^* is unique with probability one. Our main result generalizes Theorem 2 and establishes the expected time optimality of random squarish k-d trees.

THEOREM 3. *Consider a random squarish k-d tree. For $\ell \in \{1, \ldots, k-1\}$, there exist $C, C' > 0$ such that*

$$C' n^{1-\frac{\ell}{k}} \leq \mathbf{E}\left\{\sum_{i=1}^{2n+1}\prod_{j\in I} X_{ij}\right\} \leq C n^{1-\frac{\ell}{k}},$$

for any $I \subseteq \{1, \ldots, k\}$ of cardinality ℓ and all $n \in \mathbb{N}$. In particular, by Proposition 1 *the expected time of a random partial match query with s specified coordinates is $\Theta(n^{1-s/k})$.*

The next lemma complements Theorem 3 when $\ell = k$.

LEMMA 5. *Let $U_1, \ldots, U_n$ be independent uniformly distributed random variables over $[0,1]^k$. Let $\mathcal{R}_n = \{R_1, R_2, \ldots, R_{2n+1}\}$ be the hyperrectangles in the partition*

defined by the random squarish k-d tree based on $U_1, \ldots, U_n$. Let X_{ij} be the length on the jth coordinate of the ith hyperrectangle. Then,

$$\mathbf{E}\left\{\sum_{i=1}^{2n+1} X_{i1}\cdots X_{ik}\right\} = 2h_{n+1} - 1,$$

where h_n is the nth harmonic number.

We prove the following lemma that will allow us to prove the lower bound in the previous theorem.

LEMMA 6. *Let $\ell \in \{1, \ldots, k\}$; then for every $x_1, \ldots, x_k > 0$,*

$$\left(\prod_{j=1}^{k} x_j\right)^{\frac{1}{k}} \leq \max_{I:\ I\subseteq\{1,\ldots,k\}\atop |I|=\ell} \left(\prod_{j\in I} x_j\right)^{\frac{1}{\ell}}.$$

Proof. Let I^* be the subset of $\{1, \ldots, k\}$ of cardinality ℓ for which the maximum above is reached. It suffices to observe that

$$\left(\prod_{j=1}^{k} x_j\right)^{\ell} = \prod_{s=1}^{k}\left(\prod_{j=s}^{s+\ell-1} x_j\right) \leq \prod_{s=0}^{k-1}\left(\prod_{j\in I^*} x_j\right) = \left(\prod_{j\in I^*} x_j\right)^{k},$$

where the subindice j must be understood as (j mod k), if $j > k$. ∎

PROPOSITION 2. *Let $I \subseteq \{1, \ldots, k\}$ of cardinality $\ell \in \{1, \ldots, k\}$ and $p \in [1, \frac{k}{\ell})$; then there are positive constants C and C' such that*

$$C' n^{1-p\frac{\ell}{k}} \leq \mathbf{E}\left\{\sum_{i\in\mathcal{F}_n}\left(\prod_{j\in I} X_{ij}\right)^{p}\right\} \leq C n^{1-p\frac{\ell}{k}}$$

for all $n \in \mathbb{N}$.

Proof. For $I \subseteq \{1, \ldots, k\}$ with $|I| = \ell$, we define

$$S_r^{I,p} = \sum_{i\in\mathcal{F}_r}\left(\prod_{j\in I} X_{ij}\right)^{p}.$$

We first look at the upper bound. We define recursively the constants $C_k(\ell, p)$ for any integer $k > 0$, $\ell \in \{1, \ldots, k\}$ and real number $p \in [1, \frac{k}{\ell})$ as follows:

$$C_k(\ell,p) = \begin{cases} 4\Gamma(p+1) & \text{if } \ell = k; \\ (k-\ell)\left(\frac{1}{1-\frac{p\ell}{k}}\right) C_k(k,\tilde{q})^{1/\tilde{q}} C_k(\ell+1, p\tilde{p}\ell/(\ell+1))^{1/\tilde{p}} + 2 & \text{if } \ell < k, \end{cases}$$

where $\tilde{p}, \tilde{q} > 1$ depend on p, k, and ℓ, they are such that $\frac{1}{\tilde{p}} + \frac{1}{\tilde{q}} = 1$, and $1 \leq p\tilde{p}\frac{\ell}{\ell+1} < \frac{k}{\ell+1}$. For the sake of clarity we will choose $\tilde{p}$ later.

For $\ell \in \{2, \ldots, k\}$, we define the hypothesis $\mathcal{H}_\ell$ stating that the upper bound holds for all $n \in \mathbb{N}$, all $I \subseteq \{1, \ldots, k\}$ such that $|I| = \ell$, and all $p \in [1, \frac{k}{\ell})$, with constant $C_k(\ell, p)$. We will prove $\mathcal{H}_\ell$ with an inductive argument. First, note that $\mathcal{H}_k$

holds by Lemma 3. Assuming that $\mathcal{H}_\ell$ is true, we will prove $\mathcal{H}_{\ell-1}$. Let $I \subseteq \{1,\dots,k\}$ such that $\ell - 1 = |I| \geq 1$, and $p \in [1, \frac{k}{\ell-1})$. Then for any integer $r \geq 1$, we have

$$\mathbf{E}\left\{S_{r+1}^{I,p} - S_r^{I,p} | U_1,\dots,U_r\right\} = \sum_{i\in\mathcal{F}_r}\left(\prod_{j=1}^k X_{ij}\right)\left\{\mathbf{1}_{[j_i^*\notin I]}\left(\prod_{j\in I} X_{ij}\right)^p + \mathbf{1}_{[j_i^*\in I]}\left(\prod_{j\in I} X_{ij}\right)^p \int_0^1 (x^p + (1-x)^p - 1)dx\right\},$$

as we are using the longest-edge cut method. Since $\int_0^1 (x^p + (1-x)^p - 1)dx \leq 0$ for any $p \geq 1$, we can drop the second term above and take expected values so that

$$\mathbf{E}\left\{S_{r+1}^{I,p} - S_r^{I,p}\right\} \leq \sum_{t\notin I} \mathbf{E}\left\{\sum_{i\in\mathcal{F}_r}\left(\prod_{j=1}^k X_{ij}\right)\mathbf{1}_{[j_i^*=t]}\left(\prod_{j\in I} X_{ij}\right)^p\right\}.$$

Let us denote by $E(t)$ the expected value of the tth term above. Observe that $\mathbf{1}_{[j_i^*=t]} X_{ij} \leq X_{ij}^{\frac{\ell-1}{\ell}} X_{it}^{\frac{1}{\ell}}$. Thus we can bound each $E(t)$ as follows:

$$E(t) \leq \mathbf{E}\left\{\sum_{i\in\mathcal{F}_r}\left(\prod_{j=1}^k X_{ij}\right)\left(\prod_{j\in I\cup\{t\}} X_{ij}\right)^{\frac{\ell-1}{\ell}p}\right\}.$$

Now, for any $\tilde{p}, \tilde{q} > 1$ such that $\frac{1}{\tilde{p}} + \frac{1}{\tilde{q}} = 1$, we have by applying Hölder's inequality twice that

$$E(t) \leq \mathbf{E}\left\{\sum_{i\in\mathcal{F}_r}\left(\prod_{j=1}^k X_{ij}\right)^{\tilde{q}}\right\}^{\frac{1}{\tilde{q}}} \mathbf{E}\left\{\sum_{i\in\mathcal{F}_r}\left(\prod_{j\in I\cup\{t\}} X_{ij}\right)^{\frac{\ell-1}{\ell}p\tilde{p}}\right\}^{\frac{1}{\tilde{p}}}.$$

We can apply hypothesis $\mathcal{H}_\ell$ to bound the second term above, if we can choose $\tilde{p} > 1$ such that $p\tilde{p}\frac{\ell-1}{\ell} \in [1, k/\ell)$. Note that $\frac{k}{p(\ell-1)} > 1$, as $p \in [1, \frac{k}{\ell-1})$. Let us define $\tilde{p} = \max\left\{\sqrt{k/p(\ell-1)}, \frac{\ell}{(\ell-1)p}\right\}$, so that $\tilde{p} > 1$, yet $1 \leq p\tilde{p}\frac{\ell-1}{\ell} < \frac{k}{\ell}$. This completely defines the constant $C_k(\ell, p)$. We can therefore use hypothesis $\mathcal{H}_\ell$ and obtain

$$\begin{aligned} E(t) &\leq \left(\frac{C_k(k,\tilde{q})}{r^{\tilde{q}-1}}\right)^{1/\tilde{q}}\left(\frac{C_k(\ell, p\tilde{p}(\ell-1)/\ell)}{r^{\frac{\ell-1}{k}p\tilde{p}-1}}\right)^{1/\tilde{p}} \\ &= \frac{C_k(k,\tilde{q})^{1/\tilde{q}} C_k(\ell, p\tilde{p}(\ell-1)/\ell)^{\frac{1}{\tilde{p}}}}{r^{\frac{\ell-1}{k}p}}. \end{aligned}$$

We can thus bound the differences as follows:

$$\mathbf{E}\left\{S_{r+1}^{I,p} - S_r^{I,p}\right\} \leq \sum_{t\notin I} E(t) \leq \frac{(k-\ell+1) C_k(k,\tilde{q})^{1/\tilde{q}} C_k(\ell, p\tilde{p}(\ell-1)/\ell)^{1/\tilde{p}}}{r^{\frac{\ell-1}{k}p}}.$$

Since $p < \frac{k}{\ell-1}$, we have that $\sum_{r=1}^n \frac{1}{r^{p\frac{\ell-1}{k}}} \leq \frac{1}{1-p\frac{\ell-1}{k}} \frac{n}{n^{p\frac{\ell-1}{k}}}$. So, by summing the differences, we get

$$\mathbf{E}\left\{S_n^{I,p}\right\} \leq \left[C_k(\ell-1,p) - 2\right] n^{1-p\frac{\ell-1}{k}} + 2 \leq C_k(\ell-1,p) n^{1-\frac{p(\ell-1)}{k}}$$

as $\mathbf{E}\{S_1^{I,p}\} \le 2$, for every $p \ge 1$, and any nonempty $I \subseteq \{1,\dots,k\}$. Thus, hypothesis $\mathcal{H}_{\ell-1}$ is proved.

We now prove the lower bound. As we flip a perfect coin at the beginning of the process to choose the side of R_1 that we cut, all the coordinates $X_{i1},\dots,X_{ik}$ of a hyperrectangle R_i are exchangeable. So, denoting by $\mathcal{S}$ the set of all $I' \subseteq \{1,\dots,k\}$ of cardinality ℓ, all the random variables $\sum_{i\in\mathcal{F}_n}\prod_{j\in I'} X_{ij}^p$ are equally distributed so that

$$\mathbf{E}\left\{\sum_{i\in\mathcal{F}_n}\prod_{j\in I} X_{ij}^p\right\} = \frac{1}{|\mathcal{S}|}\,\mathbf{E}\left\{\sum_{I'\in\mathcal{S}}\sum_{i\in\mathcal{F}_n}\prod_{j\in I'} X_{ij}^p\right\}.$$

Then, by Lemmas 3 and 6,

$$\mathbf{E}\left\{\sum_{i\in\mathcal{F}_n}\left(\prod_{j\in I} X_{ij}\right)^p\right\} \ge \frac{1}{|\mathcal{S}|}\,\mathbf{E}\left\{\sum_{i\in\mathcal{F}_n}\left(\prod_{j=1}^k X_{ij}\right)^{\frac{p\ell}{k}}\right\} \ge C'\frac{n}{n^{\frac{p\ell}{k}}}. \qquad \square$$

We must note that by Lemma 3, if $\ell = k$, then for any $p \ge 0$, there are positive constants C and C', depending on p such that the previous result holds. We are now ready to prove Theorem 3.

Proof of Theorem 3. The lower bound follows immediately from the previous proposition. For any subset $I \subseteq \{1,\dots,k\}$ of cardinality $\ell \in \{1,\dots,k-1\}$, we define

$$S_n^I = \sum_{i=1}^{2n}\prod_{j\in I} X_{ij}.$$

As we are using the longest-edge cut method we have that

$$\begin{aligned}\mathbf{E}\left\{S_{r+1}^I - S_r^I | U_1,\dots,U_n\right\} &= \sum_{i\in\mathcal{F}_r}\prod_{j=1}^k X_{ij}\left\{\mathbf{1}_{[j_i^*\notin I]}2\prod_{j\in I}X_{ij} + \mathbf{1}_{[j_i^*\in I]}\prod_{j\in I}X_{ij}\right\}\\ &\le 3\sum_{i\in\mathcal{F}_r}\prod_{j=1}^k X_{ij}\prod_{j\in I}X_{ij}.\end{aligned}$$

We choose now $p = \sqrt{k/\ell}$, $q = 1/(1-\sqrt{\ell/k})$, so that $\frac{1}{p}+\frac{1}{q}=1$, and apply Hölder's inequality with these values to get

$$\mathbf{E}\left\{S_{r+1}^I - S_r^I\right\} \le 3\,\mathbf{E}\left\{\sum_{i\in\mathcal{F}_r}\left(\prod_{j=1}^k X_{ij}\right)^p\right\}^{1/p}\mathbf{E}\left\{\sum_{i\in\mathcal{F}_r}\left(\prod_{j\in I}X_{ij}\right)^q\right\}^{1/q}.$$

Then by Lemma 3 and Proposition 2, there exists a positive constant C depending upon ℓ and k such that

$$\mathbf{E}\left\{S_{r+1}^I - S_r^I\right\} \le \frac{C}{r^{\frac{\ell}{k}}}.$$

We add the differences to get

$$\mathbf{E}\left\{S_n^I\right\} \le C\left(\sum_{r=1}^n \frac{1}{r^{\frac{\ell}{k}}}\right) + 2 \le \frac{C}{1-\frac{\ell}{k}}\left(\frac{n}{n^{\frac{\ell}{k}}}\right) + 2. \qquad \square$$

Proof of Lemma 5. First, note that for any $1 \le i \le n$, $X_{i1} \cdots X_{ik}$ is the volume $|R_i|$ of the hyperrectangle R_i. Note that if $U_1, \ldots, U_i$ have already been inserted in $[0,1]^k$, and U_{i+1} is a new point, then the size of the two hyperrectangles generated by U_{i+1} is equal to the size of the hyperrectangle in the final partition of $[0,1]^k$ in which U_{i+1} falls. Let us denote by $R(U_{i+1})$ this hyperrectangle. Thus,

$$\mathbf{E}\left\{\sum_{i=1}^{2n+1} X_{i1}\cdots X_{ik}\right\} = 1 + \sum_{i=0}^{n-1} \mathbf{E}\left\{\mathbf{E}\left\{|R(U_{i+1})| \mid U_1, \ldots, U_i\right\}\right\},$$

where the 1 accounts for the root hyperrectangle. We claim that $\mathbf{E}\{|R(U_{i+1})|\} = \frac{2}{i+2}$. Note that the claim is obviously true for $i = 0$. Now, suppose that $U_1, \ldots, U_i$ have already been inserted in the squarish k-d tree, so that there are $i+1$ external nodes. These external nodes represent the $i+1$ hyperrectangles partitioning $[0,1]^k$. Let these hyperrectangles be $S_1, \ldots, S_{i+1}$, and let the numbering be so that the leaves are taken from left to right, in order of appearance as leaves in the squarish k-d tree of $U_1, \ldots, U_i$. Then,

$$\begin{aligned}
\mathbf{E}\{|R(U_{i+1})|\} &= \mathbf{E}\left\{\mathbf{E}\left\{\sum_{\ell=1}^{i+1} \mathbf{1}_{[U_{i+1}\in S_\ell]}\,|S_\ell| \;\middle|\; U_1, \ldots, U_i\right\}\right\} \\
&= \mathbf{E}\left\{\sum_{\ell=1}^{i+1} |S_\ell|\,\mathbf{P}\left\{U_{i+1} \in S_\ell \;\middle|\; U_1, \ldots, U_i\right\}\right\} \\
&= \mathbf{E}\left\{\sum_{\ell=1}^{i+1} |S_\ell|^2\right\}.
\end{aligned}$$

By Lemma 2, $(|S_1|, \ldots, |S_{i+1}|)$ are jointly distributed as uniform spacings. All these spacings are identically distributed following a Beta$(1,i)$ distribution. If B is a Beta$(1,i)$ random variable, then we have $\mathbf{E}\{B\} = 1/(i+1)$ and $\mathbf{E}\{B^2\} = 2/((i+1)(i+2))$. Therefore,

$$\mathbf{E}\{|R(U_{i+1})|\} = (i+1)\,\mathbf{E}\{B^2\} = \frac{2}{i+2},$$

and thus

$$1 + \sum_{i=0}^{n-1} \mathbf{E}\{|R(U_{i+1})|\} = 1 + 2(h_{n+1} - 1). \qquad \square$$

6. Orthogonal range search. In this section, we obtain tight upper bounds for the expected complexity for Bentley's range search algorithm. For random orthogonal range search, the following theorem establishes the standard for comparisons. Theorem 5 below then states that random squarish k-d trees are superior to random k-d trees for any kind of random orthogonal range search.

THEOREM 4 (Chanzy, Devroye, and Zamora-Cura (1999)). *Given is a random k-d tree of size n. Let Q be a random query hyperrectangle of dimensions $\Delta_1 \times \cdots \times \Delta_k$ (which are deterministic functions of n taking values in $[0,1]$), with center at Z which is uniformly distributed on $[0,1]^k$, and independent of the k-d tree. Let N_n be the*

number of comparisons that Bentley's orthogonal range search algorithm performs. Then, there exist constants $\gamma > \gamma' > 0$ depending upon k only such that

$$\gamma' \leq \frac{\mathbf{E}\{N_n\}}{\left(\log n + \sum_{\substack{I\subseteq\{1,\ldots,k\}\\ 0\leq|I|<k}} \left(\prod_{j\notin I}\Delta_j\right) n^{\alpha(|I|/k)}\right)} \leq \gamma,$$

where $\alpha(\cdot)$ is the function defined in Theorem 1.

THEOREM 5. *Given is a random squarish k-d tree of size n. Let Q be a random query hyperrectangle of dimensions $\Delta_1 \times \cdots \times \Delta_k$ (which are deterministic functions of n taking values in $[0,1]$), with center at Z which is uniformly distributed on $[0,1]^k$, and independent of the k-d tree. Let N_n be the number of comparisons that Bentley's orthogonal range search algorithm performs. Then, there exist constants $\gamma > \gamma' > 0$ depending upon k only such that*

$$\gamma' \leq \frac{\mathbf{E}\{N_n\}}{\left(\log n + \sum_{\substack{I\subseteq\{1,\ldots,k\}\\ 0\leq|I|<k}} \prod_{j\notin I}\Delta_j n^{1-\frac{|I|}{k}}\right)} \leq \gamma\ .$$

We can rewrite the previous result as

$$\mathbf{E}\{N_n\} \leq \gamma\left(n\prod_{j=1}^{k}\Delta_j + \sum_{\ell=1}^{k-1} n^{1-\frac{\ell}{k}} \sum_{\substack{I\subseteq\{1,\ldots,k\}\\ |I|=\ell}} \prod_{j\notin I}\Delta_j + \log n\right),$$

and therefore by allowing any r of the Δ_j's to be zero, the term that will dominate the previous bound is

$$n^{1-\frac{r}{k}} \sum_{I;|I|=r} \prod_{j\notin I}\Delta_j.$$

For example, when $k=2$, $\Delta = \Theta(1/n^\alpha)$, and $\Delta' = \Theta(1/n^\beta)$, then

$$\mathbf{E}\{N_n\} \leq \gamma\left(n^{1-\alpha-\beta} + n^{\frac{1}{2}-\alpha} + n^{\frac{1}{2}-\beta} + \log n\right).$$

By looking at the different regions in the α-β plane, we obtain

$$\mathbf{E}\{N_n\} \leq \begin{cases} \Theta(\log n) & \text{for } \alpha \geq 1/2 \text{ and } \beta \geq 1/2; \\ \Theta(\max\{n^{1/2-\alpha} n^{1/2-\beta}\}) & \text{for } \alpha > 1/2, \beta < 1/2, \text{ or } \alpha < 1/2, \beta > 1/2; \\ \Theta(n^{1-\alpha-\beta}) & \text{for } \alpha \leq 1/2, \beta \leq 1/2. \end{cases}$$

Note that if $\alpha = 0$ and $\beta \geq 1/2$, or $\beta = 0$ and $\alpha \geq 1/2$, we recover the expected complexity time of the random partial match query problem (see Figure 5).

LEMMA 7. *Let $U_1, \ldots, U_n$ be independent and uniformly distributed over $[0,1]^k$ random variables; let X_i^* be the largest side of the ith hyperrectangle generated by $U_1, \ldots, U_n$. Then, for all $n \geq 0$,*

$$\mathbf{E}\left\{\sum_{i\in\mathcal{F}_n} \mathbf{1}_{\left[X_i^* > \frac{1}{2}\right]}\right\} \leq 2^{4k-3}.$$

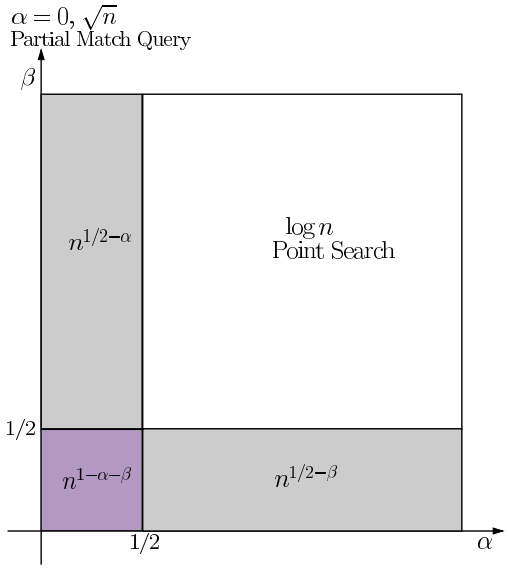

FIG. 5. *The complexity regions for* $\Delta = \Theta(1/n^{\alpha})$ *and* $\Delta' = \Theta(1/n^{\beta})$.

Proof. Note that $\mathbf{E}\{\sum_{i\in\mathcal{F}_n} \mathbf{1}_{[X_i^* > \frac{1}{2}]}\} \le 2^k \mathbf{E}\{\sum_{i\in\mathcal{F}_n} \prod_{j\in I_i} X_{ij}\}$, where $I_i = \{j : X_{ij} > \frac{1}{2}\}$. Define $S_n = \sum_{i\in\mathcal{F}_n}(\prod_{j:X_{ij}>\frac{1}{2}} 8X_{ij})$. We are going to prove that $\mathbf{E}\{S_n\}$ is decreasing so that for $n \ge 1$,

$$\mathbf{E}\left\{\sum_{i\in\mathcal{F}_n} \mathbf{1}_{[X_i^* > \frac{1}{2}]}\right\} \le 2^{k-3}\,\mathbf{E}\{S_n\} \le 2^{k-3}\,\mathbf{E}\{S_0\} = 2^{4k-3}.$$

To show $\mathbf{E}\{S_n\} \le \mathbf{E}\{S_0\}$, we look at the differences once again. Set $P_i = \prod_{j\in I_i} 8X_{ij}$. Then,

$$\begin{aligned} S_{r+1} - S_r = \sum_{i\in\mathcal{F}_r} |R_i| \mathbf{1}_{[X_i^* > \frac{1}{2}]} \Bigg\{ & -P_i + \mathbf{1}_{[XX_i^* > \frac{1}{2}]} \left(P_i X + \mathbf{1}_{[|I_i|>1]} \frac{P_i}{8X_i^*} \right) \\ & + \mathbf{1}_{[(1-X)X_i^* > \frac{1}{2}]} \left(P_i(1-X) + \mathbf{1}_{[|I_i|>1]} \frac{P_i}{8X_i^*} \right) \\ & + \mathbf{1}_{[XX_i^* \le \frac{1}{2};\ (1-X)X_i^* \le \frac{1}{2}]} \left(2\mathbf{1}_{[|I_i|>1]} \frac{P_i}{8X_i^*} \right) \Bigg\}, \end{aligned}$$

where $X \stackrel{\mathcal{L}}{=} \text{Uniform}[0,1]$, and it is independent of $U_1, \ldots, U_r$. Therefore,

$$\begin{aligned} \mathbf{E}\{S_{r+1} - S_r | U_1, \ldots, U_r\} &\le \sum_{i\in\mathcal{F}_r} |R_i| \mathbf{1}_{[X_i^* > \frac{1}{2}]} P_i \left(-1 + \int_{\frac{1}{2X_i^*}}^{1} \left(x + \frac{1}{4} \right) dx \right. \\ &\qquad \left. + \int_0^{1-\frac{1}{2X_i^*}} ((1-x) + 1/4) dx + \int_{1-\frac{1}{2X_i^*}}^{\frac{1}{2X_i^*}} 1/2 dx \right) \\ &= \sum_{i\in\mathcal{F}_r} |R_i| \mathbf{1}_{[X_i^* > \frac{1}{2}]} P_i \left(\frac{1}{4X_i^*} - \frac{1}{(2X_i^*)^2} \right) \\ &\le 0. \qquad \square \end{aligned}$$

Proof of Theorem 5. Let T be the squarish k-d tree constructed from $U_1, \ldots, U_n$. Note that a node U_i in T is visited if and only if the query hyperrectangle Q intersects R_i, where R_i is the hyperrectangle in the final partition of $[0,1]^k$ generated by $U_1, \ldots, U_{i-1}$, in which U_i falls. Thus, the running time of the range search algorithm is exactly the number of hyperrectangles in $\mathcal{R}_n$ that Q intersects

$$N_n = \sum_{i=0}^{2n} \mathbf{1}_{[R_i \cap Q \neq \emptyset]}.$$

Also, given $U_1, \ldots, U_n$, the probability that Q intersects R_i is the probability that Z has some coordinate that is within distance $\Delta_j/2$ of R_i, and this probability is clearly bounded by the volume of R_i expanded by Δ_j in the jth direction for all j. Therefore,

$$\begin{aligned}
\mathbf{E}\{N_n\} &\leq \mathbf{E}\left\{\sum_{i=1}^{2n}\prod_{j=1}^{k}(X_{ij}+\Delta_j)\right\} \\
&= \sum_{I\subseteq\{1,\ldots,k\}}\prod_{j\notin I}\Delta_j\,\mathbf{E}\left\{\sum_{i=1}^{2n}\prod_{j\in I}X_{ij}\right\}+1 \\
&\leq \gamma\left(\sum_{\substack{I\subseteq\{1,\ldots,k\}\\ 0\leq|I|<k}}\prod_{j\notin I}\Delta_j n^{1-\frac{|I|}{k}}+\log n\right)
\end{aligned}$$

for some $\gamma > 0$ by Theorem 3 and Lemma 5. For the lower bound we may assume that $\Delta_j \leq 1/2$ and do the following:

$$\begin{aligned}
\mathbf{E}\{N_n\} &\geq \mathbf{E}\left\{\sum_{i\in\mathcal{F}_n}\mathbf{1}_{[Q\cap R_i\neq\emptyset]}\mathbf{1}_{[\forall j\in\{1,\ldots,k\}:X_{ij}\leq 1/2]}\right\} \\
&\geq \mathbf{E}\left\{\sum_{i\in\mathcal{F}_n}\prod_{j=1}^{k}\left(X_{ij}+\frac{\Delta_j}{2}\right)\mathbf{1}_{[\forall j\in\{1,\ldots,k\}:X_{ij}\leq 1/2]}\right\} \\
&= \mathbf{E}\left\{\sum_{i\in\mathcal{F}_n}\prod_{j=1}^{k}\left(X_{ij}+\frac{\Delta_j}{2}\right)\right\}-\mathbf{E}\left\{\sum_{i\in\mathcal{F}_n}\prod_{j=1}^{k}\left(X_{ij}+\frac{\Delta_j}{2}\right)\mathbf{1}_{[\exists j\in\{1,\ldots,k\}:X_{ij}>1/2]}\right\} \\
&= \sum_{I\subseteq\{1,\ldots,k\}}\prod_{j\notin I}\frac{\Delta_j}{2}\,\mathbf{E}\left\{\sum_{i\in\mathcal{F}_n}\prod_{j\in I}X_{ij}\right\} \\
&\quad -\sum_{I\subseteq\{1,\ldots,k\}}\prod_{j\notin I}\frac{\Delta_j}{2}\,\mathbf{E}\left\{\sum_{i\in\mathcal{F}_n}\prod_{j\in I}X_{ij}\mathbf{1}_{[\exists j\in\{1,\ldots,k\}:X_{ij}>1/2]}\right\}.
\end{aligned}$$

We can bound the second term above for any given $I \subseteq \{1, \ldots, k\}$ as

$$\mathbf{E}\left\{\sum_{i\in\mathcal{F}_n}\prod_{j\in I}X_{ij}\mathbf{1}_{[\exists j\in\{1,\ldots,k\}:X_{ij}>1/2]}\right\} \leq \mathbf{E}\left\{\sum_{i\in\mathcal{F}_n}\mathbf{1}_{\left[X_i^*>1/2\right]}\right\} \leq 2^{4k-3}$$

by the previous lemma. Thus, for all n large enough, we can choose $\gamma' > 0$ such that

$$\mathbf{E}\{N_n\} \geq \gamma' \left(\sum_{\substack{I \subseteq \{1,\ldots,k\} \\ 0 \leq |I| < k}} \prod_{j \notin I} \Delta_j n^{1-\frac{|I|}{k}} + \log n \right). \qquad \square$$

7. Nearest neighbor search. We consider two natural nearest neighbor search algorithms. In algorithm **A**, start with an orthogonal range search with a square box of size $1/n^{1/k}$ centered at the query point X. Repeat with boxes of sizes $k^{i/2}/n^{1/k}$ for $i = 0, 1, 2, 3, \ldots$ until $i+1$, where i is the index of the first nonempty box. Report the nearest point in the $(i+1)$st box. Each orthogonal range search taken individually (for fixed i) takes expected time $O(\log n)$ by Theorem 5. We show in fact that the total expected time is $O(\log n \log\log n)$.

THEOREM 6. *Let X be a point uniformly distributed on $[0,1]^k$. Consider a squarish k-d tree based on n i.i.d. points on $[0,1]^k$. Then the expected time of algorithm* **A** *is $O(\log n \log\log n)$.*

Proof. Let $\mathcal{T}$ be the total time it takes algorithm **A** to finish. Let $\mathcal{T}_i$ be the running time of Bentley's range search algorithm on n i.i.d. points on $[0,1]^k$ and a cube Q_i centered at X of length $k^{i/2}/n^{1/k}$, and let M_i be the number of points in Q_i. Note that

$$\mathbf{E}\{\mathcal{T}\} \leq O(\log n) + \mathbf{E}\left\{ \mathcal{T}_1 + \mathcal{T}_2 + \sum_{i=3}^{m} \mathcal{T}_i \mathbf{1}_{[M_{i-2}=0]} \right\},$$

where $m = \lfloor \frac{2}{k} \log_k(2^k n) \rfloor$ bounds the maximum number of iterations the algorithms can perform. Thus, it is enough to prove that $\mathbf{E}\left\{\sum_{i=3}^{m} \mathcal{T}_i \mathbf{1}_{[M_{i-2}=0]}\right\} = O(\log n \log\log n)$. Let $t = \lceil \frac{2}{k} \log_k(2^k \log n) \rceil$; then

$$\mathbf{E}\left\{ \sum_{i=3}^{m} T_i \mathbf{1}_{[M_{i-2}=0]} \right\} \leq (t+1)\,\mathbf{E}\{\mathcal{T}_{t+1}\} + 2n \sum_{i=t+2}^{m} \mathbf{P}\{M_{i-2}=0\}.$$

Now, by Theorem 5,

$$\begin{aligned}
&(t+1)\,\mathbf{E}\{\mathcal{T}_{t+1}\} \\
&\leq \gamma \left(\frac{2}{k} \log_k(2^k \log n) + 2 \right) \left(k^{(t+1)k/2} + \sum_{\ell=1}^{k-1} n^{1-\ell/k} \sum_{\substack{I \subseteq \{1,\ldots,k\} \\ |I|=\ell}} \prod_{j \notin I} \frac{k^{(t+1)/2}}{n^{1/k}} + \log n \right) \\
&= \gamma \left(\frac{2}{k} \log_k(2^k \log n) + 2 \right) \left(k^{(t+1)k/2} + \sum_{\ell=1}^{k-1} n^{1-\ell/k} \binom{k}{\ell} \frac{k^{(t+1)(k-\ell)/2}}{n^{1-\ell/k}} + \log n \right) \\
&= \gamma \left(\frac{2}{k} \log_k(2^k \log n) + 2 \right) \left(k^{(t+1)k/2} + k^{(t+1)k/2} \sum_{\ell=1}^{k-1} \binom{k}{\ell} k^{-(t+1)\ell/2} + \log n \right) \\
&\leq \gamma \left(\frac{2}{k} \log_k(2^k \log n) + 2 \right) \left(k^{(t+1)k/2} \left(k^{-(t+1)/2} + 1 \right)^k + \log n \right) \\
&\leq \gamma \left(\frac{2}{k} \log_k(2^k \log n) + 2 \right) \left(k^k 2^k \log n \left(\frac{1}{\sqrt{k}(2^k \log n)^{1/k}} + 1 \right)^k + \log n \right) \\
&= O(\log n \log\log n)
\end{aligned}$$

for all $n \geq e$. Finally, for $i \leq m$,

$$\mathbf{P}\{M_{i-2} = 0\} \leq \left(1 - \frac{k^{k(i-2)/2}}{2^k n}\right)^n \leq e^{-k^{k(i-2)/2}/2^k},$$

and therefore $\mathbf{P}\{M_{t+2} = 0\} \leq 1/n$. Thus,

$$2n \sum_{i=t+2}^{m} \mathbf{P}\{M_{i-2} = 0\} \leq 2m = O(\log n). \qquad \square$$

Theorem 6 is in contrast with the situation for standard random k-d trees, where algorithm **A** is shown to take expected time $\Theta(n^\rho)$, where $\rho \in (0.061, 0.064)$ depends upon k only (Chanzy, Devroye, and Zamora-Cura (1999)). In algorithm **B**, insert X in the squarish k-d tree, and let Q be the rectangle associated with X. Let X' be the parent of X in the tree (note: $X' \in Q$). Perform an orthogonal range search centered at X with dimensions $2\|X' - X\|$ in all directions. Report the nearest neighbor among all points returned by this orthogonal range search. We will analyze this algorithm for $k = 2$ only.

THEOREM 7. *Let X be a point uniformly distributed on $[0,1]^2$. Consider a squarish 2-d tree based on n i.i.d. points on $[0,1]^2$. Then the expected time of algorithm* **B** *is $O(\log^2 n)$.*

The bound on algorithm **B** is a bit worse than that for algorithm **A**, because while most rectangles are squarish, a sufficient number of them are elongated. In fact, for given $M > 1$, about $1/M$ of the final (leaf) rectangles or more should have an edge ratio exceeding M. For edge ratio M, and considering that all rectangle areas are about $1/n$, we see that the orthogonal range search should take about M points. (The longest edge is about $\sqrt{M/n}$.) The expected number of returned elements is at least $\Theta(\log n)$. And the expected number of leaf rectangles visited is of the same order. But each visited leaf rectangle also induces a visit to all of its ancestors, and there are about $\log n$ of those, hence the claim. The remainder of this section contains the proof of Theorem 7.

LEMMA 8. *Let $Z, U_1, \ldots, U_n$ be independent and uniformly distributed random variables on $[0,1]^2$. Let $X_n(Z)$ and $Y_n(Z)$ be the x-length and y-length of the rectangle in the final partition (of the squarish 2-d tree) induced by $U_1, \ldots, U_n$ in which Z falls. Then, both $n\,\mathbf{E}\{X_n^2(Z)\}$ and $n\,\mathbf{E}\{Y_n^2(Z)\}$ are $O(\log^2 n)$.*

Proof. By Lemmas 3 and 4, for any $p, q > 1$ such that $\frac{1}{p} + \frac{1}{q} = 1$, we have that

$$\begin{aligned}
\mathbf{E}\{X_n^2(Z)\} &= \mathbf{E}\left\{\sum_{i \in \mathcal{F}_n} X_i^3 Y_i\right\} \\
&\leq \mathbf{E}\left\{\sum_{i \in \mathcal{F}_n} (X_i Y_i)^p\right\}^{1/p} \mathbf{E}\left\{\sum_{i \in \mathcal{F}_n} X_i^{2q}\right\}^{1/q} \\
&\leq \left(\frac{4\Gamma(p+1)}{n^{p-1}}\right)^{1/p} \left(\frac{5\Gamma(q+1)}{q-1}\left(q - \frac{1}{n^{q-1}}\right)\right)^{1/q} \\
&= \frac{4^{1/p} 5^{1/q} \left(\Gamma(p+1)\right)^{1/p} \left(\Gamma(q+1)\right)^{1/q}}{(q-1)^{1/q}} \frac{(qn^{q-1} - 1)^{1/q}}{n}.
\end{aligned}$$

Let us choose $q = 1 + \frac{1}{\log n}$, $p = \log n + 1$, and assume $n > e$. As $\Gamma(p+1) \leq \sqrt{2\pi}\left(\frac{p}{e}\right)^p e^{1/12p}$ (see, for example, Abramowitz and Stegun (1970)), there is $c > 0$,

such that $(\Gamma(p+1))^{1/p} \le cp = c(\log n+1)$, and there is $c' > 0$, such that $(\Gamma(q+1))^{1/q} \le c'q \le 4c'$. Furthermore, $(q-1)^{-1/q} = (\log n)^{\frac{\log n}{\log n+1}} \le \log n$, and $(qn^{q-1}-1)^{1/q} \le 2e-1$. Therefore $n\,\mathbf{E}\left\{X_n^2(Z)\right\} = O(\log^2 n)$. The result for $n\,\mathbf{E}\left\{Y_n^2(Z)\right\}$ follows in the same manner. □

LEMMA 9 (see Devroye (1986)). *Let H_n be the height of a random binary search tree of size n; then for any integer $k \ge \max\{1, \log n\}$ we have*

$$\mathbf{P}\left\{H_n \ge k\right\} \le \frac{1}{n}\left(\frac{2e\log n}{k}\right)^k.$$

LEMMA 10. *Let $Z, U_1, \ldots, U_n$ be independent and uniformly distributed random variables over $[0,1]^2$. Let $X_n(Z)$ and $Y_n(Z)$ be the x-length and y-length of the rectangle in the final partition induced by $U_1, \ldots, U_n$ in which Z falls. Then $\mathbf{E}\{X_n(Z)\sum_{i=1}^{2n} X_i\}$, $\mathbf{E}\{Y_n(Z)\sum_{i=1}^{2n} Y_i\}$, $\mathbf{E}\{X_n(Z)\sum_{i=1}^{2n} Y_i\}$, and $\mathbf{E}\{Y_n(Z)\sum_{i=1}^{2n} X_i\}$ are $O(\log^2 n)$.*

Proof. Let $\mathcal{F}_n$ denote the collection of final rectangles in the squarish 2-d tree T constructed from $U_1, \ldots, U_n$. For a final rectangle R_i, denote by $D(R_i)$ its depth. Then $\sum_{i=1}^{2n} X_i \le \sum_{i\in\mathcal{F}_n} D(R_i)X_i + 1$. Thus if H_n is the height of T,

$$\begin{aligned}
\mathbf{E}\left\{\sum_{i=1}^{2n} X_i X_n(Z)\right\} &\le \mathbf{E}\left\{\sum_{i\in\mathcal{F}_n} D(R_i)X_i \sum_{j\in\mathcal{F}_n} X_j^2 Y_j\right\} + 1 \\
&\le \mathbf{E}\left\{H_n \sum_{i\in\mathcal{F}_n} X_i \sum_{j\in\mathcal{F}_n} X_j^2 Y_j\right\} + 1 \\
&\le t\log n\,\mathbf{E}\left\{\sum_{i\in\mathcal{F}_n} X_i \sum_{j\in\mathcal{F}_n} X_j^2 Y_j\right\} + 1 \\
&\quad + \mathbf{E}\left\{\mathbf{1}_{[H_n\ge t\log n]} H_n \sum_{i\in\mathcal{F}_n} X_i \sum_{j\in\mathcal{F}_n} X_j^2 Y_j\right\} + 1
\end{aligned}$$

for any $t > 1$. Using Lemma 9, we see that

$$\mathbf{E}\left\{\mathbf{1}_{[H_n\ge t\log n]} H_n \sum_{i\in\mathcal{F}_n} X_i \sum_{j\in\mathcal{F}_n} X_j^2 Y_j\right\} \le n^3\,\mathbf{P}\left\{H_n \ge t\log n\right\} \le n^2 n^{t\log\left(\frac{2e}{t}\right)}.$$

We choose t such that $t\log\left(\frac{2e}{t}\right) < -2$ so that

$$\mathbf{E}\left\{\mathbf{1}_{[H_n\ge t\log n]} H_n \sum_{i\in\mathcal{F}_n} X_i \sum_{j\in\mathcal{F}_n} X_j^2 Y_j\right\} = O(1).$$

We complete the proof by showing that $\mathbf{E}\{\sum_{i\in\mathcal{F}_n} X_i \sum_{j\in\mathcal{F}_n} X_j^2 Y_j\} = O(\log n)$. For this, let $S_r = \sum_{i\in\mathcal{F}_r} X_i \sum_{j\in\mathcal{F}_r} X_j^2 Y_j$, for $r = 1, \ldots, n-1$. Note that

$$\begin{aligned}
S_{r+1} - S_r = \sum_{m\in\mathcal{F}_r} X_m Y_m \Bigg[&\mathbf{1}_{[X_m<Y_m]} X_m \sum_{j\in\mathcal{F}_r} X_j^2 Y_j \\
&+ \mathbf{1}_{[X_m>Y_m]}((XX_m)^2 Y_m + ((1-X)X_m)^2 Y_m - X_m^2 Y_m) \sum_{i\in\mathcal{F}_r} X_i \Bigg],
\end{aligned}$$

where $X \stackrel{\mathcal{L}}{=} \text{Uniform}[0,1]$, and is independent of all $U_1, \ldots, U_n$. Now, as $(XX_m)^2Y_m + ((1-X)X_m)^2Y_m - X_m^2Y_m \leq 0$, we have that

$$S_{r+1} - S_r \leq \sum_{i \in \mathcal{F}_r} (X_i Y_i)^{3/2} \sum_{j \in \mathcal{F}_r} X_j^2 Y_j.$$

Note that for any $p, q > 1$, such that $\frac{1}{p} + \frac{1}{q} = 1$,

$$\mathbf{E}\{S_{r+1} - S_r\} \leq \mathbf{E}\left\{\left(\sum_{i \in \mathcal{F}_r} (X_i Y_i)^{3/2}\right)^p\right\}^{1/p} \mathbf{E}\left\{\left(\sum_{j \in \mathcal{F}_r} X_j^2 Y_j\right)^q\right\}^{1/q},$$

and again by Hölder's inequality, and Lemma 3, by choosing $q = \sqrt{1.4}$ and $p = \frac{\sqrt{1.4}}{\sqrt{1.4}-1}$,

$$\mathbf{E}\left\{\left(\sum_{i \in \mathcal{F}_r} (X_i Y_i)^{3/2}\right)^p\right\}^{1/p} \leq \mathbf{E}\left\{r^{p/q} \sum_{i \in \mathcal{F}_r} (X_i Y_i)^{3p/2}\right\}^{1/p} \leq \frac{12}{\sqrt{r}}.$$

By applying Hölder's inequality inside the expected value,

$$\begin{aligned}
\mathbf{E}\left\{\left(\sum_{j \in \mathcal{F}_r} X_j^2 Y_j\right)^q\right\}^{1/q} &\leq \mathbf{E}\left\{r^{q/p} \sum_{j \in \mathcal{F}_r} (X_j^2 Y_j)^q\right\}^{1/q} \\
&\leq r^{1/p} \left(\mathbf{E}\left\{\sum_{j \in \mathcal{F}_r} (X_j Y_j)^{qp}\right\}^{1/p} \mathbf{E}\left\{\sum_{j \in \mathcal{F}_r} X_j^{q^2}\right\}^{1/q}\right)^{1/q} \\
&\leq 46\, r^{1/p} \left(\left(\frac{1}{r^{qp-1}}\right)^{1/p} \left(\frac{1}{r^{q^2/2-1}}\right)^{1/q}\right)^{1/q} \\
&= \frac{46}{\sqrt{r}}.
\end{aligned}$$

Thus, $\mathbf{E}\{S_{r+1} - S_r\} \leq 552/r$, and by summing the differences we finally can conclude that $\mathbf{E}\{\sum_{i \in \mathcal{F}_n} X_i \sum_{j \in \mathcal{F}_n} X_j^2 Y_j\}$ is indeed $O(\log n)$. The other expected values can be bounded in the same way. □

Proof of Theorem 7. Given $U_1, \ldots, U_n$, we define $L_n(Z) = 2(X_n(Z) + Y_n(Z))$. Note that as the expected height of T is $O(\log n)$, the expected time complexity of the nearest neighbor algorithm is bounded by $O(\log n)$ plus the expected time of random orthogonal range search with query rectangle Q having all sides of length $L_n(Z)$, and centered at Z. Let N_n be the time complexity of a range search. By the same arguments followed in Theorem 3, we have

$$\mathbf{E}\{N_n\} \leq \mathbf{E}\left\{\sum_{i=1}^{2n+1} X_i Y_i\right\} + 2\,\mathbf{E}\left\{\sum_{i=1}^{2n+1} L_n(Z)(X_i + Y_i)\right\} + 8n\,\mathbf{E}\left\{L_n^2(Z)\right\} + 1.$$

By Lemma 5, $\mathbf{E}\{\sum_{i=1}^{2n+1} X_i Y_i\} = O(\log n)$. For $\mathbf{E}\{\sum_{i=1}^{2n+1} L_n(Z)(X_i + Y_i)\}$, Lemma 10 above shows that it is $O(\log^2 n)$. As $n\,\mathbf{E}\{X_n(Z)Y_n(Z)\} = n\,\mathbf{E}\{\sum_{i \in \mathcal{F}_n} (X_i Y_i)^2\}$, Lemma 3 shows that it is $O(1)$. Finally, by Lemma 8 we have that $n\,\mathbf{E}\{L_n^2(Z)\} = O(\log^2 n)$. Thus the expected running time of algorithm $\mathbf{B}$ is $O(\log^2 n)$. □

8. Further work and open problems.

QUADTREES. For quadtree splitting in k dimensions (Finkel and Bentley (1974), Bentley and Stanat (1975)), it is easy to see that the analysis and thus Theorem 1 are not valid. In fact, for random quadtrees, the expected performance for partial match queries was shown to be of the order of that for standard random k-d trees (Flajolet, Gonnet, Puech, and Robson (1991), (1992)). For orthogonal range search with query rectangles depending upon n, see Chanzy, Devroye, and Zamora-Cura (1999).

EXPECTED WORST-CASE COMPLEXITY. We conjecture that the expected worst-case complexity over all range search rectangles of dimensions Δ_i (but with worst-case location of the center) is also bounded from above by the bound given in Theorem 2. And the expected worst-case time for an s-dimensional partial match query is conjectured to be $O(n^{1-s/k})$ for $s < k$. (For $s = k$, the complexity is clearly bounded by the expected height of the tree, $O(\log n)$.)

NONUNIFORM DISTRIBUTIONS. Finally, we also intend to study the behavior of squarish k-d trees for nonuniform distributions, although it appears once again that the upper bound of Theorem 2 remains valid for all distributions with a joint density on $[0, 1]^k$.

COMPUTATIONS OF UNIFORM RECURRENCE EQUATIONS USING MINIMAL MEMORY SIZE*

BRUNO GAUJAL†, ALAIN JEAN-MARIE‡, AND JEAN MAIRESSE§

Abstract. We consider a system of uniform recurrence equations of dimension 1 and we show how its computation can be carried out using minimal memory size with several synchronous processors. This result is then applied to register minimization for digital circuits and parallel computation of task graphs.

Key words. uniform recurrence equation, register minimization, circuit design, task graph, (max,+) linear system

1. Introduction.

We start by the definition of uniform recurrence equations.

DEFINITION 1.1 (uniform recurrence equations). *We consider $\mathcal{Q}$-valued variables $X_i(n), i \in V, n \in K$, where $\mathcal{Q}$ is an arbitrary set, V is a finite set, and $K \subset \mathbb{Z}^p$ for some $p \in \mathbb{N}$. These variables satisfy*

$$X_i(n) = F_i\Big(X_j(n-\gamma), (j,\gamma) \in \Delta_i\Big) \qquad \forall n \in K\,. \tag{1}$$

The sets Δ_i, called dependence sets*, are finite subsets of $V \times \mathbb{Z}^p$. The collection of equations* (1) *is called a set of* uniform recurrence equations (UREs).

There is no restriction on the generality of the functions F_i except the fact that they are computable. The system $\mathcal{S}$ defined by (1) is said to be uniform because the dependence sets Δ_i do not depend on n. The integers γ are called the *delays*. It is possible to have two delays $\gamma, \gamma' \in \mathbb{Z}^p, \gamma \neq \gamma'$, such that $(j,\gamma) \in \Delta_i$ and $(j,\gamma') \in \Delta_i$.

There are various motivations to study UREs. They appear in the description of differential equations using finite difference methods and in the study of discrete event systems. The case $p > 1$ and $K = \mathbb{Z}^p$ has often been studied in the literature; see [16]. In this case, some of the major issues are constructivity [16] and loop parallelization [8]. These problems and others appearing in this framework will be discussed in Appendix A.

In this paper, we consider only the simple case where $K = \mathbb{Z}$ (systems of dimension 1). The computational model considered is that of parallel processors with a shared memory (CREW-PRAM model: *concurrent read exclusive write parallel random access memory*). More precisely, a computation is performed by a processor, using data stored in the memory. For example, to compute $X_i(n)$, it is necessary to have at least $|\Delta_i|$ memory locations, each location containing one of the data $\{X_j(n-\gamma), (j,\gamma) \in \Delta_i\}$. In a model of parallel processors with shared memory, there

are several processors that can make computations simultaneously and also access the same memory locations simultaneously.

The problem investigated consists in minimizing the "memory size":

What is the minimal number of memory locations that is needed to compute all the variables $X_i(n)$ of (1) using a CREW-PRAM computational model?

We solve this problem in the recycled case (see section 2.2 for the definition) by proving that it is equivalent to the search for minimal cuts in the dependence graph associated with the system of UREs. This provides polynomial algorithms to compute the minimal memory requirements.

We show that the solution of this problem has many applications. Indeed, UREs appear in the modeling of logical circuits, systolic arrays, and program loops. Our result can be used practically for the optimization of circuit design. Given a digital circuit, we show how to find another circuit with the same functional behavior and using a minimal number of registers. This application will be discussed in section 7.

Our results can also be used in another context, namely, in order to obtain the most efficient representation of task graph systems for parallel computation purposes. The evolution of a task graph can be represented as a linear system over the (max,+) algebra of the form $x(n+1) = A(n)x(n)$, where $x(.) \in \mathbb{R}^k_{\max}$ and $A(n) \in \mathbb{R}^{k\times k}_{\max}$. Our results enable us to obtain a linear representation of a task graph with a minimal dimension k for the matrices $A(n)$. This application will be treated in section 8.

The paper is organized as follows. In section 2, we make more precise the definition of a system of UREs and present two associated graphs, the *dependence graph* and the *reduced graph*. In section 3 we describe the problem that we are going to address. In particular, we restrict our attention to recycled systems of UREs. Sections 4 and 5 investigate the relations that can be found between *cuts* in the dependence graph and the memory size required for an execution of the URE; section 6 presents the interpretation of the above quantities in the reduced graph. Finally in sections 7 and 8, two applications are described, for digital circuits and (max,+) linear systems, respectively. In Appendices A and B, we consider the related problems of scheduling and sequential executions.

2. Basic models. From now on, we consider UREs of dimension 1. More precisely, we consider the set of variables $X_i(n), i \in V, n \in \mathbb{Z}$, and the equations

$$X_i(n) = F_i\Big(X_j(n-\gamma), (j,\gamma) \in \Delta_i\Big),\ n \in \mathbb{Z}\ , \tag{2}$$

where the sets Δ_i are finite subsets of $V \times \mathbb{Z}$.

A system of UREs is *constructive* if given the values of the "negative" variables $X_i(n), n \le 0$ (*initial data*), there exists an ordering of the equations such that, $\forall i, \forall n > 0$, all the variables present in the right-hand side of the equation defining $X_i(n)$ can be computed before $X_i(n)$. Equivalently, the constructivity assumption can be written as follows: For each cycle $(i_1,\gamma_1),\dots,(i_p,\gamma_p), i_{p+1} = i_1$ such that $(i_{j+1},\gamma_{j+1}) \in \Delta_{i_j}$, $j \in \{1,\dots,p\}$, then $\sum_{j=1}^{p} \gamma_j > 0$.

Remark 2.1. Under the constructivity assumption, Farkas' lemma states that it is possible to come back to (1) with all the sets Δ_i included in $V \times \mathbb{N}$ using a simple renumbering of the variables (i.e., $X_i(n) := X_i(n + c_i)$ for some constants $c_i \in \mathbb{Z}$ independent of n). This renumbering actually amounts to a retiming of the system. This notion will be studied in detail in section 6.1.

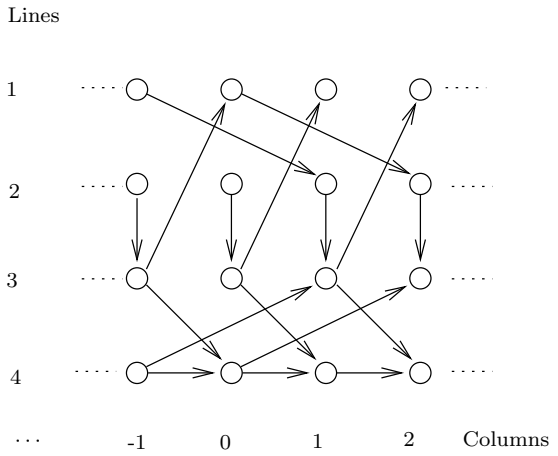

FIG. 1. *Dependence graph associated with the system* $\mathcal{S}$ *of* (3).

From now on, the system $\mathcal{S}$ that we consider is always assumed to be constructive. We present two equivalent ways of describing $\mathcal{S}$: the dependence graph and the reduced graph.

Example 2.2. The illustrative examples in this section correspond to the system

$$\text{(3)} \qquad \begin{cases} X_1(n) &= F_1(X_3(n-1)), \\ X_2(n) &= F_2(X_1(n-2)), \\ X_3(n) &= F_3(X_2(n), X_4(n-2)), \\ X_4(n) &= F_4(X_3(n-1), X_4(n-1)). \end{cases}$$

2.1. Dependence graph. We introduce the graph $\mathcal{D}$ of the dependences between the variables $X_i(n)$.

DEFINITION 2.3 (dependence graph). *The dependence graph associated with a system of UREs is the graph* $\mathcal{D}$ *with* $(V \times \mathbb{Z})$ *as the set of nodes. There is an arc from the node* (i,n) *to the node* (j,m) *if* $X_j(m) = F_j(X_i(n), \dots)$ *or, equivalently, if* $(i, m-n) \in \Delta_j$ *(notation:* $(i,n) \to (j,m)$*).*

The nth *column* in $\mathcal{D}$ is the set of nodes $\{(i,n), i \in V\}$. The ith *line* in $\mathcal{D}$ is the set of nodes $\{(i,n), n \in \mathbb{Z}\}$. In the following, we will refer to nodes $(i,n),\ n \le 0$, as *negative* nodes and nodes $(i,n),\ n \ge 0$, as *positive* nodes.

It is immediate from the definition of a URE that $\mathcal{D}$ is 1-periodic, i.e.,

$$(i,n) \to (j,m) \Longleftrightarrow (i, n+1) \to (j, m+1)\,.$$

The constructivity assumption implies that the graph $\mathcal{D}$ is acyclic. We have represented in Figure 1 the dependence graph corresponding to the system of Example 2.2.

The dependence graph appears under various forms and names in the literature, for example, developed graph, PERT graph, unfolded process graph, and activity network.

2.2. Reduced graph. Since the dependence graph $\mathcal{D}$ is 1-periodic, it can be folded into a *reduced graph* $\mathcal{R}$.

DEFINITION 2.4 (reduced graph). *The reduced graph is an arc-valued graph* $\mathcal{R} = (V, E, \Gamma)$*. The set of nodes is* V *and there is an oriented arc* $e \in E$ *from* i

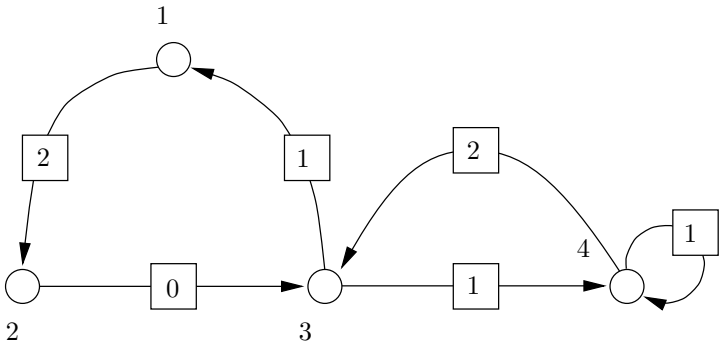

FIG. 2. *Reduced graph associated with the system* $\mathcal{S}$ *of* (3).

to j *if*

$$\exists \gamma \in \mathbb{Z} \text{ such that (s.t.) } (i,\gamma) \in \Delta_j \,. \tag{4}$$

This arc is valued with the delay $\Gamma(e) = \gamma$. *If there exist several delays* γ *verifying condition* (4), E *contains several arcs between the nodes* i *and* j, *with corresponding values. Furthermore, we consider the functions* $F_i, i \in V$, *to be associated with the nodes of* $\mathcal{R}$.

There is an arc from i to j in E if and only if there are arcs from the line $(i,.)$ to the line $(j,.)$ in the dependence graph. The system $\mathcal{S}$ is constructive if and only if the sum of the delays along any circuit in $\mathcal{R}$ is strictly positive.

The reduced graph associated with the system $\mathcal{S}$ of Example 2.2 is represented in Figure 2. The delays γ associated with the arcs are depicted in boxes.

Reduced graphs appear in the literature under the following names: computation graph, synchronous data flow graphs, process graphs, and uniform graphs.

It should be clear from the definitions that there is a one-to-one correspondence between the three models. Indeed, a system can be given by its reduced graph as well as its dependence graph or system of equations.

2.3. Recycled assumption. In the following (sections 4, 5, 7, and 8), we will study only a special case of URE, where the computation of the variable $X_i(n)$ cannot be completed before the computation of $X_i(n-1)$. This case appears naturally in task graphs (see section 8) and in other applications. This constraint can be modeled by imposing a dependence between $X_i(n-1)$ and $X_i(n)$ $\forall i$ and n. Formally, it results in having $(i,1) \in \Delta_i \, \forall i$ for the system of UREs. Equivalently, it results in having a self loop with delay 1 (hence the name recycled) at each node of $\mathcal{R}$, or in having arcs between the nodes (i,n) and $(i,n+1)$ in $\mathcal{D}$. Such arcs will be called *recycling arcs* in what follows. Figure 3 depicts an example of a recycled system.

2.4. Connectedness. We say that a system of UREs is (strongly) connected if the graph $\mathcal{R}$ is (strongly) connected. In the remainder of the paper, we will always consider systems of connected (but not necessarily strongly connected) UREs.

In fact, we will see that, for a recycled connected URE and for games $\mathcal{M}_1, \mathcal{M}_2$, and $\mathcal{M}_3$ (to be defined below), a valid computation with a minimal number of memory locations requires all its memories at each instant. It implies that the minimal number of memories necessary to compute a nonconnected recycled URE is the sum of the minimal numbers of memories necessary to compute the different connected components independently.

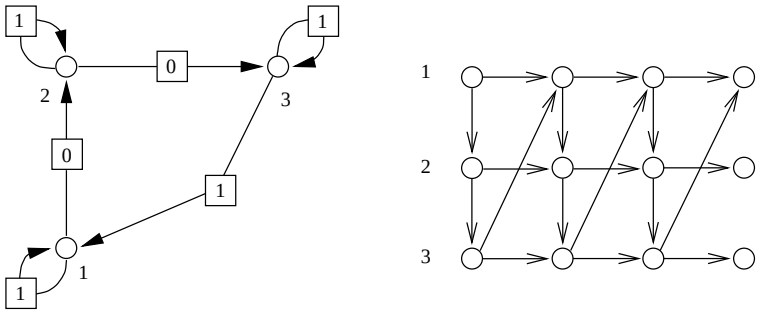

FIG. 3. *Recycled reduced graph and recycled dependence graph.*

3. Synchronous executions. We want to minimize the memory size required in the synchronous computation of a system $\mathcal{S}$.

Among the related problems that have been studied in the field of UREs, we can mention the *basic scheduling* problem and the *sequential* computations. These questions and their relation with the one considered in this paper are discussed in Appendices A and B.

3.1. Pebble games. Let us work with a URE and its associated dependence graph $\mathcal{D}$ as defined in section 2.1. We want to compute iteratively all the variables $X_i(n), n \in \mathbb{N}$. At each step, the variables which are necessary to carry out the computations have to be stored in some memory locations. Our general objective will be to solve the following problem:

What is the minimal number of memory locations
needed to compute all the variables $X_i(n)$*?*

We give a description of this problem in terms of a *pebble game*. A pebble game is played on a graph. At each step, a finite number of pebbles are located on the nodes of the graph, with at most one pebble per node. The position of the pebbles evolves by adding or removing pebbles according to some rules.

Different variants of pebble games have been used in the literature to model memory allocation problems; see, for example, [21, 25]. A pebble corresponds to a memory location, and putting a pebble on a node corresponds to the computation of the variable associated with the node and its storage into the memory. Removing a pebble from a node corresponds to erasing these data from the memory.

Now, we give a more formal definition of the pebble game in our framework. Here, the graph considered is the dependence graph $\mathcal{D}$ of a URE.

DEFINITION 3.1 (configuration). *A configuration is a finite subset of* $V \times \mathbb{Z}$*, the set of nodes of* $\mathcal{D}$*. A configuration represents the position of the pebbles at some stage of the game. There is at most one pebble per node.*

DEFINITION 3.2 (execution, successful execution, step). *An* execution *of the pebble game is a sequence of configurations* $e = \{\mathcal{A}(t), t \in \mathbb{N}\}$*, such that* $\forall t$*, the configuration* $\mathcal{A}(t+1)$ *can be obtained from* $\mathcal{A}(t)$ *through the rules of the pebble game. The passage from* $\mathcal{A}(t-1)$ *to* $\mathcal{A}(t)$ *is called the* step t *of the game. An execution of the game is* successful *if all positive nodes receive a pebble during the execution, i.e.,* $\forall (i,n) \in V \times \mathbb{N}$, $\exists\, t \in \mathbb{N}$, *s.t.* $(i,n) \in \mathcal{A}(t)$.

In the following, we will always consider successful executions and refer to them simply as executions. An execution corresponds to a computation of all the variables

$\{X_i(n), i \in V, n \in \mathbb{N}\}$. The number of pebbles used by an execution $e = \{\mathcal{A}(t), t \in \mathbb{N}\}$ is

$$\mathcal{P}(e) \stackrel{\text{def}}{=} \sup_{t\in\mathbb{N}} |\mathcal{A}(t)| , \tag{5}$$

where $|\mathcal{A}(t)|$ represents the cardinal of $\mathcal{A}(t)$. Our general objective is redefined below. It will be referred to as the problem *MinPeb*.

PROBLEM 1 (MinPeb). *Determine* $\min_e \mathcal{P}(e)$ *and an execution* e_o *such that* $\mathcal{P}(e_o) = \min_e \mathcal{P}(e)$.

In the following, we define several sets of rules, each of them defining a different pebble game. The different sets of rules, called $\mathcal{M}_1, \mathcal{M}_2$, and $\mathcal{M}_3$, correspond to different computation models for the URE and are related to different notions of cuts and delays (see sections 4 and 5). Also, their relevance will be justified by the applications given in sections 7 and 8. We use the expressions "set of rules $\mathcal{M}_i$" or "game $\mathcal{M}_i$" indifferently.

$\mathcal{M}_1$ *: Synchronous execution.* The set of rules $\mathcal{M}_1$ is as follows:

- (R1) *(starting rule).* Initially, a finite number of pebbles are put on negative nodes only, with at least one pebble on column 0: $\mathcal{A}(0) \subset V \times \mathbb{Z}^-$, $\mathcal{A}(0) \cap (V \times \{0\}) \neq \emptyset$.
- (R2) *(playing rule).* One step of the game consists of any number of moves of type (R3), followed by any number of moves of type (R4).
- (R3) *(adding pebbles).* Put a pebble on an empty node (i, n). At step t, this is possible if and only if each infinite oriented path (see Definition 4.1) ending in (i, n) intersects $\mathcal{A}(t-1)$.
- (R4) *(removing pebbles).* Remove a pebble from a node.

Remark 3.3 (comments of rule (R2)). Note that our definition of $\mathcal{P}(e)$ considers only the number of pebbles at the end of the step and not at intermediate stages (after (R3) and before (R4), for example). It corresponds to the assumption that all the moves done in one step can be performed simultaneously. This is why this is called a synchronous execution. This remark also applies to games $\mathcal{M}_2$ and $\mathcal{M}_3$.

Remark 3.4 (comments on rule (R3)). Rule (R3) may look cumbersome since one may put a pebble on a node which is very far to the right from the current position of the pebbles. Its intuitive meaning for the calculation in a system of UREs is the following: At the beginning of step t, the variables which are in memory are the ones corresponding to $\mathcal{A}(t-1)$. *A new pebble can be put on a node* (i, n) *if the corresponding variable* $X_i(n)$ *can be computed given the variables in memory.* This does not mean that this computation has to be direct. It may be done using the variables in memory and the appropriate compositions of the initial functions F_i. Since the initial functions are arbitrary, no notion of the "complexity of a function" is used here. Hence the function obtained by composition of a finite number of initial functions can be considered just as yet another arbitrary function, and its computation does not require any additional memory.

However, it seems reasonable to consider that function compositions should have a "cost," not in terms of space as mentioned above, but in terms of time. A step of the game may have a duration which depends on the "complexity" of the compositions. The discussion of this aspect of the problem is postponed until Appendix A.2.

We illustrate rule $\mathcal{M}_1$ with the example of Figure 4. We have represented a small part of the dependence graph of the URE: $X_1(n) = F_1(X_1(n-1), X_2(n-1), X_3(n-1)), X_i(n) = F_i(X_{i-1}(n), X_1(n-1), X_2(n-1), X_3(n-1))$ for $i = 2, 3$.

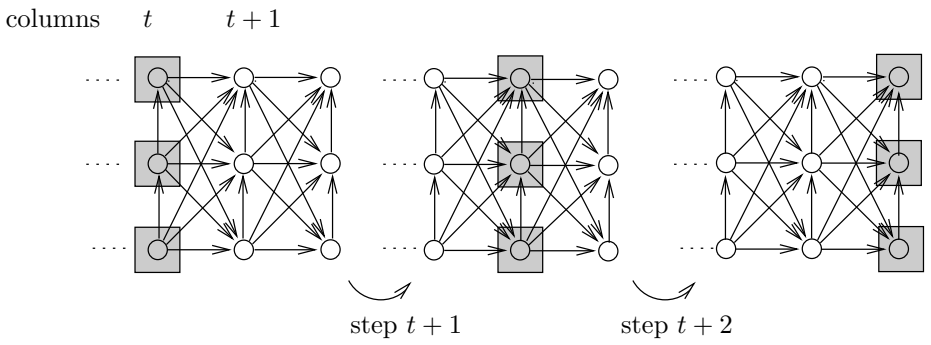

FIG. 4. *Rule $\mathcal{M}_1$. Three pebbles are needed.*

At step 0, we have three pebbles on nodes $(i, 0)$, $i = 1, 2, 3$ (rule (R1)). At step 1, it follows from rule (R3) that a pebble can be put on any positive node. For instance, let us consider node $(2, 1)$. The associated variable can be computed as follows:

$$X_2(1) = F_2\big(F_1\left(X_1(0), X_2(0), X_3(0)\right), X_1(0), X_2(0), X_3(0)\big)\,.$$

By keeping the original pebbles untouched, we can use one additional pebble to mark all the nodes one by one. In this way, we obtain a successful execution using four pebbles. It is, however, possible to do better.

Consider the following execution, illustrated in Figure 4. After step $t-1$, assume there are three pebbles on nodes $(i, t-1)$, $i = 1, 2, 3$. At step t, we can put simultaneously three pebbles on nodes (i, t), and we remove the initial pebbles (rule (R3) used three times followed by rule (R4) applied three times). At step $t+1$, we put the three pebbles on nodes $(i, t+1)$ and so on. The number of pebbles needed by this execution is three.

Game $\mathcal{M}_1$ can be seen as a model of computation of a URE where several synchronous processors are used in parallel during the computations. These processors can access the same memory locations at the same time. More precisely, this is a model of a CREW-PRAM (see, for instance, Reif [22]) computation of the URE. The number of processors needed at one step is equal to the number of moves of type (R3) (i.e., the number of computations realized). For more details, see Appendix A.2.

$\mathcal{M}_2$: Synchronous regular execution. The rules of $\mathcal{M}_2$ are obtained by restricting $\mathcal{M}_1$ as follows:

- (R1). Unchanged.
- (R2b) *(playing rule).* Same as before, with the additional restriction that configurations must be 1-periodic, i.e., $\mathcal{A}(t+1) = \mathcal{A}(t) + 1$, where

$$(i, n) \in \mathcal{A}(t) + 1 \iff (i, n-1) \in \mathcal{A}(t). \tag{6}$$

- (R3). Unchanged.
- (R4). Unchanged.

The example of Figure 4 was also verifying the set of rules $\mathcal{M}_2$. To see that $\mathcal{M}_1$ and $\mathcal{M}_2$ are indeed different, let us consider the example of Figure 5. It corresponds to the URE $X_1(n) = F_1(X_2(n-1)), X_2(n) = F_2(X_1(n))$.

In Figure 5(I), only one pebble is needed under rule $\mathcal{M}_1$. The corresponding execution verifies rule (R2) (game $\mathcal{M}_1$) but not rule (R2b) (game $\mathcal{M}_2$). In Figure 5(II),

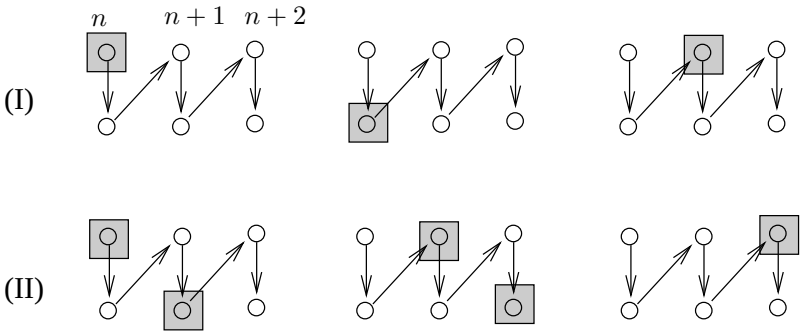

FIG. 5. *Rule* $\mathcal{M}_1$ (I) *and rule* $\mathcal{M}_2$ (II).

two pebbles are needed. The corresponding execution verifies rule (R2b). The computations are performed according to the following patterns:

(a) Rule $\mathcal{M}_1$ (Figure 5(I)).
Step t: $X_2(n) = F_2(X_1(n))$.
Step $t+1$: $X_1(n+1) = F_1(X_2(n))$.
Step $t+2$: $X_2(n+1) = F_2(X_1(n+1))\ldots$

(b) Rule $\mathcal{M}_2$ (Figure 5(II)).
Step t: $(X_1(n+1), X_2(n+2))\,(F_1 \circ F_2(X_1(n)), F_2 \circ F_1(X_2(n+1)))$.
Step t+1: $(X_1(n+2), X_2(n+3)) = (F_1 \circ F_2(X_1(n+1)), F_2 \circ F_1(X_2(n+2)))$.

Note that in the execution under rule $\mathcal{M}_2$, we have to perform the function compositions $F_2 \circ F_1$ and $F_1 \circ F_2$. In Appendix A.2, we discuss the "cost" of function compositions.

Game $\mathcal{M}_2$ corresponds to the same computational model as game $\mathcal{M}_1$, which is the CREW-PRAM model. The difference is that in an execution of $\mathcal{M}_2$, the variables in $\mathcal{A}(t)$ are obtained from those in $\mathcal{A}(t-1)$ by always applying the same operator. This is interesting for implementation purposes. A nonregular execution of $\mathcal{M}_1$ would be practically very intricate to implement since each step would be essentially different. Another advantage of an execution of $\mathcal{M}_2$ is that the number of memory locations needed to carry out the calculations is easy to compute: it is equal to $|\mathcal{A}(t)|$ (independent of t).

$\mathcal{M}_3$*: Synchronous one-pass execution.* The rules of $\mathcal{M}_3$ are obtained by restricting the ones of $\mathcal{M}_2$ as follows:

- (R1). Unchanged.
- (R2c) *(playing rule).* Same as (R2b), with the following additional restriction. Each node in $\mathcal{D}$ must be computed only once during the whole execution.
- (R3). Unchanged.
- (R4). Unchanged.

In rule (R2c), the important point is the difference that exists between computing a node and keeping the result in memory.

Let us consider the example of Figure 6(I). Each node on line 1 is computed twice, whereas each node on line 2 is computed only once. Let us detail this. Node $(1, n+2)$ is computed at step t (it is needed as an auxiliary for the computation of node $(2, n+2)$), but it is not kept in memory. Node $(1, n+2)$ is then computed a second time at step $t+1$. On the other hand, node $(2, n+2)$ is computed at step t and is kept in the memory. It does not have to be computed a second time at step $t+1$, as the computed value is just moved from one register to another.

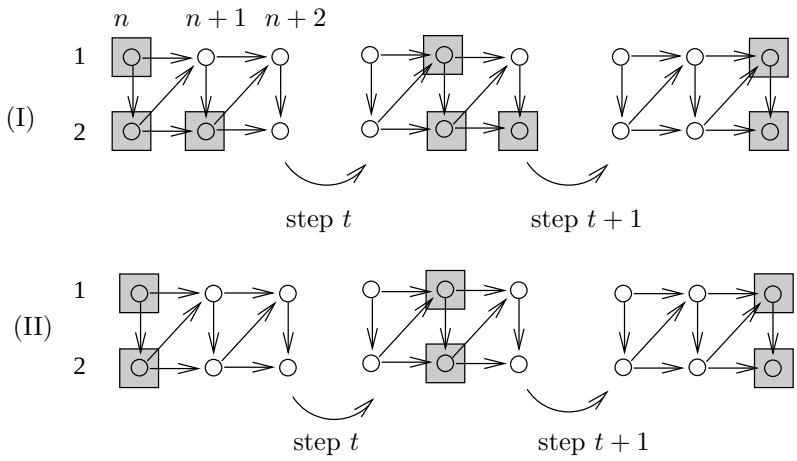

FIG. 6. *Rule* $\mathcal{M}_2$ (I) *and rule* $\mathcal{M}_3$ (II).

In Figure 6(I), we have an example of an execution satisfying rule $\mathcal{M}_2$ but not $\mathcal{M}_3$. On the other hand, in Figure 6(II), we have an execution which verifies rule $\mathcal{M}_3$. The corresponding computation pattern is as follows:

- Rule $\mathcal{M}_3$ (Figure 6(II)).
  Step t: $(X_1(n+1), X_2(n+1)) = (F_1(X_1(n), X_2(n)), F_2(F_1(X_1(n), X_2(n)), X_2(n)))$.
  Step $t+1$: $(X_1(n+2), X_2(n+2)) = (F_1(X_1(n+1), X_2(n+1)), F_2(F_1(X_1(n+1), X_2(n+1)), X_2(n+1)), X_2(n+1)))$.

The computational model corresponding to game $\mathcal{M}_3$ is still the CREW-PRAM model. Rule (R2c) may look cumbersome, but it actually corresponds to a natural notion for the applications to be detailed later on.

Notation. We will use the following notation:

- $\mathcal{E}$: the set of all possible (synchronous) executions under rule $\mathcal{M}_1$.
- $\mathcal{RE}$: the set of all possible executions under rule $\mathcal{M}_2$. Elements of $\mathcal{RE}$ will be called regular executions.
- $\mathcal{ORE}$: the set of all possible executions under rule $\mathcal{M}_3$. Elements of $\mathcal{ORE}$ will be called one-pass regular executions.

Since the rules are increasingly restrictive, we have $\mathcal{ORE} \subset \mathcal{RE} \subset \mathcal{E}$.

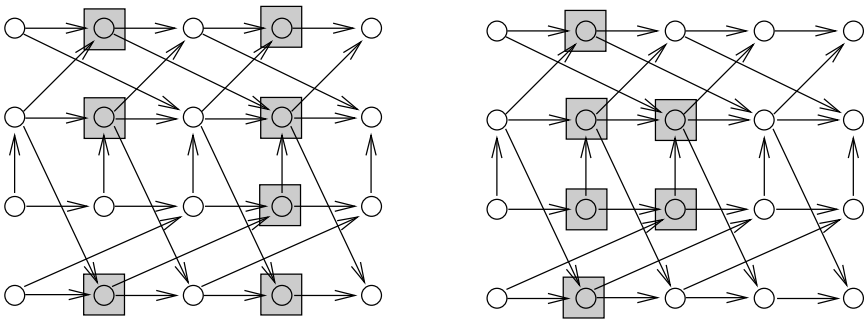
4. Cuts in the dependence graph and their relation with $\mathcal{M}_1, \mathcal{M}_2$. From now on, it is always implicitly assumed that the system under study is *recycled*; see section 2.3. In this section, we concentrate on games $\mathcal{M}_1$ and $\mathcal{M}_2$.

We introduce the notions of cuts and consecutive cuts in a dependence graph. We show that cuts (resp., consecutive cuts) are closely related to executions of the pebble game under game $\mathcal{M}_1$ (resp., game $\mathcal{M}_2$).

We show that there always exists a minimal cut which is consecutive (Lemma 4.7). It will allow us to prove Theorem 4.11, the main result of the section:

$$\min_{e \in \mathcal{RE}} \mathcal{P}(e) = \min_{e \in \mathcal{E}} \mathcal{P}(e) = \min_{C \text{ cut of } \mathcal{D}} |C| ,$$

where the notation is defined in section 3.1. As a direct consequence, we show in section 4.3 that problem MinPeb can be solved with a polynomial algorithm for games $\mathcal{M}_1$ and $\mathcal{M}_2$.



A nonconsecutive cut A consecutive cut

FIG. 7. *Consecutive and nonconsecutive cuts.*

4.1. Definitions. Let us recall some classical definitions of graph theory, all defined on the dependence graph $\mathcal{D}$. For further references, see [9, 14], for example.

DEFINITION 4.1 (path). *A path is a sequence of nodes and arcs in $\mathcal{D}$ of the form $\cdots \to (i_0, n_0) \to (i_1, n_1) \to (i_2, n_2) \to \cdots \to (i_k, n_k) \to \cdots$. A path is bi-infinite if it contains an infinite number of negative nodes and an infinite number of positive nodes.*

DEFINITION 4.2 (cut). *A cut C is a set of nodes in $\mathcal{D}$ such that any bi-infinite path contains at least one node of C. A cut with a minimal number of nodes is called a minimal cut.*

DEFINITION 4.3 (flow). *A flow is a set of bi-infinite paths such that any two paths do not share any node. A flow containing a maximal number of paths is called a maximal flow. A flow $\mathcal{F}$ is 1-periodic if the following holds: the arc $(i, n) \to (j, m)$ belongs to $\mathcal{F}$ if and only if $(i, n+1) \to (j, m+1)$ belongs to $\mathcal{F}$.*

The most classical notion of cut involves arcs rather than nodes, and a flow is a set of paths which do not share arcs rather than nodes. However, a simple transformation—each node being replaced by two nodes connected by an arc—would allow us to go back to the original definitions.

DEFINITION 4.4 (section). *A section S in $\mathcal{D}$ is a set of nodes with exactly one node per line, $S = \{(i, n_i), i \in V\}$.*

Note that since $\mathcal{D}$ is recycled, a cut contains at least one node per line. Using this property, one can define the left and right sections of a cut.

DEFINITION 4.5 (left, right sections). *The left (resp., right) section C_w, with w for* west *(resp., C_e, with e for* east*), of a finite cut C is the set of nodes (i, n) in C such that the nodes $(i, n-h), h > 0$ (resp., $(i, n+h), h > 0$), do not belong to C.*

DEFINITION 4.6 (consecutive cut). *A cut C in $\mathcal{D}$ is consecutive if on each line of $\mathcal{D}$, C contains only consecutive nodes, i.e.,*

$$\forall i \in V,\ (i, n) \in C \text{ and } (i, n+1) \notin C \Rightarrow (i, n+k) \notin C \ \ \forall k > 0.$$

Examples of consecutive and nonconsecutive cuts are displayed in Figure 7.

LEMMA 4.7. *There exists a minimal cut of $\mathcal{D}$ which is a minimal consecutive cut.*

Proof. Let C be a minimal consecutive cut. We will prove that C is a minimal cut. First, we prove that there are no arcs from C_w to $C_e + k, k \geq 2$ (where $(i, n) \in C_e + k$ if and only if $(i, n-k) \in C_e$). Let us assume that there exists such an arc, which we denote by $(i, n) \to (j, m)$. By 1-periodicity, there is an arc between nodes $(i, n-1)$

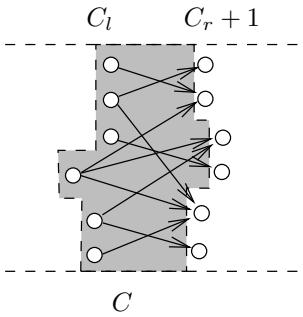


FIG. 8. *Graph G made from the right and left sections of C.*

and $(j, m-1)$. Now consider the bi-infinite path

$$\cdots \to (i, n-3) \to (i, n-2) \to (i, n-1) \to (j, m-1) \to (j, m) \to (j, m+1) \to \cdots .$$

It does not intersect C, which is a contradiction.

We consider the subgraph G of $\mathcal{D}$ made of the nodes $C_w \cup (C_e + 1)$ and the arcs between C_w and $C_e + 1$ in $\mathcal{D}$; see Figure 8. We recall that a cut in a *finite* graph G is a set of nodes such that, when removed from G, there is no arc remaining. The set C_w is a cut in G. Let Δ be a cut in G of minimal size. We have $|\Delta| \leq |C_w|$. If $|\Delta| < |C_w|$, then $(C \backslash C_w) \cup \Delta$ would be a consecutive cut in $\mathcal{D}$ strictly smaller than C, which would contradict the fact that C is a minimal consecutive cut. Therefore, we have $|\Delta| = |C_w|$.

An adapted version of a famous "minimax" theorem first proved by König (1931) states that we can find $|\Delta|$ node-disjoint arcs in G. Since $|\Delta| = |C_w| = |C_e + 1|$, these arcs define a one-to-one mapping ϕ from C_w to $C_e + 1$. From ϕ, we construct a flow in C in the following way. Select all the arcs of the form $((i, n) + k) \to (\phi(i, n) + k)$ $\forall (i, n) \in C_w$ and $\forall k \in \mathbb{Z}$. These arcs form a 1-periodic flow $\mathcal{F}$ in $\mathcal{D}$ of size $|C|$.

Let C_m be a minimal cut in $\mathcal{D}$. Since $\mathcal{F}$ is formed by node-disjoint paths, C_m must contain at least $|\mathcal{F}|$ nodes, $|C_m| \geq |\mathcal{F}| = |C|$. We conclude that $|C_m| = |C|$. ∎

This lemma is interesting on its own. In particular, it gives a proof of the minimax theorem (which exists in many versions) for an infinite 1-periodic and recycled graph.

COROLLARY 4.8. *The size of the minimal cut is equal to the size of the maximal flow in $\mathcal{D}$. Furthermore, there exists a maximal flow $\mathcal{F}$ in $\mathcal{D}$ which is 1-periodic.*

4.2. Cuts and pebbles.

LEMMA 4.9. *Let C be a finite consecutive cut. There is a regular execution $e \in \mathcal{RE}$ such that C is a configuration of e.*

Proof. Let C be a consecutive cut in $\mathcal{D}$. We want to prove that it is possible to have $\mathcal{A}(t) = C$ and $\mathcal{A}(t+1) = C + 1$ (note that $C + 1 = (C \backslash C_w) \cup (C_e + 1)$). It is enough to prove that for each node (i, n) in $C_e + 1$, there is no infinite path P terminating in (i, n) that does not intersect the cut. But if such a path could be found, then the bi-infinite path $P \cup \{(i, n+h), h \in \mathbb{N}\}$ would not intersect C. It would contradict the fact that C is a cut. ∎

The converse of Lemma 4.9 is not true: a configuration of a regular execution need not be a consecutive cut. This is illustrated in Figure 9(a). Also note that there are nonconsecutive cuts which are not configurations of a regular execution, as

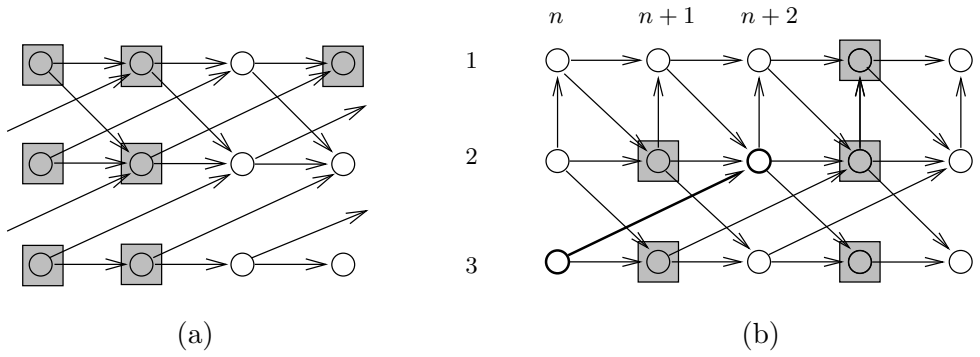

FIG. 9. *Two counterexamples.*

illustrated in Figure 9(b). In this example, the node $(2, n+2)$ belongs to $C+1$ but cannot be computed using only variables in C (as it depends on $(3, n)$, for example). Therefore, the cut C cannot belong to a regular execution.

LEMMA 4.10. *A configuration of any execution $e \in \mathcal{E}$ is a finite cut in $\mathcal{D}$. Conversely, let C be a finite cut in $\mathcal{D}$. There is an execution $e \in \mathcal{E}$ such that C is a configuration of e.*

Proof. Let $\mathcal{A}(t)$ be the tth configuration of some execution e belonging to $\mathcal{E}$. All the configurations of e are finite by definition. Therefore the total number of nodes that received a pebble up to step t is finite.

Now, assume that $\mathcal{A}(t)$ is not a cut. By definition, there exists a bi-infinite path P which does not have any node in $\mathcal{A}(t)$. According to rule (R3) of game $\mathcal{M}_1$, no node on P will receive a pebble during the execution, after step t. Combining this and the fact that the total number of nodes that received a pebble up to step t is finite, only a finite number of positive nodes on P receive a pebble during the execution e. This contradicts the fact that e has to put pebbles on all nodes.

Let us prove the converse result. Let C be a finite cut. Let $e = \{\mathcal{A}(t), t \in \mathbb{N}\}$ be any regular execution of game $\mathcal{M}_1$. Such executions exist (see Lemma 4.9). Let $\mathcal{N}$ be the set of positive nodes (i, n) such that there exists an infinite path ending in (i, n) and which does not intersect C. As C is a cut, $\mathcal{N}$ is finite. Let $T = \sup\{t \mid (\mathcal{N} \cup C) \cap \mathcal{A}(t) \neq \emptyset\}$. Note that T is finite since $\{\mathcal{A}(t)\}$ is regular and $\mathcal{N}$ is finite. We define $\tilde{e} = \{\tilde{\mathcal{A}}(t)\}$ as follows:

$$\tilde{\mathcal{A}}(t) = \begin{cases} \bigcup_{n=0}^{t} \mathcal{A}(n) & \text{if } t \leq T, \\ C & \text{if } t = T+1, \\ \mathcal{A}(t-1) & \text{if } t > T+1\,. \end{cases}$$

Let us show that $\tilde{e}$ is an execution of $\mathcal{M}_1$. We have $C \subset \bigcup_{n=0}^{T} \mathcal{A}(n)$; therefore, it is possible to set $\tilde{\mathcal{A}}(T+1) = C$. By definition of T, $\mathcal{A}(T+1)$ does not intersect $\mathcal{N}$; therefore, we can set $\tilde{\mathcal{A}}(T+2) = \mathcal{A}(T+1)$. Finally, $\tilde{e}$ contains all nodes in $\{\mathcal{A}(t), t \in \mathbb{N}\}$ and therefore all positive nodes. ∎

We are now ready to give the main result of this section, which states that, within all executions in $\mathcal{E}$, regular executions are dominant for problem MinPeb.

THEOREM 4.11. *Let us consider a recycled system of UREs. We play the pebble game on its associated dependence graph $\mathcal{D}$ under rules $\mathcal{M}_1$ and $\mathcal{M}_2$. We have*

$$\min_{e \in \mathcal{RE}} \mathcal{P}(e) = \min_{e \in \mathcal{E}} \mathcal{P}(e) = \min_{C \text{ cut of } \mathcal{D}} |C|,$$

that is, there exists a regular execution which requires a minimal number of pebbles, this number being equal to the size of a minimal cut.

Proof. It is a direct consequence of Lemmas 4.10, 4.9, and 4.7. First, note that all configurations are cuts, according to Lemma 4.10. Let C be a consecutive cut of minimal size, which exists by Lemma 4.7. By Lemma 4.9, C is a configuration of a regular execution. ∎

Theorem 4.11 has several interesting corollaries. First, it allows one to focus on regular executions since no fancy irregular execution of the URE can be done with fewer pebbles. Then it provides a polynomial method to find an optimal execution as shown in section 4.3.

4.3. Complexity results for $\mathcal{M}_1$ and $\mathcal{M}_2$.

PROPOSITION 4.12. *Let $\mathcal{R} = (V, E, \Gamma)$ be the reduced graph associated with a recycled system of UREs with nonnegative delays. We set $\Gamma_A = \sum_{e\in E} \Gamma(e)$. For games $\mathcal{M}_1$ and $\mathcal{M}_2$, problem* MinPeb *can be solved using an algorithm having a complexity $O\left(\Gamma_A^2 |V|^2\right)$.*

If the system of UREs has negative delays, it is possible to go back to nonnegative delays (see Remark 2.1) and apply Proposition 4.12 to the new system.

In order to prove Proposition 4.12, we are going to compute a maximal flow in $\mathcal{D}$ and then apply Corollary 4.8. If we want to use the algorithm of Ford and Fulkerson [9] to compute a maximal flow, we first need to restrict ourselves to a finite graph.

The *span* of a cut is the difference between the largest and the smallest of the numberings of columns containing a node of the cut.

A *slice* of $\mathcal{D}$ of dimension n is defined as the subgraph of $\mathcal{D}$ having nodes $\{(i,k), i \in V, 0 \le k \le n\} \cup \{T, B\}$, where T (top) and B (bottom) are two special nodes. There is an arc $T \to (i,k),\ 0 \le k \le n$, if $\exists (j,l), l < 0$, such that there is an arc $(j,l) \to (i,k)$ in $\mathcal{D}$. There is an arc $(i,k) \to B,\ 0 \le k \le n$, if $\exists (j,l), l > n$, such that there is an arc $(i,k) \to (j,l)$ in $\mathcal{D}$.

If a consecutive minimal cut spans less than n columns, then $\mathcal{D}$ and a slice of dimension n have the same minimal consecutive cut (the special nodes T and B are not allowed to belong to the cut). So it is important to determine, or at least to bound, the span of a consecutive minimal cut.

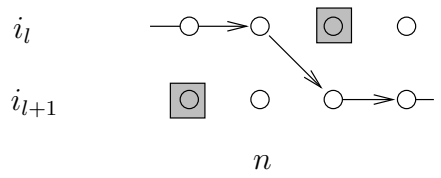
LEMMA 4.13. *If all the delays are nonnegative, the span of a minimal consecutive cut is smaller than the total sum of the delays in $\mathcal{R}$, i.e., smaller than $\Gamma_A = \sum_{e\in E} \Gamma(e)$.*

Proof. Let C be a minimal consecutive cut, and let $\mathcal{F}$ be a maximal 1-periodic flow; see Corollary 4.8.

The associated maximal 1-periodic flow (see Corollary 4.8) $\mathcal{F}$ is a set of paths in $\mathcal{D}$. First, these paths cover all the nodes in $\mathcal{D}$. Indeed, by the 1-periodicity of $\mathcal{F}$, if a node (i,n) is not in $\mathcal{F}$, then the whole line $(i,.)$ is not in $\mathcal{F}$, but this means that the bi-infinite path $\{(i,n), n \in \mathbb{Z}\}$ can be added to the flow $\mathcal{F}$, and this contradicts the maximality of $\mathcal{F}$.

Let P_1 be any path in $\mathcal{F}$. It follows from the 1-periodicity of $\mathcal{F}$ that P_1 is periodic. Let $i_0, i_1, \dots, i_{l_1}, i_0, i_1, \dots$ be the successive lines visited by the path P_1. Let (i_0, n) and $(i_0, n + k_1)$ be the consecutive nodes visited by the path P_1 on line $(i_0, .)$. Using the 1-periodicity of $\mathcal{F}$, the total number of paths intersecting lines $i_0, i_1, \dots, i_{l_1}$ in $\mathcal{F}$ is k_1. It implies that the cardinal of C over the lines $i_0, i_1, \dots, i_{l_1}$ is exactly k_1 (Corollary 4.8). Assume that the span of C on lines $i_0, i_1, \dots, i_{l_1}$ is strictly greater than k_1. Then there exists a column, say, n, not intersecting C and such that on some of the lines $\{i_0, i_1, \dots, i_{l_1}\}$, C is on the "right" of column n and on some others C is on the "left"

of column n. Let l be such that C is on the "right" of n at line i_l and on the "left" at line i_{l+1}. There exists an arc of the type $(i_l, n) \to (i_{l+1}, n+h), h \geq 0$ (the delays are



nonnegative) in the flow $\mathcal{F}$. Then the path $\{(i_l, n-u), (i_{l+1}, n+h+v), u, v \in \mathbb{N}\}$ does not intersect the cut C; see the above figure. This is a contradiction. We conclude that the span of C over the lines $i_0, i_1, \ldots, i_{l_1}$ is smaller than k_1. By definition of $\mathcal{R}$, there exists a circuit L_1 in $\mathcal{R}$ containing the nodes $i_0, i_1, \ldots, i_{l_1}$ and of total delay k_1.

The path P_1 and all its shifts are in the flow $\mathcal{F}$ and contain all the nodes in the lines $i_0, i_1, \ldots, i_{l_1}$. If $i_0, i_1, \ldots, i_{l_1}$ do not cover all the lines, a new path P_2 in $\mathcal{F}$ not intersecting the lines $i_0, i_1, \ldots, i_{l_1}$ ranges over different lines, say, $i_{l_1+1}, i_{l_1+2}, \ldots, \ldots, i_{l_2}$, and defines a circuit L_2 in $\mathcal{R}$ similarly. The span of C on the lines $i_{l_1+1}, \ldots, i_{l_2}$ is smaller than k_2, the total delay of circuit L_2. We apply the same argument until all lines in $\mathcal{D}$ are covered. This defines a set H of circuits partitioning the nodes of $\mathcal{R}$.

We build a new multigraph $\mathcal{G}$ starting with $\mathcal{R}$ and where each circuit in H is merged into one single node. The graph $\mathcal{G}$ has $|H|$ nodes and the arcs of $\mathcal{G}$ correspond to the arcs of $\mathcal{R}$ which do not belong to any circuit in H. Considering two nodes in $\mathcal{G}$, say L_1 and L_2, the span of C over lines $i_0, \ldots, i_{l_2}$ can be chosen to be smaller than $k_1 + k_2 + d$, where d is the maximum delay on all arcs between the nodes L_1 and L_2 in $\mathcal{G}$. Overall, the cut C can be chosen to have a span which is smaller than the sum of the delays on all the circuits in H plus the sum of the delays on all the arcs in $\mathcal{G}$. No delay is counted twice in this upper bound. Therefore, the total span of C is smaller than the total sum of the delays in $\mathcal{R}$. □

Proof of Proposition 4.12. A slice of $\mathcal{D}$ of size Γ_A has the same minimal consecutive cut as $\mathcal{D}$ itself. The computation of the maximal flow in a finite slice can be done using the augmenting path algorithm; see [9, 14]. Starting with a 1-periodic flow (the recycled lines) and maintaining the 1-periodicity throughout the construction yields a maximal 1-periodic flow. The complexity of this construction of the maximal flow is $O(\Gamma_A^2 |V|^2)$. By Corollary 4.8, it provides the size of a minimal cut in $\mathcal{D}$. Furthermore, a standard procedure provides a minimal consecutive cut starting from a maximal flow (with a complexity $O(\Gamma_A |V|)$). Using Lemma 4.9, an execution of game $\mathcal{M}_2$ (or $\mathcal{M}_1$), using a minimal number of pebbles, is obtained from the minimal consecutive cut.

For the game $\mathcal{M}_3$, the problem MinPeb is solved by working on the reduced graph. A polynomial algorithm is given in section 6.5.

5. Compatible cuts and their relation with $\mathcal{M}_3$. We introduce the notion of compatible cuts. It enables us to show Theorem 5.5, the main result of the section, which is the analogue of Theorem 4.11:

$$\min_{e \in \mathcal{ORE}} \mathcal{P}(e) = \min \{|C|, \ C \text{ compatible cut of } \mathcal{D}\}.$$

Let us introduce some new definitions.

DEFINITION 5.1 (crossings). *We say that an arc crosses a section* $S = \{(i, n_i), i \in V\}$ from left to right *if it is an arc of the form* $(i, n_i - h) \to (j, n_j + l)$ *with* $h \geq 0$ *and* $l \geq 1$. *An arc* $(i, n_i + l) \to (j, n_j - h)$ *crosses* S from right to left *if* $l \geq 1$ *and* $h \geq 0$.

DEFINITION 5.2 (compatible section, compatible cut). *A section in $\mathcal{D}$ is* compatible *if no arc crosses the section from right to left. A consecutive cut is said to be* compatible *if its right section is compatible.*

Roughly speaking a compatible cut is a consecutive cut which agrees with the dependence relations in the system of UREs. Compatible cuts are connected to one-pass executions through the next two lemmas.

LEMMA 5.3. *Let C be a compatible cut. There is a one-pass regular execution $e \in \mathcal{ORE}$ such that C is a configuration of e.*

Proof. Let C be a compatible cut. Since C is consecutive by definition, Lemma 4.9 tells us that C is a configuration of a regular execution which can be written as $e = \{C + t, t \in \mathbb{N}\}$. Suppose that e is not one-pass. This means that there exists a node, say, (j, m), that is computed twice in e.

Let us assume that node (j, m) receives a pebble at step t_0 and that this pebble is removed at step t_1, $t_1 > t_0$. By regularity of the execution e, node (j, m) will not be used at step $t > t_1 + 1$. Indeed, a node in $C + t$ depends only on variables in $C + t - 1$ or "below."

Now assume that node (j, m) is used at step $t < t_0$ to compute another node, say, (i, n). The path $(j, m) \to (i, n)$ crosses the right section of $C + t$ from right to left. Therefore it contains an arc that crosses the right section of $C + t$ from right to left. This contradicts the fact that C is compatible. ∎

LEMMA 5.4. *The configuration of a one-pass regular execution is a compatible cut.*

Proof. Let $e = \{C + t, t \in \mathbb{N}\}$ be a one-pass regular execution. First, C is a cut by Lemma 4.10. Next, C is consecutive. Indeed, if C is not consecutive on line i, then each variable $X_i(n)$ receives a pebble at least twice in e, and a fortiori this means it is computed at least twice.

It remains to show that C is compatible. Assume that C is not compatible. Then there exists a node (i, n) belonging to the right section of $C + t$, a positive integer k, and a node $(j, m) \in (C + t + k) \backslash (C + t)$ such that the arc $(j, m) \to (i, n)$ belongs to $\mathcal{D}$. But this implies that in the execution e, the computation of $X_j(m)$ is performed twice, once as an auxiliary computation at step t to compute $X_i(n)$ and once at step $t + k$. This contradicts the fact that e is one-pass. ∎

THEOREM 5.5. *Let us consider a recycled system of UREs. We play the pebble game on its associated dependence graph $\mathcal{D}$ under rules $\mathcal{M}_3$. We have*

$$\min_{e \in \mathcal{ORE}} \mathcal{P}(e) = \min \{|C|, \ C \text{ compatible cut of } \mathcal{D}\}.$$

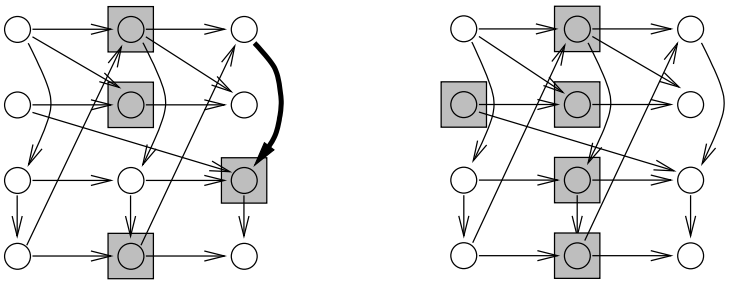
Proof. The proof is an immediate corollary of Lemmas 5.3 and 5.4. ∎

It can be that no minimal consecutive cut in $\mathcal{D}$ is compatible. This is the case in Figure 10, where the minimal compatible cut contains 5 nodes while there is a minimal consecutive cut of size 4.

Therefore, rule $\mathcal{M}_3$ requires more memory in general than rule $\mathcal{M}_2$.

6. Delays in the reduced graph. In the previous sections, we have investigated the relations between executions of a system of UREs and cuts in the dependence graph. In this section, we connect these two notions with values of the delays in the reduced graph.

Let us consider a system of URE $\mathcal{S}$ with variables $\{X_i(n), i \in V, n \in \mathbb{Z}\}$ and a regular execution $e = \{\mathcal{A}(t), t \in \mathbb{N}\}$ of the system. We introduce the modified system $\tilde{\mathcal{S}}$ with variables $\{\tilde{X}_i(n), i \in V, n \in \mathbb{Z}\}$ and the execution $\tilde{e} = \{\tilde{\mathcal{A}}(t), t \in \mathbb{N}\}$ defined as



Minimal (noncompatible) cut Minimal compatible cut

FIG. 10. *Noncompatible and compatible cuts.*

follows:

$$\begin{aligned} c_i &= \max\{n \in \mathbb{Z}^- \mid (i,n) \in \mathcal{A}(0)\}, \\ \tilde{X}_i(n) &= X_i(n + c_i), \\ \tilde{\mathcal{A}}(t) &= \{(i,n) \text{ s.t. } (i, n + c_i) \in \mathcal{A}(t)\}. \end{aligned}$$

The above definition is such that the right section of $\tilde{\mathcal{A}}(0)$ is $S_0 = \{(i,0), i \in V\}$. Viewed on the dependence graphs, the passage from $\mathcal{S}$ to $\tilde{\mathcal{S}}$ corresponds to a shift of the lines. Viewed on the reduced graphs, it corresponds to a *retiming*, i.e., a modification of the value of the delays, while preserving the graph topology.

We show (Lemma 6.6 and 6.7) that the total number of delays in $\tilde{\mathcal{R}}$ is closely related to regular executions. As a consequence, we obtain a polynomial algorithm to solve problem MinPeb under rule $\mathcal{M}_3$; see section 6.5.

6.1. Retiming.

DEFINITION 6.1 (retiming). *Let $\mathcal{R}$ be the reduced graph of a system of UREs. A* retiming *of $\mathcal{R}$ is a node function $r : V \to \mathbb{Z}$ which specifies a new graph $\mathcal{R}_r$, with the same nodes and arcs as $\mathcal{R}$. The value of the delay on an arc $e = (i,j)$ in $\mathcal{R}_r$ is equal to $\Gamma_r(e) = \Gamma(e) + r(i) - r(j)$.*

The notion of retiming is classic in digital circuits (see [17] and section 7, where we provide a detailed discussion of its usefulness in this context) and in Petri nets, where it corresponds to the firing of transitions (see section 8).

In the example of Figure 11, the new values of the delays correspond to a retiming r such that $r(1) = 1, r(2) = 1,$ and $r(3) = 0$.

Retiming may create negative delays, as in Figure 11.

LEMMA 6.2. *Two retimings r and r' yield the same value of the delays in a connected graph $\mathcal{R}$ if and only if there exists a constant $h \in \mathbb{Z}$ such that $\forall i \in V, r(i) = r'(i) + h$.*

Proof. First, if $r(i) = r'(i) + h \ \forall i \in V$, then on any arc $e = (i,j)$, $\Gamma_r(e) = \Gamma(e) + r(i) - r(j) = \Gamma(e) + r'(i) - r'(j) = \Gamma_{r'}(e)$. Conversely, if $\Gamma_{r'}(e) = \Gamma_r(e)$, then $r(i) = r'(i) + h$ and $r(j) = r'(j) + h$ for some $h \in \mathbb{Z}$. As $\mathcal{R}$ is connected, the constant h is the same for all the nodes in V. □

The question that arises now is, What is the notion corresponding to retiming in the system of UREs $\mathcal{S}$ and in the dependence graph $\mathcal{D}$? To answer this question, let us consider the graph $\mathcal{D}_r$ associated with the retimed reduced graph $\mathcal{R}_r$. This dependence graph can be constructed directly from $\mathcal{D}$ by shifting the lines as described in Lemma 6.3.

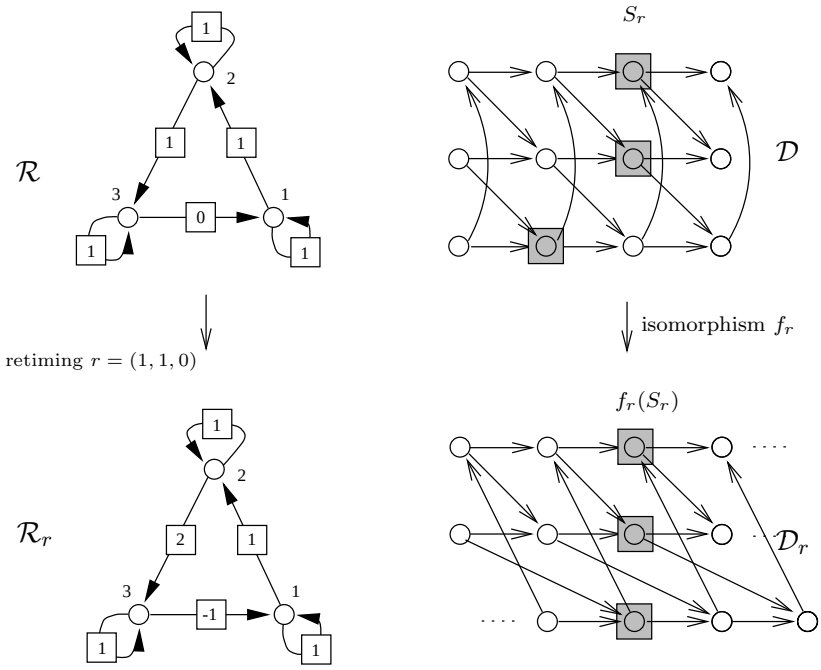


FIG. 11. *Retimed reduced graph and dependence graph.*

LEMMA 6.3. *A retiming r in $\mathcal{R}$ corresponds to a transformation f_r between $\mathcal{D}$ and $\mathcal{D}_r$ defined by*

$$\begin{array}{rccc} f_r: & \mathcal{D} & \to & \mathcal{D}_r \\ & (i,n) & \to & (i, n - r(i)). \end{array}$$

The transformation f_r is an isomorphism of graphs, meaning that there is an arc between u and v in $\mathcal{D}$ if and only if there is one between $f_r(u)$ and $f_r(v)$ in $\mathcal{D}_r$. It will also be called a retiming of $\mathcal{D}$.

Proof. By definition of $\mathcal{D}$, there is an arc from (i,n) to (j,m) in $\mathcal{D}$ if the delay in $\mathcal{R}$ on arc (i,j) is $\gamma = m - n$. The delay in $\mathcal{R}_r$ on arc (i,j) is $\gamma_r = \gamma + r(i) - r(j) = (m - r(j)) - (n - r(i))$. It implies that there is an arc between $(i, n - r(i))$ and $(j, n - r(j))$ in $\mathcal{D}_r$. Therefore, f_r is an isomorphism between $\mathcal{D}$ and $\mathcal{D}_r$. ∎

We recall that the notion of *section* was introduced in Definition 4.4. We associate with a retiming r in $\mathcal{R}$ the section $S_r = \{(i, r(i)), i \in V\}$ in $\mathcal{D}$.

Lemmas 6.2 and 6.3 tell us that two retimings r and r' are similar (in the sense that they yield the same value of the delays) if and only if they are associated with two sections S_r and S'_r with $S_r = S_{r'} + h$ for some $h \in \mathbb{Z}$. This relation enables us to define an equivalence relation between sections in $\mathcal{D}$ as well as between retimings in $\mathcal{R}$. We say that section S_r (resp., retiming r) is equivalent to section $S_{r'}$ (resp., retiming r') if $S_r = S_{r'} + h$ for some $h \in \mathbb{Z}$. In the following, we will always consider one arbitrary section among the equivalence class and call it the section associated with the retiming r; for instance, S_0 corresponds to the equivalence class of $\{(i,0), i \in V\}$.

6.2. Counting the delays. Given a graph $\mathcal{R} = (V, E, \Gamma)$, we define the *total number of delays* of $\mathcal{R}$ as follows:

$$\Gamma_A(\mathcal{R}) = \sum_{i \in V} \sum_{(j,\gamma) \in \Delta_i} \gamma \,. \tag{7}$$

It corresponds to the number of delays appearing in the graphical representation of the reduced graph $\mathcal{R}$ as defined in section 2.2. See, for example, the graph $\mathcal{R}$ on Figure 12.

Given a graph $\mathcal{R} = (V, E, \Gamma)$, another quantity of interest is the following:

$$\Gamma_B(\mathcal{R}) = \sum_{j \in V} \max\{\gamma \mid \exists i \text{ s.t. } (j,\gamma) \in \Delta_i\} \,. \tag{8}$$

When the delays are positive ($\forall e \in E, \Gamma(e) \geq 0$), Γ_B corresponds to the total number of delays (Γ_A) in a modified reduced graph obtained by performing a forward splitting of the nodes. In the context of digital circuits, this is also called register sharing; see section 7.2. Given under the form of an algorithm, here is the formal construction of the `Forward Splitting` algorithm.

ALGORITHM 6.4 (Forward Splitting).

Input: *Reduced graph $\mathcal{R} = (V, E, \Gamma)$ with $\Gamma \geq 0$, functions associated with the nodes $\{F_i, i \in V\}$.*

1. Set $V' = V$ and $E' = \emptyset$. Associated functions $F'_i = F_i, i \in V$.
2. For all node $v \in V$, let δ be the maximum delay on all the output arcs of v.
   - Set $v_0 = v$.
   - If $\delta > 0$, create δ new nodes in V', called $v_1, \ldots, v_\delta$. Set $F'_{v_i} = Id$, the identity function, for $i = 1, \ldots, \delta$.
   - For each arc $e = (v, u) \in E$ with delay $\Gamma(e) = \gamma$, create an arc $e' = (v_\gamma, u)$ in E' with delay $\Gamma'(e') = 0$.
   - Add the arcs (v_i, v_{i+1}), $0 \leq i \leq \delta - 1$, in E', with delay $\Gamma' = 1$.

Output: *Split reduced graph $\mathcal{R}' = (V', E', \Gamma')$ with $\Gamma' \geq 0$, functions associated with the nodes $\{F'_i, i \in V\}$.*

It is important to remark that the split graph $\mathcal{R}'$ is not necessarily recycled, as opposed to $\mathcal{R}$. We will come back to this point in section 6.4.

The following proposition, easy to prove, justifies the `Forward Splitting` operation.

PROPOSITION 6.5. *Let $\mathcal{R}$ be a reduced graph with positive delays and $\mathcal{R}'$ the associated split graph.*

(i) *The associated systems of UREs $\mathcal{S}$ and $\mathcal{S}'$ have the same behavior. More precisely, borrowing the notation of the algorithm, we have*

$$\forall v \in V, n \in \mathbb{Z},\ X'_v(n) = X_v(n) \quad \textit{and} \quad \forall v_i \in V' \setminus V, n \in \mathbb{Z},\ X'_{v_i}(n) = X_v(n - i) \,.$$

(ii) *Furthermore, we have*

$$\Gamma_B(\mathcal{R}) = \Gamma_A(\mathcal{R}') = \Gamma_B(\mathcal{R}') \,. \tag{9}$$

Note that in order for (9) to make sense, it is necessary to extend the definitions of Γ_A and Γ_B to nonrecycled graphs.

In Figure 12, $\mathcal{R}'$ is the `Forward Splitting` of $\mathcal{R}$. In the split graph, there are two "dummy" nodes (associated with the identity function), represented by black dots. We have $\Gamma_A(\mathcal{R}) = 8$ and $\Gamma_B(\mathcal{R}) = \Gamma_A(\mathcal{R}') = \Gamma_B(\mathcal{R}') = 5$.

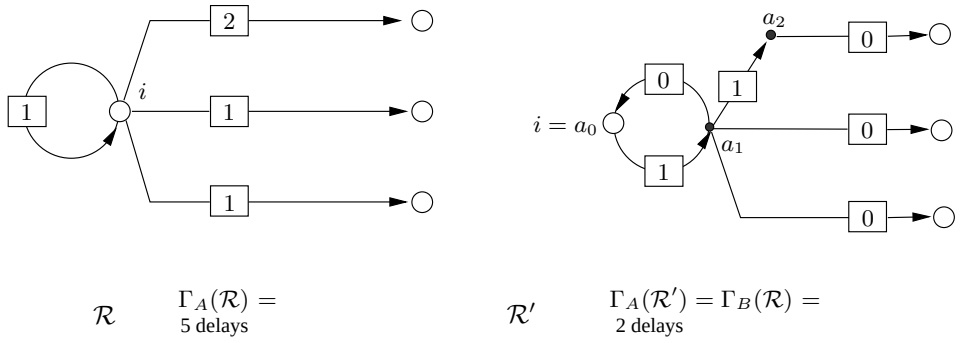

FIG. 12. *A reduced graph and the associated split graph.*

6.3. Delays, cuts, and pebbles. Given a section $S = \{(i, n_i), i \in V\}$ in $\mathcal{D}$, we define the cut $\mathcal{C}(S)$ in the following way:

$$\mathcal{C}(S) \stackrel{\text{def}}{=} \{(i,n), i \in V, n \leq n_i \mid \exists j \in V, m > n_j, (i,n) \to (j,m)\} . \tag{10}$$

The cut $\mathcal{C}(S)$ is consecutive and its right section is S. Furthermore, if any node is removed from the left section of $\mathcal{C}(S)$, then it is not a cut anymore.

In a cut C, a node $(i,n) \in C$ is *redundant* if $C \backslash \{(i,n)\}$ is a cut. Any consecutive cut C with no redundant node on its left section is characterized by its right section $\underline{S}$ only. More precisely, it verifies $C = \mathcal{C}(\underline{S})$.

We are now ready to state the relations between delays in $\mathcal{R}$ and consecutive cuts in $\mathcal{D}$.

LEMMA 6.6. (i) *The number of delays $\Gamma_B(\mathcal{R})$ is equal to the cardinal of $\mathcal{C}(S_0)$.* (ii) *Let r be a retiming of $\mathcal{R}$ and S_r an associated section in $\mathcal{D}$. Then the number of delays $\Gamma_B(\mathcal{R}_r)$ is equal to the cardinal of the cut $\mathcal{C}(S_r)$ in $\mathcal{D}$ (resp., $\mathcal{C}(S_0)$ in $\mathcal{D}_r$).*

Proof. The isomorphism f_r transforms the section $\mathcal{S}_r$ in $\mathcal{D}$ into the section $\mathcal{S}_0$ in $\mathcal{D}_r$. Hence (ii) is implied by (i). Let us work on graph $\mathcal{D}$. We are going to prove that $\Gamma_B(\mathcal{R}) = |\mathcal{C}(\mathcal{S}_0)|$. We consider a node i of $\mathcal{R}$. Let $m = \max\{\gamma \mid \exists j,\ (i,\gamma) \in \Delta_j\}$ (we have $m \geq 1$ as $(i,1) \in \Delta_i$) and let j be such that $(i,m) \in \Delta_j$. There is an arc in $\mathcal{D}$ from $(i,-m)$ to $(j,0)$ and no arc from a node on the "left" of $(i,-m)$ (and on line i) to a node on the "right" of S_0. Hence $\mathcal{C}(S_0)$ contains the nodes $(i,-m+1), \ldots, (i,0)$ on line i. The same argument repeated on each line finishes the proof. □

We recall that the arcs crossing a section *from right to left* and *from left to right* are defined in Definition 5.1.

LEMMA 6.7. (i) *The number of delays $\Gamma_A(\mathcal{R})$ is equal to the number of arcs crossing S_0 from left to right minus the number of arcs crossing it from right to left.* (ii) *Let r be a retiming of $\mathcal{R}$ and S_r an associated section in $\mathcal{D}$. The number of delays $\Gamma_A(\mathcal{R}_r)$ is equal to the number of arcs in $\mathcal{D}$ (resp., $\mathcal{D}_r$) crossing section S_r (resp., S_0) from left to right minus the number of arcs crossing S_r (resp., S_0) from right to left.*

Proof. For the same reason as in Lemma 6.6, it is enough to prove (i). Let (i,j) be an arc of $\mathcal{R}$ with delay $\gamma \geq 0$. In $\mathcal{D}$, this arc induces exactly γ arcs crossing S_0 from left to right, the arcs

$$(i,-\gamma+1) \to (j,1) \quad \cdots \quad (i,-1) \to (j,\gamma-1), \quad (i,0) \to (j,\gamma) .$$

Similarly, an arc (i,j) with delay $\gamma < 0$ induces exactly $-\gamma$ arcs crossing S_0 from right

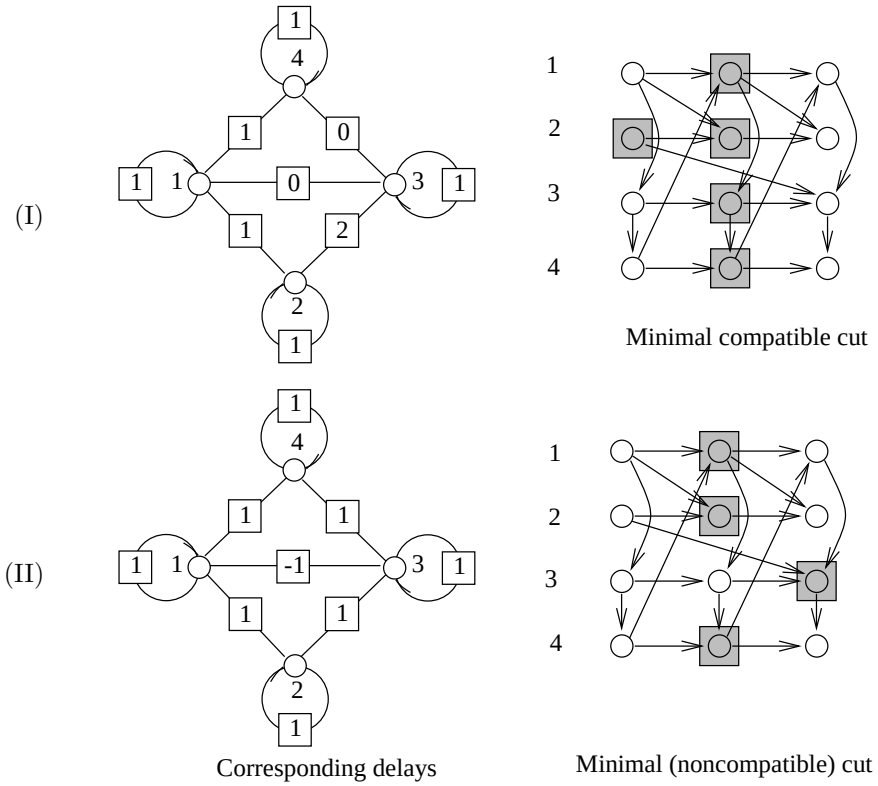

FIG. 13. *Compatible and noncompatible cuts, nonnegative and negative delays.*

to left:

$$(i,1) \to (j,\gamma+1) \quad \cdots \quad (i,-\gamma-1) \to (j,-1), \quad (i,-\gamma) \to (j,0)\,.$$

The same argument applied to all the lines finishes the proof. □

The notion of compatible cuts introduced in Definition 5.2 has a very natural interpretation in terms of delays.

LEMMA 6.8. *Let r be a retiming of $\mathcal{R}$ and S_r an associated section in $\mathcal{D}$. The retimed reduced graph $\mathcal{R}_r$ has only nonnegative delays if and only if the cut $\mathcal{C}(S_r)$ is compatible in $\mathcal{D}$ (equivalently, the cut $\mathcal{C}(S_0)$ is compatible in $\mathcal{D}_r$).*

Proof. If $\mathcal{R}_r$ has only nonnegative delays, the argument used in the proof of Lemma 6.7 shows that all the arcs crossing S_r in $\mathcal{D}$ cross it from left to right. It implies that the cut $\mathcal{C}(S_r)$ is compatible. The converse result is proved by contradiction, using again the proof of Lemma 6.7. □

In Figure 13 (this example is the same as the one in Figure 10), we have represented the retimed reduced graphs associated with two sections (cuts) of $\mathcal{D}$. One of them is compatible and the other one is not compatible.

6.4. Summary. In section 4.2, we have established the relations between executions of the pebble game and cuts in the dependence graph. In section 6.3, we have established the relations between cuts and delays. As a by-product, we obtain the relations between delays and pebble configurations.

More precisely, let $e = \{\mathcal{A}(t), t \in \mathbb{N}\}$ be an execution such that $\mathcal{A}(t)$ is a consecutive and nonredundant (see section 6.3) cut $\forall t$. Note that we did not assume that e

is regular. With the configurations $\mathcal{A}(t)$, we associate a retiming $r(t)$ and a reduced graph $\mathcal{R}_{r(t)}$ as follows:

$$r(t)_i = \max\{n_i \mid (i, n_i) \in \mathcal{A}(t)\} .$$

We have the following situations:

- If the execution e belongs to $\mathcal{E}$, the configurations $\mathcal{A}(t)$ may have different shapes at each step. Then the reduced graphs $\mathcal{R}_{r(t)}$ may have changing values for the delays.
- For an execution e belonging to $\mathcal{RE}$, the configurations are just shifted between two steps. It implies that the reduced graphs $\mathcal{R}_{r(t)}$ are all identical, with a fixed value of the delays.
- Finally, an execution e belonging to $\mathcal{ORE}$ corresponds to identical reduced graphs $\mathcal{R}_{r(t)}$ with fixed and nonnegative values of the delays.

In the following table, we provide a summary of the main relations established so far between executions of a system of UREs, cuts in $\mathcal{D}$, and delays in $\mathcal{R}$.

Games	Executions	Cuts in $\mathcal{D}$	Delays in $\mathcal{R}$
$\mathcal{M}_1$	execution in $\mathcal{E}$	arbitrary cut	changing delays
$\mathcal{M}_2$	regular execution, $\mathcal{RE}$	consecutive cut	fixed delays
$\mathcal{M}_3$	one-pass reg. exec., $\mathcal{ORE}$	compatible cut	nonnegative fixed delays

A general remark is that the main theoretical results, Theorems 4.11 and 5.5, apply only to recycled graphs. Using them, we have been able to solve problem MinPeb for an initial graph which is recycled. However, the solution proposed involves the construction of an associated graph, which is not recycled. It is not a problem, as we do not need to apply Theorems 4.11 or 5.5 on this associated graph.

6.5. Complexity results for $\mathcal{M}_3$.

PROPOSITION 6.9. *Let $\mathcal{R} = (V, E, \Gamma)$ be the reduced graph associated with a recycled system of UREs. Under game $\mathcal{M}_3$, problem* MinPeb *can be solved using an algorithm of complexity $O(|E|^2 \log |V| + |V||E| \log^2 |V|)$.*

Proof. As detailed above, there is a one-to-one correspondence between minimal one-pass regular executions and retimed reduced graphs with nonnegative delays.

In Leiserson and Saxe (section 8 of [17]) an algorithm is given to solve the following problem: find a retimed reduced graph $\mathcal{R}_r$ with only nonnegative delays and minimizing $\Gamma_B(\mathcal{R}_r)$. It is a minimum-cost flow algorithm; it provides an explicit solution and its complexity is $O(|E|^2 \log |V| + |V||E| \log^2 |V|)$. Using Lemmas 5.3 and 6.6, the cut $\mathcal{C}(S_r)$ is compatible and the execution $\{\mathcal{C}(S_r) + t, t \in \mathbb{N}\}$ is one-pass regular and solves problem MinPeb under rules $\mathcal{M}_3$ according to Theorem 5.5. □

The algorithm of [17] was developed in the context of digital circuits; see section 7. An efficient implementation of this algorithm can be found in Shenoy and Rudell [24].

7. Application 1: Registers in circuit design. In this section we will show how the previous results relate to the problem of register minimization in digital circuits. The interest of the relation is two-fold. First, algorithms developed for digital circuits can be used to get optimal executions of a system of UREs; see the previous section. Second, we will show that the results proved so far enable us to prove some new results for recycled digital circuits; see Theorem 7.4 below.

7.1. Definition of a circuit. A digital circuit is constituted by functional gates, wires, and registers. More precisely, (i) a functional element computes output data from one or several input data. For example, in the case of a logical circuit, the functional elements will be boolean logical gates (AND, OR, ...); (ii) a wire between element i and element j enables us to transfer the output data of i which becomes an input data for j; (iii) a register corresponds to a storage facility, or a memory cell of finite size. If there are p registers between elements i and j, it enables us to keep in memory the last p values computed by the element i.

The model of the behavior of the system is the following. There is a global clock for the system. Between two clock ticks, here are the operations taking place.

- Functional element: (1) receive the input data from upstream registers or elements; (2) compute a new output data; (3) send the output data to downstream registers or elements.
- Register: (1) transmit the stored data downstream to another register or a functional element; (2) remove the stored data; (3) receive and store new data from upstream from another register or a functional element.

Between two clock ticks, these operations are performed at *all* functional elements and registers.

Let $X_i(n)$ be the nth variable computed at element i. Since registers are finite size memory cells, the variables $X_i(n)$ can only take a finite number of values. The set of all these possible values is denoted by $\mathcal{W}$.

After n clock ticks, for each element i, the variables $\{X_i(m), m \leq n\}$ have been computed. The number of registers on a wire between i and j corresponds to the number of variables $X_i(n-k)$ which need to be still in the memory in order to carry on the computation of the variables $X_j(n+m), m > 0$.

It follows from the previous description that a digital circuit can be viewed as the reduced graph $\mathcal{R}$ of some system of UREs. The functional elements of the circuit correspond to the nodes of $\mathcal{R}$, the wires to the arcs, and the registers to the delays. The computation operation corresponding to the functional element i is denoted by F_i to be consistent with previous notations. In the remainder of the section, we will use interchangeably the terminology of digital circuits and the one of reduced graphs. We consider only *constructive circuits*, i.e., circuits whose associated URE is constructive, and *recycled circuits*, i.e., circuits whose associated reduced graph is recycled.

The specificity of digital circuits (with respect to general reduced graphs) is that *only nonnegative registers (delays) have a physical meaning.*

In Figure 14, we have represented the flow of data between clock ticks in a digital circuit. The graphical convention is consistent with that of reduced graphs.

7.2. Minimizing the number of registers. We consider problem *MinReg*, which is classic in circuit design; see, for instance, Leiserson and Saxe [17, section 8].

PROBLEM 2 (MinReg). *Given a recycled circuit, find a new circuit preserving the functional behavior and having a minimal number of registers.*

To make this statement precise, we have to define rigorously the *functional behavior* and the *number of registers* of a circuit.

Let $\{X_i(n), i \in V, n \in \mathbb{Z}\}$ and $\{\tilde{X}_i(n), i \in \tilde{V}, n \in \mathbb{Z}\}$ be the variables computed by the original and the new circuits, respectively. The preservation of the functional behavior means that we have

$$\forall i \in V,\ \exists u \in \tilde{V},\ \exists c_i \in \mathbb{Z} \text{ s.t. } \forall n \in \mathbb{Z},\ X_i(n) = \tilde{X}_u(n + c_i)\,. \tag{11}$$

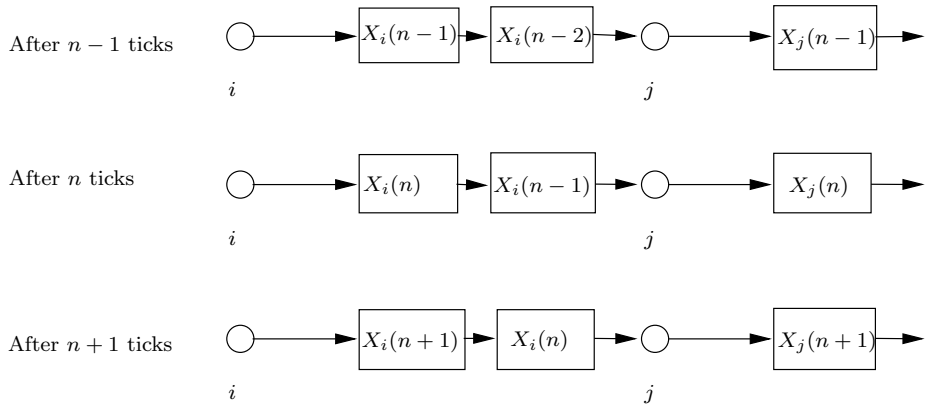

FIG. 14. *Digital circuit computing* $X_j(n) = F_j(X_i(n-2), \dots)$.

Registers can be viewed as delays in a reduced graph and the number of registers of a circuit $\mathcal{R}$ is the quantity $\Gamma_A(\mathcal{R})$ defined in section 6.2. Now, starting from a circuit $\mathcal{R}$, we can always perform the `Forward Splitting` algorithm (Algorithm 6.4) to obtain a circuit $\mathcal{R}'$. As an illustration, consider the example given in Figure 12. The `Forward Splitting` algorithm is called *register sharing* in the context of circuits; see [17].

The problem MinReg is directly connected with the notions introduced in sections 4 and 5. It enables us to propose some complements to the results of [17] for the special case of recycled circuits.

In [17], Leiserson and Saxe define a notion of retiming which is exactly that of Definition 6.1. They restrict their attention to *legal* retimings, as they are the only ones to have a physical meaning for circuits.

DEFINITION 7.1. *A retiming* r *is* legal *if* $\mathcal{R}_r$ *has only nonnegative delays.*

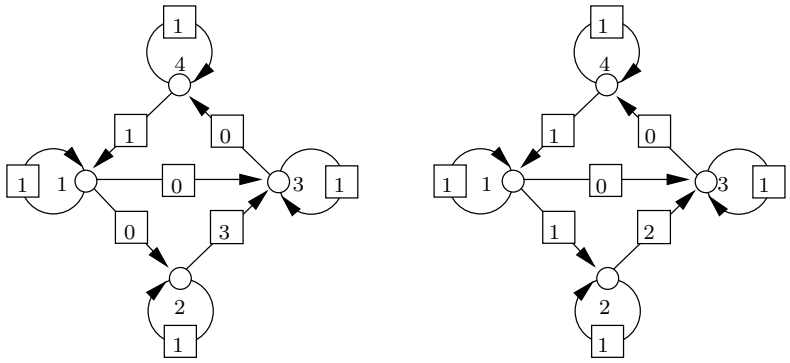
An example of legal retiming is given in Figure 15. If we perform register sharing on the original circuit (Figure 15(a)), we would obtain a circuit with six registers. After a legal retiming and register sharing, we have only five registers (Figure 15(c)).

Leiserson and Saxe proved that retiming and register sharing preserve the functional behavior of the circuit (this is also a direct consequence of Lemma 6.3 and Proposition 6.5). Then they proposed an algorithm to compute the optimal legal retiming and also the optimal legal retiming when register sharing is allowed; see section 6.5.

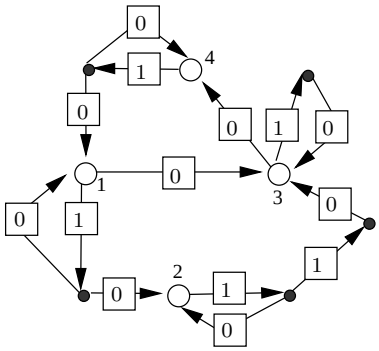
However, the question whether other circuit transformations can be used to get a circuit with even fewer registers remains to be answered.

Let us consider the best possible retiming in the original circuit without restricting ourselves to legal retimings. It corresponds to the choice of a minimal consecutive (but not necessarily compatible) cut in the associated dependence graph $\mathcal{D}$; see section 6.4. In the corresponding reduced graph, there may be some negative delays that cannot represent registers. However, it is possible to perform some appropriate modifications to go back to positive delays. It is done by duplicating some nodes in the circuit.

The `Duplicate` algorithm takes as input a graph $\mathcal{R} = (V, E, \Gamma)$ and produces a new graph $\mathcal{R}' = (V', E', \Gamma'), \Gamma' \geq 0$. In the description to follow, we use the notion of delays on paths: if P is an oriented path in $\mathcal{R}$, then the delay of P is the sum of all the delays on the arcs of P.



(a) Before retiming (8 registers). (b) After optimal legal retiming.



(c) After retiming and register sharing (5 registers).

FIG. 15. *Reducing the number of registers using legal retiming and register sharing.*

ALGORITHM 7.2 (Duplicate).

Input: *Reduced graph* $\mathcal{R} = (V, E, \Gamma)$, *functions associated with the nodes* $\{F_i, i \in V\}$.

1. Set $V' = V$ and $E' = \emptyset$. Associated functions $F'_i = F_i, i \in V$.
2. For each node v in V, let $k(v)$ be the minimum delay of all paths in $\mathcal{R}$ starting in v.
   - Set $v_0 = v$.
   - If $k(v) < 0$, then create $|k(v)|$ additional nodes in V', $v_1, \ldots, v_{|k(v)|}$, with associated functions, $F'_{v_i} = F_v$.
3. For each arc $(u, v) \in E$ with delay $\Gamma(u, v) = \gamma$, create in E' all the arcs of type $(u_{\max(0, j-\gamma)}, v_j)$ with delay $\max(0, \gamma - j) \, \forall 0 \leq j \leq \max(0, k(v))$.

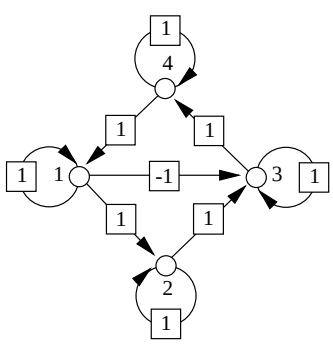
Output: *Reduced graph* $\mathcal{R}' = (V', E', \Gamma')$, $\Gamma' \geq 0$. *Associated functions* $\{F'_i, i \in V'\}$.

For each node $v \in V$, $k(v)$ is finite and is reached on a finite path since the constructivity of $\mathcal{R}$ implies that all circuits in $\mathcal{R}$ have a strictly positive delay.

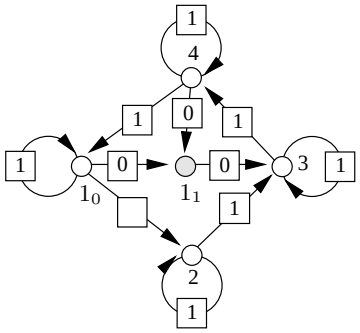
The following proposition justifies the use of the Duplicate algorithm.

PROPOSITION 7.3. *Let* $\mathcal{S}$ *and* $\mathcal{S}'$ *be the systems of UREs associated with* $\mathcal{R}$ *and* $\mathcal{R}'$, *respectively.*

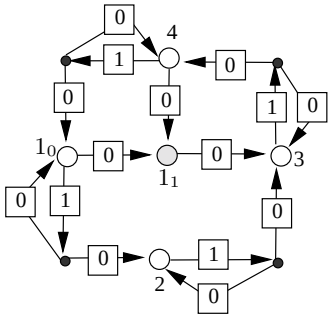
(i) S *and* S' *have the same functional behavior. More precisely, borrowing the*



(a) Circuit after optimal general retiming.



(b) After duplication.



(c) After duplication and register sharing (4 registers).

FIG. 16. *Reducing the number of registers using retiming, duplication and register sharing.*

notation of the `Duplicate` *algorithm, we have*

$$X'_{v_j}(n) = X_v(n+j) \quad \forall v_j \in V', \forall n \in \mathbb{Z}\,. \tag{12}$$

(ii) *We have* $\Gamma_B(\mathcal{R}) = \Gamma_B(\mathcal{R}')$.

Proof. The proof of (i) follows directly from the construction rules of $\mathcal{R}'$. Considering (12), specialized to $j = 0$, we get $X'_{v_0}(n) = X_v(n)$. The original circuit is embedded in the new circuit. As for (ii), note that all the arcs exiting a duplication node (of type $v_j, j > 0$) have a zero delay. As for the new arcs from the nodes of type v_0, they all have delays smaller than or equal to the delays of the arcs of the original graph. The original arcs are kept with their original delays unchanged. We conclude that $\Gamma_B(\mathcal{R}) = \Gamma_B(\mathcal{R}')$. □

It is important to remark that the reduced graph $\mathcal{R}'$ (hence the associated system of UREs) obtained by duplication is not recycled anymore.

We illustrate the algorithm `Duplicate` on an example. The circuit of Figure 16(a) is obtained from the one of Figure 15(a) by performing a nonlegal retiming. By applying the `Duplicate` algorithm, we obtain the circuit of Figure 16(b), where node 1 has been duplicated into nodes 1_0 and 1_1.

Now, after performing register sharing, the resulting circuit has only 4 registers (see Figure 16(c)). The minimal number of registers we could get with only legal retimings and register sharing was 5; see Figure 15(c).

We now state the general result.

THEOREM 7.4. *Let us consider a recycled digital circuit. When the functions computed at each node are general, a circuit with the same functional behavior and a*

minimal number of registers can be obtained by performing solely the three following operations (in this order):

1. *General retiming;* 2. `Duplicate` *algorithm;* 3. `Forward Splitting` *algorithm (register sharing).*

Proof. Let us consider a recycled graph $\mathcal{R} = (V, E, \Gamma)$ (associated dependence graph $\mathcal{D}$). We realize the following operations: 1. Perform the optimal general retiming to obtain a graph $\mathcal{R}_1$. 2. Apply the `Duplicate` algorithm to $\mathcal{R}_1$ to obtain the graph $\mathcal{R}_2$. 3. Transform the graph $\mathcal{R}_2$ into $\mathcal{R}_3$ by applying the `Forward Splitting` algorithm.

Let us detail the first operation. We find a minimal consecutive cut C of $\mathcal{D}$ (Proposition 4.12). Let $\{(i, r(i)), i \in V\}$ be the right section of C. We define the retimed graph $\mathcal{R}_1 = \mathcal{R}_r$. Using Lemma 6.6, $\Gamma_B(\mathcal{R}_1)$ is equal to the cardinal of C.

The three operations preserve the functional behavior of the circuit; see Lemma 6.3 and Propositions 6.5 and 7.3. Furthermore, as a consequence of Proposition 7.3 and (9), we have $\Gamma_B(\mathcal{R}_1) = \Gamma_B(\mathcal{R}_2) = \Gamma_A(\mathcal{R}_3)$. We conclude that $\Gamma_A(\mathcal{R}_3) = |C|$. It remains to be proved that there exists no other circuit having the same functional behavior as $\mathcal{R}$ and with fewer registers than $\mathcal{R}_3$.

We consider $\mathcal{R}' = (V', E', \Gamma')$ another circuit which has the same functional behavior as $\mathcal{R}$. Let $\mathcal{D}'$ be the dependence graph associated with $\mathcal{R}'$. The preservation of the functional behavior implies that the set of nodes in $\mathcal{D}$ is included in the set of nodes in $\mathcal{D}'$. The mapping of the nodes of $\mathcal{D}$ onto $\mathcal{D}'$ that preserves the functional behavior is denoted by ϕ. By definition, $X_i(n) = X'_{\phi(i)}(\phi(n))$ if the node (i, n) in $\mathcal{D}$ is mapped on the node $(\phi(i), \phi(n)) = \phi(i, n)$ in $\mathcal{D}'$.

We consider a minimal cut C of $\mathcal{D}$. In $\mathcal{D}'$, we suppose that there exists a cut C' such that $|C'| < |C|$. We can assume that in $\mathcal{D}'$, we have $\phi(C)$ on the "left" of C' and $\phi(C + k)$ on the "right" of C' by choosing k large enough.

We recall that $\mathcal{W}$ denotes the finite set of possible values for a variable $X_i(n)$. In the dependence graph $\mathcal{D}$, there exists a periodic flow (node-disjoint paths) from C to $C + k$ of size $|C|$ (Corollary 4.8). It implies that there is a general dependence between the variables attached to C and the variables attached to $C + k$, which can be put under the form of a general function $F : \mathcal{W}^{|C|} \to \mathcal{W}^{|C|}$. In particular, the functions F_i in (2) can be chosen such that F is bijective and does not depend on n. For example, choose $F_i(X_j(n - \gamma), \dots) = X_j(n - \gamma)$ if the arc $(j, n - \gamma) \to (i, n)$ belongs to the periodic flow. In this case, the function F is merely a permutation of the coordinates.

Now let us consider the graph $\mathcal{D}'$; using the existence of the cut C', the function F can be decomposed as $F : \mathcal{W}^{|C|} \to \mathcal{W}^{|C'|} \to \mathcal{W}^{|C|}$. As $\mathcal{W}$ is finite, it contradicts the fact that F can be bijective.

The smallest cut C' in $\mathcal{D}'$ is at least as large as C. Finally, by using Lemma 6.6, we conclude that $\Gamma_A(\mathcal{R}') \geq \Gamma_B(\mathcal{R}') = |C'| \geq |C| = \Gamma_A(\mathcal{R}_3)$. □

Recall that, in Leiserson and Saxe [17], only legal retimings were considered. In Theorem 7.4, by considering all possible retimings, we were able to obtain a circuit with fewer registers, and even a minimal number of registers. However, in doing so, we obtain a circuit with a possibly larger number of functional elements. Hence, the practical interest of Theorem 7.4 also needs to be discussed in terms of the compared costs of functional elements and registers. In fact, the number of functional elements is increased both by the `Duplicate` and by the `Forward Splitting` algorithms. On the one hand, in the `Forward Splitting` case, only "dummy functions" are added. In the context of circuits, they consist of simple wire connections and do not perform

any operation, so that they should be very cheap to implement. On the other hand, in the `Duplicate` case, the added elements are equivalent to some of the original functional elements. Hence they could be more expensive to implement.

7.3. Summary and complexity. The transformations done to a circuit in order to obtain an equivalent circuit with the minimal number of registers can be summarized by the following scheme.

$$\begin{array}{ccccccc} & \text{optimal} & & & & \text{forward} & \\ & \text{retiming} & & \text{duplicate} & & \text{splitting} & \\ \mathcal{R} & \longrightarrow & \mathcal{R}_1 & \longrightarrow & \mathcal{R}_2 & \longrightarrow & \mathcal{R}_3 \\ & & \Gamma(\mathcal{R}_1) \in \mathbb{Z}^{E_1} & & \Gamma(\mathcal{R}_2) \in \mathbb{N}^{E_2} & & \Gamma(\mathcal{R}_3) \in \{0,1\}^{E_3} \\ & & \Gamma_B(\mathcal{R}_1) \text{ minimal} & & \Gamma_B(\mathcal{R}_2) = \Gamma_B(\mathcal{R}_1) & & \Gamma_A(\mathcal{R}_3) = \Gamma_B(\mathcal{R}_2) \end{array}$$

COROLLARY 7.5. *Let us consider a recycled digital circuit. A new circuit solving problem MinReg can be obtained with an algorithm of complexity* $O(\Gamma_A(\mathcal{R})^2|V|^2 + |V|^3)$.

Proof. In the proof of Theorem 7.4, the algorithms used to go from $\mathcal{R}$ to $\mathcal{R}_1$, from $\mathcal{R}_1$ to $\mathcal{R}_2$, and from $\mathcal{R}_2$ to $\mathcal{R}_3$ are all polynomial, and $\mathcal{R}_3$ is a solution to the problem MinReg.

To obtain $\mathcal{R}_1$, we apply the algorithm of Proposition 4.12 whose complexity is $O(\Gamma_A^2|V|^2)$. To obtain $\mathcal{R}_2$, we apply the `Duplicate` algorithm (Algorithm 7.2), whose complexity is $O(|V|^3 + \Gamma_A|E|)$. Let us justify this complexity. The first step consists of computing the quantities $k(u), u \in V$. It is equivalent to the search of a minimal weight path in a weighted graph. This can be done using the Floyd algorithm with a complexity $O(|V|^3)$; see, for instance, Gondran and Minoux [14, Chapters 2 and 3]. Let $M = \max_{v\in V}(0, -k(v))$. From the constructiveness, it follows that M has to be smaller than Γ_A. Now, the second step of the algorithm consists of creating at most $M|V|$ nodes and $M|E|$ arcs. The complexity of this step is at most $O(\Gamma_A|E|)$.

To obtain $\mathcal{R}_2$, we apply the `Forward Splitting` algorithm (Algorithm 6.4). In this algorithm, we create at most Γ_B nodes and $|E|$ arcs, which accounts for a complexity $O(\Gamma_B + |E|)$. □

Corollary 7.5 is interesting, as it is not straightforward to extend the original algorithm of Leiserson and Saxe (for legal retimings, see section 6.5) to general retimings.

8. Application 2: Task graphs evaluation. Task graphs are widely used in the modeling and analysis of parallel programs and architectures [1]. Yet, the performance evaluation of task graphs is difficult in general.

The term task graphs covers a wide variety of models, with the following common feature: each task depends on a finite number of tasks and can be executed only when all the tasks it depends on are completed. Here, we consider *repetitive task graphs,* which are bi-infinite task graphs generated by the periodic replication of a given finite task graph (with set of nodes V); see [3].

Let us denote by $X_i(n), i \in V, n \in \mathbb{Z}$, the epoch when the nth occurrence of task i is completed. Let the sets $\Delta_i, i \in V$, describe the dependences between tasks. The variables $X_i(n)$ are given by a recursion of the following form:

$$X_i(n) = \max_{(j,\gamma)\in\Delta_i} (X_j(n-\gamma) + \sigma_{j,i,\gamma}(n)),\ i \in V, n \in \mathbb{Z},\ \sigma_{j,i,\gamma}(n) \in \mathbb{R}\,. \tag{13}$$

We will present the optimization problem which arises in the fast parallel computation of the evolution equations of task graphs and apply the preceding results to solve it.

8.1. Max-plus recurrences. The evolution equations (13) can be viewed as both a specialization and a generalization of a system of UREs. On the one hand, the functions have a specific form, implying only the operations max and +. On the other hand, the functions depend on n. We call a "max-plus recurrence" (MPR) an equation of the form (13). From now on, we assume that the MPR is *constructive* and *recycled*, i.e., that $\forall i, (i,1) \in \Delta_i$. It is a natural assumption for task graphs, as it means that the nth occurrence of a task cannot start before the completion of the $(n-1)$th occurrence of the same task.

The (max,+) formalism is a convenient tool to work with MPR. We briefly introduce it.

DEFINITION 8.1. *The* (max,+) semiring $\mathbb{R}_{\max}$ *is the set* $\mathbb{R} \cup \{-\infty\}$*, equipped with the two operations* max *and* + *denoted, respectively, by* $\oplus$ *and* $\otimes$ *(*$a \oplus b = \max(a,b)$ *and* $a \otimes b = a + b$*). The elements* $-\infty$ *and* 0 *are the neutral elements of the laws* $\oplus$ *and* $\otimes$*, respectively.*

For matrices of appropriate sizes, we define $(A \oplus B)_{ij} = A_{ij} \oplus B_{ij} = \max(A_{ij}, B_{ij})$, $(A \otimes B)_{ij} = \bigoplus_l A_{il} \otimes B_{lj} = \max_l (A_{il} + B_{lj})$, and for a scalar a, $(a \otimes A)_{ij} = a \otimes A_{ij} = a + A_{ij}$. When no confusion is possible, we abbreviate $A \otimes B$ to AB.

We can rewrite (13) with the previously defined notation. Let $X(n)$ be the column vectors of coordinates $X_i(n)$, and let $A(\gamma, n)$ be the matrix with coordinates $A(\gamma,n)_{ij} = \sigma_{j,i,\gamma}(n)$ if $(j,\gamma) \in \Delta_i$ and $A(\gamma,n)_{ij} = -\infty$ otherwise. Now let $U = \{\gamma \mid \exists i, j \text{ s.t. } (j,\gamma) \in \Delta_i\}$ and $\overline{\gamma} = \max_U \gamma$. We have

$$X(n) = \bigoplus_{\gamma \in U} A(\gamma, n) \otimes X(n-\gamma)\,. \tag{14}$$

This is a *linear system* in the $(\max, +)$ semiring.

Representation of order 1. A standard step in the analysis of linear systems is the transformation of a recurrence like (14) into an "equivalent" system of order 1, such as (15), where $\tilde{X}(n), \tilde{X}(n-1) \in \mathbb{R}_{\max}^{\tilde{V}}$, and $A(n-1) \in \mathbb{R}_{\max}^{\tilde{V} \times \tilde{V}}$.

$$\tilde{X}(n) \;=\; A(n-1) \otimes \tilde{X}(n-1). \tag{15}$$

The system in (15) is "equivalent" to the original one if it preserves the functional behavior, meaning that $\forall i \in V$, $\exists u \in \tilde{V}$, $\exists c_i \in \mathbb{Z}$ s.t. $\forall n \in \mathbb{Z}$, $X_i(n) = \tilde{X}_u(n + c_i)$. We say that the system in (15) is an *order* 1 *representation* of the original one.

Assume that all the delays γ in (14) are greater or equal to 1. Then the transformation can be done by setting

$$\tilde{X}_{i|V|+j}(n) = X_j(n-i), \;\; i = 0, \ldots, \overline{\gamma} - 1, \;\; j \in V.$$

In this case, the dimension of the order 1 representation is $|\tilde{V}| = |V|\overline{\gamma}$. We will see below that an order 1 representation can be obtained without any assumption on the delays (except constructivity).

We can now define the main problem to be addressed in this section.

PROBLEM 3 (MinSize). *Given a recycled MPR, find an equivalent MPR of order* 1 *and of minimal dimension.*

For strictly positive delays, it follows from the discussion above that the minimal dimension is at most equal to $|V|\overline{\gamma}$. We will see that in general it is much lower. Problem MinSize is very natural. A practical motivation for it is provided in next section.

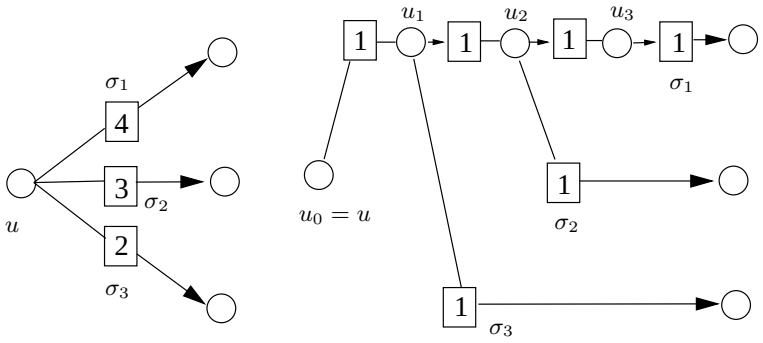


FIG. 17. `Forward Splitting-II` *of a reduced graph.*

Remark 8.2. In problem MinSize, the optimality of the size of the representation should be understood as the best possible that can be obtained without making assumptions on the value of the numbers $\sigma_{i,j,\gamma}(n)$. When these numbers are constant and known, this knowledge may be exploited to obtain a *minimal realization* in the sense of linear system theory [20, 10], which is normally smaller than ours. Finding a minimal realization is a difficult problem, and algorithms are known only in very specific cases. A deeper investigation of the relations between the two approaches is an interesting direction for further research.

8.2. Parallel evaluation of MPR. The *evaluation* of an MPR consists of computing all the variables $X(n)$. We assume that we want to perform this evaluation using a parallel machine. If we have an order 1 representation of the system, a possible and efficient algorithm is the *parallel prefix principle*: as the multiplication of matrices in (max,+) is associative, it is possible to divide the computation of $A(n) \otimes \cdots \otimes A(1)$ into smaller products $A(p) \otimes \cdots \otimes A(q)$ which may be computed by different processors.

The number of operations required to compute the variables up to $X(n)$ on a CREW-PRAM machine with P processors is $O(\ell^3(n/P + \log(P)))$, where ℓ is the size of the matrix of the linear system. Since n and P are fixed parameters, the complexity is minimized by having an order 1 representation of the MPR of minimal dimension.

8.3. Reduced graphs. As for any system of UREs, we can associate a reduced graph $\mathcal{R} = (V, E, \Gamma)$ to a given MPR. To each node $i \in V$, we associate the sequences $\{\sigma_{j,i,\gamma}(n), n \in \mathbb{Z}\}$, $(j, \gamma) \in \Delta_i$.

We will show that the solution to problem MinSize is a matrix of dimension $\min_r \Gamma_B(\mathcal{R}_r), r \in \mathbb{Z}^V$. This result seems to be new.

We transform any reduced graph by the following procedure. For each node in the reduced graph, we create new (dummy) nodes and new arcs in a tree-like fashion, as in Figure 17, such that each arc in the new reduced graph has a delay at most 1. The added dummy nodes are recycled. (The recyclings are not shown on the figure.)

More formally, the transformation can be done using the algorithm `Forward Splitting-II` described below. We use the notation $u^\bullet$ to denote the set of successor arcs of u. It is not assumed that the delays are positive.

ALGORITHM 8.3 (Forward Splitting-II).

Input: *Recycled reduced graph* $\mathcal{R} = (V, E, \Gamma)$. *Sequences* $\{\sigma_{j,i,\gamma}(n), n \in \mathbb{Z}\}$.

`1. We set` $V' = V, E' = \emptyset$.

`2. For all node` $u \in V$`, let` $\delta(u) = \max_{a \in u^\bullet} \Gamma(a)$.

(The graph is recycled, so $\delta(u) \geq 1$)
If $\delta(u) = 1$, then u and $u^\bullet$ remain unchanged.
If $\delta(u) > 1$, then
- in E', set $u_0 = u$ and create $\delta(u) - 1$ recycled nodes $u_1, \ldots, u_{\delta(u)-1}$.
  Create the arcs $a_i = (u_i, u_{i+1})$ with delay $\Gamma'(a_i) = 1$ for $i = 0, \ldots, \delta(u) - 2$.
  The sequences associated with nodes $u_i, i > 0$ are $\{\sigma'_{u_i,u_{i+1},1}(n), n \in \mathbb{Z}\} = 0$.
- For each arc (u, v) in E with delay γ,
  - if $\gamma \leq 1$, then create in E' the arc (u_0, v_0) with delay γ and sequence $\{\sigma'_{u_0,v_0,\gamma}(n)\} = \{\sigma_{u,v,\gamma}(n)\}$
  - else create in E' the arc $(u_{\gamma-1}, v_0)$ with delay 1 and sequence $\{\sigma'_{u_0,v_{\gamma-1},1}(n)\} = \{\sigma_{u,v,\gamma}(n)\}$.

Output: *Recycled reduced graph* $\mathcal{R}' = (V', E', \Gamma')$. *Sequences* $\{\sigma'_{u,v,\gamma}(n), n \in \mathbb{Z}\}$.

The new reduced graph has a maximum delay per arc equal to 1.

PROPOSITION 8.4. *We use the notation defined in the above algorithm.*

(i) *The reduced graph* $\mathcal{R}'$ *has the same functional behavior as the original graph* $\mathcal{R}$*:*

$$X'_{u_i}(n) = X_u(n - i) \quad \forall u \in V,\ \forall n \in \mathbb{Z}\,. \tag{16}$$

(ii) *The number of nodes in* $\mathcal{R}'$ *is* $|V'| = \Gamma_B(\mathcal{R})$.

Proof. Point (i) follows directly from the algorithm. Let us prove point (ii). Using the notation of Algorithm 8.3, in the new reduced graph, we have $\delta(u)$ nodes $(u_0, u_1, \ldots, u_{\delta(u)-1})$ for each node u in $\mathcal{R}$. The total number of node in $\mathcal{R}'$ is $\sum_{u\in\mathcal{R}} \delta(u) = \Gamma_B(\mathcal{R})$. □

Proposition 8.4 is already an improvement over the standard representation as we obtain an order 1 MPR of dimension $\Gamma_B(\mathcal{R})$ instead of $\overline{\gamma}|V|$. Another improvement consists of finding first a retiming r of the graph such that $\Gamma_B(\mathcal{R}_r)$ is minimized.

To fix the notation, let $\mathcal{R} = (V, E, \Gamma)$ be the original reduced graph and $\mathcal{R}_1 = (V, E, \Gamma_1)$ be a retimed reduced graph minimizing Γ_B. We perform the `Forward Splitting-II` algorithm on $\mathcal{R}_1$ to get a new graph $\tilde{\mathcal{R}} = (\tilde{V}, \tilde{E}, \tilde{\Gamma})$ with all delays smaller or equal to 1.

Some of the delays of $\tilde{\Gamma}$ might be negative. However, we prove that it is still possible to get an order 1 representation of dimension $|\tilde{V}|$ of the MPR associated with $\tilde{\mathcal{R}}$. We denote by $a^\bullet$ the ending node of an arc $a \in \tilde{E}$.

LEMMA 8.5. *Let* $\{\tilde{X}_i(n), i \in \tilde{V}, n \in \mathbb{Z}\}$ *be the variables associated with* $\tilde{\mathcal{R}}$. *We have*

$$\tilde{X}(n) = B(n) \otimes \tilde{X}(n - 1), \tag{17}$$

with $B_{ij}(n) = \max_{\pi\in\Pi_{j,i}} \sum_{a\in\pi\cap\tilde{E}} \sigma_{a,\tilde{\Gamma}(a)}(n - m(a, \pi))$, *where* $\Pi_{j,i}$ *is the set of all the paths from* j *to* i *in* $\tilde{\mathcal{R}}$ *with total delay equal to* 1 *and* $m(a, \pi)$ *is the total delay on the path* π *from* $a^\bullet$ *to node* i.

Proof. The first stage of the proof consists of showing that all paths ending in node i have a total delay at least 1 provided they are long enough. Let π be a path ending in i. The length (number of nodes) of π is denoted by $l(\pi)$. Let h be the sum of the negative delays in $\tilde{\mathcal{R}}$: $h = \sum_{a\in\tilde{E}} \min(0, \tilde{\Gamma}(a))$. Assume that $l(\pi) > (-h+2)|\tilde{V}|$. Therefore, the path π must contain at least $-h + 2$ cycles. By constructivity, each

cycle has a total delay which is strictly positive. The set of cycles contained in π is denoted $C(\pi)$. Then,

$$\begin{aligned}\tilde{\Gamma}(\pi) &= \sum_{p\in\pi}\tilde{\Gamma}(p)\\ &= \sum_{p\in C(\pi)}\tilde{\Gamma}(p) + \sum_{p\in\pi\setminus C(\pi)}\tilde{\Gamma}(p) \;\geq\; |C(\pi)| + h \;\geq 2\,.\end{aligned}$$

All the paths in $\Pi_{j,i}$ have a length smaller than $(-h+2)|\tilde{V}|$. Since the graph $\tilde{\mathcal{R}}$ is finite, then $\Pi_{j,i}$ is a finite set.

Now, the equation on variables $\tilde{X}_i(n)$ in $\tilde{\mathcal{R}}$ can be written as

$$\begin{aligned}\tilde{X}_i(n) &= \max_{(j,\gamma)\in\tilde{\Delta}_i}(\tilde{X}_j(n-\gamma)+\tilde{\sigma}_{j,i,\gamma}(n))\\ &= \max_{(j,\gamma)\in\tilde{\Delta}_i,\gamma=1}(\tilde{X}_j(n-1)+\tilde{\sigma}_{j,i,1}(n)) \vee \max_{(j,\gamma)\in\tilde{\Delta}_i,\gamma\leq 0}(\tilde{X}_j(n-\gamma)+\tilde{\sigma}_{j,i,\gamma}(n)).\end{aligned}$$

In the latest equation, we replace all the variables $\tilde{X}_j(n-\gamma), \gamma\leq 0$, by their value until getting only variables of the type $\tilde{X}_j(n-\gamma), \gamma = 1$. By using the distributivity of $+$ with respect to max, we get (17). □

Using the results of the previous sections, and in particular Theorems 4.11 and 7.4 and Lemma 6.6, we obtain the following theorem.

THEOREM 8.6. *Given a recycled MPR, its associated MPR of order* 1 *and of minimal size (problem* MinSize*) has the same size as the minimal cut in the dependence graph of the MPR.*

Proof. We provide a sketch of the proof, which is an adaptation of that of Theorem 7.4. There, we used in a critical way the existence of a *finite* set $\mathcal{W}$ of possible values for the variables in a digital circuit. In an MPR, the variables take their value in $\mathbb{R}\cup\{\infty\}$, but on the other end, the function involved are all (max,+)-linear. Hence, we adapt the argument of Theorem 7.4 as follows.

We have to prove that a (max,+)-linear function from $\mathbb{R}^{|C|}$ to $\mathbb{R}^{|C|}$ ($|C|$ being the size of the minimal cut in the dependence graph $\mathcal{D}$) where the coefficients $\sigma_{ijk}(n)$ are arbitrary may not be further reduced.

Let $C = \{(i_1,n_1),\ldots,(i_{|C|},n_{|C|})\}$ be a minimal cut in $\mathcal{D}$ and let $\{X_{i_j}(n_j), j = 1,\ldots,|C|\}$ be the corresponding set of variables. Now, choose an integer k large enough such that C and $C+k$ do not share any node. There exists $|C|$ node-disjoint paths in $\mathcal{D}$ from C to $C+k$. Let $\mathcal{F}_C$ be the flow constituted by these paths. On each one of these paths, choose all the σ variables to be equal to 0. On all the arcs between C and $C+k$ which do not belong to those paths, set the σ variable to be smaller than $-\max_{j,k}|X_{i_j}(n_j)-X_{i_k}(n_k)|$. Let (i_l,n_l+k) be the successor on $(C+k)$ of (i_j,n_j) following the flow $\mathcal{F}_C$. We have $X_{i_l}(n_l+k) = X_{i_j}(n_j)$.

The set $\{X_{i_j}(n_j+k), j=1,\ldots,|C|\}$ is formed by independent variables $\forall k$ and cannot be reduced. The corresponding matrices $B(n)$ are permutation matrices (i.e., there exists a permutation σ such that $B_{\sigma(j),j}=0$ and $B_{ij}=-\infty$ for $i\neq\sigma(j)$). The remainder of the argument follows Theorem 7.4. □

8.4. Summary and complexity. A summary of the algorithm to find a solution to problem MinSize is given by the following scheme.

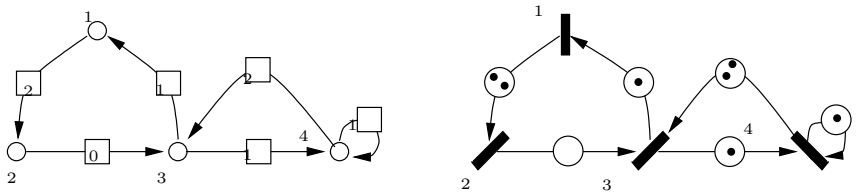

FIG. 18. *Transformation of a reduced graph* (a) *into a Petri net* (b).

$$\begin{array}{ccccccccc} & \text{reduced graph} & & \text{optimal retiming} & & & \text{forward splitting II} & & \text{Lemma 8.5} & \\ \text{MPR} & \longrightarrow & \mathcal{R} & \longrightarrow & \mathcal{R}_1 & \longrightarrow & \mathcal{R}_2 & \longrightarrow & \text{MPR} \\ \text{order } k & & & & \Gamma(\mathcal{R}_1) \in \mathbb{Z}^{E_1} & & \Gamma(\mathcal{R}_2) \leq 1 & & \text{order 1} \\ \text{dim. } |V| & & & & \Gamma_B(\mathcal{R}_1) \text{ minimal} & & |V_2| = \Gamma_B(\mathcal{R}_1) & & \text{dim. } |V_2| \end{array}$$

COROLLARY 8.7. *Let us consider a recycled MPR. An order* 1 *representation solving problem MinSize can be obtained with an algorithm of polynomial complexity to obtain graph* $\mathcal{R}_2$ *and pseudopolynomial complexity to construct matrix* $B(n)$.

Proof. This is a sketch of the proof. Let $\mathcal{R} = (V, E, \Gamma)$. The graph $\mathcal{R}_1$ is obtained using the algorithm of Proposition 4.12 whose complexity is $O(\Gamma_A(\mathcal{R})^2|V|^2)$. The graph $\mathcal{R}_3$ is obtained by applying the `Forward Splitting-II` algorithm. In this algorithm, we create at most $\Gamma_B(\mathcal{R}_2)$ nodes and $\Gamma_B(\mathcal{R}_2) + |E|$ arcs. Its complexity is at most $\Gamma_B(\mathcal{R}_2) + |E|$. The computation of an element of matrix $B(n)$ defined in Lemma 8.5 is NP-complete (reduction of knapsack with multiplicities). However, it can be obtained with pseudopolynomial complexity using dynamic programming techniques (similar to knapsack). □

Given an initial reduced graph $\mathcal{R}$, problem MinReg in section 7 and problem MinSize in section 8 are solved using the same graph $\tilde{\mathcal{R}}$, which is the retimed graph of $\mathcal{R}$ minimizing Γ_B. However, the exact solutions of problems MinReg and MinSize are obtained by performing two different types of transformations on $\tilde{\mathcal{R}}$, yielding two different graphs, say, $\mathcal{R}_{\text{reg}}$ and $\mathcal{R}_{\text{size}}$.

In general $\mathcal{R}_{\text{reg}}$ does not provide a solution to problem MinSize (it does not have a minimal number of nodes) and $\mathcal{R}_{\text{size}}$ does not provide a solution to problem MinReg (it does not have a minimal number of registers). To check this, consider, for instance, the graph of Figure 12 and apply the `Forward Splitting-II` algorithm to it. We conclude that the problems MinReg and MinSize are different, although related.

8.5. Event graphs. *Event graphs*, a subclass of *Petri nets*, are commonly used to model discrete event systems [2, 19]. The graphical formalism for event graphs is close but different from the one of reduced graphs; see Figure 18.

In the case of a timed recycled event graph, the dynamic can be represented by an MPR as in (13) with $\sigma_{i,j,\gamma}(n) = \phi_i(n) + h_{i,j},\ \phi_i(n) \geq 0, h_{i,j} \geq 0$. Since the variables $\sigma_{i,j,\gamma}(n)$ are not general, the MPR of order 1 given by Theorem 8.6 may not be minimal. For example, the removal of *implicit places* may reduce the dimension of an order 1 representation. Let us also mention that preliminary results on the problem MinSize for event graphs were proved in [4, 11, 13], precisely the existence of an order 1 representation of dimension $\Gamma_A(\mathcal{R})$ $(\geq \Gamma_B(\mathcal{R}))$.

9. Conclusion and perspectives. Let us summarize the main results obtained. We restricted our attention to recycled systems of UREs. We proved that the optimal solutions for problem MinPeb are the same for games $\mathcal{M}_1$ and $\mathcal{M}_2$; see Theorem 4.11. On the other hand, an optimal solution for game $\mathcal{M}_3$ may be strictly larger than one for the games $\mathcal{M}_1$ and $\mathcal{M}_2$; see the example of Figure 10.

There exist polynomial algorithms to solve problem MinPeb for the games $\mathcal{M}_1$, $\mathcal{M}_2$, and $\mathcal{M}_3$; see sections 4.3 and 6.5. These results have been applied to minimize the number of registers in a digital circuit and to minimize the size of a (max,+) recurrence.

To complete the picture, it would be nice to extend all the previous results to the nonrecycled case. The key results which would make everything else easy to generalize are of two types. Results related to cuts (see section 4.1) and results linking cuts and regular configurations (see section 4.2). For example, is it possible to find a minimal cut which is consecutive (generalization of Lemma 4.7)? Can we find a minimal consecutive cut which is a regular configuration (generalization of Lemma 4.9)? We are currently investigating these different issues.

Appendix A. Scheduling problems. The problem of organizing efficient computations for UREs on parallel computers has been considered by several authors. However, the investigations have often been oriented toward speeding up the execution with little or no consideration for memory requirements. We quickly describe the main results in this area as a way to put our approach into perspective.

A.1. Definition of a schedule. Assume that at time 0, the strictly negative variables $X_i(n), n < 0$, are known. Assume also that each computation of a variable is done in one time unit.

DEFINITION A.1 (schedule). *We define a* schedule *as a set of instants* $\{t_i(n), i \in V, n \in \mathbb{N}\}$ *such that* $t_i(n) \geq t_j(n-\gamma)+1$ *if* $(j,\gamma) \in \Delta_i$ *(with the convention* $t_i(n) = 0\ \forall i \in V, \forall n < 0$*).*

The instant $t_i(n)$ is necessarily larger than the length (number of arcs) of a longest path in $\mathcal{D}$ from column -1 to (i,n). A schedule is said to be *as soon as possible* (asap) if $t_i(n)$ is exactly equal to the length of the longest path from column -1 to (i,n).

A first question that has been addressed is

What is the number of processors required to carry out a computation asap?

This number is often called the *degree of parallelism* of the URE. In general, the solution is given by the size of the maximal anticliques (instead as the minimal cuts of the present paper) in the dependence graph.

Once this question is settled, and provided a sufficient number of processors is available (i.e., larger than the degree of parallelism of the system), another problem is to characterize the asap schedule. This is often called the *basic scheduling problem*. For the asap schedule, it has been proved (see [5, 6, 2]) that

$$\exists N, \forall n \geq N,\ t_i(n) = \lambda_i n + d_i(n), \tag{18}$$

where $\lambda_i \in \mathbb{R}^+$ and $d_i(n), n \geq N$, is a periodic real function. The real $\max_i \lambda_i$ is called the *cycle time* of the system. A schedule satisfying (18) is said to be *linear*. For systems of higher dimension (i.e., when $K = \mathbb{Z}^p,\ p > 1$, in (1)), there are some partial results on how to approximate the asap schedule using linear schedules; see [7, 8].

When the number of available processors is fixed and less than the degree of parallelism of the URE, finding an optimal schedule (i.e., a schedule such that the quantity $\lim_n \max_i t_i(n)/n$ is minimal) becomes NP-hard; see [15].

All the results mentioned above are more or less related to the problem of minimizing the number of processors used. On the other hand, in this paper, we considered the dual problem: How many memory locations are necessary to carry out the computation of an URE, the number of processors being unlimited?

First, we should say that, in general, a computation asap requires a lot of memory. It may not even be bounded when the reduced graph $\mathcal{R}$ is connected but not strongly connected. This makes the alternative of using a smaller memory size attractive. Second, the usual time-space trade-off tells us that some interesting results can be expected to arise when minimizing the memory size.

We have shown in the previous sections how to obtain executions using a minimal memory size. In general the schedules associated with these minimal-memory executions are not asap. A natural question to ask is whether they are very far from the asap execution or not.

For minimal-memory executions, the number of processors needed to carry out the computations will in general be greater than the degree of parallelism. A second natural question is whether it is very far from the degree of parallelism or not. These two questions are now investigated.

A.2. Number of processors and linearity of the schedule. In $\mathcal{M}_1, \mathcal{M}_2$, and $\mathcal{M}_3$, rules (R2), (R2b), or (R2c) do not limit a priori the number of moves of type (R3) which are feasible in one step. It corresponds to a computational model where the number of processors available is not limited. However, one can notice a posteriori that the total number of processors needed in the computation is bounded by the maximal number of pebbles $\mathcal{P}(e)$ used during the execution e. Hence, the number of processors needed to implement an execution solving problem MinPeb is kept under control.

In minimal-memory executions, in a single step, we have to compose several of the functions F_i defining the URE to compute the new variables; see section 3.1.

To take into account the "cost" of function composition, we give to each step a duration. We assume that step t lasts $l(t)$ units of time, where $l(t)$ is the length of the longest path in $\mathcal{D}$ joining a node of $\mathcal{A}(t-1)$ to a node of $\mathcal{A}(t)$ and containing no other node in $\mathcal{A}(t-1)$. Note that $l(t)$ is also the length of the longest chain of function compositions performed during step t. This is consistent with the assumption that each function computation requires one unit of time. With this convention, we can now define the schedule associated with a synchronous execution.

DEFINITION A.2. *Let $e = \{\mathcal{A}(t), t \in \mathbb{N}\}$ be an execution of game $\mathcal{M}_1$ (or $\mathcal{M}_2$ or $\mathcal{M}_3$), and let $l(t), t \in \mathbb{N}$, be the time duration of step t. Then the* schedule *of e, $\{\tau_i(n), i \in V, n \in \mathbb{N}\}$ is defined by*

$$\tau_i(n) = \sum_{t=0}^{T} l(t), \text{ where } T = \inf\{t \mid (i,n) \in \mathcal{A}(t)\}\,.$$

One verifies easily that this is indeed a schedule according to Definition A.1. Let us justify Definition A.2. Within one step, the computations are done in parallel. The duration of one step is the one of the longest computation done in the step. After each step, there is a synchronization barrier which makes the duration of the execution to be the sum of the durations of the steps.

One important point is that $\tau_i(n)$ denotes a time instant and not a step of the game. Indeed, there might be a big difference between the time instant and the step at which nodes are computed. Here is an illustration for game $\mathcal{M}_1$ (see also the discussion following Figure 4 in section 3.1). The initial pebbles remain untouched through the whole execution. An additional pebble is used to mark successively all the positive nodes. In such a case, marking a node on column n takes one step and $\Omega(n)$ units of time. Marking all the nodes up to column n requires $\Omega(n)$ steps and $\Omega(n^2)$ units of time. The schedule associated with this execution is *quadratic*.

We proved that minimal-memory executions can always be chosen to be regular (see section 4). It implies that all steps have a constant duration $l(t) = l$. Moreover, exactly one new variable is computed on each line of $\mathcal{D}$ at each step. It implies that the schedule is linear with cycle time l. Therefore, the linear schedules are dominant for our problem. We conclude that the loss in time efficiency, when compared with asap executions, is kept under control.

Among regular executions, one-pass regular executions (game $\mathcal{M}_3$) are dominant in terms of execution time, since they never "lose" time by computing the same variable twice. However, as seen in section 6, they may require more memory than general regular executions.

To summarize, when compared with asap executions, minimal-memory executions may lose a bit in terms of numbers of processors needed and execution speed but may gain a lot in terms of memory size. They provide new insights on the trade-offs between time and space in the computation of a system of UREs.

Appendix B. Sequential executions. In section 3.1, we introduced different variants of pebble games. All these games allow simultaneous moves of the pebbles. Here is another one, defined by rule $\mathcal{M}_4$, which is close to the ones defined in [21, 23]. Here, pebbles are put on the nodes one at a time when all direct predecessors already have a pebble.

B.1. Definition of a sequential game.

$\mathcal{M}_4$: Sequential execution rules.

- (R1) *(initial position).* $\mathcal{A}(0) \subset V \times \mathbb{Z}^-$, $\mathcal{A}(0) \cap (V \times \{0\}) \neq \emptyset$.
- (R2d) *(playing rule).* One step of the game consists in using rule (R3b) at most once followed by any number of moves of type (R4).
- (R3b) *(adding pebbles).* A pebble can be put on an empty node if all the direct predecessors of this node have a pebble.
- (R4) *(removing pebbles).* Remove a pebble from a node.

Let us consider the example of Figure 19. It corresponds to the same URE as in Figure 4.

Here is a possible execution. At step 0, there are pebbles on the nodes $(1, 0), (2, 0)$, and $(3, 0)$, so that (R1) is satisfied. After step t, suppose that there are three pebbles on the nodes $(1, n), (2, n)$, and $(3, n)$, respectively. At step $t + 1$, we can put a pebble on node $(1, n + 1)$ since all its predecessors (i, n) have a pebble (rule (R3b)). At step $t + 2$, we put a pebble on node $(2, n + 1)$. At step $t + 3$, we put a pebble on node $(3, n+1)$ and we remove the pebbles on nodes (i, n) since they are not needed anymore (rule (R3b) then rule (R4) three times). Then we reiterate the previous three steps.

It is impossible to use fewer pebbles. The minimal number of pebbles required to compute the graph under rule $\mathcal{M}_4$ is five, to be compared with the three pebbles needed under rules $\mathcal{M}_1$ or $\mathcal{M}_2$.

As for the computational model of the game, $\mathcal{M}_4$ corresponds to performing sequential computations. It is relevant if we want to model the computation of the

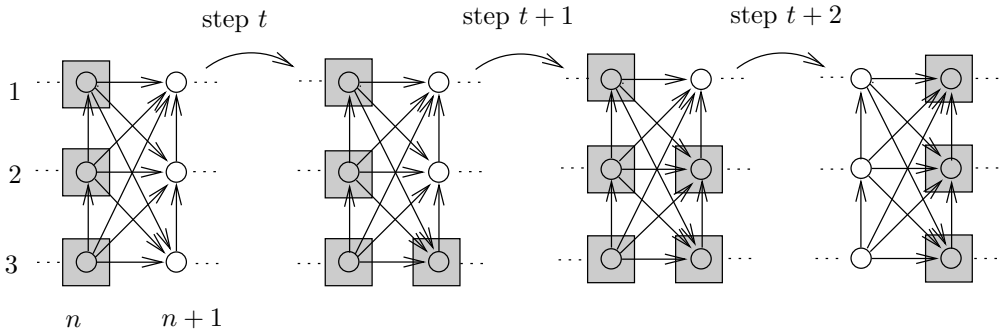

FIG. 19. *Sequential rule $\mathcal{M}_4$. Five pebbles are needed.*

URE using a sequential computer which has a single processor and makes a single computation at each step. The removal of pebbles being a "passive" operation, several such manipulations are allowed in a single step. (The data is not actually removed from the memory; it will just be overwritten the next time this memory location is used.)

In game $\mathcal{M}_4$, a single processor is used. Furthermore, any reasonable execution will compute exactly one new node at each step. Hence, the associated schedule is linear with cycle time $|V|$.

Remark B.1. Game $\mathcal{M}_4$ can be adapted to be played on a finite binary tree (for more details, see the proof of Proposition B.2). In this case, the minimal number of pebbles is known as Strahler's number. This number appears in various fields ranging from hydrology and combinatorics to molecular biology. For a nice survey paper, the reader is referred to Viennot [25].

B.2. Complexity results for $\mathcal{M}_4$. Under game $\mathcal{M}_4$, the problem of determining the minimal number of pebbles to compute a general directed acyclic graph (problem MinPeb-DAG) was proved to be NP-complete by Sethi [23]. We prove a similar result for the problem MinPeb, by showing that an instance of MinPeb-DAG can be embedded into an instance of MinPeb.

PROPOSITION B.2. *Let $\mathcal{D}$ be the dependence graph associated with a system of UREs. Solving problem* MinPeb *for game $\mathcal{M}_4$ is NP-hard. For the subclass of recycled UREs, the same problem is still NP-hard.*

Proof. First we need to define more precisely what is the pebble game $\mathcal{M}_4$ on a DAG. Let V be the set of nodes of a DAG $\mathcal{G}$. A configuration is a subset of V and an execution is a finite sequence of configurations $\{\mathcal{A}_{\mathcal{G}}(t), t = 0, \ldots, L\}$ (where L is the length of the execution). An execution is successful if all the nodes V receive a pebble during the execution. Rules (R2d), (R3b), and (R4) remain the same. Rule (R1) is modified as follows: (R1b) (initial and final position) $\mathcal{A}_{\mathcal{G}}(0) = \mathcal{A}_{\mathcal{G}}(L) = \emptyset$.

Given a DAG $\mathcal{G}$ with set of nodes V, we construct a dependence graph $\mathcal{D}$ with set of nodes $V \times \mathbb{Z}$ in the following way. If there is an arc between nodes i and j in $\mathcal{G}$, then $\forall k \in \mathbb{Z}$, we put an arc between nodes (i,k) and (j,k) and an arc between nodes (i,k) and $(j,k+1)$. We also add the recycling arcs in $\mathcal{D}$ $((i,k) \to (i,k+1)\ \forall i \in V, \forall k \in \mathbb{Z})$. An example is given in Figure 20.

Starting from an execution of the pebble game on $\mathcal{G}$, $\{\mathcal{A}_{\mathcal{G}}(t), t = 0, \ldots, L\}$, we construct an execution of the pebble game on $\mathcal{D}$, $\{\mathcal{A}(t), t \in \mathbb{N}\}$, as follows. The initial configuration is $\mathcal{A}(0) = \{(i,0), i \in V\}$. When a pebble is added on node i in $\mathcal{G}$, we add

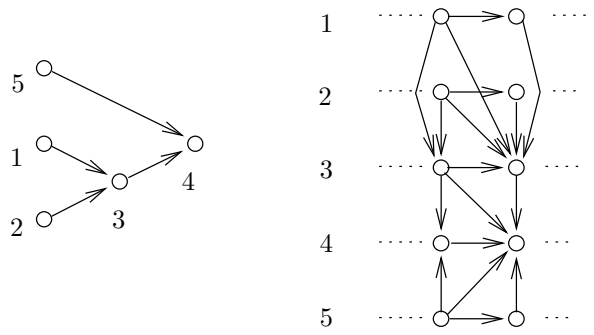

FIG. 20. *Embedding of an arbitrary DAG in a dependence graph.*

a pebble on node $(i, 1)$ in $\mathcal{D}$. When a pebble is removed from node i in $\mathcal{G}$, we remove a pebble from node $(i, 0)$ in $\mathcal{D}$. It follows that at step L, we have $\mathcal{A}(L) = \{(i, 1), i \in V\}$. Then we complete the execution $\{\mathcal{A}(t)\}$ by repeating the same steps periodically, i.e., $\mathcal{A}(t + kL) = \mathcal{A}(t) + k \ \forall t, k \in \mathbb{N}$ (see (6)). If the execution in $\mathcal{G}$ uses p pebbles, the execution in $\mathcal{D}$ requires $p + |V|$ pebbles.

Conversely, from an execution of the game on $\mathcal{D}$, we construct an execution of the game on $\mathcal{G}$ in the following way. By definition, we have $\mathcal{A}(0) \subset \{V \times \mathbb{Z}^-\}$. We set $\mathcal{A}_{\mathcal{G}}(0) = \emptyset$. When a pebble is added on node $(i, 1)$, a pebble is added on node i. When a pebble is removed from node $(i, 0)$, a pebble is removed from node i. If the execution in $\mathcal{D}$ uses P pebbles, the execution in $\mathcal{G}$ requires less than $P - |V|$ pebbles.

One can see that the above transformations map optimal executions into optimal executions (optimal in the sense of problems MinPeb and MinPeb-DAG). Hence, the minimal number of pebbles needed in $\mathcal{D}$ is the minimal number of pebbles needed in $\mathcal{G}$ plus the number of nodes of $\mathcal{G}$. Therefore, the NP-completeness of the problem for DAG (see Sethi [23]) implies that the problem for dependence graphs is at least NP-complete, i.e., NP-hard. □

Proposition B.2 contrasts with the results proved for games $\mathcal{M}_1$, $\mathcal{M}_2$, and $\mathcal{M}_3$, for which a minimal-memory execution was obtained in polynomial time in the recycled case. See section 4.3 (games $\mathcal{M}_1$ and $\mathcal{M}_2$) and section 6.5 (game $\mathcal{M}_3$).

Remark B.3. Let us consider the dependence graph of Figure 20. The execution described in the proof of Proposition B.2 solves problem MinPeb with a number of pebbles which evolves as: $5, 7, 6, 7, 6, 5, \ldots$. The number of pebbles used during an optimal execution is not always constant. Hence, if we consider a nonconnected URE, it is not true that the minimal number of pebbles needed is equal to the sum of the minimal number of pebbles needed for each connected component independently. This contrasts with the situation for games $\mathcal{M}_1, \mathcal{M}_2$, and $\mathcal{M}_3$; see section 2.4.

Acknowledgments. The authors would like to thank Jean-Claude Bermond, Alain Darte, Stéphane Gaubert, Stéphane Perennes, and Mike Robson for numerous discussions and suggestions.

APPROXIMATION ALGORITHMS FOR CURVATURE-CONSTRAINED SHORTEST PATHS*

PANKAJ K. AGARWAL† AND HONGYAN WANG†

Abstract. Let B be a point robot in the plane, whose path is constrained to have curvature of at most 1, and let Ω be a set of polygonal obstacles with n vertices. We study the collision-free, optimal path-planning problem for B. Given a parameter ε, we present an $O((n^2/\varepsilon^4)\log n)$-time algorithm for computing a collision-free, curvature-constrained path between two given positions, whose length is at most $(1+\varepsilon)$ times the length of an optimal path, provided it is robust. (Roughly speaking, a path is robust if it remains collision-free even if certain positions on the path are perturbed). Our algorithm thus runs significantly faster than the previously best known algorithm by Jacobs and Canny whose running time is $O((\frac{n+L}{\varepsilon^2})^2 + n^2(\frac{n+L}{\varepsilon^2})\log n)$, where L is the total edge length of the obstacles. More importantly, the running time of our algorithm does not depend on the size of obstacles. The path returned by this algorithm is not necessarily robust. We present an $O((n^{2.5}/\varepsilon^4)\log n)$-time algorithm that returns a robust path whose length is at most $(1+\varepsilon)$ times the length of an optimal path, provided it is robust. We also give a stronger characterization of curvature-constrained shortest paths, which, apart from being crucial for our algorithm, is interesting in its own right. Roughly speaking, we prove that, except in some special cases, a shortest path touches obstacles at points that have a visible vertex nearby.

1. Introduction.

The *path-planning* problem involves planning a collision-free path for a robot moving amid obstacles. This is one of the main problems in robotics and has been widely studied (see, e.g., the books by Latombe [32] and by Hopcroft, Schwartz, and Sharir [26] and the survey papers by Schwartz and Sharir [47, 48] and Halperin, Kavraki, and Latombe [25]). In the simplest form of the motion planning, given a moving robot B, a set O of obstacles, and a pair of placements I and F of B, we wish to find a continuous, collision-free path for B from I to F. This problem is PSPACE-complete [11, 44], and efficient algorithms have been developed for several special cases [48]. Most of these algorithms, however, do not take into account the dynamic constraints (for instance, velocity/acceleration bounds, curvature bounds), the so-called *nonholonomic constraints*, of a real robot imposed by its physical limitations. Although there has been considerable recent work in the robotics literature (see [3, 6, 8, 10, 17, 23, 28, 30, 31, 33, 34, 36, 37, 38, 40, 45, 51, 52] and references therein) on nonholonomic motion-planning problems, relatively little theoretical work has been done on these important problems, because they are considerably harder than holonomic motion-planning problems.

In holonomic motion planning, the placement of a robot with k degrees of freedom is determined by a tuple of k (typically real) parameters, each describing one degree

of freedom. The set of all placements is called the *configuration space*, and the set of placements at which the robot does not intersect any obstacles is called the *free configuration space*. There exists a path between an initial placement and a final placement if and only if the two placements lie within the same (path-) connected component of the free configuration space. This is not necessarily true if the robot has to obey nonholonomic constraints. In nonholonomic motion planning, usually a placement is not enough to describe the robot. Instead, a robot is completely described by its *state*, consisting of the k parameters and their derivatives (see [32] for a more detailed discussion), which makes the problem considerably harder.

In this paper, we study the path-planning problem for a point robot whose path is constrained to have curvature of at most 1. More formally, given a continuous differentiable path $P : I \to \mathbb{R}^2$ parameterized by arc length $s \in I$, the *average curvature* of P in the interval $[s_1, s_2] \subseteq I$ is defined by $\|P'(s_1) - P'(s_2)\|/|s_1 - s_2|$. We require that the average curvature of the robot's path is at most 1 in every interval. This restriction corresponds naturally to constraints imposed by a steering mechanism on a *car-like* robot (see [32] for a formal description), because the path traced out by the middle point between the two rear wheels has an instantaneous curvature of $\frac{1}{\lambda}\tan\phi$, where ϕ is the steering angle and λ is a parameter of the car. The maximum curvature of the path is therefore $\frac{1}{\lambda}\tan\phi_{\max}$, assuming $\phi_{\max}$ is the maximum steering angle.

Dubins [21] was perhaps the first to study the curvature-constrained shortest paths. He proved that, in the absence of obstacles, a curvature-constrained shortest path from any start position to any final position consists of at most three segments, each of which is either a straight line or an arc of a unit-radius circle. Reeds and Shepp [43] extended this obstacle-free characterization to robots that are allowed to make reversals. Using ideas from control theory, Boissonnat, Cerezo, and Leblond [7] and Sussmann and Tang [50] gave an alternative proof for both cases, and recently Sussmann [49] was able to extend the characterization for the 3-dimensional case. In the presence of obstacles, Fortune and Wilfong [22] gave a $2^{m^{O(1)}}$-time algorithm, where m is the number of bits required to specify the coordinates of all vertices of obstacles, to decide whether a feasible path exists from an initial position to a final position; their algorithm cannot find a feasible path in all the cases. Jacobs and Canny [12, 27] gave an $O((\frac{n+L}{\varepsilon^2})^2 + n^2(\frac{n+L}{\varepsilon^2})\log n)$-time algorithm (this and the next time complexities are based on [12] and are more accurate than the ones given in [27]) that finds an approximate path whose length is no more than $(1+\varepsilon)$ times the length of a shortest *ε-robust* path, where L is the total edge length of the obstacles. (Informally, a path is ε-robust if perturbations of certain positions along the path by $\pm\varepsilon/2$—in distance or in angle—do not violate the feasibility of the path; a formal definition is given in section 2.3.) The path returned by this algorithm is not necessarily robust. They also presented an $O(n^4 \log n + (\frac{n+L}{\varepsilon^2})^2)$-time algorithm that computes an $(\varepsilon/2)$-robust path whose length is no more than $(1+\varepsilon)$-times the length of an optimal ε-robust path. For the restricted case of *moderate obstacles*, i.e., when the obstacles are convex and the curvature of their boundary is also bounded by 1, Agarwal, Raghavan, and Tamaki [2] gave efficient approximation algorithms. Boissonnat and Lazard [9] gave a polynomial-time algorithm for computing the exact shortest paths for the case when the edges of the obstacles are circular arcs of unit radius and straight line segments. Wilfong [51] studied a restricted problem in which the robot must stay on one of m line segments (thought of as "lanes"), except to turn between lanes. For a scene with n obstacle vertices, his algorithm preprocesses the scene in time

$O(m^2(n^2 + \log m))$, following which queries are answered in time $O(m^2)$. There has also been work on computing curvature-constrained paths when B is allowed to make reversals [3, 30, 31, 35, 39]. Other, more general, dynamic constraints are considered in [13, 14, 15, 20, 41, 46].

2. Our model and results. Let B be a point robot. Let Ω be a set of disjoint polygonal obstacles, with a total of n vertices. We refer to edges and vertices of Ω as obstacle *features*. We assume that the edges of Ω are relatively open, so they do not contain their endpoints. A *position* X for B is a pair $(\text{LOC}(X), \text{VEC}(X))$, where $\text{LOC}(X)$ is a point in the plane, representing the location of the robot, and $\text{VEC}(X)$ is an angle between 0 and 2π, representing its orientation. Abusing the notation a little, we will use X to denote $\text{LOC}(X)$ as well if either $\text{VEC}(X)$ is not important or $\text{VEC}(X)$ is obvious from the context. We will use ℓ_X to denote the (oriented) line passing through $\text{LOC}(X)$ in direction $\text{VEC}(X)$, and C_X^+ (resp., C_X^-) to denote the counter-clockwise (resp., clockwise) oriented unit-radius circle tangent to ℓ_X at $\text{LOC}(X)$ whose center lies to the left (resp., right) of ℓ_X. We say that a position X lies on an obstacle vertex if $\text{LOC}(X) = v$ and on an obstacle edge e if $\text{LOC}(X) \in e$ and ℓ_X contains e. A *path* is an oriented curve; $\|\cdot\|$ denotes the length of a path. A path is called *legal* if its average curvature is at most 1 in every interval.

If I and F are the initial and final positions, then we regard $\text{LOC}(I)$ and $\text{LOC}(F)$ as point obstacles. A legal path is *feasible* (with respect to Ω) if it does not intersect the interior of any obstacle of Ω (see Figure 2.1). A path Π from a position X to another position Y is *optimal* if it is a feasible path with the minimum arc length, where the minimum is taken over all feasible paths from X to Y. (The minimum always exists; for a proof, see [27].)

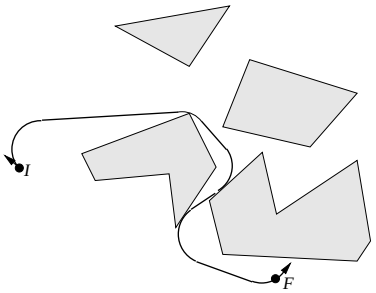

FIG. 2.1. *An example of a feasible path.*

2.1. Dubins paths and canonical paths. We call a nonempty subpath of a feasible path Π a *C-segment* (resp., *L-segment*) if it is a circular arc of unit radius (resp., line segment) and maximal. Suppose Π consists of a C-segment, an L-segment, and a C-segment; then we say that Π is of type CLC. This notion can be generalized to an arbitrarily long sequence. If the orientation of a C-segment—counter-clockwise or clockwise—is important, we use C^+ (resp., C^-) to denote a counter-clockwise (resp., clockwise) oriented C-segment, so C^+LC^- denotes a path consisting of a counter-clockwise C-segment, an L-segment, followed by a clockwise C-segment. Dubins [21] proved the following result.

THEOREM 2.1 (Dubins [21]). *In an obstacle-free environment, an optimal path between any two positions is of type CCC or CLC, or a substring thereof (see Figure 2.2).*

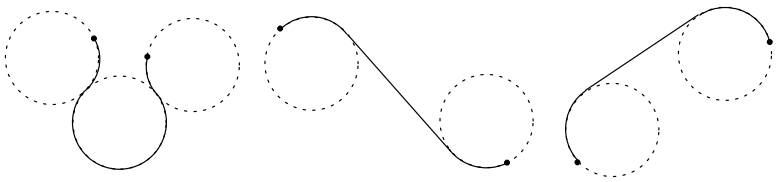

FIG. 2.2. *Examples of Dubins paths.*

We will refer to such paths as *Dubins paths*. If we fix the orientation of initial and final C-segments, then there is at most one CLC (resp., CCC) path between two positions.[1]

Therefore, there are at most four types of CLC paths, namely, C^+LC^+, C^+LC^-, C^-LC^+, and C^-LC^-, and at most two types of CCC paths, namely, $C^+C^-C^+$ and $C^-C^+C^-$. Note that not all types of path exist between two positions X and Y. For example, if the distance between the centers of C_X^+ and C_Y^- is less than 2 (i.e., the two circles intersect), then the C^+LC^- path does not exist from X to Y. Similarly, if the distance between the centers of C_X^+ and C_Y^+ is greater than 4, the $C^+C^-C^+$-type path does not exist from X to Y. Let

$$\mathcal{T} = \{C^+LC^+, C^+LC^-, C^-LC^+, C^-LC^-, C^+C^-C^+, C^-C^+C^-\}.$$

For a Dubins path Π, we define $\sigma(\Pi) \in \mathcal{T}$ to be the string that characterizes Π. If the length of a C- or an L-segment is zero, then $\sigma(\Pi)$ is not uniquely defined; in this case we choose one of them, depending on the context.

Fortune and Wilfong [22] proved that in the presence of obstacles an optimal path consists of a finite sequence of Dubins paths. We call a feasible path from a position I to a position F *canonical* if it consists of a finite sequence $\Pi_1||\cdots||\Pi_k$ of feasible paths, where each Π_i is a Dubins path from a position X_{i-1} to a position X_i, such that $X_0 = I$, $X_k = F$, and, for $0 < i < k$, $\text{LOC}(X_i) \in \partial\Omega$. Since we regard $\text{LOC}(I)$ and $\text{LOC}(F)$ as point obstacles, X_0 and X_k also lie on obstacle boundaries. Jacobs and Canny [27] proved the following property of optimal paths.

THEOREM 2.2 (Jacobs–Canny [27]). *Given a set of polygonal obstacles Ω, an initial position I, and a final position F, every optimal path from I to F is a canonical path.*

This theorem implies that an optimal path is a finite sequence of C- and L-segments, so it can be represented as a finite string over the alphabet $\{C, L\}$.

2.2. Parametrizing canonical paths. Let X be a position lying on the boundary of an obstacle. For the purpose of parametrizing canonical paths, we regard each obstacle edge pq as two oriented edges $\overrightarrow{pq}$ and $\overrightarrow{qp}$. If X lies on an oriented edge $\vec{e} = \overrightarrow{pq}$, then $\text{VEC}(X)$ is fixed, but $\text{LOC}(X)$ may lie anywhere on e. We can specify $\text{LOC}(X)$, and thus X, by a real number $x \in [0, \|e\|]$, which specifies the distance between $\text{LOC}(X)$ and p; see Figure 2.3(a). Similarly, if X lies on an obstacle vertex v, then $\text{LOC}(X)$ is fixed and $\text{VEC}(X)$ may vary. In this case, we can represent X by a real value x in an angular interval $[\theta_l, \theta_r]$, where θ_l, θ_r are the orientations of the edges adjacent to v; see Figure 2.3(b). (We could also parametrize X by a real value in a

[1] Actually, there are two CCC paths if we fix the orientations of the initial and final C-segments. But the length of the middle C-segment is less than π in one of the two paths. It is known that such a path cannot be an optimal Dubins path. Therefore, we will not consider this CCC path and assume that there is only one CCC path.

FIG. 2.3. *Parametrizing positions on obstacle boundaries.*

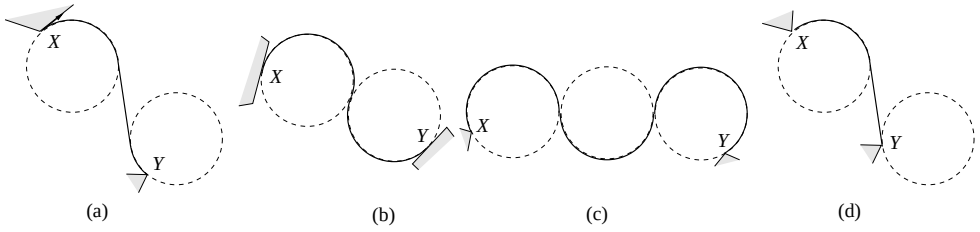

FIG. 2.4. *A few examples of singular points.*

linear interval $[0, \theta_r - \theta_l]$ or $[0, 2\pi + \theta_r - \theta_l]$ depending on whether $0 \in [\theta_l, \theta_r]$.) For two orientations $\phi_1, \phi_2 \in [\theta_l, \theta_r]$, we say that $\phi_1 \leq \phi_2$ if $\theta_l, \phi_1, \phi_2, \theta_r$ appear in that order in the counter-clockwise direction. Hence, a position X lying on an obstacle feature ϕ can be represented as a real parameter $\psi(X)$ that lies in an interval $[l_\phi, r_\phi]$; we will refer to this interval as the *feasible domain* of the feature ϕ. If $X = I$ (resp., F), then its domain is defined to be the singleton $[\text{VEC}(I), \text{VEC}(I)]$ (resp., $[\text{VEC}(F), \text{VEC}(F)]$).

Let Π be a Dubins path from a position X lying on an obstacle feature ϕ_X to another position Y lying on an obstacle feature ϕ_Y. Then Π can be represented by the 3-tuple $\psi(\Pi) = (\psi(X), \psi(Y), \sigma(\Pi))$. Let $\mathcal{I}_1, \mathcal{I}_2$ be the feasible domains of two obstacle features ϕ_1 and ϕ_2, respectively. Then $\mathcal{I}_1 \times \mathcal{I}_2 \times \mathcal{T}$ is the *configuration* space of all Dubins paths from a position on ϕ_1 to another position on ϕ_2. The configuration space of all Dubins paths from a vertex to another vertex is a subset of $\mathbb{S}^1 \times \mathbb{S}^1 \times \mathcal{T}$. By parametrizing $\psi(X), \psi(Y)$ more carefully, the configuration space can be defined as a subset of $\mathbb{R}^2 \times \mathcal{T}$, which will be useful in the following discussion. We can define the configuration space for all other cases as well. As mentioned earlier, not every point in the configuration space defines a path from X to Y.

Consider a point (τ_1, τ_2, σ) in the configuration space and vary the pair (τ_1, τ_2), keeping σ fixed; then the corresponding Dubins path deforms continuously except at certain values, at which the path either ceases to exist or the length of one of the C-segments becomes 0 or 2π, i.e., if one of the events occurs:

(i) $\psi(X)$ or $\psi(Y)$ is an endpoint of its feasible domain (e.g., τ_1 is an endpoint of $\psi(X)$ in Figure 2.4(a));
(ii) $\sigma = C^+LC^-$ and $C^+(X)$ and $C^-(Y)$ are tangent to each other (see Figure 2.4(b));
(iii) $\sigma = C^-LC^+$ and $C^-(X)$ and $C^+(Y)$ are tangent to each other;
(iv) $\sigma = CCC$ and the distance between the centers of the first and the last C-segments is 4 (see Figure 2.4(c)); and
(v) the length of a C-segment is 0 or 2π (e.g., the length of the final C-segment is 0 in Figure 2.4(d)).

A point in a configuration space (or path) satisfying any of the above five conditions

is called *singular*; see Figure 2.4 for a few examples of singular points. We call a point $\tau = (\tau_1, \tau_2, \sigma)$ in the configuration space *infeasible* if the corresponding path is either not defined or intersects the interior of an obstacle; otherwise, it is called *feasible*. The geometry of paths, configuration space of paths, and the topology of infeasible, free, and singular points are studied in detail by Jacobs and Canny [27].

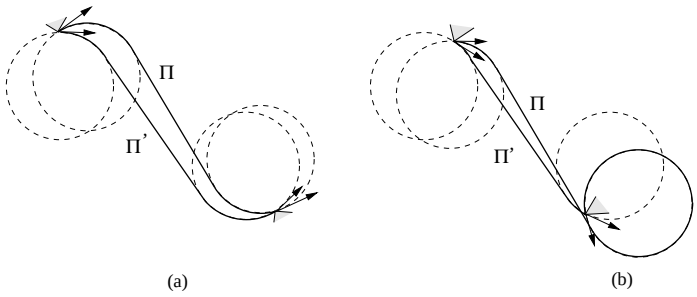

FIG. 2.5. (a) Π *and* Π' *are neighbors;* (b) Π *and* Π' *are not neighbors.*

2.3. Robust paths. Fix two obstacle features ϕ_1, ϕ_2, and let $[l_i, r_i]$ be the feasible domain of ϕ_i. Let $\tau = (\tau_1, \tau_2, \sigma)$ and $\tau' = (\tau_1', \tau_2', \sigma)$ be two points in the configuration space of $\phi_1 \times \phi_2$, i.e., $\tau_i, \tau_i' \in [l_i, r_i]$ for $i = 1, 2$. Let $R(\tau, \tau') = \{(\xi_1, \xi_2, \sigma) \mid \min\{\tau_i, \tau_i'\} < \xi_i < \max\{\tau_i, \tau_i'\}\}$ be the (open) rectangle in the configuration space formed by τ and τ'. We call τ and τ' *neighbors* if none of the points in the rectangle $R(\tau, \tau')$ is singular or infeasible (see Figure 2.5). If τ and τ' are neighbors, then τ can be deformed continuously to any point in the square without intersecting the interior of obstacles. The analysis in section 5 (see Remark 5.3 (ii)) will show that if τ and τ' are neighbors and $|\tau_i - \tau_i'| \leq \delta$ for some $0 \leq \delta \leq 1$, then the paths corresponding to points in $R(\tau, \tau')$ lie in a tube of width $O(\sqrt{\delta})$ drawn around the path corresponding to the center of $R(\tau, \tau')$.

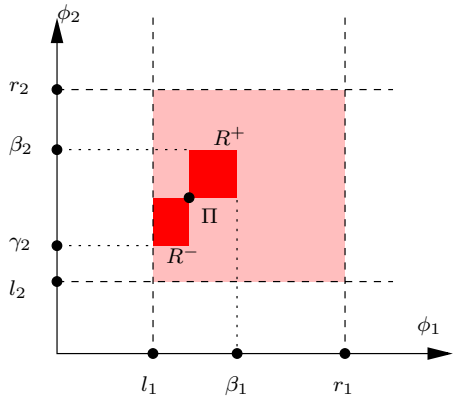

FIG. 2.6. δ^{++}*- and* δ^{--}*-robust paths.* Π *is* δ^{++}*-robust (resp.,* δ^{--}*-robust) if the square* R^+ *(resp.,* R^-*) does not contain any singular or infeasible point.*

Let Π be a Dubins path from an obstacle feature ϕ_1 to another one ϕ_2, with $\psi(\Pi) = (\tau_1, \tau_2, \sigma)$, and let $0 < \delta < 1/2$ be a real parameter. For $i = 1, 2$, let $[l_i, r_i]$ be the feasible domain of ϕ_i; set $\beta_i = \min\{r_i, \tau_i + \delta\}$ and $\gamma_i = \max\{l_i, \tau_i - \delta\}$; see

Figure 2.6. We call Π δ^{++}*-robust* if $\psi(\Pi)$ and $(\beta_1, \beta_2, \sigma)$ are neighbors and δ^{--}*-robust* if $\psi(\Pi)$ and $(\gamma_1, \gamma_2, \sigma)$ are neighbors. We define δ^{+-}*-robust,* δ^{-+}*-robust* paths in a similar manner. Intuitively, Π is δ^{++}-robust if for $0 \leq h_1, h_2 \leq \delta$, the paths $(\tau_1 + h_1, \tau_2 + h_2, \sigma)$ are homeomorphic to Π and remain in a neighborhood of Π, assuming that $\tau_i + \delta \leq r_i$. If $r_i - \tau_i < \delta$, i.e., Π lies near the boundary of the configuration space of $\phi_1 \times \phi_2$, then one has to be more careful and vary $h_i \in [\tau_i, r_i]$. The notion of "directed" robustness and the boundary conditions will be important in the subsequent discussion. (Jacobs and Canny call Π δ-robust if the points $(\tau_1 - \delta/2, \tau_2 - \delta/2, \sigma)$ and $(\tau_2 + \delta/2, \tau_2 + \delta/2, \sigma)$ are neighbors. Their definition does not take the boundary conditions into account, so the points near the boundary of feasible domains are not robust under their definition.)

Now, let Π be a canonical path consisting of Dubins paths $\Pi_1 \| \Pi_2 \| \cdots \| \Pi_k$. Jacobs and Canny call Π δ-robust if each Π_i is $(\delta/2)^{\sigma_1\sigma_2}$-robust for every pair $\sigma_1, \sigma_2 \in \{+, -\}$. (More precisely, they call Π δ-robust if each Π_i is δ-robust under their definition of δ-robustness.) A weakness of their definition is that if one of Π_i is close to a singular path, then Π_i is not robust even if no obstacle is in the neighborhood of Π_i. For example, the canonical Dubins path Π in Figure 2.7 is not robust under their definition of δ-robustness. We circumvent this problem by using a somewhat weaker definition. We call Π δ*-robust* if there exist $\sigma_i \in \{+, -\}$ for $0 \leq i \leq k$, such that Π_i is $\delta^{\sigma_{i-1}\sigma_i}$-robust.

Intuitively, Π being robust means that the tube of width $O(\sqrt{\delta})$ around Π does not intersect any obstacle except those which touch Π, and they intersect the tube only in the neighborhood of the point at which they touch Π.

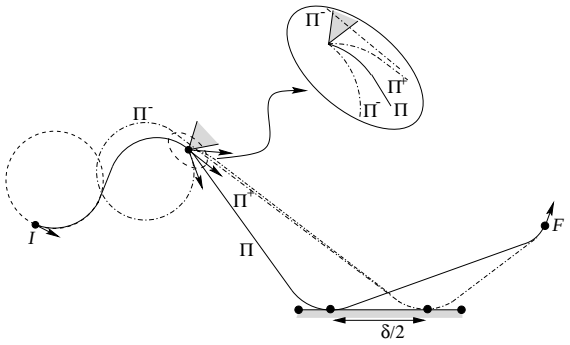

FIG. 2.7. *A robust path consisting of three canonical Dubins paths. The second canonical subpath,* $\Pi = (\tau_2, \tau_3, C^-LC^+)$*, is* δ^{++}*-robust but not* δ^{-+}*-robust because* $\Pi^- = (\tau_2 - \delta/2, \tau_3 + \delta/2, C^-LC^+)$ *and* Π *are not neighbors.*

2.4. Our results. We first obtain a stronger characterization of optimal paths (section 3.1), which besides being interesting in its own right is critical for our algorithm. Roughly speaking, we prove that, except in some very special cases, an optimal path touches an edge e of Ω only at points near a vertex v (v is not necessarily one of the endpoints of e), such that these points are visible from v. In other words, we can ignore the portions of the edges of Ω that are not near any vertex of Ω. This property enables us to develop an algorithm whose running time does not depend on the length of the boundary of Ω.

We then describe an efficient algorithm for computing a feasible path between two given positions (section 4) whose length is at most $(1 + \varepsilon)$ times that of an optimal

path, assuming that there exists an optimal path from I to F that is robust. More precisely, given an obstacle environment Ω with n vertices, two positions I and F, and a parameter ε, we present an $O((n^2/\varepsilon^4)\log n)$-time algorithm that computes a feasible path from I to F whose length is at most $(1+\varepsilon)$ times the length of an optimal ε-robust path from I to F, provided that an optimal path from I to F is robust. Compared with the Jacobs–Canny algorithm [27], our algorithm is not only considerably faster in terms of the complexity of Ω, but, more importantly, the running time is independent of L, the total edge length of Ω. The second improvement is rather significant because one cannot assume L to be small. For unconstrained optimal path planning, one can scale down the environment arbitrarily (to reduce the value of L), compute a shortest path in the scaled environment, and then scale the optimal path back. But this scaling idea does not work for curvature-constrained shortest paths, as the scaling will change the curvature of the path as well. The path returned by our algorithm is not necessarily robust. We can, however, modify the algorithm to compute an $(\varepsilon/2)$-robust path in time $O((n^{2.5}/\varepsilon^4)\log n)$, whose length is no more than $(1+\varepsilon)$ times the length of an optimal path, assuming that it is ε-robust. In fact, an $O(n^{2+\gamma}/\varepsilon^4)$-time algorithm can be obtained, using the recent range-searching data structures [1], but we will not discuss this improvement in this paper.

3. Characterization of optimal paths. In this section we characterize optimal paths in the plane in the presence of obstacles. Theorem 2.2 implies that an optimal path Π is a canonical path. However, even if we specify the sequence of obstacle edges and vertices that Π touches, there are infinitely many paths touching the same sequence of edges and vertices—an optimal path can touch a vertex at an arbitrary orientation, or it can touch an arbitrary point of an edge. Jacobs and Canny [27] observe that if one is interested only in computing $(1+\varepsilon)$-approximate paths, one can choose a finite set of orientations at which a path can touch a vertex and can also choose a finite set of points on each edge e at which a path can touch e. The number of points chosen on an edge is proportional to the length of the edge. That is why the running time of their algorithm depends on the total length of edges of Ω. We circumvent this problem by proving a stronger property of optimal paths.

A feasible C-segment is called *free* if it does not intersect the interior of Ω, *anchored* if it touches $\partial\Omega$ at two or more points (recall that we assume $\text{LOC}(I), \text{LOC}(F)$ to be point obstacles), and *semifree* if it touches $\partial\Omega$ at exactly one point. By Theorems 2.1 and 2.2, an optimal path cannot have two consecutive free C-segments. Moreover, there are only finite number of circles that touch $\partial\Omega$ at two or more points (assuming that there are no two edges parallel at distance 1), so there is only a finite number of circles that may contain anchored C-segments. We thus need a better understanding of semifree C-segments.

The following theorem states the main result of this section.

THEOREM 3.1. *If w is a semifree C-segment of an optimal path, then there is a vertex v of Ω within distance 15 from the intersection point ξ of w and $\partial\Omega$ that is visible from ξ (i.e., the segment ξv does not intersect the interior of Ω).*

3.1. Proof of Theorem 3.1. We will prove the theorem by a sequence of lemmata. We begin with a few notation and simple observations. For an oriented path Π and two points $a, b \in \Pi$, let $\Pi[a,b]$ denote the subpath of Π from a to b. For an unoriented circle C and two points $a, b \in C$, let $C[a,b]$ denote the arc of C from a to b in the clockwise direction. However, if C contains a C-segment of a path, then we assume that C is oriented the same way as the C-segment.

Recall that, by our convention, $\text{LOC}(I)$ and $\text{LOC}(F)$ are the vertices of Ω. If ξ lies within distance 15 from one of the endpoints of the obstacle edge that contains ξ, then there is nothing to prove. So assume that ξ lies in the interior of an edge $e = pq$ and $d(p, \xi), d(q, \xi) > 15$. Without loss of generality, assume that e lies on the x-axis, that w lies below the x-axis, and that w is oriented clockwise.

We divide the proof of Theorem 3.1 into a few cases. For each case, we prove the existence of a closed, simply connected region R satisfying the following properties.

- P1. R lies on or below the x-axis, R contains ξ, and either ∂R contains a vertex of Ω or the interior of R contains a point of $\partial\Omega$.
- P2. If an edge $g \in \Omega$ intersects the interior of R, it crosses ∂R in at most one point, which implies that at least one of the endpoints of g lies inside R.
- P3. $d(\xi, x) \leq 15$ for all points $x \in R$.

See Figure 3.1 for an example of R. P1–P3 (i.e., P1, P2, and P3) together imply that there is a vertex of Ω within distance 15 from ξ. In order to prove that there is also a vertex within distance 15 from ξ that is visible from ξ, we introduce R^*, the convex hull of R.

LEMMA 3.2. *If a simply connected region R satisfies* P1–P3*, then R^* also satisfies* P1–P3.

Proof. P1 is obvious. If an obstacle edge g crosses ∂R^* at two points, then, using the fact that R is simply connected, one can prove that g also crosses ∂R at two points, which contradicts property P2 of R. Hence, g crosses ∂R^* in at most one point, thereby proving P2.

For any point $x \in R^*$, the ray emanating from ξ and passing through x intersects ∂R^* at one point other than ξ itself, say, y (y may be identical to x). If $y \in R$, property P3 follows since $d(\xi, x) \leq d(\xi, y) \leq 15$. Otherwise, y lies in the interior of a line segment, both of whose endpoints, say, u and v, lie on ∂R. Property P3 also follows since $d(\xi, x) \leq d(\xi, y) \leq \max\{d(\xi, u), d(\xi, v)\} < 15$. This completes the proof of the lemma. □

LEMMA 3.3. *Let R^* be a convex region satisfying* P1–P3*. Then there exists a vertex v of Ω within distance* 15 *from ξ that is visible from ξ.*

Proof. If no obstacle edge intersects the interior of R^*, the lemma is obvious because an obstacle vertex lying on ∂R^* is visible from ξ. Otherwise, for each obstacle edge e that intersects the interior of R^*, clip it within R^*; $e \cap R^*$ is a segment. Let E denote the set of clipped segments. By property P1, $E \neq \emptyset$. We define the following partial ordering on the segments of E. We say that $e_i \prec e_j$ ($e_i, e_j \in E$) if any ray emanating from ξ and intersecting the relative interiors of both e_i and e_j intersects e_i before intersecting e_j. (That is, viewed from ξ, e_j cannot occlude any portion of e_i.) Using the fact that the segments of E are disjoint, it can be shown that $\prec$ induces a partial ordering on E; see, e.g., [18, 24]. Moreover, this partial ordering can be extended to a total ordering. By the definition of the ordering, every point on the first segment in this ordering is visible from ξ. But one of the endpoints of this segment, say, v, is a vertex of Ω (because of P2), so we have found an obstacle vertex v within distance 15 from ξ that is visible from ξ. □

The following simple lemma, which will be useful in many cases, follows from Lemma 3.2.

LEMMA 3.4. *Let α and β be two points on an optimal path Π from I to F such that α, ξ, and β appear in that order along Π, such that $\Pi[\alpha, \beta]$ lies below or on the x-axis, and such that $d(\xi, x) \leq 15$ for all $x \in \Pi[\alpha, \beta]$. Let R be the convex hull of $\Pi[\alpha, \beta]$. If α is an obstacle vertex or if it lies in the interior of an obstacle edge whose*

supporting line intersects $\Pi[\alpha, \beta]$ *at a point other than* α*, then* R *satisfies* P1–P3. *See Figure* 3.1.

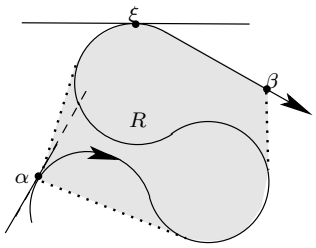

FIG. 3.1. $\Pi[\alpha, \beta]$ *and its convex hull; shaded region is* R.

Proof. Following an argument similar to the one in the proof of Lemma 3.2, we can show that R satisfies P3. Suppose an obstacle edge g intersects the interior of R; then let γ be the intersection of g with R. If both endpoints of γ lie on the boundary of ∂R, then a continuity argument implies that g crosses $\Pi[\alpha, \beta]$, which is impossible. Therefore, g crosses ∂R in at most one point, and thus R satisfies P2. If α is a vertex, R satisfies P1. Otherwise, the obstacle edge containing α lies in the interior of R near α, because the line supporting this edge intersects the interior of R. Hence, R satisfies P1 also. This completes the proof. □

Since we regard $\text{LOC}(I)$ and $\text{LOC}(F)$ as vertices of Ω and assume that ξ is not a vertex, the semifree C-segment w is not the first or the last segment of Π. Let w^- (resp., w^+) be the segment of Π immediately before (resp., after) w.

Using a perturbation argument similar to the one used in [2, 9] (see Figure 3.2), one can easily prove the following lemma, whose proof is omitted from here.

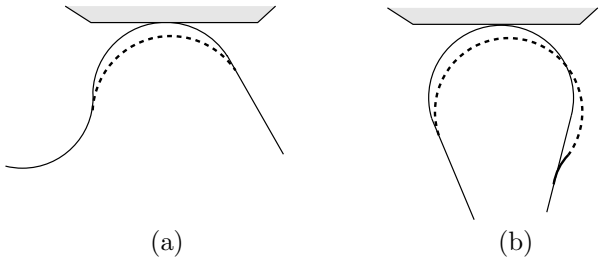

FIG. 3.2. *Length reducing perturbations:* (a) $\|w\| \leq \pi$; (b) *both* w^- *and* w^+ *are L-segments.*

LEMMA 3.5. *If* w *is neither the first segment nor the last segment of* Π*, then* (i) $\|w\| > \pi$*, and* (ii) *either* w^- *or* w^+ *is a C-segment.*

Let us assume that w^- is a C-segment. Let ξ^- (resp., ξ^+) be the point on Π that lies on $\partial\Omega$ immediately before (resp., after) ξ. Since $\Pi[\xi^-, \xi]$ is a Dubins path and w^- is a C-segment, $\Pi[\xi^-, \xi]$ consists of two or three C-segments. In either case,

$$d(\xi, x) \leq 6 \qquad \forall\, x \in \Pi[\xi^-, \xi]. \tag{3.1}$$

Since e lies on the x-axis and the endpoints of e are at distance ≥ 15 from ξ, the above inequality implies that $\Pi[\xi^-, \xi]$ lies below the x-axis. If ξ^- is a vertex or if ξ^- lies in the interior of an edge e^- and the line supporting e^- intersects $\Pi[\xi^-, \xi]$, then Theorem 3.1 follows from an application of Lemma 3.4 on the path $\Pi[\xi^-, \xi]$. In the remainder of this section, we will thus assume the following.

($\star$) ξ^- lies in the interior of an edge e^-, and the line, ℓ^-, supporting e^- does not intersect $\Pi[\xi^-, \xi]$.

Let σ be the intersection point of ℓ^- and the x-axis. Without loss of generality, assume that σ lies to the left of ξ. If ℓ^- is parallel to the x-axis, then σ lies at $x = -\infty$ and the angle $\angle\xi^-\sigma\xi = 0$.

We consider the following three cases and prove the existence of a region R satisfying P1–P3 for each case separately.

Case 1. The angle $\angle\xi^-\sigma\xi \geq \pi/6$; see Figure 3.3.

Case 2. The angle $\angle\xi^-\sigma\xi < \pi/6$.

Case 2.1. $d(\xi, x) < 8$ for all $x \in \Pi[\xi, \xi^+]$; see Figure 3.4.

Case 2.2. $d(\xi, x) \geq 8$ for some $x \in \Pi[\xi, \xi^+]$; see Figure 3.7.

LEMMA 3.6. *There exists a region R satisfying* P1–P3 *for Case* 1*, i.e., when* $\angle\xi^-\sigma\xi \geq \pi/6$.

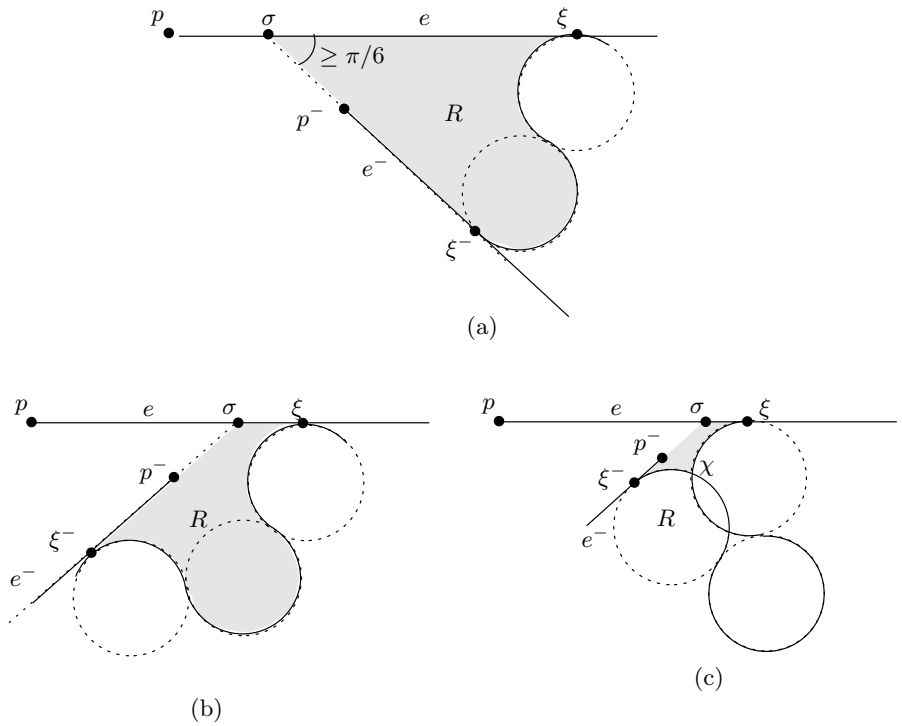

FIG. 3.3. $\angle\xi\sigma\xi^- \geq \pi/6$: (a) $\Pi[\xi^-, \xi]$ *has two C-segments;* (b), (c) $\Pi[\xi^-, \xi]$ *has three C-segments.*

Proof. If $\Pi[\xi^-, \xi]$ is simple (i.e., does not have any self-intersections), we define R to be the closed region bounded by $\Pi[\xi^-, \xi]$ and the segments $\sigma\xi$ and $\sigma\xi^-$. See Figure 3.3(a,b). Otherwise, let χ be the first self-intersection point of $\Pi[\xi^-, \xi]$, and let Γ be the simple curve obtained by discarding from $\Pi[\xi^-, \xi]$ the cycle formed by χ. We define R to be the closed region bounded by Γ and the segments $\sigma\xi$ and $\sigma\xi^-$; see the shaded region in Figure 3.3(c). Since the x-axis cannot intersect the interior of $\Pi[\xi^-, \xi]$ and, by assumption ($\star$), ℓ^- does not intersect the interior of $\Pi[\xi^-, \xi]$, R is a simply connected region. For $\angle\xi\sigma\xi^- \leq \pi/2$, using the sine law and the fact that

$d(\xi, \xi^-) \leq 6$ (see (3.1)), we obtain

$$d(\xi, \sigma) = d(\xi, \xi^-) \frac{\sin \angle \sigma\xi^-\xi}{\sin \angle \xi\sigma\xi^-} \leq \frac{d(\xi, \xi^-)}{\sin(\pi/6)} \leq \frac{6}{\sin(\pi/6)} \leq 12. \tag{3.2}$$

For $\angle \xi\sigma\xi^- > \pi/2$, $d(\xi, \sigma) < d(\xi, \xi^-) \leq 6$, since the segment $\xi\xi^-$ is the longest edge in the triangle $\Delta\xi\sigma\xi^-$. Since $d(p, \xi) > 15$, σ lies on e in both cases. The obstacle edges are disjoint, so one of the endpoints of e^-, say, p^-, lies on the segment $\sigma\xi^-$, and thus on the boundary of R, implying that R satisfies P1. R also satisfies P2 because any obstacle edge $g \in \Omega$ can cross ∂R only at the segment σp^-. Finally, (3.1) and (3.2) imply that, for any $x \in R$, $d(\xi, x) \leq \max\{d(\xi, \sigma), 6\} \leq 12$. Therefore, R satisfies P3 as well. □

LEMMA 3.7. *There exists a region R satisfying* P1–P3 *for Case* 2.1*, i.e., when $\angle \xi^-\sigma\xi < \pi/6$ and $d(\xi, x) < 8$ for all $x \in \xi^+$.*

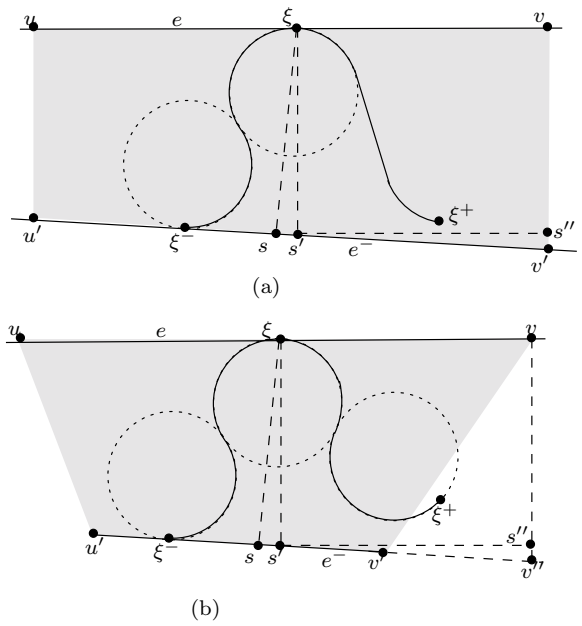

FIG. 3.4. *$\angle \xi\sigma\xi^+ < \pi/6$ and $d(\xi, \xi^+) < 8$: (a) ξ^+ lies in the interior of R; (b) v'' lies on ∂R.*

Proof. If ξ^+ is an obstacle vertex, then the claim follows from Lemma 3.4, so assume that ξ^+ lies in the interior of an obstacle edge e^+. Since $d(\xi, \xi^+) \leq 8$, ξ^+ lies in a disc D_ξ of radius 8 centered at ξ. Let u (resp., v) be the point on e at distance 8 from ξ to its left (resp., right). If the left endpoint of e^-, the edge containing the point ξ^-, lies to the left of u, let u' be the point on e^- with the same x-coordinate as u (see Figure 3.4(a)); otherwise, let u' be the left endpoint of e^- (see Figure 3.4(b)). Similarly, if the right endpoint of e^- lies to the right of v, let v' be the point on e^- with the same x-coordinate as v; otherwise, let v' be the right endpoint of e^-. We set R to be the quadrilateral $uu'v'v$.

If u' or v' is an endpoint of e^- or if any point of obstacle boundary (including ξ^+) lies in the interior of R, then R satisfies P1. Suppose neither of these conditions holds. Since uu' and vv' are vertical segments, $d(\xi, x) > 8$ for any point x on the segments uu' and vv'. Consequently, $\Pi[\xi, \xi^+]$ cannot intersect either of these two segments. We

will show in Lemma 3.8 that if the vertices of R lie in the interior of e and e^- and no obstacle intersects the interior of R, then ξ^+ cannot lie on e^- or e^+. Hence, R satisfies P1.

An obstacle edge g cannot intersect uv or $u'v'$ (as they are portions of obstacle edges), and g cannot intersect both uu' and vv' (as this would imply that g intersects $\Pi[\xi^-, \xi]$). Hence R satisfies P2.

Finally, we prove that R satisfies P3. Let v'' be the point on ℓ^- that has the same x-coordinate as v ($v'' = v'$ if the right endpoint of e^- lies to the right of v). It can be shown that, for any $x \in R$, $d(\xi, x) \leq d(\xi, v'')$. (Here we are using the assumption that ℓ and ℓ^- intersect to the left of ξ.) Let s (resp., s') be the point on ℓ^-, such that $\xi s \perp e^-$ (resp., $\xi s' \perp e$). Let s'' be the point on the segment vv'' with the same y-coordinate as that of s'. Notice that $\angle s\xi s' = \angle v''s's'' = \angle \xi\sigma\xi^- < \pi/6$, where σ is the intersection point of lines containing e and e^-. Since

$$d(v, s'') = d(\xi, s') = \frac{d(\xi, s)}{\cos \angle s\xi s'} < \frac{d(\xi, \xi^-)}{\cos \frac{\pi}{6}} \leq 6 \cdot \frac{2}{\sqrt{3}} = 4\sqrt{3}$$

and

$$d(s'', v'') = d(s', s'') \tan \angle v''s's'' < d(\xi, v) \tan \frac{\pi}{6} = 8 \cdot \frac{1}{\sqrt{3}} = \frac{8}{\sqrt{3}},$$

we have $d(v, v'') < 20/\sqrt{3}$. Therefore, for any $x \in R$,

$$d(\xi, x) \leq d(\xi, v'') = \sqrt{d(\xi, v)^2 + d(v, v'')^2} \leq \sqrt{8^2 + (20/\sqrt{3})^2} \leq 15.$$

This completes the proof of the lemma. □

We now prove the missing claim in the proof of the above lemma.

LEMMA 3.8. *Let R be the quadrilateral defined in the proof of Lemma 3.7. Suppose the vertices of R lie in the relative interiors of the edges e and e^- and the interior of R does not intersect any obstacle. If ξ^+ lies on e^- or e, then Π is not an optimal path.*

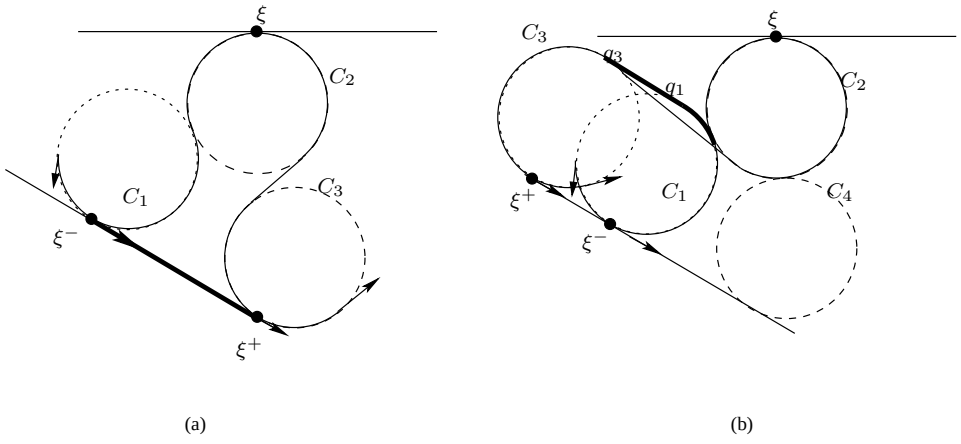

FIG. 3.5. *Shortcutting $\Pi[\xi^-, \xi^+]$ when w' is counter-clockwise oriented and ξ^+ lies to the left of ξ^-.*

Proof. We assume that ξ^+ lies on e^- and $\Pi[\xi^-, \xi]$ consists of two C-segments. We will show that we can shortcut $\Pi[\xi^-, \xi^+]$ and obtain a shorter feasible path from

I to F. A similar shortcutting procedure works if $\xi^+ \in e$ or $\Pi[\xi^-, \xi]$ consists of three C-segments. Let w' be the C-segment containing ξ^+, and let C_1, C_2, C_3 be the circles containing the C-segments w^-, w, and w'.

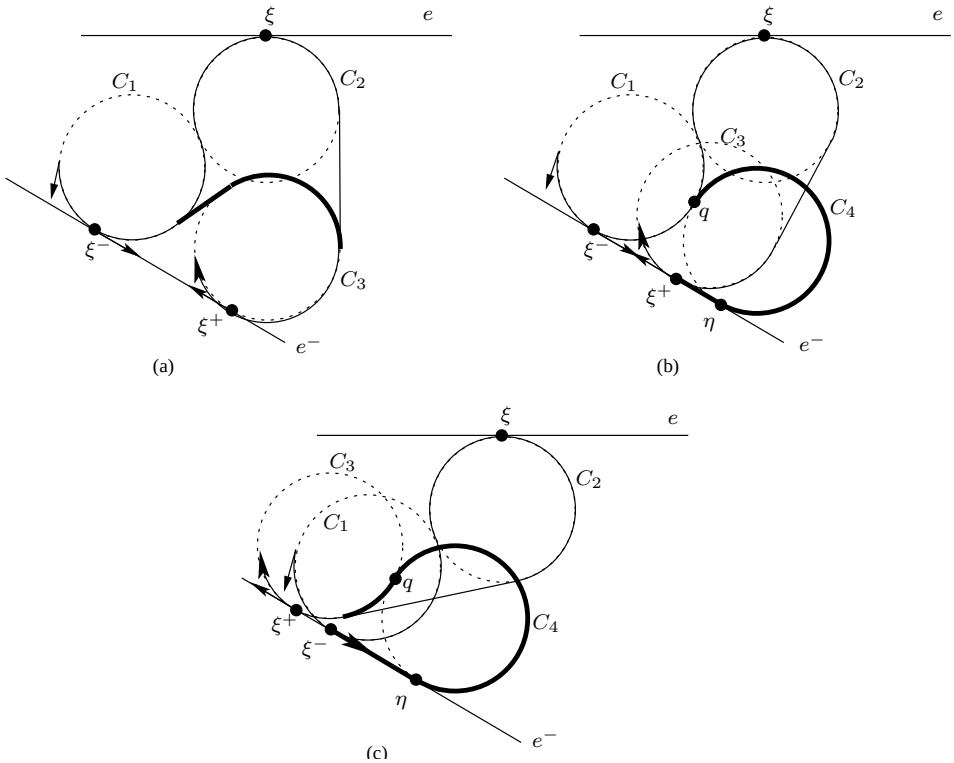

FIG. 3.6. *Shortcutting* $\Pi[\xi^-, \xi^+]$ *when* w' *is clockwise oriented; thick arcs denote the shortcutting*: (a) C_1 *and* C_3 *do not intersect,* (b) ξ^+ *lies to the right of* ξ^-*, and* (c) ξ^+ *lies to the left of* ξ^-.

Since the interior of R does not intersect any obstacle, we can prove that the interiors of circles C_1, C_2, and C_3 do not intersect any obstacle. By our assumptions, C_1 is counter-clockwise oriented and C_2 is clockwise oriented. First let us assume that w', and thus C_3, is counter-clockwise oriented. If $\xi^+ \in e^-$ lies to the right of ξ^-, we can shortcut $\Pi[\xi^-, \xi^+]$ by the segment $\overrightarrow{\xi^-\xi^+}$ (see Figure 3.5(a)), so assume that ξ^+ lies to the left of ξ^- (see Figure 3.5(b)). Since $\Pi[\xi, \xi^+]$ is a Dubins path and the C-segment w is clockwise oriented, it is a C^-LC^+-type path. This implies that the L-segment w^+ is an inner tangent of C_2 and C_3, and that C_2 and C_3 are disjoint. Let ξ' be the common endpoint of w^- and w. Using the fact that the common endpoint of w and w^+ lies on $C_2[\xi, \xi']$, the other circle (other than C_1; e.g., C_4 in Figure 3.5) tangent to both C_2 and the edge e^- lies to the right of C_1. Let $q_1 \neq \xi^-$ and $q_3 \neq \xi^+$ be the point on C_1 and C_3, respectively, so that the segment q_1q_3 is an outer common tangent of C_1 and C_3. We shortcut $\Pi[\xi^-, \xi^+]$ by the path $\Lambda = C_1[\xi^-, q_1] \parallel \overrightarrow{q_1q_3} \parallel C_3[q_3, \xi^+]$. It can be proved that $|\Lambda| \leq |\Pi[\xi^-, \xi^+]|$.

Next, let us assume that the C-segment w' is clockwise oriented. In this case we shortcut $\Pi[\xi^-, \xi^+]$ by a C^+LC^-, a C^+C^-L, or an LC^+C^- path, depending on the position of ξ^+ on e^-. If C_1 and C_3 do not intersect, we shortcut from C_1 to C_3 by

the inner tangent of C_1 and C_3 as shown in Figure 3.6(a). The new path is obviously shorter.

Suppose C_1 and C_3 intersect and ξ^+ lies to the right of ξ^-. Let C_4 be the clockwise oriented circle tangent to e^- and C_1, and that lies to the right of C_1; see Figure 3.6(b). Let $q = C_1 \cap C_4$ and $\eta = C_4 \cap e^-$. We shortcut $\Pi[\xi^-, \xi^+]$ by the C^+C^-L-type path $\Lambda = C_1[\xi^-, q] \parallel C_4[q, \eta] \parallel \overrightarrow{\eta\xi^+}$. On the other hand, if ξ^+ lies to the left of ξ^-, then we set C_4 to be the counter-clockwise oriented circle tangent to C_3 and e^-, and that lies to the right of C_1; see Figure 3.6(c). Let $q = C_3 \cap C_4$ and $\eta = C_4 \cap e^-$. We shortcut $\Pi[\xi^-, \xi^+]$ by the LC^+C^--type path $\Lambda = \overrightarrow{\xi^-\eta} \parallel C_4[\eta, q] \parallel C_3[q, \xi^+]$. We can show that in both cases, Λ is feasible and $|\Lambda| \le |\Pi[\xi^-, \xi^+]|$. □

LEMMA 3.9. *There exists a region R satisfying* P1–P3 *for Case* 2.2*, i.e., when* $\angle\xi\sigma\xi^- < \pi/6$ *and* $d(\xi, x) \ge 8$ *for some* $x \in \Pi[\xi, \xi^+]$.

Proof. Let $\eta \in \Pi[\xi, \xi^+]$ be a point for which $d(\xi, \eta) > 8$. If w^+, the segment of Π following w, is a C-segment, then, by Theorem 2.1, $\Pi[\xi, \xi^+]$ consists of at most three C-segments and $d(\xi, x) \le 6$ for all $x \in \Pi[\xi, \xi^+]$, which contradicts the assumption that $d(\xi, \eta) > 8$. Hence w^+ is an L-segment, $\Pi[\xi, \xi^+]$ is of CLC type, and $\|w^+\| \ge d(\xi, \eta) - 4 > 4$.

Let C_1 and C_2 be the circles containing w^- and w, respectively, and let h be the ray supporting w^+ and starting at the common point of w^+ and w. There are two cases to consider:

(i) h does not intersect C_1,
(ii) h intersects C_1.

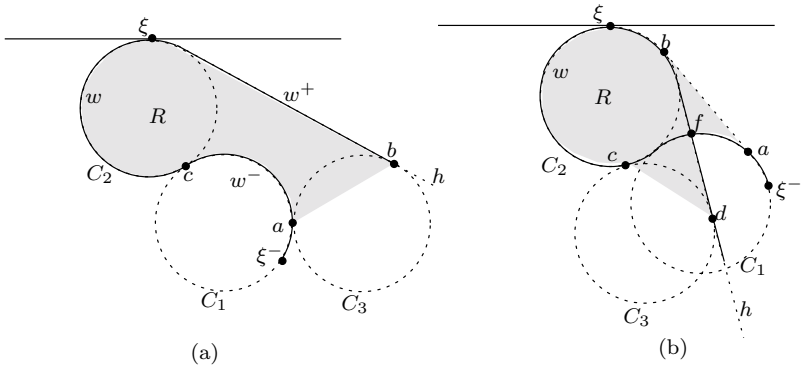

FIG. 3.7. $\angle\xi\sigma\xi^- < \pi/6$ *and* $d(\xi, \xi^+) \ge 8$: (a) h *does not intersect* C_1; (b) h *intersects* C_1.

Case (i). See Figure 3.7(a). Let C_3 be the other (unit-radius) circle tangent to both h and C_1. Let a (resp., b) be the intersection point of C_3 with C_1 (resp., h). Since $|w^+| > 4$, b lies on the segment w^+.

Let c be the common point of C_1 and C_2. Since w^- is clockwise oriented, we assume C_1 to be clockwise oriented. We consider the two cases: (a) ξ^- does not lie on $C_1[a, c]$, and (b) $\xi \in C_1[a, ac$. If $\xi^- \notin C_1[a, c]$, i.e., $a \in \Pi[\xi^-, \xi]$, define R to be the closed region bounded by $\Pi[a, b]$ and the segment ab; see the shaded region in Figure 3.7(a). If the arc $C_3[a, b]$ does not cross any obstacle edge, we can shorten Π by replacing $\Pi[a, b]$ with $C_3[a, b]$, contradicting the optimality of Π. Hence, an edge of Ω intersects $C_3[a, b]$ and thus also intersects the interior of R, thereby implying that R satisfies P1. Since an edge of Ω can cross ∂R only at ab, P2 is obvious. Finally, every point on ∂R is within distance 15 from ξ, so P3 also follows.

If $\xi^- \in C_1[a,c]$, define R to be the closed region bounded by $\Pi[\xi^-, b]$ and the segment $\xi^- b$. Since ξ^- is an interior point of the obstacle edge e^-, e^- also intersects the interior of R, proving P1. Since an edge of Ω can cross ∂R only at segment $\xi^- b$, P2 holds. P3 can also be shown.

Case (ii). See Figure 3.7(b). Let f be the first intersection point of ray h with C_1. Let ab be the segment tangent to C_1 and C_2 at a and b, respectively, such that b is on the path $\Pi[\xi, \xi^+]$. (It is easy to see that such a b exists.) Let C_3 be the unit-radius (clockwise oriented) circle tangent to C_2 and the ray h at c and d, respectively. Since $|w^+| > 4$, both d and f lie on the segment w^+.

If $a \notin \Pi[\xi^-, \xi]$, then the line ℓ^- intersects $\Pi[\xi^-, \xi]$, which contradicts the assumption ($\star$). So assume that $a \in \Pi[\xi^-, \xi]$. Define R to be the region bounded by the segment ab, the circular arc $C_2[c,b]$ the segments cd and df, and the circular arc $C_1[a,f]$; see the shaded region in Figure 3.7(b). An obstacle edge crosses either the segment ab or the arc $C_3[c,d]$, thus intersecting the interior of R, because otherwise the path obtained by concatenating the segment ab and the circular arcs $C_2[c,b]$ and $C_3[c,d]$ is shorter than the path $\Pi[a,d]$, contradicting the optimality of Π. This means that R satisfies P1. An obstacle edge can cross ∂R only at segments cd and ab, and none of the edges can cross both the segments (because then it would cross Π). P2 follows. Finally, every point on ∂R is within distance 15 from ξ, so P3 also follows. ∎

These lemmas together complete the proof of Theorem 3.1.

3.2. Anchored C-segments. Recall that a C-segment is called anchored if it touches $\partial\Omega$ at two (or more) points. We prove a property of anchored C-segments, which will be useful later. We call an anchored C-segment, touching $\partial\Omega$ at two points $p_1 \in e_1$ and $p_2 \in e_2$, *shallow* if we can find two obstacle vertices v_1 and v_2 (not necessarily distinct) such that v_i is visible from p_i and $d(p_i, v_i) \le 15$ for $i = 1, 2$. Otherwise, it is called *deep*.

LEMMA 3.10. *If w is a feasible deep anchored C-segment, then no obstacle edge intersects the interior of the circle containing w.*

Proof. Let w be an anchored C-segment touching $\partial\Omega$ at two points $p_1 \in e_1$ and $p_2 \in e_2$. Since w is a deep anchored C-segment, one of p_i, say p_1, has to be at least distance 15 away from the endpoints of e_i, because otherwise w is shallow. Without loss of generality, let $e = e_1$, $e^- = e_2$, $\xi = p_1$, $\xi^- = p_2$, where e, e^-, ξ, ξ^- are as defined in the last section.

It can be shown that the angle between e and e^- is $< \pi/6$. Otherwise, following the proof of Lemma 3.6, we can find a vertex v_i, such that v_i is visible to p_i and $d(v_i, p_i) \le 15$, contradicting the assumption that w is a deep anchored C-segment.

Let C be the circle containing w. We construct a quadrilateral $R = uu'v'v$, as in the proof of Lemma 3.7, except that we set $d(\xi, u) = d(\xi, v) = 2$, since the distance between ξ and any point on C is ≤ 2. Any obstacle edge crossing both uu' and vv' of R also crosses the C-segment w, but that is impossible because w is feasible. Hence, R satisfies P2. Obviously, R satisfies P3. If an obstacle edge intersects the interior of C, it also intersects R, making R satisfy P1. If so, by Lemma 3.3, we can find for each $i = 1, 2$ an obstacle vertex v_i that is visible from p_i and $d(v_i, p_i) \le 15$, contradicting that w is a deep anchored C-segment. Thus no obstacle edge intersects the interior of C. This proves the lemma. ∎

For a pair of nonparallel edges, there is at most one deep anchored circle, but a pair of parallel edges at distance 2 have infinitely many deeply anchored C-segments. In the next lemma, we prove that we do not have to consider parallel edges for deeply

anchored C-segments.

LEMMA 3.11. *An optimal path does not contain a deep C-segment that touches two parallel obstacle edges at their interior points.*

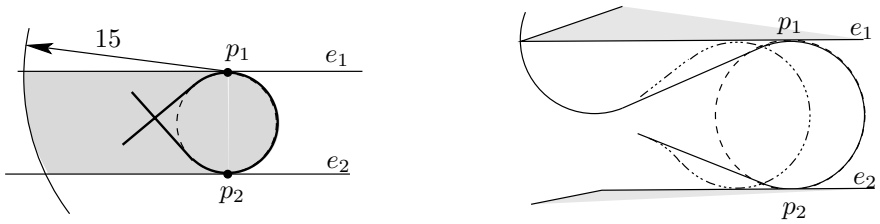

FIG. 3.8. (a) *Shaded region is R;* (b) *perturbation scheme for a deeply anchored C-segment.*

Proof. Suppose an optimal path Π contains a deep C-segment w anchored at two parallel edges e_1 and e_2. Let p_i be the intersection point of w and e_i. Since w is deep, no obstacle vertex within distance 15 is visible from one of p_i's, say, p_1. Let R be the region lying inside the disk of radius 15 centered at p_1 and the strip formed by the lines supporting e_1, e_2 and lying to the left of $w[p_1, p_2]$ (shaded region in Figure 3.8(a)). Following the same argument as in the previous lemma, we can argue that R does not intersect the obstacle boundary. If the segment preceding or following w is a C-segment, then there is an obstacle within distance 8 from ξ that lies inside the region R, and therefore both the segments are L-segments. Using a perturbation shown in Figure 3.8(b), we can now prove that Π is not optimal. This completes the proof of the lemma. □

LEMMA 3.12. *There are only $O(n)$ circles that can contain a feasible, deep anchored C-segment.*

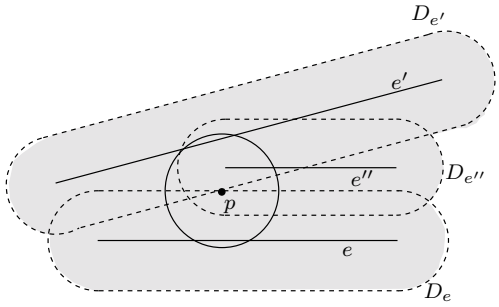

FIG. 3.9. *The straight line edges of D_e and $D_{e'}$ intersect at p. The unit radius circle centered at p is tangent to both e and e', and is crossed by e'', whose race-track $D_{e''}$ contains p in its interior.*

Proof. For each edge $e \in \Omega$, let D_e be the Minkowski sum of e and the unit-radius disk centered at the origin.[2] D_e is a race-track bounded by two semicircles of unit radius and two translated copies of e; see Figure 3.9. An intersection point p of the straight-line edges of D_e and $D_{e'}$ corresponds to the center of a unit-radius circle tangent to e and e' at their interior points. (Notice that there may be an infinite number of intersection points if e and e' are parallel and unit distance apart.) A point p lies inside D_e if and only if e intersects the interior of the unit-radius circle centered

[2]The *Minkowski sum* of two sets A and B is defined as $A \oplus B = \{a + b \mid a \in A, b \in B\}$.

at p. Set $\mathcal{D} = \bigcup_{e\in\Omega} D_e$. A unit-radius circle is tangent to two obstacle edges and does not intersect any obstacle edge in its interior only if its center lies on the intersection point σ of the boundaries of two racetracks and does not lie in the interior of any other racetrack. If the two boundary edges forming the intersection point overlap, i.e., the two corresponding obstacle edges are parallel, then by Lemma 3.11 such a circle cannot contain a deep anchored C-segment, so the intersection point σ has to be a vertex of $\mathcal{D}$. Thus the number of circles that can contain a feasible, deep anchored C-segment is at most the number of vertices of $\partial\mathcal{D}$, which, by a result of Kedem et al. [29], is $O(n)$; so the lemma follows. □

4. Computing near optimal paths. In this section we present an efficient algorithm for computing a feasible path whose length is no more than $(1+\varepsilon)$ times the length of an optimal path for any $\varepsilon > 0$, provided that the optimal path is ε-robust. As in [27], we construct a weighted directed graph $G = (V, E)$, where V is a set of discretized positions. These positions are obtained by discretizing the set of orientations at which a path touches a vertex and the set of points at which a path touches an edge. Jacobs and Canny [27] choose points uniformly spaced along each edge. We, on the other hand, use Theorem 3.1 and Lemma 3.12 to choose points more carefully, as described in section 4.1. There is an edge $(X, Y) \in E$ from a position X to another position Y if there exists a feasible Dubins path from X to Y. If there is more than one such path, we choose the one with the minimum arc length. The weight of an edge is the arc-length of the chosen Dubins path. We claim that by choosing the proper parameter δ for discretization for any optimal path Π from X to Y that is robust, there is a path from X to Y along the edges in G whose length is at most $(1+\varepsilon)$ times the length of Π. The choice of δ and the proof of this claim are given in section 5. Therefore, the problem reduces to computing a shortest path in G, which can be done in time $O(|V|^2)$, using Dijkstra's shortest-path algorithm.
