A GENERALIZATION OF RESOURCE-BOUNDED MEASURE, WITH APPLICATION TO THE BPP VS. EXP PROBLEM*

HARRY BUHRMAN†, DIETER VAN MELKEBEEK‡, KENNETH W. REGAN§, D. SIVAKUMAR¶, AND MARTIN STRAUSS‖

Abstract. We introduce *resource-bounded betting games* and propose a generalization of Lutz's resource-bounded measure in which the choice of the next string to bet on is fully adaptive. Lutz's martingales are equivalent to betting games constrained to bet on strings in lexicographic order. We show that if strong pseudorandom number generators exist, then betting games are equivalent to martingales for measure on E and EXP. However, we construct betting games that succeed on certain classes whose Lutz measures are important open problems: the class of polynomial-time Turing-complete languages in EXP and its superclass of polynomial-time Turing-autoreducible languages. If an EXP-martingale succeeds on either of these classes, or if betting games have the "finite union property" possessed by Lutz's measure, one obtains the nonrelativizable consequence BPP $\neq$ EXP. We also show that if EXP $\neq$ MA, then the polynomial-time truth-table-autoreducible languages have Lutz measure zero, whereas if EXP = BPP, they have measure one.

1. Introduction.

Lutz's theory of measure on complexity classes is now usually defined in terms of resource-bounded martingales. A martingale can be regarded as a gambling game played on unseen languages A. Let $s_1, s_2, s_3, \ldots$ be the standard lexicographic ordering of strings. The gambler G starts with capital $C_0 = \$1$ and places a bet $B_1 \in [0, C_0]$ on either "$s_1 \in A$" or "$s_1 \notin A$." Given a fixed particular language A, the bet's outcome depends only on whether $s_1 \in A$. If the bet wins, then the new capital C_1 equals $C_0 + B_1$, while if the bet loses, $C_1 = C_0 - B_1$. The gambler then places a bet $B_2 \in [0, C_1]$ on (or against) membership of the string s_2, then on

s_3, and so forth. The gambler *succeeds* if G's capital C_i grows toward $+\infty$. The class $\mathcal{C}$ of languages A on which G succeeds (and any subclass) is said to have *measure zero*. One also says G *covers* $\mathcal{C}$. Lutz and others (see [Lutz97]) have developed a rich and extensive theory around this measure-zero notion and have shown interesting connections to many other important problems in complexity theory.

We propose the generalization obtained by lifting the requirement that G must bet on strings in lexicographic order. That is, G may begin by choosing any string x_1 on which to place its first bet and, after the oracle tells the result, may choose any other string x_2 for its second bet, and so forth. Note that the sequences $x_1, x_2, x_3, \ldots$ (as well as $B_1, B_2, B_3, \ldots$) may be radically different for different oracle languages A—in complexity-theory parlance, G's queries are *adaptive*. The lone restriction is that G may not query (or bet on) the same string twice. We call G a *betting game*.

Our betting games remedy a possible lack in the martingale theory, one best explained in the context of languages that are "random" for classes $\mathcal{D}$ such as E or EXP. In this paper, E stands for deterministic time $2^{O(n)}$, and EXP stands for deterministic time $2^{n^{O(1)}}$. A language L is $\mathcal{D}$-*random* if L cannot be covered by a $\mathcal{D}$-martingale. Based on one's intuition about random 0-1 sequences, the language $L' = \{\, \mathit{flip}(x) : x \in L \,\}$ should likewise be $\mathcal{D}$-random, where $\mathit{flip}(x)$ changes every 0 in x to a 1 and vice-versa. However, this closure property is not known for E-random or EXP-random languages, because of the way martingales are tied to the fixed lexicographic ordering of Σ^*. Betting games can adapt to easy permutations of Σ^* such as that induced by *flip*. Similarly, a class $\mathcal{C}$ that is *small* in the sense of being covered by a ($\mathcal{D}$-) betting game remains small if the languages $L \in \mathcal{C}$ are so permuted. In the r.e./recursive theory of random languages, our generalization is similar to "Kolmogorov–Loveland place-selection rules" (see [Lov69]). We make this theory work for complexity classes via a novel definition of "running in time $t(n)$" for an infinite process.

Our new angle on measure theory may be useful for attacking the problem of separating BPP from EXP, which has recently gained prominence in [ImWi98]. In Lutz's theory it is open whether the class of EXP-complete sets—under polynomial-time Turing reductions—has EXP-measure zero. If so (in fact if this set does not have measure one), then by results of Allender and Strauss [AlSt94], BPP $\neq$ EXP. Since there are oracles A such that $\mathrm{BPP}^A = \mathrm{EXP}^A$ [Hel86], this kind of absolute separation would be a major breakthrough. We show that the EXP-complete sets *can* be covered by an EXP-betting game—in fact, by an E-betting game. The one technical lack in our theory as a notion of measure is also interesting here: If the "finite unions" property holds for betting games (viz., $\mathcal{C}_1$ small $\wedge$ $\mathcal{C}_2$ small $\Longrightarrow$ $\mathcal{C}_1 \cup \mathcal{C}_2$ small), then EXP $\neq$ BPP. Likewise, if Lutz's martingales do enjoy the permutation-invariance of betting games, then BPP $\neq$ EXP. Finally, we show that if a pseudorandom number generator of security $2^{n^{\Omega(1)}}$ exists, then for every EXP-betting game G one can find an EXP-martingale that succeeds on all sets covered by G. Pseudorandom generators of higher security $2^{\Omega(n)}$ likewise imply the equivalence of E-betting games and E-measure. Ambos-Spies, Lempp, and Mainhardt [ALM98] proved that the EXP-complete sets have E-measure zero under a different hypothesis, namely P = PSPACE.

Measure theory and betting games help us to dig further into questions about pseudorandom generators and complexity-class separations. Our tool is the notion of an *autoreducible* set, whose importance in complexity theory was argued by Buhrman, Fortnow, van Melkebeek, and Torenvliet [BFvMT98] (after [BFT95]). A

language L is $\leq_T^p$-*autoreducible* if there is a polynomial-time oracle Turing machine Q such that for all inputs x, Q^L correctly decides whether $x \in L$ without ever submitting x itself as a query to L. If Q is nonadaptive (i.e., computes a polynomial-time truth-table reduction), we say L is $\leq_{tt}^p$-*autoreducible*. We show that the class of $\leq_T^p$-autoreducible sets is covered by an E-betting game. Since every EXP-complete set is $\leq_T^p$-autoreducible [BFvMT98], this implies results given above. The subclass of $\leq_{tt}^p$-autoreducible sets provides the following tighter connection between measure statements and open problems about EXP.

- If the $\leq_{tt}^p$-autoreducible sets do not have E-measure zero, then EXP = MA.
- If the $\leq_{tt}^p$-autoreducible sets do not have E-measure one in EXP, then EXP $\neq$ BPP.

Here MA is Babai's "Merlin-Arthur" class, which contains BPP and NP and is contained in the level $\Sigma_2^p \cap \Pi_2^p$ of the polynomial hierarchy [Bab85, BaMo88]. Since EXP $\neq$ MA is strongly believed, one would expect the class of $\leq_{tt}^p$-autoreducible sets to have E-measure zero, but *proving* this—or proving any of the dozen other measure statements in Corollaries 6.2 and 6.5—would yield a proof of EXP $\neq$ BPP.

In sum, the whole theory of resource-bounded measure has progressed far enough to wind the issues of (pseudo)randomness and stochasticity within exponential time very tightly. We turn the wheels a few more notches and seek greater understanding of complexity classes in the places where the boundary between "measure one" and "measure zero" seems tightest.

Section 2 reviews the formal definitions of Lutz's measure and martingales. Section 3 introduces betting games and shows that they are a generalization of martingales. Section 4 shows how to simulate a betting game by a martingale of perhaps unavoidably higher time complexity. Section 5, however, demonstrates that strong pseudorandom generators (if there are any) allow one to compute the martingale in the same order of time. Section 6 presents our main results pertaining to autoreducible sets, including our main motivating example of a concrete betting game. The concluding section 7 summarizes open problems and gives prospects for future research.

2. Martingales. A *martingale* is abstractly defined as a function d from $\{0,1\}^*$ into the nonnegative reals that satisfies the following "average law": for all $w \in \{0,1\}^*$,

$$d(w) = \frac{d(w0) + d(w1)}{2}. \tag{1}$$

The interpretation in Lutz's theory is that a string $w \in \{0,1\}^*$ stands for an initial segment of a language over an arbitrary alphabet Σ as follows: Let $s_1, s_2, s_3, \ldots$ be the standard lexicographic ordering of Σ^*. Then for any language $A \subseteq \Sigma^*$, write $w \sqsubseteq A$ if for all i, $1 \leq i \leq |w|$, $s_i \in A$ iff the ith bit of w is a 1. We also regard w as a function with *domain* $dom(w) = \{s_1, \ldots, s_{|w|}\}$ and range $\{0,1\}$, writing $w(s_i)$ for the ith bit of w. A martingale d *succeeds on* a language A if the sequence of values $d(w)$ for $w \sqsubseteq A$ is unbounded.

Let $S^\infty[d]$ stand for the (possibly empty, often uncountable) class of languages on which d succeeds. Lutz originally defined the complexity of a martingale d in terms of computing fast-converging rational approximations to d. Subsequently he showed that for certain classes of time bounds one loses no generality by requiring that martingales themselves have rational values a/b such that all digits of the integers a and b (not necessarily in lowest terms) are output within the time bound. That

is, given any martingale d meeting the original definition of computability within the time bound, one can obtain a rational-valued d' computable within that bound such that $S^\infty[d] \subseteq S^\infty[d']$ [May94t, JuLu95]. We adopt this requirement throughout the paper and specify that integers are represented in standard binary notation and rationals as pairs of integers, not necessarily in lowest terms. We use the fact that a sum $a_1/b_1 + \cdots a_m/b_m$ can be computed and written down in $\ell^{O(1)}$ time, where ℓ is the sum of the lengths of the integers a_i and b_i.

DEFINITION 2.1 (cf. [Lutz92, May94t]). *Let Δ be a complexity class of functions. A class $\mathcal{C}$ of languages* has Δ-measure zero*, written $\mu_\Delta(\mathcal{C}) = 0$, if there is a martingale d computable in Δ such that $\mathcal{C} \subseteq S^\infty[d]$. One also says that d* covers *$\mathcal{C}$.*

Lutz measured the time to compute $d(w)$ in terms of the length N of w, but one can also work in terms of the largest length n of a string in the domain of w. For $N > 0$, n equals $\lfloor \log_2 N \rfloor$; all we care about is that $n = \Theta(\log N)$ and $N = 2^{\Theta(n)}$. Because complexity bounds on languages we want to analyze will naturally be stated in terms of n, we prefer to use n for martingale complexity bounds. The following correspondence is helpful:

$$\begin{array}{lcrcrcl} \text{Lutz's } \text{“}p\text{”} & \sim & N^{O(1)} & = & 2^{O(n)} & \sim & \text{measure on E,} \\ \text{Lutz's } \text{“}p_2\text{”} & \sim & 2^{(\log N)^{O(1)}} & = & 2^{n^{O(1)}} & \sim & \text{measure on EXP.} \end{array}$$

Since we measure the time to compute $d(w)$ in terms of n, we write "μ_{E}" for E-measure, "μ_{EXP}" for EXP-measure, and generally μ_Δ for any Δ that names both a language and function class. Abusing notation similarly, we define the following.

DEFINITION 2.2 (see [Lutz92]). *A class $\mathcal{C}$ has Δ-measure one, written $\mu_\Delta(\mathcal{C}) = 1$, if $\mu_\Delta(\Delta \setminus \mathcal{C}) = 0$.*

The concept of resource-bounded measure is known to be robust under several changes [May94t]. The following lemma has appeared in various forms [May94t, BuLo00]. It essentially says that we can assume a martingale grows almost monotonically (sure winnings) and not too fast (slow winnings).

LEMMA 2.3 ("slow-but-sure-winnings" lemma for martingales). *Let d be a martingale. Then there is a martingale d' with $S^\infty[d] \subseteq S^\infty[d']$ such that*

$$(\forall w)(\forall u) : d'(wu) > d'(w) - 2d(\lambda), \quad \text{and} \tag{2}$$

$$(\forall w) : d'(w) < 2(|w| + 1)d(\lambda). \tag{3}$$

If d is computable in time $t(n)$, then d' is computable in time $(2^n t(n))^{O(1)}$.

The idea is to play the strategy of d but in a more conservative way. Say we start with an initial capital of \$1. We will deposit a part c of our capital in a bank and only play the strategy underlying d on the remaining liquid part e of our capital. We start with no savings and a liquid capital of \$1. If our liquid capital reaches or exceeds \$2, we deposit an additional \$1 or \$2 to our savings account c so as to keep the liquid capital in the range $\$[1, 2)$ at all times. If d succeeds, it will push the liquid capital infinitely often to \$2 or above, so c grows to infinity, and d' succeeds too. Since we never take money out of our savings account c and the liquid capital e is bounded by \$2, once our total capital $d' = c + e$ has reached a certain level, it will never go more than \$2 below that level anymore, no matter how bad the strategy underlying d is. On the other hand, since we add at most \$2 to c in each step, $d'(w)$ cannot exceed $2(|w| + 1)$ either.

We now give the formal proof.

Proof of Lemma 2.3. Define $d' : \Sigma^* \to [0, \infty)$ by

$$d'(w) = (c(w) + e(w))d(\lambda),$$

where $c(\lambda) = 0$ and $e(\lambda) = 1$, and

$$\begin{array}{llll}
c(wb) = c(w) & \text{and} & e(wb) = e(w) & \text{if } d(w) = 0; \text{ else:} \\
c(wb) = c(w) + 2 & \text{and} & e(wb) = \frac{d(wb)}{d(w)} e(w) - 2 & \text{if } \frac{d(wb)}{d(w)} e(w) \geq 3; \\
c(wb) = c(w) + 1 & \text{and} & e(wb) = \frac{d(wb)}{d(w)} e(w) - 1 & \text{if } 2 \leq \frac{d(wb)}{d(w)} e(w) < 3; \\
c(wb) = c(w) & \text{and} & e(wb) = \frac{d(wb)}{d(w)} e(w) & \text{if } \frac{d(wb)}{d(w)} e(w) < 2.
\end{array}$$

To see that the recursion does not excessively blow up the time complexity or size of the answer, note that owing to cancellation of values of d, every value $e(w)$ where $d(w) \neq 0$ is given by a sum of the form

$$\sum_{k=0}^{N} a_k \frac{d(w)}{d(w[1 \ldots k])},$$

where each a_k is in $\{ -2, -1, 0, 1 \}$, $N = |w|$, and $w[1 \ldots k]$ stands for the first k bits of w. Each term in the sum is computable in time $O(t(n)^2 N)$ (using the naive quadratic algorithms for multiplication and integer division). Then by the property noted just before Definition 2.1, these terms can be summed in time $(Nt(n))^{O(1)}$.

By induction on $|w|$ we observe that

$$0 \leq e(w) < 2, \tag{4}$$

and that

$$d'(wb) = \begin{cases} \left[c(w) + \frac{d(wb)}{d(w)} e(w) \right] d(\lambda) & \text{if } d(w) \neq 0, \\ d'(w) & \text{otherwise,} \end{cases}$$

from which it follows that d' is a martingale.

Now let ω be an infinite 0-1 sequence denoting a language on which d succeeds. Then $e(w)$ will always remain positive for $w \sqsubseteq \omega$, and $\frac{d(wb)}{d(w)} e(w)$ will become 2 or more infinitely often. Consequently, $\lim_{w \sqsubseteq \omega, |w| \to \infty} c(w) = \infty$. Since $d'(w) \geq c(w) d(\lambda)$, it follows that $S^\infty[d] \subseteq S^\infty[d']$. Moreover, by (4) and the fact that c does not decrease along any sequence, we have that

$$d'(wu) \geq c(wu) d(\lambda) \geq c(w) d(\lambda) = d'(w) - e(w) d(\lambda) > d'(w) - 2d(\lambda).$$

Since c can increase by at most 2 in every step, $c(w) \leq 2|w|$. Together with (4), this yields that

$$d'(w) = (c(w) + e(w)) d(\lambda) < 2(|w| + 1) d(\lambda). \qquad \square$$

One can also show that $S^\infty[d'] \subseteq S^\infty[d]$ in Lemma 2.3, so the success set actually remains intact under the above transformation.

As with Lebesgue measure, the property of having resource-bounded measure zero is monotone and closed under union ("finite unions property"). A resource-bounded version of closure under countable unions also holds. The property that becomes crucial in resource-bounded measure is that the whole space Δ does not have measure zero, which Lutz calls the "measure conservation" property. With a slight abuse of meaning for "$\neq$," this property is written $\mu_\Delta(\Delta) \neq 0$. In particular, $\mu_{\mathrm{E}}(\mathrm{E}) \neq 0$ and

$\mu_{\mathrm{EXP}}(\mathrm{EXP}) \neq 0$. Subclasses of Δ that require substantially fewer resources do have Δ-measure zero. For example, P has E-measure zero. Indeed, for any fixed $c > 0$, DTIME$[2^{cn}]$ has E-measure zero and DTIME$[2^{n^c}]$ has EXP-measure zero [Lutz92].

Apart from formalizing rareness and abundance in computational complexity theory, resource-bounded martingales are also used to define the concept of a random set in a resource-bounded setting.

DEFINITION 2.4. *A set A is* Δ-random *if* $\mu_\Delta(\{A\}) \neq 0$.

In other words, A is Δ-random if no Δ-martingale succeeds on A.

3. Betting games. To capture intuitions that have been expressed not only for Lutz measure but also in many earlier papers on random sequences, we formalize a betting game as an *infinite* process, rather than as a Turing machine that has *finite* computations on string inputs.

DEFINITION 3.1. *A* betting game *G is an oracle Turing machine that maintains a "capital tape" and a "bet tape," in addition to its standard query tape and worktapes, and works in* stages $i = 1, 2, 3 \ldots$ *as follows. Beginning each stage i, the capital tape holds a nonnegative rational number C_{i-1}. The* initial capital C_0 *is some positive rational number. G computes a query string x_i to bet on, a* bet amount B_i, $0 \leq B_i \leq C_{i-1}$, *and a* bet sign $b_i \in \{-1, +1\}$. *The computation is* legal *so long as x_i does not belong to the set $\{x_1, \ldots, x_{i-1}\}$ of strings queried in earlier stages. G ends stage i by entering a special query state. For a given oracle language A, if $x_i \in A$ and $b_i = +1$, or if $x_i \notin A$ and $b_i = -1$, then the new capital is given by $C_i := C_{i-1} + B_i$, else by $C_i := C_{i-1} - B_i$. We charge M for the time required to write the numerator and denominator of the new capital C_i down. The query and bet tapes are blanked, and G proceeds to stage $i + 1$.*

In this paper, we lose no generality by not allowing G to "crash" or to loop without writing a next bet and query. Note that every oracle set A determines a unique infinite computation of G, which we denote by G^A. This includes a unique infinite sequence $x_1, x_2, \ldots$ of query strings, and a unique sequence $C_0, C_1, C_2, \ldots$ telling how the gambler fares against A .

DEFINITION 3.2. *A betting machine G* runs in time $t(n)$ *if for all oracles A, every query of length n made by G^A is made in the first $t(n)$ steps of the computation.*

DEFINITION 3.3. *A betting game G* succeeds *on a language A, written $A \in S^\infty[G]$, if the sequence of values C_i in the computation G^A is unbounded. If $A \in S^\infty[G]$, then we also say G* covers *A.*

Our main motivating example where one may wish not to bet in lexicographic order, or according to any fixed ordering of strings, is deferred to section 6. There we will construct an E-betting game that succeeds on the class of $\leq_T^p$-autoreducible languages, which is not known to have Lutz measure zero in E or EXP.

We now want to argue that the more liberal requirement of being covered by a time $t(n)$ betting game still defines a smallness concept for subclasses of DTIME$[t(n)]$ in the intuitive sense Lutz established for his measure-zero notion. The following result is a good beginning.

THEOREM 3.4. *For every time-$t(n)$ betting game G, we can construct a language in* DTIME$[t(n)]$ *that is not covered by G.*

Proof. Let Q be a nonoracle Turing machine that runs as follows on any input x. The machine Q simulates up to $t(|x|)$ steps of the single computation of G on empty input. Whenever G bets on and queries a string y, Q gives the answer that causes G to lose money, rejecting in the case of a zero bet. If and when G queries x, Q does likewise. If $t(|x|)$ steps go by without x being queried, then Q rejects x.

The important point is that Q's answer to a query $y \neq x$ is the same as the answer when Q is run on input y. The condition that G cannot query a string x of length n after $t(n)$ steps have elapsed ensures that the decision made by Q when x is not queried does not affect anything else. Hence Q defines a language on which G never does better than its initial capital C_0 and so does not succeed. □

In particular, the class E cannot be covered by an E-betting game, nor EXP by an EXP-betting game. Put another way, the "measure conservation axiom" [Lutz92] of Lutz's measure carries over to betting games.

To really satisfy the intuition of "small," however, it should hold that the union of two small classes is small. (Moreover, "easy" countable unions of small classes should be small, as in [Lutz92].) Our lack of meeting this "finite union axiom" will later be excused insofar as it has the nonrelativizing consequence BPP $\neq$ EXP. Theorem 3.4 is still good enough for the "measure-like" results in this paper.

We note also that several robustness properties of Lutz's measure treated in section 2 carry over to betting games. This is because we can apply the underlying transformations to the *capital function* c_G of G, which is defined as follows.

DEFINITION 3.5. *Let G be a betting game, and let $i \geq 0$ be an integer.*

(a) *A* play α *of length i is a sequence of i-many oracle answers. Note that α determines the first i-many stages of G, together with the query and bet for the next stage.*

(b) *$c_G(\alpha)$ is the capital C_i that G has at the end of the play α (before the next query).*

Note that the function c_G is a martingale over plays α. The proof of Lemma 2.3 works for c_G. We obtain the following lemma.

LEMMA 3.6 ("slow-but-sure winnings" lemma for betting games). *Let G be a betting game that runs in time $t(n)$. Then we can construct a betting game G' that runs in time $(2^n t(n))^{O(1)}$ such that $S^\infty[G] \subseteq S^\infty[G']$, G' always makes the same queries in the same order as G, and*

$$\forall\, \beta, \forall\, \gamma : c_{G'}(\beta\gamma) > c_{G'}(\beta) - 2c_G(\lambda), \tag{5}$$

$$\forall\, \alpha : c_{G'}(\alpha) < 2(|\alpha| + 1)c_G(\lambda). \tag{6}$$

Proof. The proof of Lemma 2.3 carries over. □

To begin comparing betting games and martingales, we note first that the latter can be considered a direct special case of betting games. Say a betting game G is *lex-limited* if for all oracles A, the sequence $x_1, x_2, x_3 \ldots$ of queries made by G^A is in lexicographic order. (It need not equal the lexicographic enumeration $s_1, s_2, s_3, \ldots$ of Σ^*.)

THEOREM 3.7. *Let $\mathcal{T}(n)$ be a collection of time bounds that is closed under squaring and under multiplication by 2^n, such as $2^{O(n)}$ or $2^{n^{O(1)}}$. Then a class $\mathcal{C}$ has time-$\mathcal{T}(n)$ measure zero iff $\mathcal{C}$ is covered by a time-$\mathcal{T}(n)$ lex-limited betting game.*

Proof. From a martingale d to a betting game G, each stage i of G^A bets on s_i an amount B_i with sign $b_i \in \{-1, +1\}$ given by $b_i B_i = d(w1) - d(w)$, where w is the first $i-1$ bits of the characteristic sequence of A. This takes $O(2^n)$ evaluations of d to run G up through queries of length n, hence the hypothesis on the time bounds $\mathcal{T}(n)$. In the other direction, when G is lex-limited, one can simulate G on a finite initial segment w of its oracle up to a stage where all queries have been answered by w and G will make no further queries in the domain of w. One can then define $d(w)$ to be the capital entering this stage. That this is a martingale and fulfills the success and run-time requirements is left to the reader. □

Hence in particular for measure on E and EXP, martingales are equivalent to betting games constrained to bet in lexicographic order. Now we will see how we can transform a *general* betting game into an equivalent martingale.

4. From betting games to martingales. This section associates to every betting game G a martingale d_G such that $S^\infty[G] \subseteq S^\infty[d_G]$, and begins examining the complexity of d_G. Before defining d_G, however, we pause to discuss some tricky subtleties of betting games and their computations.

Given a finite initial segment w of an oracle language A, one can define the partial computation G^w of the betting game up to the stage i at which it first makes a query x_i that is not in the domain of w. Define $d(w)$ to be the capital C_{i-1} that G had entering this stage. It is tempting to think that d is a martingale and succeeds on all A for which G succeeds—but neither statement is true in general. The most important reason is that d may fail to be a martingale.

To see this, suppose x_i itself is the lexicographically least string not in the domain of w. That is, x_i is indexed by the bit b of wb, and $w1 \sqsubseteq A$ iff $x_i \in A$. It is possible that G^A makes a small (or even zero) bet on x_i, *and then goes back to make more bets in the domain of* w, *winning lots of money on them*. The definitions of both $d(w0)$ and $d(w1)$ will then reflect these added winnings, and both values will be greater than $d(w)$. For example, suppose G^A first puts a zero bet on $x_i = s_j$, then bets all of its money on $x_{i+1} = s_{j-1}$ not being in A, and then proceeds with $x_{i+2} = s_{j+1}$. If $w(s_{j-1}) = 0$, then $d(w0) = d(w1) = 2d(w)$.

Put another way, a finite initial segment w may carry much more "winnings potential" than the above definition of $d(w)$ reflects. To capture this potential, one needs to consider potential plays of the betting game outside the domain of w. Happily, one can bound the length of the considered plays via the running time function t of G. Let n be the maximum length of a string indexed by w; i.e., $n = \lfloor \log_2(|w|) \rfloor$. Then after $t(n)$ steps, G cannot query any more strings in the domain of w, so w's potential is exhausted. We will define $d_G(w)$ as an *average* value of those plays that can happen, given the query answers fixed by w. We use the following definitions and notation.

DEFINITION 4.1. *For any $t(n)$ time-bounded betting game G and string $w \in \Sigma^*$, define the following.*

(a) *A play α is* t-maximal *if G completes the first $|\alpha|$ stages, but* not *the query and bet of the next stage, within t steps.*

(b) *A play α is* G-consistent with w, *written $\alpha \sim_G w$, if for all stages j such that the queried string x_j is in the domain of w, $\alpha_j = w(x_j)$. That is, α is a play that could possibly happen given the information in w. Also let $m(\alpha, w)$ stand for the number of such stages j whose query is answered by w.*

(c) *Finally, put $d_G(\lambda) = c_G(\lambda)$, and for nonempty w, with $n = \lfloor \log_2(|w|) \rfloor$ as above, let*

$$d_G(w) = \sum_{\alpha \ t(n)-maximal, \alpha \sim_G w} c_G(\alpha)\, 2^{m(\alpha,w)-|\alpha|} \quad . \tag{7}$$

The weight $2^{m(\alpha,w)-|\alpha|}$ in (7) has the following meaning. Suppose we extend the simulation of G^w by flipping a coin for every query outside the domain of w for exactly i stages. Then the number of coin-flips in the resulting play α of length i is $i - m(\alpha, w)$, so $2^{m(\alpha,w)-i}$ is its probability. Thus $d_G(w)$ returns the suitably-weighted average of $t(n)$-step computations of G with w fixed. The interested reader may verify that this is the same as averaging $d(wv)$ over all v of length $2^{t(n)}$ (or any fixed longer length), where d is the nonmartingale defined at the beginning of this section.

LEMMA 4.2. *The function $d_G(w)$ is a martingale.*

Proof. First we argue that

$$d_G(w) = \sum_{|\alpha'|=t(n),\alpha' \sim_G w} c_G(\alpha')\, 2^{m(\alpha',w)-t(n)}. \tag{8}$$

Observe that when $\alpha' = \alpha\beta$ and α is $t(n)$-maximal, $\alpha \sim_G w \iff \alpha' \sim_G w$. This is because none of the queries answered by β can be in the domain of w, else the definition of G running in time $t(n)$ would be violated. Likewise if $\alpha \sim_G w$, then $m(\alpha', w) = m(\alpha, w)$. Finally, since c_G is a martingale, $c_G(\alpha) = \sum_{|\beta|=t(n)-|\alpha|} c_G(\alpha\beta)\, 2^{|\alpha|-t(n)}$. These facts combine to show the equality of (7) and (8).

By the same argument, the right-hand side of (8) is unchanged on replacing "$t(n)$" by any $t' > t(n)$.

Now consider w such that $|w|+1$ is not a power of 2. Then the "n" for $w0$ and $w1$ is the same as the "n" for $d_G(w)$. Let P_0 stand for the set of α of length $t(n)$ that are G-consistent with $w0$ but not with $w1$, P_1 for those that are G-consistent with $w1$ but not $w0$, and P for those that are consistent with both. Then the set $\{\, \alpha : |\alpha| = t(n),\ \alpha \sim_G w \,\}$ equals the disjoint union of P, P_0, and P_1. Furthermore, for $\alpha \in P_0$ we have $m(\alpha, w0) = m(\alpha, w) + 1$, and similarly for P_1, while for $\alpha \in P$ we have $m(\alpha, w0) = m(\alpha, w1) = m(\alpha, w)$. Hence $d_G(w0) + d_G(w1)$ is given by

$$\sum_{\alpha \in P \cup P_0} c_G(\alpha) 2^{m(\alpha,w0)-t(n)} + \sum_{\alpha \in P \cup P_1} c_G(\alpha) 2^{m(\alpha,w1)-t(n)}$$

$$= \sum_{\alpha \in P_0} c_G(\alpha) 2^{m(\alpha,w0)-t(n)} + \sum_{\alpha \in P_1} c_G(\alpha) 2^{m(\alpha,w1)-t(n)} + 2 \sum_{\alpha \in P} c_G(\alpha) 2^{m(\alpha,w)-t(n)}$$

$$= 2 \sum_{\alpha \in P_0} c_G(\alpha) 2^{m(\alpha,w)-t(n)} + 2 \sum_{\alpha \in P_1} c_G(\alpha) 2^{m(\alpha,w)-t(n)} + 2 \sum_{\alpha \in P} c_G(\alpha) 2^{m(\alpha,w)-t(n)}$$

$$= 2 d_G(w).$$

Finally, if $|w|+1$ is a power of 2, then $d_G(w0)$ and $d_G(w1)$ use $t' := t(n+1)$ for their length of α. However, by the first part of this proof, we can replace $t(n)$ by t' in the definition of $d_G(w)$ without changing its value, and then the second part goes through the same way for t'. Hence d_G is a martingale. ∎

It is still the case, however, that d_G may not succeed on the languages on which the betting game G succeeds. To ensure this, we first use Lemma 3.6 to place betting games G into a suitable "normal form" satisfying the sure-winnings condition (5).

LEMMA 4.3. *If G is a betting game satisfying the sure-winnings condition* (5)*, then $S^\infty[G] \subseteq S^\infty[d_G]$.*

Proof. First, let $A \in S^\infty[G]$, and fix $k > 0$. Find a finite initial segment $w \sqsubseteq A$ long enough to answer every query made in a play α of G such that $\alpha \sim_G w$ and $c_G(\alpha) \geq k+2$ and long enough to make $t(n)$ in the definition of $d_G(w)$ (see (7)) greater than $|\alpha|$. Then every α' of length $t(n)$ such that $\alpha' \sim_G w$ has the form $\alpha' = \alpha\beta$. The sure-winnings condition (5) implies that the right-hand side of (7) defining $d_G(w)$ is an average over terms that all have size at least k. Hence $d_G(w) \geq k$. Letting k grow to infinity gives $A \in S^\infty[d_G]$. ∎

Now we turn our attention to the complexity of d_G. If G is a time-$t(n)$ betting game, it is clear that d_G can be computed deterministically in $O(t(n))$ *space*, because we need only cycle through all α of length $t(n)$, and all the items in (7) are computable in space $O(t(n))$. In particular, every E-betting game can be simulated by a martingale whose values are computable in deterministic space $2^{O(n)}$ (even counting the output against the space bound), and every EXP-betting game can be simulated by a martingale similarly computed in space $2^{n^{O(1)}}$. However, we show in the next section that one can *estimate* $d_G(w)$ well without having to cycle through all the α, using a pseudorandom generator to "sample" only a very small fraction of them.

5. Sampling results. First we determine the accuracy to which we need to estimate the values $d(w)$ of a hard-to-compute martingale. We state a stronger version of the result than we need in this section. In the next section, we will apply it to martingales whose "activity" is restricted to subsets J of $\{0,1\}^*$ in the following sense: for all strings $x \notin J$, and all w such that $s_{|w|+1} = x$, $d(w0) = d(w1) = d(w)$. Intuitively, a martingale d is inactive on a string x if there is *no* possible "past history" w that causes a nonzero bet to be made on x. For short we say that such a d is *inactive outside* J. Recall that $N = \Theta(2^n)$.

LEMMA 5.1. *Let d be a martingale that is inactive outside $J \subseteq \{0,1\}^*$, and let $[\epsilon(i)]_{i=0}^{\infty}$ be a nonnegative sequence such that $\sum_{s_i \in J} \epsilon(i)$ converges to a number K. Suppose we can compute in time $t(n)$ a function $g(w)$ such that $|g(w) - d(w)| \leq \epsilon(N)$ for all w of length N. Then there is a martingale d' computable in time $(2^n t(n))^{O(1)}$ such that for all w, $|d'(w) - d(w)| \leq 4K + 2\epsilon(0)$.*

In this section, we will apply Lemma 5.1 with $J = \{0,1\}^*$ and $\epsilon(N) = 1/N^2 = 1/2^{2n}$. In section 6.3 we will apply Lemma 5.1 in cases where J is finite.

Proof. First note that for any w (with $N = |w|$),

$$\begin{aligned} \left| g(w) - \frac{g(w0)+g(w1)}{2} \right| &\leq |g(w)-d(w)| + \left| \frac{d(w0)-g(w0)}{2} \right| + \left| \frac{d(w1)-g(w1)}{2} \right| \\ &\leq \epsilon(N) + \epsilon(N+1). \end{aligned} \tag{9}$$

In case $J = \{0,1\}^*$, we inductively define

$$\begin{cases} d'(\lambda) &= g(\lambda) + 2K + \epsilon(0), \\ d'(wb) &= d'(w) + g(wb) - \frac{g(w0)+g(w1)}{2}. \end{cases}$$

Note that d' satisfies the average law (1), and that we can compute $d'(w)$ in time $O(2^n t(n))$.

By induction on $|w|$, we can show using the estimate provided by (9) that

$$g(w) + \epsilon(N) + 2\sum_{i=N+1}^{\infty} \epsilon(i) \;\leq\; d'(w) \;\leq\; g(w) + 2\sum_{i=0}^{N-1} \epsilon(i) + \epsilon(N) + 2K.$$

It follows that

$$\begin{aligned} d'(w) &\geq g(w) + \epsilon(N) \\ &= d(w) + (g(w) - d(w)) + \epsilon(N) \geq d(w), \end{aligned}$$

and that

$$d'(w) = d(w) + (g(w) - d(w)) + (d'(w) - g(w))$$

$$\leq d(w) + \epsilon(N) + 2\sum_{i=0}^{N-1} \epsilon(i) + \epsilon(N) + 2K$$
$$\leq d(w) + 4K + 2\epsilon(0).$$

This establishes the lemma in case $J = \{0,1\}^*$. The generalization to other subsets J of $\{0,1\}^*$ is left to the reader. □

Next, we specify precisely which function f_G we will sample in order to estimate d_G and how we will do it.

Let G be a $t(n)$ time-bounded betting game. Consider a prefix w, and let n denote the largest length of a string in the domain of w. With any string ρ of length $t(n)$, we can associate a unique "play of the game" G defined by using w to answer queries in the domain of w and the successive bits of ρ to answer queries outside it. We can stop this play after $t(n)$ steps—so that the stopped play is a $t(n)$-maximal α—and then define $f_G(w,\rho)$ to be the capital $c_G(\alpha)$. Note that we can compute $f_G(w,\rho)$ in linear time, i.e., in time $O(|w| + t(n))$. The proportion of strings ρ of length $t(n)$ that map to the same play α is exactly the weight $2^{m(\alpha,w)-|\alpha|}$ in (7) for $d_G(w)$. Letting E stand for mathematical expectation, this gives us

$$d_G(w) = E_{|\rho|=t(n)}[f_G(w,\rho)].$$

To obtain good and efficient approximations to the right-hand side, we employ *pseudorandom generators*. The following supplies all relevant definitional background.

DEFINITION 5.2 (see [NiWi94]).

(a) *The* hardness $H_A(n)$ *of a set* A *at length* n *is the largest integer* s *such that for any circuit* C *of size at most* s *with* n *inputs,*

$$\left|\Pr_x[C(x) = A(x)] - \frac{1}{2}\right| \leq \frac{1}{s},$$

where x *is uniformly distributed over* Σ^n.

(b) *A* pseudorandom generator *is a function* D *that, for each* n, *maps* Σ^n *into* $\Sigma^{r(n)}$, *where* $r(n) \geq n+1$. *The function* r *is called the* stretching *of* D.

(c) *The* security $S_D(n)$ *of* D *at length* n *is the largest integer* s *such that, for any circuit* C *of size at most* s *with* $r(n)$ *inputs,*

$$\left|\Pr_x[C(x) = 1] - \Pr_y[C(D(y)) = 1]\right| \leq \frac{1}{s},$$

where x *is uniformly distributed over* $\Sigma^{r(n)}$ *and* y *over* Σ^n.

We will use pseudorandom generators with the following characteristics:

(1) an E-computable pseudorandom generator D_1 that stretches seeds super-polynomially and has super-polynomial security at infinitely many lengths;
(2) an EXP-computable pseudorandom generator D_2 of security $2^{n^{\Omega(1)}}$; and
(3) an E-computable pseudorandom generator D_3 of security $2^{\Omega(n)}$.

D_1 will be applied in the next section; in this section we will use D_2 and D_3. None of these generators is known to exist unconditionally. However, a highly plausible hypothesis suffices for the weakest generator D_1, as follows simply by combining the work of [BFNW93] and [NiWi94] with some padding.

THEOREM 5.3. *If* MA $\neq$ EXP, *then there is an* E*-computable pseudorandom generator* D_1 *with stretching* $n^{\Theta(\log n)}$ *such that for any integer* k, *there are infinitely many* n *with* $S_{D_1}(n) > n^k$.

Proof. From the proof of Lemma 4.1 of [BFNW93], it follows that if MA $\neq$ EXP, then there is a set $A \in$ EXP such that for any integer j, there are infinitely many m such that $H_A(m) > m^j$. From the proof of the main Theorem 1 in [NiWi94], it follows that for any set $A \in$ EXP, there is an EXP-computable pseudorandom generator D with stretching $n^{\Theta(\log n)}$ such that $S_D(n) = \Omega(H_A(\sqrt{n})/n)$. Say that D is computable in time 2^{n^c} for some integer constant $c > 0$. For any $k > 0$, the infinitely many m promised above with $j = 2(ck+1)$ yield infinitely many n of the form $m^{2/c}$ such that $S_D(n^{1/c}) > n^k$. Defining $D_1(x) = D(x')$, where x' denotes the prefix of x of length $|x|^{1/c}$, yields the required pseudorandom generator. □

Exponential-time computable pseudorandom generators with exponential security have the interesting property that we can blow up the stretching exponentially without significantly reducing the security. As with Theorem 5.3, credit for this observation should be distributed among the references cited in the proof.

THEOREM 5.4.

(a) *Given an* EXP*-computable pseudorandom generator* D_0 *of security* $2^{n^{\Omega(1)}}$*, we can construct an* EXP*-computable pseudorandom generator* D_2 *of security* $2^{n^{\Omega(1)}}$ *and stretching* $2^{n^{\Omega(1)}}$.

(b) *Given an* E*-computable pseudorandom generator* D_0 *of security* $2^{\Omega(n)}$*, we can construct an* E*-computable pseudorandom generator* D_3 *of security* $2^{\Omega(n)}$ *and stretching* $2^{\Omega(n)}$.

Proof. For (a), Nisan and Wigderson [NiWi94] showed that the existence of an E-computable pseudorandom generator with stretching $n+1$ (a "quick extender" in their terminology) with security $2^{n^{\Omega(1)}}$ is equivalent to the existence of an E-computable pseudorandom generator with stretching and security $2^{n^{\Omega(1)}}$. See statements (3) and (4) of their main theorem (Theorem 1) instantiated with $s(\ell) = 2^\ell$. As used in [BFNW93], their main result carries through if we replace "E-computable" by "EXP-computable" in both statements, owing to padding. Since the existence of D_0 implies the existence of an EXP-computable extender with security $2^{n^{\Omega(1)}}$, the existence of D_2 follows.

For (b), first define $D'(x)$ to be the first $|x|+1$ bits of $D_0(x)$. Then D' is an extender with security $2^{\Omega(n)}$, and this implies that the range of D' is a language in E requiring circuits of size $2^{\Omega(n)}$. Impagliazzo and Wigderson, in their proof of Theorem 2 in [ImWi97], showed how to transform such a language into a language $A \in$ E such that $H_A(n) = 2^{\Omega(n)}$. Using this A in part (3) of Theorem 2 of [NiWi94] yields an E-computable pseudorandom generator D_3 of security and stretching $2^{\Omega(n)}$. (It is also possible to argue that the range of D' is sufficiently hard to employ the technique of [NiWi94], without going through [ImWi97].) □

Pseudorandom generators of security $2^{n^{\Omega(1)}}$ (even polynomial-time computable ones) are fairly widely believed to exist (see [BlMi84, RaRu97, Bon99]), and while those of security $2^{\Omega(n)}$ are more controversial even for EXP-computability, their existence was made more plausible by the result of [ImWi97] used in the proof of (b) above. Polynomial-time computable pseudorandom generators of security $2^{\Omega(n)}$ exist relative to a random oracle [Zim95, Imp99pc], and E-computable ones also exist if P = NP. (The latter observation follows by combining the techniques of Kannan [Kan82] with padding and the above-mentioned result of [ImWi97]; it is noted by the second author as "Corollary 2.2.19" in his dissertation [Mel99].)

The following general result shows how pseudorandom generators can be used to approximate averages. It provides the accuracy and time bounds needed for applying Lemma 5.1 to get the desired martingale.

THEOREM 5.5. *Let D be a pseudorandom generator computable in time $\delta(n)$ and with stretching $r(n)$. Let $f : \Sigma^* \times \Sigma^* \to (-\infty, \infty)$ be a function that is computed in linear time on a Turing machine, and let $s, R, m : \mathbf{N} \to \mathbf{N}$ be fully time-constructible functions such that $s(N) \geq N$ and the following relations hold for any integer $N \geq 0$, $w \in \Sigma^N$, and $\rho \in \Sigma^{s(N)}$:*

$$\begin{aligned} |f(w,\rho)| &\leq R(N), \\ r(m(N)) &\geq s(N), \\ S_D(m(N)) &\geq (s(N) + R(N))^6. \end{aligned} \tag{10}$$

Then we can approximate

$$h(w) = E_{|\rho|=s(N)}[f(w,\rho)] \tag{11}$$

to within N^{-2} in time $O(2^{m(N)} \cdot (s(N) + R(N))^4 \cdot \delta(m(N)))$.

Proof. For any $N \geq 0$, let $\mathcal{I}_N$ be a partition of the interval $[-R(N), R(N)]$ into subintervals of length $\frac{1}{2N^2}$. Note that $|\mathcal{I}_N| = 4N^2R(N)$. Define for any $I \in \mathcal{I}_N$ and any string w of length N

$$\pi(I,w) = \Pr_{|\rho|=s(N)}[f(w,\rho) \in I].$$

The predicate in $[\ldots]$ can be computed by circuits of size $O(s(N) \log s(N))$, using the t-to-$O(t \log t)$ Turing-machine-time-to-circuit-size construction of Pippenger and Fischer [PiFi79]. Since $S_D(m(N)) = \omega(s(N) \log s(N))$, it follows that

$$\tilde{\pi}(I,w) = \Pr_{|\sigma|=m(N)}[f(w, D(\sigma)[1 \ldots s(N)]) \in I]$$

approximates $\pi(I,w)$ to within an additive error of $(S_D(m(N)))^{-1}$, and we can compute it in time $O(2^{m(N)} \cdot s(N) \cdot \delta(m(N)))$. We define the approximation $\tilde{h}(w)$ for $h(w)$ as

$$\tilde{h}(w) = \sum_{I \in \mathcal{I}_N} \tilde{\pi}(I,w) \min(I).$$

Since we can write $h(w)$ as

$$h(w) = \sum_{I \in \mathcal{I}_N} \pi(I,w) E_{|\rho|=s(N)}[f(w,\rho) \mid f(w,\rho) \in I],$$

we can bound the approximation error as follows:

$$\begin{aligned} &|h(w) - \tilde{h}(w)| \\ &\leq \sum_{I \in \mathcal{I}_N} \pi(I,w) \left| E_{|\rho|=s(N)}[f(w,\rho) \mid f(w,\rho) \in I] - \min(I) \right| \\ &\quad + \sum_{I \in \mathcal{I}_N} \left| \pi(I,w) - \tilde{\pi}(I,w) \right| \min(I) \\ &\leq \max_{I \in \mathcal{I}_N}(|I|) + |\mathcal{I}_N| \cdot (S_D(m(N)))^{-1} \cdot R(N) \\ &\leq \frac{1}{2N^2} + 4N^2 \cdot R^2(N) \cdot (S_D(m(N)))^{-1} \leq \frac{1}{N^2}. \end{aligned}$$

Computing $\tilde{h}(w)$ requires $|\mathcal{I}_N| = 4N^2R(N)$ evaluations of $\tilde{\pi}$, which results in the claimed upper bound for the time complexity of $\tilde{h}$. □

Now we would like to apply Theorem 5.5 to approximate $h = d_G$ given by (7) to within N^{-2}, by setting $f = f_G$ and $s(N) = t(\log N)$. However, for a general betting game G running in time $t(n)$, we can only guarantee an upper bound of $R(N) = 2^{t(\log N)} \cdot c_G(\lambda)$ on $|f(w, \rho)|$. Since S_D can be at most exponential, condition (10) would force $m(N)$ to be $\Omega(t(\log N))$. In that case, Theorem 5.5 can only yield an approximation computable in time $2^{O(t(\log N))}$. *However*, we can assume without loss of generality that G satisfies the slow-winnings condition (6) of Lemma 3.6, in which case an upper bound of $R(N) \in O(N)$ holds. Then the term $s(N)$ in the right-hand side of (10) dominates, provided $t(n) = 2^{\Omega(n)}$.

Taking everything together, we obtain the following result about transforming E- and EXP-betting games into equivalent E-, respectively, EXP-martingales.

THEOREM 5.6. *If there is a pseudorandom generator computable in* E *with security* $2^{\Omega(n)}$*, then for every* E*-betting game* G*, there exists an* E*-martingale* d *such that* $S^\infty[G] \subseteq S^\infty[d]$*. If there is a pseudorandom generator computable in* EXP *with security* $2^{n^{\Omega(1)}}$*, then for every* EXP*-betting game* G*, there exists an* EXP*-martingale* d *such that* $S^\infty[G] \subseteq S^\infty[d]$*.*

Proof. By Lemma 3.6, we can assume that c_G satisfies both the sure-winnings condition (5) as well as the slow-winnings condition (6). Because of Lemmas 4.3 and 5.1 (since the series $\sum_{i=1}^{\infty} \frac{1}{i^2}$ converges), it suffices to approximate the function $d_G(w)$ given by (7) to within N^{-2} in time $2^{O(n)}$, respectively, $2^{n^{O(1)}}$, where $N = |w|$ and $n = \log N$.

Under the given hypothesis about the existence of an E-computable pseudorandom generator D_0, we can take D to be the pseudorandom generator D_3 provided by Theorem 5.4(b). Thus we meet the conditions for applying Theorem 5.5 to $h = d_G$ with $s(N) = N^{O(1)}$, $R(N) = O(N)$, and $m(N) = O(\log N)$, and we obtain the approximation of d_G that we need. In the case of an EXP-betting game G, to obtain an EXP-martingale we can take D to be the pseudorandom generator D_2 of weaker security guarantee $2^{n^{\Omega(1)}}$ provided by Theorem 5.4(a). Then we meet the requirements of Theorem 5.5 with $s(N) = 2^{(\log N)^{O(1)}}$, $R(N) = O(N)$, and $m(N) = (\log N)^{O(1)}$. □

6. Autoreducible sets. An oracle Turing machine M is said to *autoreduce* a language A if $L(M^A) = A$, and for all strings x, M^A on input x does not query x. That is, one can learn the membership of x by querying strings other than x itself. If M runs in polynomial time, then A is P-*autoreducible*—we also write $\leq_T^p$-autoreducible. If M is also nonadaptive, then A is $\leq_{tt}^p$-*autoreducible*.

One can always code M so that for *all* oracles, it *never* queries its own input—then we call M an *autoreduction*. Hence we can define an effective enumeration $[M_i]_{i=1}^{\infty}$ of polynomial-time autoreductions, such that a language A is autoreducible iff there exists an i such that $L(M_i^A) = A$. (For a technical aside: the same M_i may autoreduce different languages A, and some M_i may autoreduce no languages at all.) The same goes for $\leq_{tt}^p$-*autoreductions*.

Autoreducible sets were brought to the polynomial-time context by Ambos-Spies [Amb84]. Their importance was further argued by Buhrman, Fortnow, Van Melkebeek, and Torenvliet [BFvMT98], who showed that all $\leq_T^p$-complete sets for EXP are $\leq_T^p$-autoreducible (while some complete sets for other classes are not). Here we demonstrate that autoreducible sets are important for testing the power of resource-bounded measure.

6.1. Adaptively autoreducible sets. As stated in the introduction, if the $\leq_T^p$-autoreducible sets in EXP (or sufficiently the $\leq_T^p$-complete sets for EXP) are covered by an EXP-martingale, then EXP $\neq$ BPP, a nonrelativizing consequence. However, it is easy to cover them by an E-betting game. Indeed, the betting game uses its adaptive freedom only to "look ahead" at the membership of lexicographically greater strings, betting nothing on them.

THEOREM 6.1. *There is an* E*-betting game* G *that covers all* $\leq_T^p$*-autoreducible languages.*

Proof. Let $M_1, M_2, \ldots$ be an enumeration of $\leq_T^p$-autoreductions such that each M_i runs in time $n^i + i$ on inputs of length n. Our betting game G regards its capital as composed of infinitely many "shares" c_i, one for each M_i. Initially, $c_i = 1/2^i$. Letting $\langle \cdot, \cdot \rangle$ be a standard pairing function, inductively define $n_0 = 0$ and $n_{\langle i,j \rangle + 1} = (n_{\langle i,j \rangle})^i + i$.

During a stage $s = \langle i, j \rangle$, G simulates M_i on input $0^{n_{s-1}}$. Whenever M_i makes a query of length less than n_{s-1}, G looks up the answer from its table of past queries. Whenever M_i makes a query of length n_{s-1} or more, G places a bet of zero on that string and makes the same query. Then G bets all of the share c_i on $0^{n_{s-1}}$ according to the answer of the simulation of M_i. Finally, G "cleans up" by putting zero bets on all strings with length in $[n_{s-1}, n_s)$ that were not queries in the previous steps.

If M_i autoreduces A, then share c_i doubles in value at each stage $\langle i, j \rangle$ and makes the total capital grow to infinity. And G runs in time $2^{O(n)}$—indeed, only the "cleanup" phase needs this much time. □

COROLLARY 6.2. *Each of the following statements implies* BPP $\neq$ EXP*.*

1. *The class of* $\leq_T^p$*-autoreducible sets has* E*-measure zero.*
2. *The class of* $\leq_T^p$*-complete sets for* EXP *has* E*-measure zero.*
3. E*-betting games and* E*-martingales are equivalent.*
4. E*-betting games have the finite union property.*

The same holds if we replace E *by* EXP *in these statements.*

Proof. Let $\mathcal{C}$ stand for the class of languages that are not $\leq_T^p$-hard for BPP. Allender and Strauss [AlSt94] showed that $\mathcal{C}$ has E-measure zero, so trivially it is also covered by an E-betting game. Now let $\mathcal{D}$ stand for the class of $\leq_T^p$-complete sets for EXP. By Theorem 6.1 and the result of [BFvMT98] cited above, $\mathcal{D}$ is covered by an E-betting game.

If EXP = BPP, the union $\mathcal{C} \cup \mathcal{D}$ contains all of EXP, and

- if $\mathcal{D}$ would have E-measure zero, so would $\mathcal{C} \cup \mathcal{D}$ and hence EXP, contradicting the measure conservation property of Lutz measure;
- if E-betting games would have the finite-union property, then $\mathcal{C} \cup \mathcal{D}$ and EXP would be covered by an E-betting game, contradicting Theorem 3.4.

Since statement 1 implies statement 2, and statement 3 implies statement 4, then these observations suffice to establish the corollary for E. The proof for EXP is similar. □

Since there is an oracle A giving $\text{EXP}^A = \text{BPP}^A$ [Hel86], this shows that relativizable techniques cannot establish the equivalence of E-martingales and E-betting games, nor of EXP-martingales and EXP-betting games. They cannot refute it either, since there are oracles relative to which strong pseudorandom generators exist—all "random" oracles, in fact [Zim95].

6.2. Nonadaptively autoreducible sets. It is tempting to think that the *non*adaptively P-autoreducible sets should have E-measure zero, or at least EXP-measure zero, insofar as betting games are the adaptive cousins of martingales. How-

ever, it is not just adaptiveness but also the freedom to bet *out of the fixed lexicographic order* that adds power to betting games. If one carries out the proof of Theorem 6.1 to cover the class of $\leq_{tt}^{p}$-autoreducible sets, using an enumeration $[M_i]$ of $\leq_{tt}^{p}$-autoreductions, one obtains a *nonadaptive* E-betting game (defined formally below) that (independent of its oracle) bets on all strings in an order given by a single permutation of Σ^*. The permutation itself is E-computable. It might seem that an E-martingale should be able to "untwist" the permutation and succeed on all these sets. However, our next results, which strengthen the above corollary, close the same "nonrelativizing" door on proving this with current techniques.

THEOREM 6.3. *For any $k \geq 1$, the $\leq_{tt}^{p}$-complete languages for Δ_k^p are $\leq_{tt}^{p}$-autoreducible.*

Here is the proof idea, which follows techniques of [BFvMT98] for the theorem that all EXP-complete sets are $\leq_{T}^{p}$-autoreducible. Call a closed propositional formula that has at most k blocks of like quantifiers (i.e., at most $k-1$ quantifier alternations) a "QBF$_k$ formula," and let $TQBF_k$ stand for the set of true QBF formulas. Let A be a $\leq_{tt}^{p}$-complete set for $\Delta_{k+1}^{p} = \mathrm{P}^{\Sigma_k^p}$. Since $TQBF_k$ is Σ_k^p-hard, there is a deterministic polynomial-time oracle Turing machine M that accepts A with oracle $TQBF_k$. Let $q(x, i)$ stand for the ith oracle query made by M on input x. Whether $q(x, i)$ belongs to $TQBF_k$ forms a Δ_{k+1}^{p}-question, so we can $\leq_{tt}^{p}$-reduce it to A. It is possible that this latter reduction will include x itself among its queries. Let b_i^+ denote the answer it gives to the question provided that any query to x is answered "yes," and similarly define b_i^- in case x is answered "no."

If $b_i^+ = b_i^-$, which holds in particular if x is not queried, then we know the correct answer b_i to the ith query. If this situation occurs for all queries, we are finished: We just have to run M on input x using the b_i's as answers to the oracle queries. The b_i's themselves are obtained *without* submitting the (possibly adaptive) queries made by M, but rather by applying the latter $\leq_{tt}^{p}$-reduction to A to the pair $\langle x, i\rangle$, and without submitting any query on x itself. Hence this process satisfies the requirements of a $\leq_{tt}^{p}$-autoreduction of A for the particular input x.

Now suppose that $b_i^+ \neq b_i^-$ for some i, and let i be minimal. Then we will have two players play the k-round game underlying the QBF$_k$-formula that constitutes the ith oracle query. One player claims that b_i^+ is the correct value for b_i, which is equivalent to claiming that $x \in A$, while his opponent claims that b_i^- is correct and that $x \notin A$. Write $\chi_A(x) = 1$ if $x \in A$, and $\chi_A(x) = 0$ if $x \notin A$. The players' strategies will consist of computing the game history so far, determining their optimal next move, $\leq_{tt}^{p}$-reducing this computation to A, and finally producing the result of this reduction under their respective assumption about $\chi_A(x)$. This approach will allow us to recover the game history in polynomial time with nonadaptive queries to A different from x. Moreover, it will guarantee that the player making the correct assumption about $\chi_A(x)$ plays optimally. Since this player is also the one claiming the correct value for b_i, he will win the game. So, we output the winner's value for b_i.

It remains to show that we can compute the above strategies in deterministic polynomial time with a Σ_k^p oracle, i.e., in $\mathrm{FP}^{\Sigma_k^p}$. It seems crucial that the number k of alternations be constant here.

Proof of Theorem 6.3. Let A be a $\leq_{tt}^{p}$-complete set for Δ_{k+1}^{p} accepted by the polynomial-time oracle Turing machine M with oracle $TQBF_k$. Let $q(x, i)$ denote the ith oracle query of M^{TQBF_k} on input x. Then $q(x, i)$ can be written in the form $(\exists y_1)(\forall y_2)\ldots(Q_k y_k)\ \phi_{x,i}(y_1, y_2, \ldots, y_k)$, where $y_1, \ldots, y_k$ stand for the vectors of variables quantified in each block, or in the opposite form beginning with the

block ($\forall y_1$). By reasonable abuse of notation, we also let y_r stand for a string of 0-1 assignments to the variables in the rth block. Without loss of generality, we may suppose every oracle query made by M has this form where each y_j is a string of length $|x|^c$, and M makes exactly $|x|^c$ queries, taking the constant c from the polynomial time bound on M. Note that the function q belongs to $\mathrm{FP}^{\Sigma_k^p}$. Hence the language

$$L_0 = \{\, \langle x, y\rangle : q(x, i) \in TQBF_k \,\}$$

belongs to Δ_{k+1}^p. Since A is $\leq_{tt}^p$-complete for Δ_{k+1}^p, there is a polynomial-time nonadaptive oracle Turing machine N_0 that accepts L_0 with oracle A. Now define $b_i^+(x) = N_0^{A\cup\{x\}}(\langle x, i\rangle)$ and $b_i^-(x) = N_0^{A\setminus\{x\}}(\langle x, i\rangle)$. We define languages $L_1, L_2, \ldots, L_k \in \Delta_{k+1}^p$ and $\leq_{tt}^p$-reductions $N_1, N_2, \ldots, N_k$ inductively as follows.

Let $1 \leq \ell \leq k$. The set L_ℓ consists of all pairs $\langle x, j\rangle$ with $1 \leq j \leq |x|^c$, such that there is a smallest i, $1 \leq i \leq |x|^c$, for which $b_i^+(x) \neq b_i^-(x)$, and the following condition holds. For $1 \leq r \leq \ell - 1$, let the sth bit of y_r equal $N_r^{A\cup\{x\}}(\langle x, s\rangle)$ if $r \equiv b_i^+(x) \bmod 2$, and $N_r^{A\setminus\{x\}}(\langle x, s\rangle)$ otherwise. We put $\langle x, j\rangle$ into L_ℓ iff there is a lexicographically least y_ℓ such that

$$\chi[(Q_{\ell+1}y_{\ell+1})(Q_{\ell+2}y_{\ell+2})\ldots(Q_k y_k)\ \phi_{x,i}(y_1, y_2, \ldots, y_k)] \equiv \ell \bmod 2,$$

and the jth bit of y_ℓ is set to 1. The form of this definition shows that L_ℓ belongs to Δ_{k+1}^p. Hence we can take N_ℓ to be a polynomial-time nonadaptive oracle Turing machine that accepts L_ℓ with oracle A.

Now, we construct a $\leq_{tt}^p$-autoreduction for A. On input x, we compute $b_i^+(x)$ and $b_i^-(x)$ for $1 \leq i \leq |x|^c$, as well as $y_r^{(b)}$ for $b \in \{0, 1\}$ and $1 \leq r \leq |x|^c$. The latter quantity $y_r^{(b)}$ is defined as follows: for $1 \leq s \leq |x|^c$, the sth bit of $y_r^{(b)}$ equals $N_r^{A\cup\{x\}}(\langle x, s\rangle)$ if $r \equiv b \bmod 2$, and $N_r^{A\setminus\{x\}}(\langle x, s\rangle)$ otherwise. Note that we can compute all these values in polynomial time by making nonadaptive queries to A, none of which equals x.

If $b_i^+(x) = b_i^-(x)$ for every $1 \leq i \leq |x|^c$, we run M on input x using $b_i^+(x) = b_i^-(x)$ as the answer to the ith oracle query. Since it always holds that at least one of $b_i^+(x)$ and $b_i^-(x)$ equals the correct oracle answer $b_i(x)$, we faithfully simulate M on input x and hence compute $\chi_A(x)$ correctly.

Otherwise, let i be the first index for which $b_i^+(x) \neq b_i^-(x)$. Since $b_j(x) = b_j^+(x) = b_j^-(x)$ for $j < i$, we can determine $q(x, i)$ by simulating M on input x until it asks the ith query. We then output 1 if

$$b_i^+(x) = \phi_{x,i}(y_1^{(b_i^+(x))}, y_2^{(b_i^+(x))}, \ldots, y_k^{(b_i^+(x))})$$

and output 0 otherwise. We claim that this gives the correct answer to whether $x \in A$.

In order to prove the claim, consider the game history $y_1^{(b_i^+(x))}$, $y_2^{(b_i^+(x))}$, $\ldots$, $y_k^{(b_i^+(x))}$. The player claiming the correct value for $b_i(x)$ gets to play the rounds that allow him to win the game no matter what his opponent does. Since this player is also the one making the correct assumption about $\chi_A(x)$, an inductive argument shows that he plays optimally: At his stages ℓ, the string y_ℓ in the above construction of L_ℓ exists, and he plays it. The key for the induction is that at later stages $\ell' > \ell$, the value of y_ℓ at stage ℓ' remains the same as what it was at stage ℓ. Thus the player with the correct assumption about $\chi_A(x)$ wins the game—that is,

$\phi_{x,i}(y_1^{(b_i^+(x))}, y_2^{(b_i^+(x))}, \ldots, y_k^{(b_i^+(x))})$ equals his guess for $b_i(x)$ (and not the other player's guess). □

In order to formalize the strengthening of Corollary 6.2 that results from Theorem 6.3, we call a betting game G *nonadaptive* if the infinite sequence $x_1, x_2, x_3, \ldots$ of queries G^A makes is the same for all oracles A. If G runs in $2^{O(n)}$ time, and this sequence hits all strings in Σ^*, then the permutation π of the standard ordering $s_1, s_2, s_3, \ldots$ defined by $\pi(s_i) = x_i$ is both computable and invertible in $2^{O(n)}$ time. It is computable in this amount of time because in order to hit all strings, G must bet on all strings in $\{0,1\}^n$ within the first $2^{O(n)}$ steps. Hence its ith bet must be made in a number of steps that is singly-exponential in the length of s_i. And to compute $\pi^{-1}(x_i)$, G need only be run for $2^{O(|x_i|)}$ steps, since it cannot query x_i after this time. Since π and its inverse are both E-computable, π is a reasonable candidate to replace lexicographic ordering in the definition of E-martingales, and likewise for EXP-martingales. We say a class $\mathcal{C}$ has π-E-measure zero if $\mathcal{C}$ can be covered by an E-martingale that interprets its input as a characteristic string *in the order given by* π.

THEOREM 6.4. *The class of $\leq_{tt}^p$-autoreducible languages can be covered by a nonadaptive* E*-betting game. Hence there is an* E*-computable and invertible permutation π of Σ^* such that this class has π-*E*-measure zero.*

Proof. With reference to the proof of Theorem 6.1, we can let $M_1, M_2, \ldots$ be an enumeration of $\leq_{tt}^p$-autoreductions such that each M_i runs in time $n^i + i$. The machine G in that proof automatically becomes nonadaptive, and since it queries all strings, it defines a permutation π of Σ^* as above with the required properties. □

COROLLARY 6.5. *Each of the following statements implies* BPP $\neq$ EXP*, as do the statements obtained on replacing* "E" *by* "EXP."

1. *The class of $\leq_{tt}^p$-autoreducible sets has* E*-measure zero.*
2. *The class of $\leq_{tt}^p$-complete sets for* EXP *has* E*-measure zero.*
3. *Nonadaptive* E*-betting games and* E*-martingales are equivalent.*
4. *If two classes can be covered by nonadaptive* E*-betting games, then their union can be covered by an* E*-betting game.*
5. *For all classes $\mathcal{C}$ and all* E*-computable and invertible orderings π, if $\mathcal{C}$ has π-*E*-measure zero, then $\mathcal{C}$ has* E*-measure zero.*

Proof. It suffices to make the following two observations to argue that the proof of Corollary 6.2 carries over to the truth-table cases.

- The construction of Allender and Strauss [AlSt94] actually shows that the class of sets that are not $\leq_{tt}^p$-hard for BPP has E-measure zero.
- If EXP = BPP, Theorem 6.3 implies that all $\leq_{tt}^p$-complete sets for EXP are $\leq_{tt}^p$-autoreducible, because BPP $\subseteq \Sigma_2^{\mathrm{p}} \subseteq \Delta_3^{\mathrm{p}} \subseteq$ EXP.

Theorem 6.4 and the finite-unions property of Lutz's measures on E and EXP do the rest. □

The last point of Corollary 6.5 asserts that Lutz's definition of measure on E is invariant under all E-computable and invertible permutations. These permutations include *flip* from the introduction and (crucially) π from Theorem 6.4. Hence this robustness assertion for Lutz's measure implies BPP $\neq$ EXP. Our "betting-game measure" (both adaptive and nonadaptive) does enjoy this permutation invariance, but asserting the finite-unions property for it also implies BPP $\neq$ EXP. The rest of this paper explores conditions under which Lutz's martingales *can* cover classes of autoreducible sets, thus attempting to narrow the gap between them and betting games.

6.3. Covering autoreducible sets by martingales. This puts the spotlight on the question: Under what hypotheses can we show that the $\leq^p_{tt}$-autoreducible sets have E-measure zero? Any such hypothesis must be strong enough to imply EXP $\neq$ BPP, but we hope to find hypotheses weaker than assuming the equivalence of (E- or EXP-) betting games and martingales, or assuming the finite-union property for betting games. Do we need strong pseudorandom generators to cover the $\leq^p_{tt}$-autoreducible sets? How close can we come to covering the $\leq^p_T$-autoreducible sets by an E-martingale?

Our final results show that the hypothesis MA $\neq$ EXP suffices. This assumption is only known to yield pseudorandom generators of super-polynomial security (at infinitely many lengths) rather than exponential security (at almost all lengths). Recall that MA contains both BPP and NP; in fact it is sandwiched between $\mathrm{NP}^{\mathrm{BPP}}$ and $\mathrm{BPP}^{\mathrm{NP}}$.

THEOREM 6.6. *If* MA $\neq$ EXP*, then the class of* $\leq^p_{tt}$*-autoreducible sets has* E*-measure zero.*

We actually obtain a stronger conclusion.

THEOREM 6.7. *If* MA $\neq$ EXP*, then the class of languages A autoreducible by polynomial-time oracle Turing machines that always make their queries in lexicographic order has* E*-measure zero.*

To better convey the essential sampling idea, we prove the weaker Theorem 6.6 before the stronger Theorem 6.7. The extra wrinkle in the latter theorem is to use the pseudorandom generator *twice*, both to construct the set of "critical strings" to bet on and to compute the martingale.

Proof of Theorem 6.6. Let $[M_i]_{i=1}^{\infty}$ enumerate the $\leq^p_{tt}$-autoreductions, with each M_i running in time n^i. Divide the initial capital into *shares* $s_{i,m}$ for $i, m \geq 1$, with each $s_{i,m}$ valued initially at $(1/m^2)(1/2^i)$. For each share $s_{i,m}$, we will describe a martingale that is active only on a finite number of strings x. The martingale will be active only if $i \leq m/2\lceil \log_2 m \rceil$ and $m \leq |x| \leq m^i$, and further only if x belongs to a set $J = J_{i,m}$ constructed below. Hence the martingale will be inactive outside J, and we will be able to apply Lemma 5.1. We will arrange that whenever M_i autoreduces A, there are infinitely many m such that share $s_{i,m}$ attains a value above 1 (in fact, close to m) along A. Hence the martingale defined by all the shares succeeds on A. We will also ensure that each active share's bets on strings of length n are computable in time 2^{an}, where the constant a is independent of i. This is enough to make the whole martingale E-computable and complete the proof.

To describe the betting strategy for $s_{i,m}$, first construct a set $I = I_{i,m}$ starting with $I = \{\, 0^m \,\}$ and iterating as follows: Let y be the lexicographically least string of length m that does not appear among queries made by M_i on inputs $x \in I$. Then add y to I. Do this until I has $3\lceil \log_2 m \rceil$ strings in it. This is possible because the bound $3\lceil \log_2 m \rceil m^i$ on the number of queries M_i could possibly make on inputs in I is less than 2^m. Moreover, 2^m bounds the time needed to construct I. Thus we have arranged that

$$\text{for all } x, y \in I \text{ with } x < y,\ M_i(x) \text{ does not query } y. \tag{12}$$

Now let J stand for I together with all the queries M_i makes on inputs in I. Adapting ideas from Definition 4.1 to this context, let us define a finite Boolean function $\beta : J \to \{\, 0, 1 \,\}$ to be *consistent with* M_i *on* I, written $\beta \sim_I M_i$, if for all $x \in I$, M_i run on input x with oracle answers given by β agrees with the value $\beta(x)$. Given a characteristic prefix w, also write $\beta \sim w$ if $\beta(x)$ and $w(x)$ agree on all x in J and

the domain of w. Since I and J depend only on i and m, we obtain a "probability density" function for each share $s_{i,m}$ via

$$\pi_{i,m}(w) = \Pr_{\beta \sim w}[\beta \sim_I M_i]. \tag{13}$$

The martingale $d_{i,m}$ standardly associated to this density (as in [Lutz92]) is definable inductively by $d_{i,m}(\lambda) = 1$ and

$$d_{i,m}(w1) = d_{i,m}(w)\frac{\pi_{i,m}(w1)}{\pi_{i,m}(w)}, \qquad d_{i,m}(w0) = d_{i,m}(w)\frac{\pi_{i,m}(w0)}{\pi_{i,m}(w)}. \tag{14}$$

(In case $\pi_{i,m} = 0$, we already have $d_{i,m}(w) = 0$, and so both $d_{i,m}(w1)$ and $d_{i,m}(w0)$ are set to 0.)

Note that the values $\pi_{i,m}(wb)$ for $b = 0, 1$ can only differ from $\pi_{i,m}(w)$ if the string x indexed by b belongs to J, i.e., $d_{i,m}$ is inactive outside J.

CLAIM 6.8. *If M_i autoreduces A, then for all sufficiently large m, if share $s_{i,m}$ could play the strategy $d_{i,m}$, then on A its value would rise to (at least) $m/2^i$. That is, $s_{i,m}$ would multiply its initial value by (at least) m^3.*

To see this, first note that for any $w \sqsubseteq A$ long enough to contain J in its domain, $\pi_{i,m}(w) = 1$. We want to show that for any v short enough to have domain disjoint from I, $\pi_{i,m}(v) = 1/2^{|I|}$. To do this, consider any fixed 0-1 assignment β_0 to strings in $J \setminus I$ that agrees with v. This assignment determines the computation of M_i on the lexicographically first string $x \in I$, using β_0 to answer queries, and hence forces the value of $\beta(x)$ in order to maintain consistency on I. This in turn forces the value $\beta(x')$ on the next string x' in I, and so on. Hence only one out of $2^{|I|}$ possible completions of β_0 to β is consistent with M_i on I. Thus $\pi_{i,m}(v) = 1/2^{|I|}$. Since $d_{i,m}(w) = d_{i,m}(v)\cdot(\pi_{i,m}(w)/\pi_{i,m}(v))$ by (14), and $2^{|I|} = 2^{3\lceil \log_2 m \rceil} \geq m^3$, Claim 6.8 is proved.

The main obstacle now is that $\pi_{i,m}$ in (13), and hence $d_{i,m}(w)$, may not be computable in time 2^{an} with a independent of i. The number of assignments β to count is on the order of $2^{|J|} \approx 2^{m^i} \approx 2^{n^i}$. Here is where we use the E-computable pseudorandom generator D_1, with super-polynomial stretching and with super-polynomial security at infinitely many lengths, obtained via Theorem 5.3 from the hypothesis MA $\neq$ EXP. For all i and sufficiently large m, D_1 stretches a seed s of length m into at least $3\lceil \log_2 m \rceil m^i$ bits, which are enough to define an assignment β_s to J (agreeing with any given w). We estimate $\pi_{i,m}(w)$ by

$$\hat{\pi}_{i,m}(w) = \Pr_{|s|=m}[\beta_s \sim_I M_i]. \tag{15}$$

Take $\epsilon = 1/m^{i+4}$. By Theorem 5.3 there are infinitely many "good" m such that $S_{D_1}(m) > m^{i+4}$.

CLAIM 6.9. *For all large enough good m,* every *estimate $\hat{\pi}_{i,m}(w)$ gives $|\hat{\pi}_{i,m}(w) - \pi_{i,m}(w)| \leq \epsilon$.*

Suppose not. First note that (13) and (15) do not depend on all of w, just on the up-to-$3\lceil \log_2 m \rceil m^i < m^{i+1}$ bits in w that index strings in J, and these can be hardwired into circuits. The tests $[\beta \sim_I M_i]$ can also be done by circuits of size $o(m^{i+1})$, because a Turing machine computation of time r can be simulated by circuits of size $O(r \log r)$ [PiFi79]. Hence we get circuits of size less than $S_{D_1}(m)$ achieving a discrepancy greater than $1/S_{D_1}(m)$, which is a contradiction. This proves Claim 6.9.

Finally, observe that the proof of Claim 6.8 gives us not only $d_{i,m}(w) \geq \pi_{i,m}(w) \cdot m^3$, but also $d_{i,m}(w) = \Theta(\pi_{i,m}(w) \cdot m^3)$, when $w \sqsubseteq A$. For $w \sqsubseteq A$ and good m, we

thus obtain estimates $g(w)$ for $d_{i,m}(w)$ within error bounds $\epsilon' = \Theta(\epsilon) = \Theta(1/m^{i+1})$. Now applying Lemma 5.1 for this $g(w)$ and $J = J_{i,m}$ yields a martingale $d'_{i,m}(w)$ computable in time 2^{an}, where the constant a is independent of i. This $d'_{i,m}(w)$ is the martingale computed by the actions of share $s_{i,m}$. Since $K = \sum_{s_i \in J} \epsilon' = |J|\epsilon' \leq (1/m) \cdot 3\lceil \log_2 m \rceil = o(1)$, we actually obtain $|d'_{i,m}(w) - d_{i,m}(w)| = o(1)$, which is stronger than what we needed to conclude that share $s_{i,m}$ returns enough profit. This completes the proof of Theorem 6.6. □

To prove Theorem 6.7, we need to construct sets $I = I_{i,m}$ with properties similar to (12), in the case where M_i is no longer a $\leq^p_{tt}$-autoreduction but makes its queries in lexicographic order. To carry out the construction of I, we use the pseudorandom generator D_1 a second time and actually need only that M_i on input 0^m makes all queries of length $< m$ before making any query of length $\geq m$. To play the modified strategy for share $s_{i,m}$, however, appears to require that all queries observe lexicographic order.

Proof of Theorem 6.7. Recall that the hypothesis EXP $\neq$ MA yields a pseudorandom generator D_1 computable in time $2^{O(m)}$ and stretching m bits to $r(m)$ bits such that for all i, all sufficiently large m give $r(m) > m^i$, and infinitely many m give hardness $S_{D_1}(m) > m^i$. Let $[M_i]_{i=1}^{\infty}$ be a standard enumeration of $\leq^p_T$-autoreductions that are constrained to make their queries in lexicographic order, with each M_i running in time $O(n^i)$. We need to define strategies for "shares" $s_{i,m}$ such that whenever M_i autoreduces A, there are infinitely many m such that share $s_{i,m}$ grows its initial capital from $1/m^2 2^i$ to $1/2^i$ or more. The strategy for $s_{i,m}$ must still be computable in time 2^{am} where a is independent of i.

To compute the strategy for $s_{i,m}$, we note first that $s_{i,m}$ can be left inactive on strings of length $< m$. The overall running time allowance $2^{O(m)}$ permits us to suppose that by the time $s_{i,m}$ becomes active and needs to be considered, the initial segment w_0 of A (where A is the language on which the share happens to be playing) that indexes strings of length up to $m-1$ is known. Hence we may regard w_0 as fixed. For any $\alpha \in \{0,1\}^{m^i}$ let $M_i^{\alpha}(x)$ stand for the computation in which w_0 is used to answer any queries of length $< m$ and α is used to answer all other queries. Because of the order in which M_i makes its queries, those queries y answered by w_0 are the same for all α, so that those answers can be coded by a string u_0 of length at most m^i. Now for any string y of length equal to m, define

$$P(x,y) = \Pr_{\alpha}[M_i^{\alpha}(x) \text{ queries } y].$$

Note that given u_0 and α, the test "$M_i^{\alpha}(x)$ queries y" can be computed by circuits of size $O(m^{i+1})$. Hence by using the pseudorandom generator D_1 at length m, we can compute uniformly in E an approximation $P_1(x,y)$ for $P(x,y)$ such that for infinitely many m, said to be "good" m, *all* pairs x, y give $|P_1(x,y) - P(x,y)| \leq \epsilon_m$, where we choose $\epsilon_m = 1/m^4$.

Here is the algorithm for constructing $I = I_{i,m}$. Start with $I := \emptyset$, and while $|I| < 3\log_2 m$, do the following: Take the lexicographically least string $y \in \Sigma^m \setminus I$ such that for all $x \in I$, $P_1(x,y) \leq \epsilon_m$. The search for such a y will succeed within $|I| \cdot m^{i+4}$ trials, since for any particular x, there are fewer than m^{i+4} strings y overall that will fail the test. (This is so even if m is not good, because it only involves P_1, and because P_1 involves simulating $M_i^{D_1(s)}$ over all seeds s.) There is enough room to find such a y provided $|I|m^{i+4} \leq 2^m$, which holds for all sufficiently large m. The whole construction of I can be completed within time 2^{2am}. It follows that for any sufficiently large good m and $x, y \in I$ with $x < y$, $\Pr_{\alpha}[M_i^{\alpha}(x) \text{ queries } y] < 2\epsilon_m =$

$2/m^4$.

At this point we would like to define J to be "I together with the set of strings queried by M_i on inputs in I" as before, but unlike the previous case where M_i was nonadaptive, this is not a valid definition. We acknowledge the dependence of the strings queried by M_i on the oracle A by defining

$$J_A := I \cup \{\, y : (\exists x \in I) M_i^A(x) \text{ queries } y \,\}.$$

Let $r = m^i \cdot \lceil 3 \log m \rceil$. Then $|J_A| \leq r$; that is, J_A has the same size as J in the previous proof. This latter definition will be OK *because* M_i makes its queries in lexicographic order. Hence the share $s_{i,m}$, having already computed I without any reference to A, can determine the strings in J_A on which it should be active on the fly, in lexicographic order. Thus we can well-define a mapping β from $\{\,0,1\,\}^r$ to $\{\,0,1\,\}$ so that for any $k \leq r$, $\beta(k) = 1$ means that the query string y that happens to be kth in order in the on-the-fly construction of J_A is answered "yes" by the oracle. Then we may write J_β for J_A, and then write $\beta(y) = 1$ in place of $\beta(k) = 1$. Most important, given any $x \in I$, every such β well-defines a computation $M_i^\beta(x)$. This entitles us to carry over the two "consistency" definitions from the proof of Theorem 6.6:

- $\beta \sim w$ if $\beta(y) = w(y)$ for all $y \in J_\beta$;
- $\beta \sim_I M_i$ if for all $x \in I$, $M_i^\beta(x)$ equals (i.e., "agrees with") $\beta(x)$.

Finally, we may apply the latter notion to initial subsets of I and define for $1 \leq \ell \leq 3 \log m$ the predicate

$$R_\ell(\beta) = (\beta \sim_{x_1,\ldots,x_\ell} M_i) \ \wedge \\ (\forall j,k : 1 \leq j \leq k \leq \ell) M_i^\beta(x_j) \text{ does not query } x_k.$$

Claim 6.10. *For all ℓ, $\Pr_\beta[R_\ell(\beta)] \leq 1/2^\ell$.*

For the base case $\ell = 1$, $\Pr_\beta[R_1(\beta)] = 1/2$, because $M_i(x)$ does not query x_1, M_i being an autoreduction, and because whether $\beta \sim_{x_1} M_i$ depends only on the bit of β corresponding to x_1. Working by induction, suppose $\Pr_\beta[R_{\ell-1}(\beta)] \leq 1/2^{\ell-1}$. If $R_{\ell-1}(\beta)$ holds, then taking β' to be β with the bit corresponding to x_ℓ flipped, $R_{\ell-1}(\beta')$ also holds. However, at most one of $R_\ell(\beta)$ and $R_\ell(\beta')$ holds, again because $M_i(x_\ell)$ does not query x_ℓ. Hence $\Pr_\beta[R_\ell(\beta)] \leq (1/2)\Pr_\beta[R_{\ell-1}(\beta)]$, and this proves Claim 6.10. (It is possible that neither $R_\ell(\beta)$ nor $R_\ell(\beta')$ holds, as happens when $M_i^\beta(x_j)$ queries x_ℓ for some j, but this does not hurt the claim.)

Now we can rejoin the proof of Theorem 6.6 at (13), defining the probability density function $\pi_{i,m}(w) = \Pr_{\beta \sim w}[\beta \sim_I M_i]$. We get a martingale $d_{i,m}$ from $\pi_{i,m}$ as before, and this represents an "ideal" strategy for share $s_{i,m}$ to play. The statement corresponding to Claim 6.8 is the following.

Claim 6.11. *If M_i autoreduces A and m is good and sufficiently large, then the ideal strategy for share $s_{i,m}$ multiplies its value by at least $m^3/2$ along A.*

To see this, note that we constructed $I = \{\, x_1, \ldots, x_{3 \log m} \,\}$ above so that for all $j < k$, $\Pr_\alpha[M_i^\alpha(x_j) \text{ queries } x_k] \leq 2/m^4$. It follows that

$$\Pr[(\exists j,k : 1 \leq j \leq k \leq 3 \log m)\ M_i(x_j) \text{ queries } x_k] \leq \binom{\lceil 3 \log m \rceil}{2} \cdot \frac{2}{m^4} \leq \frac{1}{m^3},$$

provided $m \geq \lceil 3 \log m \rceil^2$. Hence, using Claim 6.10 with $\ell = 3 \log m$, we get

$$\Pr_\beta[\beta \sim_I M_i] \leq \frac{1}{2^{3 \log m}} + \frac{1}{m^3} = \frac{2}{m^3}.$$

Since the β defined by A satisfies $\beta \sim_I M_i$, it follows by the same reasoning as in Claim 6.8 that $d_{i,m}$ profits by at least a fraction of $m^3/2$ along A. This proves Claim 6.11.

Finally, we (re)use the pseudorandom generator D_1 as before to expand a seed s of length m into a string β_s of (at least) $r = 3\lceil \log_2 m \rceil m^i$ bits. Given any w, β_s well-defines a β and a set J_β of size at most r as constructed above by using w to answer queries in the domain of w and β_s for everything else. We again obtain the estimate $\hat{\pi}_{i,m}(w) = \Pr_{|s|=m}[\beta_s \sim_I M_i]$ from (15), with the same time complexity as before. Now we repeat Claim 6.9 in this new context as follows.

CLAIM 6.12. *For all large enough good m, every estimate $\hat{\pi}_{i,m}(w)$ gives $|\hat{\pi}_{i,m}(w) - \pi_{i,m}(w)| \leq \epsilon$.*

If not, then for some fixed w the estimate fails. The final key point is that because M_i always makes its queries in lexicographic order, the queries in the domain of w that need to be covered are the same for every β_s. Hence the corresponding bits of w can be hard-wired by circuitry of size at most r. The test $[\beta_s \sim_I M_i]$ can thus still be carried out by circuits of size less than m^{i+1}, and we reach the same contradiction of the hardness value S_{D_1}.

Finally, we want to apply Lemma 5.1 to replace $d_{i,m}(w)$ by a martingale $d'_{i,m}(w)$ that yields virtually the same degree of success and is computable in time $2^{O(n)}$. Unlike the truth-table case, we cannot apply Lemma 5.1 verbatim because we no longer have a single small set J that d' is active on. However, along any set A, the values $d'_{i,m}(w)$ and $d'_{i,m}(wb)$ ($b = 0$ or 1) can differ only for cases where b indexes a string in the small set J corresponding to A, and the reader may check that the argument and bounds of Lemma 5.1 go through unscathed in this case. This finishes the proof of Theorem 6.7. □

7. Conclusions. The initial impetus for this work was a simple question about measure: is the pseudorandomness of a characteristic sequence invariant under simple permutations such as that induced by *flip* in the introduction? The question for *flip* is tantalizingly still open. However, in section 6.2 we showed that establishing a "yes" answer for any permutation that intuitively *should* preserve the same complexity-theoretic degree of pseudorandomness, or even for a single specific such permutation as that in the simple proof of the nonadaptive version of Theorem 6.1, would have the major consequence that EXP $\neq$ BPP.

Our "betting games" in themselves are a natural extension of Lutz's measures for deterministic time classes. They preserve Lutz's original idea of "betting" as a means of "predicting" membership in a language, without being tied to a fixed order of instances that one tries to predict, or to a fixed order of how one goes about gathering information on the language. We have shown some aspects in which betting games are robust and well-behaved. We also contend that some current defects in the theory of betting games, notably the lack of a finite-unions theorem pending the status of pseudorandom generators, trade off with lacks in the resource-bounded measure theory, such as being tied to the lexicographic ordering of strings.

The main open problems in this paper are interesting in connection with recent work by Impagliazzo and Wigderson [ImWi98] on the BPP vs. EXP problem. First we remark that the main result of [ImWi98] implies that either BPP = EXP or BPP has E-measure zero [Mel98]. Among the many measure statements in the last section that imply BPP $\neq$ EXP, the most constrained and easiest to attack seems to be item 4 in Corollary 6.5. Indeed, in the specific relevant case starting with the assumption BPP = EXP, one is given a nonadaptive E-betting game G and an E-martingale

d, and to obtain the desired contradiction that proves BPP $\neq$ EXP, one needs only construct an EXP-betting game G' that covers $S^\infty[G] \cup S^\infty[d]$. What we *can* obtain is a "randomized" betting game G'' that flips one coin at successive intervals of input lengths to decide whether to simulate G or d on that interval. (The intervals come from the proof of Theorem 6.4.) Any hypothesis that can derandomize this G'' implies BPP $\neq$ EXP. We do not know whether the weak hypotheses considered in [ImWi98], some of them shown to follow from BPP $\neq$ EXP itself, are sufficient to do this.

Stepping back from trying to prove BPP $\neq$ EXP outright or trying to prove that these measure statements are equivalent to BPP $\neq$ EXP, we also have the problem of narrowing the gap between BPP $\neq$ EXP and the sufficient condition EXP $\neq$ MA used in our results. Moreover, does EXP $\neq$ MA suffice to make the $\leq_T^p$-autoreducible sets have E-measure zero? Does that suffice to simulate every betting game by a martingale of equivalent complexity? We also inquire whether there exist oracles relative to which EXP = MA, but strong pseudorandom generators still exist. Our work seems to open many opportunities to tighten the connections among pseudorandom generators, the structure of classes within EXP, and resource-bounded measure.

The kind of statistical sampling used to obtain martingales in Theorems 5.5 and 5.6 was originally applied to construct martingales from "natural proofs" in [RSC95]. The derandomization technique from [BFNW93] based on EXP $\neq$ MA that is used here is also applied in [BuMe98, KoLi98, LSW98]. "Probabilistic martingales" that can use this sampling to simulate betting games are formalized and studied in [ReSi98]. This paper also starts the task of determining how well the betting game and random-sampling ideas work for measures on classes below E. Even straightforward attempts to carry over Lutz's definitions to classes below E run into difficulties, as described in [May94t] and [AlSt94, AlSt95]. We look toward further applications of our ideas in lower-level complexity classes.

Acknowledgments. The authors especially thank Klaus Ambos-Spies, the late Ron Book, and Jack Lutz for organizing a special Schloss Dagstuhl workshop in July 1996, where preliminary versions of results and ideas in this paper were presented and extensively discussed. We thank the STACS '98 referees and the referees of this journal paper for helpful comments—one of the latter gave us many insightful notes that helped us steer away from errors and ambiguities in this final version.

CAVITY MATCHINGS, LABEL COMPRESSIONS, AND UNROOTED EVOLUTIONARY TREES*

MING-YANG KAO†, TAK-WAH LAM‡, WING-KIN SUNG‡, AND HING-FUNG TING‡

Abstract. We present an algorithm for computing a maximum agreement subtree of two unrooted evolutionary trees. It takes $O(n^{1.5}\log n)$ time for trees with unbounded degrees, matching the best known time complexity for the rooted case. Our algorithm allows the input trees to be mixed trees, i.e., trees that may contain directed and undirected edges at the same time. Our algorithm adopts a recursive strategy exploiting a technique called label compression. The backbone of this technique is an algorithm that computes the maximum weight matchings over many subgraphs of a bipartite graph as fast as it takes to compute a single matching.

Key words. computational biology, evolutionary trees, all-cavity maximum weight matchings, label compressions, unrooted trees, mixed trees

1. Introduction.

An *evolutionary* tree is one whose leaves are labeled with distinct symbols representing species. Evolutionary trees are useful for modeling the evolutionary relationship of species [1, 4, 6, 16, 17, 25]. An *agreement subtree* of two evolutionary trees is an evolutionary tree that is also a topological subtree of the two given trees. A *maximum* agreement subtree is one with the largest possible number of leaves. Different models about the evolutionary relationship of the same species may result in different evolutionary trees. A fundamental problem in computational biology is to determine how much two models of evolution have in common. To a certain extent, this problem can be solved by computing a maximum agreement subtree of two given evolutionary trees [12].

Algorithms for computing a maximum agreement subtree of two unrooted evolutionary trees as well as two rooted trees have been studied intensively in the past few years. The unrooted case is more difficult than the rooted case. There is indeed a linear-time reduction from the rooted case to the unrooted one, but the reverse is not known. Steel and Warnow [24] gave the first polynomial-time algorithm for unrooted trees, which runs in $O(n^{4.5}\log n)$ time. Farach and Thorup reduced the time to $O(n^{2+o(1)})$ for unrooted trees [10] and $O(n^{1.5}\log n)$ for rooted trees [11]. For the unrooted case, the time was improved by Lam, Sung, and Ting [22] to $O(n^{1.75+o(1)})$. Algorithms that work well for rooted trees with degrees bounded by a constant have also been revealed recently. The algorithm of Farach, Przytycka, and Thorup [9] takes $O(n\log^3 n)$ time, and that of Kao [20] takes $O(n\log^2 n)$ time. Cole and Hariharan [7]

gave an $O(n \log n)$-time algorithm for the case where the input is further restricted to binary rooted trees.

This paper presents an algorithm for computing a maximum agreement subtree of two unrooted trees. It takes $O(n^{1.5} \log n)$ time for trees with unbounded degrees, matching the best known time complexity for the rooted case [11]. If the degrees are bounded by a constant, the running time is only $O(n \log^4 n)$. We omit the details of this reduction since Przytycka [23] recently devised an $O(n \log n)$-time algorithm for the same case.

Our algorithm allows the input trees to be *mixed* trees, i.e., trees that may contain directed and undirected edges at the same time [15, 18]. Such trees can handle a broader range of information than rooted and unrooted trees. To simplify the discussion, this paper focuses on unrooted trees. Our subtree algorithm adopts a conceptually simple recursive strategy exploiting a novel technique called *label compression*. This technique enables our algorithm to process overlapping subtrees iteratively while keeping the total tree size very close to the original input size. Label compression builds on an unexpectedly fast algorithm for the *all-cavity maximum weight matching* problem [21], which asks for the weight of a maximum weight matching in $G - \{u\}$ for each node u of a bipartite graph G with integer edge weights. If G has n nodes, m edges and maximum edge weight N, the algorithm takes $O(\sqrt{n}m \log(nN))$ time, which matches the best known time bound for computing a single maximum weight matching of G, due to Gabow and Tarjan [13].

In section 2, we solve the all-cavity matching problem. In section 3, we formally define maximum agreement subtrees and outline our recursive strategy for computing them. We describe label compression in section 4, detail our subtree algorithm in section 5, and discuss how to compute auxiliary information for label compression in sections 6 and 7. We conclude by extending the subtree algorithm to mixed trees in section 8.

2. All-cavity maximum weight matching. Let $G = (X, Y, E)$ be a bipartite graph with n nodes and m edges where each edge (u, v) has a positive integer weight $w(u, v) \leq N$. Let $\mathrm{mwm}(G)$ denote the weight of a maximum weight matching in G. The all-cavity matching problem asks for $\mathrm{mwm}(G - \{u\})$ for all $u \in X \cup Y$. A naive approach to solve this problem is to compute $\mathrm{mwm}(G - \{u\})$ separately for each u using the fastest algorithm for computing a single maximum weight matching [13], thus taking $O(n^{1.5} m \log(nN))$ total time. A main finding of this paper is that the matchings in different subgraphs $G - \{u\}$ are closely related and can be represented succinctly. From this representation, we can solve the problem in $O(\sqrt{n}m \log(nN))$ time. By symmetry, we detail only how to compute $\mathrm{mwm}(G - \{u\})$ for all $u \in X$. Below we assume $m \geq n/2$; otherwise, we remove the degree-zero nodes and work on the smaller resultant graph.

A node v of G is *matched* by a matching of G if v is an endpoint of an edge in the matching. In the remainder of this section, let M be a fixed maximum weight matching of G; also let $w(H)$ be the total weight of a set H of edges. An *alternating path* is a simple path P in G such that (1) P starts with an edge in M; (2) the edges of P alternate between M and $E - M$; and (3) if P ends at an edge $(u, v) \notin M$, then v is not matched by M. An *alternating cycle* is a simple cycle C in G whose edges alternate between M and $E - M$. P (respectively, C) can *transform* M to another matching $M' = P \cup M - P \cap M$ (respectively, $C \cup M - C \cap M$). The *net change* induced by P, denoted by $\Delta(P)$, is $w(M') - w(M)$, i.e., the total weight of the edges of P in $E - M$ minus that of the edges of P in M. The *net change* induced by C is

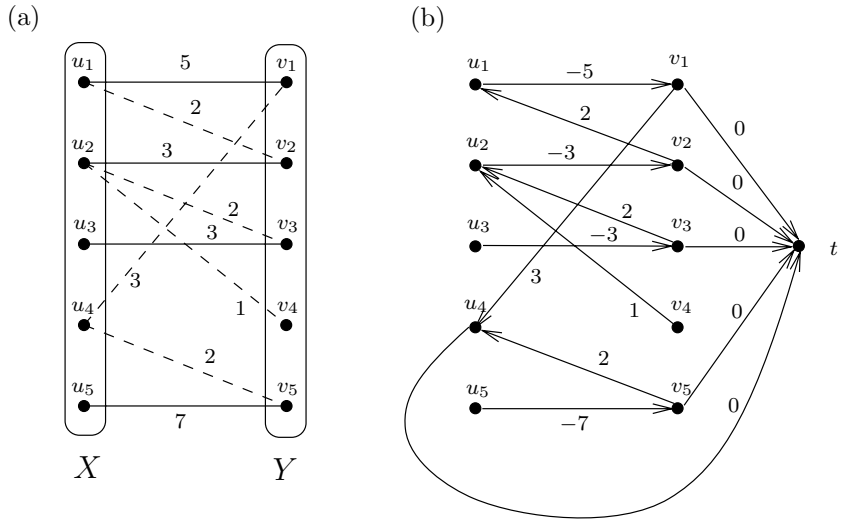

FIG. 1. (a) *a bipartite graph G;* (b) *the corresponding directed graph D.*

defined similarly.

The next lemma divides the computation of $\mathrm{mwm}(G - \{u\})$ into two cases.

LEMMA 2.1. *Let $u \in X$.*

1. *If u is not matched by M, then M is also a maximum weight matching in $G - \{u\}$ and $\mathrm{mwm}(G - \{u\}) = \mathrm{mwm}(G)$.*
2. *If u is matched by M, then G contains an alternating path P starting from u, which can transform M to a maximum weight matching in $G - \{u\}$.*

Proof. Statement 1 is straightforward. To prove statement 2, let M' be a maximum weight matching in $G - \{u\}$. Consider the edges in $M \cup M' - M \cap M'$. They form a set S of alternating paths and cycles. Since u is matched by M but not by M', u is of degree 1 in $M \cup M' - M \cap M'$. Let P be the alternating path in S with u as an endpoint. Let M'' be the matching obtained by transforming M only with P. Since u is not matched by M'', M'' is a matching in $G - \{u\}$. M' can be obtained by further transforming M'' with the remaining alternating paths and cycles in S. The net change induced by each of these alternating paths and cycles is nonpositive; otherwise, such a path or cycle can improve M and we obtain a contradiction. Therefore, $w(M'') \geq w(M')$, i.e., both M' and M'' are maximum weight matchings in $G - \{u\}$. □

By Lemma 2.1(2), we can compute $\mathrm{mwm}(G - \{u\})$ for any $u \in X$ matched by M by finding the alternating path starting from u with the largest net change. Below we construct a directed graph D, which enables us to identify such an alternating path for every node easily. The node set of D is $X \cup Y \cup \{t\}$, where t is a new node. The edge set of D is defined as follows; see Figure 1 for an example.

- If $x \in X$ is not matched by M, D has an edge from x to t with weight zero.
- If $y \in Y$ is matched by M, D has an edge from y to t with weight zero.
- If M has an edge (x, y) where $x \in X$ and $y \in Y$, D has an edge from x to y with weight $-w(x, y)$.
- If $E - M$ has an edge (x, y) where $x \in X$ and $y \in Y$, D has an edge from y to x with weight $w(x, y)$.

Note that D has $n + 1$ nodes and at most $n + m$ edges. The weight of each edge

in D is an integer in $[-N, N]$.

LEMMA 2.2.

1. *D contains no positive-weight cycle.*
2. *Each alternating path P in G that starts from $u \in X$ corresponds to a simple path Q in D from u to t, and vice versa. Also, $\Delta(P) = w(Q)$.*
3. *For each $u \in X$ matched by M, $\mathrm{mwm}(G - \{u\})$ is the sum of $\mathrm{mwm}(G)$ and the weight of the longest path in D from u to t.*

Proof. Statement 1. Consider a simple cycle $C = u_1, u_2, \ldots, u_k, u_1$ in D. Since t has no outgoing edges, no u_i equals t. By the definition of D, C is also an alternating cycle in G. Therefore, $w(C)$ is the net change induced by transforming M with C. Since M is a maximum weight matching in G, this net change is nonpositive.

Statement 2. Consider an alternating path $P = u, u_1, u_2, \ldots, u_k$ in G starting from u. In D, P is also a simple path. If $u_k \in X$, then u_k is not matched by M, and D contains the edge (u_k, t). If $u_k \in Y$, then u_k is matched by M, and D again contains the edge (u_k, t). Therefore, D contains the simple path $Q = u, u_1, u_2, \ldots, u_k, t$. The weight of Q is $\Delta(P)$. The reverse direction of the statement is straightforward.

Statement 3. This statement follows from Lemma 2.1(2) and Statement 2. □

THEOREM 2.3. *Given G, we can compute $\mathrm{mwm}(G - \{u\})$ for all nodes $u \in G$ in $O(\sqrt{n}m \log(nN))$ time.*

Proof. By symmetry and Lemmas 2.1(1) and 2.2(3), we compute $\mathrm{mwm}(G - \{u\})$ for all $u \in X$ as follows.

1. Compute a maximum weight matching M of G.
2. Construct D as above and find the weights of its longest paths to t.
3. For each $u \in X$, if u is matched by M, then $\mathrm{mwm}(G - \{u\})$ is the sum of $\mathrm{mwm}(G)$ and the weight of the longest path from u to t in D; otherwise, $\mathrm{mwm}(G - \{u\}) = \mathrm{mwm}(G)$.

Step 1 takes $O(\sqrt{n}m \log(nN))$ time. At step 2, constructing D takes $O(n + m)$ time, and the single-destination longest paths problem takes $O(\sqrt{n}m \log N)$ time [14]. Step 3 takes $O(n)$ time. Thus, the total time is $O(\sqrt{n}m \log(nN))$. □

3. The main result. This section gives a formal definition of maximum agreement subtrees and an overview of our new subtree algorithm.

3.1. Basics. Throughout the remainder of this paper, unrooted trees are denoted by U or X, and rooted trees by T, W, or R. A node of degree 0 or 1 is a *leaf*; otherwise, it is *internal*. Adopted to avoid technical trivialities, this definition is somewhat nonstandard in that if the root of a rooted tree is of degree 1, it is also a leaf.

For an unrooted tree U and a node $u \in U$, let U^u denote the rooted tree constructed by rooting U at u. For a rooted tree T and a node $v \in T$, let T^v denote the *rooted subtree* of T that comprises v and its descendents. Similarly, for a node $v \in U^u$, U^{uv} is the rooted subtree of U^u rooted at v, which is also called a *rooted subtree* of U.

An *evolutionary* tree is a tree whose leaves are labeled with distinct symbols. Let T be a rooted evolutionary tree with leaves labeled over a set L. A label subset $L' \subseteq L$ *induces* a subtree of T, denoted by $T|L'$, whose nodes are the leaves of T labeled over L' as well as the least common ancestors of such leaves in T, and whose edges preserve the ancestor-descendent relationship of T. Consider two rooted evolutionary trees T_1 and T_2 labeled over L. Let T_1' be a subtree of T_1 induced by some subset of L. We similarly define T_2' for T_2. If there exists an isomorphism between T_1' and T_2' mapping each leaf in T_1' to one in T_2' with the same label, then T_1'

and T_2' are each called *agreement subtrees* of T_1 and T_2. Note that this isomorphism is unique. Consider any nodes $u \in T_1$ and $v \in T_2$. We say that u *is mapped to* v *in* T_1' and T_2' if this isomorphism maps u to v. A *maximum* agreement subtree of T_1 and T_2 is one containing the largest possible number of labels. Let $\text{mast}(T_1, T_2)$ denote the number of labels in such a tree. A *maximum agreement subtree* of two unrooted evolutionary trees U_1 and U_2 is one with the largest number of labels among the maximum agreement subtrees of U_1^u and U_2^v over all nodes $u \in U_1$ and $v \in U_2$. Let

$$\text{mast}(U_1, U_2) = \max\{\text{mast}(U_1^u, U_2^v) \mid u \in U_1, v \in U_2\}. \tag{3.1}$$

Remark. The nodes u (or v) can be restricted to internal nodes when the trees have at least three nodes. We can also generalize the above definition to handle a pair of rooted tree and unrooted tree (T, U). That is, $\text{mast}(T, U)$ is defined to be $\max\{\text{mast}(T, U^v) \mid v \in U\}$.

3.2. Our subtree algorithm. The next theorem is our main result. The *size* $|U|$ (or $|T|$) of an unrooted tree U (or a rooted tree T) is its node count.

THEOREM 3.1. *Let U_1 and U_2 be two unrooted evolutionary trees. We can compute* $\text{mast}(U_1, U_2)$ *in* $O(N^{1.5} \log N)$ *time, where* $N = \max\{|U_1|, |U_2|\}$.

We prove Theorem 3.1 by presenting our algorithm in a top-down manner with an outline here. As in previous work, our algorithm only computes $\text{mast}(U_1, U_2)$ and can be augmented to report a corresponding subtree. It uses graph separators. A *separator* of a tree is an internal node whose removal divides the tree into connected components each containing at most half of the tree's nodes. Every tree that contains at least three nodes has a separator, which can be found in linear time.

If U_1 or U_2 has at most two nodes, $\text{mast}(U_1, U_2)$ as defined in (3.1) can easily be computed in $O(N)$ time. Otherwise, both trees have at least three nodes each, and we can find a separator x of U_1. We then consider three cases.

Case 1. In some maximum agreement subtree of U_1 and U_2, the node x is mapped to a node $y \in U_2$. In this case, $\text{mast}(U_1, U_2) = \text{mast}(U_1^x, U_2)$. To compute $\text{mast}(U_1^x, U_2)$, we might simply evaluate $\text{mast}(U_1^x, U_2^y)$ for different y in U_2. This approach involves solving the mast problem for $\Theta(N)$ different pairs of rooted trees and introduces much redundant computation. For example, consider a rooted subtree R of U_2. For all $y \in U_2 - R$, R is a common subtree of U_2^y. Hence, R is examined repeatedly in the computation of $\text{mast}(U_1^x, U_2^y)$ for these y. To speed up the computation, we devise the technique of label compression in section 4 to elicit sufficient information between U_1^x and R so that we can compute $\text{mast}(U_1^x, U_2^y)$ for all $y \in U_2 - R$ without examining R. This leads to an efficient algorithm for handling Case 1; the time complexity is stated in the following lemma.

LEMMA 3.2. *Assume that U_1 and U_2 have at least three nodes each. Given an internal node $x \in U_1$, we can compute* $\text{mast}(U_1^x, U_2)$ *in* $O(N^{1.5} \log N)$ *time.*

Proof. See section 4 to section 7. □

Case 2. In some maximum agreement subtree of U_1 and U_2, two certain nodes v_1 and v_2 of U_1 are mapped to nodes in U_2, and x is on the path in U_1 between v_1 and v_2. This case is similar to Case 1. Let $\tilde{U}_2$ be the tree constructed by adding a dummy node in the middle of every edge in U_2. Then, $\text{mast}(U_1, U_2) = \text{mast}(U_1^x, \tilde{U}_2^y)$ for some dummy node y in $\tilde{U}_2$. Thus, $\text{mast}(U_1, U_2) = \text{mast}(U_1^x, \tilde{U}_2)$. As in Case 1, $\text{mast}(U_1^x, \tilde{U}_2)$ can be computed in $O(N^{1.5} \log N)$ time.

Case 3. Neither Case 1 nor Case 2 holds. Let $U_{1,1}, U_{1,2}, \ldots, U_{1,b}$ be the evolutionary trees formed by the connected components of $U_1 - \{x\}$. Let $J_1, \ldots, J_b$ be the sets of labels in these components, respectively. Then, a maximum agreement subtree of

```
/* U_1 and U_2 are unrooted trees. */
mast(U_1, U_2)
  find a separator x of U_1;
  construct Ũ_2 by adding a dummy node w at the middle of each edge (u, v) in
  U_2;
  val = mast(U_1^x, U_2);
  val' = mast(U_1^x, Ũ_2);
  let U_{1,1}, U_{1,2}, ..., U_{1,b} be the connected components of U_1 − {x};
  for all i ∈ [1, b], let J_i be the set of labels of U_{1,i};
  for all i ∈ [1, b], set val_i = mast(U_{1,i}, U_2|J_i)};
  return max{val, val', max_{1≤i≤b} val_i};
```

FIG. 2. *Algorithm for computing* $\mathrm{mast}(U_1, U_2)$.

U_1 and U_2 is labeled over some J_i. Therefore, $\mathrm{mast}(U_1, U_2) = \max\{\mathrm{mast}(U_{1,i}, U_2|J_i) \mid i \in [1, b]\}$, and we compute each $\mathrm{mast}(U_{1,i}, U_2|J_i)$ recursively.

Figure 2 summarizes the steps for computing $\mathrm{mast}(U_1, U_2)$. Here we analyze the time complexity $T(N)$ based on Lemma 3.2. Cases 1 and 2 each take $O(N^{1.5} \log N)$ time. Let $N_i = |U_{1,i}|$. Then Case 3 takes $\sum_{i\in[1,b]} T(N_i)$ time. By recursion,

$$T(N) = O(N^{1.5} \log N) + \sum_{i\in[1,b]} T(N_i).$$

Since x is a separator of U_1, $N_i \leq \frac{N}{2}$. Then, since $\sum_{i\in[1,b]} N_i \leq N$, $T(N) = O(N^{1.5} \log N)$ [5, 19] and the time bound in Theorem 3.1 follows. To complete the proof of Theorem 3.1, we devote section 4 through section 7 to proving Lemma 3.2.

4. Label compressions. To compute a maximum agreement subtree, our algorithm recursively processes overlapping subtrees of the input trees. The technique of label compression compresses overlapping parts of such subtrees to reduce their total size. We define label compressions with respect to a rooted subtree in section 4.1 and with respect to two label-disjoint rooted subtrees in section 4.2. We do not use label compression with respect to three or more trees.

As a warm-up, let us define a concept called *subtree shrinking*, which is a primitive form of label compression. Let T be a rooted tree. Let R be a rooted subtree of T. Let $T \ominus R$ denote the rooted tree obtained by replacing R with a leaf γ. We say that γ is a *shrunk* leaf. The other leaves are *atomic* leaves. Similarly, for two label-disjoint rooted subtrees R_1 and R_2 of T, let $T \ominus (R_1, R_2)$ denote the rooted tree obtained by replacing R_1 and R_2 with *shrunk* leaves γ_1 and γ_2, respectively. We extend these notions to an unrooted tree U and define $U \ominus R$ and $U \ominus (R_1, R_2)$ similarly.

4.1. Label compression with respect to one rooted subtree. Let T be a rooted tree. Let v be a node in T and u an ancestor of v. Let P be the path of T from u to v. A node *lies* between u and v if it is in P but differs from u and v. A subtree of T is *attached* to u if it is some T^w where w is a child of u. A subtree of T *hangs* between u and v if it is attached to some node lying between u and v, but its root is not in P and is not v.

We are now ready to define the concept of label compression. Let T and R be rooted evolutionary trees labeled over L and K, respectively. The *compression* of T with respect to R, denoted by $T \otimes R$, is a tree constructed by affixing extra nodes to

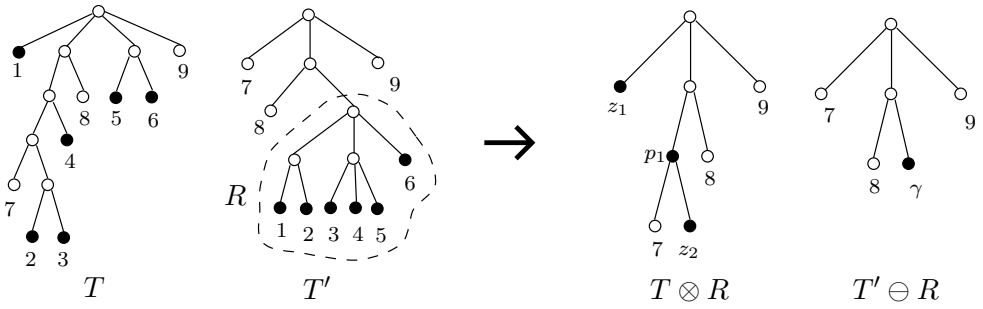

FIG. 3. *An example of label compression.*

$T|(L-K)$ with the following steps; see Figure 3 for an example. Consider each node y in $T|(L-K)$, let x be its parent in $T|(L-K)$.

- Let $\mathcal{A}(T,K,y)$ denote the set of subtrees of T that are attached to y and whose leaves are all labeled over K. If $\mathcal{A}(T,K,y)$ is nonempty, compress all the trees in $\mathcal{A}(T,K,y)$ into a single node z_1 and attach it to y.
- Let $\mathcal{H}(T,K,y)$ denote the set of subtrees of T that hang between x and y (by definition of $T|(L-K)$, these subtrees are all labeled over K). If $\mathcal{H}(T,K,y)$ is nonempty, compress the parents $p_1,\ldots,p_m$ of the roots of the trees in $\mathcal{H}(T,K,y)$ into a single node p_1, and insert it between x and y; also compress all the trees in $\mathcal{H}(T,K,y)$ into a single node z_2 and attach it to p_1.

The nodes z_1, z_2, and p_1 are called *compressed* nodes, and the leaves in $T\otimes R$ that are not compressed are *atomic* leaves.

We further store in $T\otimes R$ some auxiliary information about the relationship between T and R. For an internal node v in $T\otimes R$, let $\alpha(v) = \mathrm{mast}(T^v, R)$. For a compressed leaf v in $T\otimes R$, if it is compressed from a set of subtrees $T^{v_1},\ldots,T^{v_s}$, let $\alpha(v) = \max\{\mathrm{mast}(T^{v_1},R),\ldots,\mathrm{mast}(T^{v_s},R)\}$.

Let T_1 and T_2 be two rooted evolutionary trees. Assume T_2 contains a rooted subtree R. Given $T_1\otimes R$, we can compute $\mathrm{mast}(T_1,T_2)$ without examining R. We first construct $T_1\ominus R$ by replacing R of T_2 with a shrunk leaf and then compute $\mathrm{mast}(T_1,T_2)$ from $T_1\otimes R$ and $T_2\ominus R$. To further our discussion, we next generalize the definition of maximum agreement subtree for a pair of trees that contain compressed leaves and a shrunk leaf, respectively.

Let $W_1 = T_1\otimes R$ and $W_2 = T_2\ominus R$. Let γ be the shrunk leaf in W_2. We define an agreement subtree of W_1 and W_2 similar to that of ordinary evolutionary trees. An atomic leaf must still be mapped to an atomic leaf with the same label. However, the shrunk leaf γ of W_2 can be mapped to any internal node or compressed leaf v of W_1 as long as $\alpha(v) > 0$. The size of an agreement subtree is the number of its atomic leaves, plus $\alpha(v)$ if γ is mapped to a node $v \in W_1$. A *maximum* agreement subtree of W_1 and W_2 is one with the largest size. Let $\mathrm{mast}(W_1,W_2)$ denote the size of such a subtree. The following lemma is the cornerstone of label compression.

LEMMA 4.1. $\mathrm{mast}(T_1,T_2) = \mathrm{mast}(W_1,W_2)$.

Proof. It follows directly from the definition. □

We can compute $\mathrm{mast}(W_1,W_2)$ as if W_1 and W_2 were ordinary rooted evolutionary trees [9, 11, 20] with a special procedure on handling the shrunk leaf. The time complexity is stated in the following lemma. Let $n = \max\{|W_1|,|W_2|\}$ and $N = \max\{|T_1|,|T_2|\}$.

LEMMA 4.2. *Suppose that all the auxiliary information of W_1 has been given.*

Then $\text{mast}(W_1, W_2)$ *can be computed in* $O(n^{1.5} \log N)$ *time, and afterwards we can retrieve* $\text{mast}(W_1^v, W_2)$ *for any node* $v \in W_1$ *in* $O(1)$ *time.*

Proof. We adapt Farach and Thorup's rooted subtree algorithm [11] to compute $\text{mast}(W_1, W_2)$. Details are given in Appendix A. □

We demonstrate a scenario where label compression speeds up the computation of $\text{mast}(U_1^x, U_2)$ for Lemma 3.2. Suppose that we can identify a rooted subtree R of U_2 such that x is mapped to a node outside R, i.e., we can reduce (3.1) to

$$\text{mast}(U_1^x, U_2) = \max\{\text{mast}(U_1^x, U_2^y) \mid y \text{ is an internal node not in } R\}. \tag{4.1}$$

Note that every U_2^y contains R as a common subtree. To avoid overlapping computation on R, we construct $W = U_1^x \otimes R$ and $X = U_2 \ominus R$. Then $X^y = U_2^y \ominus R$ and from Lemma 4.1, $\text{mast}(U_1^x, U_2^y) = \text{mast}(W, X^y)$. We rewrite (4.1) as

$$\text{mast}(U_1^x, U_2) = \max\{\text{mast}(W, X^y) \mid y \text{ is an internal node of } X\}. \tag{4.2}$$

If R is large, then W and X are much smaller than U_1^x and U_2. Consequently, it is beneficial to compress U_1^x and compute $\text{mast}(U_1^x, U_2)$ according to (4.2).

4.2. Label compression with respect to two rooted subtrees. Let T, R_1, R_2 be rooted evolutionary trees labeled over L, K_1, K_2, respectively, where $K_1 \cap K_2 = \phi$. Let $K = K_1 \cup K_2$. The *compression* of T with respect to R_1 and R_2, denoted by $T \otimes (R_1, R_2)$, is a tree constructed from $T|(L - K)$ by the following two steps. For each node y and its parent x in $T|(L - K)$,

1. if $\mathcal{A}(T, K, y)$ is nonempty, compress all the trees in $\mathcal{A}(T, K, y)$ into a single leaf z and attach it to y; create and attach an auxiliary node $\bar{z}$ to y;
2. if $\mathcal{H}(T, K, y)$ is nonempty, compress the parents $p_1, \ldots, p_m$ of the roots of the subtrees in $\mathcal{H}(T, K, y)$ into a single node p_1 and insert it between x and y; compress the subtrees in $\mathcal{H}(T, K, y)$ into a single node z and attach it to p_1; create and insert an auxiliary node $\bar{p}_1$ between p_1 and y; create auxiliary nodes $\bar{z}$ and $\bar{\bar{z}}$ and attach them to p_1 and $\bar{p}_1$, respectively.

The nodes p_1 and z are *compressed* nodes of $T \otimes (R_1, R_2)$. The nodes $\bar{p}_1, \bar{z}$, and $\bar{\bar{z}}$ are *auxiliary* nodes. These nodes are added to capture the topology of T that is isomorphic with the subtrees R_1 and R_2 of T'.

We also store auxiliary information in $T \otimes (R_1, R_2)$. Let R^+ be the tree obtained by connecting R_1 and R_2 together with a node, which becomes the root of R^+.

Consider the internal nodes of $T \otimes (R_1, R_2)$. If v is an internal node inherited from $T|(L - K)$, then let $\alpha_1(v) = \text{mast}(T^v, R_1)$ and $\alpha_2(v) = \text{mast}(T^v, R_2)$. If p_1 and $\bar{p}_1$ are internal nodes compressed from some path $p_1, \ldots, p_m$ of T, then only p_1 stores the values $\alpha_1(p_1) = \text{mast}(T^{p_1}, R_1)$, $\alpha_2(p_1) = \text{mast}(T^{p_1}, R_2)$, and $\alpha_+(p_1) = \text{mast}(T^{p_1}, R^+)$.

We do not store any auxiliary information at the atomic leaves in $T \otimes (R_1, R_2)$. Consider the other leaves in $T \otimes (R_1, R_2)$ based on how they are created.

Case 1. Nodes $z, \bar{z}$ are leaves created with respect to $\mathcal{A}(T, K, y)$ for some node y in $T|(L - K)$. Let $\mathcal{A}(T, K, y) = \{T^{v_1}, \ldots, T^{v_k}\}$. We store the following values at z.

- $\alpha_1(z) = \max\{\text{mast}(T^{v_i}, R_1) \mid i \in [1, k]\}$, $\alpha_2(z) = \max\{\text{mast}(T^{v_i}, R_2) \mid i \in [1, k]\}$, $\alpha_+(z) = \max\{\text{mast}(T^{v_i}, R^+) \mid i \in [1, k]\}$;
- $\beta(z) = \max\{\text{mast}(T^{v_i}, R_1) + \text{mast}(T^{v_{i'}}, R_2) \mid T^{v_i}$ and $T^{v_{i'}}$ are distinct subtrees in $\mathcal{A}(T, K, y)\}$.

Case 2. Nodes $z, \bar{z}$, and $\bar{\bar{z}}$ are leaves created with respect to the subtrees in $\mathcal{H}(T, K, y) = \{T^{v_1}, \ldots, T^{v_k}\}$ for some node y in $T|(L - K)$. We store the following values at z:

- $\alpha_1(z)$, $\alpha_2(z)$, and $\alpha_+(z)$ as in Case 1;
- $\beta(z) = \max\{\text{mast}(T^{v_i}, R_1)+\text{mast}(T^{v_j}, R_2) \mid T^{v_i}$ and T^{v_j} are distinct subtrees in $\mathcal{H}(T, K, y)$ that are attached to the same node in $T\}$;
- $\beta_{1\succ 2}(z) = \max\{\text{mast}(T^{v_j}, R_1) + \text{mast}(T^{v_{j'}}, R_2) \mid (j, j') \in Z\}$ and $\beta_{2\succ 1}(z) = \max\{\text{mast}(T^{v_j}, R_2) + \text{mast}(T^{v_{j'}}, R_1) \mid (j, j') \in Z\}$, where $Z = \{(j, j') \mid T^{v_j}, T^{v_{j'}} \in \mathcal{H}(T, K, y)$ and the parent of v_j in T is a proper ancestor of the parent of $v_{j'}\}$.

Let T_1 and T_2 be rooted evolutionary trees. Let R_1 and R_2 be label-disjoint rooted subtrees of T_2. Let $W_1 = T \otimes (R_1, R_2)$ and $W_2 = T' \ominus (R_1, R_2)$. Below, we give the definition of a maximum agreement subtree of W_1 and W_2.

Let γ_1 and γ_2 be the two shrunk leaves in W_2 representing R_1 and R_2, respectively. Let y_c be the least common ancestor of γ_1 and γ_2 in W_2. Intuitively, in a pair of agreement subtrees (W_1', W_2') of W_1 and W_2, atomic leaves are mapped to atomic leaves, and shrunk leaves are mapped to internal nodes or leaves. Moreover, we allow W_2' to contain y_c as a leaf, which can be mapped to an internal node or leaf of W_1'. More formally, we require that there is an isomorphism between W_1' and W_2' satisfying the following conditions:

1. Every atomic leaf is mapped to an atomic leaf with the same label.
2. If W_2' contains y_c as a leaf and thus neither γ_1 nor γ_2 is found in W_2', then y_c is mapped to a node v with $\alpha_+(v) > 0$.
3. If only one of γ_1 and γ_2 exists in W_2', say γ_1, then it is mapped to a node v with $\alpha_1(v) > 0$.
4. If both γ_1 and γ_2 exist in W_2', then any of the following cases is permitted:
   - γ_1 and γ_2, respectively, are mapped to a compressed leaf z and its sibling $\bar{z}$ in W_1' with $\beta(z) > 0$.
   - γ_1 and γ_2, respectively, are mapped to a compressed leaf z and the accompanying auxiliary leaf $\bar{\bar{z}}$ in W_1' with $\beta_{1\succ 2}(z) > 0$, or the leaves $\bar{\bar{z}}$ and z in W_1' with $\beta_{2\succ 1}(z) > 0$.
   - γ_1 and γ_2, respectively, are mapped to two leaves or internal nodes v and w with $\alpha_1(v)$, $\alpha_2(w) > 0$.

The way we measure the size of W_1' and W_2' depends on their isomorphism. For example, if y_c is mapped to some node v in W_1', then the size is the total number of atomic leaves in W_1' plus $\alpha_+(v)$. More precisely, the size of W_1' and W_2' is defined to be the total number of atomic leaves in W_1' plus the corresponding α or β values depending on the isomorphism between W_1' and W_2'. A *maximum* agreement subtree of W_1 and W_2 is one with the largest possible size. Let $\text{mast}(W_1, W_2)$ denote the size of such a subtree. The following lemma, like Lemma 4.1, is also the cornerstone of label compression.

LEMMA 4.3. $\text{mast}(T_1, T_2) = \text{mast}(W_1, W_2)$.

Proof. It follows directly from the definition of $\text{mast}(W_1, W_2)$. □

Again, $\text{mast}(W_1, W_2)$ can be computed by adapting Farach and Thorup's rooted subtree algorithm [11]. The time complexity is stated in the following lemma. Let $n = \max\{|W_1|,|W_2|\}$ and $N = \max\{|T_1|, |T_2|\}$.

LEMMA 4.4. *Suppose that all the auxiliary information of W_1 has been given. Then we can compute* $\text{mast}(W_1, W_2)$ *in* $O(n^{1.5} \log N)$ *time. Afterwards we can retrieve* $\text{mast}(W_1^v, W_2)$ *for any* $v \in W$ *in* $O(1)$ *time.*

Proof. See Appendix A. □

5. Computing mast(U_1^x, U_2)—proof of Lemma 3.2. At a high level, we first apply label compression to the input instance (U_1^x, U_2). We then reduce the problem

```
/* W is a rooted tree with compressed leaves. X is unrooted with shrunk leaves. */
mast(W, X)
  let y be a separator of X;
  val = mast(W, X^y);
  if (X has at most one shrunk leaf) or (y lies between the two shrunk leaves)
  then
    new_subproblem(W, X, y);
    for each (W_i, X_i), val_i = mast(W_i, X_i);
  else
    let y' be the node on the path between the two shrunk leaves that is the closest to
    y;
    val = mast(W, X^{y'});
    new_subproblem(W, X, y');
    for each (W_i, X_i), set val_i = mast(W_i, X_i);
  return max{val, max_{i=1}^{b} val_i};

/* Generate new subproblems {(W_1, X_1), ..., (W_b, X_b)}. */
new_subproblem(W, X, y)
  let v_1, ..., v_b be the neighbors of y in X;
  for all i ∈ [1, b]
    let X_i be the unrooted tree formed by shrinking the subtree X^{v_i y} into a shrunk leaf;
    let W_i be the rooted tree formed by compressing W with respect to X^{v_i y};
  compute and store the auxiliary information in W_i for all i ∈ [1, b];
```

FIG. 4. *Algorithm for computing* $\mathrm{mast}(W, X)$.

to a number of smaller subproblems (W, X), each of which is similar to (U_1^x, U_2) and is solved recursively. For each (W, X) generated, X is a subtree of U_2 with at most two shrunk leaves, and W is a label compression of U_1^x with respect to some rooted subtrees of U_2 that are represented by the shrunk leaves of X. Also, W and X contain the same number of atomic leaves.

5.1. Recursive computation of mast(W, X). Our subtree algorithm initially sets $W = U_1^x$ and $X = U_2$. In general, $W = U_1^x \otimes R$ and $X = U_2 \ominus R$, or $W = U_1^x \otimes (R, R')$ and $X = U_2 \ominus (R, R')$ for some rooted subtrees R and R' of U_2. If W or X has at most two nodes, then $\mathrm{mast}(W, X)$ can easily be computed in linear time. Otherwise, both W and X each have at least three nodes. Let $N = \max\{|U_1|, |U_2|\}$ and $n = \max\{|W|, |X|\}$. Our algorithm first finds a separator y of X and computes $\mathrm{mast}(W, X)$ for the following two cases. The output is the larger of the two cases. Figure 4 outlines our algorithm.

Case 1. $\mathrm{mast}(W, X) = \mathrm{mast}(W, X^y)$. We root X at y and evaluate $\mathrm{mast}(W, X^y)$. By Lemma 4.4, this takes $O(n^{1.5} \log N)$ time.

Case 2. $\mathrm{mast}(W, X) = \mathrm{mast}(W, X^z)$ for some internal node $z \neq y$. We compute $\max\{\mathrm{mast}(W, X^z) \mid z \text{ is an internal node and } z \neq y\}$ by solving a set of subproblems $\{\mathrm{mast}(W_1, X_1), \ldots, \mathrm{mast}(W_b, X_b)\}$ such that their total size is n and $\max\{\mathrm{mast}(W, X^z) \mid z \text{ is an internal node and } z \neq y\} = \max\{\mathrm{mast}(W_i, X_i) \mid i \in [1, b]\}$. Moreover, our algorithm enforces the following properties:

- If X contains at most one shrunk leaf, every subproblem generated has size at most half that of X.
- If X has two shrunk leaves, at most one subproblem (W_{i_o}, X_{i_o}) has size

greater than half that of X, but X_{i_o} contains only one shrunk leaf. Thus, in the next recursion level, every subproblem spawned by (W_{i_o}, X_{i_o}) has size at most half that of X.

To summarize, whenever the recursion goes down by two levels, the size of a subproblem reduces by half.

The subproblems $\text{mast}(W_1, X_1), \ldots, \text{mast}(W_b, X_b)$ are formally defined as follows. Assume that the separator y has b neighbors in X, namely, $v_1, \ldots, v_b$. For each $i \in [1, b]$, let C_i be the connected component in $X - \{y\}$ that contains v_i. The size of C_i is at most half that of X. Intuitively, we would like to shrink the subtree $X^{v_i y}$ into a leaf, producing a smaller unrooted tree X_i. We first consider the simple case where X has at most one shrunk leaf. Then no C_i contains more than one shrunk leaf.

If C_i contains no shrunk leaf, then X_i contains only one shrunk leaf representing the subtree $X^{v_i y}$. Note that $X^{v_i y}$ corresponds to the subtree $U_2^{v_i y}$ in U_2 and $X_i = U_2 \ominus U_2^{v_i y}$. Let $W_i = U_1^x \otimes U_2^{v_i y}$.

If C_i contains one shrunk leaf γ_1, then X_i contains γ_1 as well as a new shrunk leaf representing the subtrees $X^{v_i y}$. The two subtrees are label-disjoint. Again, $X^{v_i y}$ corresponds to the subtree $U_2^{v_i y}$ in U_2. Assume that γ_1 corresponds to a subtree $U_2^{v' y'}$ in U_2. Then $X_i = U_2 \ominus (U_2^{v' y'}, U_2^{v_i y})$. Let $W_i = U_1^x \otimes (U_2^{v' y'}, U_2^{v_i y})$.

We now consider the case where X itself already has two shrunk leaves γ_1 and γ_2. If y lies on the path between γ_1 and γ_2, then no C_i contains more than one shrunk leaf and we define the smaller problem instances (W_i, X_i) as above. Otherwise, there is a C_i containing both γ_1 and γ_2. X_i as defined contains three compressed leaves, violating our requirement. In this case, we replace y with the node y' on the path between γ_1 and γ_2, which is the closest to y. Now, to compute $\text{mast}(W, X)$, we consider the two cases depending on whether the root of W is mapped to y' or not. Again, we first compute $\text{mast}(W, X^{y'})$. Then, we define the connected components C_i and the smaller problem instances (W_i, X_i) with respect to y'. Every X_i has at most two compressed leaves, but y' may not be a separator and we cannot guarantee that the size of every subproblem is reduced by half. However, there can exist only one connected component C_{i_o} with size larger than half that of X. Indeed, C_{i_o} is the component containing y. In this case, both γ_1 and γ_2 are not inside C_{i_o}, and X_{i_o} as defined contains only one compressed leaf. Thus, the subproblems that $\text{mast}(W_{i_0}, X_{i_0})$ spawns in the next recursion level each have size of at most half that of (W, X).

With respect to y or y', computing the topology of all X_i and W_i from X and W is straightforward; see section 5.2. Computing the auxiliary information in all W_i efficiently requires some intricate techniques, which are detailed in sections 6 and 7.

5.2. Computing the topology of compressed trees. The topology of X_i can be constructed from X by replacing the subtree $X^{v_i y}$ of X with a shrunk leaf. Let J and J_i be the sets of labels in X and X_i, respectively. For the trees W_i, recall that the definitions of W and the trees W_i are based on affixing some nodes to the trees $U_1^x|J$ and $U_1^x|J_i$, respectively. Observe that $W|J$ and $U_1^x|J$ have the same topology. Moreover, $W|J_i = (W|J)|J_i$ and $U_1^x|J_i = (U_1^x|J)|J_i$. Thus, $W|J_i$ and $U_1^x|J_i$ have the same topology. We can obtain $U_1^x|J_i$ by constructing $W|J_i$. Note that $J = \bigcup_{1 \le i \le b} J_i$ and all the label sets J_i are disjoint. We can construct all the trees $W|J_i$ from W in $O(n)$ time [7, 10]. Next, we show how to construct W_i from $W|J_i$ in time linear in the size of $W|J_i$. We only detail the case where X_i consists of two shrunk leaves. The case for one shrunk leaf is similar. The following procedure is derived directly from the definition of the compression of U_1^x with respect to two subtrees.

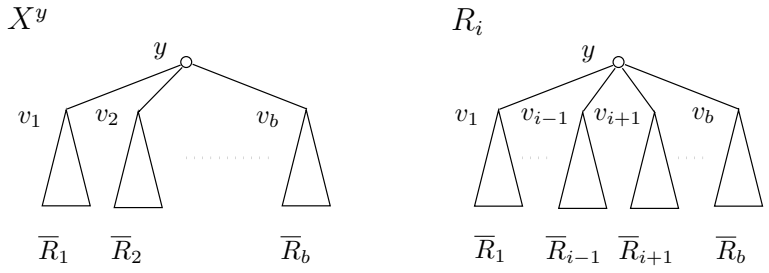

FIG. 5. *The structures of X^y and R_i.*

Let v be any node of $W|J_i$. If v is not the root, let u be the parent of v in $W|J_i$.

- If $\mathcal{A}(U_1^x, L-J_i, v)$ is nonempty or equivalently the degree of v in U_1^x is different from its degree in $W|J_i$, then attach auxiliary leaves z and $\bar{z}$ to v.
- If $\mathcal{H}(U_1^x, L-J_i, v)$ is nonempty or equivalently u is not the parent of v in U_1^x, then create a path between u and v consisting of two nodes p and $\bar{p}$, attach auxiliary leaves z and $\bar{z}$ to p, and attach $\bar{\bar{z}}$ to $\bar{p}$.

5.3. Time complexity of computing mast(W, X).

LEMMA 5.1. *We can compute* $\mathrm{mast}(W, X)$ *in* $O(n^{1.5}\log N)$ *time.*

Proof. Let $T(n)$ be the computation time of $\mathrm{mast}(W, X)$. The computation is divided into two cases. Case 1 of section 5.1 takes $O(n^{1.5}\log N)$ time. For Case 2, a set of subproblems $\{\mathrm{mast}(W_i, X_i) \mid i \in [1, b]\}$ is generated. As to be shown in sections 6 and 7, the time to prepare all these subproblems is also $O(n^{1.5}\log N)$. These subproblems, except possibly one, are each of size less than $n/2$. For the exceptional subproblem, say, $\mathrm{mast}(W_l, X_l)$, its computation is again divided into two cases. One case takes $O(n^{1.5}\log N)$ time. For the other case, another set of subproblems is generated in $O(n^{1.5}\log N)$ time. This time every such subproblem has size less than $n/2$. Let Σ be the set of all the subproblems generated in both steps. The total size of the subproblems in Σ is at most n, and

$$T(n) = O(n^{1.5}\log N) + \sum_{\mathrm{mast}(W', X') \in \Sigma} T(|X'|).$$

It follows that $T(n) = O(n^{1.5}\log N)$. ∎

By letting $W = U_1^x$ and $X = U_2$, we have proved Lemma 3.2. What remains is to show how to compute the auxiliary information stored in all W_i from (W, X) in $O(n^{1.5}\log N)$ time. Note that X contains at most two shrunk leaves. Depending on the number of shrunk leaves in X, we divide our discussion into sections 6 and 7.

6. Auxiliary information for X with no shrunk leaf. The case of X containing no shrunk leaf occurs only when the algorithm starts, i.e., $W = U_1^x$, $X = U_2$, and $N = n$. The subproblems $\mathrm{mast}(W_1, X_1), \ldots, \mathrm{mast}(W_b, X_b)$ spawned from (W, X) are defined by an internal node y in X, which is adjacent to the nodes $v_1, \ldots, v_b$. Let R_i and $\overline{R}_i$ denote the rooted subtrees $X^{v_i y}$ and $X^{y v_i}$, respectively. Note that the rooted tree X^y is composed of the subtrees $\overline{R}_1, \ldots, \overline{R}_b$. Also, $W_i = W \otimes R_i$ and $X_i = W \ominus R_i$. The total size of all $\overline{R}_i$ is at most n. Furthermore, each R_i is X^y with $\overline{R}_i$ removed; see Figure 5. This section discusses how to compute the auxiliary information required by each W_i in $O(n^{1.5}\log N)$ time.

6.1. Auxiliary information in the compressed leaves of W_i. Consider any compressed leaf v in W_i. Let S_v denote the set of subtrees from which v is compressed. Then, the auxiliary information to be stored in v is

$$\alpha(v) = \max\{\text{mast}(W^z, R_i) \mid W^z \in S_v\}. \tag{6.1}$$

Observe that for any $W^z \in S_v$, W^z contains no labels outside R_i. Thus, $\text{mast}(W^z, R_i) = \text{mast}(W^z, X^y)$ and we can rewrite (6.1) as

$$\alpha(v) = \max\{\text{mast}(W^z, X^y) \mid W^z \in S_v\}.$$

We use the rooted subtree algorithm of [11] to compute $\text{mast}(W, X^y)$ in $O(n^{1.5} \log N)$ time. Then, we can retrieve the value of $\text{mast}(W^z, X^y)$ for any node $z \in W$ in $O(1)$ time. To compute $\max\{\text{mast}(W^z, X^y) \mid W^z \in S_v\}$ efficiently, we assume that for any node $u \in W$, the subtrees attached to u are numbered consecutively, starting from 1. We consider a preprocessing for efficient retrieval of the following types of values:

- for some node $u \in W$ and some interval $[a, b]$, $\max\{\text{mast}(W^z, X^y) \mid W^z$ is a subtree attached to u and its number falls in $[a, b]\}$;
- for some path P of W, $\max\{\text{mast}(W^z, X^y) \mid W^z$ is a subtree attached to some node in $P\}$.

LEMMA 6.1. *Assume that we can retrieve* $\text{mast}(W^z, X^y)$ *for any* $z \in W$ *in* $O(1)$ *time. Then we can preprocess* W *and* X *and construct additional data structures in* $O(n \log^* n)$ *time so that any value of the above types can be retrieved in* $O(1)$ *time.*

Proof. We adapt preprocessing techniques for on-line product queries in [3]. □

With the preprocessing stated in Lemma 6.1, we can determine $\alpha(v)$ as follows. Note that S_v is either a subset of the subtrees attached to a node u in W or the set of subtrees attached to nodes on a particular path in W. In the former case, u is also a parent of v and S_v is partitioned into at most $d_u + 1$ intervals where d_u is the degree of u in W_i. From Lemma 6.1, $\alpha(v)$ can be found in $O(d_u + 1)$ time. Similarly, for the latter case, $\alpha(v)$ can be found in $O(1)$ time. Thus, the compressed leaves in W_i are processed in $O(|W_i|)$ time. Summing over all W_i, the time complexity is $O(n)$. Therefore, the overall computation time for preprocessing and finding auxiliary information in the leaves of all W_i is $O(n^{1.5} \log N)$.

6.2. Auxiliary information in the internal nodes of W_i. Consider any internal node v in W_i with $i \in [1, b]$. Our goal is to compute the auxiliary information $\alpha(v) = \text{mast}(W^v, R_i)$. Note that R_i may be of size $\Theta(n)$, and even computing one particular $\text{mast}(W^v, R_i)$ already takes $O(n^{1.5} \log N)$ time. Fortunately, these R_i are very similar. Each R_i is X^y with $\overline{R}_i$ removed. Exploiting this similarity and using the algorithm in section 2 for all-cavity matchings, we can perform an $O(n^{1.5} \log N)$-time preprocessing so that we can retrieve $\text{mast}(W^v, R_i)$ for any internal node v in W and $i \in [1, b]$ in $O(\log^2 n)$ time. Therefore, it takes $O(|W_i| \log^2 n)$ time to compute $\alpha(v)$ for all internal nodes v of one particular W_i, and $O(n \log^2 n)$ time for all W_i. The $O(n^{1.5} \log N)$-time preprocessing is detailed as follows.

First, note that if we remove y from X^y, the tree would decompose into the subtrees $\overline{R}_1, \ldots, \overline{R}_b$. Thus, the total size of all $\overline{R}_i$ is at most n. The next lemma suggests a way to retrieve efficiently $\text{mast}(W^v, \overline{R}_i)$ and $\max\{\text{mast}(W^v, \overline{R}_j) \mid j \in I\}$ for any $v \in W$ and and $I \subseteq [1, b]$.

LEMMA 6.2. *We can compute* $\text{mast}(W, \overline{R}_i)$ *for all* $i \in [1, b]$ *in* $O(n^{1.5} \log N)$ *time. Then, we can retrieve* $\text{mast}(W^v, \overline{R}_i)$ *for any node* v *in* W *and* $i \in [1, b]$ *in* $O(\log n)$ *time. Furthermore, we can build a data structure to retrieve* $\max\{\text{mast}(W^v, \overline{R}_j) \mid j \in I\}$ *for any* $v \in W$ *and* $I \subseteq [1, b]$ *in* $O(\log^2 n)$ *time.*

Proof. This lemma follows from the rooted subtree algorithm and related data structures in [11]. □

Below, we give a formula to compute $\text{mast}(W^v, R_i)$ efficiently. For any $z \in W$ and $i \in [1, b]$, let $\text{r-mast}(W^z, R_i)$ denote the maximum size among all the agreement subtrees of W^z and R_i in which z is mapped to the root of R_i.

LEMMA 6.3.

$$\text{mast}(W^v, R_i) = \max \begin{cases} \max\{\text{mast}(W^v, \overline{R}_j) \mid j \in [1, b], j \neq i\}; \\ \max\{\text{r-mast}(W^z, R_i) \mid z \in W^v\}. \end{cases}$$

Proof. Observe that $\text{mast}(W^v, R_i) = \text{mast}(W^z, R_i) = \text{r-mast}(W^z, R_i)$ if in some maximum agreement subtree of W^v and R_i, the root of R_i is mapped to some node z in W^v. On the other hand, $\text{mast}(W^v, R_i) = \text{mast}(W^v, \overline{R}_j)$ for some $j \neq i$ if in some maximum agreement subtree of W^v and R_i, the root of R_i is not mapped to any node z in W^v. □

By Lemma 6.3, we decompose the computation of $\text{mast}(W^v, R_i)$ into two parts. The value $\max\{\text{mast}(W^v, \overline{R}_j) \mid j \in [1, b], j \neq i\}$ is determined by answering two queries $\max\{\text{mast}(W^v, \overline{R}_j) \mid j \in [1, i-1]\}$ and $\max\{\text{mast}(W^v, \overline{R}_j) \mid j \in [i+1, b]\}$ in $O(\log^2 n)$ time by Lemma 6.2. The computation of $\max\{\text{r-mast}(W^z, R_i) \mid z \in W^v\}$ makes use of a maximum weight matching of some bipartite graph as follows.

Let $\text{Ch}(z)$ denote the set of children of a node z in a tree. Let $G_{z,i} \subseteq \text{Ch}(z) \times \{\overline{R}_1, \ldots, \overline{R}_{i-1}, \overline{R}_{i+1}, \ldots, \overline{R}_b\}$ be a bipartite graph where $w \in \text{Ch}(z)$ is connected to $\overline{R}_j$ if and only if $\text{mast}(W^w, \overline{R}_j) > 0$. Such an edge has weight $\text{mast}(W^w, \overline{R}_j) \leq N$.

FACT 6.4 (see [11]). *If the root of R_i is mapped to z in some maximum agreement subtree of W^z and R_i, then a maximum weight matching of $G_{z,i}$ consists of at least two edges, and* $\text{mwm}(G_{z,i}) = \text{r-mast}(W^z, R_i)$.

Note that if a maximum weight matching of $G_{z,i}$ consists of one edge, it corresponds to an agreement subtree of W^z and R_i in which the root of R_i is not mapped to any node in W^z. Thus, it is possible that $\text{mwm}(G_{z,i}) > \text{r-mast}(W^z, R_i)$. Nevertheless, in this case we are no longer interested in the exact value of $\text{r-mast}(W^z, R_i)$ since in a maximum agreement subtree of W^z and R_i, the root of R_i is not mapped to any node in W^z. In fact, Lemma 6.3 can be rewritten with the $\text{r-mast}(W^z, R_i)$ replaced by $\text{mwm}(G_{z,i})$. Furthermore, since $G_{z,1}, G_{z,2}, \ldots, G_{z,b}$ are very similar, the weights of a maximum weight matching cannot be all distinct.

LEMMA 6.5. *At least $b - d_z$ of* $\text{mwm}(G_{z,1})$, $\text{mwm}(G_{z,2}), \ldots, \text{mwm}(G_{z,b})$ *have the same value, where d_z denotes the degree of z in W.*

Proof. Consider the bipartite graph $K \subseteq \text{Ch}(z) \times \{\overline{R}_1, \ldots, \overline{R}_b\}$ in which a node $w \in \text{Ch}(z)$ is connected to $\overline{R}_i$ if and only if $\text{mast}(W^w, \overline{R}_i) > 0$. This edge is given a weight of $\text{mast}(W^w, \overline{R}_i)$. Then, every $G_{z,i}$ is a subgraph of K. Let M be a maximum weight matching of K. Observe that if an R_i is not adjacent to any edge in M, then M is also a maximum weight matching of $G_{z,i}$. Since M contains at most d_z edges, there are at least $b - d_z$ trees R_i not adjacent to any edge in M and the corresponding $\text{mwm}(G_{z,i})$ have the same value. □

We next use $O(n^{1.5} \log N)$ time to find for all z in W, $\text{mwm}(G_{z,1}), \ldots, \text{mwm}(G_{z,b})$. The results are to be stored in an array A_z of dimension b for each node z, i.e., $A_z[i] = \text{mwm}(G_{z,i})$. Note that if we represent each A_z as an ordinary array, then filling these arrays entry by entry for all $z \in W$ would cost $\Omega(bn)$ time. Nevertheless, by Lemma 6.5, most of the weights $\text{mwm}(G_{z,i})$ have the same value. Thus, we store these values in sparse arrays. Like an ordinary array, any entry in a *sparse array* A can be read and modified in $O(1)$ time. In addition, we require that all the entries

in A can be initialized to a fixed value in $O(1)$ time and that all the distinct values stored in A can be retrieved in $O(m)$ time, where m denotes the number of distinct values in A. For an implementation of sparse array, see Exercise 2.12, page 71 of [2].

Before showing how to build these sparse arrays, we illustrate how they support the computation of

$$\max\{\mathrm{mwm}(G_{z,i}) \mid z \in W^v\} = \max\{A_z[i] \mid z \in W^v\}. \tag{6.2}$$

An efficient data structure for answering such a query is given in Appendix B. Let m_z be the number of distinct values in A_z, and $m = \sum_{z \in W}(m_z + 1)$. Let $\alpha(n)$ denote the inverse Ackermann function. Appendix B shows how to construct a data structure on top of the sparse arrays A_z in $O(m\alpha(|W|))$ time such that we can retrieve for any $v \in W$ and $i \in [1, b]$ the value of $\max\{A_z[i] \mid z \in W^v\}$ in $O(\log |W|)$ time. From Lemma 6.5, $m_z \leq d_z + 1$ for all $z \in W$; thus, $m = O(|W|)$. Therefore, the data structure can be built in time $O(m\alpha(|W|)) = O(|W|\alpha(|W|)) = O(n \log n)$ and the retrieval time of (6.2) is $O(\log |W|) = O(\log n)$.

To summarize, after building all the necessary data structures, we can retrieve $\max\{\mathrm{mast}(W^v, \overline{R}_j) \mid j \in [1, b], j \neq i\}$ in $O(\log^2 n)$ time and $\max\{\text{r-mast}(W^z, R_i) \mid z \in W^v\}$ in $O(\log n)$ time. Hence, for any $v \in W$ and $i \in [1, b]$, $\mathrm{mast}(W^v, R_i)$ can be computed in $O(\log^2 n)$ time.

To complete our discussion, we show below how to construct a sparse array A_z or equivalently compute the weights $\{\mathrm{mwm}(G_{z,i}) \mid i \in [1, b]\}$ efficiently. We cannot afford to examine every $G_{z,i}$ and compute $\mathrm{mwm}(G_{z,i})$ separately. Instead we build only one weighted graph $G_z \subseteq \mathrm{Ch}(z) \times \{\overline{R}_1, \ldots, \overline{R}_b\}$ as follows.

For a node z in W, the *max-child* z' of z is a child of z such that the subtree rooted at z' contains the maximum number of atomic leaves among all the subtrees attached to z. Let $\kappa(z)$ denote the total number of atomic leaves that are in W^z but not in $W^{z'}$. The edges of G_z are specified as follows.

- For any non-max-child u of z, G_z contains an edge between u and some $\overline{R}_i$ if and only if $\mathrm{mast}(W^u, \overline{R}_i) > 0$. There are at most $\kappa(z)$ such edges.
- Regarding the max-child z' of z, we put into G_z only a limited number of edges between z' and $\{\overline{R}_1, \ldots, \overline{R}_b\}$. For each $\overline{R}_i$ already connected to some non-max-child of z, G_z has an edge between z' and $\overline{R}_i$ if $\mathrm{mast}(W^{z'}, \overline{R}_i) > 0$. Among all other $\overline{R}_i$, we pick $\overline{R}_{i'}$ and $\overline{R}_{i''}$ such that $\mathrm{mast}(W^{z'}, \overline{R}_{i'})$ and $\mathrm{mast}(W^{z'}, \overline{R}_{i''})$ are the first and second largest.
- Every edge $(u, \overline{R}_i)$ in G_z is given a weight of $\mathrm{mast}(W^u, \overline{R}_i)$.

LEMMA 6.6. *For all* $i \in [1, b]$, $\mathrm{mwm}(G_z - \{\overline{R}_i\}) = \mathrm{mwm}(G_{z,i})$. *Furthermore,* G_z *can be built in* $O((\kappa(z) + 1) \log^2 n)$ *time.*

Proof. The fact that $\mathrm{mwm}(G_z - \{\overline{R}_i\}) = \mathrm{mwm}(G_{z,i})$ follows from the construction of G_z. Note that G_z contains $O(\kappa(z) + 1)$ edges. All edges in G_z, except $(z', \overline{R}_{i'})$ and $(z', \overline{R}_{i''})$, can be found using $O(\kappa(z))$ time. The weight of these edges can be found in $O(\kappa(z) \log n)$ time using Lemma 6.2. To identify $(z', \overline{R}_{i'})$ and $(z', \overline{R}_{i''})$, note that at most $\kappa(z)$ instances of $\overline{R}_i$ are connected to some non-max-child of z. All other $\overline{R}_i$ are partitioned into at most $\kappa(z) + 1$ intervals. For each interval, say $I \subseteq [1, b]$, by Lemma 6.2, the corresponding $\mathrm{mast}(W^{z'}, \overline{R}_i)$ which attains the maximum in the set $\{\mathrm{mast}(W^{z'}, \overline{R}_j) \mid j \in I\}$ can be found in $O(\log^2 n)$ time. Thus, by scanning all the $\kappa(z) + 1$ intervals, $\overline{R}_{i'}$ can be found in $O((\kappa(z) + 1) \log^2 n)$ time. $\overline{R}_{i''}$ can be found similarly. ∎

Since G_z contains $O(\kappa(z) + 1)$ edges, and each edge has weight at most N, we use the Gabow–Tarjan algorithm [13] to compute $\mathrm{mwm}(G_z)$ in $O(\sqrt{\kappa(z) + 1}(\kappa(z) +$

$1)\log N)$ time. Then, using our algorithm for all-cavity maximum weight matching, we can compute $\mathrm{mwm}(G_z - \{\overline{R}_i\})$ for all $i \in [1, b]$, and store the results in a sparse array A_z in the same amount of time.

Thus, all G_z with $z \in W$ can be constructed in time $\sum_{z\in W} O((\kappa(z)+1)\log^2 n)$, which is $O(n^{1.5}\log N)$ as $\sum_{z\in W}\kappa(z) = O(n\log n)$ [9]. Given all G_z, the time for computing A_z for all $z \in W$ is $O(\sum_{z\in W}(\kappa(z)+1)^{1.5}\log N)$.

LEMMA 6.7. $\sum_{z\in W}(\kappa(z)+1)^{1.5}\log N = O(n^{1.5}\log N)$.

Proof. Let $T(W) = \sum_{z\in W}(\kappa(z)+1)^{1.5}\log N$. Let P be a path starting from the root of W such that every next node is the max-child of its predecessor. Then $\sum_{z\in P}\kappa(z) \le |W| \le n$. Let $\chi(P)$ denote the set of subtrees attached to some node on P. The subtrees in $\chi(P)$ are label-disjoint and each has size at most $n/2$. Thus,

$$\begin{aligned} T(W) &\le \sum_{z\in P}(\kappa(z)+1)^{1.5}\log N + \sum_{W'\in\chi(P)} T(W') \\ &\le n^{1.5}\log N + \sum_{W'\in\chi(P)} T(W') \\ &= O(n^{1.5}\log N). \qquad \square \end{aligned}$$

7. Auxiliary information for X with one or two shrunk leaves.

7.1. X has one shrunk leaf. Consider the computation of $\mathrm{mast}(W, X)$. According to the algorithm, $\mathrm{mast}(W, X)$ will spawn b subproblems $\mathrm{mast}(W_1, X_1), \ldots, \mathrm{mast}(W_b, X_b)$, which are defined by an internal node y in X adjacent to the nodes $v_1, \ldots, v_b$. Also, for every $i \in [1, b]$, R_i and $\overline{R}_i$ denote the subtrees $X^{v_i y}$ and $X^{y v_i}$, respectively. Suppose that X has one shrunk leaf and without loss of generality, assume that the shrunk leaf of X is in $\overline{R}_b$, i.e., X_b has two shrunk leaves and all the other X_i have one shrunk leaf each. This section shows how to find the auxiliary information required by $W_1, \ldots, W_b$ in $O(n^{1.5}\log N)$ time.

LEMMA 7.1. *The auxiliary information required by $W_1, \ldots, W_{b-1}$ can be computed in $O(n^{1.5}\log N)$ time.*

Proof. Note that $\mathrm{mast}(W_1, X_1), \ldots, \mathrm{mast}(W_{b-1}, X_{b-1})$ are almost identical to the subproblems considered in section 6 in that all the X_i have exactly one shrunk leaf each. Using exactly the same approach, we can compute the auxiliary information in $W_1, \ldots, W_{b-1}$. $\square$

The remaining section focuses on computing the auxiliary information in W_b. Let γ_1 and γ_2 be the two shrunk leaves of X_b. Assume that γ_1 is also a shrunk leaf in X, and γ_2 represents R_b. Let Q^+ be the subtree obtained by connecting γ_1 and R_b together with a node. To compute the auxiliary information in W_b, we require the values $\mathrm{mast}(W^v, \gamma_1)$, $\mathrm{mast}(W^v, R_b)$, and $\mathrm{mast}(W^v, Q^+)$ for all nodes $v \in W$. These values are computed based on the following lemma.

LEMMA 7.2. $\mathrm{mast}(W^v, \gamma_1)$, $\mathrm{mast}(W^v, R_b)$, *and* $\mathrm{mast}(W^v, Q^+)$ *for all nodes $v \in W$ can be computed in $O(n^{1.5}\log N)$ time.*

Proof. By Lemma 4.2, $\mathrm{mast}(W, R_b)$ and $\mathrm{mast}(W, Q^+)$ can be computed in time $O(n^{1.5}\log N)$ and afterwards, for each node $v \in W$, $\mathrm{mast}(W^v, R_b)$ and $\mathrm{mast}(W^v, Q^+)$ can be retrieved in $O(1)$ time. For each node $v \in W$, $\mathrm{mast}(W^v, \gamma_1)$ is the auxiliary information stored at v in W and can be retrieved in $O(1)$ time. $\square$

Now, we are ready to compute the auxiliary information stored at each node $v \in W_b$. No auxiliary information is required for atomic leaves. Below, Lemmas 7.3 and 7.4 show that using $O(n)$ additional time, we can compute the auxiliary information

in internal nodes and in compressed leaves, respectively. In summary, the auxiliary information in $W_1, \ldots, W_b$ can be computed in $O(n^{1.5} \log N)$ time.

LEMMA 7.3. *Given* $\text{mast}(W^v, \gamma_1)$, $\text{mast}(W^v, R_b)$, *and* $\text{mast}(W^v, Q^+)$ *for all nodes* $v \in W$, *the auxiliary information stored at the internal nodes in* W_b *can be found in* $O(n)$ *time.*

Proof. Let J_b be the set of labels of the atomic leaves of W_b. An internal node v can be either an auxiliary node, a compressed node, or a node of $W|J_b$. If $v \in W|J_b$, then $v \in W$. Thus, $\alpha_1(v) = \text{mast}(W^v, \gamma_1)$ and $\alpha_2(v) = \text{mast}(W^v, R_b)$.

If v is a compressed node, then we need to compute $\alpha_1(v), \alpha_2(v)$ and $\alpha_+(v)$. Recall that v represents some tree path $\sigma = v_1, \ldots, v_k$ of W, where v_1 is the closest to the root, i.e., $v = v_1$. Thus, $\alpha_1(v) = \text{mast}(W^{v_1}, \gamma_1)$, $\alpha_2(v) = \text{mast}(W^{v_1}, R_b)$, and $\alpha_+(v) = \text{mast}(W^{v_1}, Q^+)$.

Thus, $O(n)$ time is sufficient for finding the auxiliary information stored at every internal node of W_b. □

LEMMA 7.4. *Given* $\text{mast}(W^v, \gamma_1)$, $\text{mast}(W^v, R_b)$, *and* $\text{mast}(W^v, Q^+)$ *for all nodes* $v \in W$, *the auxiliary information stored at the compressed leaves in* W_b *can be found in* $O(n)$ *time.*

Proof. If v is a compressed leaf in W, v's parent u must not be an auxiliary node. Depending on whether u is a compressed node, we have two cases.

Case A. u is not a compressed node. We need to compute $\alpha_1(v), \alpha_2(v), \alpha_+(v), \beta(v)$. Note that u is also in W. When W_b is constructed from W, some of the subtrees of W attached to u are replaced by v and no longer exist in W_b. Let $W^{p_1}, \ldots, W^{p_k}$ be these subtrees. Observe that both v and $W^{p_1}, \ldots, W^{p_k}$ represent the same set of subtrees in T_1. Thus,

- $\alpha_1(v) = \max\{\text{mast}(W^{p_i}, \gamma_1) \mid 1 \le i \le k\}$;
- $\alpha_2(v) = \max\{\text{mast}(W^{p_i}, R_b) \mid 1 \le i \le k\}$;
- $\alpha_+(v) = \max\{\text{mast}(W^{p_i}, Q^+) \mid 1 \le i \le k\}$;
- $\beta(v) = \max\{\text{mast}(W^{p_i}, \gamma_1) + \text{mast}(W^{p_j}, R_b) \mid 1 \le i \ne j \le k\}$.

These four values can be found in $O(k)$ time. Since $W^{p_1}, \ldots, W^{p_k}$ are subtrees attached to u in W, k is at most the degree of u in W. Moreover, the sum of the degrees of all internal nodes of W is $O(n)$. Therefore, $O(n)$ time suffices to compute the auxiliary information for all the compressed leaves in W_b whose parents are not compressed node.

Case B. u is a compressed node. We need to compute $\alpha_1(v)$, $\alpha_2(v)$, $\alpha_+(v)$, $\beta(v)$, $\beta_{1\succ 2}(v)$, and $\beta_{1\succ 2}(v)$. Note that u is compressed from a tree path $p_1, \ldots, p_k$ in W, where p_1 is the closest to the root. Moreover, v is compressed from the subtrees hanging between p_1 and p_k. For every $i \in [1, k]$, let $\mathcal{T}_i$ be the set of subtrees of W attached to p_i that are compressed into v. Both v and the subtrees in $\cup_{1 \le i \le k} \mathcal{T}_i$ represent the same set of subtrees in T_1. The auxiliary information stored at v can be expressed as follows.

- $\alpha_1(v) = \max\{\text{mast}(W^q, \gamma_1) \mid W^q \in \mathcal{T}_i \text{ for some } i \in [1, k]\}$.
- $\alpha_2(v) = \max\{\text{mast}(W^q, R_b) \mid W^q \in \mathcal{T}_i \text{ for some } i \in [1, k]\}$.
- $\alpha_+(v) = \max\{\text{mast}(W^q, Q^+) \mid W^q \in \mathcal{T}_i \text{ for some } i \in [1, k]\}$.
- $\beta(v) = \max_{1 \le i \le k}[\max\{\text{mast}(W^q, \gamma_1) + \text{mast}(W^{q'}, R_b) \mid W^q, W^{q'} \in \mathcal{T}_i\}]$.
- $\beta_{1\succ 2}(v) = \max_{1 \le j < i \le k}[\max\{\text{mast}(W^q, \gamma_1) \mid W^q \in \mathcal{T}_i\} + \max\{\text{mast}(W^{q'}, R_b) \mid W^{q'} \in \mathcal{T}_j\}]$.
- $\beta_{2\succ 1}(v) = \max_{1 \le j < i \le k}[\max\{\text{mast}(W^q, R_b) \mid W^q \in \mathcal{T}_i\} + \max\{\text{mast}(W^{q'}, \gamma_1) \mid W^{q'} \in \mathcal{T}_j\}]$.

These values can be found in $O(\sum_{1 \le i \le k} d_{p_i})$ time, where d_{p_i} is the degree of p_i in W.

Thus, the auxiliary information for every compressed leaf of W_b, whose parents are compressed nodes, can be computed in $O(n)$ time. □

7.2. X has two shrunk leaves. Recall that the subproblems $\text{mast}(W_1, X_1)$, $\ldots, \text{mast}(W_b, X_b)$ are spawned from $\text{mast}(W, X)$. This section considers the case where X has two shrunk leaves. Without loss of generality, assume that the two shrunk leaves are in $\overline{R}_{b-1}$ and $\overline{R}_b$, respectively. Then, $X_1, \ldots, X_{b-2}$ each have one shrunk leaf. X_{b-1} and X_b each have two shrunk leaves. Below, we show how to compute the auxiliary informations of $W_1, \ldots, W_b$ in $O(n^{1.5} \log N)$ time.

LEMMA 7.5. *The auxiliary information required by $W_1, \ldots, W_{b-2}$ can be computed in $O(n^{1.5} \log N)$ time.*

Proof. The proof of this lemma is the same as that of Lemma 7.1. □

For the remaining subproblems $\text{mast}(W_{b-1}, X_{b-1})$ and $\text{mast}(W_b, X_b)$, both X_{b-1} and X_b have two shrunk leaves. By symmetry, it suffices to discuss the computation of $\text{mast}(W_b, X_b)$ only. Lemma 7.6 shows that the auxiliary information in W_b can be computed in $O(n^{1.5} \log N)$ time. Therefore, the auxiliary information in $W_1, \ldots, W_b$ can be computed in $O(n^{1.5} \log N)$ time.

LEMMA 7.6. *The auxiliary information in W_b can be computed in $O(n^{1.5} \log N)$ time.*

Proof. Let γ_1 and γ_2 be the two shrunk leaves of X_b. Assume that γ_1 is also a shrunk leaf in X and γ_2 represents R_b, i.e., γ_2 represents the subtree $U_2^{v_b y}$ of T_1. Let Q^+ be the subtree obtained by connecting γ_1 and R_b. By the same argument as in Lemmas 7.3 and 7.4, the auxiliary information in W_b can be computed based on the values $\text{mast}(W^v, \gamma_1)$, $\text{mast}(W^v, R_b)$, and $\text{mast}(W^v, Q^+)$ for all $v \in W$. The value $\text{mast}(W^v, \gamma_1)$ can be found in W. The values $\text{mast}(W^v, R_b)$ and $\text{mast}(W^v, Q^+)$ for all $v \in W$ can be retrieved in $O(1)$ time after $\text{mast}(W, R_b)$ and $\text{mast}(W, Q^+)$ are computed in $O(n^{1.5} \log N)$ time based on Lemma 4.4. Then the auxiliary information in W_b can be computed in $O(n)$ time. □

8. Extension. We have presented an $O(N^{1.5} \log N)$-time algorithm for computing a maximum agreement subtree of two unrooted evolutionary trees of at most N nodes each. This algorithm can be modified slightly to compute a maximum agreement subtree for two mixed trees M_1 and M_2.

For a mixed tree M, a node ℓ is *consistent* with a node u if the directed edges on the path between u and ℓ all point away from u. Let M^u be the rooted tree constructed by assigning u in M as the root and removing the nodes of M inconsistent with u. Given two mixed tree M_1 and M_2, we define a maximum agreement subtree of M_1 and M_2 to be the one with the largest number of labels among the maximum agreement subtree of M_1^u and M_2^v over all nodes $u \in M_1$ and $v \in M_2$. That is,

$$\text{mast}(M_1, M_2) = \max\{\text{mast}(M_1^u, M_2^v) \mid u \in M_1, v \in M_2\}.$$

As in the unrooted case, to compute $\text{mast}(M_1, M_2)$, we find a separator y of M_1 and compute $\text{mast}(M_1^y, M_2)$. However, we need to delete the nodes of M_1 not in M_1^y. When computing $\text{mast}(M_1^y, M_2)$, we construct some rooted subtrees of M_2. Again, we delete the nodes of M_2 not in these rooted subtrees. Such deletions are straightforward and do not increase the time complexity of computing $\text{mast}(M_1, M_2)$. Thus, $\text{mast}(M_1, M_2)$ can be computed in $O(N^{1.5} \log N)$ time.

Appendix A. Computing $\text{mast}(W_1, W_2)$. Let T_1 and T_2 be rooted evolutionary trees. Let R_1 and R_2 be two label-disjoint rooted subtrees of T_2. Let $W_1 = T_1 \otimes (R_1, R_2)$ and $W_2 = T_2 \ominus (R_1, R_2)$. This section shows that $\text{mast}(W_1, W_2)$

can be computed as if W_1 and W_2 were ordinary rooted evolutionary trees [9, 11, 20] with some special procedures on handling compressed and shrunk leaves. Note that the case where W_1 and W_2 are compressed and shrunk with respect to a subtree can be treated as the special case where R_1 is empty.

LEMMA A.1. *We can compute* $\text{mast}(W_1, W_2)$ *in* $O(n^{1.5} \log N)$ *time, where* $n = \max\{|W_1|, |W_2|\}$ *and* $N = \max\{|T_1|, |T_2|\}$. *Afterwards, we can retrieve* $\text{mast}(W_1^u, W_2)$ *for any node* u *of* W_1 *in* $O(1)$ *time.*

Proof. We adopt the framework of Farach and Thorup's algorithm [11], which is essentially a sparsified dynamic programming based on the following formula. For any internal nodes u of W_1 and v of W_2,

$$\text{mast}(W_1^u, W_2^v) = \max \begin{cases} \max\{\text{mast}(W_1^x, W_2^v) \mid x \text{ is a child of } u\}; \\ \max\{\text{mast}(W_1^u, W_2^y) \mid y \text{ is a child of } v\}; \\ \text{r-mast}(W_1^u, W_2^v), \end{cases} \tag{A.1}$$

where $\text{r-mast}(W_1^u, W_2^v)$ denotes the maximum size of all the agreement subtrees of W_1^u and W_2^v in which u is mapped to v.

Our algorithm differs from Farach and Thorup's algorithm in the way how each individual $\text{mast}(W_1^u, W_2^v)$ is computed. When W_1 and W_2 are ordinary evolutionary trees, each $\text{mast}(W_1^u, W_2^v)$ is found by computing a maximum weight matching of some bipartite graph, and it takes $O(n^{1.5} \log n)$ time to compute $\text{mast}(W_1, W_2)$. Below, we show that when W_1 and W_2 have compressed and shrunk leaves, each $\text{mast}(W_1^u, W_2^v)$ can be found either in constant time or by computing at most two maximum weight bipartite matchings of similar graphs but with edge weights bounded by N instead of n. Thus, we can compute $\text{mast}(W_1, W_2)$ using the same sparsified dynamic programming in [11]; as a by-product, we can afterwards retrieve $\text{mast}(W_1^u, W_2)$ for any node u of W_1 in $O(1)$ time. The enlarged upper bound of edge weights increases the time complexity to $O(n^{1.5} \log N)$, though.

In the rest of this section, we show how each $\text{mast}(W_1^u, W_2^v)$ is computed. First, we consider the case when u is a leaf. The following case analysis shows that $O(1)$ time suffices to compute $\text{mast}(W_1^u, W_2^v)$.

Case 1. u is an atomic leaf. If W_2^v contains a leaf with the same label as that of u, then $\text{mast}(W_1^u, W_2^v) = 1$; otherwise it equals zero.

Case 2. u is an auxiliary leaf. Then, $\text{mast}(W_1^u, W_2^v) = 0$.

Case 3. u is a compressed leaf. By definition, u can only be mapped to γ_1, γ_2, or the least common ancestor y_c of γ_1 and γ_2. If W_2^v has no shrunk leaves, then $\text{mast}(W_1^u, W_2^v) = 0$. If W_2^v has only one shrunk leaf, say γ_1, then $\text{mast}(W_1^u, W_2^v) = \alpha_1(u)$. If W_2^v has two shrunk leaves, then W_2^v must also contain y_c and $\text{mast}(W_1^u, W_2^v) = \max\{\alpha_1(u), \alpha_2(u), \alpha_+(u)\}$.

Next, we consider the case when u is an internal node. Assume that v is an atomic leaf. Then $\text{mast}(W_1^u, W_2^v) = 1$ if W_1^u contains a leaf with the same label as that of v, and zero otherwise. If v is a shrunk leaf, say γ_1, then $\text{mast}(W_1^u, W_2^v) = \alpha_1(u)$. It remains to consider the case when v is an internal node. Due to the nature of dynamic programming, we only need to compute $\text{r-mast}(W_1^u, W_2^v)$, then we can apply (A.1) to compute $\text{mast}(W_1^u, W_2^v)$. We further divide our discussion into the following three cases.

Case 1. u is an auxiliary internal node. In such case, u has only two children; one of them is an auxiliary leaf. By definition, an auxiliary leaf will not be mapped to any node in any agreement subtree of W_1^u and W_2^v; thus, there is no agreement subtree in which u is mapped to v and $\text{r-mast}(W_1^u, W_2^v) = 0$.

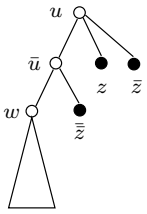

FIG. 6. *Structure of* W_1^u.

Case 2. u is an ordinary internal node. As in [11], we first construct the bipartite graph defined as follows: Let A and B be the set of children of u and v, respectively; define $G[A, B]$ to be the bipartite graph formed by the edges $(x, y) \in A \times B$ with $\text{mast}(W_1^x, W_2^y) > 0$, and (x, y) is given a weight $\text{mast}(W_1^x, W_2^y)$.

If none of u's children is an auxiliary leaf, then $\text{r-mast}(W_1^u, W_2^v) = \text{mwm}(G[A, B])$. Otherwise, let $\bar{z}$ be the child of u which is an auxiliary. In this case, u also has a compressed child z. Other than z and $\bar{z}$, no other child of u is a compressed and auxiliary leaf. On the other hand, consider the rooted subtrees W_2^x rooted at the children x of v. If the shrunk leaves appear together in one of such subtrees, then by definition, $\bar{z}$ cannot be mapped to any shrunk leaf in any agreement subtree of W_1^u and W_2^v, and $\text{r-mast}(W_1^u, W_2^v) = \text{mwm}(G[A, B] - \{\bar{z}\})$. If the shrunk leaves appear in two different subtrees rooted at two children y_1 and y_2 of v, then

$$\text{r-mast}(W_1^u, W_2^v) = \max\Big\{\text{mwm}(G[A, B]-\{\bar{z}\}), \text{mwm}(G[A, B]-\{z, \bar{z}, y_1, y_2\})+\beta(z)\Big\}.$$

Case 3. u is a compressed internal node. By definition of a compressed node, the structure of W_1^u is very restrictive—u has exactly three children z, $\bar{z}$, and an auxiliary internal node $\bar{u}$; $\bar{u}$ has two children, an auxiliary leaf $\bar{\bar{z}}$ and an uncompressed internal node w; see Figure 6. To find $\text{r-mast}(W_1^u, W_2^v)$, we note that there are only six possible ways for how $z, \bar{z}, \bar{\bar{z}}$ are mapped to γ_1 and γ_2. We consider each of these cases and $\text{r-mast}(W_1^u, W_2^v)$ is the maximum of the values found. We discuss only the case where γ_1 and γ_2 are mapped to z and $\bar{\bar{z}}$, respectively. The other cases can be handled similarly. Let P be the path between γ_2 and y_c. Let $S(P)$ denote the set of subtrees hanged on P. The size of the largest agreement subtrees of W_1^u and W_2^v in which γ_1 and γ_2 are mapped to z and $\bar{z}$, respectively, equals

$$\beta_{1\succ 2}(z) + \max\{\text{mast}(W_1^w, \tau) \mid \tau \in S(P)\}. \tag{A.2}$$

Note that using the technique in [11], we can precompute $\max\{\text{mast}(W_1^x, \tau) \mid \tau \in S(P)\}$ for all $x \in W_1$ in $O(n^{1.5} \log N)$ time. Afterwards, (A.2) can be found in constant time. □

Appendix B. Preprocessing for finding $\max\{A_z[i] | z \in W^v\}$.

Let h be the number of nodes in W. Consider the h arrays A_z of dimension b where $z \in W$. Recall that m_z is the number of distinct values in A_z, and $m = \sum_{z \in W}(m_z + 1)$. This section describes an $O(m\alpha(h))$-time preprocessing, which supports finding $\max\{A_z[i] \mid z \in W^v\}$, for any $i \in [1, b]$ and any node v of W, in $O(\log h)$ time.

By definition, each A_z has at least $b - m_z$ entries storing some common value c_z. For every $i \in [1, b]$, let Γ_i be the set of nodes z where $A_z[i]$ stores a value different from c_z. Note that $\sum m_z = \sum_{1 \le i \le b} |\Gamma_i|$. We assume that each node of W is identified

uniquely by an integer in $[1, h]$ assigned by a preorder tree traversal [8]. For any node $v \in W$, let $\beta(v)$ be the number of proper descendents of v in W.

Based on Lemma B.1, $\max\{A_z[i] \mid z \in W^v\} = \max\{A_z[i] \mid z \in [v, v + \beta(v)]\}$ for any $v \in W$, $i \in [1, b]$. Therefore, to solve our problem, it is sufficient to give an $O(m\alpha(h))$-time preprocessing to support finding $\max\{A_z[i] \mid z \in H\}$ for any $i \in [1, b]$ and any interval $H \subseteq [1, h]$ in $O(\log h)$ time.

LEMMA B.1. *For any $v \in W$ and $i \in [1, b]$, $\max\{A_z[i] \mid z \in W^v\} = \max\{A_z[i] \mid z \in [v, v + \beta(v)]\}$.*

Proof. It is straightforward. □

Our preprocessing does not work on each sequence $A_1[i], A_2[i], \ldots, A_h[i]$ directly. Instead, it first draws out useful information about the common values c_z stored in the sequences and applies a contraction technique to shorten each sequence. Then, it executes Fact B.2 on these shortened sequences.

FACT B.2 (see [3]). *Given any sequence $a_1, \ldots, a_h$ of real numbers, we can preprocess these h numbers in $O(h)$ time so that we can find the maximum of any subsequence $a_x, a_{x+1}, \ldots, a_y$ in $O(\alpha(h))$ time.*

Our preprocessing is detailed as follows. Its time complexity is $O(m\alpha(h))$ as shown in Lemma B.3.

1. For each $i \in [1, b]$, find Γ_i and arrange the integers in Γ_i in ascending order.
2. Apply Fact B.2 to the sequence $c_1, \ldots, c_h$.
3. For every nonempty $\Gamma_i = \{x_1 < \cdots < x_d\}$, compute $\beta_\ell = \max\{A_x[i] \mid x \in (x_\ell, x_{\ell+1})\}$ for every $\ell \in [1, d-1]$, and then apply Fact B.2 to the sequence $A_{x_1}[i], \beta_1, A_{x_2}[i], \ldots, \beta_{d-1}, A_{x_d}[i]$.

LEMMA B.3. *The preprocessing requires $O(m\alpha(h))$ time.*

Proof. We can examine all the entries of A_z whose values differ from c_z in $O(m_z)$ time. By examining all such entries of $A_1, \ldots, A_h$, we can construct Γ_i and arrange the integers in Γ_i in ascending order. Thus, step 1 takes $O(m)$ time. Step 2 takes $O(h) = O(m)$ time. For step 3, we first analyze the time required to process one nonempty $\Gamma_i = \{x_1 < \cdots < x_d\}$. Note that $(x_\ell, x_{\ell+1}) \cap \Gamma_i = \phi$ for every $\ell \in [1, d-1]$. Thus, $\beta_\ell = \max\{c_x \mid x \in (x_\ell, x_{\ell+1})\}$ can be computed in $O(\alpha(n))$ time using the result of step 2. Summing over all $\ell \in [1, d-1]$, computing all β_ℓ takes $O(|\Gamma_i|\alpha(h))$ time. Applying Fact B.2 to the sequence $A_{x_1}[i], \beta_1, A_{x_2}[i], \ldots, \beta_{d-1}, A_{x_d}[i]$ takes $O(|\Gamma_i|)$ time. In total, it takes $O(|\Gamma_i|\alpha(h))$ time to process one Γ_i, and step 3 takes $O(\sum |\Gamma_i|\alpha(h)) = O(m\alpha(h))$ time. Thus, the total time of our preprocessing is $O(m\alpha(h))$. □

After the preprocessing, each query can be answered in $O(\log h)$ time as stated in the following lemma.

LEMMA B.4. *After the preprocessing, $\max\{A_z[i] \mid z \in H\}$ can be found in $O(\log n)$ time for any $i \in [1, b]$ and any interval $H \subseteq [1, h]$.*

Proof. Let $H = [p, q]$. A crucial step is to find $[p, q] \cap \Gamma_i$. Without loss of generality, assume $\Gamma_i \neq \phi$. To find $[p, q] \cap \Gamma_i$, we first find the smallest integer x_s in Γ_i that is greater than p, and the largest integer x_t in Γ_i that is smaller than q. Since Γ_i is sorted, we can find x_s and x_t in $O(\log |\Gamma_i|) = O(\log h)$ time. If $x_s > x_t$, then $[p, q] \cap \Gamma_i = \phi$; otherwise, $[p, q] \cap \Gamma_i$ is the set of integers between x_s and x_t in Γ_j.

If $[p, q] \cap \Gamma_i = \phi$, then $\max\{A_x[i] \mid x \in [p, q]\} = \max\{c_x \mid x \in [p, q]\}$. Because of step 1 of our preprocessing, we can find $\max\{c_x \mid x \in [p, q]\}$ in $O(\alpha(h))$ time.

If $[p, q] \cap \Gamma_i = \{x_s < x_{s+1} < \cdots < x_t\}$, then $[p, q] = [p, x_s - 1] \cup \{x_s\} \cup (x_s, x_{s+1}) \cup \cdots \cup \{x_t\} \cup [x_t + 1, q]$ and $\max\{A_z[i] \mid z \in [p, q]\}$ equals the maximum of

1. $\max\{A_x[i] \mid x \in [p, x_s - 1]\}$,

2. $\max\{A_x[i] \mid x \in \{x_s\} \cup (x_s, x_{s+1}) \cup \cdots \cup (x_{t-1}, x_t) \cup \{x_t\}\}$,
3. $\max\{A_x[i] \mid x \in [x_t + 1, q]\}$.

Note that item 2 equals the maximum of $A_{x_s}[i], \beta_s, \ldots, \beta_{t-1}, A_{x_t}[i]$, which can be computed in $O(\alpha(h))$ time after step 3 of our preprocessing. Since $\Gamma_i \cap [p, x_s - 1] = \phi$ and $\Gamma_i \cap [x_t + 1, q] = \phi$, step 2 enables us to compute items 1 and 3 in $O(\alpha(h))$ time. As a result, $\max\{A_z[i] \mid z \in [p, q]\}$ can be answered in $O(\log h)$ time. □

CONSTRUCTIVE, DETERMINISTIC IMPLEMENTATION OF SHARED MEMORY ON MESHES*

ANDREA PIETRACAPRINA†, GEPPINO PUCCI†, AND JOP F. SIBEYN‡

Abstract. This paper describes a scheme to implement a shared address space of size m on an n-node mesh, with m polynomial in n, where each mesh node hosts a processor and a memory module. At the core of the simulation is a hierarchical memory organization scheme (HMOS), which governs the distribution of the shared variables, each replicated into multiple copies, among the memory modules, through a cascade of bipartite graphs. Based on the expansion properties of such graphs, we devise a protocol that accesses any n-tuple of shared variables in worst-case time $O(n^{1/2+\eta})$, for any constant $\eta > 0$, using $O(1/\eta^{1.59})$ copies per variable, or in worst-case time $O(n^{1/2}\log n)$, using $O(\log^{1.59} n)$ copies per variable. In both cases the access time is close to the natural $O(\sqrt{n})$ lower bound imposed by the network diameter. A key feature of the scheme is that it can be made fully constructive when m is not too large, thus providing in this case the first efficient, constructive, deterministic scheme in the literature for bounded-degree processor networks. For larger memory sizes, the scheme relies solely on a nonconstructive graph of weak expansion. Finally, the scheme can be efficiently ported to other architectures, as long as they exhibit certain structural properties. In the paper we discuss the porting to multidimensional meshes and to the pruned butterfly, an area-universal network which is a variant of the fat-tree.

1. Introduction.

A desirable feature of a parallel computer is the provision of a *shared address space* that can be accessed concurrently by all the processors of the machine. Indeed, the manipulation of shared data provides a powerful and uniform mechanism for interprocessor communication and constitutes a valuable tool for the development of simple and portable parallel software. Unfortunately, when the number of processors exceeds a certain (modest) threshold, any efficient hardware realization of shared memory is either prohibitively expensive or out of reach of current technology. Therefore, a shared address space must be provided *virtually* on hardware platforms consisting of a set of processor/memory module pairs which are connected through a network of point-to-point communication links.

This problem has received considerable attention over the past two decades and has been the target of a large number of investigations, both theoretical and applied. In the theoretical community, the problem is best known as the *PRAM simulation* problem. An (n, m)-PRAM is an abstraction of a shared-memory machine consisting of n synchronous RAM processors that have direct access to m shared *variables*. In a PRAM step, executed in unit time, any set of n variables can be read or written in parallel by the processors. A solution to the PRAM simulation problem is a scheme to perform *any* computation of an (n, m)-PRAM on a target machine consisting of a network of n processor/memory pairs. A typical PRAM simulation scheme distributes the PRAM shared variables among the n modules local to the machine processors and recasts a parallel access to the shared memory into the routing of messages from the processors requesting the variables to the processors storing such variables.

Several randomized PRAM simulation schemes have been proposed in the literature. In all these schemes, the shared variables are distributed among the memory modules via one (or more) hash functions randomly drawn from a suitable universal class. Among the most relevant results, we recall that a PRAM step can be simulated, with high probability, in $O(\log\log\log n \log^* n)$ time on the complete network [CMS95], in $O(\log n)$ time on the butterfly [Ran91], and in $O(\sqrt{n})$ time on the mesh [LMRR94].

In contrast, the development of efficient deterministic schemes, that is, schemes that guarantee a fast worst-case simulation time for any PRAM step, appears to be much harder. A simple argument shows that in order to avoid trivial worst-case scenarios, where all the variables requested in the PRAM step are stored in a small region of the network, one has to use several copies for each variable, so that only a subset of "convenient" copies needs to be reached by each operation. The number of copies used for each variable is called the *redundancy* of the scheme.

The idea of replicating each variable into multiple copies dates back to the pioneering work of Mehlhorn and Vishkin [MV84]. In their approach, a read operation need access only one (the most convenient) copy. For $m = O(n^R)$, the authors obtain a scheme for the complete interconnection which uses R copies per variable and allows any set of n reads to be satisfied in time $O(n^{1-1/R})$. However, the execution of n write operations, where all copies of the variables must be accessed, is penalized and requires $O(Rn)$ time in the worst case.

Later, Upfal and Wigderson [UW87] proposed a more balanced protocol requiring that, in order to read or write a variable, only a majority of its copies be accessed. They also represent the allocation of the copies to the modules by means of a *memory organization scheme* (MOS). An MOS is a bipartite graph $G = (V, U)$, where V is the set of shared variables, U is the set of memory modules of the underlying machine, and R edges connect each variable to the modules storing its copies. For m polynomial in n and $R = \Theta(\log n)$, the authors show that there exist suitable expanding graphs that guarantee a worst-case $O(\log n\,(\log\log n)^2)$ time to access any n variables on the complete interconnection. This bound was later improved to $O(\log n)$ in [AHMP87]. Several authors pursued the ideas in [UW87] to develop simulation schemes for *bounded-degree networks* of various topologies. In particular, schemes have been devised to simulate an arbitrary step of an (n, m)-PRAM, with m polynomial in n, in time $O(\log^2 n/\log\log n)$ on a mesh of trees (MoT) with n processors and $\Theta(n^2)$ switching elements [LPP90], or in time $O(\log n \log m/\log\log n)$ on an n-processor expander-based network [HB94], or in time $O(\log n \log\log n \log\log(m/n))$ on a suitably augmented MoT [Her96].

All of the aforementioned deterministic schemes (except for the one in [MV84] which, however, is not general since write accesses are heavily penalized) suffer from two major limitations.

1. The MOS graphs must exhibit maximum expansion relatively to the m/n ratio. Although the existence of such graphs can be proved through standard counting arguments, no efficient constructions are yet available. In addition, it is unlikely that the (few) constructions known for expanders may be of use when m is much larger than n.

2. The expansion properties of the MOS are exclusively used to curb memory contention. Network congestion issues are either ignored, as in the case of simulations on the complete network, or solved by means of separate mechanisms tailored to the specific network's topology.[1]

Recently, constructive deterministic schemes exhibiting nontrivial performance have been developed for the complete interconnection. In [PP97] three schemes are presented for $m = O(n^{3/2})$, $m = O(n^2)$, and $m = O(n^3)$ variables, which attain $O(n^{1/3})$, $O(n^{1/2})$, and $O(n^{2/3})$ access time, respectively, for any n-tuple of variables using constant redundancy. These schemes rely on MOS graphs that admit efficient explicit constructions but exhibit weak expansion. In this paper we will exploit the same constructions in a more complex framework to achieve efficient implementations of shared data on realistic, low-bandwidth machines. Specifically, we will develop a novel approach where the inefficiencies caused by the weak expansion of the memory map are absorbed into the inherent bandwidth limitations of the interconnection, and where both memory contention and network congestion are controlled through a single mechanism.

1.1. Overview of results. This paper presents a deterministic scheme for implementing a shared address space of size m on an n-node square mesh, with m polynomial in n, where each node consists of a processor with direct access to a local memory module. The scheme provides a protocol to access an arbitrary set of n shared variables in nearly optimal time for all values of m. The scheme is fully constructive for $m = O(n^{3/2})$, whereas for larger values of m it embodies only a nonconstructive component graph of constant degree whose expansion properties, however, are much weaker than those required of the graphs used in previous works. Full constructiveness can also be attained for memory sizes up to $m = O(n^{9/2})$, at the expense of a progressive degradation in performance when m gets closer to the upper bound.

The scheme adopts a novel redundant representation of the shared variables and is centered around the *hierarchical memory organization scheme* (HMOS), which provides a structured distribution of the copies of the variables among the memory modules. The HMOS consists of $k+1$ levels of logical modules built upon the set of shared variables. The modules of the first level (level 0) store copies of variables, whereas modules of level $i > 0$ store replicas of modules of level $i - 1$. The HMOS is represented by a cascade of bipartite graphs, where the first graph governs the distribution of the copies of the variables to the modules of level 0, and the other graphs govern the distribution of the replicas of modules at higher levels. Each level of the HMOS corresponds to a tessellation of the mesh into submeshes of appropriate size, with each module of that level assigned to a distinct submesh.

[1] In fact, in [HB94], an MOS with slightly less than maximum expansion is employed in order to reduce the redundancy and, consequently, network congestion, at the expense of an increase in memory contention. However, such an MOS does not embody any specific mechanism to explicitly control network congestion.

TABLE 1.1
Results in this paper.

$m = n^\tau$	Access time	Constructive	Redundancy
$\tau > \frac{3}{2}$	$O(n^{\frac{1}{2}+\eta})$ $\forall$ constant $\eta > 0$	no	$O(1/\eta^{1.59})$
$\tau > \frac{3}{2}$	$O(\sqrt{n}\log n)$	no	$O(\log^{1.59} n)$
$1 \le \tau \le \frac{3}{2}$	$O(n^{\frac{1}{2}+\eta})$ $\forall$ constant $\eta > 0$	yes	$O(1/\eta^{1.59})$
$1 \le \tau \le \frac{3}{2}$	$O(\sqrt{n}\log n)$	yes	$O(\log^{1.59} n)$
$\frac{3}{2} < \tau \le \frac{13}{6}$	$O(n^{\frac{2\tau+1}{8}})$	yes	$\Theta(1)$
$\frac{13}{6} \le \tau \le \frac{5}{2}$	$O(n^{\frac{2}{3}})$	yes	$\Theta(1)$
$\frac{5}{2} \le \tau \le \frac{9}{2}$	$O(n^{\frac{2\tau+3}{12}})$	yes	$\Theta(1)$

We devise an access protocol to satisfy n arbitrary read/write requests issued by the n processors, which takes advantage of the hierarchical structure of the HMOS. As customary in any multicopy approach, an access to a variable is executed on a selected subset of its copies. A suitable copy selection mechanism is developed to limit the number of copies to be accessed in each submesh, and, ultimately, in each individual module. In this sense, the HMOS provides a single mechanism to cope with both memory contention and network congestion, which represents a novelty with respect to previous works, where the two issues were dealt with separately.

In order to guarantee low memory contention and network congestion, the HMOS component graphs must exhibit certain expansion properties. Compared to those employed in previous schemes, our graphs have much weaker expansion, attainable using only constant (rather than logarithmic) input degree. This makes the HMOS more amenable to explicit construction. Indeed, all HMOS graphs but the first one are taken as subgraphs of a well-known combinatorial structure, the BIBD, for which an explicit and simple construction is known. As for the first graph, an explicit construction can be provided when m is not too large, thus making the HMOS fully constructive, while for large values of m, the graph can be shown to exist through a standard counting argument. Our results are reported in detail below and summarized in Table 1.1.

THEOREM 1.1. *For any constant $\tau \ge 1$, there exists a scheme to distribute $m = n^\tau$ shared variables among the local memory modules of an n-node mesh with redundancy R so that any n variables can be read/written in time*

$$T = O(n^{\frac{1}{2}+\eta})$$

for any constant $\eta > 0$, with $R = O(1/\eta^{1.59})$, or in time

$$T = O(n^{\frac{1}{2}}\log n)$$

with $R = O(\log^{1.59} n)$.

As mentioned before, for arbitrary values of m, the HMOS embodies one nonconstructive graph. Full constructiveness can be achieved when $m = O(n^{9/2})$, as reported below.

THEOREM 1.2. *For any constant τ, with $1 \le \tau < 9/2$, there exists a fully constructive scheme to distribute $m = n^\tau$ shared variables among the local memory*

modules of an n-node mesh, which, for $\tau \leq 3/2$*, achieves the same performances as those stated in Theorem* 1.1 *while, for* $\tau > 3/2$*, achieves the following access times:*

$$\begin{aligned} T &= O(n^{\frac{2\tau+1}{8}}) \quad \text{for } \tfrac{3}{2} < \tau \leq \tfrac{13}{6}, \\ T &= O(n^{\frac{2}{3}}) \quad \text{for } \tfrac{13}{6} \leq \tau \leq \tfrac{5}{2}, \\ T &= O(n^{\frac{2\tau+3}{12}}) \quad \text{for } \tfrac{5}{2} \leq \tau \leq 9/2, \end{aligned}$$

with redundancy $R = \Theta(1)$.

Compared to the natural $\Omega(\sqrt{n})$ lower bound imposed by the network diameter, our fastest access time is only a logarithmic factor away from optimal.

Prior to the present work, no efficient deterministic schemes for implementing shared memory explicitly designed for the mesh topology were known in the literature. However, the schemes designed for the complete interconnection can be implemented on the mesh through sorting and routing. In particular, $O(\sqrt{n}\log n)$ access time can be obtained by implementing the nonconstructive scheme in [AHMP87], and $O(n^{1/2+t})$ access time can be obtained by porting the constructive schemes of [PP97] to the mesh, with $t = 1/6$ for $m = O(n^{3/2})$, $t = 1/4$ for $m = O(n^2)$, and $t = 1/3$ for $m = O(n^3)$.

Our results improve upon previously published ones in the following ways. First, we attain $O(\sqrt{n}\log n)$ access time, as in [AHMP87], with a memory organization which is fully constructive when $m = O(n^{3/2})$, while, for all other values of m polynomial in n, it embodies a nonconstructive graph exhibiting much weaker expansion than that required in [AHMP87]. The recent results of [PP97] suggest that our memory map is more amenable to explicit construction. Note also that our constructive results outperform the ones obtainable by the straightforward porting to the mesh of the schemes in [PP97] discussed above.

Finally, it is important to observe that our scheme is not specifically tailored to the mesh topology but can be ported, with minor adjustments, to other topologies. In particular, the same access times reported in Theorems 1.1 and 1.2 can be attained on an n-leaf pruned butterfly, an area-universal network which is a variant of the fat-tree, and Theorem 1.1 can be generalized to hold for d-dimensional meshes, with constant d, by substituting $n^{1/d}$ for $n^{1/2}$ in the formulas.

The rest of this paper is organized as follows. Section 2 defines the machine model and introduces the routing and sorting primitives used by the access protocol. Section 3 describes the HMOS (section 3.1) and its implementation on the mesh (section 3.2). A suitable construction for the BIBDs used in the HMOS is given in an appendix to the paper. Section 4 presents the protocol for accessing an arbitrary n-tuple of shared variables. This section is subdivided into two subsections that describe the selection of the copies and the routing protocol, respectively. In section 5, suitable values for the design parameters of the HMOS are selected, and Theorems 1.1 and 1.2 are proved. Section 6 shows how the scheme can be generalized to other architectures, such as the pruned butterfly and multidimensional meshes. Section 7 closes with some final remarks.

2. Machine model. We present our shared memory implementation on a *mesh*, consisting of an array of $\sqrt{n} \times \sqrt{n}$ processor-memory pairs, connected through a two-dimensional grid of communication links. The machine operates in lock-step, where in each step a processor can perform a constant amount of local computation (including accesses to its local memory) and can exchange a constant number of words with one of its direct neighbors. Our objective is to devise a distributed representation of

$m \geq n$ shared variables on the mesh so that any n-tuple of read/write accesses to these variables can be served efficiently. The approach will be generalized to other architectures in section 6.

The access protocol will make use of the following primitives, for which optimal algorithms are known in the literature. We call *ℓ-sorting* a sorting instance in which at most ℓ keys are initially assigned to each processor and are to be redistributed so that the ℓ smallest keys will be held by the first processor, the next ℓ smallest ones by the second processor, and so on, with the processors numbered in row major order. We have the following fact.

FACT 2.1 (see [Kun93]). *Any ℓ-sorting can be performed on an n-node mesh in $O(\ell\sqrt{n})$ time.*

We call *(ℓ_1, ℓ_2)-routing* a routing problem in which each mesh processor is the source of at most ℓ_1 packets and the destination of at most ℓ_2 packets. We have the following fact.

FACT 2.2 (see [SK94]). *Any (ℓ_1, ℓ_2)-routing can be performed on an n-node mesh in $O(\sqrt{\ell_1 \ell_2 n})$ time.*

A simple bisection-based argument shows that this result is optimal in the general case. However, for a special class of (ℓ_1, ℓ_2)-routings, a better performance can be achieved as follows. Fix a tessellation of the mesh into n/s submeshes of s nodes each, and consider an (ℓ_1, ℓ_2)-routing where at most δs packets are destined for each submesh. We first use ℓ_1-sorting and (ℓ_1, δ)-routing to spread the packets evenly among the nodes of their destination submeshes, and then complete the routing by running n/s independent instances of (δ, ℓ_2)-routing within each submesh. The overall routing time becomes

$$O(\ell_1\sqrt{n} + \sqrt{\ell_1 \delta n} + \sqrt{\delta \ell_2 s}).$$

Comparing the $O(\sqrt{\ell_1 \ell_2 n})$ complexity of the general (ℓ_1, ℓ_2)-routing algorithm with the above routing time, we see that the new algorithm is profitable when $\delta, \ell_1 = o(\ell_2)$ and $\delta s = o(\ell_1 n)$. This fact will be exploited in our access protocol, where packet routing is used to access selected copies of the variables. In particular, we will employ several nested tessellations of the mesh and provide strong bounds on the congestion within the submeshes of each tessellation, so that the above strategy can be applied. The packets will then be routed gradually to their destinations through a sequence of smaller and smaller submeshes.

3. The HMOS. This section introduces the HMOS, a mechanism through which m shared variables are distributed among the n memory modules of a processor network. The section is organized in two subsections: section 3.1 presents the logical structure of HMOS, while section 3.2 describes its actual implementation on the mesh.

3.1. Logical structure of the HMOS. The HMOS is structured as $k+1$ levels of logical modules built upon the shared variables, where $k = O(\log \log n)$ is a nonnegative integer function of n to be specified by the analysis. More specifically, starting from $m = n^\tau$ shared variables, for a fixed constant $\tau > 1$, the HMOS comprises m_i modules at level i, called *i-modules* for $0 \leq i \leq k$, where the m_i's are strictly decreasing values that will be specified later. Modules are nested collections of variables, obtained as follows. First, each variable is replicated into $r = \Theta(1)$ copies, which are assigned to distinct 0-modules. The contents of each 0-module, viewed as an indivisible unit, are in turn replicated into 3 copies, which are assigned to distinct 1-modules. In general, the contents of each $(i-1)$-module, viewed as an indivisible unit, are replicated into 3 copies, which are assigned to distinct i-modules, for

$0 < i \leq k$. It is easy to see that the above process will eventually create 3^{k-i} replicas of each i-module and $r3^k$ copies per variable. In the rest of this paper, we will reserve the term *copy* to denote the replica of a variable, and *i-block* to denote the replica of an i-module.

The difference between an i-module and one of its i-blocks is akin to the difference between a variable and one of its copies. Namely, an i-module represents an abstract entity, of which several physical replicas, its i-blocks, exist. Since the contents of k-modules are not replicated, the terms k-module and k-block will be used interchangeably. Note that a k-block is made of $(k-1)$-blocks, which in turn are made of $(k-2)$-blocks, and so on until 0-blocks are reached. The latter contain copies of variables.

Let V denote the set of shared variables, and U_i the set of i-modules for $0 \leq i \leq k$. The HMOS is represented as a leveled *direct acyclic graph* (dag) $\mathcal{H}$, which is defined by a cascade of $k+1$ bipartite graphs, namely (V, U_0) and (U_{i-1}, U_i), $0 < i \leq k$, whose edges are directed left to right. In (V, U_0), each variable $v \in V$ is adjacent to r 0-modules, denoted by $\gamma_0(v, j)$, $1 \leq j \leq r$. For $0 < i \leq k$ in (U_{i-1}, U_i), each $(i-1)$-module u is adjacent to three i-modules denoted by $\gamma_i(u, j)$, $1 \leq j \leq 3$. For notational convenience, we will number the levels in the HMOS starting from -1, the level of the variables. As a consequence, nodes at level i, $0 \leq i \leq k$, are i-modules.

In the HMOS, each variable v uniquely identifies a single-source subdag $\mathcal{H}_v$ induced by all nodes reachable from $v \in V$. A straightforward property of $\mathcal{H}_v$ is that it contains $r3^k$ distinct source-sink paths which are in one-to-one correspondence with the $r3^k$ copies of v. Each source-sink path in $\mathcal{H}_v$ (hence, each copy of v) is uniquely identified by the string of nodes traversed by the path. Moreover, for $0 \leq i \leq k$, the suffix of any such string starting with a node u at level i of $\mathcal{H}_v$, identifies a specific i-block storing a copy of v. Note that several source-sink paths in $\mathcal{H}_v$ may correspond to strings with a common suffix starting from level i. In this case, the i-block corresponding to the common suffix will store several distinct copies of v. A small HMOS for 8 shared variables is shown in Figure 3.1.

The component bipartite graphs of the HMOS must be carefully chosen in order to guarantee a good distribution of the copies of the variables, once the HMOS is mapped onto the processors' memory modules. More specifically, we require that the graphs exhibit good *expansion*, according to the following definition.

DEFINITION 3.1. *Let $G = (X, Y)$ be a bipartite graph, where each input node in X has degree d. For $0 < \alpha \leq 1$, $0 < \epsilon < 1$, and $1 \leq \mu \leq d$, G is said to have* (α, ϵ, μ)-expansion *if for any subset $S \subseteq X$, $|S| \leq \alpha|X|$, and for any set E of $\mu|S|$ edges, μ outgoing edges for each node in S, the set $\Gamma^E(S) \subseteq Y$ reached by the chosen edges has size*

$$|\Gamma^E(S)| = \Omega(|S|^{1-\epsilon}).$$

We let $|U_0| = n^\rho$, where $0 < \rho < 3/2$ is a parameter to be fixed by the analysis. We require that (V, U_0) has input degree r, for a fixed odd constant $r > 0$, output degree $|V|r/|U_0|$, and exhibits (α, ϵ, μ)-expansion, where $\alpha = n/m$, ϵ is a positive constant less than 1, and $\mu = (r+1)/2$. Clearly, a necessary condition for the existence of such a graph is $(\alpha|V|)^{1-\epsilon} = n^{1-\epsilon} \leq n^\rho$, which implies $\rho + \epsilon - 1 \geq 0$. The analysis will determine suitable values for r, ϵ, and ρ that guarantee the existence of (V, U_0). Moreover, an explicit construction for such graph will be available when $m = O(n^{9/2})$.

The graphs (U_{i-1}, U_i) for $0 < i \leq k$ are derived from instances of varying size of the same combinatorial structure, the *balanced incomplete block design* (BIBD), defined below.

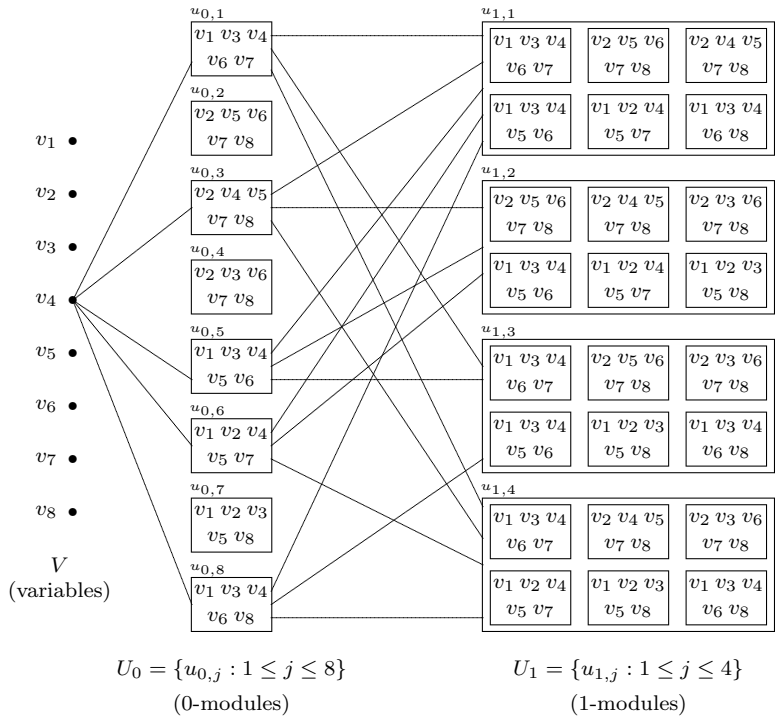

FIG. 3.1. *An HMOS $\mathcal{H}$ built upon 8 shared variables, with $r = 5$ and $k = 1$. There are 8 0-modules and 4 1-modules/1-blocks. Each 1-block contains 6 0-blocks (physical copies of 0-modules), each of which in turn contains 5 copies of the variables. The edges shown in the figure are those of the subdag $\mathcal{H}_{v_4}$. Note that there are 15 edge-disjoint, source-sink paths in $\mathcal{H}_{v_4}$, each path corresponding to one of the 15 copies of v_4.*

DEFINITION 3.2 (see [Hal86]). *A* BIBD *with parameters w and q, or (w, q)-*BIBD*, is a bipartite graph (X, Y) such that*

- *$|Y| = w$;*
- *the degree of each node in X is q;*
- *for any two nodes $y_1, y_2 \in Y$ there is exactly one node $x \in X$ adjacent to both.*

From the definition, it immediately follows that $|X| = w(w-1)/(q(q-1))$ and that the degree of each node in Y is $(w-1)/(q-1)$. One important property of the BIBD, which we will heavily exploit, is stated in the following lemma.

LEMMA 3.3. *Let $G = (X, Y)$ be a (w, q)-BIBD. Consider a node $y \in Y$ and a subset $S \subseteq X$ such that any node in S is adjacent to y. Let E be a set of $\mu|S|$ edges, with $\mu \le q$, containing μ outgoing edges from each x in S, and let $\Gamma^E(S)$ denote the set of nodes of U reached by the chosen edges. Then*

$$|\Gamma^E(S)| \ge (\mu - 1)|S| + 1.$$

Proof. The definition of BIBD implies that no two nodes in S share a neighbor other than y. If $y \notin \Gamma^E(S)$, then $|\Gamma^E(S)| = \mu|S|$. Otherwise, at most $|S|$ of the selected edges reach y; the other $(\mu - 1)|S|$ reach distinct nodes. ∎

COROLLARY 3.4. *A (w, q)-BIBD has $(1, 1/2, \mu)$-expansion for every $2 \le \mu \le q$.*

Proof. Let $G = (X, Y)$ be a (w, q)-BIBD, and let S be an arbitrary subset of input nodes. We now show that $|\Gamma^E(S)| > \sqrt{(\mu - 1)\mu|S|}$ for an arbitrary set E containing

μ outgoing edges from each node in S. Assume that $|\Gamma^E(S)| \leq \sqrt{(\mu-1)\mu|S|}$. Then, there must be an output node in $\Gamma^E(S)$ that is adjacent to at least $\sqrt{|S|\mu/(\mu-1)}$ nodes in S. According to Lemma 3.3, this implies that $|\Gamma^E(S)| \geq (\mu-1)\sqrt{|S|\mu/(\mu-1)}+1 > \sqrt{(\mu-1)\mu|S|}$, which contradicts our assumption. □

For convenience, we assume that both n and $3^k n^\rho$ are even powers of three. Consider the sequence of integers $d_0, d_1, \ldots, d_k$ defined as

$$\begin{cases} d_0 &= \log_3 n^\rho, \\ d_i &= 2\left\lceil \frac{1}{2}\left(\frac{d_{i-1}}{2}+1+k-i\right)\right\rceil - k + i \quad \text{for } 1 \leq i \leq k. \end{cases}$$

For $0 \leq i \leq k$, set the number of i-modules to be $m_i = 3^{d_i}$. The following two properties are easily established.

(i) $d_i + k - i$ is even, for $0 \leq i \leq k$.

(ii) $3\sqrt{m_{i-1}} \leq m_i \leq 16\sqrt{m_{i-1}}$, which implies that $m_{i-1} \leq m_i(m_i-1)/6$ for $1 \leq i \leq k$, and $m_i = \Theta(n^{\rho/2^i})$ for $0 \leq i \leq k$.

We choose (U_{i-1}, U_i) as a subgraph of a $(m_i, 3)$-BIBD, where $m_i(m_i-1)/6 - m_{i-1}$ inputs are removed along with their incident edges. The inputs to be removed are chosen in such a way that the remaining edges are evenly distributed among the outputs, so that each node of U_i becomes adjacent to

$$n_i = \frac{3m_{i-1}}{m_i}$$

nodes of U_{i-1}. An efficient construction of such subgraphs is described in the appendix.

3.2. Mapping the HMOS onto the mesh. The HMOS is physically mapped onto the mesh by storing each i-block in a distinct submesh of appropriate size. For some values of the parameter ρ, the number of 0-blocks exceeds the mesh nodes, hence a single mesh node must store more than one 0-block. There are $3^{k-i}m_i = \Theta(3^{k-i}n^{\rho/2^i})$ i-blocks, $0 \leq i \leq k$, and each i-block contains exactly n_i $(i-1)$-blocks, $1 \leq i \leq k$. We define k nested tessellations of the mesh into submeshes as follows. The outermost tessellation is a subdivision of the mesh into m_k submeshes (*k-submeshes*), each storing a distinct k-block. Each k-submesh is in turn tessellated into n_k $(k-1)$-*submeshes* storing the component $(k-1)$-blocks of the k-block assigned to the k-submesh. In general, for $2 \leq i \leq k$, each *i-submesh*, storing a given i-block, is tessellated into n_i $(i-1)$-*submeshes* storing its component $(i-1)$-blocks. Thus, for $1 \leq i \leq k$, we have a total of

$$m_k n_k n_{k-1} \cdots n_{i+1} = 3^{k-i}m_i = \Theta(3^{k-i}n^{\rho/2^i})$$

i-submeshes, each of size

$$t_i = \frac{n}{3^{k-i}m_i} = \frac{n}{3^{d_i+k-i}} = \Theta(3^{i-k}n^{1-\rho/2^i}).$$

Note that the assumption $k = O(\log\log n)$ ensures $t_i \geq 1$ for $i \geq 1$ and n sufficiently large. Moreover, since both $\log_3 n$ and $d_i + k - i$ are even, we have that t_i is an even power of three, hence $\sqrt{t_i}$ is integral and $\sqrt{t_{i-1}}$ divides $\sqrt{t_i}$. As a consequence, the $(i-1)$-submeshes storing the n_i component $(i-1)$-blocks of an i-block are all contained within the i-submesh storing the i-block. Finally, the organization of the

$3^k n^\rho$ 0-blocks depends on the parameter ρ. When $3^k n^\rho < n$, we assign each 0-block to a submesh of $t_0 = n^{1-\rho}/3^k$ nodes and evenly partition the contents of the block among these nodes. Otherwise, when $3^k n^\rho > n$ there are more 0-blocks than processors, so we assign $3^k n^{\rho-1}$ 0-blocks to each processor. In either case, each processor stores $r3^k m/n$ copies of variables.

4. The access protocol. Suppose that m shared variables are distributed among the n mesh nodes according to the HMOS. In this section, we present the protocol that realizes a parallel access to any n-tuple of variables, where each processor issues a read/write request for a distinct variable. (The case of concurrent accesses can be reduced to the case of exclusive accesses in time $O(\sqrt{n})$ by means of standard sorting-based techniques for leader election and data distribution [Lei92].)

Let S denote the set of variables to be accessed. The access protocol consists of a *copy selection phase* followed by a *routing phase*. In the first phase, a suitable set of copies for the variables in S is chosen, so that accessing these copies will enforce data consistency and generate low memory contention and network congestion. In the subsequent phase, the selected copies are effectively accessed through an appropriate routing strategy. In case of read operations, the accessed data are returned to the requesting processors along the reverse routing paths.

4.1. Copy selection phase. Copy selection achieves the double objective of controlling both memory contention and network congestion by means of a single mechanism. The hierarchical structure of the HMOS provides a geographical distribution of the copies into nested regions of the network. By carefully limiting the number of copies that have to be accessed in any block at any level, we reduce the number of packets that will ever be routed to any such region, which allows us to adopt the efficient routing strategy illustrated in section 2.

4.1.1. A new consistency rule. Recall from section 3.1 that the $r3^k$ copies of a variable v are associated with the source-sink paths of $\mathcal{H}_v$, the subdag of $\mathcal{H}$ induced by v and by all of its descendants. Suppose that we want to read/write v. In order to guarantee consistency, the copies of v to be accessed are selected according to a new rule, which extends the majority protocol of [UW87] to fit the structure of the HMOS. Specifically, we require that the selected copies form a *target set*, which is defined as follows. Let C_v be a set of copies of v, and let $\mathcal{N}(C_v)$ be the set of nodes of $\mathcal{H}_v$ belonging to the source-sink paths associated with these copies. Recall that r is odd, and let $\mu = (r+1)/2$.

DEFINITION 4.1. *C_v is a* target set *for v if $|C_v| = \mu 2^k$ and the following condition holds: a majority (μ) of the nodes at level 0 of $\mathcal{H}_v$ belong to $\mathcal{N}(C_v)$, and, for each node at level i belonging to $\mathcal{N}(C_v)$, a majority (two) of its successors at level $i+1$ belong to $\mathcal{N}(C_v)$ for $0 \le i < k$.*

Figure 4.1 depicts the source-sink paths corresponding to a target set C_{v_4} for variable v_4 in the HMOS of Figure 3.1.

An easy inductive argument shows that any two target sets for the same variable have nonempty intersection. Based on such a property we can guarantee consistency, that is, ensure that a read always returns the most updated value, as follows. As customary in any multicopy approach, we equip each copy with a time-stamp, which is set to the current step whenever the copy is written. A read or write operation on a variable v is simulated by accessing a target set of its copies. By the intersection property of target sets, the copies accessed for reading a variable v must include at least one of the most recently written copies for v, which can be identified by looking

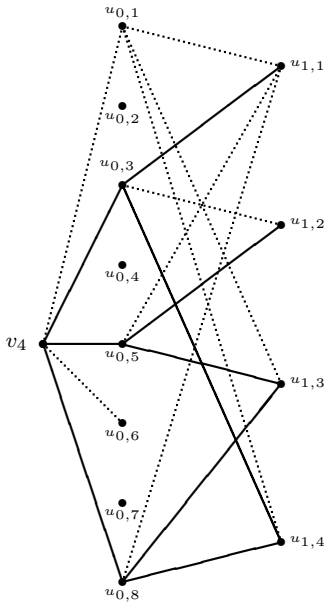

FIG. 4.1. *The source-sink paths (solid lines) in $\mathcal{H}_{v_4}$ corresponding to a target set C_{v_4} of* 6 *copies for variable v_4 in the HMOS $\mathcal{H}$ of Figure* 3.1.

for the most recent time-stamp. It should be noted that a target set contains only $\mu 2^k$ copies out of the $r3^k$ total copies of a variable. Therefore, unlike previous protocols, we maintain consistency by accessing much less than a majority of the copies.

4.1.2. The selection procedure. The copy selection phase determines a target set C_v for each $v \in S$. This is accomplished in $k+1$ iterations, numbered from 0 to k, during which the nodes of the $\mathcal{H}_v$'s are marked in a top-down fashion from the sources to the sinks. More specifically, for every $\mathcal{H}_v$, with $v \in S$, Iteration 0 marks the source v and μ of its successors (0-modules); Iteration i, $0 < i \leq k$, marks two successors (i-modules) of each marked node at level $i-1$. In this fashion, at the end of Iteration i, $0 \leq i \leq k$, the marked nodes in each $\mathcal{H}_v$ form exactly $\mu 2^i$ distinct paths from the source to nodes at level i (in what follows we refer to such paths as *marked paths*). We choose C_v as the set of copies of v corresponding to the $\mu 2^k$ source-sink marked paths in $\mathcal{H}_v$ at the end of the last iteration.

It is important to notice that a node of $\mathcal{H}$, say an i-module u, may belong to several subdags $\mathcal{H}_v$ corresponding to variables in S. During the copy selection procedure, we keep track of u independently in each such subdag; hence, u may result marked in some of the subdags and unmarked in the others. Suppose that, at the end of Iteration i, u is marked in some subdags and that a total of h marked paths in these subdags reach u. This implies that at the end of copy selection there will be $h2^{k-i}$ marked paths that pass through u, that is, $h2^{k-i}$ copies in $\bigcup_{v \in S} C_v$ stored in i-blocks of u. In Iteration $i+1$, the two successors of u to be marked are chosen to be the same for all subdags in which u is marked; hence, for each chosen successor node, u will contribute h paths to the total number of marked paths that will pass through that node at the end of the iteration. The main idea behind the copy selection phase is to control congestion in $(i+1)$-blocks by choosing the nodes to be marked in Iteration $i+1$ in such a way as to keep the number of marked paths passing through each such

node under some reasonable bound.

The following notations will be needed to describe the copy selection procedure.

DEFINITION 4.2. *For $0 \leq i \leq k$, $A_i \subseteq U_i$ denotes the set of i-modules that are marked in some $\mathcal{H}_v$, with $v \in S$, during Iteration i. The modules in A_i are called* active modules.

DEFINITION 4.3. *The* weight $w(u)$ *of an active module $u \in A_i$ is the sum, over all variables $v \in S$, of the number of marked paths from v to u in $\mathcal{H}_v$.*

From the previous discussion we conclude that exactly $w(u)$ copies in $\bigcup_{v \in S} C_v$ will reside in *each* of the selected 2^{k-i} i-blocks of u, while the other i-blocks of u will not contain any copy in $\bigcup_{v \in S} C_v$. Using the expansion properties of the HMOS, we will be able to guarantee suitably low values for the $w(u)$'s.

The actions performed by the copy selection procedure are reported below. Since Iteration 0 is different from the others, it is described separately. In order to understand the parameters used in Iteration 0, recall that we chose (V, U_0) to have $(n/m, \epsilon, \mu)$-expansion, where $0 < \epsilon < 1$ and $\mu = (r+1)/2$. In other words, the graph guarantees that for any set S of at most $|S| \leq n$ variables and any choice of μ 0-modules adjacent to each variable, the overall number of chosen 0-modules is at least $\beta |S|^{1-\epsilon}$ for some constant $\beta > 0$. Finally, recall that each processor is in charge of a distinct variable.

Iteration 0.

1. For $v \in S$, let p_v denote the processor in charge of v. Each p_v creates r *copy-packets* denoted by the tuples $[p_v, v, u_j = \gamma_0(v, j), h_{v,u_j} = 1]$ for $1 \leq j \leq r$. Upon creation, all copy-packets are regarded as *unmarked*.

2. Let $\mathcal{CP}_0$ denote an initially empty set. The following three substeps are executed until μ copy-packets for each variable are put in $\mathcal{CP}_0$.

(i) *Sorting*: Sort all unmarked copy-packets by their third component.

(ii) *Selection*: For each $u \in U_0$, let c_u be the number of copy-packets with third component u in the sorted sequence. If $c_u \leq (2r/\beta)n^{\epsilon}$, then all such packets are marked. Otherwise, none of them is marked. Subsequently, all the packets are sent back to their originating processors.

(iii) *Counting*: For each $v \in S$, p_v counts the total number of its copy-packets marked so far. If these are at least μ, then exactly μ of them are put in $\mathcal{CP}_0$ while the remaining $r - \mu$ copy-packets are discarded. Otherwise, the marked copy-packets are locally buffered.

3. For each $v \in S$, p_v marks the source of $\mathcal{H}_v$ and μ of its successors corresponding to the copy-packets for v included in $\mathcal{CP}_0$.

The analysis will show that the set $\mathcal{CP}_0$ is determined in at most $\log n + 1$ iterations of step 2.

Iteration i $(1 \leq i \leq k)$. At the beginning of Iteration i, the mesh processors store a set $\mathcal{CP}_{i-1}$ of copy-packets. Specifically, each processor p_v stores copy-packets of type $[p_v, v, u, h_{v,u}]$, where $u \in A_{i-1}$ and $\sum_u h_{v,u} = \mu 2^{i-1}$. The value $h_{v,u}$ reflects the *multiplicity* of u with respect to v, that is, the number of distinct marked paths in $\mathcal{H}_v$ from v to u. Iteration i consists of the following steps.

1. The copy-packets in $\mathcal{CP}_{i-1}$ are sorted by their third component.

2. For each group of packets with the same third component $u \in A_{i-1}$, a *leader* processor p_u is elected. Each p_u computes $w(u)$ as the sum of the multiplicities carried by the packets in its group, and creates the three *module-packets* $[p_u, u, \gamma(u, j), w(u)]$ for $1 \leq j \leq 3$.

3. The $3|A_{i-1}|$ module-packets are sorted lexicographically by their third and

fourth components.

4. For each $x \in U_i$, a maximal subset $\mathcal{P}_x$ of module-packets with third component x is chosen, such that

$$\sum_{[p_u,u,x,w(u)]\in\mathcal{P}_x} w(u) \le c\mu 2^{i-1}\left(n^{1-\frac{1-\epsilon}{2^i}} + n^{1-\frac{1-\epsilon}{2^{i-1}}}\right).$$

5. The chosen packets are sent back to their originating leader processors.

6. Assume that a leader processor p_u receives $h \le 3$ module-packets back. If $h < 2$, then p_u selects $2-h$ extra module-packets from the $3-h$ that were not chosen in the previous step. Otherwise, p_u selects two module-packets among those received.

7. Let $[p_u, u, \gamma(u, j_1), w(u)]$ and $[p_u, u, \gamma(u, j_2), w(u)]$ be the two module-packets selected by p_u. Processor p_u sends the names $\gamma(u, j_1)$ and $\gamma(u, j_2)$ to the processors storing the copy-packets in its group.

8. Each copy-packet $[p_v, v, u, h_{v,u}] \in \mathcal{CP}_{i-1}$ is augmented with two extra components containing $\gamma(u, j_1)$ and $\gamma(u, j_2)$.

9. The augmented copy-packets are routed back to the processors in charge of their respective variables.

10. For any augmented copy-packet $[p_v, v, u, h_{v,u}, \gamma(u, j_1), \gamma(u, j_2)]$ received at processor p_v, the nodes $\gamma(u, j_1)$ and $\gamma(u, j_2)$ at level i of $\mathcal{H}_v$ are marked (note that the same node may be redundantly marked more than once). Moreover for each newly marked node u' at level i, a copy-packet $[p_v, v, u', h_{v,u'}]$ is created, where $h_{v,u'}$ is obtained by summing up the multiplicities of the received (augmented) copy-packets carrying u' in one of the two extra components. These new copy-packets form the set $\mathcal{CP}_i$, while all other packets are discarded.

When Iteration k terminates, for each $v \in S$, p_v determines the set C_v of copies to be accessed as those corresponding to the $\mu 2^k$ source-sink marked paths in $\mathcal{H}_v$. It is easily seen that for each $v \in S$, the set C_v computed by the copy selection procedure is indeed a target set for v.

4.1.3. Analysis of the selection procedure. We now determine the running time of the selection procedure described above. Let us first consider Iteration 0. By Fact 2.1 and since $r = O(1)$, steps 1 and 3 require altogether $O(\sqrt{n})$ time. The sorting, selection and counting substeps of step 2 can be implemented in terms of sorting and prefix operations in $O(\sqrt{n})$ time. It will be shown in Lemma 4.4 that $\log n + 1$ executions of such substeps are sufficient. Therefore, Iteration 0 requires $O(\sqrt{n}\log n)$ time altogether. For $i \ge 1$, Iteration i can be implemented in terms of a constant number of sorting and prefix operations on a set of $O(\mu 2^{i-1}n)$ packets, yielding a running time of $O(\sqrt{n}2^{i-1})$. Therefore, copy selection is completed in time

$$O\left(\sqrt{n}\log n + \sqrt{n}\sum_{i=1}^{k} 2^{i-1}\right) = O\left(\sqrt{n}\left(\log n + 2^k\right)\right). \tag{4.1}$$

LEMMA 4.4. *After* $\log n + 1$ *executions of step* 2 *in Iteration* 0, *the set* $\mathcal{CP}_0$ *contains exactly* μn *copy-packets. Moreover, for each active* 0*-module* $u \in A_0$, $w(u) \le (2r/\beta)n^{\epsilon}$.

Proof. Let S_j be the number of variables for which fewer than μ copy packets have been selected by the end of the jth execution of step 2. For the sake of convenience, set $S_0 = |S| = n$. We now show by induction that

$$S_j \le \frac{n}{2^j}$$

for any $j \geq 0$, and this will imply that for $T = \log n + 1$, $S_T = 0$. The inequality for S_0 is immediate, establishing the basis. Assume that the inequality holds for $j-1$, and suppose, for a contradiction, that $S_j > n/2^j$. By using the expansion properties of (V, U_0), it is easy to see that in the jth execution of the selection substep, at least $\beta S_j^{1-\epsilon}$ 0-modules are addressed by unmarked copy-packets. All such 0-modules must have been congested in the previous iteration (i.e., addressed by more than $(2r/\beta)n^\epsilon$ copy-packets), which accounts for a total of at least

$$\frac{2r}{\beta} n^\epsilon \beta S_j^{1-\epsilon} > r S_{j-1}$$

unmarked copy-packets involved in that iteration. However, this is impossible since S_{j-1} variables account for at most rS_{j-1} copy packets.

The bound on $w(u)$ is easily established by observing that for each 0-module u, all copy-packets with third component u that are added to $\mathcal{CP}_0$ are marked during the same iteration of step 2. Therefore

$$w(u) \leq \frac{2r}{\beta} n^\epsilon. \qquad \square$$

It must be remarked that the copy selection phase can be improved in a number of ways to obtain a faster running time at the expense of a more complex implementation. However, to avoid further complications to the presentation, we chose to describe a simpler yet slightly less efficient implementation, since, as shown in section 5, its complexity does not influence the overall running time of the access protocol.

To complete the analysis, it remains to establish the bound on the weight $w(u)$ of any $u \in A_i$, at the end of Iteration i. Recall that the sum of the multiplicities of the copy-packets in $\mathcal{CP}_i$ with third component u yields $w(u)$. Therefore, for $0 \leq i \leq k$,

$$\sum_{u \in A_i} w(u) = \mu 2^i n. \tag{4.2}$$

LEMMA 4.5. *There is a suitable constant $c \geq 3$ such that, at the end of Iteration i, for each $u \in A_i$, $0 \leq i \leq k$,*

$$w(u) \leq c\mu 2^i n^{1-\frac{1-\epsilon}{2^i}}.$$

Proof. The proof proceeds by induction on i. The basis ($i = 0$) is established by Lemma 4.4. Suppose that the inequality holds for $i-1$, and let x be an i-module. The weight of x is determined by steps 4 and 6 of Iteration i. More precisely, recall that $\mathcal{P}_x$ is the set of module-packets of kind $[p_u, u, x, w(u)]$ selected in step 4, and let $\mathcal{P}'_x$ be the set of additional module-packets (still with third component x) not in $\mathcal{P}_x$, selected in step 6. It is easy to see that

$$w(x) \leq \sum_{[p_u, u, x, w(u)] \in \mathcal{P}_x \cup \mathcal{P}'_x} w(u).$$

Because of the way the module-packets are selected in step 4, we already know that

$$\sum_{[p_u, u, x, w(u)] \in \mathcal{P}_x} w(u) \leq c\mu 2^{i-1} \left(n^{1-\frac{1-\epsilon}{2^i}} + n^{1-\frac{1-\epsilon}{2^{i-1}}} \right).$$

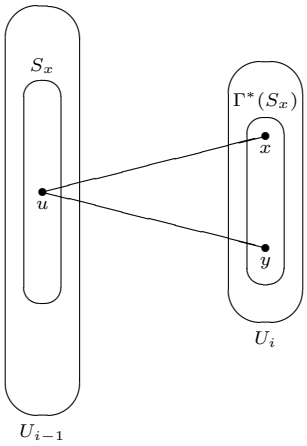

FIG. 4.2. *Critical modules in the proof of Lemma* 4.5.

We must only show that the contribution of $\mathcal{P}'_x$ to $w(x)$ is not too large. In order to derive a contradiction, we suppose that $w(x) > c\mu 2^i n^{1-\frac{1-\epsilon}{2^i}}$. This implies

$$\sum_{[p_u,u,x,w(u)]\in\mathcal{P}'_x} w(u) > c\mu 2^{i-1}\left(n^{1-\frac{1-\epsilon}{2^i}} - n^{1-\frac{1-\epsilon}{2^{i-1}}}\right).$$

Define $S_x = \{u \in A_{i-1} \,:\, [p_u, u, x, w(u)] \in \mathcal{P}'_x\}$, so that

$$\sum_{[p_u,u,x,w(u)]\in\mathcal{P}'_x} w(u) = \sum_{u\in S_x} w(u).$$

By the inductive hypothesis, the weight of each $u \in S_x$ is at most $c\mu 2^{i-1} n^{1-\frac{1-\epsilon}{2^{i-1}}}$; therefore

$$|S_x| \geq \frac{\sum_{u\in S_x} w(u)}{c\mu 2^{i-1} n^{1-\frac{1-\epsilon}{2^{i-1}}}} > n^{\frac{1-\epsilon}{2^i}} - 1.$$

Note that for each $u \in S_x$, at least two module-packets, including $[p_u, u, x, w(u)]$, have not been selected in step 4. Let

$$\Gamma^*(S_x) = \{y \in U_i \,:\, \exists\, u \in S_x \text{ s.t. } [p_u, u, y, w(u)] \text{ has not been selected in step 4}\}.$$

Note that in the graph (U_{i-1}, U_i) each $u \in S_x$ is adjacent to either two or three nodes in $\Gamma^*(S_x)$, one of which is x (see Figure 4.2).

Since (U_{i-1}, U_i) is a BIBD, we can apply Lemma 3.3 and conclude that $|\Gamma^*(S_x)| \geq |S_x|+1 > n^{\frac{1-\epsilon}{2^i}}$. We now show that the global weight assigned in step 4 to all the nodes in $\Gamma^*(S_x)$ exceeds the total weight carried by all the module-packets, thereby leading to a contradiction. Let $y \in \Gamma^*(S_x)$, and let $[p_{u'}, u', y, w(u')]$ be a module-packet which has not been selected in step 4, with $u' \in S_x$. Then, we must have

$$w(u') + \sum_{[p_u,u,y,w(u)]\in\mathcal{P}_y} w(u) > c\mu 2^{i-1}\left(n^{1-\frac{1-\epsilon}{2^i}} + n^{1-\frac{1-\epsilon}{2^{i-1}}}\right);$$

that is,

$$\sum_{[p_u,u,y,w(u)]\in\mathcal{P}_y} w(u) > c\mu 2^{i-1}\left(n^{1-\frac{1-\epsilon}{2^i}}+n^{1-\frac{1-\epsilon}{2^{i-1}}}\right)-c\mu 2^{i-1}n^{1-\frac{1-\epsilon}{2^{i-1}}}=c\mu 2^{i-1}n^{1-\frac{1-\epsilon}{2^i}}.$$

Adding up the contributions of all nodes in $\Gamma^*(S_x)$, we get

$$\begin{aligned}\sum_{y\in\Gamma^*(S_x)}\sum_{[p_u,u,y,w(u)]\in\mathcal{P}_y} w(u) &> |\Gamma^*(S_x)|c\mu 2^{i-1}\left(n^{1-\frac{1-\epsilon}{2^i}}\right)\\ &> n^{\frac{1-\epsilon}{2^i}}c\mu 2^{i-1}\left(n^{1-\frac{1-\epsilon}{2^i}}\right)=c\mu 2^{i-1}n.\end{aligned}$$

Since $c\geq 3$, the above inequality leads to a contradiction because

$$\sum_{y\in\Gamma^*(S_x)}\sum_{[p_u,u,y,w(u)]\in\mathcal{P}_y} w(u)\leq\sum_{y\in U_i}\sum_{[p_u,u,y,w(u)]\in\mathcal{P}_y} w(u)\leq 3\sum_{u\in A_{i-1}} w(u)=3\mu 2^{i-1}n,$$

where the last equality follows from (4.2). □

4.2. Routing phase. After copy selection is completed, the copies in $\bigcup_{v\in S}C_v$ have to be accessed. Each request is encapsulated in a distinct packet, routed from the requesting processor (*origin*) to the processor storing the copy (*destination*), and back to the origin. The idea is to route the packets in stages so that they are moved gradually closer to their destinations through smaller and smaller submeshes, in accordance with the tessellations defined on the mesh. As argued in section 2, when the number of packets destined for any submesh is not too large, such a strategy yields more profitable results than sending the packets directly to their destinations.

The origin-destination part of a packet's journey consists of $k+2$ routing stages, numbered from $k+1$ down to 0. Stage i, with $k+1\geq i\geq 1$, is executed in parallel and independently in every i-submesh (here, the whole mesh is viewed as a $(k+1)$-submesh). In this stage the packets are routed to arbitrary positions in the $(i-1)$-submeshes hosting their destination $(i-1)$-blocks, in such a way that the processors of each submesh receive approximately the same number of packets. This can be achieved by first sorting the packets according to their destination submeshes and then ranking the packets destined to the same submesh. Observe that when $3^k n^\rho < n$, a 0-block is assigned to a 0-submesh of $t_0 = n^{1-\rho}/3^k$ nodes. By the end of stage 1, each packet reaches a processor within its destination 0-submesh, and in stage 0 is sent to its final destination. Instead, when $3^k n^\rho \geq n$, there are $n^{\rho-1}3^k$ 0-blocks stored within a single processor, hence each packet is at its final destination by the end of stage 1, and stage 0 is not needed. In either case, once the packet reaches its final destination, the request it carries is satisfied.

In order to estimate the time complexity of the above protocol, we need to determine the maximum number of packets sent and received by any processor in each stage. More formally, let δ_i, for $k+1\geq i\geq 0$, denote the maximum number of packets held by any processor at the beginning of stage i. Let also δ_{-1} be the maximum number of packets received by a processor at the end of stage 0, when such stage is needed (i.e., when $3^k n^\rho < n$). We have the following lemma.

LEMMA 4.6. *Let $k\geq 0$. Then*

$$\begin{aligned}\delta_{k+1} &= \mu 2^k,\\ \delta_i &= O\left(\mu 2^i 3^{k-i} n^{\frac{\rho+\epsilon-1}{2^i}}\right) \qquad \text{for } k\geq i\geq 0.\end{aligned}$$

When $3^k n^\rho < n$, we also have $\delta_{-1} = O(\mu n^\epsilon)$.

Proof. The statement is immediately evident for δ_{k+1}, since every target set contains $\mu 2^k$ copies. By Lemma 4.5, an i-block is addressed by at most $c\mu 2^i n^{1-(1-\epsilon)/2^i}$ packets for $k \geq i \geq 1$. Since there are $t_i = \Theta(3^{i-k} n^{1-\rho/2^i})$ processors storing an i-block, we have

$$\delta_i \leq \frac{c\mu 2^i n^{1-\frac{1-\epsilon}{2^i}}}{t_i} = O\left(\mu 2^i 3^{k-i} n^{\frac{\rho+\epsilon-1}{2^i}}\right).$$

In order to establish the bound for δ_0, we distinguish between two cases. If $3^k n^\rho < n$, each 0-block is assigned to a submesh of $t_0 = n^{1-\rho}/3^k$ nodes and, by Lemma 4.5, is addressed by at most $c\mu n^\epsilon$ packets, whence $\delta_0 = c\mu n^\epsilon / t_0 = O(\mu 3^k n^{\rho+\epsilon-1})$. In this case, stage 0 is needed to bring the packets to their final destinations. At the end of this stage, each processor receives at most $\delta_{-1} \leq c\mu n^\epsilon$ packets. Otherwise, if $3^k n^\rho \geq n$, there are $3^k n^{\rho-1}$ 0-blocks stored within a single processor, from which $\delta_0 = c\mu n^\epsilon 3^k n^{\rho-1} = O(\mu 3^k n^{\rho+\epsilon-1})$ as before, but the routing terminates with stage 1. ∎

Set $t_{k+1} = n$, the size of the entire mesh, and let T_i be the time complexity of stage i for $k+1 \geq i \geq 0$.

LEMMA 4.7. *We have*

$$T_{k+1} = O(2^k n^{\frac{1}{2}+\frac{\rho+\epsilon-1}{2^{k+1}}}),$$
$$T_i = O(2^i 3^{\frac{k-i}{2}} n^{\frac{1}{2}+\frac{2\rho+3\epsilon-3}{2^{i+1}}}) \qquad \text{for } k \geq i \geq 1.$$

When $3^k n^\rho < n$, we also have $T_0 = O(n^\epsilon)$.

Proof. Recall that for $k+1 \geq i \geq 1$, stage i is executed in parallel and independently in each i-submesh. The initial sorting and ranking are accomplished in $O(\delta_i \sqrt{t_i})$ time. By Fact 2.2, the subsequent (δ_i, δ_{i-1})-routing requires $O(\sqrt{\delta_i \delta_{i-1} t_i})$ time. Since $\delta_i \leq \delta_{i-1}$, we get $T_i = O(\sqrt{\delta_i \delta_{i-1} t_i})$. When $3^k n^\rho < n$, stage 0 consists of a (δ_0, δ_{-1})-routing in each submesh of size t_0, requiring $O(\sqrt{\delta_0 \delta_{-1} t_0})$ time. The lemma follows by plugging in the values for the δ_i's and the t_i's and by recalling that μ is a constant. ∎

After reaching their destinations, the packets relative to read operations must return to their origins carrying the accessed data. This second part of the routing can be accomplished by running the above protocol backwards, thus maintaining the same time complexity.

THEOREM 4.8. *The access protocol requires overall time*

$$O\left(n^\epsilon + n^{\frac{1}{2}}\left(\log n + 2^k n^{\frac{\rho+\epsilon-1}{2^{k+1}}} + \sum_{i=1}^{k} 2^i 3^{\frac{k-i}{2}} n^{\frac{2\rho+3\epsilon-3}{2^{i+1}}}\right)\right).$$

Proof. The running time of the access protocol is obtained by adding the contributions of the copy selection and routing phases together. The complexity of copy selection is given by (4.1), while the routing time is obtained by the summing of the T_i's given in Lemma 4.7. Note that $\rho + \epsilon - 1 \geq 0$; therefore the term $n^{1/2} 2^k n^{(\rho+\epsilon-1)/2^{k+1}}$ dominates the term $n^{1/2} 2^k$ coming from copy selection. Note also that the term n^ϵ, which accounts for the complexity of stage 0, does not dominate when $3^k n^\rho \geq n$. ∎

5. Tuning of the parameters. The complexity of the access protocol established by Theorem 4.8 is a function of the following design parameters:

(i) k: there are $k+1$ levels in the HMOS;
(ii) ρ: there are n^ρ 0-modules in U_0;
(iii) ϵ: the first graph of the HMOS (V, U_0) has $(n/m, \epsilon, \mu)$-expansion;
(iv) r: the (odd) input degree of (V, U_0).

Furthermore, recall that $m = |V| = n^\tau$ for some constant $\tau > 1$ and that $\mu = (r+1)/2$.

The goal of this section is to determine suitable values of the above parameters that guarantee the existence of graph (V, U_0) and yield a good performance of the access protocol. Such performance is closely related to the redundancy of the HMOS, that is, the number of copies ($r3^k$) used per variable. On the one hand, using many copies per variable yields better access times, while, on the other, lower redundancy yields simpler and space-efficient schemes. We will consider two scenarios: in the first scenario, we optimize the parameters under the assumption that the number of copies for each variable $r3^k$ can grow arbitrarily large. In the second scenario, we optimize under the restriction that the scheme uses no more than a constant number of copies for each variable.

We need the following technical result, which is a straightforward adaptation of Lemma 4 in [PP97a].

LEMMA 5.1. *Let $m = n^\tau$, with constant $\tau > 1$. There is a suitable constant $c > 0$ such that for any odd constant $r \geq c\tau \log \tau$, a random bipartite graph $G = (V, U_0)$ with $|V| = m$, $|U_0| = n$, input degree r, and output degree mr/n has $(n/m, \epsilon, \mu)$-expansion with $\mu = (r+1)/2$ and $\epsilon = (\tau - 1)/\mu$, with high probability.*

We are now ready to prove one of the main results of this paper, which was stated in section 1.1.

Proof of Theorem 1.1. We fix $\rho = 1$ and choose r to be the smallest odd integer greater than $\max\{c\tau \log \tau, 6(\tau - 1)\}$. For such values, Lemma 5.1 ensures the existence of (V, U_0) with $(n/m, \epsilon, (r+1)/2)$-expansion, where $\epsilon \leq 1/3$. Since $2\rho + 3\epsilon - 3 \leq 0$, the complexity of the access protocol given in Theorem 4.8 becomes

$$T = O\left(2^k n^{\frac{1}{2} + \frac{\epsilon}{2^{k+1}}}\right). \tag{5.1}$$

By fixing $k = \max\{0, \lfloor \log_2(\epsilon/\eta) \rfloor\}$, we have $2^{k+1} \geq \epsilon/\eta$, whence $T = O(n^{1/2+\eta})$ and $R = r3^k = O(1/\eta^{\log_2 3}) = O(1/\eta^{1.59})$. By instead fixing $k = \log_2 \log_2 n + O(1)$, so that $2^{k+1} \geq \epsilon \log_2 n$, we have $T = O(n^{\frac{1}{2}} \log n)$ and $R = O(\log^{1.59} n)$. □

As already noted before, the HMOS underlying the above result is fully constructive, except for the first graph (V, U_0), for which Lemma 5.1 only guarantees existence. In practice, one can resort to a random graph for (V, U_0), which, as the lemma shows, will exhibit the required expansion property with high probability. Although no explicit construction for (V, U_0) is known in the general case, this graph needs only weak expansion, which makes it more amenable to explicit constructions than the graphs employed in previous schemes (e.g., [UW87, AHMP87]).

In fact, an explicit construction for (V, U_0) can be obtained when the shared memory size m is within certain ranges. For example, [PP97] shows how to construct a bipartite graph with $m = \Theta(n^{3/2})$ inputs, n outputs, and input degree $r = 3$, which has $(n/m, 1/3, 2)$-expansion. This graph can be efficiently represented using constant storage per node. Thus, using this graph as (V, U_0) when $m = \Theta(n^{3/2})$, the result of Theorem 1.1 still holds, and the HMOS becomes fully constructive.

A larger range of values for m for which the HMOS can be made fully constructive, still yielding nontrivial performance, can be obtained by employing other graphs for

(V, U_0). This is shown below, thus proving Theorem 1.2, which was stated in the introduction.

Proof of Theorem 1.2. Let us consider first the case $\tau \leq 3/2$. We assume $m = x(x-1)/6$, where x is an even power of three. The argument for different values of m requires only trivial modifications. Fix $n^\rho = x = \Theta(n^{\tau/2})$, and choose (V, U_0) as an $(n^\rho, 3)$-BIBD. By Corollary 3.4, such graph has $(1, \epsilon, 2)$-expansion, with $\epsilon = 1/2$. Since $2\rho + 3\epsilon - 3 = O(1/\log n)$, the complexity of the access protocol is still given by (5.1), and the same argument used to prove Theorem 1.1 carries through. Consider now the range $3/2 < \tau \leq 13/6$, and choose n^ρ and (V, U_0) as before. By plugging $\epsilon = 1/2$ and $n^\rho = \Theta(n^{\tau/2})$ in the complexity formula given in Theorem 4.8 and choosing $k = O(1)$ large enough and even, the complexity of the access protocol becomes

$$T = O(n^{\frac{1}{2} + \frac{2\tau - 3}{8}}) = O(n^{\frac{2\tau+1}{8}}).$$

For $\tau \geq 13/6$, it is convenient to choose (V, U_0) as a $3-(n^\rho, 5, 3)$ *design*, a graph with the following properties: $|U_0| = n^\rho$, each node of V has degree 5, and for every three distinct nodes u_1, u_2, u_3 of U_0 there are exactly 3 nodes of V adjacent to all three of them. This implies that $m = |V| = \Theta(n^{3\rho})$. (See [Hal86] for a formal definition of the graph). In [PP97], an explicit construction for the graph is provided, and it is shown that it has $(1, 2/3, 3)$-expansion. With this choice for (V, U_0), we can plug $\epsilon = 2/3$ and $n^\rho = \Theta(n^{\tau/3})$ in the formula of Theorem 4.8, and by choosing $k = O(1)$ large enough, we get access time

$$T = O\left(n^{\frac{2}{3}} + n^{\frac{1}{2} + \frac{2\tau/3 - 1}{4}}\right) = O\left(n^{\frac{2}{3}} + n^{\frac{2\tau+3}{12}}\right).$$

This yields $T = O(n^{2/3})$ for $13/6 \leq \tau \leq 5/2$ and $T = O(n^{(2\tau+3)/12})$ for $5/2 \leq \tau \leq 9/2$, which completes the proof. □

Note that the access time of the constructive scheme tends to $O(n)$ as m approaches $n^{9/2}$, a performance that can be obtained through a straightforward scheme.

6. Extension to other architectures. A closer look at the access protocol developed in the previous sections for the mesh reveals that it solely relies upon a recursive decomposition of the network into subnetworks of the same type, and upon ℓ-sorting and (ℓ_1, ℓ_2)-routing primitives. As a consequence, our scheme can be ported to any network topology that exhibits a suitable decomposition into subnetworks, and for which an efficient implementation of the above primitives is available. In this section we briefly discuss the porting of the scheme to the pruned butterfly and to multidimensional meshes.

An n-leaf *pruned butterfly*, introduced in [BB95], is a variant of Leiserson's fat-tree [Lei85]. Its coarse structure may be interpreted as an n-leaf complete binary tree, where the leaves represent the processor-memory nodes of the machine, the internal nodes represent clusters of routing switches, and the edges represent channels whose bandwidth doubles every other level from the leaves to the root. More precisely, each subtree of n' leaves is connected to its parent through a channel of capacity $\Theta(\sqrt{n'})$. The pruned butterfly is an important interconnection since it is *area-universal* in the sense that it can route any set of messages almost as efficiently as any circuit of similar area.

It follows from the definition that an n-leaf pruned butterfly can be decomposed into 4^i $(n/4^i)$-leaf pruned butterflies connected through channels of capacity $\sqrt{n/4^i}$, a decomposition similar to the one of the mesh employed in our scheme. Moreover,

it is shown in [HPP95] that ℓ-sorting and (ℓ_1, ℓ_2)-routing can be performed on the pruned butterfly in the same running time as on the mesh. This immediately implies that both Theorem 1.1 and Theorem 1.2 also hold for the pruned butterfly.

We now consider the extension of the scheme to d-dimensional meshes, with d constant. For $d \geq 3$, a decomposition of an n-node d-dimensional mesh into submeshes is obtained as an immediate generalization of the two-dimensional case. As for the primitives, ℓ-sorting and (ℓ_1, ℓ_2)-routing, with $\ell_1 < \ell_2$, require time $\Theta(\ell n^{1/d})$ and $\Theta(\ell_2^{1-1/d}(n\ell_1)^{1/d})$, respectively [SK94]. Then, the same argument presented in section 4.2 shows that the access protocol can be executed on a d-dimensional mesh in time

$$T = O\left(n^{\epsilon} + n^{\frac{1}{d}}\left(\log n + 2^k n^{\frac{(d-1)(\rho+\epsilon-1)}{d2^k}} + \sum_{i=1}^{k} 2^i 3^{\frac{(d-1)(k-i)}{d}} n^{\frac{2(d-1)(\rho+\epsilon-1)+\epsilon-1}{d2^i}}\right)\right).$$

Let us fix $\rho = 1$ and $\epsilon < 1/(2d-1)$, which, based on Lemma 5.1, requires $r = \Omega(d\tau)$ in order to guarantee the existence of the first graph (V, U_0) of the HMOS. Straightforward calculations show that the above formula becomes

$$T = O\left(2^k n^{\frac{1}{d} + \frac{(d-1)\epsilon}{d2^k}}\right).$$

Arguing as in the proof of Theorem 1.1, we can prove the following result.

THEOREM 6.1. *For any constant $\tau \geq 1$, there exists a scheme to distribute $m = n^{\tau}$ shared variables among the local memory modules of an n-node d-dimensional mesh (d constant) with redundancy R so that any n variables can be read/written in time*

$$T = O\left(n^{\frac{1}{d}+\eta}\right)$$

for any constant $\eta > 0$, with $R = O(1/\eta^{1.59})$, or in time

$$T = O\left(n^{\frac{1}{d}} \log n\right)$$

with $R = O(\log^{1.59} n)$.

It has to be remarked that the bandwidth of a d-dimensional mesh increases with d; hence, in order to achieve access time close to the natural $\Omega(n^{1/d})$ lower bound, the expansion required of (V, U_0) must also increase with d. For this reason, the graphs for which an explicit construction is currently available do not exhibit sufficient expansion to grant a generalization of Theorem 1.2; however, they can still be used to yield fully constructive schemes with nontrivial $O(n^{1/d+\xi_d})$ access time for suitable constants $\xi_d < (d-1)/d$. The details follow from tedious yet trivial arithmetic manipulations, which are omitted for the sake of brevity.

7. Conclusions. In this paper, we devised a scheme for implementing a shared address space on a mesh of processor/memory pairs. The scheme enables the processors to read/write any n-tuple of shared variables concurrently and yields a quasi-optimal access time in the worst case. One of the most relevant novelties of our implementation is represented by the hierarchical memory organization scheme, the HMOS, which provides a structured distribution of copies of the shared variables among the memory modules. In particular, the HMOS succeeds in the following objectives, which were not attained by the memory organizations known in the literature: (i) it provides

a single mechanism to cope with both memory contention and network congestion. In this fashion, copy selection can be employed to reduce both; (ii) it yields fast access time by using a cascade of bipartite graphs with weak expansion, rather than using one graph of maximum expansion, which greatly simplifies the implementation. Indeed, the HMOS is fully constructive and yields quasi-optimal performance for any memory size $m = O(n^{3/2})$, which is sufficient, for example, to run any NC algorithm. For large memory sizes, the HMOS embodies only one nonconstructive graph of weak expansion.

The design of the HMOS is not specifically cast for the mesh topology. We showed that it can be implemented on the pruned butterfly and on d-dimensional meshes yielding good performance. More generally, our scheme is efficiently portable to any low-bandwidth interconnection where routing takes advantage of partitions of the processors into subnetworks, in the sense that it achieves higher performance by moving messages gradually closer to their destinations through smaller and smaller subnetworks, rather than by sending them directly to their destinations.

A challenging and long-standing open problem remains the construction of bipartite graphs that exhibit good expansion. The availability of explicit constructions and concise representations for such graphs is crucial for attaining simple and efficient deterministic shared memory implementations for all memory sizes. Recent developments in this area [PP97] seem to indicate that the construction of graphs with a linear number of edges and moderate expansion, such as those required in our scheme, are easier than the construction of the highly expanding graphs used in previous schemes. If this is true, our scheme could become a general and constructive tool for the implementation of shared memory on distributed memory machines based on low-bandwidth interconnections.

Finally, we wish to point out that in a recent paper [HPP95], which appeared after the results in the present paper were first presented [PPS94, PP95], a shared memory implementation scheme for the mesh is devised that, through a novel and complex protocol, achieves $O(\sqrt{n \log n})$ access time. However, this scheme relies on a nonconstructive graph of maximum expansion; hence it suffers from the same limitations affecting other schemes in the literature, as discussed in the introduction. The paper also proves an $\Omega(\sqrt{n \log(m/n^2)/\log\log(m/n^2)})$ lower bound on the access time of any deterministic scheme for implementing $m = \Omega(n^2)$ shared variables. The lower bound assumes that variables are accessed through a point-to-point protocol, which requires that a processor dispatch a separate message for each copy it wants to update. The assumption is satisfied by the scheme presented in this paper, which implies that our access time is only a sublogarithmic factor away from optimal.

Appendix. In this appendix, we show how to construct a bipartite graph $G = (X, Y)$ which is a subgraph of a (q^d, q)-BIBD with the same number of output nodes, i.e., $|Y| = q^d$, fewer input nodes, say $|X| = m$, $1 \leq m < q^{d-1}(q^d - 1)/(q - 1)$, and such that each input $x \in X$ has degree q, as in the original BIBD, and each output $y \in Y$ has degree ρ, with

$$\left\lfloor \frac{qm}{q^d} \right\rfloor \leq \rho \leq \left\lceil \frac{qm}{q^d} \right\rceil .$$

As explained in section 3.1, these subgraphs (with $q = 3$ and m a power of three) govern the assignment of replicas of $(i - 1)$ modules to i-modules in the HMOS, for $1 \leq i \leq k$. The construction is obtained by modifying the one for a (q^d, q)-BIBD given in [PP93].

Let q be a prime power and let $\mathbb{F}_q$ be the finite field with q elements, with its elements represented by the integers $0, 1, \ldots, q-1$. The q^d output nodes of the BIBD are associated with the set of d-dimensional vectors over $\mathbb{F}_q$, and the inputs with the $q^{d-1}(q^d-1)/(q-1)$ pairs of vectors of kind

$$\begin{array}{llllllll} (a_{d-2}, & \ldots, & a_h, & 0, & a_{h-1}, & \ldots, & a_1, & a_0) \\ (0, & \ldots, & 0, & 1, & b_{h-1}, & \ldots, & b_1, & b_0), \end{array}$$

where the a_i's and b_i's are elements of the field, and h ranges between 0 and $d-1$. For convenience, each such pair will be denoted by $\chi(h, A, B)$, where A is the integer in $[0, q^{d-1})$ whose representation in base q is $(a_{d-2} \ldots a_h a_{h-1} \ldots a_1 a_0)$, and B is the integer in $[0, q^h)$ whose representation in base q is $(b_{h-1} \ldots b_1 b_0)$. The subgraph G is obtained from this BIBD by taking the same output set and selecting a subset of m inputs as follows. Let $\ell < d$ be the index such that

$$q^{d-1}\frac{q^\ell - 1}{q-1} \le m < q^{d-1}\frac{q^{\ell+1}-1}{q-1},$$

so that

$$m = q^{d-1}\left(\frac{q^\ell - 1}{q-1} + w\right) + z \tag{A.1}$$

for some w, $0 \le w < q^\ell$ and z, $0 \le z < q^{d-1}$. The m pairs $\chi(h, A, B)$ that we select to represent the nodes of X consist of the union of the three sets X_1, X_2, and X_3 defined below:

$$\begin{aligned} X_1 &= \left\{\chi(h, A, B) : 0 \le h < \ell,\ 0 \le A < q^{d-1},\ 0 \le B < q^h\right\}; \\ X_2 &= \left\{\chi(h, A, B) : h = \ell,\ 0 \le A < q^{d-1},\ 0 \le B < w\right\}; \\ X_3 &= \left\{\chi(h, A, B) : h = \ell,\ 0 \le A < z,\ B = w\right\}. \end{aligned}$$

It is easy to verify that $|X_1| + |X_2| + |X_3| = m$.

The edges are defined as follows: the input node

$$\begin{array}{llllllll} (a_{d-2}, & \ldots, & a_h, & 0, & a_{h-1}, & \ldots, & a_1, & a_0) \\ (0, & \ldots, & 0, & 1, & b_{h-1}, & \ldots, & b_1, & b_0) \end{array}$$

is adjacent to the q outputs

$$(a_{d-2}, \ldots, a_h, x, a_{h-1} + x \cdot b_{h-1}, \ldots, a_1 + x \cdot b_1, a_0 + x \cdot b_0)$$

for every $x \in \mathbb{F}_q$, where $+$ and $\cdot$ denote the field operations. We now show that the edges in G are evenly distributed among the outputs.

THEOREM A.1. *Any node $u \in Y$ is connected to ρ nodes of X, where*

$$\left\lfloor \frac{qm}{q^d} \right\rfloor \le \rho \le \left\lceil \frac{qm}{q^d} \right\rceil.$$

Proof. Let u be associated with the vector $(a_{d-1}, \ldots, a_0)$. We determine the value of ρ by separately counting the contributions of the nodes in the three subsets X_1, X_2, and X_3. Consider X_1 and fix $h < \ell$. Using the properties of field operations, one can easily show that for any B, $0 \le B < q^h$, there exists exactly one value

A such that the node $\chi(h, A, B)$ is connected to u. Therefore, there are exactly $\sum_{h=0}^{\ell-1} q^h = (q^\ell - 1)/(q-1)$ nodes of X_1 connected to u. A similar argument shows that exactly w nodes of X_2 are connected to u. Finally, it can be seen that the z nodes of X_3 are connected to qz distinct output nodes; therefore, according to whether u is one of such nodes or not, we know that either $\rho = (q^\ell - 1)/(q-1) + w$ or $\rho = (q^\ell - 1)/(q-1) + w + 1$. By (A.1) we conclude that

$$\left\lfloor \frac{qm}{q^d} \right\rfloor \leq \rho \leq \left\lceil \frac{qm}{q^d} \right\rceil.$$

Note that when m is a power of q, it must be $z = 0$, and therefore $\rho = qm/q^d$ for every output node. □

Let $X = U_{i-1}$ be the set of $(i-1)$-modules, and $Y = U_i$ the set of i-modules. Thus, $q = 3$, $d = d_i$, and $m = 3^{d_{i-1}}$. Each $(i-1)$-module is adjacent to the 3 i-modules that contain its $(i-1)$-blocks, and, accordingly, each i-module u is adjacent to the ρ $(i-1)$-modules, each of which has one of its $(i-1)$-blocks stored in u. For each $(i-1)$-module, we must be able to efficiently determine the i-modules that store its $(i-1)$-blocks and the location of each block within the module.

It is easy to establish a bijection between the $(i-1)$-modules and the pairs $\chi(h, A, B)$ in X so that given an index s, $1 \leq s \leq m$, the pair associated with the sth module is determined in $O(d)$ time. Similarly, a bijection between the i-modules and the d-dimensional vectors over $\mathbb{F}_3$ is easily established. Consider the $(i-1)$-module associated with the pair

$$\chi(h, A, B) = \begin{array}{cccccccc} (a_{d-2}, & \ldots, & a_h, & 0, & a_{h-1}, & \ldots, & a_1, & a_0) \\ (0, & \ldots, & 0, & 1, & b_{h-1}, & \ldots, & b_1, & b_0). \end{array}$$

We adopt the convention that, for $0 \leq j < 3$, the jth $(i-1)$-block of this module is the ℓth item stored in the i-module u, where

$$u = (a_{d-2}, \ldots, a_h, j, a_{h-1} + jb_{h-1}, \ldots, a_1 + jb_1, a_0 + jb_0).$$

and

$$\ell = \frac{3^h - 1}{2} + B.$$

In [PP93] it is proved that the above rule is correct, i.e., no two $(i-1)$-blocks of $(i-1)$-modules are assigned the same location within the same i-module. Moreover, it is not difficult to show that $0 \leq \ell < \rho$.

Observe that the structure of any (U_{i-1}, U_i) is completely determined by the parameter d_i. Since each d_i can be derived from n, we conclude that, in order to represent (U_{i-1}, U_i), a processor needs to know only n. From this parameter, the processor can determine the exact location of any copy of any $(i-1)$-module performing $O(\log n)$ operations (arithmetic or in $\mathbb{F}_3$).

Acknowledgments. This paper benefited from discussions with Matteo Frigo, Tim Harris, and Franco Preparata. The authors wish to thank the anonymous referees for their valuable comments that helped improve both the presentation and the quality of the paper.

HOW TO MAKE A SQUARE GRID FRAMEWORK WITH CABLES RIGID*

HAROLD N. GABOW† AND TIBOR JORDÁN‡

Abstract. This paper solves the problem of making a bipartite digraph strongly connected by adding the smallest number of new edges that preserve bipartiteness. A result of Baglivo and Graver shows that this corresponds to making a two-dimensional square grid framework with cables rigid by adding the smallest number of new cables. We prove a min-max formula for the smallest number of new edges in the digraph problem and give a corresponding linear-time algorithm. We generalize these results to the problem of making an arbitrary digraph strongly connected by adding the smallest number of new edges, each of which joins vertices in distinct blocks of a given partition of the vertex set.

Key words. graph algorithms, strong connectivity, connectivity augmentation, min-max theorems, rigidity, square grid framework

1. Introduction.

In the *connectivity augmentation problem* we are given a graph and a positive integer k. We wish to find a smallest set of edges whose addition makes the graph k-connected. Here "k-connected" can refer to vertex- or edge-connectivity. Practical applications include the design of reliable networks [9], [16]. Much of the work on connectivity augmentation is discussed in the survey article [7]. The result most relevant to this paper is one of the first augmentation algorithms, due to Eswaran and Tarjan, which makes a digraph strongly connected in linear time [6].

Restricted versions of the augmentation problem may be even more interesting in terms of both theory and practical applications. Many restrictions can be modeled by the minimum cost augmentation problem. However, even special cases of this problem are NP-hard, e.g., making a digraph strongly connected by adding the smallest number of edges from a given set [6]. Other restrictions that have been investigated include the following: augmenting to achieve k-edge-connectivity while preserving simplicity of the given graph [2], [12]; augmenting while preserving planarity [13], [14]; and augmenting an undirected bipartite graph to achieve 2-vertex-connectivity [10] or k-edge-connectivity [3] while preserving bipartiteness. Augmenting a biconnected graph to achieve both k-edge-connectivity and 3-vertex-connectivity is studied in [11].

This paper investigates the problem of making a bipartite digraph strongly connected while preserving bipartiteness. We prove a min-max formula for the smallest possible number of new edges. We give a corresponding linear-time algorithm. In addition we generalize these results to the problem of strong-connectivity augmentation with partition constraints (precisely defined below). We now give some motivation for the problem.

A basic two-dimensional structure in statics is the *square-grid framework* (see Figure 1.1). It consists of horizontal and vertical *rods*. Each rod has the same length,

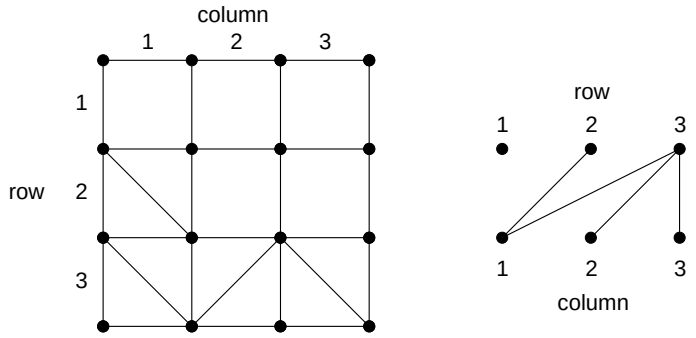

FIG. 1.1. *Row* 1 *can pivot in this square grid framework. But if we add a rod in row* 1*, column* 3*, the framework becomes rigid and the bipartite graph becomes connected.*

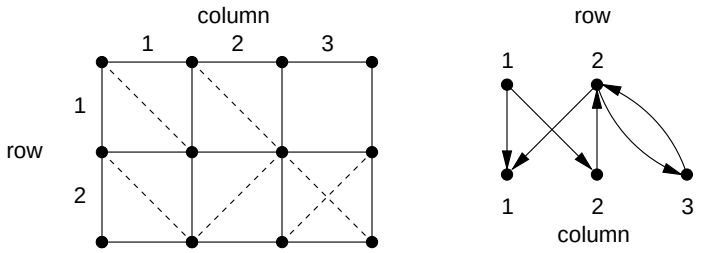

FIG. 1.2. *Here dashed lines represent cables. The joint at the upper left corner can move inwards, compressing the cables in row* 1*, columns* 1 *and* 2*, and row* 2*, column* 1*. But if we rotate the cable in row* 1*, column* 1*, by* 90°*, the framework becomes rigid and the bipartite digraph becomes strongly connected.*

and is rigid. Incident rods are connected by a *joint* which allows the rods to pivot. The rods collectively join all grid-points that are in a rectangular region and are adjacent horizontally or vertically. In addition there may be a number of "diagonal rods" that join two diagonally opposite points of a grid square. Such a framework is *rigid* if it has no nontrivial deformations, i.e., fixing the position of one rod in the plane, the positions of all other rods are uniquely determined. (These concepts are described more precisely in [15].) Bolker and Crapo [4] show that any square-grid framework has a natural representation as a bipartite graph, and the framework is rigid if and only if its bipartite graph is connected (Figure 1.1). Because of this relation the results of [3] solve problems such as, find a smallest set of new rods whose addition results in a framework that is rigid, even after an arbitrary set of k diagonal rods fail.

A potentially cheaper way to make a framework rigid is to use pliable material along the diagonals. A *cable* can be compressed but not stretched and can join two diagonally opposite points of a grid square (see Figure 1.2). Baglivo and Graver [1] show that a framework with cables has a natural representation as a bipartite digraph, such that the framework is rigid if and only if its bipartite digraph is strongly connected (Figure 1.2). The *cable-framework rigidity problem* is to make a given framework with diagonal cables rigid by adding the smallest number of new cables. Our solution to the graph augmentation problem solves the cable-framework rigidity problem, by the theorem of Baglivo and Graver.

The main part of our solution to the problem of bipartite strong-connectivity augmentation is a min-max formula for the optimum number of new edges (Lemma 5.3).

This formula extends to the general problem of strong-connectivity augmentation with partition constraints (Theorem 7.8). Roughly put, the formula states that the optimum number of new edges either equals a natural lower bound or is one more than that. The latter holds exactly when the graph belongs to one of four infinite families.

This result has similar overall structure to the min-max formula of [3] for bipartite undirected graph k-edge-connectivity augmentation: Both formulas have an infinite number of exceptional graphs that require one extra edge. The formula of [3] has a single family of exceptional graphs. Our problem, just for the $k = 1$ case, seems to have more complicated structure, with four distinct families. Together these two results give evidence that min-max formulas with exceptions may be a general phenomenon.

Our result corresponds to the $k = 1$ case of [3]. This case is the problem of augmenting a bipartite graph to make it connected and bipartite. This simple problem has no exceptional families. It is equivalent to the rod-framework rigidity problem, which was solved in [1] and [15]. Until now the cable-framework rigidity problem has been left open, perhaps because the phenomenon of exceptional families has been ignored.

Section 2 of this paper gives basic facts about our augmentation problem, including lower and upper bounds on the solution size. Sections 3–5 prove the min-max formula for bipartite augmentation. Sections 6 and 7 prove the formula in general (reducing to the case covered in section 3). Section 8 presents efficient algorithms for the augmentation problems. Section 9 discusses some augmentation problems related to ours.

The material in section 5 is not logically necessary for proving the general formula. However, it gives a simpler proof of the special case needed for the cable-framework rigidity problem. Furthermore this proof is the basis of the algorithm in section 8 that is more efficient than the general algorithm. The reader should also be aware at the outset that many details of the algorithms in section 8 are omitted because they directly follow the proofs in preceding sections.

This section closes with some terminology. In the problem of *(strong-connectivity) augmentation with partition constraints* we are given a digraph $D = (V, E)$ together with a partition $\mathcal{P}$ of V into disjoint sets called *color classes*. We wish to make D strongly connected, if possible, by adding the smallest number of new directed edges, where no new edge joins vertices in the same color class. The *bipartite strong-connectivity augmentation problem* is the special case where D is a bipartite digraph and the color classes are the two sets of the given bipartition of V.

We use B, W ("black," "white") as typical colors. A vertex v is *colored* B if $v \in B \in \mathcal{P}$. A *singleton vertex* v has $\{v\} \in \mathcal{P}$, i.e., no other vertex has its color. There is no restriction on a new edge incident with a singleton vertex. Note that in our general augmentation problem there is no restriction on an original edge of E: it can join vertices of the same color. We will refer to the augmentation problem for a graph D without mentioning $\mathcal{P}$ when $\mathcal{P}$ is clear from context.

The symbols $\subseteq$ and $\subset$ denote set containment and proper set containment, respectively. An over-bar denotes set complement (with the universe understood), e.g., $\overline{B}$ denotes the set of nonblack vertices $V - B$. A set consisting of a single element x is usually denoted by x.

Consider a digraph. If S is a set of vertices containing y but not x, then an edge (x, y) *enters* S and an edge (y, x) *leaves* S. A vertex x *precedes* a vertex y (alternatively, x *can reach* y) if there is a path from x to y.

A digraph with no cycles is a *dag* (directed acyclic graph). A *source* (*sink*) is

a vertex with no entering (leaving) edge. An *extreme* vertex is a source or a sink. The *strong component graph* of a digraph is formed by contracting every strongly connected component. It is a dag.

2. Basic facts. This section presents basic concepts and notation. In particular it defines the quantity Φ and proves that an optimum solution to our augmentation problem uses either Φ or $\Phi+1$ new edges. It also presents several graph families that require exactly Φ new edges. These graph families provide the foundation of our general solution.

The special case of strong-connectivity augmentation with partition constraints when D is a dag is called the *dag problem*. The general problem reduces to the dag problem, as follows. Let D be a given digraph. Let H be its strong component graph. To assign colors to the vertices of H let a vertex x of H correspond to the strong component X of D. If every vertex of X is colored B, then x is colored B. If X contains vertices of two or more colors, then x is a singleton vertex. Solutions to the augmentation problem with partition constraints on D and H correspond because of the following observation: For two vertices x_i, $i=1,2$, of H corresponding to strong components X_i, $i=1,2$, of D, x_1 and x_2 have different colors if and only if some vertex of X_1 and some vertex of X_2 have different colors.

From now on we will work on the dag problem for a dag $H=(V,E)$. We use the following notation. OPT is the smallest number of new edges needed to solve the given dag problem. By definition $OPT=0$ if $|V|=1$ and $OPT=\infty$ (i.e., there is no solution) if $|V|>1$ and all vertices have the same color.

Let X be a set of vertices of H. X^+ denotes the set of all sources in X and X^- the set of all sinks. For instance V^+ is the set of all sources of H. An isolated vertex belongs to $V^+\cap V^-$.

$R^-(X)$ denotes the set of all sinks that can be reached from some source of X. Similarly $R^+(X)$ denotes the set of all sources that can reach some sink of X. For $X,Y\subseteq V$, the predicate $r(X,Y)$ is true when some source of X precedes some sink of Y. This is equivalent to $R^-(X)\cap Y\neq\emptyset$. Note as a special case that if x is a source and y is a sink, $r(x,y)$ means x precedes y. We abbreviate $r(X,X)$ to $r(X)$. Negation is denoted by $\neg$, e.g., $\neg r(X,Y)$.

We will characterize OPT in terms of the following quantity:

$$\Phi=\begin{cases}0 & \text{if } |V|=1,\\ \infty & \text{if } |V|>1 \text{ and } |\mathcal{P}|=1,\\ \max\{|V^+|,\,|V^-|,\,|B^+|+|B^-| : B\in\mathcal{P}\} & \text{otherwise.}\end{cases}$$

Clearly $OPT=\Phi$ in the first two cases. In the third case $OPT\geq\Phi$: A solution must contain an edge entering every source and an edge leaving every sink. This implies $OPT\geq|V^+|,|V^-|$. One new edge cannot leave a sink and enter a source of the same color. This implies $OPT\geq|B^+|+|B^-|$ for any color B.

There are simple graphs with $OPT>\Phi$. For instance, the graph on four vertices $b^+\in B^+$, $b^-\in B^-$, $w^+\in W^+$, $w^-\in W^-$ with edges (b^+,w^-) and (w^+,b^-) has $\Phi=2$ and $OPT=3$.

Any instance of the dag problem has a *directionally symmetric* instance, obtained by reversing the orientations of all edges. Solutions to these two problems correspond, and OPT and Φ are the same. We invoke directional symmetry to simplify the proofs.

It is convenient to work with graphs that have no isolated vertices. If $|V|>1$ we eliminate an isolated vertex x by replacing it with vertices x_1,x_2 having the same color as x and an edge (x_1,x_2). (There is no edge (x_2,x_1), so the transformed graph

is a dag.) A solution on the transformed graph gives a solution on the original graph by contracting x_1, x_2 to a vertex we call x.

PROPOSITION 2.1. *The transformation to eliminate an isolated vertex does not change the value of* $|V^+|$, $|V^-|$, $|B^+| + |B^-|$ *for* $B \in \mathcal{P}$, Φ *or* OPT.

Proof. We show OPT does not change. Let H be the original graph and H' the transformed graph. Clearly a solution on H' gives a solution on H that is no larger. For the converse let F be a set of new edges in H and let $F' = \{(y, x_1) : (y, x) \in F\} \cup \{(x_2, z) : (x, z) \in F\}$. A path in $H + F$ corresponds to a path in $H' + F'$ if the vertex x is replaced by x_1, x_2. This implies $H' + F'$ is strongly connected if $H + F$ is. □

From now on assume the given dag H has no isolated vertices. We drop this assumption in the statement of our main results (Lemma 5.3 and Theorem 7.8).

In a *unicolored dag* the extreme vertices all have the same color. In a *bicolored (tricolored) dag* the extreme vertices are contained in at most two (three) color classes, which we take as B and W (and G).

LEMMA 2.2. *A unicolored dag has* $OPT = \Phi$.

Proof. Assume $|\mathcal{P}| > 1$, else, obviously, $OPT = \Phi = \infty$. Thus $\Phi = |V^+| + |V^-|$. Choose any vertex y of a color different from the extreme vertices. Add edges (y, x^+) for every $x^+ \in V^+$ and (x^-, y) for every $x^- \in V^-$. Thus y can reach every source and every sink can reach y. This implies y can reach every vertex and every vertex can reach y. □

A *rooted dag* is a dag with exactly one source or exactly one sink.

LEMMA 2.3. *Any rooted dag has* $OPT = \Phi$.

Proof. By symmetry assume the given dag H has exactly one source x^+. Assume H is not unicolored (Lemma 2.2). Hence $\Phi = |V^-|$ and some sink y^- is differently colored from x^+. Add edge (y^-, x^+). The new strong component graph K has a unique source that is a singleton vertex. Also Φ has decreased by 1. Now add an edge from each sink of K to the source to get a strongly connected graph. This shows $OPT = \Phi$. □

A set of extreme vertices is *consistently colored* unless it contains a source and sink of the same color. The dag is *consistently colored* if $V^+ \cup V^-$ is consistently colored. (Equivalently, every color B has B^+ or B^- empty.)

DEFINITION 2.4. *A pair of vertices* $x^- \in V^-$ *and* $y^+ \in V^+$ *is* compatible *if the pair is consistently colored and there are vertices* $x^+ \in V^+ - y^+$, $y^- \in V^- - x^-$ *with* $r(x^+, x^-)$ *and* $r(y^+, y^-)$.

LEMMA 2.5. *Any consistently colored set of two sources and two sinks contains a compatible pair.*

Proof. Let the consistently colored set consist of sources y_i^+, $i = 1, 2$, and sinks x_i^-, $i = 1, 2$. For $i = 1, 2$, if x_i^-, y_i^+ is not compatible, then $r(y_i^+, x_i^-)$. This makes x_1^-, y_2^+ compatible. □

If vertices $x^- \in V^-$, $y^+ \in V^+$ form a compatible pair, *augmenting* x^-, y^+ means adding a new edge (x^-, y^+) to the graph and passing to the new strong component graph. Thus if $H + (x^-, y^+)$ has a strong component containing x^- and y^+, we contract it. The augment operation also adds the new edge (x^-, y^+) to the solution set of the augmentation problem.

LEMMA 2.6. *Augmenting a compatible pair* x^-, y^+ *decreases* $|V^+|$, $|V^-|$, *and* $|B^+| + |B^-|$ *for* B *the color of* x^- *or* y^+, *each by one. Furthermore it does not create an isolated vertex.*

Proof. Let H be the given graph. Let K be the strong component graph of

$H + (x^-, y^+)$. Any vertex of $V^+ - y^+$ is a source of K since it has no entering edge. Any other vertex of H is not a source of K since it is preceded by a vertex of $V^+ - y^+$. (In particular y^+ is preceded by x^+ of Definition 2.4.) This proves $|V^+|$ decreases by one. The other parts are similar. □

LEMMA 2.7. *Any consistently colored dag has $OPT = \Phi$.*

Proof. A consistently colored dag has $\Phi = \max\{|V^+|, |V^-|\}$. Without loss of generality let $\Phi = |V^-|$. If the given graph H is rooted, we are done by Lemma 2.3. If not, H has a compatible pair by Lemma 2.5. Augment it. Lemma 2.6 shows the graph remains consistently colored and Φ decreases by 1. Repeating this procedure eventually makes H rooted. □

LEMMA 2.8. *Let H be a dag with no compatible pair of vertices. Then H is either rooted, unicolored, or bicolored. In the third alternative if H is bicolored by B and W, then H contains two subgraphs that are rooted dags, one spanning $B^+ \cup W^-$, the other spanning $W^+ \cup B^-$, and $B^+, B^-, W^+, W^- \neq \emptyset$.*

Proof. Suppose H is neither rooted nor unicolored. We show the third alternative of the lemma holds. If H is consistently colored, then Lemma 2.5 gives a compatible pair. Hence assume some color B has $B^+, B^- \neq \emptyset$.

Claim. $\overline{B}^- \neq \emptyset$ implies H contains a rooted dag spanning $B^+ \cup \overline{B}^-$ and $\overline{B}^+ \neq \emptyset$.

Proof. The hypothesis and Lemma 2.5 imply at least one of the sets B^+, $\overline{B}^-$ has exactly one vertex. First suppose $B^+ = \{b^+\}$. Since H is not rooted, $\overline{B}^+ \neq \emptyset$. Since any sink $\bar{b}^- \in \overline{B}^-$ is incompatible with b^+, $r(b^+, \bar{b}^-)$.

Next suppose $\overline{B}^- = \{\bar{b}^-\}$ and $|B^+| > 1$. Since any source b^+ is incompatible with $\bar{b}^-$, $r(b^+, \bar{b}^-)$. Furthermore b^+ does not precede any other sink, which with $B^- \neq \emptyset$ implies $\overline{B}^+ \neq \emptyset$. This proves the claim. □

Since H is not unicolored, $\overline{B}^+ \cup \overline{B}^- \neq \emptyset$. The claim and its directionally symmetric version show H contains two rooted dags, spanning $B^+ \cup \overline{B}^-$ and $\overline{B}^+ \cup B^-$, respectively. If two vertices of $\overline{B}^+$ and $\overline{B}^-$ have different colors, they are compatible. Hence all extremes of $\overline{B}$ have the same color. □

LEMMA 2.9. *Any dag has $OPT \leq \Phi + 1$.*

Proof. First assume the given dag H is bicolored. If H is unicolored or rooted, Lemmas 2.2 and 2.3 show $OPT = \Phi$. If H has a compatible pair, augment it. Lemma 2.6 shows this reduces Φ by one, so by induction we are done. Now Lemma 2.8 shows we can assume H contains two subgraphs that are rooted dags, one spanning $B^+ \cup W^-$ and the other spanning $W^+ \cup B^-$. We consider two cases that, using directional symmetry, cover all possibilities.

Case 1. $|W^+| = |W^-| = 1$.

Lemma 2.8 shows $B^+, B^- \neq \emptyset$. Hence $\Phi = |B^+| + |B^-|$. Add an edge from each black sink to the unique white sink. The resulting graph has a unique sink, $1 + |B^+|$ sources, and $\Phi = 1 + |B^+|$. Hence Lemma 2.3 implies H has $OPT \leq \Phi + 1$.

Case 2. $|W^+| = |B^+| = 1$ and $|W^-|, |B^-| > 1$.

We show $OPT = \Phi$ in this case. Observe that $\Phi = |V^-|$. Take distinct vertices $w^+ \in W^+$, $b^+ \in B^+$, $w_1^-, w_2^- \in W^-$, $b_1^-, b_2^- \in B^-$. Add edges (w_1^-, b_1^-), (b_1^-, w^+) and let K be the new strong component graph. The two new edges decrease $|V^-|$ by two (since w^+ precedes the sink b_2^-). K is a rooted dag with unique source b^+. Since K has a white sink w_2^-, K has $\Phi = |V^-|$. Lemma 2.3 implies $OPT = \Phi$ for both K and H.

Now we show that a dag H that is not bicolored reduces to the bicolored case. First suppose $\Phi > |B^+| + |B^-|$ for every $B \in \mathcal{P}$. Lemma 2.8 shows a compatible pair exists, so augment it. Lemma 2.6 and the assumption on Φ show this decreases Φ by

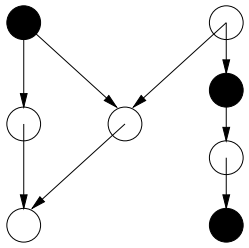

FIG. 3.1. *A* 1*-blocker for* B*. Black and white vertices are in* B *and* W*, respectively.*

1. Repeat this as many times as possible until the graph becomes bicolored, rooted, or $\Phi = |B^+| + |B^-|$ for some $B \in \mathcal{P}$. It remains only to analyze this last case.

Suppose $\Phi = |B^+| + |B^-|$. Let K be the same dag using just two colors, B and $\overline{B}$. This does not change Φ, i.e., $\Phi \geq |\overline{B}^+| + |\overline{B}^-|$, since $2\Phi \geq |V^+| + |V^-| = |B^+|+|B^-|+|\overline{B}^+|+|\overline{B}^-| = \Phi+|\overline{B}^+|+|\overline{B}^-|$. Since K is bicolored it has $OPT \leq \Phi+1$. Any solution to the augmentation problem on K is a valid solution on H. Hence $OPT \leq \Phi + 1$ for H. □

COROLLARY 2.10. *Any bicolored dag with* $\Phi > |B^+| + |B^-|$ *for every* $B \in \mathcal{P}$ *has* $OPT = \Phi$*.*

Proof. Apply the above argument. An augment decreases all four quantities that define Φ, by Lemma 2.6. Hence it preserves the inequality of the lemma, and the given dag eventually becomes rooted or satisfies Case 2 (or its directionally symmetric version). □

This result is generalized by Lemma 3.5.

3. Bicolored dags. Our solution to the augmentation problem works by reducing the graph to one of the simple families analyzed in section 2 or to a bicolored dag. This section gives the key part of the argument for bicolored dags. We have already seen that for such graphs $OPT = \Phi$ unless Φ is the number of extreme vertices in some color (Corollary 2.10). Hence we will complete the analysis of bicolored dags by considering two cases,

$$\Phi = |B^+| + |B^-| > |W^+| + |W^-|;$$

$$\Phi = |B^+| + |B^-| = |W^+| + |W^-|.$$

In both cases it is possible to have $OPT = \Phi + 1$. This occurs precisely when the graph is what we call a 1-blocker. This section proves that a bicolored graph that is not a 1-blocker has $OPT = \Phi$ (Lemma 3.4). Blockers are discussed in section 4.

The following definition of 1-blocker applies to graphs in general, not necessarily bicolored. Recall the function R^- introduced at the start of section 2.

DEFINITION 3.1. *A dag is a* 1-blocker *if for some color* B, (i) $\Phi = |B^+| + |B^-|$; (ii) $B^+, \overline{B}^+ \neq \emptyset$; (iii) $R^-(B) \subseteq \overline{B}$.

Figure 3.1 illustrates a 1-blocker. In a bicolored graph we can replace $\overline{B}$ by W in Definition 3.1. As mentioned a 1-blocker always has $OPT > \Phi$. This fact is not needed in this section and is proved in Lemma 4.3.

LEMMA 3.2. *A bicolored dag with* $\Phi = |B^+|+|B^-| > |W^+|+|W^-|$ *has* $OPT = \Phi$ *unless the dag is a* 1*-blocker.*

Proof. If $B^+ = \emptyset$, then $|B^-| = \Phi \geq |V^-|$ implies $V^- \subseteq B$. Hence the graph H is consistently colored and Lemma 2.7 shows $OPT = \Phi$. So by directional symmetry assume $B^+, B^- \neq \emptyset$.

Assume H is not a 1-blocker. This implies $r(B)$. In proof, we can assume $W^+ \neq \emptyset$, since otherwise $V^+ \subseteq B$ and $B^- \neq \emptyset$ imply $r(B)$. Now since H is not a 1-blocker condition (iii) fails, which means $r(B)$.

Choose two vertices $b^+ \in B^+$ and $b^- \in B^-$ with $r(b^+, b^-)$ and call them *witnesses*. Say that a pair of vertices x^-, y^+ is *witness-compatible* if it is compatible and in addition, for x^+ and y^- as in Definition 2.4, $x^- = b^-$ implies $y^- \in B$, and $y^+ = b^+$ implies $x^+ \in B$.

Assume $V^+ - b^+$, $V^- - b^- \neq \emptyset$, since otherwise H is rooted and Lemma 2.3 shows we are done. These two sets together contain a white extreme vertex, since otherwise all extremes are black and Lemma 2.2 shows we are done. The two sets contain a black extreme vertex, by the lemma's hypothesis on Φ. Hence without loss of generality assume there are vertices $y^+ \in W^+$ and $y^- \in B^- - b^-$. Observe that there exists a witness-compatible pair: If $r(y^+, y^-)$, then b^-, y^+ is witness-compatible. If $\neg r(y^+, y^-)$, then y^-, y^+ is witness-compatible.

Call the witness-compatible pair x^-, y^+ and augment it. Lemma 2.6 shows the augment decreases Φ by 1 and the resulting dag K satisfies the hypothesis of the lemma on Φ. K is not a 1-blocker because (iii) fails, i.e., K has two witnesses. This is clear if neither b^+ nor b^- is involved in the augment. If $x^- = b^-$, then K has source b^+ and sink y^-, both black with $r(b^+, y^-)$. Similarly if $y^+ = b^+$, then $r(x^+, b^-)$.

Now the lemma follows by applying induction to K. □

LEMMA 3.3. *A bicolored dag with* $\Phi = |B^+| + |B^-| = |W^+| + |W^-|$ *has* $OPT = \Phi$ *unless the dag is a* 1*-blocker.*

Proof. First observe that $\Phi = |V^+| = |V^-|$. In proof, the hypothesis on Φ implies $2\Phi \geq |V^+| + |V^-| = (|B^+| + |B^-|) + (|W^+| + |W^-|) = 2\Phi$. Thus equality holds throughout and $\Phi = |V^+| = |V^-|$.

If $B^+ = \emptyset$, then $\Phi = |V^-| = |B^-|$ so $V^- \subseteq B$. The graph H is consistently colored and Lemma 2.7 shows $OPT = \Phi$. Hence by symmetry assume $B^+, W^+ \neq \emptyset$. Also assume H is not a 1-blocker, i.e., $r(B)$ and $r(W)$.

Choose as witnesses four vertices $b^+ \in B^+$, $b^- \in B^-$, $w^+ \in W^+$, $w^- \in W^-$ where $r(b^+, b^-)$ and $r(w^+, w^-)$. Say that a pair of vertices x^-, y^+ is *witness-compatible* if it is compatible and in addition, for x^+ and y^- as in Definition 2.4, y^- has the same color as x^- if x^- is a witness, and x^+ has the same color as y^+ if y^+ is a witness.

If the four witnesses are not the only extreme vertices, then H has a witness-compatible pair. In proof, without loss of generality assume there is another source $y^+ \in W^+ - w^+$. Since $\Phi = |V^+| = |V^-| = |B^+| + |B^-|$ there is a sink $y^- \in B^- - b^-$. If $r(y^+, y^-)$, then b^-, y^+ is witness-compatible. If $\neg r(y^+, y^-)$, then y^-, y^+ is witness-compatible.

Augment the witness-compatible pair. This decreases Φ by 1 and the resulting dag satisfies the hypothesis of the lemma and is not a 1-blocker. This is proved by the same argument as Lemma 3.2 (even when x^- and y^+ are both witnesses).

Now we can assume by induction that the four witnesses are the only extremes. Augment b^-, w^+ to reduce Φ from 2 to 1. Lemma 2.3 completes the argument. □

Corollary 2.10 and Lemmas 3.2 and 3.3 give the following.

LEMMA 3.4. *A bicolored dag has* $OPT = \Phi$ *unless it is a* 1*-blocker.* □

We extend part of this analysis to arbitrarily colored dags as follows.

LEMMA 3.5. *An arbitrarily colored dag* H *with* $\Phi = |V^-| > |V^+|, |B^+| + |B^-|$ *for every* $B \in \mathcal{P}$ *has* $OPT = \Phi$.

Proof. Assume H is not rooted or bicolored by Lemma 2.3 and Corollary 2.10. Lemma 2.8 shows there is a compatible pair. We will show how to augment a com-

patible pair so that Φ decreases by one, and the new graph either has $OPT = \Phi$ or continues to satisfy the inequality of the lemma. By induction this completes the proof. Call a color B *big* if $|B^+| + |B^-| = \Phi - 1$.

Suppose a given compatible pair contains a vertex from every big color. Augment it. This decreases $|V^-|$ and $|V^+|$ each by 1, so Φ decreases by 1. Furthermore the inequality of the lemma is preserved. Hence we can assume that no compatible pair contains a vertex from every big color.

Suppose there are two (or more) big colors, say, B and W. Since H has fewer than 2Φ extreme vertices and is not bicolored, exactly one extreme vertex g is in $B \cup W$. By symmetry let g be a source. Without loss of generality g precedes a black sink. Change the color of g to black. This does not change Φ. The resulting bicolored graph is not a 1-blocker since $r(B)$ and W has fewer than Φ extremes. Hence Lemma 3.4 gives the desired conclusion.

We can now assume there is a unique big color B and no compatible pair contains a vertex of B. Take a compatible pair x^-, y^+. Every vertex of B^+ is incompatible with x^- and so precedes x^-. Similarly every vertex of B^- is preceded by y^+. B^+ and B^- are both nonempty. (This follows since $\Phi = |V^-| > |V^+| \geq 2$ implies that B has at least two extremes. If all these extremes are sources (sinks), then some compatible pair involves B by Lemma 2.5.) Now augment the pair x^-, y^+. This decreases Φ by 1 and makes $\Phi = |B^+| + |B^-|$. Also the new graph K has $r(B)$. Take B and $\overline{B}$ as the two colors of K. $\overline{B}$ has less than Φ extreme vertices, since H has $2\Phi > |V^+| + |V^-|$. We conclude that K is bicolored and is not a 1-blocker. A solution using $OPT = \Phi$ new edges on K gives a similar solution on H. □

To summarize the argument up to this point, we have shown how to augment a bicolored dag that is not a 1-blocker by adding Φ new edges. This does not solve even the bipartite strong-connectivity augmentation problem, since our reduction to the dag problem can create new (singleton) colors. We solve the augmentation problem by following the strategy of Lemma 3.5, i.e., we attempt to recolor vertices to get a bicolored dag with the same value of Φ that is not a 1-blocker. Successful recoloring can be blocked by 1-blockers as well as several other families, all of which we call blockers. The next section studies blockers. Then section 5 executes our recoloring strategy to solve the bipartite problem, and sections 6 and 7 do the same for the general problem.

4. Blockers. This section defines blockers and shows they have $OPT > \Phi$ (Lemma 4.3). It also completes the solution of our augmentation problem in another major case (Lemma 4.5).

We define blockers for arbitrarily colored dags. The four types of blockers are illustrated in Figure 4.1. For convenience we repeat Definition 3.1 for 1-blockers here.

DEFINITION 4.1. *A dag is a* blocker *if it is a* 1-, 2-, 3-, *or* 4-*blocker as defined by the conditions below. In these conditions B and W denote two distinct colors.*

A 1-blocker *has*

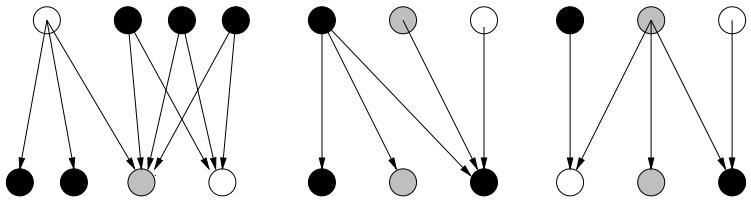
(i) $\Phi = |B^+| + |B^-|$;
(ii) $B^+, \overline{B}^+ \neq \emptyset$;
(iii) $R^-(B) \subseteq \overline{B}$.

The remaining blockers have the same first condition:

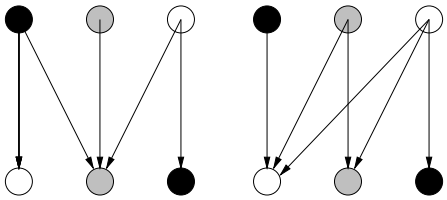
(i) $\Phi = |V^+| = |V^-|$.

A 2-blocker *has*

(ii) $B^+, \overline{B}^+ \neq \emptyset$;
(iii) $R^-(\overline{B}) \subseteq B$.



(a) 1-blocker for B. (b) 2-blocker for B. (c) 3^+-blocker for B, W.



(d) 3^--blocker for B, W. (e) 4-blocker for B, W.

FIG. 4.1. *Simple examples of blockers. Black, white, and shaded vertices are in B, W, and $V - B - W$, respectively.*

A 3-blocker *is a* 3^+*-blocker or a* 3^-*-blocker, where a* 3^+-blocker *has*

(ii) $B^+, W^+ \neq \emptyset$;

(iii) $R^-(B) \subseteq W$, $R^-(W) \subseteq B$, $|V^+ - B - W| = 1$;

and a 3^--blocker *satisfies the reverse conditions*

(ii) $B^-, W^- \neq \emptyset$;

(iii) $R^+(B) \subseteq W$, $R^+(W) \subseteq B$, $|V^- - B - W| = 1$.

A 4-blocker *has*

(ii) $B^+, B^- \neq \emptyset$;

(iii) $R^-(B) \cup R^+(B) \subseteq W$, $|B^+| + |B^-| = \Phi - 1$.

The five varieties of blockers (differentiating between 3^+ and 3^-) are distinct. For instance, each blocker in Figure 4.1 satisfies only one set of blocker conditions.

The *reachability conditions* of a blocker are the containment relations in condition (iii). We specify the color classes associated with a blocker by saying a 1- *or* 2-*blocker for* B, or a 3- *or* 4-*blocker for* B, W. A *blocker for* B *(*B, W*)* is a 1- or 2-blocker for B, or a 3- or 4-blocker for B, W. The roles of B and W are asymmetric in a 4-blocker for B, W. We say a 4-*blocker for* B if we do not wish to refer to the second color W. We say a 3^+- *(*3^-*-) blocker for* z if z is the (unique) vertex of $V^+ - B - W$ ($V^- - B - W$).

LEMMA 4.2. *The reverse graph of a blocker is a blocker of the same type* $(1, 2, 3,$ *or* $4)$*. Furthermore the reverse graph of a* 3^+*-blocker (*3^-*-blocker) is a* 3^-*-blocker (*3^+*-blocker).*

Proof. The lemma is obvious except for 1- and 2-blockers. For these we use two simple properties of the reachability functions: Consider any two sets of vertices X and Y in H. The set $R^+(X)$ ($R^-(X)$) in H is equal to the set $R^-(X)$ ($R^+(X)$) in the reverse graph. In H, $R^-(X) \subseteq Y$ if and only if $R^+(\overline{Y}) \subseteq \overline{X}$. Now we consider the two types of blockers.

1-*blocker.* The reachability condition $R^-(B) \subseteq \overline{B}$ is equivalent to $R^+(B) \subseteq \overline{B}$,

which in the reverse graph is the reachability condition $R^-(B) \subseteq \overline{B}$. Next we verify condition (ii) in the reverse graph. Conditions (ii) and (iii) in H imply $\overline{B}^- \neq \emptyset$. Conditions (i) and (ii) imply $|B^+| + |B^-| = \Phi \geq |V^+| > |B^+|$, so $B^- \neq \emptyset$.

2-*blocker.* The argument is similar: The reachability condition $R^-(\overline{B}) \subseteq B$ is equivalent to $R^+(\overline{B}) \subseteq B$, which in the reverse graph is the reachability condition $R^-(\overline{B}) \subseteq B$. For condition (ii) in the reverse graph, conditions (ii) and (iii) in H imply $B^- \neq \emptyset$. Conditions (i) and (ii) imply $|V^-| = \Phi \geq |B^+| + |B^-| > |B^-|$, so $\overline{B}^- \neq \emptyset$. □

LEMMA 4.3. *Any blocker has* $OPT > \Phi$.

Proof. We consider each of the four types of blockers in turn.

1-*blocker.* Let X be the set of all vertices preceded by a vertex of B^+. X is a nonempty proper subset of V, since $B^+ \subseteq X$ and $X \cap \overline{B}^+ = \emptyset$. Hence some new edge e leaves X. If $OPT = \Phi = |B^+| + |B^-|$, then every new edge either leaves a black sink or enters a black source, so e either leaves a black sink of X or enters a black source of $\overline{X}$. Such a sink does not exist since $R^-(B) \subseteq \overline{B}$, and such a source does not exist since $B^+ \subseteq X$. We conclude $OPT > \Phi$.

We give a similar argument for each of the remaining blockers. They all have $\Phi = |V^+| = |V^-|$. We will assume that $OPT = \Phi$. This implies every new edge must leave a sink and enter a source. For each blocker we will derive a contradiction.

2-*blocker.* Let X be the set of all vertices preceded by a vertex of $\overline{B}^+$. X is a nonempty proper subset of V, since $\overline{B}^+ \subseteq X$ and $X \cap B^+ = \emptyset$. Hence some new edge e leaves X, i.e., it leaves a sink of X and enters a source of $\overline{X}$. Every sink of X is black since $R^-(\overline{B}) \subseteq B$, and every source of $\overline{X}$ is black since $\overline{B}^+ \subseteq X$. Hence e joins two black vertices. This contradiction shows $OPT > \Phi$.

3-*blocker.* Let H be a 3^+-blocker for B, W and vertex z. Let X be the set of all vertices preceded by a vertex of B^+. X is a nonempty proper subset of V, since $B^+ \subseteq X$ and $z \notin X$. Hence some new edge e leaves X, i.e., it leaves a sink of X and enters a source of $\overline{X}$. The sink of X is white since $R^-(B) \subseteq W$. This implies the source of $\overline{X}$ is z, since $B^+ \subseteq X$. We conclude e is directed from a white sink to z. A similar argument shows that a new edge e' is directed from a black sink to z. Clearly $e \neq e'$. This gives the desired contradiction, since $OPT = \Phi$ implies at most one new edge is directed to z.

If H is a 3^--blocker, the lemma follows from the previous argument with Lemma 4.2.

4-*blocker.* Let X be the set of all vertices preceded by a vertex of B^+. X is a nonempty proper subset of V, since $B^+ \subseteq X$ and $X \cap B^- = \emptyset$. (The latter holds since $R^-(B) \subseteq W$.) Hence a new edge e leaves X. The condition $R^-(B) \subseteq W$ implies e goes from a white sink to a nonblack source.

The same argument on the reverse graph shows a new edge e' goes from a nonblack sink to a white source. A new edge cannot join two white vertices so $e' \neq e$. Thus we have two new edges, neither incident to a black vertex. But $|B^+| + |B^-| = \Phi - 1 = OPT - 1$ implies there is at most one such new edge. □

The next lemma is needed only for the general case of our theorem in sections 6 and 7. Call a dag a *proper* i*-blocker* if it is an i-blocker and in addition, for i equal to 3 or 4, it is not also a 1- or 2-blocker. Note that Lemma 4.2 implies the reverse of a proper i-blocker is a proper i-blocker.

LEMMA 4.4. *A* 3- *or* 4-*blocker for* B, W *has* $r(\overline{B \cup W})$ *if it is proper.*

Proof. Consider a proper 3-blocker H. Lemma 4.2 implies we can assume H is a 3^+-blocker. We claim $\overline{B \cup W}$ contains a sink. This claim establishes the lemma

for 3^+-blockers, since any source that precedes such a sink must be in $\overline{B \cup W}$ by the reachability conditions of a 3^+-blocker.

To prove the claim note that $\Phi > |B^+| + |B^-|, |W^+| + |W^-|$ since H is not a 1-blocker. Since a 3^+-blocker has 2Φ extremes, this implies at least two extremes are not in $B \cup W$. The definition of 3^+-blocker shows at least one sink is not in $B \cup W$.

Suppose H is a proper 4-blocker. Since H is not a 2-blocker and $B^+, W^+ \neq \emptyset$, $R^-(\overline{W}) \not\subseteq W$. So let x be a source of $\overline{W}$ that precedes a sink y of $\overline{W}$. The reachability conditions of a 4-blocker show $x, y \notin B$. Thus x and y are the desired vertices. □

We conclude this section by analyzing another type of arbitrarily colored dag.

LEMMA 4.5. *An arbitrarily colored dag H with $\Phi = |B^+| + |B^-|$ for some $B \in \mathcal{P}$ has $OPT = \Phi$ unless H is a* 1- *or* 2*-blocker.*

Proof. Let K be the given dag H with color classes taken to be B and $\overline{B}$. As shown at the end of Lemma 2.9, K has the same value of Φ as H and a solution on K is valid on H. Lemma 3.4 shows K has $OPT = \Phi$ unless K is a 1-blocker. If K is a 1-blocker for B, then so is H. Suppose K is a 1-blocker for $\overline{B}$. Thus $\Phi = |\overline{B}^+| + |\overline{B}^-|$. Hence $|V^+| + |V^-| = |B^+| + |B^-| + |\overline{B}^+| + |\overline{B}^-| = 2\Phi \geq |V^+| + |V^-|$, where we have used $\Phi \geq |V^+|,\ |V^-|$. We conclude equality holds, i.e., $\Phi = |V^+| = |V^-|$. This plus $R^-(\overline{B}) \subseteq B$ shows H is a 2-blocker for B. □

Lemma 4.5, Lemma 3.5, and symmetry leave only one case to complete the analysis of arbitrarily colored dags,

$$\Phi = |V^-| = |V^+| > |B^+| + |B^-| \text{ for every } B \in \mathcal{P}.$$

The next section analyzes this last case for the dags that arise in bipartite strong-connectivity augmentation. Sections 6 and 7 do the same for general augmentation.

5. Bipartite augmentation theorem. Consider the bipartite strong-connectivity augmentation problem. The reduction of section 2 transforms a given bipartite digraph into a dag H whose nonsingleton vertices have only two colors. We call such a dag *core-bicolored*. This section gives the analysis of the last case mentioned above for core-bicolored dags (Lemma 5.2). This completes the solution to the bipartite strong connectivity augmentation problem and the cable-framework rigidity problem. A dag is *core-bicolored for B, W* if every vertex not colored B or W is a singleton.

LEMMA 5.1. *A core-bicolored dag for B, W is consistently colored if it is not a blocker but it satisfies conditions* (i) *and* (iii) *of a blocker for B (B, W).*

Proof. Let H be a dag satisfying the hypotheses of the lemma. We consider each of the five varieties of blockers in turn. For each variety we assume H satisfies conditions (i) and (iii) of that blocker for B (or B, W), and we show H is consistently colored.

1-*blocker.* If $\overline{B}^+ = \emptyset$, then $V^+ \subseteq B$ and condition (iii) implies $V^- = R^-(V) = R^-(B) \subseteq \overline{B}$. Thus H is consistently colored. If $B^+ = \emptyset$, then $\Phi = |B^+| + |B^-| \geq |V^-|$ implies $V^- \subseteq B$. Again H is consistently colored.

2-*blocker.* If $B^+ = \emptyset$, then $V^+ \subseteq \overline{B}$ and (iii) implies $V^- = R^-(V) = R^-(\overline{B}) \subseteq B$. Hence H is consistently colored. If $\overline{B}^+ = \emptyset$, then $V^+ \subseteq B$. Thus $|B^+| + |B^-| \geq |V^+| = \Phi$ so equality holds, and $B^- = \emptyset$. Thus H is consistently colored.

3^+-*blocker.* Without loss of generality assume $W^+ = \emptyset$. With (iii) this shows $|B^+| = |V^+| - 1$. We can assume $B^+, B^- \neq \emptyset$ since otherwise H is consistently colored. Now (i) implies $\Phi = |B^+| + |B^-|$. In fact H is a 1-blocker for B, a contradiction.

3^--*blocker.* The reverse graph satisfies the hypotheses of the lemma for a 3^+-blocker (Lemma 4.2), so the previous argument applies.

4-*blocker.* Suppose $B^- = \emptyset$. Conditions (i) and (iii) imply there are $|V^+|-1$ black sources. We can assume $W^+, W^- \neq \emptyset$ since otherwise H is consistently-colored. Now H is a 2-blocker for W, a contradiction.

If $B^+ = \emptyset$, then using Lemma 4.2 the previous argument applies to the reverse graph. □

LEMMA 5.2. *If H is core-bicolored and $\Phi = |V^+| = |V^-| > |B^+|+|B^-|$ for every $B \in \mathcal{P}$, then $OPT = \Phi$ unless H is a blocker.*

Proof. Let H be core-bicolored for B, W. Let $G = V - B - W$, so every vertex of G is a singleton. Assume H is not a blocker. Lemma 2.7 shows we can assume H is not consistently colored. Lemma 5.1 implies condition (iii) of a 2-, 3-, or 4-blocker for B (B, W) fails. Define the sets

$$\mathcal{W} = \{(x^+, x^-) \in \overline{B}^+ \times \overline{B}^- : r(x^+, x^-)\};$$
$$\mathcal{B} = \{(x^+, x^-) \in \overline{W}^+ \times \overline{W}^- : r(x^+, x^-)\}.$$

We establish the properties of these sets in four claims.

Claim 1. $\mathcal{W}, \mathcal{B} \neq \emptyset$.

Proof. $\mathcal{W} \neq \emptyset$ since condition (iii) of a 2-blocker for B fails. □

Claim 2. No vertex is common to every ordered pair of $\mathcal{W} \cup \mathcal{B}$.

Proof. A common vertex z must belong to G. If $z \in G^+$, then $R^-(B) \subseteq W$, $R^-(W) \subseteq B$, and $G^+ = \{z\}$. We have deduced condition (iii) of a 3^+-blocker for B, W, a contradiction. A symmetric argument holds if $z \in G^-$. □

Claim 3. $\mathcal{W} \cup \mathcal{B}$ contains two ordered pairs that do not contain a common vertex.

Proof. Take any pair $(x^+, x^-) \in \mathcal{W} \cup \mathcal{B}$. Since x^+ is not in every pair of $\mathcal{W} \cup \mathcal{B}$, there is a pair containing some $y^+ \in V^+ - x^+$. The pair must be (y^+, x^-), else we are done. Similarly there is a pair (x^+, y^-) with $y^- \in V^- - x^-$. Pairs (y^+, x^-) and (x^+, y^-) have no common vertex. □

Claim 4. Some ordered pair in $\mathcal{W}$ and some ordered pair in $\mathcal{B}$ do not contain a common vertex.

Proof. Assume Claim 4 fails. Claim 3 shows there are ordered pairs (x^+, x^-), (y^+, y^-) with all four vertices distinct, so by symmetry assume both pairs belong to $\mathcal{W} - \mathcal{B}$. Claim 1 shows $\mathcal{B}$ has a pair, which must have a vertex in common with both (x^+, x^-) and (y^+, y^-). Hence assume $(x^+, y^-) \in \mathcal{B}$. This makes

$$x^+, y^- \in G, \quad x^-, y^+ \in W.$$

It is now clear that $\mathcal{B} = \{(x^+, y^-)\}$. This implies $R^-(B) \cup R^+(B) \subseteq W$.

Next we show $G = \{x^+, y^-\}$. Suppose there is a vertex $g^+ \in G^+ - x^+$. Let g^+ precede a sink z^-. Since $(g^+, z^-) \notin \mathcal{B}$, $z^- \in W$. We have $z^- \neq y^-$, $(g^+, z^-) \in \mathcal{W}$ and $(x^+, y^-) \in \mathcal{B}$, contradicting the failure of Case 4. A symmetric argument applies to a vertex $g^- \in G^- - y^-$.

Since $|G^+| + |G^-| = 2$, the hypothesis of the lemma implies $|B^+| + |B^-| = |W^+| + |W^-| = |V^+| - 1$. Hence condition (iii) of a 4-blocker for B, W is satisfied, a contradiction. □

By Claim 4, take $(x^+, x^-) \in \mathcal{B}$ and $(y^+, y^-) \in \mathcal{W}$ with all four vertices distinct. Recolor the vertices of G to B or W so $x^+, x^- \in B$, $y^+, y^- \in W$, and, if possible, $|V^+| \geq |B^+| + |B^-|, |W^+| + |W^-|$. If possible, this recoloring gives a bicolored graph K that has the same value of Φ and is not a 1-blocker. Hence Lemma 3.4 shows K has $OPT = \Phi$. The solution to the augmentation problem on K is valid on H and shows H has $OPT = \Phi$.

If the recoloring is impossible, the inequality hypothesized in the lemma and symmetry imply $x^+, x^- \in G$ and $|V^+| - 1 = |B^+| + |B^-|$. Since condition (iii) of a 4-blocker fails, $R^-(B) \cup R^+(B) \not\subseteq W$. Thus $\mathcal{B}$ contains a pair (z^+, z^-) with at least one black vertex.

Suppose the pairs $(z^+, z^-) \in \mathcal{B}$ and $(y^+, y^-) \in \mathcal{W}$ have all four vertices distinct. Use these pairs in the above recoloring procedure. The procedure succeeds and shows $OPT = \Phi$. To prove this note the procedure fails only if $y^+, y^- \in G$ and $|V^+| - 1 = |W^+| + |W^-|$. But this implies the contradiction $2|V^+| = |V^+| + |V^-| = (|B^+| + |B^-|) + (|W^+| + |W^-|) + (|G^+| + |G^-|) \geq 2(|V^+| - 1) + 4$.

Finally suppose vertices z^+, z^-, y^+, y^- are not all distinct. The unique common vertex belongs to G. This makes vertices z^+, z^-, x^+, x^- distinct. Furthermore $|W^+| + |W^-| \leq |V^+| - 2$, since $|B^+| + |B^-| = |V^+| - 1$ and $|G^+| + |G^-| \geq 3$. Thus we can use the pairs $(z^+, z^-) \in \mathcal{B}$ and $(x^+, x^-) \in \mathcal{W}$ in the recoloring procedure to show $OPT = \Phi$. □

We now put together the various results that solve the bipartite strong connectivity augmentation and cable-framework rigidity problems.

LEMMA 5.3. *Any core-bicolored dag has $OPT = \Phi$ unless it is a blocker, in which case $OPT = \Phi + 1$.*

Proof. If H is a blocker, then $OPT = \Phi + 1$ by Lemmas 4.3 and 2.9. If H is not a blocker, then $OPT = \Phi$ by Lemmas 4.5, 3.5, and 5.2.

Finally recall that we assumed the graph H has no isolated vertices. If there are isolated vertices, we use the transformation of Proposition 2.1. The transformed graph is a blocker if and only if the original graph is a blocker. This follows from the observation that the transformation does not change any of the colors appearing in any set $R^-(X)$, $R^+(X)$. □

6. Merging colors. The general case of our theorem is proved in two steps, presented in this section and the next. This section reduces the number of colors to at most three, i.e., a tricolored dag (Lemma 6.2). The next section completes the proof by analyzing tricolored dags.

We reduce the number of colors by merging colors. To *merge* color classes C_i, $i = 1, \ldots, k$, means to replace them by a new color $\bigcup_1^k C_i$ in $\mathcal{P}$. Throughout this section assume H is the given graph with partition $\mathcal{P}$, where $\mathcal{P}$ contains at least four nonempty color classes.

We start with two observations that follow easily from the definition of blocker. First, if H is not a blocker and a merge does not change Φ but results in a blocker for color B or colors B, W, then B or W is not a class of $\mathcal{P}$. Second, if a color class with no extreme vertices is merged with any other color, the new graph is an i-blocker if and only if the original graph is. In particular we can assume every color of $\mathcal{P}$ contains an extreme vertex.

We avoid creating blockers of certain types by using witnesses analogous to those used in Lemmas 3.2 and 3.3. The following lemma gathers together some useful facts for establishing witnesses.

LEMMA 6.1. *Let H be a blocker with exactly three colors C_i, $i = 1, 2, 3$.*

(i) *Suppose $r(C_i)$ for $i = 1, 2$. Then H is a 1- or 4-blocker for C_3.*

(ii) *Suppose $r(C_1)$, $r(C_2, C_3)$ and either $r(C_1, C_3)$ and $|C_1^+| > 1$ or $r(C_3, C_1)$ and $|C_1^-| > 1$. Then H is a 1-blocker for C_2 or C_3, or a 4-blocker for C_2.*

Proof. First consider an arbitrary dag having a color C with $r(C)$. The definition of blocker shows that H is not a 1-, 3-, or 4-blocker for C. If H is a 2-blocker, it is a 2-blocker for C.

Part (i) follows by applying the above observation. We turn to part (ii). If H is a 2-blocker, the above observation shows it is a 2-blocker for C_1, but $r(C_2, C_3)$ makes this impossible. If H is a 3^+-blocker, say, for vertex z, then $z \in C_1$ (since $r(C_1)$). But this implies $|C_1^+| = 1$ and $\neg r(C_3, C_1)$, contradicting the hypothesis. Similarly if H is a 3^--blocker for z, then $z \in C_1$. But this implies $|C_1^-| = 1$ and $\neg r(C_1, C_3)$, contradicting the hypothesis. H is not a 4-blocker for C_1 by the preliminary observation. Suppose H is a 4-blocker for C_3. The other color of the blocker must be C_2 since $r(C_2, C_3)$, but it must be C_1 since $r(C_1, C_3)$ or $r(C_3, C_1)$. This contradiction gives part (ii). □

LEMMA 6.2. *If a graph H has $|\mathcal{P}| \geq 4$, then some merge gives a new graph with the same value of Φ and $|\mathcal{P}| = 3$. Furthermore the new graph is a blocker only if H is.*

Proof. Call a merge of $\mathcal{P}$ into three classes *permissible* if it does not change Φ. A permissible merge can be found by repeatedly merging two color classes until a merge of classes C_1 and C_2 would produce a class with at least Φ extreme vertices. Then the desired permissible merge consists of classes C_1, C_2, and $\overline{C_1 \cup C_2}$.

For the rest of the argument assume H is not a blocker. We must show some permissible merge gives a graph that is not a blocker. Order the blocker types as 2, 1, 3, 4. We will consider the blockers in this order. For each type i, we suppose K is an i-blocker that results from a permissible merge of H. We will construct a new permissible merge of H which results in a graph L. We will show that L is not a blocker of type i or a type listed before i. Repeated application of this argument eventually gives the desired merge.

2- and 1-blockers.

Claim. Let V be the disjoint union of X and Y, where X and Y are both the result of a merge. Suppose further that $R^-(X) \subseteq Y$ and $X^+, X^- \neq \emptyset$. Then X (Y) can be partitioned into disjoint sets X_i (Y_i), $i = 0, 1$, where each X_i (Y_i) is the result of merging classes of $\mathcal{P}$ contained in X (Y), such that $r(X_i \cup Y_i)$ for $i = 0, 1$.

Proof. Start by choosing $X_0 \subseteq X$ as a class of $\mathcal{P}$ containing a source. Take $Y_0 \subseteq Y$ as a class of $\mathcal{P}$ containing a sink preceded by X_0^+. Let X_1 and Y_1 consist of the remaining classes of $\mathcal{P}$ contained in X (Y). If $r(X_1 \cup Y_1)$, we are done. Hence assume the opposite:

$$R^-(X_1) \subseteq Y_0 \text{ and } R^-(Y_1) \subseteq X_0 \cup Y_0.$$

We will prove $r(X_0 \cup Y_1)$ and $r(X_1 \cup Y_0)$. Clearly this implies the claim.

The first relation $r(X_0 \cup Y_1)$ holds if $r(Y_1, X_0)$, so suppose the opposite. This implies $R^-(Y_1) \subseteq Y_0$. Next note that $Y_0^+ \neq \emptyset$. This follows since $X^- \neq \emptyset$, so a sink in X is preceded by a source of Y, and that source cannot be in Y_1. Now since H is not a 2-blocker for Y_0, $R^-(X_0) \not\subseteq Y_0$. Thus $r(X_0, Y_1)$. This implies the first relation.

Consider the second relation $r(X_1 \cup Y_0)$. If $X_1^+ \neq \emptyset$, then $r(X_1, Y_0)$. If $X_1^+ = \emptyset$, then $X_1^- \neq \emptyset$, which implies $r(Y_0, X_1)$. □

Now suppose K is a 2- or 1-blocker. First note that the claim applies to B and $\overline{B}$. (For a 2-blocker the claim requires $\overline{B}^- \neq \emptyset$. For a 1-blocker the claim requires $B^- \neq \emptyset$. Both of these are shown in the proof of Lemma 4.2.)

So let B $(\overline{B})$ be partitioned into sets A_i (C_i), $i = 0, 1$, where $r(A_i \cup C_i)$ for $i = 0, 1$. For at least one index i, $A_i \cup C_i$ contains at most Φ extreme vertices. Without loss of generality let the index be $i = 0$. Let the three new color classes be $A_0 \cup C_0$, A_1, and C_1.

The new graph L is not a 2-blocker. In proof $r(A_0 \cup C_0)$ implies L can only be a 2-blocker for $X = A_0 \cup C_0$. However, this is inconsistent with $r(\overline{X})$, i.e., $r(A_1 \cup C_1)$.

L is not a 1-blocker if K is a 1-blocker. In proof suppose L is a 1-blocker for color X. $X \neq A_0 \cup C_0$ because $r(A_0 \cup C_0)$. $X \neq A_1, C_1$ since $A_0 \cup A_1$ contains exactly Φ extreme vertices, so $C_0 \cup C_1$ contains at most Φ extreme vertices. This implies A_1 and C_1 both contain fewer than Φ extremes.

3^+-blockers. Suppose K is a proper 3^+-blocker for B, W.

Claim. Without loss of generality B can be partitioned into disjoint sets A_i, $i = 0, 1$, where each A_i is a merge of classes of $\mathcal{P}$, such that (i) $r(A_0, W)$, (ii) $r(A_1, W)$ or $r(W, A_1)$.

Proof. Suppose B contains at least two classes of $\mathcal{P}$. Let A_0 be a class of $\mathcal{P}$ contained in B that contains a source, and let A_1 consist of the remaining classes of $\mathcal{P}$ in B. Clearly property (i) holds. Suppose (ii) fails. Thus $A_1^+ = \emptyset$ and $\neg r(W, A_1)$. This means that K is a proper 3^+-blocker for A_0, W. W must contain at least two classes of $\mathcal{P}$ since H is not a blocker. Repeat the above argument on the set W instead of B. This time (ii) cannot fail, since that would make H a 3-blocker. □

Assume B, A_0, and A_1 satisfy the claim. Let $G = \overline{B \cup W}$. Either $A_0 \cup W$ or $A_1 \cup G$ contains at most Φ extreme vertices. Thus we get a permissible merging consisting of either colors $A_0 \cup W$, A_1, and G or A_0, W, and $A_1 \cup G$. Recall the relation $r(G)$ from Lemma 4.4. Also note that A_0, A_1, and W each have fewer than Φ extreme vertices, since both B and W contain fewer than Φ extremes in any proper 3-blocker for B, W.

Suppose the permissible merging is $A_0 \cup W$, A_1, and G. Lemma 6.1(i) with $r(A_0 \cup W)$ and $r(G)$ shows that if L is a blocker, it is a 1-blocker for A_1 or a 4-blocker. The former is impossible since, as noted, A_1 has fewer than Φ extreme vertices.

Suppose the permissible merging is $A_1 \cup G$, A_0, and W. These sets satisfy the hypothesis of Lemma 6.1(ii), since we have $r(A_1 \cup G)$, $r(A_0, W)$ and furthermore, either $r(A_1, W)$, in which case $A_1 \cup G$ has at least two sources, or $r(W, A_1)$, in which case $A_1 \cup G$ has at least two sinks. Now Lemma 6.1(ii) shows that if L is a blocker, it is either a 1-blocker for A_0 or W, or L is a 4-blocker. It is not a 1-blocker because, as noted above, both A_0 and W have fewer than Φ extreme vertices.

3^--blockers. Suppose K is a proper 3^--blocker. Lemma 4.2 shows its reverse graph is a proper 3^+-blocker. Apply the construction for proper 3^+-blockers to the reverse graph. If the new merging is a blocker, it must be a 4-blocker. The same holds for the original graph.

4-blockers. Suppose K is a proper 4-blocker. Let $X = B$, $Y = W$ if B contains two or more classes of $\mathcal{P}$; otherwise let $X = W$, $Y = B$. So X contains two or more classes of $\mathcal{P}$. Let $G = \overline{B \cup W} = \overline{X \cup Y}$.

Claim. X can be partitioned into disjoint sets A_i, $i = 0, 1$, where each A_i is a merge of classes of $\mathcal{P}$, such that $r(A_0, Y)$ and either $r(A_1, Y)$ or $r(Y, A_1)$. In addition A_0 and A_1 each contain fewer than $\Phi - 1$ extreme vertices. Furthermore $r(G)$.

Proof. The last part of the claim $r(G)$ holds by Lemma 4.4.

Suppose $X = B$. Let A_0 be a class of $\mathcal{P}$ contained in X that contains a source, and let A_1 consist of the remaining classes in B. Hence $r(A_0, W)$. Furthermore $r(A_1, W)$ or $r(W, A_1)$. In addition each A_i has fewer than $\Phi - 1$ extreme vertices since $A_i \subset B$.

Suppose $X = W$. Let A_0 be a class of $\mathcal{P}$ contained in W such that $r(A_0, B)$. Let A_1 consist of the remaining classes of $\mathcal{P}$ in W. We have $r(A_1, B)$ or $r(B, A_1)$, since

otherwise H is a 4-blocker for B, A_0 (both classes of $\mathcal{P}$). Each set A_i contains fewer than $2\Phi - (\Phi - 1) - 2 = \Phi - 1$ extreme vertices. □

Either $A_0 \cup Y$ or $A_1 \cup G$ contains at most Φ extreme vertices. Thus we get a permissible merging consisting of colors $A_0 \cup Y$, A_1, and G or A_0, Y, and $A_1 \cup G$.

Consider a permissible merging $A_0 \cup Y$, G, and A_1. These sets satisfy the hypothesis of Lemma 6.1(i). The new graph L is not a 1- or 4-blocker for A_1, since the claim shows A_1 has too few extreme vertices. Thus L is not a blocker.

Consider a permissible merging $A_1 \cup G$, A_0, and Y. These sets satisfy the hypothesis of Lemma 6.1(ii). L is not a 1- or 4-blocker for A_0, since the claim shows A_0 has too few extremes. Finally L is not a 1-blocker for Y, since Y is B or W and K is a proper 4-blocker. This proves Lemma 6.2. □

We finish this section with a simple result also proved by merging colors. The result can be seen from Lemma 5.3, but the following proof is independent of section 5.

LEMMA 6.3. *Let H be a tricolored dag with $\Phi = |V^+| = |V^-|$, where some color does not contain a source. Then $OPT = \Phi$ if H is not a blocker.*

Proof. Let the extreme vertex colors of H be B, W, and G, where $G^+ = \emptyset$. By Lemma 4.5 assume each color has fewer than Φ extreme vertices.

We can change the color of every extreme vertex of G to B or W without changing Φ. This follows since $2\Phi = |V^+| + |V^-|$, and we start with both B and W containing fewer than Φ extremes. In fact we can do this recoloring even with the requirement that a given vertex of G be colored B and another given vertex of G be colored W.

If every source has the same color, then $\Phi = |V^+|$ implies H is consistently colored. In this case $OPT = \Phi$ (Lemma 2.7). So assume $B^+, W^+ \neq \emptyset$. We can assume H is not a 2-blocker, so $r(\overline{B})$. This implies $r(W, \overline{B})$. Similarly $r(B, \overline{W})$.

G contains at least two sinks, since $|V^+| + |V^-| = 2\Phi \geq |B^+| + |B^-| + |W^+| + |W^-| + 2$. Now it is easy to see that there is a sink $w \in \overline{B}$ preceded by a source of W and a different sink $b \in \overline{W}$ preceded by a source of B.

If b is colored G, change it to B. If w is colored G, change it to W. Change the color of the remaining extreme vertices of G to B or W without changing Φ. The new bicolored graph is not a 1-blocker since $r(B)$ and $r(W)$. Lemma 3.4 shows it has a solution with $OPT = \Phi$ new edges, which gives a similar solution on H. □

7. General augmentation theorem. This section solves the augmentation problem for tricolored dags as follows. Section 7.1 presents various witness relations that allow us to avoid generating blockers, as in sections 3 and 6. Then section 7.2 shows how to find an augmenting pair that does not create a blocker.

We use the following notational conventions throughout this section. The three colors of the tricolored dag are designated as B, W, and G ("black," "white," and "gray"). Sources of $B, W, G, \overline{B}, \overline{W}, \overline{G}$ are usually designated by $b, w, g, \overline{b}, \overline{w}, \overline{g}$, respectively. Sinks of $B, W, G, \overline{B}, \overline{W}, \overline{G}$ are usually designated by $\beta, \omega, \gamma, \overline{\beta}, \overline{\omega}, \overline{\gamma}$, respectively.

7.1. Witness relations. We begin with some simple relations that preclude various blocker types.

LEMMA 7.1. *Let H be a tricolored blocker with colors B, W, G.*

(i) *$r(B)$ and $r(\overline{B})$ imply H is not a 2-blocker.*

(ii) *$r(\overline{B})$, $r(\overline{W})$, and $r(\overline{G})$ imply H is not a 2-blocker.*

(iii) *$r(B, W)$, $r(W, G)$, and $r(G, B)$ imply H is a 1-blocker.*

(iv) *Suppose*

$$r(\overline{b}, \omega), \ r(w, \beta), \text{ and } r(g, \gamma)$$

for $\overline{b} \in \overline{B}^+$, $\omega \in W^-$, $w \in W^+$, $\beta \in B^-$, $g \in G^+$, $\gamma \in G^-$, where the six vertices are distinct (i.e., $\overline{b} \neq w, g$). Then either H is a 1-blocker or H is a 4-blocker for B.

Proof. Parts (i) and (ii) follow from the definition of 2-blocker.

(iii) H is not a 2-blocker for B because $r(W, G)$. H is not a 3^+-blocker for B because $r(B, W)$ and $r(W, G)$. Similarly H is not a 3^--blocker for B because $r(G, B)$ and $r(W, G)$. H is not a 4-blocker for B because $r(B, W)$ and $r(G, B)$. Now symmetry of the colors gives the desired conclusion.

(iv) $r(g, \gamma)$ and $r(w, \beta)$ show H is not a 2-blocker. If H is a 3^+-blocker, then $r(g, \gamma)$ shows it is a 3^+-blocker for vertex g. Since $\overline{b} \neq g$ we must have $\overline{b} \in W$, but then $r(\overline{b}, \omega)$ shows H is not a 3^+-blocker. If H is a 3^--blocker, then $r(g, \gamma)$ shows it is a 3^--blocker for γ. But this is inconsistent with $r(\overline{b}, \omega)$. $r(g, \gamma)$ shows H is not a 4-blocker for G. $r(w, \beta)$ and $r(\overline{b}, \omega)$ show it is not a 4-blocker for W. □

Now we analyze the blocker types that can occur after augmenting a pair in some commonly occurring configurations.

COROLLARY 7.2. *Let H be a tricolored dag, with colors B, W, G, that is not a blocker.*

(i) *Suppose*

$$r(b, \chi), r(x, \beta), \text{ and } r(\overline{b}, \overline{\beta})$$

for six distinct vertices $b \in B^+$, $\chi \in V^-$, $x \in V^+$, $\beta \in B^-$, $\overline{b} \in \overline{B}^+$, $\overline{\beta} \in \overline{B}^-$, where χ and x have different colors. Augmenting the compatible pair χ, x does not give a 2-blocker.

(ii) *Suppose*

$$r(g, \gamma), r(w, \chi), \text{ and } r(x, \omega)$$

for six distinct vertices $g \in G^+$, $\gamma \in G^-$, $w \in W^+$, $\chi \in V^-$, $x \in V^+$, and $\omega \in W^-$, where χ and x have different colors. Augmenting the compatible pair χ, x gives either a nonblocker, a 1-blocker, or a 4-blocker for B. The latter cannot occur if $B - \{x, \chi\}$ has less than $\Phi - 2$ extremes.

(iii) *Suppose*

$$r(b, \omega),\ r(w, \beta),\ r(g, \gamma), \text{ and } r(\overline{b}, \overline{\beta})$$

for eight distinct vertices $b \in B^+$, $\omega \in W^-$, $w \in W^+$, $\beta \in B^-$, $g \in G^+$, $\gamma \in G^-$, $\overline{b} \in \overline{B}^+$, $\overline{\beta} \in \overline{B}^-$ (i.e., $\overline{b} \neq w, g$ and $\overline{\beta} \neq \omega, \gamma$). Augmenting the compatible pair $\overline{\beta}, b$ gives either a nonblocker, a 1-blocker, or a 4-blocker for B. The latter cannot occur if B has less than $\Phi - 1$ extremes.

Proof. (i) The new graph has $r(b, \beta)$ and $r(\overline{b}, \overline{\beta})$, so it is not a 2-blocker by Lemma 7.1(i).

(ii) Follows from Lemma 6.1(i).

(iii) Follows from Lemma 7.1(iv). □

7.2. Finding an augmenting pair. To complete the solution of our augmentation problem we wish to show that a dag H that is not a blocker has $OPT = \Phi$. Toward this end we can make the following assumptions: H satisfies

$$\Phi = |V^-| = |V^+| > |B^+| + |B^-| \text{ for every } B \in \mathcal{P},$$

since as mentioned at the end of section 4 this is the only case that remains to be analyzed. H has exactly three nonempty colors, by Lemmas 3.4 and 6.2. Each color

contains both a source and a sink, by Lemma 6.3. We make all these assumptions throughout this section until the final result, Theorem 7.8, is presented. Now we give the overall structure of the argument proving that H has $OPT = \Phi$.

Lemma 2.8 shows H has a compatible pair. Augment such a pair. This decreases Φ by 1, by the above assumption on Φ. The new graph K is still tricolored. If K is not a blocker, induction (and the analysis of the previous sections) shows we are done. So assume K is a blocker. It suffices to show how to augment a different compatible pair so the new graph is not a blocker.

We accomplish this in a manner similar to section 6: Order the blocker types as 2, 3, 4, 1. For each type i, we suppose K is an i-blocker resulting from an augment of H. We will augment a new compatible pair of H to get a new graph L. We will show L is not a blocker of type i or a type listed before i. Repeated application of this argument eventually gives the desired augment.

The rest of this section shows for each blocker type how to find a compatible pair giving the desired graph L. The arguments refer to the three graphs H, K, L. The functions R^- and R^+ always refer to H, as does the predicate r. r_K and r_L refer to graphs K and L, respectively.

The following simple principle will be used repeatedly. For motivation note that if χ, x is a compatible pair, then some source u and sink ξ satisfy $r(u, \chi)$ and $r(x, \xi)$.

LEMMA 7.3. *Suppose graph K results from augmenting the pair χ, x. Then $r_K(a, \delta)$ implies $r(a, \delta)$ when*

$$r(u, \chi), r(x, \xi), \text{ and either } \neg r_K(a, \xi) \text{ or } \neg r_K(u, \delta)$$

for vertices $u, x, a \in V^+$, $\chi, \xi, \delta \in V^-$.

Proof. $r_K(a, \delta)$ with $\neg r(a, \delta)$ means the path from a to δ in K includes edge (χ, x). Thus $r_K(a, \xi)$ and $r_K(u, \delta)$. □

Now we present the argument for each blocker type. It is convenient to consider 1-blockers first since that case gets used by the others.

1-blockers. This section shows that if an augment gives a 1-blocker, a different augment gives a bicolored graph. In fact we prove a stronger result that is useful later on.

Suppose an augment of H gives a 1-blocker for B. B must have $\Phi - 1$ extremes (by the assumption on Φ) and the augment cannot involve a vertex colored B. The latter implies $\neg r(B)$. These facts show the following lemma handles the case of augments that give 1-blockers.

LEMMA 7.4. *Let H be a dag having a color B with exactly $\Phi - 1$ extreme vertices and $\neg r(B)$. Then some augment of H gives a dag L that is not a blocker. Furthermore two colors of L can be merged without changing Φ to get a bicolored dag that is not a blocker.*

Proof. Vertices x^-, y^+ form a *good pair* if neither vertex is colored B, the vertices are compatible, and augmenting x^-, y^+ gives a new graph L with

$$r_L(B) \text{ and } r_L(\overline{B}).$$

We will find a good pair of vertices. This suffices to prove the lemma: L has $\Phi = |B^+| + |B^-| = |\overline{B}^+| + |\overline{B}^-|$, so using colors $B, \overline{B}$ gives a bicolored graph that is not a 1-blocker, as desired. We will argue by contradiction. So suppose no good pair exists.

We first show there are four distinct vertices $b \in B^+$, $\omega \in W^-$, $g \in G^+$, $\beta \in B^-$ such that

$$r(b, \omega) \text{ and } r(g, \beta).$$

In proof $\neg r(B)$ implies there are vertices $b \in B^+$ and $\beta \in B^-$ with $r(b,\chi)$, $r(x,\beta)$ for some $x, \chi \notin B$. Since H is not a 4-blocker x and χ can be chosen to have different colors. Naming colors appropriately gives the desired vertices.

The compatible pair ω, g is a good pair if $r_L(\overline{B})$. (Whenever we refer to a good pair, L denotes the graph that results from augmenting that pair.) The latter holds if either $r(\overline{B}-g, \overline{B}-\omega)$ or $r(\overline{B}-g,\omega)$ and $r(g,\overline{B}-\omega)$. So neither of these two alternatives holds. The failure of the second alternative implies that we can assume $\neg r(\overline{B}-g,\omega)$ (since we can replace H by its reverse graph). This plus the failure of the first alternative implies

$$R^-(\overline{B}-g) \subseteq B. \tag{7.1}$$

Equation (7.1) with $r(\overline{B})$ (since H is not a 2-blocker) implies there is a vertex $\overline{\beta} \in \overline{B}^-$ with

$$r(g,\overline{\beta}).$$

(It is possible that $\overline{\beta} = \omega$.)

Next we show

$$r(B,G) \Longrightarrow G^- = \{\overline{\beta}\} \text{ and } R^+(W) \subseteq B. \tag{7.2}$$

Suppose $r(b',\gamma)$ for vertices $b' \in B^+, \gamma \in G^-$. $W^+ \neq \emptyset$ and (7.1) show there are vertices $w \in W^+, \beta' \in B^-$ with $r(w,\beta')$. The compatible pair γ, w is good if $r_L(\overline{B})$, so $\neg r_L(\overline{B})$. Since $r(g,\overline{\beta})$ and $g \neq w$ we must have $\gamma = \overline{\beta}$. Thus $\overline{\beta} \in G$. Furthermore $R^+(W) \subseteq B$, since otherwise we can choose $\overline{\beta} \in W$.

We complete the proof of (7.2) by showing $G^- = \{\overline{\beta}\}$: Consider a vertex $\gamma' \in G^- - \overline{\beta}$. We have shown $\gamma = \overline{\beta}$ holds for every choice of γ and $\overline{\beta}$, so these two vertices are unique. We have $\neg r(B,\gamma')$ (since otherwise γ' could be chosen as γ), $\neg r(g,\gamma')$ (since otherwise γ' could be chosen as $\overline{\beta}$), and $\neg r(\overline{B}-g,\gamma')$ (by (7.1)). Hence γ' does not exist.

We can now assume without loss of generality that $\overline{\beta} \in G$: This relation has just been proved if $r(B,G)$. On the other hand $\neg r(B,G)$ implies any vertex of G^- can be chosen as $\overline{\beta}$.

Next we show $G^+ = \{g\}$: Suppose $g' \in G^+ - g$. g' precedes a black sink β' by (7.1). The pair ω, g' is compatible since we have $r(b,\omega)$ and $r(g',\beta')$. In fact ω, g' is a good pair: The relation $r_L(\overline{B})$ holds since $r(g,\overline{\beta})$ and $\overline{\beta} \neq \omega$ (because $\overline{\beta} \in G$). Since there are no good pairs, g' does not exist.

Since H is not a 3^+-blocker but $|G^+| = 1$ and $R^-(W) \subseteq B$, we have $r(B,\overline{W})$. Together with the hypothesis $\neg r(B)$ we get $r(B,G)$. Hence the hypothesis and conclusion of (7.2) hold. Thus $|G^+| = |G^-| = 1$, so W (as well as B) has exactly $\Phi - 1$ extreme vertices. This along with $R^-(W) \cup R^+(W) \subseteq B$ makes H a 4-blocker, a contradiction. □

2-blockers.

LEMMA 7.5. *If an augment of H gives a graph K that is a 2-blocker, a different augment of H gives a graph L that is not a 2-blocker.*

Proof. Suppose K is a 2-blocker for B. Since H is not a 2-blocker there are vertices $x \in \overline{B}^+, \chi \in \overline{B}^-$ with $r(x,\chi)$ and either x or χ (or both) a vertex in the augment. By possibly changing to the reverse graph (using Lemma 4.2) we can assume x is a vertex in the augment. Without loss of generality assume $x \in G^+$. We consider two cases.

Case 1. χ is not a vertex in the augment.

In this case the augment forming K gives four distinct vertices $b \in B^+$, $\overline{\gamma} \in \overline{G}^-$, $g \in G^+$, $\overline{\beta} \in \overline{B}^-$ such that

$$r(b, \overline{\gamma}) \text{ and } r(g, \overline{\beta}).$$

Here we have replaced x and χ by g and $\overline{\beta}$, respectively, and b and $\overline{\gamma}$ are the other two vertices involved in the augment. $\overline{\gamma}$ must be in $\overline{G}$ since the edge added by the augment joins differently colored vertices. b must be in B because it precedes $\overline{\beta}$ in K, which is a 2-blocker for B. Finally $\overline{\gamma} \neq \overline{\beta}$ by the assumption of Case 1.

Next we show there are vertices $\overline{b} \in \overline{B}^+$, $\beta \in B^-$ that are distinct from the other four vertices such that

$$r(\overline{b}, \beta).$$

In proof, such a pair of vertices with $r_K(\overline{b}, \beta)$ exists, since a 2-blocker has $\overline{B}^+ \neq \emptyset$. The relation $r(\overline{b}, \beta)$ follows from Lemma 7.3 (using $\neg r_K(\overline{b}, \overline{\beta})$).

If $\overline{b}$ can be chosen to have a color different from $\overline{\gamma}$, then Corollary 7.2(i) applies to the six vertices $b, \overline{\gamma}, \overline{b}, \beta, g, \overline{\beta}$ and we are done. So suppose no such vertex $\overline{b}$ exists. This implies

$$\overline{\gamma},\ \overline{b} \in W.$$

In proof, the two vertices have different colors if $\overline{\gamma} \in B$. Hence $\overline{\gamma} \in W$ and so $\overline{b} \in W$.

We now show $R^-(W \cup G - g) \subseteq B$. If not, then $r(W \cup G - g, \overline{B})$. This continues to hold in graph K, even if the only sink of $\overline{B}$ reachable from $W \cup G - g$ is $\overline{\gamma}$. But this contradicts K a 2-blocker.

The inclusion $R^-(W \cup G - g) \subseteq B$ implies $|G^+| = 1$ (otherwise a vertex of $G^+ - g$ could be chosen as $\overline{b}$; here we use $\overline{\gamma} \in W$). The inclusion also implies $R^-(W) \subseteq B$. Since H is not a 3^+-blocker we conclude $r(B, \overline{W})$. Hence we can take vertices $b' \in B^+$, $\overline{\omega} \in \overline{W}^-$ with

$$r(b', \overline{\omega}).$$

Corollary 7.2(i) applies to the six vertices $b', \overline{\omega}, \overline{b}, \beta, g, \overline{\beta}$ if the three sinks are distinct (recall $\overline{b} \in W$). That leaves us with two possibilities, $\overline{\omega} = \beta$ and $\overline{\omega} = \overline{\beta}$.

Suppose $\overline{\omega} = \beta$. Form L by augmenting the pair $\overline{\beta}, b$. If $b' \neq b$, then $r_L(b', \beta)$ and $r_L(g, \overline{\gamma})$, with $\overline{\gamma} \in W$, show L is not a 2-blocker by Lemma 7.1(i). If $b' = b$, then $r_L(g, \overline{\gamma})$, $r_L(g, \beta)$, and $r_L(\overline{b}, \beta)$ with $\overline{\gamma}, \overline{b} \in W$ show L is not a 2-blocker by Lemma 7.1(ii).

Suppose $\overline{\omega} = \overline{\beta}$. Form L by augmenting the pair β, g. We have $r_L(b, \overline{\gamma})$, $r_L(b', \overline{\beta})$, and $r_L(\overline{b}, \overline{\beta})$. The supposition implies $\overline{\beta} \in G$, and we have $\overline{\gamma}, \overline{b} \in W$. So Lemma 7.1(ii) shows L is not a 2-blocker.

Case 2. χ is a vertex in the augment.

The augment forming K gives four distinct vertices $b \in B^+$, $\omega \in W^-$, $g \in G^+$, $\beta \in B^-$ such that

$$r(b, \omega), r(g, \omega), \text{ and } r(g, \beta).$$

Here we have replaced x and χ by g and ω, respectively. We can assume $b, \beta \in B$ because otherwise, renaming vertices puts us in Case 1.

Lemma 6.3 shows there are vertices $w \in W^+$ and $\gamma \in G^-$. Clearly these vertices are distinct from the four vertices above. Since K is a 2-blocker, $\neg r_L(w,\gamma)$, so $\neg r(w,\gamma)$. Thus w,γ is a compatible pair. Form L by augmenting w,γ. The three relations displayed above hold in L. So Lemma 7.1(ii) shows that L is not a 2-blocker. □

3-blockers.

LEMMA 7.6. *If an augment of H gives a graph K that is a proper 3^+-blocker, a different augment of H gives a graph L that is not a 2- or 3-blocker.*

Proof. Suppose K is a 3^+-blocker for B, W, and vertex $g \in G$. H has $|G^+|$ equal to 1 or 2. We consider these cases separately.

Case 1. $|G^+| = 2$.

Case 1.1. $R^-(B) \subseteq W$ and $R^-(W) \subseteq B$.

If B has $\Phi - 1$ extreme vertices, we are done by Lemma 7.4. Hence we can assume both B and W have less than $\Phi - 1$ extremes. This implies $|G^-| \geq 2$.

We claim there are vertices $b \in B^+$, $\omega \in W^-$, $w \in W^+$, $\beta \in B^-$, $g \in G^+$, and $\gamma \in G^-$ with

$$r(b,\omega), r(w,\beta), \text{ and } r(g,\gamma).$$

The first two relations follow from the assumptions of Case 1.1. $r_K(G)$ holds since K is a proper 3-blocker (recall Lemma 4.4). This implies $r(G)$, since the augment involves a source of G^+. Now we have proved the last relation $r(g,\gamma)$.

There are vertices $g' \in G^+ - g$ and $\gamma' \in G^- - \gamma$. Suppose these vertices can be chosen so $r(g',\gamma')$. This gives eight vertices satisfying the hypothesis of Corollary 7.2(iii), so we are done. Now assume such vertices do not exist.

Case 1.1 implies $R^+(G) \subseteq G$. So the assumption just made implies $R^+(G) = \{g\}$. Thus g' precedes a sink of $B \cup W$. Without loss of generality $r(g',\omega')$ for some $\omega' \in W^-$. Now the relations $r(g,\gamma)$, $r(w,\beta)$, and $r(g',\omega')$ satisfy the hypothesis of Corollary 7.2(ii), so we are done.

If Case 1.1 does not hold, then without loss of generality the following applies.

Case 1.2. $R^-(B) \not\subseteq W$.

The augment that produces K involves the source $g' \in G^+$. Hence there are vertices $b \in B^+$, $\beta \in B^-$, $\omega \in W^-$ with

$$r(b,\beta) \text{ and } r(g',\omega).$$

Here the augment is for β, g'. The assumption of Case 1.2 implies we must have β a nonwhite vertex preceded by a black source b. Since β is also nongray, $\beta \in B$. Finally $\omega \in W$ since $r_K(b,\omega)$.

Since K is a proper 3-blocker there are vertices $g \in G^+ - g'$, $\gamma \in G^-$ with $r_K(g,\gamma)$. This implies $r(g,\gamma)$ by Lemma 7.3 (since $\neg r_K(b,\gamma)$). Similarly there are vertices $w \in W^+, \beta' \in B^- - \beta$ with $r(w,\beta')$ (use $\neg r_K(b,\beta')$). Now the relations $r(g,\gamma)$, $r(w,\beta')$, and $r(g',\omega)$ show Corollary 7.2(ii) applies and we are done.

Case 2. $|G^+| = 1$.

Case 2.1. $R^-(B) \not\subseteq W$, $R^-(W) \not\subseteq B$.

We can assume there are vertices $b \in B^+$, $\overline{\omega} \in \overline{W}^-$, $w \in W^+$, $\omega \in W^-$ such that

$$r(b,\overline{\omega}) \text{ and } r(w,\omega).$$

Here the augment is for $\overline{\omega}, w$. The source of the augment is not in G by Case 2, so without loss of generality $w \in W$. The first relation of Case 2.1 now shows $\overline{\omega} \in \overline{W}$ and is preceded by a source $b \in B$. Finally $\omega \in W^-$ since $r_K(b,\omega)$.

Since K is a 3^+-blocker it contains vertices $w' \in W^+ - w$, $\beta \in B^- - \overline{\omega}$ such that $r_K(w', \beta)$. Lemma 7.3 shows $r(w', \beta)$, since $\neg r_K(w', \omega)$. Now the relations $r(w, \omega)$, $r(b, \overline{\omega})$, and $r(w', \beta)$ show Corollary 7.2(ii) applies and we are done.

If Case 2.1 does not hold, then without loss of generality the following applies.

Case 2.2. $R^-(B) \subseteq W$, $R^-(W) \not\subseteq B$.

Call vertices $w \in W^+$, $\overline{\beta} \in \overline{B}^-$ a *bad pair* if $r(w, \overline{\beta})$. The augment producing K involves a vertex in a bad pair. We examine three corresponding possibilities.

First suppose there is only one bad pair, and the augment involves both its vertices. Then there are vertices $g \in G^+$, $\gamma \in G^-$, $w \in W^+$, $\beta \in B^-$ such that

$$r(g, \gamma), r(w, \gamma), \text{ and } r(w, \beta),$$

where the augment is for the bad pair γ, w. $\beta \in B$ since w, β is not a bad pair. $\gamma \in G$ because $\gamma \in \overline{B}$ (since γ, w is bad) and $\gamma \in \overline{W}$ (since we augment γ, w). This implies $g \in G$ since g, γ is not a bad pair and $R^-(B) \subseteq W$.

Since K is a 3^+-blocker it contains vertices $b \in B^+$, $\omega \in W^-$ with $r_K(b, \omega)$. Lemma 7.3 shows $r(b, \omega)$. Lemma 4.4 shows there is a vertex $\gamma' \in G^- - \gamma$ with $r_K(g, \gamma')$. The uniqueness of the bad pair shows $\neg r(w, \gamma')$, so $r(g, \gamma')$. The relations $r(g, \gamma')$, $r(w, \gamma)$, and $r(b, \omega)$ show Corollary 7.2(ii) applies and we are done.

Now we can assume there is a bad pair with only one of its vertices in the augment. Suppose the sink is in the augment. Then there are vertices $w, w' \in W^+$, $\gamma \in G^-$, $\beta \in B^-$ such that

$$r(w', \gamma) \text{ and } r(w, \beta),$$

where the augment is for γ, w. The assumed bad pair is w', γ, so $w' \in W$. This implies $\beta \in B$ since K is a 3^+-blocker. The assumptions of Cases 2 and 2.2 imply $w \in W$. Finally $\gamma \in G$ since $\gamma \in \overline{B}$ (for a bad pair) and $\gamma \in \overline{W}$ (by the augment).

Since K is a 3^+-blocker it contains vertices $b \in B^+$, $\omega \in W^-$ with $r_K(b, \omega)$. Lemma 7.3 shows $r(b, \omega)$, since $\neg r_K(w', \omega)$. Lemma 4.4 shows there are vertices $g \in G^+$, $\gamma' \in G^- - \gamma$ with $r_K(g, \gamma')$. Lemma 7.3 shows $r(g, \gamma')$, since $\neg r_K(w', \gamma')$. The relations $r(g, \gamma')$, $r(w', \gamma)$, and $r(b, \omega)$ show Corollary 7.2(ii) applies and we are done.

In the remaining case there is a bad pair having only its source in the augment. There are vertices $g \in G^+$, $\overline{\omega} \in \overline{W}^-$, $w \in W^+$, $\overline{\beta} \in \overline{B}^-$ such that

$$r(g, \overline{\omega}) \text{ and } r(w, \overline{\beta}),$$

where the augment is for $\overline{\omega}, w$. $w, \overline{\beta}$ is the assumed bad pair. $g \in G$ because $g \notin B$ (since $R^-(B) \subseteq W$) and $g \notin W$ (since K is a 3^+-blocker).

Since K is a 3^+-blocker there are vertices $w' \in W^+ - w$, $\beta \in B^- - \overline{\omega}$ with $r_K(w', \beta)$. Lemma 7.3 with $\neg r_K(w', \overline{\beta})$ shows

$$r(w', \beta).$$

The pair $\overline{\omega}, w'$ is compatible, so augment it to get the graph L. We will show L has the desired properties. We consider two cases depending on the color of $\overline{\beta}$.

Suppose every possible choice for $\overline{\beta}$ is colored W. Since K is a 3^+-blocker there is a vertex $\gamma \in G^- - \overline{\omega}$ with $r_K(g, \gamma)$ (Lemma 4.4). The assumption on $\overline{\beta}$ shows $\neg r(w, \gamma)$, which implies $r(g, \gamma)$. Graph L has $r_L(g, \gamma)$ and $r_L(w, \overline{\beta})$. Since $\overline{\beta} \in W$, Lemma 6.1(i) shows we are done.

Suppose we can choose $\overline{\beta} \in G$. The hypothesis of Case 2.2 shows there are vertices $b \in B^+$, $\omega \in W^-$ with $r(b, \omega)$. Graph L has $r_L(g, \beta)$, $r_L(b, \omega)$, and $r_L(w, \overline{\beta})$. Since $\overline{\beta} \in G$, Lemma 7.1(iii) gives the desired conclusion. □

It remains to consider when an augment of H gives a graph K that is a proper 3^--blocker. Lemma 4.2 shows the reverse of K is a proper 3^--blocker resulting from an augment. So the above lemma shows a different augment gives a graph L that is not a 2- or 3-blocker. The reverse of L is the result of the reverse augment and is also not a 2- or 3-blocker.

4-blockers.

LEMMA 7.7. *If an augment of H gives a graph K that is a proper 4-blocker, a different augment of H gives a graph L that is a nonblocker or a 1-blocker.*

Proof. Suppose K is a proper 4-blocker for B. In H color B has $\Phi - 1$ or $\Phi - 2$ extreme vertices, since the augment decreases Φ by one. We consider these cases separately.

Case 1. B has $\Phi - 1$ extreme vertices.

Lemma 7.4 shows we can assume $r(B)$. Hence the augment producing K involves a black extreme vertex. By possibly changing to the reverse graph, assume it involves a black source. Thus there are vertices $w \in W^+$, $\overline{\beta} \in \overline{B}^-$, $b \in B^+$, $\beta \in B^-$ with

$$r(w, \overline{\beta}) \text{ and } r(b, \beta).$$

The relation $r_K(w, \beta)$ implies $w \in \overline{B}$, so without loss of generality take $w \in W$, making K a 4-blocker for B, W.

Lemma 4.4 shows there are vertices $g \in G^+, \gamma \in G^- - \overline{\beta}$ with $r_K(g, \gamma)$. Lemma 7.3 shows $r(g, \gamma)$, since $\neg r_K(g, \beta)$. Augment the compatible pair γ, w. In the resulting graph L, $r_L(b, \beta)$, $r_L(g, \overline{\beta})$, and B has Φ extreme vertices. Taking the colors as B and $\overline{B}$, L is not a blocker.

Case 2. B has $\Phi - 2$ extreme vertices.

In this case the augment involves two nonblack extremes. Note this implies $\neg r(B)$. As before assume K is a 4-blocker for B, W.

Case 2.1. $R^-(B) \cup R^+(B) \not\subseteq W$.

Together with the preceding observation this implies $r(B, G)$ or $r(G, B)$. By possibly changing to the reverse graph assume $r(B, G)$. Hence there are vertices $b \in B^+$, $\gamma \in G^-$, $w \in W^+$, $\omega \in W^-$ with

$$r(b, \gamma) \text{ and } r(w, \omega).$$

Here vertices b, γ come from the assumption $r(B, G)$, and the augment is for γ, w. $\omega \in W$ since K is a 4-blocker.

Next we show there are vertices $w' \in W^+ - w$, $\beta \in B^-$, $g \in G^+$, $\gamma' \in G^- - \gamma$ with

$$r(w', \beta) \text{ and } r(g, \gamma').$$

Vertices satisfying these relations in graph K exist since K is a proper 4-blocker. Lemma 7.3 with $\neg r_K(b, \{\beta, \gamma'\})$ shows the same relations hold in H.

Augment the compatible pair β, w. The resulting graph L has $r_L(g, \gamma')$ and $r_L(w', \omega)$. Lemma 6.1(i) shows L is either a nonblocker, a 1-blocker, or a 4-blocker for B. The last alternative does not hold since B has $\Phi - 2$ extreme vertices in L.

Case 2.2. $R^-(B) \cup R^+(B) \subseteq W$.

There are vertices $b \in B^+$, $\omega \in W^-$, $w \in W^+$, $\beta \in B^-$, $g \in G^+$, $\gamma \in G^-$ with

$$r(b,\omega), r(w,\beta), \text{ and } r(g,\gamma).$$

The first two relations and their four vertices come from Case 2.2. The two gray vertices exist and satisfy $r_K(g,\gamma)$, since K is a proper 4-blocker. We can assume $r(g,\gamma)$, since the augment involves a gray source or sink.

Suppose there are vertices $g' \in G^+ - g$, $\gamma' \in G^- - \gamma$ with $r(g',\gamma')$. Corollary 7.2(iii) shows we are done.

Next suppose there are vertices $g' \in G^+ - g$, $\omega' \in W^-$ with $r(g',\omega')$. This relation plus $r(w,\beta)$ and $r(g,\gamma)$ satisfy the hypothesis of Corollary 7.2(ii), so we are done. We can apply the same argument to the reverse graph if there are vertices $w' \in W^+$, $\gamma' \in G^- - \gamma$ with $r(w',\gamma')$.

Note that $|G^+|+|G^-| \geq 3$ since $|B^+|+|B^-|+|W^+|+|W^-| \leq (\Phi-2)+(\Phi-1) = 2\Phi-3$. By possibly changing to the reverse graph, assume $|G^-| \geq 2$. Every vertex of $G^- - \gamma$ has g as its only source predecessor, since otherwise one of the previous cases applies. Now the same reasoning extends this remark to every vertex of G^- (including γ). If $|G^+| \geq 2$, then one of the previous cases applies (specifically the case for $r(g',\omega')$). Thus $|G^+| = 1$. Since H is not a 3^+-blocker we conclude $r(W)$.

The preceding paragraph shows there are vertices $w' \in W^+$, $\omega' \in W^-$, and $\gamma' \in G^- - \gamma$ with

$$r(w',\omega') \text{ and } r(g,\gamma').$$

(Possibly $\omega' = \omega$.) Augment the compatible pair γ', b. For the resulting graph L, $r_L(g,\gamma)$, $r_L(w',\omega')$, and B has $\Phi - 2$ extreme vertices. Lemma 6.1(i) shows we are done. □

THEOREM 7.8. *Any dag has $OPT = \Phi$ unless it is a blocker, in which case $OPT = \Phi + 1$.*

Proof. If H is a blocker, then $OPT = \Phi + 1$ by Lemmas 4.3 and 2.9. Suppose H is not a blocker. $OPT = \Phi$ unless $\Phi = |V^-| = |V^+| > |B^+| + |B^-|$ for every $B \in \mathcal{P}$, by Lemmas 4.5 and 3.5. For the remaining case, Lemma 6.2 reduces an arbitrarily colored H to a tricolored dag. Lemmas 7.4–7.7 prove the theorem on tricolored dags in the remaining case. If the given dag has an isolated vertex, the theorem still applies, as in the proof of Lemma 5.3. □

8. Algorithms. This section gives algorithms to solve the bipartite strong-connectivity augmentation problem in time $O(n+m)$ and the general augmentation problem in time $O((n+m)\log n)$. Here n and m denote the number of vertices and edges in the input graph, respectively. The main ingredient is an algorithm to find compatible pairs. This is given in section 8.1. The rest of the algorithm consists of procedures that follow the proofs already presented. These procedures are given in sections 8.2–8.5.

We start with two general observations. First recall that the strong component graph of a given digraph can be constructed in linear time, using routines for depth-first search and contraction [5]. Next observe that $OPT \leq \Phi + 1 = O(n)$ new edges get added to the graph. Hence all graphs we work with contain $O(n+m)$ edges.

8.1. Compatible pairs. This section describes several routines to find compatible pairs. A *compatible pair sequence* x_i^-, y_i^+, $i = 1, \ldots, k$, in a dag H has $x_i^- \in V^-$, $y_i^+ \in V^+$ with x_i^-, y_i^+ a compatible pair in the strong component dag of $H + \{(x_j^-, y_j^+) : 1 \leq j < i\}$. Consider two sets $X^- \subseteq V^-$, $Y^+ \subseteq V^+$ that have equal

cardinality and are consistently colored. We give an algorithm to find a compatible pair sequence whose vertices are in $X^- \cup Y^+$ and whose length is $|X^-|-1 = |Y^+|-1$.

The algorithm is based on a procedure ONE-PAIR that finds the next pair in the desired sequence. Suppose we have found compatible pairs (x_j^-, y_j^+), $j = 1, \ldots, i-1$. Let H_i be the strong component graph of $H + \{(x_j^-, y_j^+) : 1 \le j < i\}$. Throughout this discussion let V^-, V^+, X^-, and Y^+ refer to H_i. Thus V^- and V^+ represent the sinks and sources of H_i. X^- and Y^+ represent the vertices of these sets V^- and V^+ that are in the original sets X^- and Y^+. The algorithm maintains a mapping $\sigma : X^- \cup Y^+ \to V^- \cup V^+$ with the property that for each source $z^+ \in Y^+$ and each sink $z^- \in X^-$,

$$r(z^+, \sigma(z^+)) \text{ and } r(\sigma(z^-), z^-).$$

The following procedure finds a compatible pair x^-, y^+ with $x^- \in X^-$, $y^+ \in Y^+$ and augments it. The procedure assumes $|X^-| = |Y^+| \ge 2$. It uses the above mapping σ and updates σ to make it valid in the augmented graph.

PROCEDURE ONE-PAIR.

Step 1. Choose distinct vertices $v_i^- \in X^-$, $i = 1, 2$, having $|\sigma^{-1}(v_i^-)| \le 2$. Similarly choose distinct vertices $w_i^+ \in Y^+$, $i = 1, 2$, having $|\sigma^{-1}(w_i^+)| \le 2$.

Step 2. This step chooses x^- as some v_i and y^+ as some w_j so that after possibly modifying σ,

$$\sigma(x^-) \ne y^+ \text{ and } \sigma(y^+) \ne x^-. \tag{8.1}$$

If for some $i \in \{1, 2\}$, $\sigma(v_i^-) \ne w_i^+$ and $\sigma(w_i^+) \ne v_i^-$, take (x^-, y^+) to be (v_i^-, w_i^+). Otherwise redefine $\sigma(v_1^-) = w_1^+$, $\sigma(w_2^+) = v_2^-$ and take (x^-, y^+) to be (v_1^-, w_2^+).

Step 3. Augment the compatible pair x^-, y^+. Update σ for the new graph H_i as follows: For every $z^+ \in \sigma^{-1}(x^-) - y^+$, change $\sigma(z^+)$ to $\sigma(y^+)$. Similarly for every $z^- \in \sigma^{-1}(y^+) - x^-$, change $\sigma(z^-)$ to $\sigma(x^-)$. □

We now show that ONE-PAIR is correct. First note that the vertices of Step 1 exist. In proof take v_i^-, $i = 1, 2$, to be the two vertices of X^- with smallest value $|\sigma^{-1}(v_i^-)|$. Since the average value of $|\sigma^{-1}(v_i^-)|$, $v_i \in X^-$, is at most $|Y^+|/|X^-| = 1$, we have $|\sigma^{-1}(v_1^-)| + |\sigma^{-1}(v_2^-)| \le 2$. Hence these vertices have the desired property.

It is clear that Step 2 chooses (x^-, y^+) so (8.1) holds. Also note that if Step 2 redefines σ we have $r(w_i^+, v_i^-)$ for $i = 1, 2$, so the defining property of σ is maintained.

Equation (8.1) implies x^-, y^+ is compatible by the defining property of σ. Hence the augment in Step 3 is valid. Finally we show Step 3 updates σ correctly. Recall from Lemma 2.6 that the new graph H_i has sources $V^+ - y^+$ and sinks $V^- - x^-$. Hence Step 3 updates all vertices whose σ value is no longer an extreme vertex. The update is correct by (8.1).

We conclude that ONE-PAIR is correct. This procedure can be repeated to find a compatible pair until $|X^-| = |Y^+| = 1$.

Now we show how to find the desired compatible pair sequence in linear time $O(m + n)$. We use these data structures: The values $\sigma(z)$ are stored in an array. Each vertex $z \in X^- \cup Y^+$ has a list of the vertices in $\sigma^{-1}(z)$. There is a list $SHORT[X^-]$ containing all vertices $x^- \in X^-$ that have $|\sigma^{-1}(x^-)| \le 2$, and a similar list $SHORT[Y^+]$. All lists are doubly linked.

The mapping σ can be constructed initially in time $O(m + n)$ by two depth-first searches: The first labels each vertex of Y^+ with a sink that it can reach. The second labels each vertex of X^- with a source that can reach it. Finally we initialize the $SHORT$ lists.

Now we implement ONE-PAIR in time $O(1)$. (This implies the desired time bound for finding the compatible pair sequence.) Step 1 chooses vertices from the appropriate $SHORT$ list. In Step 2, suppose $\sigma(x^-) = z^+ \in Y^+$. Delete x^- from $\sigma^{-1}(z^+)$; if this makes $|\sigma^{-1}(z^+)| \leq 2$, add z^+ to $SHORT[Y^+]$. Process y^+ similarly. Step 3 changes the appropriate σ-values and adds vertices to the lists $\sigma^{-1}(z)$ for $z = \sigma(x^-), \sigma(y^+)$. This may cause these vertices to be deleted from the $SHORT$ lists. Note that Steps 1 and 2 imply $|\sigma^{-1}(x^-)|,\ |\sigma^{-1}(y^+)| \leq 2$. Hence Step 3 changes $O(1)$ σ values.

We extend this algorithm using the following observations.

LEMMA 8.1. *Take any vertex $b \in B^+$ and let C be the set of all vertices compatible with b. Let $S = R^-(b)$ and $T = R^-(V^+ - b) - B$. If $|S| > 1$, then $C = T$. If $|S| = 1$, then $C = T - S$.* □

LEMMA 8.2. *A pair of vertices x^-, y^+ that is compatible after an augment was compatible before the augment.*

Proof. Suppose x^-, y^+ was incompatible before the augment, i.e., before the augment we have $R^-(y^+) = \{x^-\}$ or $R^+(x^-) = \{y^+\}$. Suppose $R^-(y^+) = \{x^-\}$. The edge added by the augment is directed from a sink other than x^-, since x^- is a sink after the augment. Thus $R^-(y^+) = \{x^-\}$ after the augment. Similarly the condition $R^+(x^-) = \{y^+\}$ is preserved by the augment. □

In the given dag H let U be an arbitrary set of vertices. A *maximal compatible pair sequence for U* is a compatible pair sequence with all its vertices in U that cannot be extended by another pair. We will give an algorithm to find such a sequence. We start with an algorithm C-SEQUENCE that finds a maximal compatible pair sequence for U when the sources and sinks of U are consistently colored.

PROCEDURE C-SEQUENCE(U).

Step 1. Define sets $X^- \subseteq U^-$ and $Y^+ \subseteq U^+$ arbitrarily except for the constraint that each has cardinality $\min\{|U^-|,\ |U^+|\}$. If this cardinality is 0, return. Otherwise apply the algorithm given above to find and augment a compatible pair sequence with $|X^-| - 1$ pairs. (In the resulting graph at least one of the sets U^-, U^+ has cardinality one. Hence there may be one more compatible pair that can be augmented, which is found in Step 2.)

Step 2. Let u be the unique vertex of U^+ (U^-). Apply Lemma 8.1 to find the vertices of U compatible with u. If such a vertex exists, augment the corresponding pair. □

Next we show how to find a maximal compatible pair sequence for U when the extreme vertices of U have two colors, say, B and W. First execute C-SEQUENCE($(U^- \cap B) \cup (U^+ \cap W)$). Then execute C-SEQUENCE($(U^- \cap W) \cup (U^+ \cap B)$). This procedure is correct by Lemma 8.2.

Finally we give an algorithm MAX-SEQUENCE(U) to find a maximal compatible pair sequence for U when the extreme vertices of U have three colors, B, W, and G. Apply the above two-color procedure, taking the two colors as B and $\overline{B}$. Then apply the two-color procedure taking the two colors as W and $\overline{W}$.

LEMMA 8.3. MAX-SEQUENCE(U) *finds a maximal compatible pair sequence for U in a tricolored dag in time $O(n + m)$.*

Proof. MAX-SEQUENCE is correct by Lemma 8.2 and the fact that any augment involves either a black vertex or a white vertex. For the time bound note that Step 2 of C-SEQUENCE finds the sets of Lemma 8.1 by depth-first search. As already noted the graph contains $O(n + m)$ edges. □

We conclude this section by implementing the procedures for section 2. The

implementations for Proposition 2.1, Lemmas 2.2 and 2.3 are straightforward. To implement Lemmas 2.7 and 2.9, use MAX-SEQUENCE. In Lemma 2.9 if the graph is not bicolored, after the augments are executed we determine the first time a color B has $\Phi = |B^+| + |B^-|$. We undo all subsequent augments.

8.2. Bicolored dags.

Lemmas 3.2 and 3.3. To implement both lemmas, we must augment a maximal sequence of witness-compatible pairs, where the witnesses are $b^+ \in B^+$, $b^- \in B^-$ in Lemma 3.2 and $b^+ \in B^+$, $b^- \in B^-$, $w^+ \in W^+$, $w^- \in W^-$ in Lemma 3.3. We give a linear-time procedure for this task.

Define the initial two or four witnesses as in Lemma 3.2 or 3.3. Let X be the set of these initial witnesses. Execute MAX-SEQUENCE($V - X$). Then do the following for the two or four vertices of X. We illustrate for $b^- \in X$ (the other witnesses are similar). Suppose in the current graph $V - X$ contains both a white source y^+ and a black sink y^-. These vertices are incompatible (by Lemma 8.2), so $r(y^+, y^-)$. Hence b^-, y^+ is witness-compatible. Augment this pair and (as in Lemmas 3.2 and 3.3) change b^- to y^-.

This procedure augments a maximal sequence of witness-compatible pairs. In proof let K be the dag at the end of the procedure and let X' be the set of witnesses at the end. Lemma 8.2 shows that in K, $V - X'$ has no pairs that are compatible in the ordinary sense.

We claim that in K, $V - X'$ does not contain both a white source and a black sink. This is obvious if no augment was done for b^-, so suppose an augment was done. After executing MAX-SEQUENCE($V - X$), we have either a unique white source in $W^+ - X$ or a unique black sink in $B^- - X$ (by Lemma 2.5). The augment destroys that source or sink.

The claim implies that K does not have a witness-compatible pair b^-, y^+ for $y^+ \notin X'$. The only other possibility is that b^-, w^+ is witness-compatible. If it were there would be a white source $y^+ \notin X'$ and a black sink $y^- \notin X'$ with $r(y^+, b^-)$ and $r(w^+, y^-)$. But this makes y^-, y^+ compatible, a contradiction.

We conclude our procedure augments a maximal sequence of witness-compatible pairs. It is clear that the time is $O(m + n)$.

Lemma 3.5. The algorithm starts by augmenting a maximal compatible pair sequence until the graph becomes bicolored or some color becomes big. This is done by executing MAX-SEQUENCE(V) and undoing the augments that occur after the first time the termination condition is achieved. If there are two big colors, we reduce to a bicolored dag as shown in the lemma. If there is a unique big color B, augment a maximal compatible sequence where each augment involves a black vertex by executing MAX-SEQUENCE(V) with the colors taken to be B and $\overline{B}$. If some augment creates a second big color, undo any subsequent augments and proceed as above.

8.3. Blockers.

Detecting a blocker. We decide if an arbitrarily colored dag is a blocker in linear time as follows. A set $R^-(X)$ or $R^+(X)$ can be computed in linear time by depth-first search. Hence we can check if a dag is a blocker for a given color B in linear time. (For 3- and 4-blockers, color B determines W.) At most two colors can have Φ extreme vertices, so we can check for a 1-blocker in linear time. At most three colors of a proper 4-blocker can have $\Phi - 1$ extreme vertices (Lemma 4.4 implies $\Phi \geq 3$). So we can check for such a blocker in linear time. V^+ contains vertices of exactly three colors in a 3^+-blocker. Hence we can check for a 3-blocker in linear time. For a 2-blocker, find two vertices $x \in V^+$, $y \in V^-$ with $r(x, y)$. If the dag is a 2-blocker, it

must be a 2-blocker for the color of x or the color of y. So we can check for a 2-blocker in linear time.

Implementing Lemma 4.5 is trivial.

8.4. Core-bicolored dags.

Lemma 5.2. Call a pair $(x^+, x^-) \in \mathcal{B}$ *good* if $|B^+| + |B^-| \leq |V^+| - 2$ or $|B^+| + |B^-| = |V^+| - 1$ and at most one vertex of the pair belongs to G. A pair of $\mathcal{W}$ is good if it satisfies the symmetric condition. The proof of Lemma 5.2 shows if H is not a blocker, then it has good pairs $(x^+, x^-) \in \mathcal{B}$, $(y^+, y^-) \in \mathcal{W}$ with all four vertices distinct. We give an algorithm to find two such pairs. Using these pairs we recolor vertices to reduce to the bicolored case, as shown in the lemma.

First note that we can find a good pair in $\mathcal{B}$ by depth-first search: If $|B^+|+|B^-| \leq |V^+|-2$, we do a depth-first search from $(B \cup G)^+$. If $|B^+| + |B^-| = |V^+| - 1$, we do a depth-first search from B^+ and a second depth-first search from G^+.

Start by finding a good pair $(x^+, x^-) \in \mathcal{B}$. Then try to find a good pair of $\mathcal{W}$ in the graph $H - \{x^+, x^-\}$. If such a pair exists, we are done. Otherwise execute the case below that applies.

Case 1. $H - x^+$ does not contain a good pair of $\mathcal{W}$.

This implies x^+ is in every good pair of $\mathcal{W}$. Let (x^+, y_1^-) be a good pair of $\mathcal{W}$. If it is the only good pair of $\mathcal{W}$, then use it with a good pair of $\mathcal{B}$ in $H - \{x^+, y^-\}$ as the desired pairs. Otherwise let (x^+, y_2^-) be a second good pair of $\mathcal{W}$. There is a good pair of $\mathcal{B}$ in $H - \{x^+\}$, say, (z^+, z^-). Use (z^+, z^-) with (x^+, y_i^-), where $i \in \{1, 2\}$ is chosen so $y_i^- \neq z^-$, as the desired pairs.

Case 2. Both $H - x^+$ and $H - x^-$ contain a good pair of $\mathcal{W}$, but $H - \{x^+, x^-\}$ does not.

This implies we can find good pairs (x^+, y^-) and (y^+, x^-) of $\mathcal{W}$, where $y^- \neq x^-$ and $y^+ \neq x^+$. $x^+, x^- \in G$ since $(x^+, x^-) \in \mathcal{B}$. If $y^- \in G$, then (x^+, y^-) is good for $\mathcal{B}$, so take (x^+, y^-) and (y^+, x^-) as the desired pairs. Now without loss of generality assume that both y^+ and y^- are white. There is a good pair of $\mathcal{B}$ in either $H - x^+$ or $H - x^-$. Find such a pair and use it with either (x^+, y^-) or (y^+, x^-) to form the desired pairs.

THEOREM 8.4. *The bipartite strong-connectivity augmentation problem and the cable-framework rigidity problem can be solved in linear time.* □

8.5. General algorithm.

Merging colors. Lemma 6.2 is straightforward to implement in time $O(n+m)$. The algorithm finds a permissible merge into three colors that gives a nonblocker after trying at most five merges.

The implementation of Lemma 6.3 is similar to Case 1 of Lemma 5.2 in the previous section.

Augmentation algorithm. We are given a tricolored dag H that is not a blocker. We implement the proof of section 7 to solve the strong connectivity augmentation problem on H. Recall that the proof orders the blocker types as 2, 3, 4, 1. The relation $\prec$ corresponds to precedence in this list, e.g., $2 \prec 3, 4, 1$. Similarly for $\preceq, \succ, \succeq$.

For $i = 2, 3, 4$ define an *i-witness set* to be a set of vertices that satisfies one of the conditions of Lemma 7.1 or Lemma 6.1(i) that preclude H from being a blocker of type $\preceq i$. For instance the six vertices of Lemma 7.1(iv) form a 3-witness set, as well as a 2-witness set. Vertices $b^+ \in B^+$, $b^- \in B^-$, $x^+ \in \overline{B}^+$, $x^- \in \overline{B}^-$ with $r(b^+, b^-)$ and $r(x^+, x^-)$ form a 2-witness set, since they satisfy the condition of Lemma 7.1(i). A 4-witness set differs from the others because it has an additional condition: There

is a distinguished color B that has $\Phi - 2$ extreme vertices. For instance, the above 3-witness set is a 4-witness set in a dag where B has $\Phi - 2$ extremes.

Each of Lemmas 7.4–7.7 is easily implemented in linear time. Lemma 7.4 reduces the graph to a bicolored dag. Lemmas 7.5–7.7 each start with a dag that has an augment giving an i-blocker ($i = 2, 3, 4$) and execute a different augment that is guaranteed not to give a blocker of type $\preceq i$. This guarantee holds because the lemma (and its corresponding algorithm) produces an i-witness set. (Lemma 7.7 produces a 4-witness set in a graph where B has $\Phi - 2$ extreme vertices.)

These observations show we can execute one augment in linear time. This implies an algorithm for the augmentation problem that runs in time $O((n + m)\Phi)$.

Now we give an algorithm with the improved time bound $O((n + m) \log \Phi)$. The algorithm consists of four stages: an initial stage and a stage for i-blockers, $i = 2, 3, 4$. We refer to the stage for i-blockers as *stage* i. The algorithm starts in the initial stage. After that it executes between zero and three blocker stages, always progressing from a stage i to a higher-numbered stage.

Each stage has as input a tricolored dag that is not a blocker. For the initial stage this is the given dag H. For subsequent stages it is an augmented version of H. Stage i is also given an i-witness set.

Each stage begins by executing a sequence of augments that end with a dag K, such that the following properties hold.

(i) Each augment decreases Φ by 1.
(ii) K is not a blocker.
(iii) No augment involves a vertex in the given witness set. (This set is $\emptyset$ in the initial stage.)
(iv) In stage 4 each augment involves a vertex of color B (so B always has $\Phi - 2$ extreme vertices).
(v) K is either (a) rooted, (b) bicolored, (c) has $\Phi = |B^+| + |B^-|$ for some color B, (d) has $\Phi = O(1)$, or (e) an augment for K has been found whose execution gives a blocker.

In cases (v(a))–(v(d)) complete the solution to the augmentation problem in time $O(n + m)$ using the procedure for Lemmas 2.3, 3.4, 4.5, or the above $O((n + m)\Phi)$ algorithm, respectively. (Note K may be strongly connected, in which case it satisfies (v(b)).)

Suppose case (v(e)) holds. If some color has no source or no sink, execute the procedure of Lemma 6.3 to get a bicolored dag and complete the solution as in the previous paragraph. Otherwise execute the procedure of Lemmas 7.4–7.7 to get a dag L that is not a blocker. (For example, suppose K has an augment giving a 2-blocker. Lemma 7.5 may give an augment that produces a nonblocker or perhaps a 4-blocker. In the first case we take the nonblocker as L. In the second case we execute the procedure for Lemma 7.7. Eventually we get a nonblocker L.) If L satisfies any of conditions (v(a))–(v(c)), complete the solution as in the previous paragraph. Otherwise the last lemma whose procedure is executed gives a j-witness set for L, where $j \in \{2, 3, 4\}$. Proceed to stage j. (Note that if Lemma 7.4 for 1-blockers is executed, it gives a graph satisfying (v(b)), so the solution gets completed.)

This algorithm executes each of the four stages at most once. In proof suppose stage i ends with (v(e)) satisfied. The augment of (v(e)) gives a blocker of type $\succ i$. This follows since the i-witness set is preserved (by (iii)–(iv)). Hence the procedure of Lemmas 7.4–7.7 gives a nonblocker L that, if not bicolored, has a j-witness set for some $j \succ i$. In this case the algorithm advances to stage j, so no stage gets repeated.

Now we show how to implement a stage. We need only describe the procedure that executes the sequence of augments satisfying (i)–(v).

Let X be the given set of i-witnesses ($X = \emptyset$ for the initial stage). The initial stage and stages 2 and 3 begin by executing MAX-SEQUENCE($V - X$). Stage 4 executes MAX-SEQUENCE($V - X$) in the dag with colors taken to be B and $\overline{B}$ (for the distinguished color B).

Let S be the sequence of augments that get executed in MAX-SEQUENCE. Undo these augments. Take the final dag K to be the result of executing augments of S, in order, until one of conditions (v(a))–(v(d)) holds, or executing the next augment in S would give a blocker (so (v(e)) holds).

Correctness of this procedure depends on two facts. First note that the final sequence of augments satisfies (i). This holds since an augment that does not decrease Φ is executed in a dag that has a color B with Φ extreme vertices, so (v(c)) holds.

The second fact is that (v) is satisfied when the entire sequence S gets executed to produce K. We show that in this case (v(d)) holds, $\Phi = O(1)$. Note that any i-witness set has $O(1)$ vertices (specifically it has at most 6 vertices). Hence the following lemma is sufficient.

LEMMA 8.5. *Let H be a tricolored graph with $X \subseteq V$.*

(i) *If* MAX-SEQUENCE($V - X$) *results in a dag K with $\Phi = |V^+| = |V^-|$, then K has $\Phi \leq |X| + 3$.*

(ii) *Suppose executing* MAX-SEQUENCE($V - X$) *in the dag with colors taken to be B and $\overline{B}$ results in a dag K that (using the original colors) has $\Phi = |V^+| = |V^-| = |B^+| + |B^-| + 2$. Then K has $\Phi \leq |X| + 4$.*

Proof. (i) Consider K. If every color B has $|(B - X)^+| \leq 1$, then $\Phi = |V^+| \leq |X| + |V^+ - X| \leq |X| + 3$. Hence assume some color B has $|(B - X)^+| > 1$. This implies $|(\overline{B} - X)^-| \leq 1$ (Lemma 2.5). If $|(B - X)^-| \leq 1$, then $\Phi = |V^-| \leq |X| + |V^- - X| \leq |X| + 2$. So assume $|(B - X)^-| > 1$. This implies $|(\overline{B} - X)^+| \leq 1$ (Lemma 2.5). Hence $\overline{B}$ contains at most $|X| + 2$ extreme vertices. But $\overline{B}$ contains at least Φ extreme vertices (since B contains at most Φ extremes). We have deduced $\Phi \leq |X| + 2$.

(ii) If $|(B - X)^+|, |(B - X)^-| \leq 1$, then $\Phi = |B^+| + |B^-| + 2 \leq |X| + 4$. So without loss of generality assume $|(B - X)^+| > 1$. The rest of the argument proceeds as in part (i). □

The efficiency of a stage depends on how fast we can find the subsequence of augments of S that get executed. We start by finding the first augment in S that results in a dag satisfying any of the conditions (v(a))–(v(c)). This is easy to do in linear time. Let S' be the sequence S up to and including the augment just found. Now we must find the first augment in S' that produces a blocker. This can be done by a binary search of S', where each probe tests if the corresponding dag is a blocker.

To see that this binary search is correct, note that the first augment in S' that produces a blocker changes a dag with $OPT = \Phi$ into a dag with $OPT = \Phi + 1$. Every subsequent dag has $OPT = \Phi + 1$ (since each augment decreases Φ by 1, and an augment decreases OPT by at most 1). Hence every subsequent dag is a blocker.

Each probe of the binary search takes time $O(n + m)$ (section 8.3). Thus the time for the binary search is $O((n + m) \log \Phi)$.

THEOREM 8.6. *The problem of strong-connectivity augmentation with partition constraints can be solved in time $O((n + m) \log n)$ (the value of OPT can be found in time $O(n + m)$).* □

9. Related problems. The weighted version of bipartite strong-connectivity augmentation is NP-hard, by reduction from the bipartite Hamiltonian cycle problem.

[3] solves the problem of making an undirected bipartite graph k-edge-connected while preserving bipartiteness, i.e., bipartite k-edge-connectivity augmentation. This paper has solved the $k = 1$ case of bipartite directed k-edge-connectivity augmentation. We believe this directed problem is harder than the undirected problem of [3]. As evidence first recall that the directed problem for $k = 1$ already has a richer set of blockers than the undirected problem for arbitrary k. Also for $k = 1$ the directed problem can have $OPT > \Phi$ for graphs with arbitrarily large values of OPT. In contrast [3] shows that for the undirected problem, $OPT \geq 2k + 1$ implies $OPT = \Phi$. Finally [8] shows that in the directed problem with arbitrary k, OPT takes on values between Φ and $\Phi + k$ (for an appropriate definition of Φ). In contrast [3] shows any undirected bipartite graph has OPT equal to Φ or $\Phi + 1$.

We close by noting that if our operation is not adding new cables but replacing existing cables by rods, the rigidity problem can be solved by the Lucchesi–Younger Theorem [7].

ON A CONJECTURE BY COFFMAN, FLATTO, AND WRIGHT ON STOCHASTIC MACHINE MINIMIZATION*

NAH-OAK SONG† AND DEMOSTHENIS TENEKETZIS‡

Abstract. We investigate a conjecture stated by Coffman, Flatto, and Wright within the context of a stochastic machine minimization problem with a hard deadline. We prove that the conjecture is true.

Key words. stochastic allocation, hard deadlines, machine minimization, Bellman equation, time thresholds

1. Introduction.

Problems of optimal stochastic allocation of machines under waiting-time constraints have recently received considerable attention, as they are important in the design of computer and communication networks and in stochastic real-time scheduling problems (see [1], [2], [3]). From a theoretical point of view these problems are complementary to makespan minimization problems (see, for example, [4], [6], [7], [8]).

The general class of problems of optimal stochastic allocation of machines under waiting-time constraints (also known as stochastic machine minimization problems) can be formulated as follows: There are N jobs with processing times $T_1, T_2, \ldots, T_N$, deterministic or random with known distributions. Job waiting times are bounded by a time W that is independent of $T_1, T_2, \ldots, T_N$, and may be deterministic or random with a known distribution. There is an unlimited number of machines (processors) initially available to process these jobs. At time 0, a timer is started with initial value W and job scheduling begins. When the timer expires, all jobs not running at that time and still waiting to be processed are assigned to available machines. The objective is to determine, within the class of nonpreemptive policies, a policy that minimizes the expected cost, with cost defined as the number of distinct machines used throughout the schedule.

Several cases within the above class of problems have been considered so far in the literature [1], [2], [3]. A problem of practical importance is the hard deadline case where W is a constant. A partial analysis of this problem has been presented in [1], where the structure of an optimal policy was proved under a conjecture that remains so far an open problem. In this paper we prove that the conjecture stated in [1] is true; consequently, the structure of the optimal policy proposed in [1] is correct.

The paper is organized as follows: the conjecture stated in [1] is precisely formulated in section 2; an outline of the conjecture's proof is given in section 3 and

the technical details of the proof appear in section 4. Discussion of the results and suggestions for further research appear in section 5.

2. The conjecture. Coffman, Flatto, and Wright [1] considered a stochastic machine minimization problem (described in section 1) where the job processing times $T_1, T_2, \ldots, T_N$ are independent samples of an exponentially distributed random variable T with $E(T) = 1$, and the job waiting times are bounded by a constant W.

For this particular stochastic machine minimization problem it is possible to define a Markov process on the set of states (n, k, s), where n is the number of unfinished jobs, k is the number of jobs currently assigned to processors, and s is the time remaining on the timer (see [1]). Let $V(n, k, s)$ denote the expected cost incurred by an optimal allocation policy when the initial state is (n, k, s), and define

$$V(n, s) = \min_{1 \le k \le n} V(n, k, s) \tag{1}$$

as the expected cost incurred by an optimal allocation policy when there are n jobs to be processed with s units of time remaining on the timer, and there is an unlimited number of machines initially available. $V(n, k, s)$ can be computed by the Bellman equation,

(2)

$$V(n, k, s) = \inf_{0 \le t \le s} \left\{ e^{-k(s-t)} V(n, k+1, t) + \int_0^{s-t} k e^{-ku} V(n-1, k, s-u) du \right\}, \; k < n,$$

$$V(n, n, s) = n. \tag{3}$$

Coffman, Flatto, and Wright [1] proved that $V(n, k, s)$ has the following properties.

LEMMA 2.1. (i) $V(n, k, 0) = n$, $V(n, k, \infty) = k$. (ii) $V(n, k, s)$ *is nondecreasing in* k *for fixed* n *and* s, *strictly increasing in* n *for fixed* k *and* s, *and strictly decreasing in* s *for fixed* n *and* $k < n$.

Furthermore, the following assertion was made in [1].

CONJECTURE. *For each* $n > 1$, *there exist nonnegative numbers* l_{nk}, $1 \le k \le n-1$, *such that*

$$V(n, k+1, s) > V(n, k, s) \quad \text{for } s > l_{nk}, \tag{4}$$

$$V(n, k+1, s) = V(n, k, s) \quad \text{for } s \le l_{nk}, \tag{5}$$

$$l_{n(n-1)} \le l_{n(n-2)} \le \cdots \le l_{n1}. \tag{6}$$

Based on Lemma 2.1 and the above conjecture, Coffman, Flatto, and Wright proved the following result in [1].

THEOREM 2.2. *For all* k, $1 \le k \le n-2$,

$$l_{(n-1)k} < l_{nk}. \tag{7}$$

The above theorem and the conjecture imply the following structure of an optimal policy.

THEOREM 2.3 (see [1, Theorem 5.3]). *Let the initial state have $n > 1$ jobs to be scheduled, an unlimited number of machines available, and a clock time s such that $l_{nk} < s \leq l_{n(k-1)}$ for some $1 \leq k \leq n-1$. Then assign jobs to k machines and start running jobs in state (n, k, s). Continue running jobs in any given state until one of the following three events occurs:* (1) *The clock expires; in this case assign the remaining $n - k \geq 0$ waiting jobs to new machines.* (2) *A machine completes a job in some state $(n', k', s'), k' < n'$; in this case replenish the machine and continue in state $(n' - 1, k', s')$.* (3) *A state $(n', k', s'), k' < n'$, is reached in which the remaining time has reduced to $s' = l_{n'k'}$; in this case assign a waiting job to a new machine and continue in state $(n', k' + 1, s')$.*

In the remainder of this paper, we prove that the above stated conjecture is true, thus completing the proof of the optimality of the policy described in Theorem 2.3. We proceed as follows: First we briefly outline the main ideas of the proof and then we present all the technical details.

3. Outline of the proof of the conjecture. We establish, via the Bellman equation, the existence of "time thresholds" $l_{nk}, n = 1, 2, \ldots$ and $k = 1, 2, \ldots, n-1$ that have the following features:

(F1) When the initial state is $(n, k, s), s > l_{nk}$, then along sample path realizations where there are no job completions it is optimal not to assign any new (i.e., previously unused) machines to jobs waiting to be processed as long as the time remaining in the timer is strictly larger than l_{nk}. (Along the same sample path realizations it is optimal to assign a new machine to a job waiting to be processed when the time remaining in the timer is equal to l_{nk}.)

(F2) If the initial state is (n, k, t) and $t \leq l_{nk}$, then it is optimal to assign right away at least one new machine to a job waiting to be processed.

(F3) For any $n, n = 1, 2, \ldots$ and $k = 1, 2, \ldots, n-1$ the "time thresholds" l_{nk} are ordered as follows:

$$l_{n(n-1)} \leq l_{n(n-2)} \leq \cdots \leq l_{n1}.$$

To establish (F1) we use the Bellman equation and consider an initial state (n, k, s) with the following characteristic: The earliest time l_{nks} (according to the Bellman equation) at which it is optimal to add a new machine along sample path realizations where there are no job completions is such that $l_{nks} < s$. We prove that for all states (n, k, s') such that $s' > l_{nks}$ we have $l_{nks} = l_{nks'} := l_{nk}$. This result and the definition of l_{nks} (see (8)–(9)) lead to the proof of the first part of the conjecture (see (4)).

To establish (F2) we consider an instance where the initial state is $(n, k, s), s > l_{nk}$, and an optimal allocation policy satisfying the Bellman equation is used. We show that along sample path realizations where there are no job completions until t units of time remain on the timer ($t < l_{nk}$ by assumption) it is optimal to have at least $k + 1$ jobs under processing at t. This implies that if the initial state is (n, k, t) and an optimal allocation policy (satisfying the Bellman equation) is used, at least one new machine must be allocated to a job waiting to be processed at t. This feature together with a property of the cost function $V(n, k, s)$, described by Lemma 2.1(ii), leads to the proof of the second part of the conjecture (Eq. (5)).

To establish (F3) we use the first and second parts of the conjecture (already proved), a property of the cost function $V(n, k, s)$ described by Lemma 2.1 (ii), the Bellman equation, and a contradiction argument. Feature (F3) of the "time thresholds" l_{nk} describes the last part of the conjecture (see (6)).

Thus, the validity of the conjecture is established.

4. Proof of the conjecture. Consider the Bellman equation and for each state (n,k,s) define

$$A^s_{n,k} := \left\{ l : l = \arg \inf_{0\le t\le s} \left[e^{-k(s-t)} V(n,k+1,t) + \int_0^{s-t} k e^{-ku} V(n-1,k,s-u)du \right] \right\} \tag{8}$$

and

$$l_{nks} := \max \left\{ l : l \in A^s_{n,k} \right\}. \tag{9}$$

Let π^* denote the allocation policy that satisfies the Bellman equation and has the following characteristic: Along sample paths that originate at any state (n,k,s), with $n > k$, $s > l_{nks}$, and have no job completions until l_{nks} units of time remain on the timer, π^* adds a new machine at that point.

Proof of (4). Consider an initial state (n,k,s) such that $s > l_{nks}$. We prove that for all $s' > l_{nks}$ we have

$$l_{nks} = l_{nks'} := l_{nk}. \tag{10}$$

This fact together with the definition of l_{nks} leads to the proof of the first part of the conjecture, namely, (4). To prove (10) we proceed in two steps.

Step (i). Take s' such that $l_{nks} < s' < s$. We prove that $A^s_{n,k} = A^{s'}_{n,k}$. Pick $l \in A^{s'}_{n,k}$; then

$$V(n,k,s') = e^{-k(s'-l)} V(n,k+1,l) + \int_0^{s'-l} k e^{-ku} V(n-1,k,s'-u)du. \tag{11}$$

Furthermore, since $s > s' > l_{nks}$,

$$V(n,k,s) = e^{-k(s-s')} V(n,k,s') + \int_0^{s-s'} k e^{-ku} V(n-1,k,s-u)du. \tag{12}$$

Substituting (11) into (12), we get

$$V(n,k,s) = e^{-k(s-s')} \left[e^{-k(s'-l)} V(n,k+1,l) + \int_0^{s'-l} k e^{-ku} V(n-1,k,s'-u)du \right] + \int_0^{s-s'} k e^{-ku} V(n-1,k,s-u)du. \tag{13}$$

Letting

$$v = s - s' + u \tag{14}$$

in the second term of (13), we obtain

$$V(n,k,s) = e^{-k(s-l)} V(n,k+1,l) + \int_0^{s-l} k e^{-ku} V(n-1,k,s-u)du. \tag{15}$$

Equation (15) proves that $l \in A^s_{n,k}$. Hence,

$$A^{s'}_{n,k} \subset A^s_{n,k}. \tag{16}$$

Next, take $l \in A^s_{n,k}$; suppose that $l \notin A^{s'}_{n,k}$. Then, since by assumption $s > s' > l_{nks} \geq l$, it follows that

$$\begin{aligned} V(n,k,s) &= e^{-k(s-s')}V(n,k,s') + \int_0^{s-s'} ke^{-ku}V(n-1,k,s-u)du \\ &< e^{-k(s-s')}\left[e^{-k(s'-l)}V(n,k+1,l) + \int_0^{s'-l} ke^{-ku}V(n-1,k,s'-u)du\right] \\ &\quad + \int_0^{s-s'} ke^{-ku}V(n-1,k,s-u)du \\ &= e^{-k(s-l)}V(n,k+1,l) + \int_0^{s-l} ke^{-ku}V(n-1,k,s-u)du; \end{aligned} \tag{17}$$

the inequality in (17) results because $l \notin A^{s'}_{n,k}$. According to (17), $l \notin A^s_{n,k}$ and this is a contradiction. Hence, $l \in A^{s'}_{n,k}$; therefore,

$$A^s_{n,k} \subset A^{s'}_{n,k}. \tag{18}$$

From (16) and (18), we conclude that

$$A^s_{n,k} = A^{s'}_{n,k} \qquad \text{for all } s' \text{ such that } l_{nks} < s' < s. \tag{19}$$

Step (ii). Consider s' such that $\ell_{nks} < s < s'$. We prove that there is no $\hat{\ell} \in A^{s'}_{n,k}$ such that $\hat{\ell} \geq s$. The proof is by contradiction.

Suppose there exists $\hat{\ell} \in A^{s'}_{n,k}$ such that $\hat{\ell} \geq s$; then $\ell_{nks'} \geq s$. Start at (n,k,s') and use the optimal allocation policy π^*. Let Ω' be the set of sample paths that start at (n,k,s') and along which there are no job completions until s units of time remain on the timer. Since $\ell_{nks'} \geq s$, the expected cost incurred by the optimal policy π^* along Ω' is $V(n,k+\hat{k},s)$, where $\hat{k} \geq 1$. Furthermore, since $\hat{k}$ machines are added by the optimal policy π^* along Ω', we conclude that when there are n unfinished jobs and s units of time remain on the timer it is optimal to use $k+\hat{k}$ machines ($\hat{k} \geq 1$). That is,

$$V(n,s) = V(n,k+\hat{k},s). \tag{20}$$

On the other hand, since $s > \ell_{nks}$, (1), Lemma 2.1(ii), the Bellman equation, and the definition of ℓ_{nks} imply that

$$V(n,s) < V(n,k+1,s) \leq V(n,k+\hat{k},s), \tag{21}$$

which, in turn, implies that when there are n unfinished jobs and s units of time remain on the timer it is optimal to use less than $k+1$ machines. Thus, under the assumption that there exists $\hat{\ell} \in A^{s'}_{n,k}$ such that $\hat{\ell} \geq s$, a contradiction (see (20) and (21)) is reached. Consequently, every $\hat{\ell} \in A^{s'}_{n,k}$ satisfies $\hat{\ell} < s$. Furthermore, since $s' > s > l_{nks'}$, by arguments similar to those of step (i), we conclude that

$$A^{s'}_{n,k} = A^s_{n,k} \qquad \text{for all } s' \text{ such that } l_{nks} < s < s'. \tag{22}$$

Hence, for all states $(n,k,s),(n,k,s')$ such that $s > l_{nks}, s' > l_{nks}$, we have

$$l_{nks} = l_{nks'} := l_{nk}. \tag{23}$$

From (2), (3), (8), (9), (19), (22), and (23), we conclude that there exists l_{nk} such that

$$V(n,k,s) < V(n,k+1,s) \qquad \text{for all } s > l_{nk}. \tag{24}$$

Proof of (5). Consider any $t \leq l_{nk}$. We want to prove that for such a t,

$$V(n,k,t) = V(n,k+1,t). \tag{25}$$

To do this we formalize the idea outlining the proof of (F2) in section 3. Take (n,k,s), $s > l_{nk}$, as the initial state and use the allocation policy π^*. Let $\overline{\Omega}$ be the set of sample paths starting at (n,k,s) along which there are no job completions until t time units remain on the timer. Then, because of (2), (8), (9), and the definition of policy π^*, the expected cost incurred by the optimal policy π^* along $\overline{\Omega}$ is $V(n,k+r,s)$ for some $r \geq 1$. Moreover, since r machines are added by the optimal policy π^* along $\overline{\Omega}$, it follows that when there are n unfinished jobs and t units of time remain on the timer it is optimal to use $k+r$ machines ($r \geq 1$). Hence,

$$V(n,k+r,t) = V(n,t) \leq V(n,k,t). \tag{26}$$

On the other hand, by Lemma 2.1(ii)

$$V(n,k+r,t) \geq V(n,k,t). \tag{27}$$

From (26) and (27) we conclude that

$$V(n,k,t) = V(n,k+r,t). \tag{28}$$

From (28) and Lemma 2.1(ii) we obtain

$$V(n,k,t) = V(n,k+1,t) \qquad \text{for } t \leq l_{nk}. \tag{29}$$

Proof of (6). We use (4) and (5) and formalize the idea outlining the proof of (F3) in section 3. Suppose that $l_{nk} > l_{n(k-1)}$. Consider t such that $l_{nk} > t > l_{n(k-1)}$ and assume that there are n jobs to be processed at t. Then $t < l_{nk}$ and (5) imply that

$$V(n,k,t) = V(n,k+1,t). \tag{30}$$

From (1), (30), Lemma 2.1(ii), and the Bellman equation it follows that it is optimal to use at least $k+1$ machines when there are n jobs to be processed with t units of time remaining on the timer. On the other hand, $t > l_{n(k-1)}$ and (4) imply that

$$V(n,k,t) > V(n,k-1,t). \tag{31}$$

From (1), (31), Lemma 2.1(ii), and the Bellman equation we conclude that it is optimal to use less than k machines when there are n jobs to be processed with t units of time left on the timer. Thus, under the assumption $l_{nk} > l_{n(k-1)}$ we reach a contradiction. Consequently, $l_{nk} \leq l_{n(k-1)}$. By arguments similar to the above we obtain the remaining inequalities in (6).

The proof of the conjecture is now complete. □

5. Discussion. The proof of the conjecture stated in [1] and described in section 2 completes the proof of optimality of the policy described in Theorem 2.3. Theorem 2.3 describes the nature of an optimal policy for the stochastic machine minimization problem formulated in [1] and described in sections 1 and 2 of this paper. According to this optimal policy allocation decisions are made at job completions, when the timer expires, or when the "time thresholds" l_{nk} are reached. These "time thresholds" can be computed for all $n, k, k = 1, 2, \ldots, n-1$ by (8) and (9). The computation of l_{nk} is a challenging and formidable task that will not be further pursued in this paper.

The stochastic machine minimization problems investigated by Coffman, Flatto, and Wright in [1], [2], [3] consider only the scheduling of jobs (tasks, projects) that are initially available (i.e., they are available at time 0) in the system. Stochastic machine minimization problems with arrivals are interesting extensions of the problems considered in [1], [2], [3], as they arise in wireless communication networks and in automated target recognition systems (see [5]). A stochastic machine minimization problem with Poisson arrivals, exponential service times, and hard deadlines has been investigated in [5].

A class of interesting technical questions is to determine whether the structure of the optimal policies described in [1], [2], [3] remains unaltered when arrivals are included in the problem formulation.

Acknowledgments. The authors are grateful to the anonymous reviewers, whose comments helped to significantly improve the presentation of the results of this paper.

ALL OF US ARE SMARTER THAN ANY OF US: NONDETERMINISTIC WAIT-FREE HIERARCHIES ARE NOT ROBUST*

WAI-KAU LO† AND VASSOS HADZILACOS†

Abstract. A wait-free hierarchy [*ACM Transactions on Programming Languages and Systems*, 11 (1991), pp. 124–149; *Proceedings of the* 12th *ACM Symposium on Principles of Distributed Computing*, 1993, pp. 145–158] classifies object types on the basis of their strength in supporting wait-free implementations of other types. Such a hierarchy is robust if it is impossible to implement objects of types that it classifies as "strong" by combining objects of types that it classifies as "weak." We prove that if nondeterministic types are allowed, the only wait-free hierarchy that is robust is the trivial one, which lumps all types into a single level. In particular, the consensus hierarchy (the most closely studied wait-free hierarchy) is not robust. Our result implies that, in general, it is not possible to determine the power of a concurrent system that supports a given set of primitive object types by reasoning about the power of each primitive type in isolation.

1. Introduction.

1.1. Background and overview of the result. Interest in asynchronous shared-memory distributed computing dates back at least to Dijkstra's work on mutual exclusion [4]. In this model of computation, a set of processes cooperate toward some common task (such as excluding each other from a critical section) by asynchronously taking steps, some of which access shared registers. The operations that the processes can apply to the shared registers may be simple read and write operations, or more complex ones such as test-and-set, fetch-and-add, and so forth.

In a more general version of this model of computation, processes communicate by accessing shared objects. An object is accessed by applying an operation to it; the operation changes the state of the object and returns a value to the process that invoked it. Each object belongs to a type. A type consists of a set of states, a set of operations, a set of responses to operations, and a state transition relation that describes the effect of applying each operation to an object of that type. More specifically, the state transition relation specifies the responses the object may return and the states it may enter if an operation is applied when the object is in a particular state. Examples of types include register (with read and write operations only), test-and-set-register (with test-and-set operation), stack, queue, and priority-queue, among many others. (We use the sans serif font to indicate object types.)

The research of the second author was supported by a grant from the Natural Sciences and Engineering Research Council of Canada and a fellowship from the Engineering and Physical Sciences Research Council of the UK.

A distributed system supports, in hardware or software, a certain fixed set of "base" object types. To enhance the usability of such a system, a programmer may wish to enrich the set of available object types by implementing new types not directly supported by the system. To implement a type T from a set of base types $\mathcal{B}$ in a system of n processes, the programmer must provide n procedures for each operation *op* of T; these are the procedures that may be invoked by the n processes to apply *op* to an object of type T. These procedures may use any number of objects, all belonging to types in $\mathcal{B} \cup \{\mathsf{register}\}$. Note that this notion of implementation takes registers for granted. (For convenience, in the rest of the paper we say simply "registers" instead of "objects of type register.") This is reasonable since any realistic shared-memory system will provide at least this much.[1]

An implementation is required to be *linearizable* [7]: Any concurrent execution E consisting of invocations of the procedures written by the programmer must be equivalent to a *sequential* execution E_s consisting of the same procedure invocations, where each invocation returns a response and changes the state of the object it accesses in accordance with the state transition relation of the implemented type. Moreover, the sequential execution E_s must respect the order of procedure invocations that did not overlap in E; it may serialize in any way procedure invocations that were active concurrently in E.

Of special interest are *wait-free* implementations. In such implementations, a process is guaranteed to complete any procedure it invokes within a finite number of its own steps, regardless of whether other processes are fast, slow, or have even crashed (i.e., halted before completing). The requirement of wait freedom precludes the use of critical sections and busy waiting. In this paper, we consider only wait-free and linearizable implementations.

A fundamental question is whether, in a system of n processes, it is possible to implement a type T from a given set of base types $\mathcal{B}$. In a seminal paper [6], Herlihy established an important link between a type's ability to support implementations of other types and its ability to solve the well-known consensus problem [5], in which processes must reach agreement on one of their input values. (This problem is formally defined in section 3.1.) More specifically, he showed that if objects that belong to a set of types $\mathcal{B}$ (together with registers) can be used to solve consensus among n processes, then objects that belong to types in $\mathcal{B}$ (together with registers) can be used to implement *any* type in a system of n processes. This fact is referred to as "the universality of consensus."

Define the *consensus number* of a type T, as the maximum number n such that there is an algorithm that solves consensus among n processes using only objects of type T (and registers)—or ∞, if no such maximum exists. We can now place each type in the *consensus hierarchy* according to its consensus number. By the universality of consensus, the relative strength of two types T and T' is captured by their levels, say, n and n', respectively, in the consensus hierarchy. If $n \geq n'$, then T is at least as strong as T': in a system of n processes, T can be used to implement T'. If, further, $n > n'$, then T is strictly stronger than T': T' cannot be used to implement T in a system of n processes.

Although consensus numbers allow us to make *pairwise* comparisons on the

[1] The notion of implementation that we use in this paper is the most prevalent in the literature, although more restricted ones have also been studied. For instance, in some definitions registers are not taken for granted, while in others only one object of each base type may be used in the implementation. For further discussion on such more restricted definitions, see [8] and [10].

strength of types, it is not clear whether they can also be used to answer the more general implementability question: Can we implement T from a *set* of base types $\mathcal{B}$, in a system of n processes? Jayanti [8] observed that consensus numbers could be used to answer this question if the consensus hierarchy is *robust*; i.e., no type at level n can be implemented from types at levels strictly below n in a system of n processes.

If the consensus hierarchy is robust, a type T of consensus number n can be implemented from the set of base types $\mathcal{B}$ in a system of n processes if and only if $\mathcal{B}$ contains a type with consensus number n or more. Thus, we can answer the implementability question by looking at the consensus numbers of the base types and the desired target type. Another way of thinking about robustness is that if the consensus hierarchy has this property, a set of types $\mathcal{B}$ is as strong as the strongest of the types it contains. Thus, we can determine the power of a given set of types by reasoning about the power of each type in isolation. If, on the other hand, the consensus hierarchy is not robust, then to determine the power of a set of types we must, in general, take into account the interactions between the types in the set—a more formidable task. In view of the importance of the consensus hierarchy and the salutary consequences of robustness, it is useful to know whether the consensus hierarchy is robust.

Borowsky, Gafni, and Afek [1] and Peterson, Bazzi, and Neiger [15] proved that if we restrict our attention to *deterministic* types, the consensus hierarchy is robust. A type is deterministic if whenever we apply an operation to the type, the current state uniquely determines the response of the operation and the new state of the type. Although most of the common types are deterministic, some useful types are most naturally specified as nondeterministic ones. For example, consider a priority queue where keys are not unique. If several elements are in the queue with the same maximum priority, it is natural to allow the priority queue to remove and return any one of these elements. It is, of course, always possible to turn a nondeterministic type into a deterministic one by restricting the allowable behavior of the type. This, however, results in unnecessary restrictions for the implementor of the type. As pointed out in [11], by arbitrarily and artificially excluding legitimate behavior, we may be inadvertently ruling out efficient implementations of the type. Thus, the investigation of properties of nondeterministic types is of practical relevance.

In this paper we prove that if we allow nondeterministic types, then the consensus hierarchy is *not* robust. In view of this, a natural question is whether there is some other hierarchy of types which, like the consensus hierarchy, classifies types according to their strength in supporting wait-free implementations, but, unlike the consensus hierarchy, is robust. Jayanti proved that only a coarsening of the consensus hierarchy can have these properties [8]. In this paper we show that, in fact, the only hierarchy that has these properties is the trivial one in which all types are lumped into level one!

1.2. Overview of the proof. To prove our result we demonstrate two nondeterministic (but finite) object types, negation and booster; each of these is at level one of the consensus hierarchy, but, when combined, they can implement any type in a system of n processes, for any n. The central idea behind our proof is the formulation of *equality negation*, a weaker variant of the consensus problem which is formally defined in section 3.2. An object of type negation enables processes to directly solve this problem. An object of type booster allows processes to solve consensus provided they can prove that they can solve equality negation among them using initial values specified by the booster object.

We give a simple algorithm that allows n processes to solve consensus using a negation object, a booster object, and registers. (This algorithm suggests itself almost immediately from the definition of the booster type.) By the universality of consensus, this implies that the two types together can implement any type in a system of n processes. The difficult part of our result is in proving that each of negation and booster has consensus number one. The usual technique for proving upper bounds on the consensus number of a type, known as the "bivalence argument" [5], works well for deterministic types but runs into difficulties in the context of nondeterministic types. The bulk of the technical work in the paper (sections 7 and 8) seeks ways to circumvent these difficulties.

1.3. Related work. Jayanti was the first to raise the question of robustness of the consensus hierarchy [8]. Before his work, it had been widely, though tacitly, assumed that the hierarchy is robust. Jayanti showed that various natural variants of the consensus hierarchy (including the one used in [6]) are not robust. He also proved that if a robust hierarchy that classifies types according to their ability to implement other types exists, it must be either the consensus hierarchy or a coarsening of it—i.e., a hierarchy obtained by collapsing together adjacent levels of the consensus hierarchy.

As mentioned earlier, Borowsky, Gafni, and Afek [1] and Peterson, Bazzi, and Neiger [15] proved that the consensus hierarchy, restricted to deterministic types, is robust. In recent work, Ruppert [18] gave simple proofs of robustness if we restrict our attention to certain interesting classes of deterministic types.

In the next paragraph we describe some results concerning the (non)robustness of the consensus hierarchy in a model of objects that differs from the "standard" model introduced in [6] (and used in the present paper). To explain the different models we recall that, in a system of n processes, each object of type T has n procedures for each operation *op* of T. Processes trying to apply *op* to an object concurrently must invoke different procedures. In the "standard" model of objects a process that wishes to apply *op* to the object invokes one of these n procedures and remains bound to it only for the duration of the invocation. Other processes may later use that procedure. In the alternative model, each process permanently binds itself to one procedure. Objects in this model are sometimes called *hardwired*, since the binding of processes to procedures is fixed.

Chandra et al. [2] prove that in the model of hardwired objects, the consensus hierarchy is not robust if nondeterministic types are allowed. Moran and Rappoport [14] strengthen this result by proving that it applies even if only deterministic types are allowed. We borrowed from [2] the idea of a booster type, which "boosts" the power of a weak type T if it is given satisfactory evidence that processes have access to T. The booster of [2] promotes a type that solves consensus between two processes to a type that solves consensus among three processes. In our case, the booster promotes a type that solves equality negation for n processes to a type that solves consensus for n processes.

Closest to our results is the work of Schenk [19, 20], which precedes ours. He also exhibits two nondeterministic object types each of which (together with registers) is individually too weak to solve consensus between two processes, but which, taken together, can solve consensus for any number of processes. Our result strengthens this in two related ways: First, Schenk's result requires a type that exhibits infinite nondeterminism, while our types exhibit only bounded nondeterminism. Second, and perhaps more important, his result requires a definition of wait freedom that is different from the usual one. Specifically, he defines an algorithm to be wait-free if,

for any input, there is a bound on the number of steps a process may take before it halts. In the context of objects with infinite nondeterminism this definition is strictly stronger than the usual definition of wait freedom, which requires only that all executions of the algorithm be finite.

In [17], Rachman proved that for each n, there is a (nondeterministic) type with consensus number n that cannot implement some type with consensus number smaller than n in a system of $2n+1$ processes. This result addresses a point of implementability between types, but it has no bearing on the nonrobustness of the consensus hierarchy. Informally, nonrobustness asserts that some "strong" type (i.e., a type at level n) *can be implemented by* a combination of "weak" types (i.e., types at levels below n) *in a system of n processes*. In contrast, Rachman's result says that some "strong" type (i.e., a type at level n) *cannot implement* some "weak" type (i.e., a type at a level below n) *in a system with sufficiently many processes*.

1.4. Organization of the paper. In section 2 we define the model of computation used in this paper. In section 3 we review the consensus problem and introduce the equality negation problem. In section 4 we define the types negation and booster. In section 5 we show how to solve consensus for any number of processes using registers along with a negation and a booster object. In section 6 we define some concepts and derive technical results needed in the next two sections. In sections 7 and 8 we prove that registers and negation objects alone, as well as registers and booster objects alone, cannot be used to solve consensus for two processes. Section 9 concludes the paper.

2. The model of computation. In this section we describe the model of computation used in this paper.

2.1. Types and objects. An *object type* T is a tuple (Q, OP, RES, δ), where Q is a set of *states*, OP is a set of *operations*, RES is a set of *responses* to operations, and $\delta \subseteq Q \times OP \times RES \times Q$ is a *state transition relation*, which describes the possible behaviors of objects of type T, and is sometimes called the type's *sequential specification*. More specifically, $(q, op, res, q') \in \delta$ means that if the current state of an object of type T is q and operation op is applied to it, then it is possible that response res will be returned to the operation and the object will enter state q'. We say that T is *deterministic* if for any $q \in Q$ and $op \in OP$ there is at most one $res \in RES$ and $q' \in Q$ so that $(q, op, res, q') \in \delta$; otherwise, we say that T is *nondeterministic*.

For convenience, in this paper we require each type (Q, OP, RES, δ) to be *total*: For any $q \in Q$ and $op \in OP$, there is at least one $res \in RES$ and $q' \in Q$ such that $(q, op, res, q') \in \delta$. That is, the type can do *something* in response to any operation in any state. Further, we assume that for any $q \in Q$, $op \in OP$, and $res \in RES$ there is at most one $q' \in Q$ so that $(q, op, res, q') \in \delta$. In other words, if an operation is applied in a given state, the type does not lead to different states unless it returns different responses. We remark that this assumption is not necessary for the results in this paper, but it simplifies the presentation of their proofs. All types considered in this paper have this property, so we can make this assumption without loss of generality.

An *object* is an instance of an object type. For the purposes of this paper, we can think of an object O of type T as an automaton whose states and state transition relation are as in T—except that states are labeled with O, to distinguish them from the states of other objects of the same type.

2.2. Processes and algorithms. A *process* is a deterministic automaton that interacts with objects. More precisely, let $\mathcal{O}$ be a set of objects, and let OP and

RES be the set of all operations and responses, respectively, of the types to which the objects in $\mathcal{O}$ belong. We define a *process that uses* $\mathcal{O}$ as a tuple $P = (\Sigma, \Sigma_0, \nu, \tau)$, where Σ is a set of *states*, $\Sigma_0 \subseteq \Sigma$ is a set of *initial states*, and $\nu : \Sigma \to OP \times \mathcal{O}$ and $\tau : \Sigma \times RES \to \Sigma$ are functions that describe the interaction of the process with the objects. Intuitively, if P is in a state $\sigma \in \Sigma$ and $\nu(\sigma) = \langle op, O \rangle$, then in its next step P will apply operation *op* to object O. (If $\nu(\sigma) = \langle op, O \rangle$, we require that *op* be an operation of O's type.) Based on its current state, O will return a response *res* to P and will enter a new state, in accordance with the state transition relation of the type to which O belongs. Finally, P will enter state $\tau(\sigma, res)$, as a result of the response it received from O. For convenience, we assume that the function ν is total. In other words, it is always possible for a process to apply another operation. Note that we can easily accommodate processes that terminate in this framework by imagining that a process that reaches a final state applies infinitely many "DO-NOTHING" operations to a local dummy object which always returns *ack* to such operations.

An *algorithm* **A** consists of a set of processes Π, a set of objects $\mathcal{O}$ so that each $P \in \Pi$ uses a subset of $\mathcal{O}$, and an initial state for each object in $\mathcal{O}$. The designated initial state of an object is one of the states of the type to which the object belongs. If $\mathcal{S}$ is a set of types, we say that **A** *uses* $\mathcal{S}$ if every object that **A** uses belongs to a type in $\mathcal{S}$ and **A** uses at least one object of every type in $\mathcal{S}$. A *configuration* C of **A** is a tuple consisting of a state for each process in Π and each object in $\mathcal{O}$. C is an *initial* configuration of **A** if each process is in one of its initial states, and each object is in the state designated as the initial state by **A**.

A *step* of process P is a tuple (P, op, O, res); this indicates that P has applied operation *op* to object O and received response *res*. Let $P = (\Sigma, \Sigma_0, \nu, \tau)$ and let C be a configuration, where the state of P in C is σ. If $\nu(\sigma) = \langle op, O \rangle$, we say that P has operation *op* to O *pending* in C. If, in addition, the state of O in C is q, and *res* is a legitimate response of O to *op* in state q (i.e., for some state q' of O, (q, op, res, q') is in the state transition relation of O's type), then we say that the step $e = (P, op, O, res)$ is *applicable* to C. If $e = (P, op, O, res)$ is applicable to C, $e(C)$ denotes the configuration resulting from C after step e. More precisely, if in C the state of P is σ and the state of O is q, then $e(C)$ is the configuration in which P has state $\tau(\sigma, res)$, O is in state q' such that (q, op, res, q') is in the state transition relation of O's type, and all other processes and objects are in the same state as in C.[2]

A *schedule* S *of algorithm* **A** is a (finite or infinite) sequence of steps of **A**'s processes. $S = e_1, e_2, \ldots, e_i, \ldots$ is *applicable* to a configuration C if e_1 is applicable to C, and e_{i+1} is applicable to $e_i(e_{i-1}(\ldots(e_1(C))\ldots))$ for all i. If S is finite and has k steps, $S(C)$ denotes $e_k(e_{k-1}(\ldots(e_1(C))\ldots))$, i.e., the configuration that results after applying the steps in S one at a time, starting with configuration C. If S and S' are schedules such that S is finite, then $S \cdot S'$ denotes their concatenation. If every step in schedule S is a step of the same process P, then S is called a *solo* schedule of P. If S is an infinite schedule and process P has infinitely many steps in S, then P is *correct* in S.

2.3. Wait-free hierarchies and robustness. Recall from section 1.1 that the consensus number of a type T is the maximum number n so that there is an algorithm that solves consensus among n processes and uses only objects of type T and registers;

[2]It is here we use the assumption that, to go to different states, the object must return different responses. Without this assumption, we have to define $e(C)$ as a *set* of configurations, rather than as a single one.

if there is no such maximum, the consensus number of T is ∞. By the universality of consensus, the consensus number of a type is a measure of its strength, i.e., of its ability to support (wait-free and linearizable) implementations of other types.

A *hierarchy* (of types) is a function that assigns to each type a positive integer or ∞, called the type's *level*. The intention is that a type's level reflects its strength: the higher the level, the stronger the type. A hierarchy is *wait-free* if no type is assigned to a level higher than the type's consensus number. Intuitively, a wait-free hierarchy does not overstate any type's strength. Thus, a hierarchy must be wait-free in order to comply with the intention that its levels somehow reflect the strength of types. The *consensus hierarchy* is the hierarchy that maps each type exactly to its consensus number. Clearly, the consensus hierarchy is wait-free.

A hierarchy h is *robust* if for any $n \geq 1$ such that there is a type at level n and any set of types $\mathcal{B}$, there is no algorithm that solves consensus among n processes and uses only objects that belong to types in $\mathcal{B}$ and registers, unless $\mathcal{B}$ contains a type of level n or higher. Thus, if a wait-free hierarchy is robust, a type that is classified as "strong" by the hierarchy cannot be implemented by types that are classified as "weak." To see this assume the contrary: a type T at level n can be implemented using only objects of types below n (and registers). Since the hierarchy is wait-free and T is at level n, we can solve consensus among n processes using only objects of type T (and registers). Since T can be implemented from types in levels below n and registers, we can solve consensus among n processes using only objects of types in levels below n and registers, which contradicts the definition of robustness.

A hierarchy is *nontrivial* if it assigns types to at least two different levels. Jayanti and Toueg [9] showed that the consensus hierarchy assigns types to all levels, and so the consensus hierarchy is nontrivial.

3. The consensus and equality negation problems. In this section we review the consensus problem and define equality negation, a problem that plays a central role in our results.

3.1. The consensus problem. In the consensus problem, each of n processes starts with a private initial value, drawn from the set $\{0, 1\}$. Each correct process must eventually irrevocably decide one of these initial values, so that no two processes decide different values. Thus, a *consensus algorithm* $\mathbf{A}_c$ *for* n *processes* satisfies the following properties. Each process in $\mathbf{A}_c$ has two initial states associated with input values 0 and 1, respectively, and two disjoint sets of states associated with decisions 0 and 1, respectively. Since a decision is irrevocable, we require that once a process has entered a state associated with decision $d \in \{0, 1\}$, all states that it may subsequently enter are also associated with d. In addition, for any schedule S that is applicable to an initial configuration I of $\mathbf{A}_c$, the following three properties hold.

Termination: If S is infinite, then for every correct process in S there is a prefix S' of S such that the process has decided in $S'(I)$.

Validity: If a process has decided in $S(I)$, then its decision must be the initial value of some process in I.

Agreement: If two processes have decided in $S(I)$, then their decisions are the same.

The termination property requires correct processes to eventually decide in all executions, regardless of the number of processes that are correct. Thus, this formulation of this property commits us to so-called *wait-free* algorithms, where correct processes satisfy their liveness properties (in this case, to eventually decide) regardless of the progress made by other processes.

3.2. The equality negation problem. We now define the equality negation problem for $n \geq 2$ processes, $P_0, \ldots, P_{n-1}$. To understand the definition it is best to first consider the special case of two processes ($n = 2$). In this special case, each of P_0 and P_1 has a private initial value, drawn from the set $\{0, 1, 2\}$ (instead of $\{0, 1\}$ in consensus). Each correct process must irrevocably decide either 0 or 1 so that the decisions of the processes are the same if and only if the initial values of the processes are different.

We now generalize the problem for arbitrary $n \geq 2$; the idea is to replace the role of P_1 by a *group* of $n - 1$ processes $\mathcal{P}_1 = \{P_1, \ldots, P_{n-1}\}$. More specifically, each process has an initial value drawn from the set $\{0, 1, 2\}$. Additionally, we assume that all processes in $\mathcal{P}_1$ have the same initial value; if not, the problem imposes no constraints whatsoever on the behavior of processes. Every process must eventually decide irrevocably either 0 or 1, so that no two processes in $\mathcal{P}_1$ decide different values; and if P_0 and any process in $\mathcal{P}_1$ decide, then their decisions are the same if and only if their initial values are different. Thus, an *equality negation algorithm* $\mathbf{A}_{en}$ *for processes* $P_0, \ldots, P_{n-1}$ satisfies the following properties. Each process in $\mathbf{A}_{en}$ has three initial states associated with input values 0, 1, and 2, respectively. As in a consensus algorithm, each process has two disjoint sets of states associated with decisions 0 and 1, respectively. Since a decision for equality negation is also irrevocable, once a process has entered a state associated with decision $d \in \{0, 1\}$, all states that it may subsequently enter must be associated with d as well. In addition, for any schedule S applicable to an initial configuration I of $\mathbf{A}_{en}$ in which all processes in $\mathcal{P}_1$ have the same initial value, the following three properties hold.

Termination: If S is infinite, then for every correct process in S, there is a prefix S' of S such that the process has decided in $S'(I)$.

Negation: If process P_0 and any process in $\mathcal{P}_1$ have decided in $S(I)$, then their decisions are the same if and only if their initial values are different.

Agreement: If any two processes in $\mathcal{P}_1$ have decided in $S(I)$, then their decisions are the same.

It is well known that there is no consensus algorithm for even two processes that uses only registers [3, 13]. In the appendix we prove that the same is true for equality negation.

THEOREM 3.1. *There is no algorithm that solves equality negation for two processes and uses only registers.*

4. Specification of types negation and booster. We define two nondeterministic object types, named negation and booster, that will be used later to establish the result that no nontrivial wait-free hierarchy is robust. Both of these types have bounded nondeterminism; indeed, each has only finitely many states.

4.1. Type negation. The specification of negation appears in Figure 4.1.[3] To understand the specification, it is useful to keep in mind the following intuitive explanation of the type. This type supports only one kind of operation, called NEGATE, with two parameters $i \in \{0, 1\}$ and $v \in \{0, 1, 2\}$. For reasons that will be clear later, we shall refer to i as the *process* parameter and to v as the *initial-value* parameter. A negation object will become "upset" if and only if two NEGATE operations with process parameter 0 are applied or two NEGATE operations with process parameter 1, but with different initial-value parameters, are applied. If the negation object is

[3] In this figure, and throughout this paper, for any variable $v \in \{0, 1\}$, $\overline{v}$ denotes the complement of v; i.e., $\overline{v} = 1 - v$.

Let $\mathcal{A}$ be the set of four-tuples of the form $\langle v_0, v_1, u_0, u_1\rangle$, where $v_0, v_1 \in \{\perp, 0, 1, 2\}$, $u_0, u_1 \in \{\perp, 0, 1\}$, and the following conditions apply:

- $v_0 = \perp$ if and only if $u_0 = \perp$;
- $v_1 = \perp$ if and only if $u_1 = \perp$;
- at least one of v_0, v_1 is not $\perp$; and
- if $v_0, v_1 \neq \perp$ then $v_0 = v_1$ if and only if $u_0 \neq u_1$.

Set of states: $\{☺, ☹\} \cup \mathcal{A}$.

Set of operations: $\{\,\text{NEGATE}(i, v) : i \in \{0, 1\}, v \in \{0, 1, 2\}\,\}$.

Set of responses: $\{0, 1\}$.

```
NEGATE(i, v), i ∈ {0,1}, v ∈ {0,1,2}, return either 0 or 1
  case current_state
    ☹: return Choose({0,1})
    ☺: u ← Choose({0,1})
       if i = 0 then current_state ← ⟨v, ⊥, u, ⊥⟩
       else current_state ← ⟨⊥, v, ⊥, u⟩
       return u
    ⟨v0, v1, u0, u1⟩:
       if i = 0 then
          if v0 ≠ ⊥ then current_state ← ☹; return Choose({0,1})
          else (* v0 = ⊥ and, thus, v1, u1 ≠ ⊥ *)
             if v ≠ v1 then u ← u1
             else u ← ū1
             current_state ← ⟨v, v1, u, u1⟩; return u
       else (* i = 1 *)
          if v1 ≠ ⊥ then
             if v ≠ v1 then current_state ← ☹; return Choose({0,1})
             else return u1
          else (* v1 = ⊥ and, thus, v0, u0 ≠ ⊥ *)
             if v ≠ v0 then u ← u0
             else u ← ū0
             current_state ← ⟨v0, v, u0, u⟩; return u
```

FIG. 4.1. *Specification of type* negation.

upset, it will arbitrarily return either 0 or 1 to any operation, and will remain upset forever. As long as the negation object is not upset, it responds to invocations with values that satisfy the following: All NEGATE operations with process parameter 1 receive the same response; any two NEGATE operations with different process parameters receive the same response if and only if their initial-value parameters are different. Thus, an object O of type negation can be used to solve equality negation for processes $P_0, \ldots, P_{n-1}$ in a direct way: P_0 applies NEGATE$(0, v)$ to O, where v is P_0's initial value; each process in $\{P_1, \ldots, P_{n-1}\}$ applies NEGATE$(1, v')$ to O, where v' is the process's initial value; each process decides the value returned by object O.

To achieve this behavior, type negation has two distinguished states: the *fresh* state, denoted by ☺, and the *upset* state, denoted by ☹. The remaining states are of the form $\langle v_0, v_1, u_0, u_1\rangle$, where $v_0, v_1 \in \{\perp, 0, 1, 2\}$ and $u_0, u_1 \in \{\perp, 0, 1\}$. The intended meaning of state $\langle v_0, v_1, u_0, u_1\rangle$, assuming the object is initialized to the fresh state, is as follows: v_0 is the initial-value parameter of the first NEGATE operation

with process parameter 0; u_0 is the value returned to that operation; v_1 and u_1 have corresponding interpretations for the first NEGATE operation with process parameter 1. By maintaining this information, the object knows all it needs in order to respond appropriately to the NEGATE operations applied to it.

The pseudocode in Figure 4.1 describes the state transition relation of negation. In addition to standard programming constructs, we use the function "Choose," which takes as a parameter a set V of integers and returns an arbitrary value in V. We also assume that the present state of the type is recorded in variable *current_state*.

4.2. Type booster. The specification of type booster is shown in Figure 4.2. To understand the specification, it is useful to keep in mind the following intuitive explanation of the type. There are two kinds of operations that can be applied to a booster object: ENROLL and REVEAL. An ENROLL operation requires a parameter $i \in \{0,1\}$ and arbitrarily returns a value in $\{0,1,2\}$. A REVEAL operation requires three parameters $i \in \{0,1\}$, $v \in \{0,1,2\}$, and $u \in \{0,1\}$ and returns a value in $\{0,1\}$; we shall refer to these three parameters as the *process*, *challenge*, and *decision* parameters, respectively. A booster object will be "upset" if (and only if) any one of the following holds:

- Two ENROLL(0) operations are applied.
- For some $i \in \{0,1\}$ and $v \in \{0,1,2\}$, a REVEAL(i,v,u) operation is applied such that no ENROLL(i) operation has previously been applied or v is not the response of any such ENROLL(i) operation.
- A REVEAL(i_0,v_0,u_0) and a REVEAL(i_1,v_1,u_1) operation are applied such that one of the following is true: (a) $i_0 = i_1 = 0$, or (b) $i_0 = i_1 = 1$ and either $v_0 \neq v_1$ or $u_0 \neq u_1$, or (c) $i_0 \neq i_1$ and $v_0 = v_1 \Leftrightarrow u_0 = u_1$.

Once upset, the booster object remains upset forever. If not upset, the object maintains a secret: the parameter of the first ENROLL operation applied. The object will reveal this secret to every process that subsequently accesses it with a REVEAL operation. If upset, however, the object arbitrarily returns either 0 or 1 to every REVEAL operation.

The intended use of a booster object by processes $P_0, \ldots, P_{n-1}$ is as follows: The first thing process P_0 does to a booster object is to apply ENROLL(0) to "enroll" itself in the object. Similarly, the first thing any process in $\mathcal{P}_1 = \{P_1, \ldots, P_{n-1}\}$ does to a booster object is to apply ENROLL(1) to enroll its group in the object. In response to the ENROLL operation it applies, every process receives a value in $\{0,1,2\}$ from the booster object. This value is a "challenge" given by the object with which the process is required to solve equality negation. More specifically, process P_0 uses the challenge, say, v_0, received from the booster object as its initial value to solve equality negation. The different processes in $\mathcal{P}_1$, however, may receive different challenges from the booster object. Thus, before embarking upon solving equality negation, processes in $\mathcal{P}_1$ must first choose a unique initial value, say, v_1, from the set of challenges they received. After solving equality negation and deciding a value $u \in \{0,1\}$, process P_0 (respectively, every process in $\mathcal{P}_1$) applies the operation REVEAL$(0,v_0,u)$ (respectively, REVEAL$(1,v_1,u)$) to the booster object to obtain the secret.

To achieve the behavior described above, type booster (like type negation) has two distinguished states: the *fresh* state, denoted ☺, and the *upset* state, denoted ☹. The remaining states are of the form $\langle V, v_0, v_1, u_0, u_1, d\rangle$, where $V \subseteq \{0,1,2\}$, $v_0, v_1 \in \{\perp, 0, 1, 2\}$, $u_0, u_1 \in \{\perp, 0, 1\}$, and $d \in \{0,1\}$. The intended meaning of state $\langle V, v_0, v_1, u_0, u_1, d\rangle$ is as follows (assuming the object is initialized to the fresh state):

- d is the "secret"—the parameter the first ENROLL operation applied, i.e.,

Let $\mathcal{A}$ be the set of six-tuples of the form $\langle V, v_0, v_1, u_0, u_1, d\rangle$, where $V \subseteq \{0,1,2\}$, $v_0, v_1 \in \{\perp, 0, 1, 2\}$, $u_0, u_1 \in \{\perp, 0, 1\}$, $d \in \{0,1\}$, and the following conditions apply:

- if $d = 0$ then $v_0 \neq \perp$; if $d = 1$ then $V \neq \emptyset$;
- if $v_0 = \perp$ then $u_0 = \perp$;
- $v_1 = \perp$ if and only if $u_1 = \perp$, and if $v_1 \neq \perp$ then $v_1 \in V$; and
- if $v_0, v_1 \neq \perp$ then $v_0 = v_1$ if and only if $u_0 \neq u_1$.

Set of states: $\{☺, ☹\} \cup \mathcal{A}$.
Set of operations: $\{\,\text{ENROLL}(i) : i \in \{0,1\}\,\} \cup \{\,\text{REVEAL}(i, v, u) : i, u \in \{0,1\}, v \in \{0,1,2\}\,\}$.
Set of responses: $\{0,1,2\}$.

```
ENROLL(i), i ∈ {0,1}, return a value in {0,1,2}
    v ← Choose({0,1,2})
    case current_state
        ☹: no state change
        ☺: if i = 0 then current_state ← ⟨∅, v, ⊥, ⊥, ⊥, 0⟩

```

FIG. 4.2. *Specification of type* booster.

whether P_0 or some process in $\mathcal{P}_1$ is the process that applied the first ENROLL. More accurately, d is the parameter of the first ENROLL operation.

- V is the set of challenges given to processes in $\mathcal{P}_1$, one of which these processes must use to solve equality negation. More accurately, V is the set of values returned to ENROLL(1) operations.
- v_0 is the challenge with which P_0 must solve equality negation. More accurately, the value returned to the first ENROLL(0) operation.
- v_1 is the challenge chosen from V by processes in $\mathcal{P}_1$, with which these pro-

cesses solve equality negation. More accurately, v_1 is the challenge parameter of the first REVEAL$(1, *, *)$ operation.[4]

- u_0 is the decision reached for equality negation by P_0. More accurately, u_0 is the decision parameter of the first REVEAL$(0, *, *)$ operation.
- u_1 is the decision reached for equality negation by the first process in $\mathcal{P}_1$ that tries to get the secret. More accurately, u_1 is the decision parameter of the first REVEAL$(1, *, *)$ operation.

With this information, the object knows all it needs in order to respond appropriately to operations.

5. The proof of nonrobustness. Later in the paper we shall prove that negation and booster each has consensus number one. Taking this for granted, in this section we prove our main result: in the context of nondeterministic types, no nontrivial wait-free hierarchy can be robust. The key to this proof is the following lemma.

LEMMA 5.1. *For any $n \geq 1$, if consensus among n processes can be solved using only* negation *and* booster *objects and registers, then consensus among $n+1$ processes can also be solved using only* negation *and* booster *objects and registers.*

Proof. Suppose that consensus among n processes can be solved using only negation and booster objects and registers. Let $\mathbf{A}_c^1$ and $\mathbf{A}_c^2$ be algorithms that solve consensus among n processes, $P_1, P_2, \ldots, P_n$, and use only negation and booster objects and registers. Without loss of generality, we may assume that $\mathbf{A}_c^1$ and $\mathbf{A}_c^2$ solve consensus with initial values drawn from the set {0,1,2}.[5]

We shall show that the algorithm in Figure 5.1 uses $\mathbf{A}_c^1$ and $\mathbf{A}_c^2$ to solve consensus among $n+1$ processes, $P_0, P_1, \ldots, P_n$. The following are some conventions used in the pseudocode in Figure 5.1 and other algorithms described later. We use capital letters for names of shared objects (including registers) and lower-case letters for names of local variables. Local variables with the same name that belong to different processes are distinct. The notation "Apply(P, op, O)" denotes the procedure by which process P applies operation op to object O; the procedure returns the response of the object to that operation. We use a special (but familiar) notation for the application of operations to an object R of type register: we place R on the left-hand side of an assignment statement to indicate a WRITE operation applied to R, and we use the name R in any other context to indicate a READ operation applied to R. If $\mathbf{A}$ is an equality negation or consensus algorithm and P is a process of $\mathbf{A}$, the procedure Execute$(P, \mathbf{A}, k)$ causes the caller to execute the steps of process P in algorithm $\mathbf{A}$ using k as its initial value and returns the decision of P in the simulated execution of that algorithm.

Before proving that the algorithm in Figure 5.1 does, in fact, solve consensus, we informally explain how it works.

- P_0 first writes its initial value into register R_0. It then enrolls in the booster object O_b by applying ENROLL(0) and obtains a challenge, say, v, with which it is required to solve equality negation. To do so, P_0 applies NEGATE$(0, v)$ to the negation object O_n. Let u be the value returned by O_n. By applying REVEAL$(0, v, u)$ to O_b, P_0 determines whether it or one of $\{P_1, \ldots, P_n\}$ was the first to enroll in O_b.

[4]Here, and in the rest of the paper, we use "$*$" to indicate a "don't care" entry.

[5]In our definition of consensus (sometimes called *binary* consensus for emphasis), the initial values of processes are drawn from the set $\{0, 1\}$. It is well known [16] that if a set of types that includes register can be used to solve (binary) consensus, it can also be used to solve consensus with initial values drawn from an arbitrary set.

Shared: all booster and negation objects and registers used in $\mathbf{A}_c^1$ and $\mathbf{A}_c^2$, each initialized as specified by $\mathbf{A}_c^1$ or $\mathbf{A}_c^2$
O_b: booster, initialized to ☺
O_n: negation, initialized to ☺
R_0, R_1: register, each initialized to $\perp$

Code for process P_0

1 $R_0 :=$ initial value of P_0
2 $v := \text{Apply}(P_0, \text{ENROLL}(0), O_b)$
3 $u := \text{Apply}(P_0, \text{NEGATE}(0, v), O_n)$
4 $d := \text{Apply}(P_0, \text{REVEAL}(0, v, u), O_b)$
5 **decide** R_d

Code for process P_k, $k \in \{1, \ldots, n\}$

1 *init* := initial value of P_k
2 $R_1 := \text{Execute}(P_k, \mathbf{A}_c^1, \mathit{init})$
3 $w := \text{Apply}(P_k, \text{ENROLL}(1), O_b)$
4 $v := \text{Execute}(P_k, \mathbf{A}_c^2, w)$
5 $u := \text{Apply}(P_k, \text{NEGATE}(1, v), O_n)$
6 $d := \text{Apply}(P_k, \text{REVEAL}(1, v, u), O_b)$
7 **decide** R_d

FIG. 5.1. *A consensus algorithm for $n+1$ processes using only objects of types* negation *and* booster *and registers.*

- Processes $P_1, \ldots, P_n$ first agree on one of their initial values; they use $\mathbf{A}_c^1$ for that purpose. They then write the agreed-upon initial value into register R_1 (multiple processes may write into R_1, but they all write the same value). Each P_k, $k \in \{1, \ldots, n\}$, then enrolls in O_b by applying ENROLL(1) and obtains a challenge. Since, object O_b may hand out different challenges to processes $P_1, \ldots, P_n$, these processes use the consensus algorithm $\mathbf{A}_c^2$ to agree upon one of these challenges, say, v. Each P_k, $k \in \{1, \ldots, n\}$, uses v as its initial value to solve equality negation. To do so, P_k applies NEGATE$(1, v)$ to the negation object O_n. Let u be the value returned by O_n. By applying REVEAL$(1, v, u)$ to O_b, P_k determines whether P_0 or one of the other processes was the first to enroll in O_b.

Since all processes agree on whether P_0 or one of the other processes was the first to enroll in O_b, they can agree on the initial value of some process: If P_0 was the first to enroll, all processes agree on the value they read from R_0; otherwise, they all agree on the value they read from R_1.

We now prove that the algorithm in Figure 5.1 solves consensus. It is clear that the algorithm satisfies termination, since both $\mathbf{A}_c^1$ and $\mathbf{A}_c^2$ do. Consider any execution of the algorithm. From the specification of booster and negation, it is easy to verify that the algorithm accesses O_b and O_n in such a way that these objects never become upset. Furthermore, if d is the parameter of the first ENROLL operation applied to O_b, then that ENROLL operation will cause O_b to enter a state of the form $\langle *, *, *, *, *, d \rangle$. The last component of the state is never changed once it is set. Furthermore, any REVEAL operation applied to O_b that does not cause the object to become upset returns the last component of the state. Thus,

(1) every REVEAL operation applied to O_b returns d, where d is the parameter of the first ENROLL operation applied to O_b.

Next we claim that, for each $k \in \{0, 1\}$, at most one value is written into register R_k and that value is an initial value of some process. This is clearly true for $k = 0$, since only P_0 writes into R_0, and the value it writes there is its initial value. For $k = 1$, this follows from the agreement and validity properties of the consensus algorithm $\mathbf{A}_c^1$ used by the processes in $\{P_1, \ldots, P_n\}$ to determine the value they each write into R_1.

Thus, to prove the algorithm in Figure 5.1 satisfies validity, it suffices to show that if a process decides the value in register R_d, then some process has previously written a value into R_d. This follows from (1), since in the algorithm a process writes into R_k before applying ENROLL(k), for each $k \in \{0, 1\}$.

It remains to show that the algorithm satisfies agreement. Consider any execution in which two distinct processes P and P' have decided. By (1), P and P' decide the value in the same register R_d, where d is the parameter of the first ENROLL operation applied to O_b. By validity, a process decides the value in R_d only if some process has written a value into R_d. As argued earlier, only one value is written into R_d in any given execution. Therefore, P and P' decide the same value, the one written in R_d. Therefore, the algorithm satisfies agreement.

Thus the algorithm in Figure 5.1 solves consensus for $n + 1$ processes. It uses only registers and booster and negation objects because, in addition to the (registers, booster and negation) objects used by $\mathbf{A}_c^1$ and $\mathbf{A}_c^2$, the algorithm uses only two registers, one booster object, and one negation object. □

THEOREM 5.2. *For any $n \geq 1$, consensus among n processes can be solved using only registers and objects of types* negation *and* booster.

Proof. The theorem is proved by induction on n. The basis, $n = 1$ is trivial (because consensus for one process is trivial). The induction step is Lemma 5.1. □

COROLLARY 5.3. *There is no nontrivial wait-free hierarchy that is robust.*

Proof. Suppose h is a nontrivial wait-free hierarchy of types. We shall prove that h is not robust. By Theorems 7.10 and 8.15 (see sections 7 and 8, respectively) the consensus number of negation and booster is 1. Since h is wait-free, $h(\text{negation}) \leq 1$ and $h(\text{booster}) \leq 1$, and thus $h(\text{negation}) = h(\text{booster}) = 1$. Since h is nontrivial, there is some level $n > 1$ and some type T such that $h(T) = n$. Let $\mathcal{B} = \{\text{negation}, \text{booster}\}$. By Theorem 5.2, there is an algorithm that solves consensus among n processes and uses only objects that belong to types in $\mathcal{B}$ and registers. Since $h(\text{negation}) = h(\text{booster}) = 1$ and $n > 1$, $\mathcal{B}$ contains no type that is at level n or higher. Thus, h is not robust, as wanted. □

6. Some technical preliminaries. In this section we define some concepts and prove some technical results that are needed in our proofs that each of the types negation and booster has consensus number one.

6.1. Computation trees. Let $\mathbf{A}$ be an algorithm, and let I be an initial configuration of $\mathbf{A}$. Consider a tree $\mathcal{T}$ whose nodes are finite schedules of $\mathbf{A}$ that are applicable to I (not necessarily all of them), so that the root of $\mathcal{T}$ is the empty schedule, denoted $S_\perp$, and there is an edge from node S to node S' only if $S' = S \cdot e$ for some step e. We say that $\mathcal{T}$ is a *computation tree of* $\mathbf{A}$ *from* I if for any node S of $\mathcal{T}$ and any process P of $\mathbf{A}$ S has at least one child $S \cdot e$, where e is a step of P. In what follows we shall not distinguish between a node in a computation tree and the (finite) schedule corresponding to the node. Similarly, we shall not distinguish between a (finite or infinite) path in a computation tree and the (finite or infinite) schedule corresponding to the path.

Informally, a computation tree of $\mathbf{A}$ from I represents executions of $\mathbf{A}$ starting from I for all possible interleavings of the processes. A node S represents a point in some execution; at that point the algorithm is in configuration $S(I)$. It is easy to see that if all object types used by $\mathbf{A}$ are deterministic, there is a unique computation tree of $\mathbf{A}$ from I. If, however, some object types are nondeterministic, there may be more than one computation tree of $\mathbf{A}$ from I.

A computation tree of **A** from I is *full* if its set of nodes is the entire set of finite schedules of **A** that are applicable to I. The full computation tree of **A** from I is unique, regardless of whether the object types used by **A** are deterministic. If **A** uses nondeterministic object types, we can think of the different computation trees of **A** from I as obtained from the full computation tree of **A** from I by (repeatedly) applying the following pruning rule: If there are multiple edges out of a node S corresponding to steps of a single process P (because of the nondeterministic responses of the object accessed by P in the operation pending in $S(I)$), then some, but not all, of these edges may be pruned.

We use the following notation and terminology for computation trees. Let $\mathcal{T}$ be a computation tree of **A** from an initial configuration I, let S be a node in $\mathcal{T}$, and let P be a process of **A**. The subtree of $\mathcal{T}$ that is rooted at S is denoted *subtree*$(S, \mathcal{T})$, and we say that it is *full* if it is equal to *subtree*$(S, \mathcal{F})$, where $\mathcal{F}$ is the full computation tree of **A** from I. The set of nodes $\{ S \cdot e : S \cdot e \text{ is a node in } \mathcal{T} \text{ and } e \text{ is a step of } P \}$ is denoted *children*$(P, S, \mathcal{T})$; these are the nodes reached from S by a single step of process P. We say that S_1 is a *P-sibling* of S_2 in $\mathcal{T}$ if there is a node S in $\mathcal{T}$ so that $S_1, S_2 \in$ *children*$(P, S, \mathcal{T})$.

LEMMA 6.1. *Let* **A** *be an algorithm, and let $\mathcal{T}$ and $\mathcal{T}'$ be any computation trees of* **A** *from (not necessarily distinct) initial configurations I and I', respectively. Consider any nodes S_0 and $S_0 \cdot S$ in $\mathcal{T}$ and node S_1 in $\mathcal{T}'$ such that subtree$(S_1, \mathcal{T}')$ is full and every process that takes a step in S and every object is in the same state in $S_0(I)$ as in $S_1(I')$. Then $S_1 \cdot S$ is a node in $\mathcal{T}'$, and every process that takes a step in S and every object is in the same state in $S_0 \cdot S(I)$ as in $S_1 \cdot S(I')$.*

Proof. Let S^i be the schedule consisting of the first i steps of S for all $0 \leq i \leq |S|$. Using the fact that *subtree*$(S_1, \mathcal{T}')$ is full and every process that takes a step in S and every object is in the same state in $S_0(I)$ as in $S_1(I')$, a straightforward induction on i proves that S^i is applicable to $S_1(I')$, and every process that takes a step in S and every object is in the same state in $S_0 \cdot S^i(I)$ as in $S_1 \cdot S^i(I')$. The lemma follows from this, since $S = S^\ell$, where $\ell = |S|$. □

6.2. Valence of nodes. Let **A** be a consensus or equality negation algorithm for processes $P_0, P_1, \ldots, P_{n-1}$, where $n \geq 2$. Let I be an initial configuration of **A**, $\mathcal{T}$ be a computation tree of **A** from I, and S be a node in $\mathcal{T}$. For any $v \in \{0, 1\}$, we say that S is *v-valent in $\mathcal{T}$* if there is no descendant S' of S in $\mathcal{T}$ such that process P_0 decides $\overline{v}$ in $S'(I)$. S is *univalent in $\mathcal{T}$* if it is v-valent in $\mathcal{T}$ for some $v \in \{0, 1\}$. S is *bivalent in $\mathcal{T}$* if there are descendants S_0 and S_1 of S in $\mathcal{T}$ so that process P_0 decides 0 in $S_0(I)$ and it decides 1 in $S_1(I)$. (Note that in this definition it is the same process, P_0, whose decisions are 0 and 1 in $S_0(I)$ and $S_1(I)$, respectively.) Informally, a univalent node represents a point in an execution of **A** where the outcome (of consensus or equality negation) has been "sealed"—even if no process has actually decided yet. A bivalent node represents a point in an execution where both outcomes are still possible.

The *valence* of a node S in $\mathcal{T}$ refers to whether S is bivalent or univalent in $\mathcal{T}$ and, in the latter case, whether it is 0-valent or 1-valent. As noted in section 6.1, if **A** uses nondeterministic types, there may be many computation trees of **A** from I. Therefore, a node S that appears in two different computation trees may have a different valence in one than in the other, because the valence of S in a computation tree $\mathcal{T}$ depends on the subset of S's descendants in the *full* computation tree that are actually present in $\mathcal{T}$.

Let S_0 and S_1 be two univalent nodes in $\mathcal{T}$. We say that S_0 and S_1 *have the same valence* in $\mathcal{T}$ if they are both 0-valent or both 1-valent in $\mathcal{T}$. We say that they *have*

opposite valence in $\mathcal{T}$ if one is 0-valent and the other is 1-valent in $\mathcal{T}$.

The notions of v-valence, univalence, and bivalence for *configurations* of *consensus* algorithms were originally defined in [5] and subsequently used extensively in the literature. Although the above definitions are very much in the spirit of those in [5], there are some minor differences. We now explain the reasons for these differences. First, we define valence with respect to nodes of computation trees rather than configurations. This is because some of our results (in particular, those in section 7) are more conveniently proved using computation trees. A second, and more important, difference is the fact that we now wish to have a more general definition that encompasses both consensus and equality negation algorithms; in the past, valence was defined only in the context of consensus algorithms. The need for this greater generality underlies the other difference of our definition relative to the earlier ones: In the "classical" definition, a node is v-valent if there is no descendant of it in which *any* process (not P_0 in particular) decides $\overline{v}$. An analogous comment applies to the definition of bivalence. In the case of consensus, there is no difference between the two definitions, since the agreement property requires that any two processes that decide, decide the same value. In the case of equality negation, however, if the initial values of all processes are the same, then P_0 is supposed to decide a different value than the other processes. Thus, in this case, we should specify whether it is the decision of P_0 or the decision of the other processes that is taken to be the "outcome" of the computation. It is not important *which* of the two is chosen. In our definition we arbitrarily chose P_0.

6.3. Properties of computation trees. In this section we prove several properties of computation trees of any consensus or equality negation algorithm for two processes. These properties are used in sections 7 and 8. For the rest of this section, let $\mathbf{A}$ be a consensus or equality negation algorithm for processes P_0 and P_1, and I be any initial configuration of $\mathbf{A}$.

LEMMA 6.2. *Let $\mathcal{T}$ be any computation tree of $\mathbf{A}$ from initial configuration I, and let S be any node in $\mathcal{T}$. For each $k \in \{0,1\}$, there exists a solo schedule S_k of process P_k such that $S \cdot S_k$ is a node in $\mathcal{T}$ and P_k has decided in $S \cdot S_k(I)$.*

Proof. The proof is immediate from the termination requirement (of consensus or equality negation) and the definition of computation tree. □

By Lemma 6.2, every node S in $\mathcal{T}$ has a descendant S' such that process P_0 has decided in $S'(I)$. From the definition of valence it follows that S has exactly one of the three possible attributes: 0-valent, 1-valent, or bivalent. Therefore, the valence of each node in $\mathcal{T}$ is well defined.

LEMMA 6.3. *Let $\mathcal{T}$ be any computation tree of $\mathbf{A}$ from initial configuration I. Let S_0 and S_1 be any univalent nodes in $\mathcal{T}$ such that some process has decided the same value in $S_0(I)$ as in $S_1(I)$. Then S_0 and S_1 have the same valence in $\mathcal{T}$.*

Proof. Observe that if a process decides a value, say, v, in a node S of $\mathcal{T}$, then the initial configuration I and v uniquely determine the value w that P_0 can decide in any descendant of S in $\mathcal{T}$. (If $\mathbf{A}$ is a consensus algorithm, then $w = v$ regardless of the initial configuration. If $\mathbf{A}$ is an equality negation algorithm, then $w = v$ (respectively, $w = \overline{v}$) if the initial values of P_0 and P_1 in I are different (respectively, the same).)

Let P_k for some $k \in \{0,1\}$ be the process that has decided the same value, say, v, in $S_0(I)$ as in $S_1(I)$. Let S_0' and S_1' be descendants of S_0 and S_1, respectively, such that P_0 has decided in $S_0'(I)$ and $S_1'(I)$ (S_0' and S_1' exist by Lemma 6.2). By the preceding observation, P_0 decides the same value, say, w, in $S_0'(I)$ as in $S_1'(I)$. Recalling that S_0 and S_1 are both univalent, from the definition of w-valent node,

it follows that S_0 and S_1 are both w-valent in $\mathcal{T}$. Thus, S_0 and S_1 have the same valence in $\mathcal{T}$. □

A computation tree $\mathcal{T}$ of $\mathbf{A}$ is 1-*full* if every subtree rooted at a 1-valent node in $\mathcal{T}$ is full; in particular, every full computation tree of $\mathbf{A}$ is 1-full.

LEMMA 6.4. *Let $\mathcal{T}$ be any 1-full computation tree of $\mathbf{A}$ from initial configuration I. Let S_0 and S_1 be any univalent nodes in $\mathcal{T}$ such that the state of some process and each object is the same in $S_0(I)$ as in $S_1(I)$. Then, S_0 and S_1 have the same valence in $\mathcal{T}$.*

Proof. Suppose, for contradiction, that S_0 and S_1 have opposite valence. Without loss of generality, assume that S_0 is 0-valent and S_1 is 1-valent in $\mathcal{T}$. Let P be the process whose state in $S_0(I)$ is the same as in $S_1(I)$. By Lemma 6.2 (applied to node S_0 in $\mathcal{T}$), there exists a solo schedule S of P such that $S_0 \cdot S$ is a node in $\mathcal{T}$ and P has decided in $S_0 \cdot S(I)$. Since $\mathcal{T}$ is 1-full and S_1 is 1-valent in $\mathcal{T}$, it follows that *subtree*$(S_1, \mathcal{T})$ is full. By hypothesis, the state of process P and each object is the same in $S_0(I)$ as in $S_1(I)$. Since S is a solo schedule of P, by Lemma 6.1 (applied for $I' = I$), $S_1 \cdot S$ is a node in $\mathcal{T}$ and P has the same state in $S_0 \cdot S(I)$ as in $S_1 \cdot S(I)$. Thus, P decides the same value in $S_0 \cdot S(I)$ as in $S_1 \cdot S(I)$. By Lemma 6.3, $S_0 \cdot S$ and $S_1 \cdot S$ have the same valence in $\mathcal{T}$. This contradicts our assumption that S_0 and S_1 have opposite valence in $\mathcal{T}$. □

Let $\mathcal{T}$ be any computation tree of $\mathbf{A}$ from initial configuration I, let S be any node in $\mathcal{T}$, and let e_0 and e_1 be any steps of $\mathbf{A}$. We say e_0 *and* e_1 *commute at* S *in* $\mathcal{T}$ if both $S \cdot e_0 \cdot e_1$ and $S \cdot e_1 \cdot e_0$ are nodes in $\mathcal{T}$ and the state of each process and each object is the same in $S \cdot e_0 \cdot e_1(I)$ as in $S \cdot e_1 \cdot e_0(I)$. We say that e_k *overwrites* $e_{\overline{k}}$ *at* S *in* $\mathcal{T}$ for some $k \in \{0, 1\}$ if both $S \cdot e_k$ and $S \cdot e_{\overline{k}} \cdot e_k$ are nodes in $\mathcal{T}$ and the state of P_k and each object is the same in $S \cdot e_k(I)$ as in $S \cdot e_{\overline{k}} \cdot e_k(I)$.

LEMMA 6.5. *Let $\mathcal{T}$ be any 1-full computation tree of $\mathbf{A}$ from initial configuration I. Let S be any node in $\mathcal{T}$, and let e_0 and e_1 be any steps of $\mathbf{A}$ such that $S \cdot e_0$ and $S \cdot e_1$ are univalent nodes of opposite valence in $\mathcal{T}$. Then*

(a) *e_0 and e_1 do not commute at S in $\mathcal{T}$; and*

(b) *neither e_0 nor e_1 overwrites the other at S in $\mathcal{T}$.*

Proof. Without loss of generality, assume that $S \cdot e_0$ is 0-valent and $S \cdot e_1$ is 1-valent in $\mathcal{T}$.

(a) Suppose, for contradiction, that e_0 and e_1 commute at S in $\mathcal{T}$. Then, by definition, $S \cdot e_0 \cdot e_1$ and $S \cdot e_1 \cdot e_0$ are nodes in $\mathcal{T}$ and the state of each process and object is the same in $S \cdot e_0 \cdot e_1(I)$ as in $S \cdot e_1 \cdot e_0(I)$. By Lemma 6.4, $S \cdot e_0 \cdot e_1$ and $S \cdot e_1 \cdot e_0$ have the same valence in $\mathcal{T}$. This contradicts the fact that $S \cdot e_0 \cdot e_1$ and $S \cdot e_1 \cdot e_0$ have opposite valence in $\mathcal{T}$ (because $S \cdot e_0$ and $S \cdot e_1$ do).

(b) Suppose, for contradiction, that e_k overwrites $e_{\overline{k}}$ at S in $\mathcal{T}$ for some $k \in \{0, 1\}$. Then, by definition, $S \cdot e_k$ and $S \cdot e_{\overline{k}} \cdot e_k$ are nodes in $\mathcal{T}$ and the state of P_k and each object is the same in $S \cdot e_k(I)$ as in $S \cdot e_{\overline{k}} \cdot e_k(I)$. By Lemma 6.4, $S \cdot e_k$ and $S \cdot e_{\overline{k}} \cdot e_k$ have the same valence in $\mathcal{T}$. This contradicts the fact that $S \cdot e_k$ is k-valent and $S \cdot e_{\overline{k}} \cdot e_k$ is $\overline{k}$-valent in $\mathcal{T}$ (because $S \cdot e_{\overline{k}}$ is). □

LEMMA 6.6. *Let $\mathcal{F}$ be any full computation tree of $\mathbf{A}$. Let S be any node in $\mathcal{F}$, and let e_0 and e_1 be any steps of processes P_0 and P_1, respectively, such that $S \cdot e_0$ and $S \cdot e_1$ are univalent nodes of opposite valence in $\mathcal{F}$. Then, e_0 and e_1 access the same object.*

Proof. Suppose, for contradiction, that e_0 and e_1 access different objects. Then e_1 is applicable to $S \cdot e_0(I)$ and e_0 is applicable to $S \cdot e_1(I)$. Since $\mathcal{F}$ is a full computation tree, $S \cdot e_0 \cdot e_1$ and $S \cdot e_1 \cdot e_0$ are nodes in $\mathcal{F}$. Furthermore, each process and object has

the same state in $S \cdot e_0 \cdot e_1(I)$ as in $S \cdot e_1 \cdot e_0(I)$. Thus, e_0 and e_1 commute at S in $\mathcal{F}$. This contradicts Lemma 6.5(a) (because $\mathcal{F}$ is full and hence 1-full). □

Let $\mathcal{T}$ be any computation tree of $\mathbf{A}$, and S be any node in $\mathcal{T}$. We say that S is a *critical node* in $\mathcal{T}$ if S is bivalent and all of its children are univalent in $\mathcal{T}$.

LEMMA 6.7. *Let $\mathcal{T}$ be any computation tree of $\mathbf{A}$ with a bivalent root. Then $\mathcal{T}$ has a critical node.*

Proof. Suppose, for contradiction, that $\mathcal{T}$ has no critical node. Then every bivalent node in $\mathcal{T}$ has at least one child that is also bivalent in $\mathcal{T}$. Thus, there is an *infinite* path S of $\mathcal{T}$ that starts at the (bivalent) root of $\mathcal{T}$ and consists entirely of bivalent nodes. Consider any node S' on this path; since S' is bivalent, no process has decided in $S'(I)$. Thus, there is an infinite schedule S of $\mathbf{A}$ that is applicable to I such that, for any prefix S' of S, no process has decided in $S'(I)$. Since S is infinite, at least one process takes infinitely many steps in S and therefore is correct in S. As we have just shown, however, in every prefix S' of S, no process—and, in particular, no correct process in S—decides in $S'(I)$. This contradicts the fact that $\mathbf{A}$ is a consensus algorithm or an equality negation algorithm (in particular, it contradicts the termination property of $\mathbf{A}$). □

7. Type negation has consensus number one. In this section we prove that type negation has consensus number one—i.e., that consensus for two processes cannot be solved using only negation objects and registers.

7.1. The bivalence argument and some limitations. There is a standard technique for proving that there is no consensus algorithm for n processes using a certain set of object types, known as "the bivalence argument." This technique goes back to the ground-breaking result of Fischer, Lynch, and Paterson [5] for the asynchronous message-passing model and was further adapted by others, e.g., [3, 6, 13], for the asynchronous read/write-memory model. In this subsection, we sketch the main ingredients of this technique for two processes and call attention to a difficulty that arises when it is applied to nondeterministic object types.

The bivalence argument employs proof by contradiction. It begins by assuming that there is a consensus algorithm $\mathbf{A}_c$ for processes P_0 and P_1 that uses only objects of some given types. Consider the full computation tree $\mathcal{F}$ of this algorithm from an initial configuration I in which the two processes have different initial values. The root of $\mathcal{F}$ is bivalent because, by validity, in a solo schedule a process can decide only its own initial value. Thus, by Lemma 6.7, $\mathcal{F}$ has a critical node S. By definition, some of the (univalent) children of the critical node S must be 0-valent and some must be 1-valent in $\mathcal{F}$. If the object types used by $\mathbf{A}_c$ are deterministic, then S has exactly two children in $\mathcal{F}$, say, $S \cdot e_0$ and $S \cdot e_1$, where e_k is a step of process P_k for $k \in \{0, 1\}$. Thus, in this case, we can say that *the outcome of consensus after S is determined by which one of the two processes takes the next step.* By Lemma 6.6, e_0 and e_1 both access the same object. Finally, by a case analysis involving the types of operations applied in steps e_0 and e_1, the following is shown: There exist schedules S_0 and S_1 such that (i) both $S \cdot e_0 \cdot S_0$ and $S \cdot e_1 \cdot S_1$ are nodes in $\mathcal{F}$, and (ii) some process has decided the same value in $S \cdot e_0 \cdot S_0(I)$ and $S \cdot e_1 \cdot S_1(I)$. This contradicts the fact that the outcome of consensus is determined by which of the two processes takes the next step after S.

This type of argument runs into difficulties when applied to algorithms that use *nondeterministic* types. Specifically, we can no longer assert that at the critical node S, the outcome of consensus is determined by which of the two processes takes the next step. Since the object types are nondeterministic, it is possible that *each* of the

For $k, v \in \{0,1\}$, $e_k^v = (P_k, \text{NEGATE}(k,k), O, v)$.

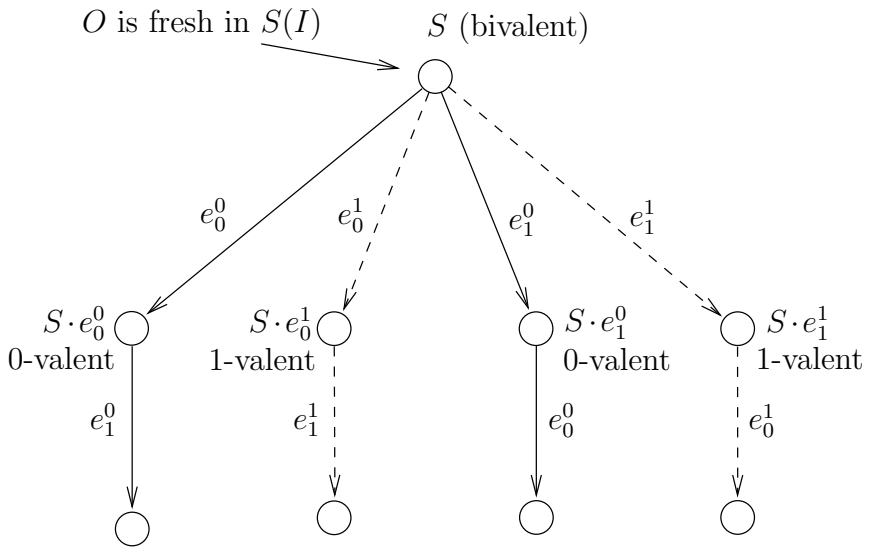

FIG. 7.1. *A critical node in* $\mathcal{F}$.

two processes can lead to both a 0-valent node and a 1-valent node, depending on the response of the object accessed.

To appreciate this point in more concrete terms, suppose that the consensus algorithm $\mathbf{A}_c$ uses negation objects and that the critical node S is such that, in configuration $S(I)$, each process P_k has a NEGATE(k,k) operation pending to a negation object O in the fresh state. Recall that a NEGATE operation applied to a fresh negation object can return either 0 or 1. Suppose, further, that each process P_k decides the value returned by the NEGATE(k,k) operation (see Figure 7.1). Now the step of process P_k that causes it to decide v, namely, e_k^v, is not applicable after the other process, $P_{\overline{k}}$, has applied the step that causes it to decide the opposite value, $\overline{v}$, for all $k \in \{0,1\}$ and all $v \in \{0,1\}$. This means that the we cannot derive a contradiction in the style of the bivalence argument.

Despite this, it turns out that the negation type is not powerful enough to solve consensus between two processes. To prove this, we use a modified version of the bivalence argument, based on a restricted computation tree. This is described in the following subsection.

7.2. The pruned computation tree. In the remainder of section 7, we assume, for contradiction, that $\mathbf{A}_c$ is a consensus algorithm for processes P_0 and P_1 that uses only negation objects and registers. Let I be an initial configuration of $\mathbf{A}_c$ in which P_0 and P_1 have different initial values, $\mathcal{T}$ be any computation tree of $\mathbf{A}_c$ from I, and $\mathcal{F}$ be the full computation tree of $\mathbf{A}_c$ from I. By the definition of type negation and the definition of computation tree, it is easy to see that $1 \leq |\mathit{children}(P, S, \mathcal{T})| \leq 2$ for every node S in $\mathcal{T}$ and each process P.

Consider a nonroot node S in $\mathcal{T}$ and let P be the process that takes the last step in S. We say that S is an *avoidable* 1*-valent node* in $\mathcal{T}$ if S is 1-valent in $\mathcal{F}$ and has a P-sibling S' in $\mathcal{F}$ such that S' is not 1-valent in $\mathcal{F}$. Intuitively, an avoidable 1-valent

node S in $\mathcal{F}$ is reached from its (bivalent) parent, $\hat{S}$, by a step of some process P; that step seals the outcome of consensus to be 1. Furthermore, S has a P-sibling S' that is not 1-valent; this means that the object accessed by the operation of P that is pending in $\hat{S}(I)$ *could* have returned a value that would leave open the possibility of the outcome of consensus being 0. In other words, starting from configuration $\hat{S}(I)$, outcome 1 could be avoided by a fortuitous choice of the value returned by the object accessed by the operation of process P that is pending in $\hat{S}(I)$. As a concrete illustration, the computation tree shown in Figure 7.1 contains two avoidable 1-valent nodes, namely, $S \cdot e_0^1$ and $S \cdot e_1^1$.

The *pruned computation tree of* $\mathbf{A}_c$ *from* I, denoted $\mathcal{L}$, is the tree obtained from the *full* computation tree $\mathcal{F}$ of $\mathbf{A}_c$ from I by pruning all its avoidable 1-valent nodes—i.e., removing them and their descendants. $\mathcal{L}$ is, in fact, a computation tree: If a node S in $children(P, \hat{S}, \mathcal{F})$ is pruned, then some P-sibling of S is not pruned. In other words, $\hat{S}$ has at least one child $\hat{S} \cdot e$ in $\mathcal{L}$ where e is a step of P. Thus, the pruning of S will not inhibit P from taking the next step after $\hat{S}$. Intuitively, pruning the avoidable 1-valent nodes from the full computation tree amounts to restricting the nondeterministic behavior of objects: Whenever an object has two responses to an operation, one of which forecloses the possibility of outcome 0 while the other leaves the possibility of outcome 0 open, we restrict the behavior of the object by choosing the latter response.

The following lemmas establish some basic properties of the pruned computation tree $\mathcal{L}$.

LEMMA 7.1. *The root of* $\mathcal{L}$ *is bivalent.*

Proof. Recall that $\mathcal{L}$ is a computation tree of $\mathbf{A}_c$ from initial configuration I in which the two processes have different initial values. Without loss of generality, assume that P_0 has initial value 0 and P_1 has initial value 1 in I. By Lemma 6.2 (applied to the root, $S_\perp$, of $\mathcal{L}$), for each $k \in \{0, 1\}$ there exists a solo schedule S_k of P_k such that $S_\perp \cdot S_k = S_k$ is a node in $\mathcal{L}$ and P_k has decided in $S_k(I)$. Since P_k has initial value k in I and S_k is a solo schedule of P_k, by validity, P_k must decide k in $S_k(I)$. By Lemma 6.2 (applied to node S_1 of $\mathcal{L}$), there is a solo schedule S_0' of P_0 such that $S_1 \cdot S_0'$ is a node in $\mathcal{L}$ and P_0 has decided in $S_1 \cdot S_0'(I)$. Since P_1 has decided 1 in $S_1(I)$ and the decision is irrevocable, P_1 has decided 1 in $S_1 \cdot S_0'(I)$. By agreement, P_0 has also decided 1 in $S_1 \cdot S_0'(I)$. Thus, the root of $\mathcal{L}$ has two descendants, S_0 and $S_1 \cdot S_0'$ so that P_0 has decided 0 and 1, respectively, in $S_0(I)$ and $S_1 \cdot S_0'(I)$. Thus, the root of $\mathcal{L}$ is bivalent. □

LEMMA 7.2. *Let* S *be any node in the full computation tree* $\mathcal{F}$. *Then*

(a) S *is not a node in* $\mathcal{L}$ *if and only if* S *is a descendant of an avoidable* 1*-valent node in* $\mathcal{F}$. *(By convention, a node is a descendant of itself.)*
(b) *If* S *is* 1*-valent in* $\mathcal{F}$ *and is also in* $\mathcal{L}$, *then* S *is* 1*-valent in* $\mathcal{L}$.
(c) *If* S *is* 0*-valent in* $\mathcal{F}$, *then it is in* $\mathcal{L}$ *and is* 0*-valent in* $\mathcal{L}$.
(d) *If* S *is in* $\mathcal{L}$ *and* $children(P, S, \mathcal{F}) = \{S'\}$, *then* S' *is in* $\mathcal{L}$.

Proof. Immediate consequences of the definition of $\mathcal{L}$. □

LEMMA 7.3. $\mathcal{L}$ *is* 1*-full.*

Proof. We must show that every subtree rooted at a 1-valent node in $\mathcal{L}$ is full. Consider any 1-valent node S in $\mathcal{L}$. S cannot have any 0-valent descendants in $\mathcal{F}$: by Lemma 7.2(c), any such descendants would exist in $\mathcal{L}$ and be 0-valent in $\mathcal{L}$, contradicting that S is 1-valent in $\mathcal{L}$. Thus, S is 1-valent in $\mathcal{F}$. Consequently, all nodes in $subtree(S, \mathcal{F})$ are 1-valent, and therefore none of them can be an avoidable 1-valent node in $\mathcal{F}$. Hence, by Lemma 7.2(a), all nodes in $subtree(S, \mathcal{F})$ are in $\mathcal{L}$, proving that

subtree$(S, \mathcal{L}) =$ *subtree*$(S, \mathcal{F})$. Therefore, *subtree*$(S, \mathcal{L})$ is full. □

LEMMA 7.4. *Let S be any node in $\mathcal{L}$ and P be any process such that* $|$*children*$(P, S, \mathcal{F})| = 2$, *each node in* *children*$(P, S, \mathcal{L})$ *is univalent, and one of them is* 1*-valent in* $\mathcal{L}$. *Then* *children*$(P, S, \mathcal{L}) =$ *children*$(P, S, \mathcal{F})$ *and both nodes in* *children*$(P, S, \mathcal{L})$ *are* 1*-valent in* $\mathcal{L}$.

Proof. Let *children*$(P, S, \mathcal{F}) = \{S', S''\}$. By the hypothesis of the lemma we may assume, without loss of generality, that $S' \in$ *children*$(P, S, \mathcal{L})$ and S' is 1-valent in $\mathcal{L}$. It remains to show that S'' is also in $\mathcal{L}$ and is 1-valent in $\mathcal{L}$.

By Lemma 7.3, $\mathcal{L}$ is 1-full. Since S' is 1-valent in $\mathcal{L}$, *subtree*$(S', \mathcal{L}) =$ *subtree*$(S', \mathcal{F})$ and thus S' is 1-valent in $\mathcal{F}$. Since S' is in $\mathcal{L}$, by Lemma 7.2(a) S' is not a proper descendant of an avoidable 1-valent node in $\mathcal{F}$. Therefore, as S'' is a P-sibling of S' in $\mathcal{F}$, S'' is not a proper descendant of an avoidable 1-valent node in $\mathcal{F}$ either. Also, S'' is not an avoidable 1-valent node in $\mathcal{F}$, because its only P-sibling in $\mathcal{F}$, namely, S', is a 1-valent node in $\mathcal{F}$. By Lemma 7.2(a), S'' is in $\mathcal{L}$. Furthermore, S'' must be a 1-valent node in $\mathcal{F}$. If not, then by definition S' would be an avoidable 1-valent node in $\mathcal{F}$ and, by Lemma 7.2(a), S' would not be in $\mathcal{L}$—a contradiction. Since S'' is 1-valent in $\mathcal{F}$ and is also in $\mathcal{L}$, by Lemma 7.2(b), S'' is 1-valent in $\mathcal{L}$. □

7.3. The impossibility result. The proof that no algorithm can solve consensus between two processes using only negation objects and registers is a bivalence argument based on the pruned computation tree $\mathcal{L}$. The only remaining tricky point is to ensure that the computation tree nodes that exhibit the contradictory behavior required by the bivalence argument have not been pruned away!

By Lemmas 6.7 and 7.1, $\mathcal{L}$ has a critical node E. By definition of a critical node, there are steps e_0 and e_1 of processes P_0 and P_1, respectively, such that $E \cdot e_0$ and $E \cdot e_1$ are univalent nodes of opposite valence in $\mathcal{L}$. Without loss of generality, suppose that $E \cdot e_0$ is 0-valent and $E \cdot e_1$ is 1-valent in $\mathcal{L}$. (Otherwise, we rename e_0 and e_1 and apply the same argument.) To derive a contradiction, we first show that e_0 and e_1 access the same object (Lemma 7.5). Then we prove that the object accessed in e_0 and e_1 cannot be a register (Lemma 7.6). Finally, we prove that the object cannot be a negation object (Corollary 7.8 and Lemma 7.9).

LEMMA 7.5. *Steps e_0 and e_1 access the same object.*

Proof. Suppose, for contradiction, that e_0 and e_1 access, respectively, objects O_0 and O_1, where $O_0 \neq O_1$. Then, e_1 is applicable to $E \cdot e_0(I)$ and e_0 is applicable to $E \cdot e_1(I)$ and, in fact, $E \cdot e_0 \cdot e_1(I) = E \cdot e_1 \cdot e_0(I)$. Thus $E \cdot e_0 \cdot e_1$ and $E \cdot e_1 \cdot e_0$ are nodes in $\mathcal{F}$. Since $\mathcal{L}$ is 1-full (by Lemma 7.3) and $E \cdot e_1$ is 1-valent in $\mathcal{L}$, *subtree*$(E \cdot e_1, \mathcal{L}) =$ *subtree*$(E \cdot e_1, \mathcal{F})$. Since $E \cdot e_1 \cdot e_0$ is in $\mathcal{F}$, it follows that it is also in $\mathcal{L}$. We shall prove that $E \cdot e_0 \cdot e_1$ is also a node in $\mathcal{L}$. This fact implies that e_0 and e_1 commute at E in $\mathcal{L}$, contrary to Lemma 6.5(a).

To show that $E \cdot e_0 \cdot e_1$ is in $\mathcal{L}$, we consider two cases, depending on whether *children*$(P_1, E, \mathcal{F})$ has one or two nodes.

Case 1. $|$*children*$(P_1, E, \mathcal{F})| = 1$: Then that unique child has to be $E \cdot e_1$ (since $E \cdot e_1$ is a node in $\mathcal{F}$). Since $O_0 \neq O_1$, each of P_1 and O_1 is in the same state in $E(I)$ as in $E \cdot e_0(I)$. It follows that e_1 is the only step of P_1 that is applicable to $E \cdot e_0(I)$; thus, *children*$(P_1, E \cdot e_0, \mathcal{F}) = \{E \cdot e_0 \cdot e_1\}$. By Lemma 7.2(d), $E \cdot e_0 \cdot e_1$ is in $\mathcal{L}$.

Case 2. $|$*children*$(P_1, E, \mathcal{F})| = 2$: Recall that all nodes in *children*$(P_1, E, \mathcal{L})$ are univalent. Recall also that, by assumption, $E \cdot e_1$ is in *children*$(P_1, E, \mathcal{L})$ and is 1-valent in $\mathcal{L}$. Since $|$*children*$(P_1, E, \mathcal{F})| = 2$, by Lemma 7.4, *children*$(P_1, E, \mathcal{F}) =$ *children*$(P_1, E, \mathcal{L})$ and both nodes in *children*$(P_1, E, \mathcal{L})$ are actually 1-valent in $\mathcal{L}$. Let the two nodes in *children*$(P_1, E, \mathcal{L})$ be $E \cdot e_1$ and $E \cdot e_1'$. Because each of P_1 and O_1 is

in the same state in $E(I)$ as in $E \cdot e_0(I)$, both e_1 and e_1' are applicable to $E \cdot e_0(I)$ and access the same object. Therefore, it must be that $E \cdot e_0 \cdot e_1$ or $E \cdot e_0 \cdot e_1'$ is in $\mathcal{L}$. Since $E \cdot e_1$ and $E \cdot e_1'$ are 1-valent in $\mathcal{L}$ and since e_1 was chosen arbitrarily as a 1-valent node in *children*$(P_1, E, \mathcal{L})$, we may assume without loss of generality that $E \cdot e_0 \cdot e_1$ is in $\mathcal{L}$. (Otherwise, we repeat the argument with e_1' instead of e_1.) □

In the remainder of this section, let $\mathcal{O}$ denote the object accessed in both e_0 and e_1.

LEMMA 7.6. *$\mathcal{O}$ is not a register.*

Proof. Assume, by way of contradiction, that $\mathcal{O}$ is a register. Since register is a deterministic type, *children*$(P_0, E, \mathcal{F})$ and *children*$(P_1, E, \mathcal{F})$ contain a single node each. Let op_0 and op_1 be the (READ or WRITE) operations applied to $\mathcal{O}$ in steps e_0 and e_1, respectively. There are two cases.

Case 1. *op_k is a* WRITE *operation for some $k \in \{0, 1\}$*: Let v be the value written into $\mathcal{O}$ by process P_k in step e_k. Since P_k has the same state in $E(I)$ as in $E \cdot e_{\overline{k}}(I)$, e_k is also applicable to $E \cdot e_{\overline{k}}(I)$, and therefore *children*$(P_k, E \cdot e_{\overline{k}}, \mathcal{F}) = \{E \cdot e_{\overline{k}} \cdot e_k\}$. By Lemma 7.2(d), $E \cdot e_{\overline{k}} \cdot e_k$ is in $\mathcal{L}$. Clearly, $\mathcal{O}$ has value v in both $E \cdot e_k(I)$ and $E \cdot e_{\overline{k}} \cdot e_k(I)$. In addition, each other object and process P_k has the same state in $E \cdot e_k(I)$ as in $E \cdot e_{\overline{k}} \cdot e_k(I)$. But then e_k overwrites $e_{\overline{k}}$ at E in $\mathcal{L}$. This contradicts Lemma 6.5(b).

Case 2. *op_0 and op_1 are both* READ *operations:* Let v be the value of $\mathcal{O}$ in configuration $E(I)$. Since the value of a register is not changed by READ operations, $\mathcal{O}$ has the same value v in $E \cdot e_0(I)$ and $E \cdot e_1(I)$. It follows that e_0 and e_1 are applicable to $E \cdot e_1(I)$ and $E \cdot e_0(I)$, respectively. Thus *children*$(P_0, E \cdot e_0, \mathcal{F}) = \{E \cdot e_0 \cdot e_1\}$ and *children*$(P_1, E \cdot e_1, \mathcal{F}) = \{E \cdot e_1 \cdot e_0\}$. By Lemma 7.2(d), $E \cdot e_0 \cdot e_1$ and $E \cdot e_1 \cdot e_0$ are nodes in $\mathcal{L}$ as well. Clearly, the state of each process and each object in $E \cdot e_0 \cdot e_1(I)$ is the same as in $E \cdot e_1 \cdot e_0(I)$. But then e_0 and e_1 commute at E in $\mathcal{L}$. This contradicts Lemma 6.5(a). □

Since $\mathcal{O}$ is not a register and the assumed consensus algorithm $\mathbf{A}_c$ uses only registers and negation objects, $\mathcal{O}$ must be of type negation. We shall now prove that this is not the case by proving that the state of $\mathcal{O}$ in $E(I)$ is not a legitimate state of type negation. We say that $\mathcal{O}$ is *fresh* in a configuration C of $\mathbf{A}_c$ if its state in C is ☺ and *upset* in C if its state in C is ☹.

For each $k \in \{0, 1\}$, let $j_k \in \{0, 1\}$ and $w_k \in \{0, 1, 2\}$ be the process and initial-value parameters, respectively, of the NEGATE operation to $\mathcal{O}$ of process P_k that is pending in $E(I)$. In other words, the operation to $\mathcal{O}$ of P_k pending in $E(I)$ is NEGATE(j_k, w_k). Recall that the response of a NEGATE operation is 0 or 1. For each $k, u \in \{0, 1\}$, let $d_k^u = (P_k, \text{NEGATE}(j_k, w_k), \mathcal{O}, u)$—i.e., d_k^u is a step in which P_k applies NEGATE(j_k, w_k) to $\mathcal{O}$ and receives u as response. Thus, $e_k \in \{d_k^0, d_k^1\}$ for each $k \in \{0, 1\}$.

The next lemma states that the application of the two NEGATE operations pending in $E(I)$ does not upset $\mathcal{O}$.

LEMMA 7.7. *For each $k \in \{0, 1\}$, let d_k be any step in $\{d_k^0, d_k^1\}$ such that $E \cdot e_{\overline{k}} \cdot d_k$ is a node in $\mathcal{F}$. Then $\mathcal{O}$ is not upset in $E \cdot e_{\overline{k}} \cdot d_k(I)$.*

Proof. Suppose, for contradiction, that $\mathcal{O}$ is upset in $E \cdot e_{\overline{k}} \cdot d_k(I)$ for some $k \in \{0, 1\}$. We first show that $\mathcal{O}$ is also upset in $E \cdot e_k \cdot d_{\overline{k}}(I)$. Since $\mathcal{O}$ is upset in $E \cdot e_{\overline{k}} \cdot d_k(I)$, by the specification of negation, it is easy to verify that one of the following conditions must hold (in verifying this, recall that e_0 and d_0 are NEGATE(j_0, w_0) steps to $\mathcal{O}$, and e_1 and d_1 are NEGATE(j_1, w_1) steps to $\mathcal{O}$):

- $\mathcal{O}$ is upset in $E(I)$.

- $\mathcal{O}$ is fresh in $E(I)$, and either
  (a) $j_0 = j_1 = 0$, or
  (b) $j_0 = j_1 = 1$ and $w_0 \neq w_1$.
- The state of $\mathcal{O}$ in $E(I)$ is of the form $\langle v_0, v_1, u_0, u_1\rangle$ and either
  (a) $v_0 \neq \perp$ and, for some $\ell \in \{0,1\}$, $j_\ell = 0$, or
  (b) $v_1 \neq \perp$ and, for some $\ell \in \{0,1\}$, $j_\ell = 1$ and $w_\ell \neq v_1$.

In each of these cases, it can be verified that $\mathcal{O}$ is also upset in $E\cdot e_k \cdot d_{\overline{k}}(I)$.

Since $\mathcal{O}$ is upset in $E\cdot e_1\cdot d_0(I)$, it is easy to verify that the step $d_0' \in \{d_0^0, d_0^1\}\setminus\{d_0\}$ is also applicable to $E\cdot e_1(I)$ and $\mathcal{O}$ is upset in $E\cdot e_1\cdot d_0'(I)$ as well. Therefore, *children*$(P_0, E\cdot e_1, \mathcal{F}) = \{E\cdot e_1\cdot d_0^0, E\cdot e_1\cdot d_0^1\}$, and $\mathcal{O}$ is upset in both $E\cdot e_1\cdot d_0^0(I)$ and $E\cdot e_1\cdot d_0^1(I)$. Likewise, as $\mathcal{O}$ is upset in $E\cdot e_0\cdot d_1(I)$, *children*$(P_1, E\cdot e_0, \mathcal{F}) = \{E\cdot e_0\cdot d_1^0, E\cdot e_0\cdot d_1^1\}$, and $\mathcal{O}$ is upset in both $E\cdot e_0\cdot d_1^0(I)$ and $E\cdot e_0\cdot d_1^1(I)$. Since $\mathcal{L}$ is 1-full (by Lemma 7.3) and $E\cdot e_1$ is 1-valent in $\mathcal{L}$, it follows that both $E\cdot e_1\cdot d_0^0$ and $E\cdot e_1\cdot d_0^1$ are nodes in $\mathcal{L}$. Furthermore, they are 1-valent in $\mathcal{L}$ because $E\cdot e_1$ is. Therefore, as $e_0 \in \{d_0^0, d_0^1\}$, $E\cdot e_1\cdot e_0$ is a 1-valent node in $\mathcal{L}$. Since $\mathcal{L}$ is a computation tree, there exists $d \in \{d_1^0, d_1^1\}$ such that $E\cdot e_0\cdot d$ is a node in $\mathcal{L}$. This node is 0-valent in $\mathcal{L}$ because $E\cdot e_0$ is. As we have just shown, $\mathcal{O}$ is upset in $E\cdot e_0\cdot d(I)$. Therefore, the state of P_0 and each object is the same in $E\cdot e_1\cdot e_0(I)$ as in $E\cdot e_0\cdot d(I)$. By Lemma 6.4, $E\cdot e_1\cdot e_0$ and $E\cdot e_0\cdot d$ have the same valence in $\mathcal{L}$. This contradicts the fact that $E\cdot e_1\cdot e_0$ is 1-valent and $E\cdot e_0\cdot d$ is 0-valent in $\mathcal{L}$.

We reached this contradiction by assuming $\mathcal{O}$ is upset in $E\cdot e_{\overline{k}}\cdot d_k$ for some $k \in \{0,1\}$. Therefore, $\mathcal{O}$ is not upset in $E\cdot e_0\cdot d_1$ or in $E\cdot e_1\cdot d_0$. □

Since once it has become upset, a negation object remains upset forever, we have the following.

COROLLARY 7.8. *$\mathcal{O}$ is not upset in $E(I)$, $E\cdot e_0(I)$, or $E\cdot e_1(I)$.*

We now rule out the remaining possibilities for the state of $\mathcal{O}$ in $E(I)$.

LEMMA 7.9. *$\mathcal{O}$ is neither fresh nor in a state of the form $\langle v_0, v_1, u_0, u_1\rangle$ in $E(I)$.*

Proof. Suppose, for contradiction, that $\mathcal{O}$ is either fresh or in a state of the form $\langle v_0, v_1, u_0, u_1\rangle$ in $E(I)$. There are two cases, depending on the values of j_0 and j_1 (the process parameters of the two NEGATE operations pending in $E(I)$).

Case 1. *For some $k \in \{0,1\}$, $j_k = 0$*: If $j_{\overline{k}} = 0$, then both $d_{\overline{k}}^0$ and $d_{\overline{k}}^1$ are applicable to $E\cdot e_k(I)$, and $\mathcal{O}$ is upset in both $E\cdot e_k\cdot d_{\overline{k}}^0(I)$ and $E\cdot e_k\cdot d_{\overline{k}}^1(I)$, contrary to Lemma 7.7. Thus, $j_{\overline{k}} = 1$. We distinguish two subcases.

Subcase 1(a). *$\mathcal{O}$ is fresh in $E(I)$*: Since $\mathcal{O}$ is fresh in $E(I)$, by the specification of negation, both d_1^0 and d_1^1 are applicable to $E(I)$. Thus, $E\cdot d_1^0$ and $E\cdot d_1^1$ are in $\mathcal{F}$. Since E is a critical node in $\mathcal{L}$, by definition, every node in *children*$(P_1, E, \mathcal{L})$ is univalent. Recall that $E\cdot e_1$ is 1-valent. By Lemma 7.4, both $E\cdot d_1^0$ and $E\cdot d_1^1$ are nodes in $\mathcal{L}$ and are 1-valent in $\mathcal{L}$.

Let $u \in \{0,1\}$ be such that $e_0 = d_0^u$. We further distinguish two cases, depending on whether the initial-value parameters, w_0 and w_1, of the two pending NEGATE operations in $E(I)$ are equal or not:

(i) $w_0 \neq w_1$: By the specification of negation, e_0 is the only step of P_0 that is applicable to $E\cdot d_1^u(I)$, and d_1^u is the only step of P_1 that is applicable to $E\cdot e_0(I)$. Therefore, by Lemma 7.2(d), $E\cdot d_1^u\cdot e_0$ and $E\cdot e_0\cdot d_1^u$ are in $\mathcal{L}$. Furthermore, $E\cdot d_1^u\cdot e_0$ is 1-valent in $\mathcal{L}$ (because, as we just showed, $E\cdot d_1^u$ is); and $E\cdot e_0\cdot d_1^u$ is 0-valent in $\mathcal{L}$ (because $E\cdot e_0$ is). By the specification of negation, it can be checked that $\mathcal{O}$ is in the same state in $E\cdot e_0\cdot d_1^u(I)$ as in $E\cdot d_1^u\cdot e_0(I)$ (namely, in state $\langle w_0, w_1, u, u\rangle$ if $j_0 = 0$, and in state $\langle w_1, w_0, u, u\rangle$ if $j_0 = 1$). Therefore, $E\cdot e_0\cdot d_1^u$ and $E\cdot d_1^u\cdot e_0$ are both nodes in $\mathcal{L}$, and each

process and each object is in the same state in $E \cdot e_0 \cdot d_1^u(I)$ as in $E \cdot d_1^u \cdot e_0(I)$. This implies that e_0 and d_1^u commute at E in $\mathcal{L}$, contrary to Lemma 6.5(a).

(ii) $w_0 = w_1$: The argument of Subcase 1(a)(i) also applies in this subcase by replacing d_1^u with $d_1^{\overline{u}}$ throughout. (But now the state of $\mathcal{O}$ in $E \cdot e_0 \cdot d_1^{\overline{u}}(I)$ and $E \cdot d_1^{\overline{u}} \cdot e_0(I)$ is $\langle w_0, w_0, u, \overline{u} \rangle$ if $j_0 = 0$ and $\langle w_0, w_0, \overline{u}, u \rangle$ if $j_0 = 1$.)

Subcase 1(b). *$\mathcal{O}$ is in a state of the form $\langle v_0, v_1, u_0, u_1 \rangle$ in $E(I)$*: First we claim that $v_0 = \perp$. If not, then by the specification of negation, $\mathcal{O}$ is upset in $E \cdot e_k(I)$ (since e_k is a NEGATE$(0, w_k)$ step to $\mathcal{O}$). This contradicts Corollary 7.8. Thus, $v_0 = \perp$. Given this, by the definition of the states of negation, it must be that $u_0 = \perp$ and $v_1, u_1 \neq \perp$. Recall that, in this case, $e_{\overline{k}}$ is a NEGATE$(1, w_{\overline{k}})$ step to $\mathcal{O}$. Since $v_1 \neq \perp$ and by Corollary 7.8 $\mathcal{O}$ is not upset in $E \cdot e_{\overline{k}}(I)$, it must be that $w_{\overline{k}} = v_1$. Then, it is easy to verify that $d_{\overline{k}}^{u_1}$ is the only step of $P_{\overline{k}}$ that is applicable to $E(I)$. Thus, $e_{\overline{k}} = d_{\overline{k}}^{u_1}$. We further distinguish two cases:

(i) $w_k \neq w_{\overline{k}}$: From the specification of negation, we can check that $d_k^{u_1}$ is the only step of P_k that is applicable to $E(I)$ and $E \cdot e_{\overline{k}}(I)$. Thus, $e_k = d_k^{u_1}$, and by Lemma 7.2(d), $E \cdot e_{\overline{k}} \cdot e_k$ is in $\mathcal{L}$. Also, $e_{\overline{k}}$ is the only step of $P_{\overline{k}}$ that is applicable to $E \cdot e_k$ (since $\mathcal{O}$ is in state $\langle w_k, v_1, u_1, u_1 \rangle$ in $E \cdot e_k(I)$). By Lemma 7.2(d), $E \cdot e_k \cdot e_{\overline{k}}$ is a node in $\mathcal{L}$.
By the specification of negation, it can be checked that $\mathcal{O}$ is in the same state in $E \cdot e_0 \cdot e_1(I)$ as in $E \cdot e_1 \cdot e_0(I)$ (namely, in state $\langle w_k, v_1, u_1, u_1 \rangle$). Therefore, each process and each object is in the same state in $E \cdot e_0 \cdot e_1(I)$ as in $E \cdot e_1 \cdot e_0(I)$. But then e_0 and e_1 commute at E in $\mathcal{L}$, contrary to Lemma 6.5(a).

(ii) $w_k = w_{\overline{k}}$: The argument in Subcase 1(b)(i) also applies in this case by replacing $d_k^{u_1}$ with $d_k^{\overline{u}_1}$ throughout. (But now $\mathcal{O}$ is in state $\langle w_k, v_1, \overline{u}_1, u_1 \rangle$ in both $E \cdot e_0 \cdot e_1(I)$ and $E \cdot e_1 \cdot e_0(I)$.)

Case 2. *For both $k \in \{0, 1\}$, $j_k = 1$*: In this case, it must be that $w_0 = w_1 = w$, for some $w \in \{0, 1\}$. (Otherwise, for each $k \in \{0, 1\}$, both $d_{\overline{k}}^0$ and $d_{\overline{k}}^1$ are applicable to $E \cdot e_k(I)$ and $\mathcal{O}$ is upset in $E \cdot e_k \cdot d_{\overline{k}}^0(I)$ and $E \cdot e_k \cdot d_{\overline{k}}^1(I)$, contrary to Lemma 7.7.) We distinguish two subcases.

Subcase 2(a). *$\mathcal{O}$ is fresh in $E(I)$*: The argument of Subcase 1(a)(i) applies here as well (but now the state of $\mathcal{O}$ in $E \cdot e_0 \cdot d_1^u(I)$ and $E \cdot d_1^u \cdot e_0(I)$ is $\langle \perp, w, \perp, u \rangle$).

Subcase 2(b). *$\mathcal{O}$ is in a state of the form $\langle v_0, v_1, u_0, u_1 \rangle$ in $E(I)$*: We further distinguish two cases:

(i) $v_1 = \perp$: By the definition of the states of negation, we have $u_1 = \perp$ and $v_0, u_0 \neq \perp$. Define u as

$$u = \begin{cases} u_0 & \text{if } w \neq v_0, \\ \overline{u}_0 & \text{if } w = v_0. \end{cases}$$

From the specification of negation, for each $k \in \{0, 1\}$, d_k^u is the only step of P_k that is applicable to $E(I)$. Hence, $e_k = d_k^u$, for each $k \in \{0, 1\}$. Also, e_k is the only step of P_k that is applicable to $E \cdot e_{\overline{k}}(I)$. Thus, by Lemma 7.2(d), both $E \cdot e_0 \cdot e_1$ and $E \cdot e_1 \cdot e_0$ are in $\mathcal{L}$. By the specification of negation, $\mathcal{O}$ is in the same state in $E \cdot e_0 \cdot e_1(I)$ as in $E \cdot e_1 \cdot e_0(I)$ (namely, in state $\langle v_0, w, u_0, u \rangle$). Therefore, each process and each object is in the same state in $E \cdot e_0 \cdot e_1(I)$ as in $E \cdot e_1 \cdot e_0(I)$. But then e_0 and e_1 commute at E in $\mathcal{L}$, contrary to Lemma 6.5(a).

(ii) $v_1 \neq \perp$: Since $v_1 \neq \perp$, by the definition of the states of negation, $u_1 \neq \perp$. The argument of Subcase 2(b)(i) applies in this case by taking u to be u_1 (instead of defining it as above).

Since all cases lead to a contradiction, the lemma follows. □

By Corollary 7.8 and Lemma 7.9, the state of $\mathcal{O}$ in $E(I)$ is not a legitimate state of type negation. Thus, $\mathcal{O}$ is not a negation object. This, together with Lemma 7.6 which shows that $\mathcal{O}$ is not a register, contradicts our hypothesis that $\mathbf{A}_c$ uses only negation objects and registers. Thus, we have the following.

THEOREM 7.10. *Type* negation *has consensus number one.*

8. Type booster has consensus number one. In this section, we show that type booster has consensus number one. Unfortunately, even the modified version of the bivalence argument of section 7 does not appear to be helpful in proving that consensus between two processes cannot be solved using only booster objects and registers. Instead, we use a different technique, originally used (in a somewhat different context) in [12]. Here is the outline of the proof.

Suppose, for contradiction, that type booster has consensus number at least two. By the universality of consensus [6], we can implement a negation object for two processes using only booster objects and registers. Thus, the equality negation problem for two processes is solvable using only booster objects and registers. Let $\mathbf{A}_{en}$ be an equality negation algorithm for two processes that uses a minimal number of booster objects (together with any number of registers).[6] By Theorem 3.1, $\mathbf{A}_{en}$ must use at least one booster object. We will show that $\mathbf{A}_{en}$ can be modified into an equality negation algorithm that uses one booster object less than $\mathbf{A}_{en}$, thus contradicting the definition of $\mathbf{A}_{en}$.

In this section we deal exclusively with *full* computation trees of $\mathbf{A}_{en}$. We first establish some properties of such trees that will be needed later on.

LEMMA 8.1. *Let I be any initial configuration of $\mathbf{A}_{en}$, and let $\mathcal{F}$ be the full computation tree of $\mathbf{A}_{en}$ from I. Let S_0, $S_0 \cdot S$, and S_1 be any nodes in $\mathcal{F}$ such that every process that takes a step in S and every object, except a* booster *object O, is in the same state in $S_0(I)$ as in $S_1(I)$. Suppose further that*

- *the state of O in $S_1(I)$ is ☹, or*
- *the state of O in $S_1(I)$ is of the form $\langle *, *, *, *, *, d\rangle$ for some $d \in \{0, 1\}$ and S contains no* REVEAL *step to O with return value $\overline{d}$ (i.e., S contains no step of the form $(*, \text{REVEAL}(*, *, *), O, \overline{d})$).*

Then, $S_1 \cdot S$ is a node in $\mathcal{F}$, and every process that takes a step in S and every object except O is in the same state in $S_0 \cdot S(I)$ as in $S_1 \cdot S(I)$.

Proof. From the specification of booster, it is easy to verify that

- the only state that is reachable from ☹ is itself, and a REVEAL operation can return either 0 or 1 when applied to a booster object in state ☹;
- every state reachable from a state of the form $\langle *, *, *, *, *, d\rangle$ is either of the same form or ☹, and a REVEAL operation can return d when applied to a booster object in a state of the form $\langle *, *, *, *, *, d\rangle$ or in state ☹.

Let S^i be the schedule consisting of the first i steps of S for $0 \le i \le |S|$. Using the above two properties, by a straightforward induction on i, we can show that for all i, $0 \le i \le |S|$, S^i is applicable to $S_1(I)$, and every process that takes a step in S and every object except O is in the same state in $S_0 \cdot S^i(I)$ as in $S_1 \cdot S^i(I)$. The lemma follows immediately from these facts, since $S = S^\ell$, where $\ell = |S|$. □

If the root of a full computation tree of $\mathbf{A}_{en}$ is univalent, the following lemma tells how the valence of the root relates to the possible decisions of the processes.

[6] This number must be finite by the termination property of equality negation and the fact that type booster is bounded nondeterministic.

LEMMA 8.2. *Let $k, u, v \in \{0,1\}$, I be any initial configuration of $\mathbf{A}_{en}$, $\mathcal{F}$ be the full computation tree of $\mathbf{A}_{en}$ from I, and S be any node of $\mathcal{F}$. If the root of $\mathcal{F}$ is v-valent and P_k has decided u in $S(I)$, then*

$$u = \begin{cases} v & \text{if } k = 0, \\ v & \text{if } k = 1 \text{ and } P_0, P_1 \text{ have different initial values in } I, \\ \overline{v} & \text{if } k = 1 \text{ and } P_0, P_1 \text{ have the same initial value in } I. \end{cases}$$

Proof. Let S_0 be a solo schedule of P_0 such that $S \cdot S_0$ is in $\mathcal{F}$ and P_0 has decided in $S \cdot S_0(I)$ (S_0 exists by Lemma 6.2). Since (by hypothesis) the root of $\mathcal{F}$ is v-valent, P_0 has decided v in $S \cdot S_0(I)$. By hypothesis, P_k has decided u in $S(I)$; since the decision of a process is irrevocable, P_k has decided u in $S \cdot S_0(I)$. If $k = 0$, clearly $u = v$, as wanted. If $k = 1$, then P_0 has decided v in $S \cdot S_0(I)$, and P_1 has decided u in $S \cdot S_0(I)$. By the negation property, $u = v$ if P_0 and P_1 have different initial values in I; and $u = \overline{v}$ if P_0 and P_1 have the same initial value in I—as wanted. □

LEMMA 8.3. *For some initial configuration I of algorithm $\mathbf{A}_{en}$, the full computation tree $\mathcal{F}$ of $\mathbf{A}_{en}$ from I has a bivalent root.*

Proof. Suppose, for contradiction, that the root of every full computation tree of $\mathbf{A}_{en}$ is univalent. For each $i, j \in \{0,1,2\}$, let $I_{i,j}$ be the initial configuration of $\mathbf{A}_{en}$ in which P_0 and P_1 have initial values i and j, respectively, and let $\mathcal{F}_{i,j}$ be the full computation tree of $\mathbf{A}_{en}$ from $I_{i,j}$.

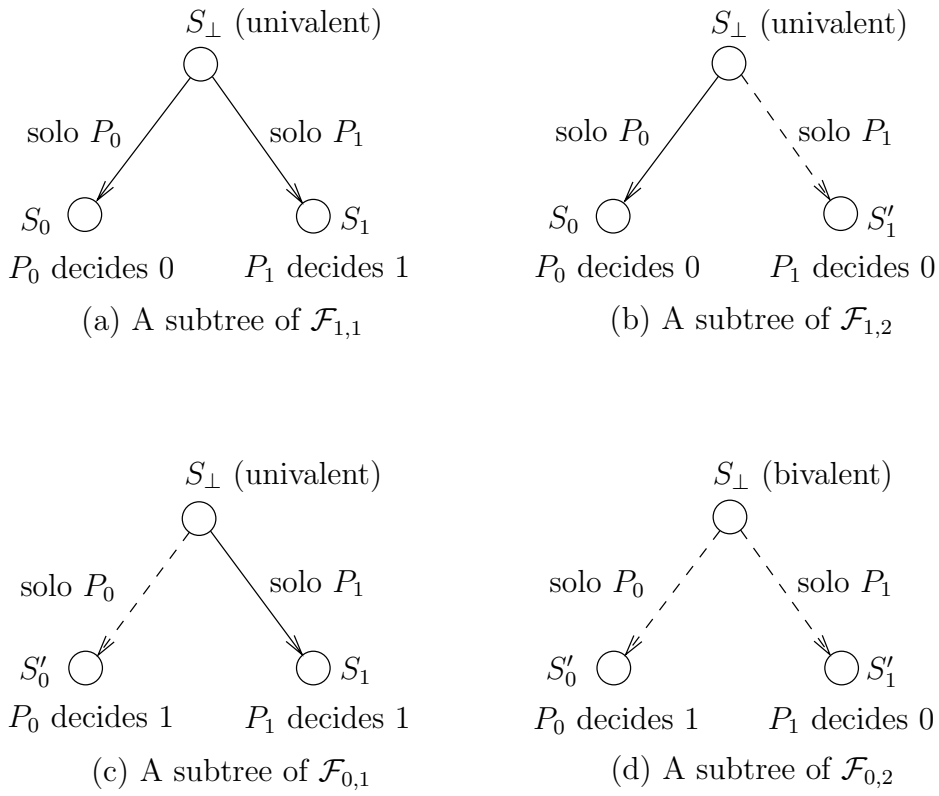
Without loss of generality, assume that the root of $\mathcal{F}_{1,1}$ is 0-valent. By Lemma 6.2 (applied to the root, $S_\perp$, of $\mathcal{F}_{1,1}$), for each $k \in \{0,1\}$ there is a solo schedule S_k of P_k such that $S_\perp \cdot S_k = S_k$ is a node in $\mathcal{F}_{1,1}$ and P_k has decided in $S_k(I_{1,1})$. By Lemma 8.2, P_k decides k in $S_k(I_{1,1})$; see Figure 8.1(a).

Since $I_{1,1}$ and $I_{1,2}$ differ only in the state of process P_1 and since S_0 is a solo schedule of P_0, by Lemma 6.1, S_0 is node in $\mathcal{F}_{1,2}$ and P_0 has the same state in $S_0(I_{1,2})$ as in $S_0(I_{1,1})$; see Figure 8.1(b). Thus, P_0 decides 0 in $S_0(I_{1,2})$. By the hypothesis that the root of $\mathcal{F}_{1,2}$ is univalent, it follows that the root of $\mathcal{F}_{1,2}$ is 0-valent. By Lemma 6.2 (applied to the root of $\mathcal{F}_{1,2}$), there is a solo schedule S_1' of P_1 such that S_1' is a node in $\mathcal{F}_{1,2}$ and P_1 has decided in $S_1'(I_{1,2})$. By Lemma 8.2, P_1 decides 0 in $S_1'(I_{1,2})$. Repeating the argument in this paragraph with $I_{1,2}$ replaced by $I_{0,1}$ and with the roles of 0 and 1 interchanged, we can prove that there exists a solo schedule S_0' of P_0 such that S_0' is a node in $\mathcal{F}_{0,1}$ and P_0 decides 1 in $S_0'(I_{0,1})$; see Figure 8.1(c).

Since $I_{0,1}$ and $I_{0,2}$ differ only in the state of P_1 and S_0' is a solo schedule of P_0, by Lemma 6.1, S_0' is a node in $\mathcal{F}_{0,2}$ and P_0 has the same state in $S_0'(I_{0,1})$ as in $S_0'(I_{0,2})$. Since P_0 decides 1 in $S_0'(I_{0,1})$, it also decides 1 in $S_0'(I_{0,2})$. By a similar argument, replacing $I_{0,1}$ and S_0' by $I_{1,2}$ and S_1', respectively, and interchanging the roles of P_0 and P_1, we can show that S_1' is a node in $\mathcal{F}_{0,2}$ and P_1 decides 0 in $S_1'(I_{0,2})$; see Figure 8.1(d). Thus, the root of $\mathcal{F}_{0,2}$ has descendants, namely, S_0' and S_1', in which processes have decided different values in the corresponding configurations. By Lemma 8.2, the root of $\mathcal{F}_{0,2}$ cannot be univalent. This contradicts our hypothesis that the root of every full computation tree of $\mathbf{A}_{en}$ is univalent. □

In the remainder of the section we focus exclusively on the initial configuration I and the full computation tree $\mathcal{F}$ of $\mathbf{A}_{en}$ from I whose existence is asserted by Lemma 8.3. Thus, from now on, we refer to the valence of a node without explicitly specifying the computation tree, since that will always be $\mathcal{F}$.

Since the root of $\mathcal{F}$ is bivalent, by Lemma 6.7, $\mathcal{F}$ has a critical node E. By the definition of critical node, there are steps e_0 and e_1 of processes P_0 and P_1, respectively,



(a) A subtree of $\mathcal{F}_{1,1}$ (b) A subtree of $\mathcal{F}_{1,2}$

(c) A subtree of $\mathcal{F}_{0,1}$ (d) A subtree of $\mathcal{F}_{0,2}$

FIG. 8.1. *Subtrees of four full computation trees of* $\mathbf{A}_{en}$.

such that $E \cdot e_0$ and $E \cdot e_1$ are univalent nodes of opposite valence. Without loss of generality, assume that $E \cdot e_0$ is 0-valent and $E \cdot e_1$ is 1-valent (if not, we simply rename e_0 and e_1). By Lemma 6.6, e_0 and e_1 access the same object, say, $\mathcal{O}$. We can show that $\mathcal{O}$ is not a register by using an argument similar to the one used in the proof of Lemma 7.6 (except simpler, since we are now working with the full computation tree and need not worry about whether certain schedules applicable to I have been pruned). Thus, $\mathcal{O}$ is a booster object. In what follows, we say that $\mathcal{O}$ is *fresh* in a configuration C of $\mathbf{A}_{en}$ if its state in C is ☺ and *upset* in C if its state in C is ☹.

We now outline how the proof proceeds: To show that the assumed equality negation algorithm $\mathbf{A}_{en}$ that uses only booster objects and registers does not exist, we derive a contradiction in two stages. In the first stage, we prove certain facts about the configuration $E(I)$ and the booster object $\mathcal{O}$. Specifically, we show that $\mathcal{O}$ is fresh in $E(I)$ (Corollary 8.5 and Lemma 8.7), that each process has an ENROLL operation (with a different parameter) to $\mathcal{O}$ pending in $E(I)$, and that neither process can decide before one of them has applied a REVEAL operation to $\mathcal{O}$ (Lemma 8.11). Furthermore, if neither process has yet applied a REVEAL operation to $\mathcal{O}$ but each is about to, then the parameters of the two pending REVEAL operations must be such as to ensure that $\mathcal{O}$ does not become upset (Lemma 8.13). These facts are then exploited in the second stage of the proof to show how to solve equality negation using only registers and the booster objects of $\mathbf{A}_{en}$ *except* $\mathcal{O}$. We have thus reached a contradiction, as $\mathbf{A}_{en}$ was assumed to use the smallest possible number of booster objects. The details of these

two stages are carried out in the next two subsections.

8.1. Stage 1 of the proof. We now show that $\mathcal{O}$ is fresh in $E(I)$. We do this by proving that, in $E(I)$, $\mathcal{O}$ is neither upset (Corollary 8.5) nor in a state of the form $\langle V, v_0, v_1, u_0, u_1, d\rangle$ (Lemma 8.7).

LEMMA 8.4. *Object $\mathcal{O}$ is not upset in $E\cdot e_0(I)$ or in $E\cdot e_1(I)$.*

Proof. Suppose, for contradiction, that $\mathcal{O}$ is upset in $E\cdot e_k(I)$ for some $k \in \{0,1\}$. By Lemma 6.2 (applied to node $E\cdot e_{\overline{k}}$ in $\mathcal{F}$), there is a solo schedule $S_{\overline{k}}$ of $P_{\overline{k}}$ such that $E\cdot e_{\overline{k}}\cdot S_{\overline{k}}$ is a node in $\mathcal{F}$ and $P_{\overline{k}}$ has decided in $E\cdot e_{\overline{k}}\cdot S_{\overline{k}}(I)$. Comparing configurations $E(I)$ and $E\cdot e_k(I)$, we note that $P_{\overline{k}}$ and each object other than $\mathcal{O}$ is in the same state in both. Since, by assumption, $\mathcal{O}$ is upset in $E\cdot e_k(I)$ and $e_{\overline{k}}\cdot S_{\overline{k}}$ is a solo schedule of $P_{\overline{k}}$, by Lemma 8.1, $E\cdot e_k\cdot e_{\overline{k}}\cdot S_{\overline{k}}$ is a node in $\mathcal{F}$, and $P_{\overline{k}}$ is in the same state in $E\cdot e_{\overline{k}}\cdot S_{\overline{k}}(I)$ as in $E\cdot e_k\cdot e_{\overline{k}}\cdot S_{\overline{k}}(I)$. Thus, $P_{\overline{k}}$ decides the same value in both $E\cdot e_{\overline{k}}\cdot S_{\overline{k}}(I)$ and $E\cdot e_k\cdot e_{\overline{k}}\cdot S_{\overline{k}}(I)$. By Lemma 6.3, $E\cdot e_{\overline{k}}\cdot S_{\overline{k}}$ and $E\cdot e_k\cdot e_{\overline{k}}\cdot S_{\overline{k}}$ have the same valence. Since $E\cdot e_{\overline{k}}$ and $E\cdot e_k$ are univalent and have descendants of the same valence, they also have the same valence. This contradicts the fact that $E\cdot e_0$ is 0-valent while $E\cdot e_1$ is 1-valent. □

Once a booster object is upset, it remains upset forever. Thus, Lemma 8.4 implies the following.

COROLLARY 8.5. *Object $\mathcal{O}$ is not upset in $E(I)$.*

LEMMA 8.6. *$E\cdot e_0\cdot e_1$ and $E\cdot e_1\cdot e_0$ are nodes in $\mathcal{F}$.*

Proof. By definition of $\mathcal{F}$, it suffices to show that for each $k \in \{0,1\}$ e_k is applicable to $E\cdot e_{\overline{k}}(I)$. If e_k is an ENROLL step, the lemma follows immediately by the specification of booster.

Suppose that e_k is a REVEAL step. If $\mathcal{O}$ is fresh in $E(I)$, then $\mathcal{O}$ is upset in $E\cdot e_k(I)$, contrary to Lemma 8.4. Thus, $\mathcal{O}$ is not fresh in $E(I)$. By Corollary 8.5, $\mathcal{O}$ is not upset in $E(I)$. Thus, $\mathcal{O}$ is in a state of the form $\langle *, *, *, *, *, d\rangle$ in $E(I)$ for some $d \in \{0,1\}$. By the specification of booster, and since $\mathcal{O}$ is not upset in $E\cdot e_k(I)$, the response returned by the REVEAL operation in e_k is d. Since $\mathcal{O}$ is in a state of the form $\langle *, *, *, *, *, d\rangle$ in $E(I)$ and is not upset in $E\cdot e_{\overline{k}}(I)$, it must be in a state of the form $\langle *, *, *, *, *, d\rangle$ in $E\cdot e_{\overline{k}}(I)$ as well (because the last component of the state is never changed, once it is set). By the specification of booster, a REVEAL operation to $\mathcal{O}$ applied in such a state can return the response d. Thus, e_k is indeed applicable to $E\cdot e_{\overline{k}}(I)$. □

LEMMA 8.7. *The state of $\mathcal{O}$ in $E(I)$ is not of the form $\langle V, v_0, v_1, u_0, u_1, d\rangle$.*

Proof. Suppose, for contradiction, that the state of $\mathcal{O}$ in $E(I)$ is $\langle V, v_0, v_1, u_0, u_1, d\rangle$. By Lemma 8.6, both $E\cdot e_0\cdot e_1$ and $E\cdot e_1\cdot e_0$ are nodes in $\mathcal{F}$. We shall show that

(2) the state of $\mathcal{O}$ is the same in $E\cdot e_0\cdot e_1(I)$ as in $E\cdot e_1\cdot e_0(I)$.

Clearly, the state of each process and object except $\mathcal{O}$ is the same in $E\cdot e_1\cdot e_0(I)$ as in $E\cdot e_0\cdot e_1(I)$. By (2), we have thus shown that e_0 and e_1 commute at E in $\mathcal{F}$. This contradicts Lemma 6.5(a), as wanted.

It remains to show (2). Let op_0 and op_1 be the (ENROLL or REVEAL) operations to $\mathcal{O}$ of processes P_0 and P_1 that are pending in $E(I)$, respectively. There are three cases, depending on the types of op_0 and op_1.

Case 1. *Both operations pending in $E(I)$ are* ENROLL: Let $op_0 = \text{ENROLL}(i_0)$ and $op_1 = \text{ENROLL}(i_1)$ for some $i_0, i_1 \in \{0,1\}$. For each $k \in \{0,1\}$, let r_k be the response of $\mathcal{O}$ to the $\text{ENROLL}(i_k)$ operation in step e_k. There are three subcases.

Subcase 1(a). $i_0 = i_1 = 0$: From the specification of booster, $\mathcal{O}$ is upset in both $E\cdot e_0\cdot e_1(I)$ and $E\cdot e_1\cdot e_0(I)$.

Subcase 1(b). $i_0 = i_1 = 1$: From the specification of booster, $\mathcal{O}$ is in state $\langle V \cup \{r_0, r_1\}, v_0, v_1, u_0, u_1, d\rangle$ in both $E \cdot e_0 \cdot e_1(I)$ and $E \cdot e_1 \cdot e_0(I)$.

Subcase 1(c). *For some* $k \in \{0,1\}$, $i_k = 0$ *and* $i_{\overline{k}} = 1$: Without loss of generality we assume that $i_0 = 0$ and $i_1 = 1$. Then $v_0 = \perp$; if not, $\mathcal{O}$ would be upset in $E \cdot e_0(I)$, which contradicts Lemma 8.4. By the definition of the set of states of booster, $u_0 = \perp$. From this, it follows that $\mathcal{O}$ is in state $\langle V \cup \{r_1\}, r_0, v_1, \perp, u_1, d\rangle$ in both $E \cdot e_0 \cdot e_1(I)$ and $E \cdot e_1 \cdot e_0(I)$.

Case 2. *One of the two operations pending in* $E(I)$ *is* ENROLL *and the other is* REVEAL: Without loss of generality, we may assume that $op_0 = \text{ENROLL}(i_0)$ and $op_1 = \text{REVEAL}(i_1, v, u)$ for some $i_0, i_1, u \in \{0,1\}$ and $v \in \{0,1,2\}$. Let r be the response of the $\text{ENROLL}(i_0)$ operation that is returned in step e_0. There are three subcases.

Subcase 2(a). $i_0 = 0$: Then $v_0 = \perp$ (otherwise, $\mathcal{O}$ would be upset in $E \cdot e_0(I)$, contrary to Lemma 8.4), and hence $u_0 = \perp$ (by the definition of the set of states of booster). Also, $i_1 = 1$ (otherwise, $\mathcal{O}$ would be upset in $E \cdot e_1(I)$). Thus, $\mathcal{O}$ is in state $\langle V, \perp, v_1, \perp, u_1, d\rangle$ in $E(I)$ and the operations of P_0 and P_1 pending in $E(I)$ are $\text{ENROLL}(0)$ and $\text{REVEAL}(1, v, u)$, respectively. From the specification of booster, the state of $\mathcal{O}$ in both $E \cdot e_0 \cdot e_1(I)$ and $E \cdot e_1 \cdot e_0(I)$ is

$$\begin{cases} \langle V, r, v, \perp, u, d\rangle & \text{if } v \in V \textbf{ and } (u_1 = \perp \textbf{ or } (v = v_1 \textbf{ and } u = u_1)), \\ \text{☹} & \text{otherwise.} \end{cases}$$

Subcase 2(b). $i_0 = 1$ *and* $i_1 = 0$: Since $\mathcal{O}$ is not upset in $E \cdot e_1(I)$, the Boolean expression

$$v = v_0 \textbf{ and } u_0 = \perp \textbf{ and } (u_1 = \perp \textbf{ or } (v = v_1 \Leftrightarrow u \neq u_1))$$

is true, and $\mathcal{O}$ is in state $\langle V, v_0, v_1, u, u_1, d\rangle$ in $E \cdot e_1(I)$. Thus, $\mathcal{O}$ is in state $\langle V \cup \{r\}, v_0, v_1, u, u_1, d\rangle$ in $E \cdot e_1 \cdot e_0(I)$.

The state of $\mathcal{O}$ in $E \cdot e_0(I)$ is $\langle V \cup \{r\}, v_0, v_1, \perp, u_1, d\rangle$ (recall that $u_0 = \perp$). Since the preceding Boolean expression is true, by the specification of booster, the application of $\text{REVEAL}(0, v, u)$ to $\mathcal{O}$ in state $\langle V \cup \{r\}, v_0, v_1, \perp, u_1, d\rangle$ does not cause $\mathcal{O}$ to become upset; in fact, it causes it to enter state $\langle V \cup \{r\}, v_0, v_1, u, u_1, d\rangle$. Thus, e_1 is applicable to $E \cdot e_0(I)$, and the state of $\mathcal{O}$ in $E \cdot e_0 \cdot e_1(I)$ is $\langle V \cup \{r\}, v_0, v_1, u, u_1, d\rangle$, which is the same as in $E \cdot e_1 \cdot e_0(I)$.

Subcase 2(c). $i_0 = 1$ *and* $i_1 = 1$: Similar to Subcase 2(b), except that in this case the state of $\mathcal{O}$ in $E \cdot e_0 \cdot e_1(I)$ and $E \cdot e_1 \cdot e_0(I)$ is $\langle V \cup \{r\}, v_0, v, u_0, u, d\rangle$ instead of $\langle V \cup \{r\}, v_0, v_1, u, u_1, d\rangle$.

Case 3. *Both operations pending in* $E(I)$ *are* REVEAL: Let $op_0 = \text{REVEAL}(i_0, v, u)$ and $op_1 = \text{REVEAL}(i_1, v', u')$ for some $i_0, i_1, u, u' \in \{0,1\}$ and $v, v' \in \{0,1,2\}$. There are three subcases.

Subcase 3(a). $i_0 = i_1 = 0$: Then $\mathcal{O}$ is upset in both $E \cdot e_0 \cdot e_1(I)$ and $E \cdot e_1 \cdot e_0(I)$.

Subcase 3(b). $i_0 \neq i_1$: Without loss of generality, we may assume that $i_0 = 0$ and $i_1 = 1$. It must be the case that $v = v_0$ and $u_0 = \perp$ (otherwise $\mathcal{O}$ is upset in $E \cdot e_0(I)$, contrary to Lemma 8.4). Also $v' \in V$ and either $u_1 = \perp$, or $v' = v_1$ and $u' = u_1$ (otherwise $\mathcal{O}$ is upset in $E \cdot e_1(I)$). Thus, the state of $\mathcal{O}$ in $E(I)$ is either $\langle V, v, \perp, \perp, \perp, d\rangle$ or $\langle V, v, v', \perp, u', d\rangle$. In either case, it can be verified from the specification of booster that the state of $\mathcal{O}$ in both $E \cdot e_0 \cdot e_1(I)$ and $E \cdot e_1 \cdot e_0(I)$ is

$$\begin{cases} \langle V, v, v', u, u', d\rangle & \text{if } v = v' \Leftrightarrow u \neq u', \\ \text{☹} & \text{otherwise.} \end{cases}$$

Subcase 3(c). $i_0 = i_1 = 1$: Since $\mathcal{O}$ is not upset in either one of $E \cdot e_0(I)$ or $E \cdot e_1(I)$, it must be that $v, v' \in V$ and $\mathcal{O}$ is in state $\langle V, v_0, v, u_0, u, d\rangle$ in $E \cdot e_0(I)$ and in $\langle V, v_0, v', u_0, u', d\rangle$ in $E \cdot e_1(I)$. From the specification of booster, it can be checked that the state of $\mathcal{O}$ in $E \cdot e_0 \cdot e_1(I)$ is

$$\begin{cases} \langle V, v_0, v', u_0, u', d\rangle & \text{if } v' = v \text{ and } u' = u, \\ \text{☹} & \text{otherwise.} \end{cases}$$

Similarly, the state of $\mathcal{O}$ in $E \cdot e_1 \cdot e_0(I)$ is

$$\begin{cases} \langle V, v_0, v, u_0, u, d\rangle & \text{if } v = v' \text{ and } u = u', \\ \text{☹} & \text{otherwise.} \end{cases}$$

Thus, $\mathcal{O}$ is in the same state in $E \cdot e_0 \cdot e_1(I)$ as in $E \cdot e_1 \cdot e_0(I)$. This completes the proof of (2), and thereby of the lemma. □

By Corollary 8.5 and Lemma 8.7, $\mathcal{O}$ must be fresh in $E(I)$. Furthermore, each P_k must have an ENROLL operation to $\mathcal{O}$ pending in $E(I)$. (Otherwise, by the specification of booster, $\mathcal{O}$ would be upset in $E \cdot e_k(I)$, contrary to Lemma 8.4.) For each $k \in \{0, 1\}$, let $j_k \in \{0, 1\}$ be the parameter of the ENROLL operation of P_k pending in $E(I)$.

The next lemma states that the parameters of the two ENROLL operations to $\mathcal{O}$ pending in $E(I)$ are different.

LEMMA 8.8. $j_0 \neq j_1$.

Proof. Suppose, for contradiction, that $j_0 = j_1$. As in the proof of Lemma 8.7, we shall show that $\mathcal{O}$ is in the same state in $E \cdot e_0 \cdot e_1(I)$ as in $E \cdot e_1 \cdot e_0(I)$. This fact, together with Lemma 8.6, implies that e_0 and e_1 commute at E in $\mathcal{F}$, thus contradicting Lemma 6.5(a).

Recall that $j_0, j_1 \in \{0, 1\}$. There are two cases.

Case 1. $j_0 = j_1 = 0$: Then $\mathcal{O}$ is upset in both $E \cdot e_0 \cdot e_1(I)$ and $E \cdot e_1 \cdot e_0(I)$.

Case 2. $j_0 = j_1 = 1$: Let r_0 and r_1 be the responses of $\mathcal{O}$ returned to the ENROLL operations in e_0 and e_1, respectively. Then $\mathcal{O}$ is in state $\langle \{r_0, r_1\}, \perp, \perp, \perp, \perp, 1\rangle$ in both $E \cdot e_0 \cdot e_1(I)$ and $E \cdot e_1 \cdot e_0(I)$. □

We next show that after applying its ENROLL operation that is pending in $E(I)$ no process can decide unless some process has applied at least one REVEAL operation to $\mathcal{O}$ (Lemma 8.11). In the next two lemmas, we establish some properties of schedules applicable to $E(I)$ used to prove this fact.

LEMMA 8.9. *For any $k \in \{0, 1\}$ and any node $E \cdot S$ in $\mathcal{F}$, if P_k is the process that takes the first step in S, then $E \cdot S$ is k-valent.*

Proof. Later we prove that

(3) for each $k \in \{0, 1\}$, the nodes in *children*$(P_k, E, \mathcal{F})$ have the same valence.

Let e be the first step in S, which is taken by process P_k for some $k \in \{0, 1\}$. Thus, $E \cdot e$ is a node in *children*$(P_k, E, \mathcal{F})$. By (3), all nodes in *children*$(P_k, E, \mathcal{F})$ are univalent and have the same valence. One of these children, namely, $E \cdot e_k$, is k-valent. Therefore, $E \cdot e$ is also k-valent. Since $E \cdot S$ is a descendant of $E \cdot e$, it follows that $E \cdot S$ is k-valent.

It remains to prove (3). We prove it for $k = 0$. (The proof for $k = 1$ can be obtained by interchanging the roles of 0 and 1 in the argument below.) For each $v \in \{0, 1, 2\}$, let $e_0^v = (P_0, \text{ENROLL}(j_0), \mathcal{O}, v)$. Since $\mathcal{O}$ is fresh in $E(I)$ and an ENROLL operation applied to a fresh booster object can return any value in $\{0, 1, 2\}$, it follows

that $children(P_0, E, \mathcal{F}) = \{ E \cdot e_0^v : 0 \leq v \leq 2 \}$. Since E is a critical node, all nodes in $children(P_0, E, \mathcal{F})$ are univalent. To prove (3), it suffices to show that for any $v, v' \in \{0, 1, 2\}$, $E \cdot e_0^v$ and $E \cdot e_0^{v'}$ have the same valence. From the specification of booster and the fact that $\mathcal{O}$ is fresh in $E(I)$ we have the following:

(a) For any $v \in \{0, 1, 2\}$, the state of $\mathcal{O}$ in $E \cdot e_0^v(I)$ is $\langle *, *, *, *, *, j_0 \rangle$.
(b) For any $v \in \{0, 1, 2\}$, if S is a schedule applicable to $E \cdot e_0^v(I)$, then the state of $\mathcal{O}$ in $E \cdot e_0^v \cdot S(I)$ is either of the form $\langle *, *, *, *, *, j_0 \rangle$ or ☹.
(c) A REVEAL operation can return j_0 when applied to a booster object in a state of the form $\langle *, *, *, *, *, j_0 \rangle$ or in state ☹.

Let v be any element of $\{0, 1, 2\}$. By Lemma 6.2 (applied to node $E \cdot e_0^v$ in $\mathcal{F}$), there is a solo schedule S of P_1 such that $E \cdot e_0^v \cdot S$ is a node in $\mathcal{F}$ and P_1 has decided in $E \cdot e_0^v \cdot S(I)$. Since $\mathcal{F}$ is a full computation tree, by (a)–(c) we may assume, without loss of generality, that S contains no step of the form $(*, \text{REVEAL}(*, *, *), \mathcal{O}, \overline{j}_0)$.

For any $v' \in \{0, 1, 2\}$, the state of P_1 and each object except $\mathcal{O}$ is the same in $E \cdot e_0^v(I)$ as in $E \cdot e_0^{v'}(I)$. Since the state of $\mathcal{O}$ in $E \cdot e_0^{v'}(I)$ is of the form $\langle *, *, *, *, *, j_0 \rangle$ and since S does not contain a REVEAL step to $\mathcal{O}$ with return value $\overline{j}_0$, the hypothesis of Lemma 8.1 applies for $S_0 = E \cdot e_0^v$ and $S_1 = E \cdot e_0^{v'}$. Thus, $E \cdot e_0^{v'} \cdot S$ is a node in $\mathcal{F}$, and P_1 is in the same state in $E \cdot e_0^v \cdot S(I)$ as in $E \cdot e_0^{v'} \cdot S(I)$. This implies that P_1 decides the same value in these two configurations. By Lemma 6.3, nodes $E \cdot e_0^v \cdot S$ and $E \cdot e_0^{v'} \cdot S$ have the same valence. Hence, $E \cdot e_0^v$ and $E \cdot e_0^{v'}$ (which are univalent since E is critical) must also have the same valence. This completes the proof of (3) and thereby of the lemma. □

LEMMA 8.10. *Let $E \cdot S$ be any node in $\mathcal{F}$ such that S contains no* REVEAL *step to $\mathcal{O}$, and d_k be the first step of P_k in S for any $k \in \{0, 1\}$. Let $\hat{S}$ be the schedule obtained from S by moving d_k to the beginning (i.e., if $S = S' \cdot d_k \cdot S''$ for some S' and S'', then $\hat{S} = d_k \cdot S' \cdot S''$). Then, $E \cdot \hat{S}$ is a node in $\mathcal{F}$, and the state of each process and each object other than $\mathcal{O}$ is the same in $E \cdot \hat{S}(I)$ as in $E \cdot S(I)$.*

Proof. Let S' and S'' be such that $S = S' \cdot d_k \cdot S''$. Recall that process P_k has an ENROLL(j_k) to $\mathcal{O}$ pending in $E(I)$. Since S' is a solo schedule of $P_{\overline{k}}$ (because d_k is the first step of P_k in S), the operation of P_k pending in $E \cdot S'(I)$ is still ENROLL(j_k) to $\mathcal{O}$. Thus, d_k is an ENROLL step to $\mathcal{O}$. By the specification of booster, d_k is applicable to $E(I)$. Clearly, as d_k is a step of P_k that accesses (only) $\mathcal{O}$, the state of $P_{\overline{k}}$ and each object other than $\mathcal{O}$ is the same in $E(I)$ as in $E \cdot d_k(I)$. Also, the state of $\mathcal{O}$ in $E \cdot d_k(I)$ is of the form $\langle *, *, *, *, *, j_k \rangle$ (recall that d_k is an ENROLL(j_k) step to $\mathcal{O}$). Since $E \cdot S'$ is a node in $\mathcal{F}$ and S' is a solo schedule of $P_{\overline{k}}$ that does not contain a REVEAL step to $\mathcal{O}$, by Lemma 8.1 (applied for $S_0 = E$, $S_1 = E \cdot d_k$, and $S = S'$), $E \cdot d_k \cdot S'$ is a node in $\mathcal{F}$, and the state of $P_{\overline{k}}$ and each object other than $\mathcal{O}$ is the same in $E \cdot d_k \cdot S'(I)$ as in $E \cdot S'(I)$. It follows that each process and each object other than $\mathcal{O}$ is in the same state in $E \cdot d_k \cdot S'(I)$ as in $E \cdot S' \cdot d_k(I)$. By hypothesis, $E \cdot S' \cdot d_k \cdot S''$ is a node in $\mathcal{F}$ and S'' does not contain a REVEAL step to $\mathcal{O}$. Again by Lemma 8.1 (applied for $S_0 = E \cdot S' \cdot d_k$, $S_1 = E \cdot d_k \cdot S'$, and $S = S''$), $E \cdot d_k \cdot S' \cdot S''$ is a node in $\mathcal{F}$, and the state of each process and each object other than $\mathcal{O}$ is the same in $E \cdot S' \cdot d_k \cdot S''(I)$ as in $E \cdot d_k \cdot S' \cdot S''(I)$. □

LEMMA 8.11. *Let $E \cdot S$ be any node in $\mathcal{F}$ such that some process has decided in $E \cdot S(I)$. Then S has a* REVEAL *step to $\mathcal{O}$.*

Proof. Suppose, for contradiction, that some process has decided in $E \cdot S(I)$, but S contains no REVEAL step to $\mathcal{O}$. Without loss of generality, we may assume that both processes take steps in S. (If S contains only steps of process P_k for some $k \in \{0, 1\}$, we extend S by a step of $P_{\overline{k}}$, which cannot be a REVEAL step to $\mathcal{O}$ because

the operation of $P_{\bar{k}}$ pending in $E(I)$ is an ENROLL to $\mathcal{O}$, and consider the extended schedule instead.)

Let P_ℓ, $\ell \in \{0,1\}$, be the process that does *not* take the first step in S, and $\hat{S}$ be the schedule obtained from S by moving the first step of P_ℓ to the beginning. By Lemma 8.10, $E \cdot \hat{S}$ is a node in $\mathcal{F}$, and the state of each process and each object except $\mathcal{O}$ is the same in $E \cdot \hat{S}(I)$ as in $E \cdot S(I)$. In particular, the process that has decided in $E \cdot S(I)$ decides the same value in $E \cdot \hat{S}(I)$. By Lemma 6.3, $E \cdot S$ and $E \cdot \hat{S}$ have the same valence. This contradicts Lemma 8.9, since P_ℓ takes the first step in $\hat{S}$ while $P_{\bar{\ell}}$ takes the first step in S. □

To summarize, $\mathcal{O}$ is fresh in $E(I)$, each P_k has an ENROLL(j_k) operation to $\mathcal{O}$ pending in $E(I)$, and $j_0 \neq j_1$. By Lemma 8.11, no process can decide unless a REVEAL operation is applied to $\mathcal{O}$. Thus, by the termination requirement of equality negation, there is a schedule S applicable to $E(I)$ so that no process has taken a REVEAL step to $\mathcal{O}$ in S, and each process has a REVEAL operation to $\mathcal{O}$ pending in $E \cdot S(I)$. S contains ENROLL steps of both processes because each process P_k, $k \in \{0,1\}$, has an ENROLL(j_k) operation to $\mathcal{O}$ pending in $E(I)$ but has a REVEAL operation to $\mathcal{O}$ pending in $E \cdot S(I)$. By Lemma 8.8, S contains both ENROLL(0) and ENROLL(1) steps to $\mathcal{O}$.

The next lemma proves that, in any execution starting from configuration $E(I)$, if each of the two processes is about to apply its first REVEAL operation to $\mathcal{O}$, then the application of these two operations does not cause $\mathcal{O}$ to become upset.

LEMMA 8.12. *Consider any node $E \cdot S$ in $\mathcal{F}$ such that S contains no* REVEAL *step to $\mathcal{O}$ and both processes have a* REVEAL *operation to $\mathcal{O}$ pending in $E \cdot S(I)$. For each $k \in \{0,1\}$, let d_k be any step of P_k and $c_{\bar{k}}$ be any step of $P_{\bar{k}}$ such that $E \cdot S \cdot d_k \cdot c_{\bar{k}}$ is a node in $\mathcal{F}$. (Note that d_k and $c_{\bar{k}}$ are* REVEAL *steps that access $\mathcal{O}$.) Then $\mathcal{O}$ is not upset in $E \cdot S \cdot d_k \cdot c_{\bar{k}}(I)$.*

Proof. Suppose, to the contrary, that $\mathcal{O}$ is upset in $E \cdot S \cdot d_k \cdot c_{\bar{k}}(I)$ for some $k \in \{0,1\}$. Let P_ℓ, $\ell \in \{0,1\}$, be the process that does *not* take the first step in S, and $\hat{S}$ be the schedule obtained from S by moving the first step of P_ℓ to the beginning. By Lemma 8.10, $E \cdot \hat{S}$ is a node in $\mathcal{F}$, and each process and each object except $\mathcal{O}$ is in the same state in $E \cdot S(I)$ as in $E \cdot \hat{S}(I)$. Let $\hat{d}_k$ be any step of P_k such that $E \cdot \hat{S} \cdot \hat{d}_k$ is a node in $\mathcal{F}$. We shall prove that

$$E \cdot \hat{S} \cdot \hat{d}_k \cdot c_{\bar{k}} \text{ is a node in } \mathcal{F}, \text{ and } \mathcal{O} \text{ is upset in } E \cdot \hat{S} \cdot \hat{d}_k \cdot c_{\bar{k}}(I). \tag{4}$$

Given (4), process $P_{\bar{k}}$ and each object (including $\mathcal{O}$) is in the same state in $E \cdot S \cdot d_k \cdot c_{\bar{k}}(I)$ as in $E \cdot \hat{S} \cdot \hat{d}_k \cdot c_{\bar{k}}(I)$. By Lemma 6.4, $E \cdot S \cdot d_k \cdot c_{\bar{k}}$ and $E \cdot \hat{S} \cdot \hat{d}_k \cdot c_{\bar{k}}$ have the same valence. This contradicts Lemma 8.9, since P_ℓ takes the first step in $\hat{S}$, while $P_{\bar{\ell}}$ takes the first step in S.

It remains to show (4). There are three cases.

Case 1. *$\mathcal{O}$ is upset in $E \cdot S(I)$*: Since S contains only ENROLL operations to $\mathcal{O}$, it must contain two ENROLL(0) operations to $\mathcal{O}$ (otherwise $\mathcal{O}$ would not be upset in $E \cdot S(I)$). Then so does $\hat{S}$, and $\mathcal{O}$ is upset in $E \cdot \hat{S}(I)$. It is immediate from the specification of booster that $\mathcal{O}$ is upset in $E \cdot \hat{S} \cdot \hat{d}_k(I)$ and $c_{\bar{k}}$ is applicable to $E \cdot \hat{S} \cdot \hat{d}_k(I)$. Therefore, $E \cdot \hat{S} \cdot \hat{d}_k \cdot c_{\bar{k}}$ is a node in $\mathcal{F}$, and $\mathcal{O}$ is upset in $E \cdot \hat{S} \cdot \hat{d}_k \cdot c_{\bar{k}}(I)$ (because once a booster object becomes upset, it remains upset forever).

Case 2. *$\mathcal{O}$ is not upset in $E \cdot S(I)$ but it is upset in $E \cdot S \cdot d_k(I)$*: S contains exactly one ENROLL(0) and at least one ENROLL(1) step. (We have already argued, in the paragraph preceding Lemma 8.12, that S contains both ENROLL(0) and ENROLL(1)

steps. It cannot contain two ENROLL(0) steps because, otherwise, $\mathcal{O}$ would be upset in $E \cdot S(I)$, contrary to the hypothesis of this case.) By assumption, S does not contain any REVEAL steps. Since $\mathcal{O}$ is fresh in $E(I)$ and it is not upset in $E \cdot S(I)$, the state of $\mathcal{O}$ in $E \cdot S(I)$ is $\langle V, v, \perp, \perp, \perp, j_{\overline{\ell}} \rangle$, where V is the set of return values of the ENROLL(1) steps in S, and v is the return value of the ENROLL(0) step in S. (To see why the last component of the state is $j_{\overline{\ell}}$, recall that $P_{\overline{\ell}}$ has an ENROLL($j_{\overline{\ell}}$) operation to $\mathcal{O}$ pending in $E(I)$. Since $P_{\overline{\ell}}$ is the process that takes the first step in S, that step involves an ENROLL($j_{\overline{\ell}}$) operation to $\mathcal{O}$. Since $\mathcal{O}$ is fresh in $E(I)$, when that ENROLL($j_{\overline{\ell}}$) operation is applied to $\mathcal{O}$, the state of $\mathcal{O}$ is set to a state of the form $\langle *, *, \perp, \perp, \perp, j_{\overline{\ell}} \rangle$. The last component of the state is not changed, once it is set.) Similarly, the state of $\mathcal{O}$ in $E \cdot \hat{S}(I)$ is $\langle V, v, \perp, \perp, \perp, j_\ell \rangle$—i.e., the same as in $E \cdot S(I)$, except for the last component.

Since $\mathcal{O}$ is upset in $E \cdot S \cdot d_k(I)$ it follows, from the specification of booster, that d_k is a REVEAL(i_k, v_k, u_k) step to $\mathcal{O}$ so that one of the following holds:

(a) $i_k = 0$ and $v_k \neq v$ (i.e., v_k is not the return value of the ENROLL(0) step in S);
(b) $i_k = 1$ and $v_k \notin V$ (i.e., v_k is not the return value of some ENROLL(1) step in S).

In either case, it is immediate from the specification of booster that the application of REVEAL(i_k, v_k, u_k) to $\mathcal{O}$ in state $\langle V, v, \perp, \perp, \perp, j_\ell \rangle$ will cause $\mathcal{O}$ to become upset (and can return any value in $\{0, 1\}$). Since the state of process P_k is the same in $E \cdot S(I)$ as is $E \cdot \hat{S}(I)$, $\hat{d}_k$ is also a REVEAL(i_k, v_k, u_k) step to $\mathcal{O}$. Thus, $\mathcal{O}$ is upset in $E \cdot \hat{S} \cdot \hat{d}_k(I)$. Hence, $c_{\overline{k}}$ is applicable to $E \cdot \hat{S} \cdot \hat{d}_k(I)$. This implies that $E \cdot \hat{S} \cdot \hat{d}_k \cdot c_{\overline{k}}$ is a node in $\mathcal{F}$, and $\mathcal{O}$ is upset in $E \cdot \hat{S} \cdot \hat{d}_k \cdot c_{\overline{k}}(I)$.

Case 3. *$\mathcal{O}$ is not upset in $E \cdot S \cdot d_k(I)$ but it is upset in $E \cdot S \cdot d_k \cdot c_{\overline{k}}(I)$*: Let the REVEAL operation applied to $\mathcal{O}$ in d_k be REVEAL(i_k, v_k, u_k). Since $\mathcal{O}$ is not upset in $E \cdot S \cdot d_k(I)$, and S does not contain any REVEAL steps, we conclude the following about the state of $\mathcal{O}$ in $E \cdot S \cdot d_k(I)$:

- If $i_k = 0$, then that state is $\langle V, v, \perp, u_k, \perp, j_{\overline{\ell}} \rangle$, where V is the set of return values of the ENROLL(1) steps in S, v is the return value of the ENROLL(0) step in S, and $v_k = v$.
- If $i_k = 1$, then that state is $\langle V, v, v_k, \perp, u_k, j_{\overline{\ell}} \rangle$, where V is the set of return values of the ENROLL(1) steps in S, v is the return value of the ENROLL(0) step in S, and $v_k \in V$.

As argued in the preceding case, $\hat{d}_k$ is also a REVEAL(i_k, v_k, u_k) step to $\mathcal{O}$. Thus, the state of $\mathcal{O}$ in $E \cdot \hat{S} \cdot \hat{d}_k(I)$ is as above, except that the last component is j_ℓ instead of $j_{\overline{\ell}}$. Since $\mathcal{O}$ is upset in $E \cdot S \cdot d_k \cdot c_{\overline{k}}(I)$, from the specification of booster it follows that $c_{\overline{k}}$ is a REVEAL$(i_{\overline{k}}, v_{\overline{k}}, u_{\overline{k}})$ step to $\mathcal{O}$ so that one of the following holds:

(a) $i_{\overline{k}} = 0$ and $v_{\overline{k}} \neq v$ (i.e., $v_{\overline{k}}$ is not the return value of the ENROLL(0) step in S).
(b) $i_{\overline{k}} = 1$ and $v_{\overline{k}} \notin V$ (i.e., $v_{\overline{k}}$ is not the return value of some ENROLL(1) step in S).
(c) $i_{\overline{k}} = i_k = 0$.
(d) $i_{\overline{k}} = i_k = 1$, and either $v_{\overline{k}} \neq v_k$, or $u_{\overline{k}} \neq u_k$.
(e) $i_{\overline{k}} \neq i_k$ and it is not the case that $v_{\overline{k}} = v_k \Leftrightarrow u_{\overline{k}} \neq u_k$.

In each of these cases, it can be seen that the application of a REVEAL$(i_{\overline{k}}, v_{\overline{k}}, u_{\overline{k}})$ operation to $\mathcal{O}$ when in a state of the form $\langle V, v, \perp, u_k, \perp, j_\ell \rangle$ or $\langle V, v, v_k, \perp, u_k, j_\ell \rangle$ (the only possible states of $\mathcal{O}$ in $E \cdot \hat{S} \cdot \hat{d}_k(I)$) will cause $\mathcal{O}$ to become upset and can return any value in $\{0, 1\}$. Thus, $c_{\overline{k}}$ is applicable to $E \cdot \hat{S} \cdot \hat{d}_k(I)$. Therefore, $E \cdot \hat{S} \cdot \hat{d}_k \cdot c_{\overline{k}}$ is a node in $\mathcal{F}$, and $\mathcal{O}$ is upset in $E \cdot \hat{S} \cdot \hat{d}_k \cdot c_{\overline{k}}(I)$. This completes the proof of (4), and

thereby of the lemma. □

Using Lemma 8.12, we can show that starting from $E(I)$, if each of the two processes is about to apply its first REVEAL operation to $\mathcal{O}$, then the parameters of these two REVEAL operations satisfy certain properties.

LEMMA 8.13. *Consider any node $E \cdot S$ in $\mathcal{F}$ such that S contains no* REVEAL *step to $\mathcal{O}$ and both processes have a* REVEAL *operation to $\mathcal{O}$ pending in $E \cdot S(I)$. For each $k \in \{0, 1\}$, let i_k, v_k, and u_k be the parameters of the* REVEAL *operation to $\mathcal{O}$ of P_k that is pending in $E \cdot S(I)$. Then*

(a) *for each $k \in \{0, 1\}$, v_k is the response of an* ENROLL(i_k) *step to $\mathcal{O}$ contained in S;*
(b) *i_0 and i_1 cannot be both equal to 0;*
(c) *if $i_0 = i_1 = 1$, then $v_0 = v_1$ and $u_0 = u_1$;*
(d) *if $i_0 \neq i_1$, then $v_0 = v_1 \Leftrightarrow u_0 \neq u_1$.*

Proof. For each $k \in \{0, 1\}$, let d_k be a step of P_k and $c_{\overline{k}}$ be a step of $P_{\overline{k}}$ such that $E \cdot S \cdot d_k \cdot c_{\overline{k}}$ is a node in $\mathcal{F}$. By the specification of booster, if any of the properties (a)–(d) failed to hold, $\mathcal{O}$ would be upset in $E \cdot S \cdot d_k \cdot c_{\overline{k}}(I)$ for any $k \in \{0, 1\}$. This would contradict Lemma 8.12. Thus, (a)–(d) must all hold. □

8.2. Stage 2 of the proof. We now describe an algorithm that solves equality negation between two processes, Q_0 and Q_1, and uses one less booster object than $\mathbf{A}_{en}$. Intuitively, the algorithm works as follows: Each process Q_k simulates the actions of the corresponding process P_k in an execution of $\mathbf{A}_{en}$, and uses this execution to determine what value to decide. In this simulation, the processes are allowed to access all objects used by $\mathbf{A}_{en}$ except $\mathcal{O}$, each of which is initialized to the state it has in configuration $E(I)$.

The simulation of P_k by Q_k starts by pretending that P_k is in the state it has in configuration $E(I)$. Based on the current state of (the simulated) P_k, Q_k determines the operation *op* that P_k would apply next, and the object O to which *op* would be applied. If $O \neq \mathcal{O}$, then Q_k has access to O and can apply *op* to it directly to determine the response and update the (simulated) state of P_k accordingly. If, however, $O = \mathcal{O}$, this is not possible, since Q_k is not allowed to access $\mathcal{O}$. Instead, in this case, Q_k acts as follows:

- If *op* is an ENROLL(i) operation, P_k pretends that it applied this operation to $\mathcal{O}$ and received as the response the initial value for which Q_k must solve equality negation. In other words, Q_k pretends that when P_k enrolls in $\mathcal{O}$ it receives as the "challenge" with which to solve equality negation just the input value for which Q_k is required to solve equality negation! Q_k then updates the (simulated) state of P_k as if this step were executed and proceeds with the simulation of the next operation of P_k.
- If *op* is a REVEAL operation, Q_k does *not* simulate any more steps of $\mathbf{A}_{en}$. Instead, it decides a value based on the parameters of this REVEAL operation and the parameter of the first ENROLL operation to $\mathcal{O}$ that it previously simulated.

The algorithm is described more formally in Figure 8.2. A few remarks about the conventions used in the pseudocode are in order. Recall, from Figure 5.1, that Apply(P_k, op, O) is the procedure by which P_k invokes operation *op* on object O; it returns the result of this invocation (and updates the state of O accordingly). In addition, we assume that we are given two functions that describe the behavior of processes P_0 and P_1 in $\mathbf{A}_{en}$. (These correspond to the functions ν and τ discussed when we formally defined processes in section 2.2.)

Shared: every object other than $\mathcal{O}$ used in algorithm $\mathbf{A}_{en}$,

21                 else (* i = j = 1 *)
22                     if v = init then decide u
23                     else decide ū
```

FIG. 8.2. *Solving equality negation for two processes using* $\mathbf{A}_{en}$ *with one less* booster *object.*

- NextOp(P_k, s): returns the pair $\langle op, O\rangle$, where the next operation that P_k executes in $\mathbf{A}_{en}$ when in state s is to apply op to object O.
- NextState(P_k, s, r): returns the state that P_k enters in $\mathbf{A}_{en}$ if it receives response r from the operation it invokes when in state s.

In the algorithm we also use an auxiliary variable S whose value, informally speaking, is the schedule of steps of $\mathbf{A}_{en}$ that have been simulated by Q_0 and Q_1 so far. This variable is not needed by the algorithm, but it is useful in proving its correctness (see Lemma 8.14). In one atomic step, besides accessing an ordinary (local or shared) variable, each process can also modify the auxiliary variable S. To emphasize this, we bracket with "$[\![\cdots]\!]$" the line that corresponds to a single atomic step affecting both an ordinary variable and the auxiliary variable S (line 7).

LEMMA 8.14. *If* $\mathbf{A}_{en}$ *is an equality negation algorithm for processes* P_0 *and* P_1*, then the algorithm in Figure* 8.2 *also solves equality negation for processes* Q_0 *and* Q_1 *using one fewer* booster *object than* $\mathbf{A}_{en}$*.*

Proof. It is obvious from Figure 8.2 that the algorithm uses one booster object less than $\mathbf{A}_{en}$. In the remainder of this proof we show that the algorithm solves equality negation for Q_0 and Q_1. To this end, fix an arbitrary execution of the algorithm. We shall prove that in this execution, the three properties of equality

negation—termination, negation, and agreement—are satisfied.

First we establish some properties of this execution. Let S_i be the value of the auxiliary variable S when the schedule it contains consists of exactly i steps. By lines 7 and 11 of Figure 8.2, it is clear that for all i, j, where $0 \leq i \leq j$, if S_j is defined, then S_i is a prefix of S_j. A straightforward induction on i shows that for all $i \geq 0$ such that S_i is defined, the following invariants hold.

(a) S_i is a schedule of $\mathbf{A}_{en}$ that is applicable to $E(I)$ (hence, $E \cdot S_i$ is a node in $\mathcal{F}$) and contains no REVEAL step to $\mathcal{O}$.

(b) Let Q_k be the process that assigns S_i to S, and $state_k$ be the value to which Q_k sets its local variable *state* after assigning S_i to S (cf. lines 8 and 12). Then, for all $j \geq i$, such that S_j is defined and there is no step of P_k in S_j after S_i, $state_k$ is the state of P_k in configuration $S_j(I)$ of $\mathbf{A}_{en}$.

With these invariants, we are now ready to prove that the execution satisfies the three properties of equality negation.

Since only two processes execute the algorithm, the agreement requirement of equality negation is trivially satisfied. We now show that the execution satisfies termination. Suppose, for contradiction, that some correct process Q_k is correct and never decides. This means that the **while** loop of Q_k does not terminate, and hence S_i is defined for all integers $i \geq 0$. By invariant (a), S_i is applicable to $E(I)$ and contains no REVEAL step to $\mathcal{O}$ for all $i \geq 0$. Thus, there is an infinite schedule S^* of $\mathbf{A}_{en}$ that is applicable to $E(I)$, contains infinitely many steps of P_k, and does not contain a REVEAL step to $\mathcal{O}$. By Lemma 8.11, P_k does not decide in $E \cdot S'(I)$ for all prefixes S' of S^*. This contradicts the fact that $\mathbf{A}_{en}$ satisfies the termination property. Thus, the execution satisfies termination.

It remains to show that the execution satisfies the negation property. Assume that both Q_0 and Q_1 decide in the execution. (Otherwise, negation is trivially satisfied.) For each $k \in \{0, 1\}$, let $init_k$ be the initial value of process Q_k (i.e., the value assigned to local variable *init* of Q_k in line 1); let j_k be the value assigned to local variable j of process Q_k in line 3; and let $state_k$ be the value of local variable *state* of process Q_k when Q_k decides. Let S^* be the value of S when Q_0 and Q_1 have both decided (i.e., S^* is the final value of the auxiliary variable S). By the algorithm, the next operation that P_k will execute when in $state_k$ is a REVEAL operation to object $\mathcal{O}$; let i_k, v_k, and u_k be the parameters of that REVEAL operation. From invariant (b), it follows that the operation of P_k pending in $E \cdot S^*(I)$ is a REVEAL(i_k, v_k, u_k) to $\mathcal{O}$. By invariant (a), $E \cdot S^*$ is a node in $\mathcal{F}$, and S^* contains no REVEAL operations to $\mathcal{O}$. Thus, the hypothesis of Lemma 8.13 holds (with $S = S^*$); we will make use of parts (a)–(d) of this lemma below. By line 11 of the algorithm, the only return values of ENROLL operations to $\mathcal{O}$ that appear in S^* are $init_0$ and $init_1$. Thus, by Lemma 8.13(a), $v_0, v_1 \in \{init_0, init_1\}$. There are three cases.

Case 1. *For both* $k \in \{0, 1\}$, $i_k \neq j_k$: In this case, each Q_k decides by line 16 or 17 (depending on whether $v_k = init_k$). Also, $i_0 \neq i_1$ (because $i_0, i_1, j_0, j_1 \in \{0, 1\}$ and, by Lemma 8.8, $j_0 \neq j_1$). Thus, by Lemma 8.13(7.2), $u_0 = u_1$ if and only if $v_0 \neq v_1$.

By a case analysis of the four possible combinations of lines by which Q_0 and Q_1 can decide, we have that Q_0 and Q_1 decide the same value if and only if

$$
\begin{array}{lll}
 & (v_0 = init_0 \textbf{ and } v_1 = init_1 \textbf{ and } u_0 = u_1) & /* \ Q_0\text{'s line 16; } Q_1\text{'s line 16 } */ \\
\textbf{or} & (v_0 = init_0 \textbf{ and } v_1 \neq init_1 \textbf{ and } u_0 \neq u_1) & /* \ Q_0\text{'s line 16; } Q_1\text{'s line 17 } */ \\
\textbf{or} & (v_0 \neq init_0 \textbf{ and } v_1 = init_1 \textbf{ and } u_0 \neq u_1) & /* \ Q_0\text{'s line 17; } Q_1\text{'s line 16 } */ \\
\textbf{or} & (v_0 \neq init_0 \textbf{ and } v_1 \neq init_1 \textbf{ and } u_0 = u_1). & /* \ Q_0\text{'s line 17; } Q_1\text{'s line 17 } */
\end{array}
$$

Since $u_0 = u_1$ if and only if $v_0 \neq v_1$, the above expression is equivalent to

$$\begin{array}{rl} & (v_0 = \mathit{init}_0 \textbf{ and } v_1 = \mathit{init}_1 \textbf{ and } v_0 \neq v_1) \\ \textbf{or} & (v_0 = \mathit{init}_0 \textbf{ and } v_1 \neq \mathit{init}_1 \textbf{ and } v_0 = v_1) \\ \textbf{or} & (v_0 \neq \mathit{init}_0 \textbf{ and } v_1 = \mathit{init}_1 \textbf{ and } v_0 = v_1) \\ \textbf{or} & (v_0 \neq \mathit{init}_0 \textbf{ and } v_1 \neq \mathit{init}_1 \textbf{ and } v_0 \neq v_1). \end{array}$$

As argued above, $v_0, v_1 \in \{\mathit{init}_0, \mathit{init}_1\}$. Thus, the above disjunction is equivalent to $\mathit{init}_0 \neq \mathit{init}_1$. In other words, Q_0 and Q_1 decide the same value if and only if they have different initial values.

Case 2. *For both* $k \in \{0,1\}$, $i_k = j_k$: By Lemma 8.8, $j_0 \neq j_1$. Thus, for some $k \in \{0,1\}$, $i_k = j_k = 0$ and $i_{\overline{k}} = j_{\overline{k}} = 1$. Then Q_k decides by line 20 and $Q_{\overline{k}}$ decides by line 22 or 23 (depending on whether $v_{\overline{k}} = \mathit{init}_{\overline{k}}$). Thus, Q_k decides u_k. So we have that Q_0 and Q_1 decide the same value if and only if

$$\begin{array}{rll} & (v_{\overline{k}} = \mathit{init}_{\overline{k}} \textbf{ and } u_k = u_{\overline{k}}) & /* \ Q_{\overline{k}}\text{'s line 22 } */ \\ \textbf{or} & (v_{\overline{k}} \neq \mathit{init}_{\overline{k}} \textbf{ and } u_k = \overline{u}_{\overline{k}}). & /* \ Q_{\overline{k}}\text{'s line 23 } */ \end{array}$$

In this case, $i_k \neq i_{\overline{k}}$. By Lemma 8.13(7.2), $u_k = u_{\overline{k}}$ if and only if $v_k \neq v_{\overline{k}}$. Thus, the above expression is equivalent to

$$(v_{\overline{k}} = \mathit{init}_{\overline{k}} \textbf{ and } v_k \neq v_{\overline{k}}) \textbf{ or } (v_{\overline{k}} \neq \mathit{init}_{\overline{k}} \textbf{ and } v_k = v_{\overline{k}}).$$

S^* does not contain two ENROLL(0) steps: Otherwise, $\mathcal{O}$ would be upset in $E \cdot S^*(I)$—and therefore still upset after the application of the two REVEAL operations pending in $E \cdot S^*(I)$—contrary to Lemma 8.12. Since $j_k = 0$, P_k has an ENROLL(0) to $\mathcal{O}$ pending in $E(I)$. Hence, the unique ENROLL(0) to $\mathcal{O}$ in S^* is a step of P_k. By line 11, the response to that unique ENROLL(0) step to $\mathcal{O}$ in S^* is the initial value of P_k, init_k. By Lemma 8.13(a) and the fact that $i_k = 0$, v_k is the response of the unique ENROLL(0) step to $\mathcal{O}$ that is contained in S^*. Therefore, $v_k = \mathit{init}_k$. Thus, the above expression is equivalent to

$$(v_{\overline{k}} = \mathit{init}_{\overline{k}} \textbf{ and } \mathit{init}_k \neq v_{\overline{k}}) \textbf{ or } (v_{\overline{k}} \neq \mathit{init}_{\overline{k}} \textbf{ and } \mathit{init}_k = v_{\overline{k}}).$$

As argued earlier, $v_{\overline{k}} \in \{\mathit{init}_0, \mathit{init}_1\}$; so the above expression is equivalent to $\mathit{init}_k \neq \mathit{init}_{\overline{k}}$. In other words, Q_0 and Q_1 decide the same value if and only if they have different initial values.

Case 3. *For some* $k \in \{0,1\}$, $i_k \neq j_k$ *and* $i_{\overline{k}} = j_{\overline{k}}$: By Lemma 8.8, $j_k \neq j_{\overline{k}}$, so $i_k = i_{\overline{k}}$. By Lemma 8.13(b), i_k and $i_{\overline{k}}$ cannot both be 0. Hence, we must have $i_k = i_{\overline{k}} = j_{\overline{k}} = 1$ and $j_k = 0$. By Lemma 8.13(c), $v_0 = v_1$ and $u_0 = u_1$. Also, since in this case $i_k \neq j_k$, while $i_{\overline{k}} = j_{\overline{k}} = 1$, Q_k decides by line 16 or 17 (depending on whether $v_k = \mathit{init}_k$), and $Q_{\overline{k}}$ decides by line 22 or 23 (depending on whether $v_{\overline{k}} = \mathit{init}_{\overline{k}}$). Keeping in mind that $u_0 = u_1$, we have that Q_0 and Q_1 decide the same value if and only if

$$\begin{array}{rll} & (v_k = \mathit{init}_k \textbf{ and } v_{\overline{k}} \neq \mathit{init}_{\overline{k}}) & /* \ Q_k\text{'s line 16; } Q_{\overline{k}}\text{'s line 23 } */ \\ \textbf{or} & (v_k \neq \mathit{init}_k \textbf{ and } v_{\overline{k}} = \mathit{init}_{\overline{k}}). & /* \ Q_k\text{'s line 17; } Q_{\overline{k}}\text{'s line 22 } */ \end{array}$$

Since $v_0 = v_1$ and, as argued earlier, $v_0, v_1 \in \{\mathit{init}_0, \mathit{init}_1\}$, the above expression is equivalent to $\mathit{init}_k \neq \mathit{init}_{\overline{k}}$. Hence, Q_0 and Q_1 decide the same value if and only if they have different initial values. In all cases the negation property is satisfied. □

We now have all the pieces needed to prove the main result of this section.

THEOREM 8.15. *Type* booster *has consensus number one.*

Proof. Suppose, to the contrary, that booster has consensus number at least two. Then we can solve consensus for two processes using only booster objects and registers. By the universality of consensus [6], we can implement a negation object shared by two processes using only booster objects and registers. Hence, we can solve equality negation for two processes using only booster objects and registers. Let $\mathbf{A}_{en}$ be an equality negation algorithm for two processes that uses a minimal number of booster objects. By Theorem 3.1, $\mathbf{A}_{en}$ uses at least one booster object. By Lemma 8.14, however, we can solve equality negation for two processes using one booster object less than $\mathbf{A}_{en}$. This contradicts the definition of $\mathbf{A}_{en}$. □

9. Conclusion. In this paper we showed that if nondeterministic object types are allowed, then the only robust wait-free hierarchy is the trivial one, which lumps all types into level one. In contrast, if only deterministic types are allowed, then the consensus hierarchy is robust [1, 15]. Our understanding of the results regarding deterministic types is far from complete. In view of the sharply contrasting results regarding the robustness of wait-free hierarchies for deterministic and nondeterministic types it would be interesting to understand the fundamental reason(s) why the restriction to determinism inherently rules out types with properties like negation and booster.

The unfortunate fact that (nontrivial) wait-free hierarchies are not robust suggests that it would be desirable to investigate other ways of classifying types according to their strength. A classification based on consensus numbers is computability-based: it depends on whether objects of a certain type can be used to solve consensus for a certain number of processes with no regard as to the efficiency of this solution. It would be interesting to investigate complexity-based classifications, where the level of a type may depend not only on its ability to solve consensus but also on doing so efficiently (in some appropriate sense). Could a complexity-based hierarchy classify types according to their strength in (efficiently) implementing other types, while being robust in the sense that "powerful" types are not (efficiently) implementable by "weak" ones?

A different line of research might proceed from the observation that the types negation and booster, although well within the set prescribed by the general definition of type given in section 2.1, are not "natural" types. Is there a sensible definition of "natural" types that excludes negation, booster, and other such "anomalous" types without excluding any useful ones?

Appendix. Unsolvability of equality negation using only registers. In this appendix we prove Theorem 3.1, which states that there is no algorithm that solves equality negation for two processes and uses only registers. The proof is by contradiction. Suppose that there is an equality negation algorithm, $\mathbf{A}_{en}$, for processes P_0 and P_1 that uses only registers. For each $k \in \{0, 1\}$ and $v \in \{0, 1, 2\}$, consider a solo execution of process P_k in algorithm $\mathbf{A}_{en}$, where the initial value of P_k is v. Since $\mathbf{A}_{en}$ uses only registers (which are deterministic), the solo execution of P_k with initial value v is uniquely defined. Let Δ_k^v be the decision of P_k in this solo execution.

LEMMA A.1. *There exist* $\alpha_0, \alpha_1 \in \{0, 1, 2\}$ *such that* $\alpha_0 = \alpha_1$ *if and only if* $\Delta_0^{\alpha_0} = \Delta_1^{\alpha_1}$.

Proof. Suppose, for contradiction, that no choice of values for $\alpha_0, \alpha_1 \in \{0, 1, 2\}$ satisfies the required property. Thus, (a) for all $v \in \{0, 1, 2\}$, $\Delta_0^v \neq \Delta_1^v$; and (b) for all $v_0, v_1 \in \{0, 1, 2\}$ such that $v_0 \neq v_1$, $\Delta_0^{v_0} = \Delta_1^{v_1}$. By (b), $\Delta_0^0 = \Delta_1^1$, $\Delta_1^1 = \Delta_0^2$, and $\Delta_0^2 = \Delta_1^0$. Therefore, $\Delta_0^0 = \Delta_1^0$, which contradicts (a). □

Shared: all registers used in $\mathbf{A}_{en}$, each initialized as specified by $\mathbf{A}_{en}$
R_0, R_1: register, each initialized to $\perp$
Code for process Q_k, $k \in \{0,1\}$
1 $R_k :=$ initial value of Q_k
2 $w :=$ Execute$(P_k, \mathbf{A}_{en}, \alpha_k)$
3 **if** $w = \Delta_k^{\alpha_k}$ **then decide** R_k
4 **else decide** $R_{\overline{k}}$

FIG. A.1. *Solving consensus for processes Q_0 and Q_1 using $\mathbf{A}_{en}$.*

As the lemma below proves, the algorithm in Figure A.1 solves consensus for processes Q_0 and Q_1. Since this algorithm uses two registers in addition to the objects used by $\mathbf{A}_{en}$, and since $\mathbf{A}_{en}$ uses only regusters, we have a consensus algorithm for two processes that uses only registers. This contradicts the fact that no such algorithm exists [3, 13]. Therefore, $\mathbf{A}_{en}$ cannot use only registers, as wanted.

LEMMA A.2. *The algorithm in Figure* A.1 *solves consensus for processes Q_0 and Q_1.*

Proof. The algorithm in Figure A.1 satisfies termination, since $\mathbf{A}_{en}$ does.

To prove that the algorithm satisfies validity, it suffices to show that if process Q_k decides the value in register R_d in an execution of the algorithm in Figure A.1, then Q_d has previously written its initial value into R_d. (Note that R_d is written only once.) This property follows immediately if Q_k decides the value in R_k in line 3. It remains to cover the case where Q_k decides in line 4. In this case, we want to prove that before Q_k decides $R_{\overline{k}}$ in line 4, $Q_{\overline{k}}$ has previously written its initial value into $R_{\overline{k}}$ (line 1). For this, it suffices to show that the execution of P_k that Q_k simulated in line 2 is not a solo P_k execution of $\mathbf{A}_{en}$. (If the simulated execution is not a solo P_k execution, Q_k and $Q_{\overline{k}}$ execute their line 2 concurrently, and therefore $Q_{\overline{k}}$ executes line 1 before Q_k executes line 4.) To see why the execution of P_k that Q_k simulated is not a solo P_k execution, suppose the contrary. Then, by definition of $\Delta_k^{\alpha_k}$, P_k would have decided $\Delta_k^{\alpha_k}$ in that execution, and the value that Q_k assigned to its local variable w in line 2 would have been equal to $\Delta_k^{\alpha_k}$. But then Q_k would be deciding in line 3, not 4.

To prove that the algorithm satisfies agreement, consider any execution in which both Q_0 and Q_1 decide. Let w_0 and w_1 be the values of the local variables w of Q_0 and Q_1, respectively, assigned in line 2 during that execution. Consider the execution of algorithm $\mathbf{A}_{en}$ by P_0 and P_1 that Q_0 and Q_1 simulated in line 2. In this simulated execution P_0 and P_1 have initial values α_0 and α_1 and decide w_0 and w_1. By the negation property, $w_0 = w_1$ if and only if $\alpha_0 \neq \alpha_1$. Combining with Lemma A.1, we have $w_0 = w_1$ if and only if $\Delta_0^{\alpha_0} \neq \Delta_1^{\alpha_1}$. Since $w_0, w_1, \Delta_0^{\alpha_0}, \Delta_1^{\alpha_1} \in \{0,1\}$, it follows that $w_0 = \Delta_0^{\alpha_0}$ if and only if $w_1 \neq \Delta_1^{\alpha_1}$. By the algorithm in Figure A.1, for any $k \in \{0,1\}$, Q_k decides the value in R_k in line 3 if and only if $w_k = \Delta_k^{\alpha_k}$ and hence if and only if $w_{\overline{k}} \neq \Delta_{\overline{k}}^{\alpha_{\overline{k}}}$. This, in turn, happens if and only if $Q_{\overline{k}}$ decides the value in $R_{\overline{k}} = R_k$ in line 4. This means that both Q_0 and Q_1 decide the value in the same register R_d for some $d \in \{0,1\}$. By validity, a process decides the value in R_d only after Q_d has written its initial value into R_d. Since only one value is written into R_d, agreement follows. □

FROM GENE TREES TO SPECIES TREES*

BIN MA†, MING LI‡, AND LOUXIN ZHANG§

Abstract. This paper studies various algorithmic issues in reconstructing a species tree from gene trees under the duplication and the mutation cost model. This is a fundamental problem in computational molecular biology. Our main results are as follows.

1. A linear time algorithm is presented for computing all the losses in duplications associated with the least common ancestor mapping from a gene tree to a species tree. This answers a problem raised recently by Eulenstein, Mirkin, and Vingron [*J. Comput. Bio.*, 5 (1998), pp. 135–148].
2. The complexity of finding an optimal species tree from gene trees is studied. The problem is proved to be NP-hard for the duplication cost and for the mutation cost. Further, the concept of reconciled trees was introduced by Goodman et al. and formalized by Page for visualizing the relationship between gene and species trees. We show that constructing an optimal reconciled tree for gene trees is also NP-hard. Finally, we consider a general reconstruction problem and show it to be NP-hard even for the well-known nearest neighbor interchange distance.
3. A new and efficiently computable metric is defined based on the duplication cost. We show that the problem of finding an optimal species tree from gene trees is NP-hard under this new metric but it can be approximated within factor 2 in polynomial time. Using this approximation result, we propose a heuristic method for finding a species tree from gene trees with uniquely labeled leaves under the duplication cost. Our experimental tests demonstrate that when the number of species is larger than 15 and gene trees are close to each other, our heuristic method is significantly better than the existing program in Page's GeneTree 1.0 that starts the search from a random tree.

1. Introduction.

As DNA sequences become easier to obtain, in the field of evolutionary moleculor biology emphasis has been placed on constructing gene trees and, from the gene trees, reconstructing evolutionary trees for species (called *species trees*) [9, 11, 20]. The current strategy for reconstructing species trees is based on the separate consideration of distinct gene families represented by homologous sequences; these homologous sequences are assumed to evolve in the same way as species. However, because of the presence of paralogy, sorting of ancestral polymorphism, and horizontal transfer, gene trees and species trees are often inconsistent [21, 25, 31, 33] and a "correct" species tree may simply not exist. Hence, a fundamental problem that arises is how to reconcile different, sometimes contradictory, gene trees into a

species tree [10]. This problem has been studied extensively for the last two decades. Several similarity/dissimilarity measures for gene trees and species trees have been proposed and efficient comparison methods have also been investigated. See, for example, [8, 14, 15, 18, 32].

This paper studies the problem of reconciling different gene trees into a species tree under two well-known duplication-based similarity measures. These measures were proposed by Goodman et al. [14], Page [23], and Guigó, Muchnik, and Smith [15]. Genes have *gene trees* because of gene replication. As a gene copy at a locus in the whole genome replicates and its copies are passed onto offsprings, branch points are generated. Since the gene copy has a single ancestral copy, the resulting history is a branching tree. Gene divergence causes all the inconsistencies among different gene trees. Such divergence can be the result of either speciation or duplication events [22]. If the common ancestry of two genes can be tracked back to a speciation event, then they are said to be related by *orthology*; if it is tracked back to a duplication event, then they are related by *paralogy* [10]. Taking orthology and paralogy into account, Goodman et al. proposed a similarity measure for annotating species trees with duplications, gene losses, and nucleotide replacements [14]. Later, Page developed a method based only on duplications for interpreting inconsistency between vertebrate globin gene trees and the species tree that is constructed from morphological data [23]; Guigó, Muchnik, and Smith elaborated the idea for locating the gene duplications in eukaryotic history [15].

A *species tree* can be defined as the pattern of branching of species lineages via the process of speciation. When species are split by speciation, the gene copies within species likewise are split into separate bundles of descent. Thus, gene trees are contained within species trees. However, a gene tree may disagree with the containing species tree because of the reasons mentioned above. The duplication and mutation costs were defined using a least common ancestor (LCA) mapping M from gene trees to a species tree. Assume that only genes from each contemporary species are presented in gene trees. In a gene tree, leaves denote the genes from contemporary species; internal nodes are considered as ancestral genes. We may think that an ancestral gene is uniquely determined by the subset of contemporary genes descending from it in the gene tree. Similarly, in a species tree, an internal node is considered as an ancient species (which might not exist today) and is determined by the contemporary species descending from it. We may denote a contemporary species and the genes from that species by the same label. The mapping M from a gene tree to a species tree just maps a contemporary gene to the corresponding species, and an ancestral one to the most recent species which contains that gene (as a subset). Hence, we call it the *LCA mapping* in this paper. When the gene and species trees are inconsistent, it maps an ancestral gene g, and its child gene $c(g)$ to the same ancient species. In this case, we say that a *duplication* happens at g. Furthermore, roughly speaking, the number of gene losses associated with g is defined as the total number of ancient species between $M(g)$ and $M(c(g))$ for all children $c(g)$. To measure the similarity between a gene and species trees, Page defined the duplication cost as the number of duplications, and Guigó, Muchnik, and Smith defined the mutation cost as the sum of the number of duplications and the number of gene losses [15]. The mutation cost is not only efficiently computable, as shown in [4] and [34] independently (see also [5]), but also biologically meaningful [18]. Reconstructing a global species tree is based on the parsimonious criterion of minimizing the concerned cost between the gene trees and the species tree. In their paper [15], Guigó, Muchnik, and Smith developed a heuristic method for the problem using a nearest neighbor interchange (NNI) search

algorithm and applied it to infer the most likely phylogenetic relationship among 16 major eukaryotic taxa from the sequences of 53 different genes. In spite of having several serious flaws, their work demonstrated the potential of these measures in studies of genome evolution.

The contributions of this paper are in three aspects. First, we study the properties of the LCA mapping as well as the duplication and mutation costs. In particular, we prove a less obvious fact that the duplication cost satisfies the triangle inequality (Lemma 5.1) and study the relation between the duplication cost and the best-known NNI distance. We also present a linear time algorithm for computing all the losses in all duplications (section 3). Secondly, the complexity of reconstructing a species tree from gene trees is investigated. We prove that the problem is NP-hard under the duplication cost and under the mutation cost. The concept of a reconciled tree was introduced by Goodman et al. [14] for studying hemoglobin gene phylogeny, where there were significant discrepancies between gene and organismal phylogenies; later it was formalized by Page [23] as a means of describing historical associations such as those between genes and species. We prove that finding the best reconciled tree from a gene tree is NP-hard. We also consider a general reconstruction problem and prove it to be NP-hard even for the NNI distance. These results justify the necessity of developing heuristic methods and experimental research for reconstructing species trees [15, 24]. Finally, we give a heuristic method for reconstructing species trees. To this end, we propose a new and efficiently computable metric, satisfying the metric axioms, based on the duplication cost. Under this new metric, we show that the problem of reconstructing a species tree from gene trees is NP-hard but can be approximated within factor 2 in polynomial time. Using this approximation result, we present a new heuristic method for reconstructing species trees from uniquely leaf-labeled gene trees under the duplication cost.

The rest of the paper is divided into six sections. In section 2, we define the concepts of gene duplications and losses, review the duplication cost and the mutation cost and their basic properties, and formalize three problems of reconstructing a species tree from gene trees. In section 3, we present a linear time algorithm for computing all the losses between a gene tree and a species tree. In section 4, we prove that the problems defined in section 2 are NP-hard. In section 5, a new metric is proposed based on the duplication cost. We prove that, under the new metric, reconstructing a species tree from gene trees is NP-hard but can be approximated within factor 2 in polynomial time. Then a new heuristic method for reconstructing species trees is proposed. Experimental results are given to demonstrate that our new heuristic works quite well. In section 6, we consider a general reconstruction problem and prove it to be NP-hard even for the popular NNI distance. In section 7, we discuss further research and open questions.

We refer the reader to [2, 13] for textbooks on NP-completeness and approximation algorithms.

2. Comparing gene and species trees: Duplications and losses. In this section we first define the gene trees and species trees. We then introduce the two duplication-based measures for comparing gene and species trees: the duplication and mutation costs. For their biological meaning, we refer the reader to [14, 15, 23].

2.1. Species trees and gene trees. For a set I of N biological taxa, the model for their evolutionary history is a rooted full binary tree T where there are N leaves each uniquely labeled by a taxon in I and $N-1$ unlabeled internal nodes. Here the term "full" means that each internal node has exactly two children. Such a tree is

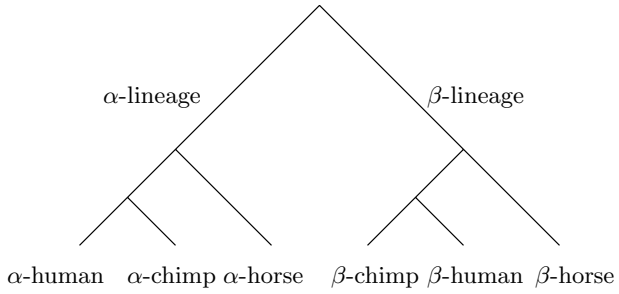

FIG. 1. *A gene tree based on α-hemoglobin and β-hemoglobin* [4].

called a *species tree*. In a species tree, we treat an internal node as a subset (called a *cluster*) which includes as its members its subordinate species represented by the leaves below it. Thus, the evolutionary relation "m is a descendant of n" is expressed using set-theoretic notation as "$m \subset n$."

The model for gene relationship is a rooted full binary tree with labeled leaves. Usually, a gene tree is constructed from a collection of genes each having several copies appearing in the studied species. For example, the gene family of hemoglobin genes in vertebrates contains α-hemoglobin and β-hemoglobin. A gene tree based on these two genes is illustrated in Figure 1 for human, chimpanzee, and horse. We use the species to label the genes appearing in it. Thus, the labels in a gene tree may not be unique. An internal node g corresponds to a multiset $\{x_1^{i_1}, x_2^{i_2}, \ldots, x_m^{i_m}\}$, where i_j is the number of its subordinate leaves labeled with x_j. The *cluster* of g is simply the set

$$S_g = \{x_1, x_2, \ldots, x_m\}.$$

Finally, we use $L(T)$ to denote the set of leaf labels in a species or gene tree T.

2.2. Gene duplications and the duplication cost. Given a gene tree G and a species tree S such that $L(G) \subseteq L(S)$. For any node $g \in G$, we define $M(g)$ to be the LCA of g in S, i.e., the smallest node $s \in S$ such that $S_g \subseteq s$. Here we used the term "smallest" to mean "farthest from the root." This correspondence M, first considered by Goodman et al. [14], is referred to as a mapping of G into S by Page [23]. We call M the *LCA mapping* from G to S. Obviously, if $g' \subset g$, then $M(g') \subseteq M(g)$, and any leaf is mapped onto a leaf with the same label. For an internal node g, we use $c(g)$ (sometimes $a(g)$ and $b(g)$) to denote a child of g and $G(g)$ the subtree rooted at g.

DEFINITION 2.1. *Let g be an internal node of G. If $M(c(g)) = M(g)$ for some child $c(g)$ of g, then we say $G(g)$ and $S(M(g))$ are root-inconsistent or a duplication happens at g.*

The total number $t_{dup}(G, S)$ of duplications happening in G under the LCA mapping M is proposed as a measure for the similarity between G and S [14, 23]. We call such a measure the *duplication cost*.

A subset A of (internal or leaf) nodes in a species tree S is *disjoint* if $x \cap y = \phi$ for any $x, y \in A$. For a disjoint subset A in S, the *restriction* of S on A is the smallest subtree of S containing A as its leaf set, denoted by $R_S(A)$. The *homomorphic subtree* $S|_A$ of S induced by A is a tree obtained from $R_S(A)$ by contracting all degree 2 nodes except the root. These concepts are illustrated in Figure 2. We state, without proofs, the following facts which will be used implicitly in the rest of this paper.

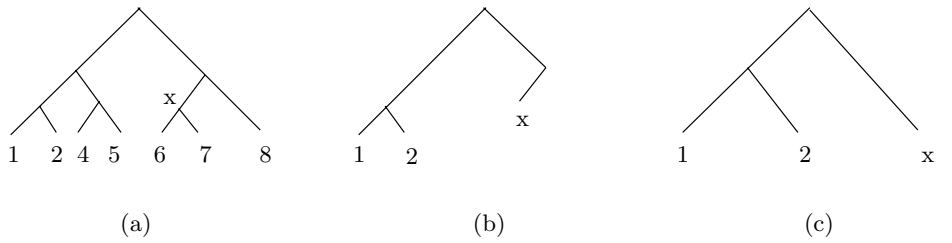

FIG. 2. (a) *A species tree S;* (b) *the restriction subtree $R_S(A)$ for $A = \{1, 2, x\}$;* (c) *the homomorphic subtree $S|_A$ induced by A.*

PROPOSITION 2.2. *Let G be a gene tree and S a species tree. Then $t_{dup}(G, S) = 0$ if and only if G is identical to $S|_{L(G)}$.*

PROPOSITION 2.3. *Let g be the root of G with children $a(g)$ and $b(g)$ and let s be the root of S with children $a(s)$ and $b(s)$. Then, if a duplication happens at g under the LCA mapping from G to S, then $t_{dup}(G, S) = 1 + t_{dup}(a(g), S) + t_{dup}(b(g), S)$.*

Furthermore, the duplication cost also satisfies the triangle inequality, which will be proved in Lemma 5.1 in section 5. Under the duplication cost, the problem of finding the "best" species tree from a set of known gene trees can be formulated as the following minimization problem.

Optimal Species Tree I (OST I).
INSTANCE: n gene trees $G_1, G_2, \ldots, G_n$.
QUESTION: Find a species tree S with the minimum duplication cost $\sum_{i=1}^{n} t_{dup}(G_i, S)$.

One can easily convert the above optimization problem into its *decision version* by having an extra integer c as input and requiring the minimum duplication cost to be less than c. This comment applies to all other optimization problems in this paper.

2.3. Gene losses and the mutation cost. After defining the duplication cost, we now introduce the mutation cost. We first define the *number of gene losses* associated with the LCA mapping M from G to S. Since $L(G) \subseteq L(S)$, $S|_{L(G)}$ is well defined and M induces an LCA mapping M' from G to $S|_{L(G)}$. Let g and g' be two nodes in $S|_{L(G)}$ such that $g \subseteq g'$. Define

$$d(g, g') = |\{h \in S|_{L(G)} \mid M'(g) \subset h \subset M'(g')\}|.$$

Let $a(g)$ and $b(g)$ denote the two children of g. The *number of losses* l_g associated to g is

$$l_g = \begin{cases} 0 & \text{if } M'(g) = M'(a(g)) = M'(b(g)); \\ d(a(g), g) + 1 & \text{if } M'(a(g)) \subset M'(g) \ \&\ M'(g) = M'(b(g)); \\ d(a(g), g) + d(b(g), g) & \text{if } M'(a(g)) \subset M'(g) \ \&\ M'(b(g)) \subset M'(g). \end{cases}$$

Note that our definition of $l(g)$ is a *generalization* of the one defined by Guigó, Muchnik, and Smith [15]. When $L(G) = L(S)$ and gene tree G is also uniquely labeled, our definition is identical to the one defined in [15]. The *mutation cost* is defined as the sum of t_{dup} and the total number of losses $l(G, S) = \sum_{g \in G} l_g$. This measure turns out to be identical to a biologically meaningful measure defined in Mirkin, Muchnik, and Smith [18] when G has the same number of uniquely labeled leaves as S. The problem of finding the "best" species tree from a set of known gene trees under this measure is formulated as the following.

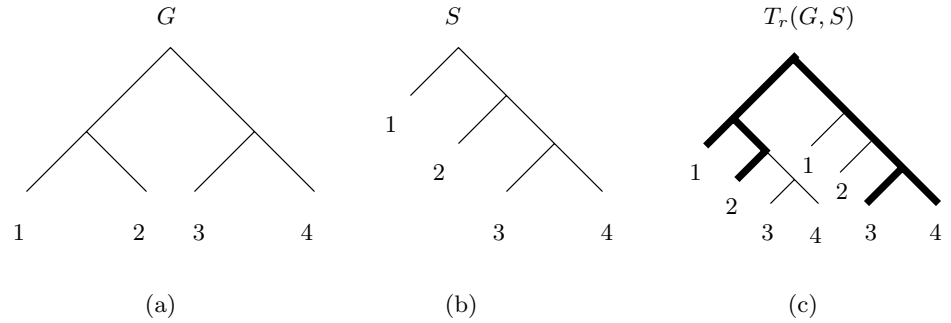

FIG. 3. (a) *A gene tree G;* (b) *a species tree S;* (c) *the reconciled tree* $T_r(G,S)$ *of G with respect to S.*

Optimal Species Tree II (OST II).
INSTANCE: n gene trees $G_1, G_2, \ldots, G_n$.
QUESTION: Find a species tree S with the minimum mutation cost $\sum_{i=1}^{n}(t_{dup}(G_i,S)+l(G_i,S))$.

2.4. Reconciled trees. For visualizing the relationship between gene and species trees, we use a third tree called the *reconciled tree* [14]. The reconciled tree has two important properties. The first property is that the observed gene tree is a subtree of the reconciled tree. The second property is that the clusters of the reconciled tree are all clusters of the species tree. Formally, the reconciled tree is defined as follows.

Let T' and T'' be two rooted trees; we use $T' \triangle T''$ to denote the rooted tree T obtained by adding a node r as the root and connecting r to $r(T')$ and $r(T'')$ so that T' and T'' are two subtrees rooted at the children of r. Further, let t be an internal node in T'; then $T'|_{\,t\to T''}$ denotes the tree formed by replacing the subtree rooted at t with T''. Similarly, $T'|_{\,t\to T_1,\, t'\to T_2}$ can be defined for disjoint nodes t and t'.

For a gene tree G rooted at g and a species tree S rooted at s such that $L(G) \subseteq L(S)$, let M be the LCA mapping from G to S and let $s' = M(a(g))$ and $s'' = M(b(g))$. The *reconciled tree* $R = R(G,S)$ of G with respect to S is defined as

$$(1)\qquad R = \begin{cases} R(G(a(g)),S) \triangle R(G(b(g)),S) & \text{if } s' = s'' = s, \\ S|_{\,s'\to R(G(a(g)),\, S(s'))} \triangle R(G(b(g)),S) & \text{if } s' \subseteq a(s),\ s'' = s, \\ S|_{\,s'\to R(G(a(g)),S(s')),\, s''\to R(G(b(g)),S(s''))} & \text{if } s' \subseteq a(s),\ s'' \subseteq b(s), \\ S|_{\,a(s)\to R(G,S(a(s)))} & \text{if } M(g) \subseteq a(s). \end{cases}$$

Such a concept is illustrated in Figure 3. An efficient algorithm was presented in [23] for computing a reconciled tree given a set of gene trees and a species trees. It is easy to see that the reconciled tree $R(G,S)$ satisfies the following three properties, of which the first two are mentioned above:

1. It contains G as a subtree, i.e., there is a subset L of leaves such that $R(G,S)|_L$ is isomorphic to G.
2. All clusters are in S, where a cluster is defined as a subset of species below an internal node in S (see subsection 2.1).
3. For any two children $a(g)$ and $b(g)$ of a node $g \in R(G,S)$, $a(g) \cap b(g) = \phi$, or $a(g) = b(g) = g$.

Actually, Page also defined the reconciled tree $R(G,S)$ as the smallest tree satisfying the above properties. However, these two definitions are not obviously equivalent. A

rigorous proof of this equivalence is needed and unknown. Reconstructing a species tree from a gene tree can be formulated as the following.

Optimal Species Tree III (OST III).
INSTANCE: A gene tree G.
QUESTION: Find a species tree S with the minimum duplication cost $t_{dup}(T_r(G,S),S)$.

3. Computing all loss events. When comparing a gene tree and a species tree, one may need to know both mutation cost and all "loss events" (to be defined). It is an open problem to compute all loss events efficiently [5]. In this section, we will develop a linear time algorithm to solve the problem. In the rest of this section, we assume that both gene tree G and species tree S are uniquely leaf labeled and $L(G) = L(S)$. We first introduce the concept of the gene loss events.

Let $u \in G$ and a duplication d_u occur at u. Recall that $S(M(u))$ denotes the subtree of S below $M(u)$. A node $v \in S(M(u))$ is *mixed* in the duplication d_u if $v \cap c(u) \neq \phi$ for any child $c(u)$ of u; it is *speciated* if $v \cap a(u) \neq \phi$ but $v \cap b(u) = \phi$ or vice versa; it is *gapped* if $v \cap c(u) = \phi$ for any $c(u)$. Finally, we say that a *loss event* occurs at a maximal speciated/gapped node in d_u. Note that a unique loss event occurs at some node on the path from $M(u)$ to any leaf in S. Figure 4 presents a mapping from a gene tree G (in (b)) to a species tree S (in (a)). Three duplications occur at nodes $r(g)$, $\{4,5,6\}$, and $\{7,8,9\}$ that are shown in (c), (d), and (e), respectively, where mixed nodes are labeled with "+−," speciated nodes with "+" or "−" depending on which intersection is empty, and gapped nodes are not labeled. All 14 loss events are marked by square boxes.

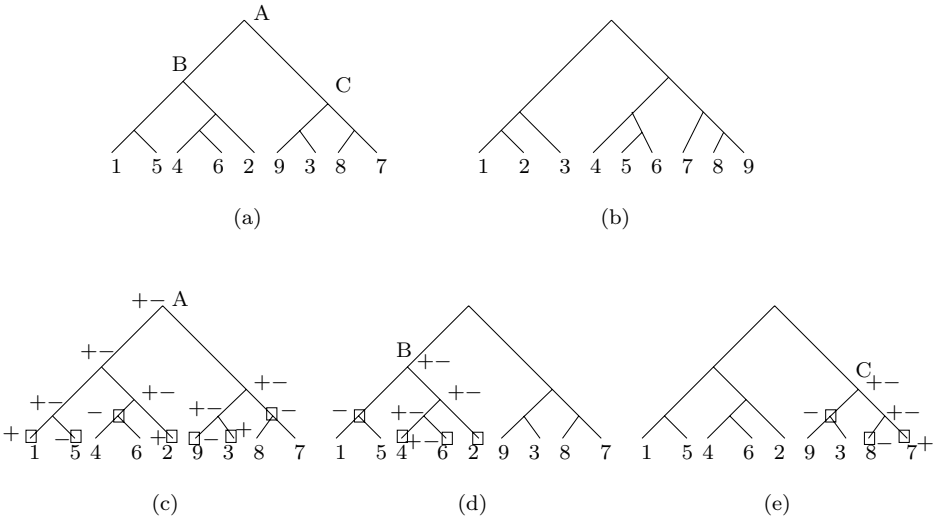

FIG. 4. *Duplications between a species tree* (a) *and a gene tree* (b).

Formally, the problem of computing all the loss events is formulated as follows. Given a gene tree G and a species tree S such that $L(G) = L(S)$, to find for each duplication d occurring at a node $g \in G$, the subtree $S(M^{-1}(g))$ of S with all the loss events as its leaves. For example, for the gene tree and species tree illustrated in Figure 4, the output is the three subtrees shown in Figure 5.

Note that the species tree S and gene tree G are rooted. We first impose an arbitrary ordering on the children of each node and produce an in-order traversal of G and S, respectively. Recall that in an in-order traversal, $i < j$ if and only if i is in

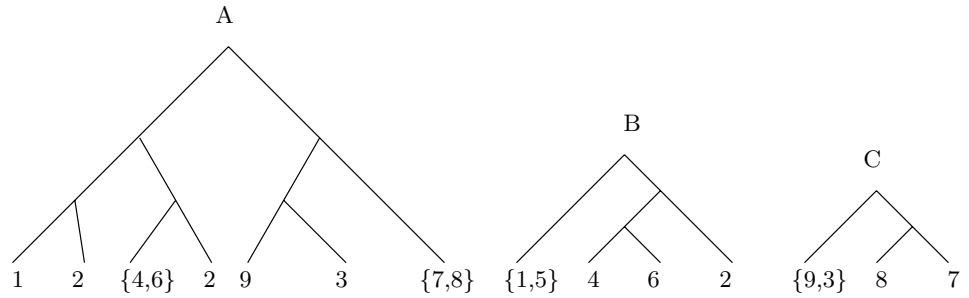

FIG. 5. *Output from computing all the loss events.*

the left subtree of j [2]. Without loss of generality, we may assume that each node of S is labeled by a number $k \leq 2n-1$, which is called the *in-order number* of the node. Preprocess the tree S in $O(n)$ steps so that an LCA query can be answered in constant time [16, 28]. Using this preprocessing, we can also compute the LCA mapping from G to S in linear time [34].

We store M in G as follows. To each node x in G, we associate a pair of $\langle i, j\rangle$, where i is its in-order number while j is the in-order number of $M(x)$ in S.

DEFINITION 3.1 (see [34]). *Let g be an internal node of G. It is said to be type-*1 *under the LCA mapping $M : G \to S$ if $M(a(g)) \subset M(g)$ and $M(b(g)) \subset M(g)$; it is type-*2 *if $M(a(g)) \subset M(g)$ and $M(b(g)) = M(g)$ or vice versa; it is type-*3 *if $M(a(g)) = M(b(g)) = M(g)$. Recall that $a(g)$ and $b(g)$ denote the children of g.*

To each node $y \in S$, we also assign an ordered pair $\langle i, n_{23}\rangle$, where i is its in-order number and n_{23} is the number of type-2 or type-3 nodes in G that is mapped to y. Observe that duplications occur at type-2 or type-3 nodes.

For a type-1 node g_1, $M(a(g_1))$ and $M(b(g_1))$ are distinct from $M(g_1)$. The unique path from $M(a(g_1))$ to $M(b(g_1))$ through $M(g_1)$ is called an *arc* in the mapping M from G to T. For our purpose, we say that such an arc *starts* at $M(g_1)$. We also say that such an arc *passes* through any intermediate nodes between $M(a(g_1))$ and $M(g_1)$ and between $M(b(g_1))$ and $M(g_1)$. For a type-2 node g_2, assume $M(a(g_2)) \subset M(g_2)$ and $M(b(g_2)) = M(g_2)$. The unique path from $M(g_2)$ to its descendant $M(a(g_2))$ is called an *arc* in the mapping M from G to T,[1] *starting* at $M(g_2)$. Such an arc *passes* through all intermediate nodes between $M(a(g_2))$ and $M(g_2)$. To each node y in S we associate a (linked) list $A(y)$ of all arcs passing or starting from y and two integers s_y and p_y, where s_y is the number of arcs starting at y, and p_y is the number of arcs passing y.

PROPOSITION 3.2. *The $A(y)$'s, s_y's, and p_y's can be computed in $O(l+2n)$ time, where l denotes the total number of loss events.*

Proof. We use breadth-first search starting from the root on the gene tree G. For each node $x \in G$, if $M(x) \neq M(a(x))$ and $M(x) \neq M(b(x))$, then $M(a(x)), M(b(x))$ is below $M(x)$ in S, we use the in-order numbers of $M(x)$, $M(a(x))$, and $M(b(x))$ to travel down from $M(x)$ to $M(a(x))$ and $M(b(x))$ in S, and add the arc $(a(x), b(x))$ to the list $A(y)$ and update s_y and p_y for each node y on the arc. If x is a type-2 node, let $M(x) \neq M(a(x))$ but let $M(x) = M(b(x))$. Then, we use the in-order numbers of $M(x)$, $M(a(x))$ to travel down from $M(x)$ to $M(a(x))$, during which we add the arc $(x, a(x))$ to the list $A(y)$ and update s_y and p_y for each node y on the arc.

[1] In [34], this is called a path.

Now we analyze the time complexity. For each node x, we take $O(d(M(a(x)), M(b(x))))$ in total to update the linked lists $A(y)$, the starting numbers s_y, and passing numbers p_y of nodes y on the arc. Thus, the algorithm takes

$$\begin{aligned} t &= \sum_{x \in G-L(G)} d(M(a(x)), M(b(x))) \\ &= \sum_{y \in S-L(S)} |A(y)| \\ &= n-1+\sum_{y \in Mixed(S)} |A(y)| \\ &\leq n+l+t_{dup} \\ &\leq 2n+l, \end{aligned}$$

where the third equality follows from the fact that the number of duplications in which a node y is mixed is equal to $s_y + p_y - 1$ [34], and the first inequality is based on the fact that for each duplication, the number of losses is equal to one plus the number of mixed nodes [34]. This concludes the proof. □

PROPOSITION 3.3. *Let x be an internal node in the species trees S; then a loss event occurs at x in some duplication if and only if $s_{p(x)} + p_{p(y)} - p_x - s_x + n_{23} > 0$, where n_{23} is the number of type-2 or type-3 nodes mapped to x under the LCA mapping M.*

Proof. There are exactly $s_{p(x)} + p_{p(y)} - 1$ duplications in which the parent $p(x)$ of x is a mixed node [34]. On the other hand, there are $s_x + p_x - 1$ duplications in which x is a mixed node. Further, n_{23} of these duplications occur at x. Thus, there are exactly $s_{p(x)} + p_{p(y)} - s_x - p_x + n_{23}$ duplications in which $p(x)$ is a mixed node but x is a speciation, i.e., a loss event occurs at x if $s_{p(x)} + p_{p(y)} - p_x - s_x + n_{23} > 0$. This concludes the proof. □

Thus, by Proposition 3.3, we can list all the nodes at which a loss event occurs in $O(n)$ steps by traveling down the species tree S. Moreover, we need to find out for each loss event which duplication causes it. Recall that $A(y)$ denotes the set of all arcs that pass or start at y for each node $y \in S$. Let

$$A(y) = \{(x_i, x_i') \mid i \leq m\}$$

and let $A^{-1}(y) = \{M^{-1}x_i, M^{-1}x_i' \mid i \leq m\}$. The following proposition is a combination of Claim 1 and Claim 2 in the proof of Proposition 3.4 in [34].

PROPOSITION 3.4. *The homomorphic subtree $G|_{A_y^{-1}}$ contains all the duplication nodes z in which y is a mixed node.*

By Proposition 3.4, we have the following.

PROPOSITION 3.5. *An in-order traversal of $G|_{A_y^{-1}}$ can be computed in $O(|A^{-1}(y)|)$ steps.*

Proof. Let $|A^{-1}(y)| = k$. Then $k = O(m)$. Radix sort $A^{-1}(y)$ in $O(m)$ steps. Let $z_1, z_2, \ldots, z_k$ be the in-order list of leaves of $G|_{A_y^{-1}}$. Let $z'_{2j-1} = z_j$ and $z'_{2j} = \mathrm{LCA}(z_j, z_{j+1})$. Then $z'_1, z'_2, \ldots, z'_{2m-1}$ is the in-order traversal of $G|_{A_y^{-1}}$. □

Let $\mathrm{Dup}(G, S)$ denote the set of all duplications occurring under the LCA mapping from G to S. For each duplication $d \in \mathrm{Dup}(G, S)$, let $\mathrm{Loss}(d)$ denote the set of nodes of S on which a loss event occurs in d. For each node $y \in S_{loss} = \cup \mathrm{Loss}(d)$ on which a loss event occurs, let

$$S_y = \{d \in \mathrm{Dup(G)} \mid y \in \mathrm{Loss}(d)\}. \tag{2}$$

Since for a duplication d, a loss event occurs at a node y if and only if the parent $p(y)$ of y is a mixed node in d, but y is a speciation node. Then, by Proposition 3.4, an in-order traversal of S_y can be obtained from difference between the in-order traversal of $G|_{A^{-1}(p(y))}$ and $G|_{A^{-1}(y)}$, which takes at most $O(s_{p(y)}+p_{p_y}+s_y+p_y)$ steps. Therefore, we have the following.

PROPOSITION 3.6. *The S_y's for all nodes y can be computed in $O(l+n)$ steps.*

Proof. Do a breadth-first search for loss nodes in S. For each loss node y, we find the in-order traversals of $G|_{A^{-1}(y)}$ and $G|_{A^{-1}(p(y))}$ and then find S_y from them as described above. The complexity is

$$t = \sum_{y \in S_{loss}} (O(s_{p(y)} + p_{p(y)} + s_y + p_y)) \leq O(l + 2n).$$

This concludes the proof. □

Recall that, for each duplication d, we use $\text{Loss}(d)$ to denote the set of nodes on which a loss event occurs in d and let

$$L_d = \{y \in S \mid y \in \text{Loss}(d)\}. \tag{3}$$

Then, from all S_y constructed above, we can derive all L_d as follows.

PROPOSITION 3.7. *All L_d can be computed in $O(l)$ steps. Thus, all loss subtrees can be constructed in $O(l)$ steps.*

Proof. Radix sort S_{loss} and let

$$y_1, y_2, \ldots, y_c$$

be the in-order list of nodes in S_{loss}. For a duplication, we will keep L_d in a linked list which is denoted by the same symbol. Let there be m duplications $d_1, d_2, \ldots, d_m$. Initially, L_{d_i} is empty for every i. Then, we examine $S_{y_1}, S_{y_2}, \ldots, S_{y_c}$ in order one by one. First, for each $d \in S_{y_1}$, we insert y_1 in L_d. In general, after $S_{y_1}, S_{y_2}, \ldots, S_{y_i}$ have been examined, we search $S_{y_{i+1}}$ in the same way: for each $d \in S_{y_i}$, we insert y_{i+1} in L_d. After all S_{y_i} have been examined, L_d stores all the nodes on which a loss event occurs in duplication d. Actually, following the construction carefully, one will see that L_d is an in-order traversal. Therefore, one can easily construct the loss subtree for duplication d from L_d. The time bound is obvious. □

We have proved the following theorem.

THEOREM 3.8. *Given a gene tree G and a species tree S, Algorithm* A *constructs the loss subtrees in $O(n+l)$ time.*

ALGORITHM A.
INPUT: A gene tree G and species tree S.
1. Impose an arbitrary ordering on the children of each node and produce an in-order traversal of G and S, respectively. Assume i_x denotes the in-order number of x for $x \in G, S$.
2. Compute the LCA mapping $M : G \to S$. To each $x \in G$ assign a pair $< i_x, i_{M(x)} >$; To each $y \in S$ assign a pair $< i_y, n_{23} >$, where n_{23} is the number of type-2 or type-3 nodes in G that are mapped to y.
3. Compute the set S_{loss} of all the nodes in which a loss event occurs using Proposition 3.3.
4. For each $y \in S_{loss}$, compute the set S_y that is defined in equation (2).
5. For each duplication d, use the sets S_y to compute L_d that is defined in equation (3).
6. Reconstruct all the loss subtrees from the L_d's.

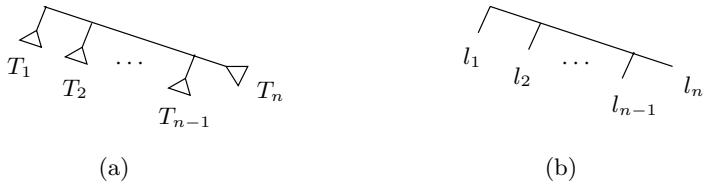

FIG. 6. (a) *The tree* $L[T_1, T_2, \ldots, T_n]$ *and* (b) *a line tree.*

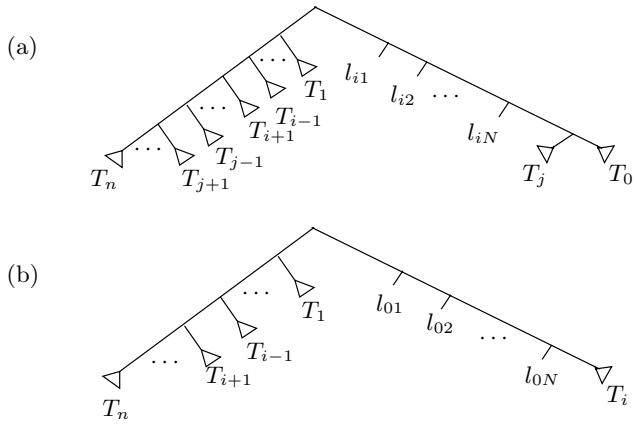

FIG. 7. (a) *The gene tree* G_{ij} *is constructed from the edge* (v_i, v_j). (b) *The gene tree* G_i *is constructed from the node* v_i.

4. The complexity of finding optimal species trees.

4.1. Optimal species tree I. Given n trees $T_1, T_2, \ldots, T_n$, we use $L[T_1, T_2, \ldots, T_n]$ to denote the tree T shown in Figure 6(a). When T_i is a single labeled node, the resulting tree is just a *line tree* as in Figure 6(b).

THEOREM 4.1. *The decision version of OST* I *is NP-complete.*

Proof. The problem is trivially in NP. To prove its NP-hardness, we reduce the independent set problem to OST I. Recall that the independent set problem is as follows: given a graph $G = (V, E)$ and an integer $d \leq |V|$, decide if G contains an independent set of size d, i.e., a subset of $V' \subseteq V$ such that $|V'| = d$ and no two nodes in V' are joined by an edge in E. Given an instance $G = (V, E)$ of the independent set problem, where $V = \{v_1, v_2, \ldots, v_n\}$, we construct a corresponding instance of OST I as follows.

Let $N = 5n^3$. For each v_i, we introduce N labels l_{ip}, $1 \leq p \leq N$, and a line tree $T_i = L[l_{i1}, l_{i2}, \ldots, l_{iN}]$. We also introduce extra N labels l_{0p}, $1 \leq p \leq N$, and a line tree $T_0 = L[l_{01}, l_{02}, \ldots, l_{0N}]$. For each pair (i, j) $(1 \leq i \neq j \leq n)$ such that $(v_i, v_j) \in E$, we define a tree G_{ij} with leaves labeled by $A = \{l_{ip} \mid 0 \leq i \leq n, 1 \leq p \leq N\}$ as shown in Figure 7(a). In G_{ij}, the left subtree is formed by connecting all T_p's $(p > 1)$ except for T_i and T_j by a line tree. Note that G_{ij} and G_{ji} have different right subtrees. Hence, we use two trees G_{ij} and G_{ji} to encode an edge (i, j). Finally, for each $v_i \in V$, we define a tree G_i with leaves labeled by A as shown in Figure 7(b). The left subtree of G_i is formed by connecting all T_p's except for T_i by a line tree, and the right subtree is a line tree with leaves l_{0k} $(1 \leq k \leq N)$ and l_{ik} $(1 \leq k \leq N)$ from left to right. Overall, we encode an edge (v_i, v_j) by two trees G_{ij} and G_{ji} and a node v_i by one

tree G_i. Obviously, such a construction can be carried out in polynomial time. The NP-hardness of OST I derives from the following lemma. □

LEMMA 4.2. *The graph G contains an independent set of size d if and only if there is a species tree S for all the gene trees G_{ij} and G_i constructed above with the duplication cost $c < (|E| + n - d + \frac{1}{2})N$.*

Proof. ($\Rightarrow$) Assume that G contains an independent set K of size d. Without loss of generality, we assume $V(K) = \{v_1, v_2, \ldots, v_d\}$. Then, we define a species tree S as

$$S = L[l_{n1}, \ldots, l_{nN}, \ldots, l_{(d+1)1}, \ldots, l_{(d+1)N}, l_{01}, \ldots, l_{0N}, l_{d1}, \ldots, l_{dN}, \ldots, l_{11}, \ldots, l_{1N}].$$

For each $i \le d$, $t_{dup}(G_i, S) = n - 1$. For each $i > d$, $t_{dup}(G_i, S) = N + n - 1$. Further, for any $(v_i, v_j) \in E$, either $i > d$ or $j > d$, and so

$$N \le t_{dup}(G_{ij}, S) + t_{dup}(G_{ji}, S) \le N + 2n. \tag{4}$$

Thus, the duplication cost c of S is

$$\begin{aligned}
&\sum_{(v_i,v_j)\in E} (t_{dup}(G_{ij}, S) + t_{dup}(G_{ji}, S)) + \sum_{1\le i\le n} t_{dup}(G_i, S) \\
&\quad \le |E|(N + 2n) + (n - d)(N + n - 1) + d(n - 1) \\
&\quad \le (|E| + n - d)N + 2n^3 \\
&\quad < \left(|E| + n - d + \frac{1}{2}\right) N.
\end{aligned}$$

($\Leftarrow$) We prove the converse by contradiction. Suppose that the optimal duplication cost is c for gene trees G_{ij} and G_i. Denote $A_i = \{l_{ip} \mid 1 \le p \le N\}$. Let S be an optimal species tree. Then one can define a total order $\prec$ on $\{A_i | 1 \le i \le n\}$ such that $LCA(A_i) \subset LCA(A_j)$ implies $A_i \prec A_j$. Suppose $A_{i_n} \prec A_{i_{n-1}} \prec \cdots \prec A_{i_0}$ is such a total order; then we define a line tree S' as

$$S' = L[l_{i_0 1}, \ldots, l_{i_0 N}, l_{i_1 1}, \ldots, l_{i_1 N}, \ldots, l_{i_n 1}, \ldots l_{i_n N}].$$

Let S' have duplication cost c'. Then we have the following two facts.

Fact 1. $c' \le 2\,n^3 + c$.

Proof. Since $S'|_{A_i} = T_i$, no duplication happens at all subtrees T_i ($0 \le i \le n$) in each gene tree $G_{i'j'}$ and $G_{i'}$. On the other hand, let u be any internal node on a right subtree of G_{ij}. If u is a parent of some l_{ip} ($0 \le p \le N - 1$) and u is not a duplication node in the mapping from G_{ij} to S, then it is easy to see $LCA(A_j) \subset LCA(A_i)$ and $LCA(A_0) \subset LCA(A_i)$. Thus $A_j \prec A_i$ and $A_0 \prec A_i$. Therefore, u is not a duplication node in the mapping from G_{ij} to S'. Note that two exceptions are the parent and the brother of l_{iN}. Similarly, for each internal node $x \in G_i$ that is a parent of l_{0p} ($1 \le p \le N - 1$), it will not be a duplication node for S' if it is not for S. Thus, the duplication cost for S' on all the right subtrees of gene trees is at most the cost for S plus $2n^2$.

Since there are at most $n' = n^2 + n(n - 1)(n - 2)$ extra internal nodes on the left subtrees of gene trees that have not been considered above, we have that $c' \le 2n^2 + n' + c \le 2n^3 + c$. This finishes the proof of Fact 1. □

Fact 2. $c' \ge (|E| + n - d + 1)N$.

Proof. Let $E_< = \{(v_i, v_j) \in E \mid \text{parent}_{S'}(l_{i1}), \text{parent}_{S'}(l_{j1}) \subset \text{parent}_{S'}(l_{01})\}$ and $V_< = \{v_i \in V | \text{parent}_{S'}(l_{i1}) \subset \text{parent}_{S'}(l_{01})\}$. If $G = (V, E)$ does not contain

(a) (b)

FIG. 8. *Rooted line trees.*

an independent set of size d, then $|E_<| - |V_<| \geq 1 - d$. In fact, this is trivial if $|V_<| < d$. Otherwise, let the largest independent set of restriction subgraph $G|_{V_<}$ be K'. Then $|K'| \leq d-1$. Since K' is largest, for any node $v \in V_< - K'$, $(v, v') \in E$ for some $v' \in K'$. This implies that $|E_<| \geq |V_<| - |K'| \geq |V_<| - d + 1$ or, equivalently, $|E_<| - |V_<| \geq 1 - d$ when $|V_<| \geq d$.

It is easy to verify that, for any i, j, if $(v_i, v_j) \in E_<$, then

$$t_{dup}(G_{ij}, S') + t_{dup}(G_{ji}, S') \geq 2N, \tag{5}$$

and if $v_i \notin V_<$, then

$$t_{dup}(G_i, S') \geq N. \tag{6}$$

By formulae (4), (5), and (6), we have

$$\begin{aligned} c' &\geq \sum_{v_i \in V - V_<} t_{dup}(G_i, S') + \sum_{(v_i,v_j) \in E - E_<} (t_{dup}(G_{ij}, S') + t_{dup}(G_{ji}, S')) \\ &\quad + \sum_{(v_i,v_j) \in E_<} (t_{dup}(G_{ij}, S') + t_{dup}(G_{ji}, S')) \\ &\geq N\,(n - |V_<|) + N\,(|E| - |E_<|) + 2\,N\,|E_<| \\ &\geq (|E| + n + |E_<| - |V_<|)N \\ &\geq (|E| + n - d + 1)N. \end{aligned}$$

Thus, Fact 2 is proved. □

Combining Fact 1 and Fact 2, we have that $c > (|E| + n - d + \frac{1}{2})N$, a contradiction. Thus, we finish the proof of the lemma. □

Remark 1. We have actually proved that OST I is NP-hard even for all gene trees with the same uniquely labeled leaves. Such a stronger conclusion will be used to prove that OST III is NP-hard in section 4.3.

Remark 2. Based on the above remark, we can also prove that the decision version of OST I remains NP-complete even for one gene tree that are not uniquely leaf-labeled. The proof of this result can be found in the proof of Theorem 4.7.

4.2. Optimal species tree II. Let C be a set of full binary trees G with leaves uniquely labeled by $L(G)$, and let T be a full binary tree with leaves uniquely labeled by $\sum_{G \in C} L(G)$. We say that C is *compatible* with T if for every $G \in C$, the homomorphic subtree $T|_{L(G)}$ of T induced by $L(G)$ is G, and it is *compatible* if it is compatible with some tree. Finally, recall that $L[z, w, v, u, x]$ denotes a rooted line tree with 5 leaves z, w, v, u, x as shown in Figure 8(a).

LEMMA 4.3. *If a collection C of 5-leave rooted line trees $L[y, w_i, v_i, u_i, x]$, $1 \leq i \leq k$, is compatible, then it is compatible with a rooted line tree $L[y, x_n, x_{n-1}, \ldots, x_1, x]$, where $\{x_1, x_2, \ldots, x_n\} = \cup_{i=1}^{k} \{u_i, v_i, w_i\}$.*

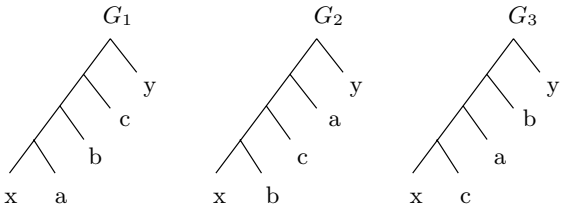

FIG. 9. *Three trees correspond to an ordered triple* (a, b, c).

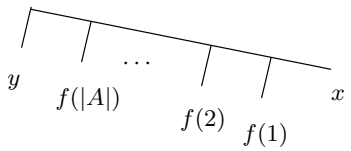

FIG. 10. *The species tree constructed from a cyclic ordering* f.

Proof. Choose a label z not in $\{x, y\}$ and $\cup_{i=1}^{k}\{u_i, v_i, w_i\}$. For each $t = L[y, w_i, v_i, u_i, x]$, we add an edge between z and the root so that the resulting tree t^z is an unrooted full binary tree in which each internal node has degree 3. It is not difficult to see that t^z is defined by the following set of quartets [29]:

$$Q(t^z) = \{xu_i|v_iz, xv_i|w_iz, xu_i|yz, xv_i|yz, xw_i|yz\}.$$

Suppose that C is compatible with a rooted full binary tree T; then $C^z = \{t^z \mid t \in C\}$ is compatible with T^z, and thus quartet set $\cup_{t\in C}Q(t^z)$ is compatible with T^z. By a lemma in [29], $\cup_{t\in C}Q(t^z)$ is compatible with a line tree $L[x, u_1, u_2, \ldots, u_{|A|}, y, z]$. This implies that C is compatible with the binary tree rooted at the internal node that is jointed with z (after the removal of z), which has the form shown in Figure 8(b). □

THEOREM 4.4. *The decision version of OST* II *is NP-complete.*

Proof. The problem is obviously in NP. To prove its NP-hardness, we now describe a transformation from the cyclic ordering problem [13] to OST II. The cyclic ordering problem is defined as follows.

> INSTANCE: A finite set A, and a collection C of ordered triples (a, b, c) of distinct elements from A.
> QUESTION: Is there a one-to-one function $f : A \to \{1, 2, \ldots, |A|\}$ such that, for each $(a, b, c) \in C$, we have either $f(a) < f(b) < f(c)$ or $f(b) < f(c) < f(a)$ or $f(c) < f(a) < f(b)$?

The problem is proved to be NP-complete in [12].

Suppose an instance (A, C) of the cyclic ordering problem is given. We construct for each ordered triple $\pi = (a, b, c) \in C$ three gene trees $G_1^\pi = L[y, c, b, a, x]$, $G_2^\pi = L[y, a, c, b, x]$, and $G_3^\pi = L[y, b, a, c, x]$ as shown in Figure 9, where x and y are two new labels fixed for all triples in C. Now, we consider a collection $G(C) = \{G_i^\pi \mid 1 \le i \le 3, \pi \in C\}$ of $3|C|$ gene trees. Obviously, such a construction can be carried out in polynomial time.

We claim that there is a species tree, with leaves $A \cup \{x, y\}$, which has mutation cost at most $14|C|$ if and only if A has a cyclic ordering.

Suppose a cyclic ordering f exists. Let $f(i)$ denote the ith smallest element in A and let $S = L[y, f(|A|), \ldots, f(2), f(1), x]$ as in Figure 10.

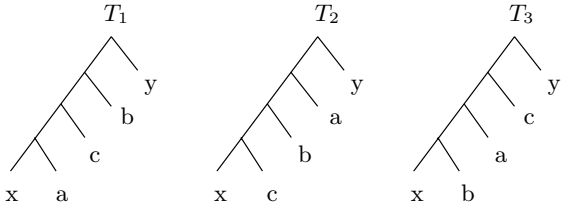

FIG. 11. *Three trees in the first column in Table* 1.

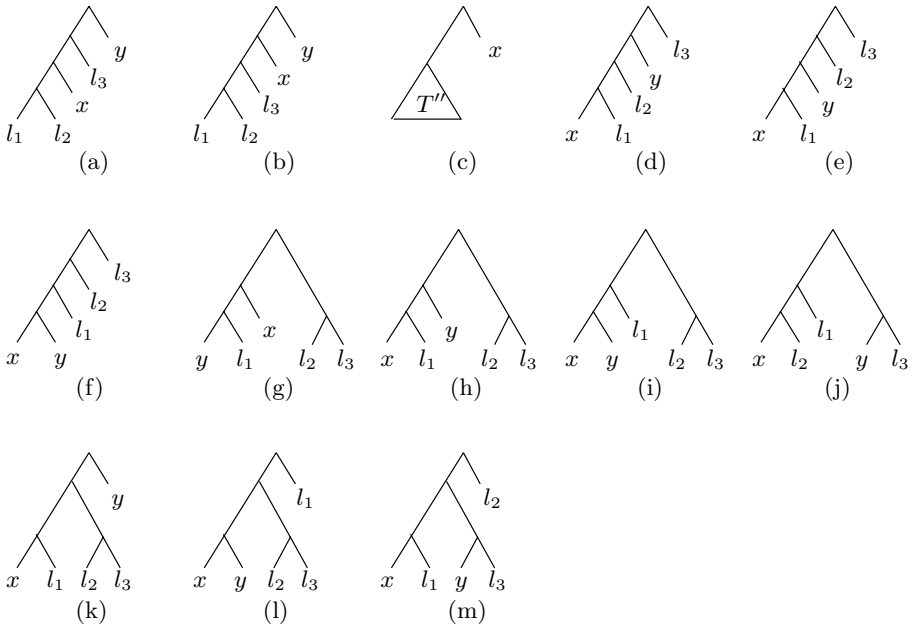

FIG. 12. *Cases* (a)–(m) *in the proof of Claim* 1.

For a triple $\pi = (a, b, c) \in C$, without loss of generality, we may assume that $f(a) < f(b) < f(c)$. Then G_1^π is the homomorphic subtree of S on $\{x, a, b, c, y\}$. Thus, $c(G_1, S) = 0$, $c(G_2, S) = 5$, and $c(G_3, S) = 9$. Hence, the total mutation cost over all $3|C|$ gene trees is $14|C|$.

Conversely, suppose that T is a species tree with leaves $A \cup \{x, y\}$ and with mutation cost at most $14|C|$. Then we have the following fact.

Fact. For any $\pi = (a, b, c) \in C$, the homomorphic subtree of T on $\{x, a, b, c, y\}$ is G_1, G_2, or G_3 as shown in Figure 9.

Proof. The homomorphic subtree T' of T on $\{x, a, b, c, y\}$ is a full binary tree with five labeled leaves. Assume that it is not one of G_1^π, G_2^π, or G_3^π. All possible homomorphic subtrees are illustrated in Figure 11 and Figure 12 and a case-by-case analysis of the mutation cost of G_1, G_2, and G_3 with T is shown in Table 1.

Hence, T has mutation cost at least $14|C| + 1$. This is a contradiction. Thus we conclude the fact. ∎

By Lemma 4.3, there exists a line tree such that for each triple $\pi = (a, b, c)$, the homomorphic subtree on $\{x, y, a, b, c\}$ is one of the gene trees $G_1^\pi, G_2^\pi, G_3^\pi$. It is not difficult to see that such a line tree induces a cyclic ordering. This concludes the proof of Theorem 4.4. ∎

4.3. Optimal species tree III. To prove the hardness result, we need to establish Lemma 4.5 and Lemma 4.6, which are derived from the definition of reconciled trees. Recall that for a node g in a gene tree G, $G(g)$ denotes the subtree of G rooted at g.

LEMMA 4.5. *Given a gene tree G and a species tree S, let T_r be the reconciled tree of G with respect to S, and let g be an internal node in G. If g is mapped to $t \in T_r$ when G is considered as a subtree of T_r, then $T_r(t)$ is the reconciled tree of $G(g)$ with respect to $S(t)$.*

Proof. The lemma follows from the definition of reconciled trees. □

LEMMA 4.6. *Let T_r be the reconciled tree of G with respect to S. Then $t_{dup}(T_r, S) = t_{dup}(G, S)$.*

Proof. We prove this lemma by induction on the number of leaves in G. It is obviously true for a gene tree G that has only three leaves. Now assume that G has at least four leaves. Let t be the root of T_r with children $a(t)$ and $b(t)$, let g be the root of G with children $a(g)$ and $b(g)$, and let s be the root of S with children $a(s)$ and $b(s)$. We consider the following cases.

Case 1. $a(t) \cap b(t) = \phi$.

Note that $t = s$ and $a(t)$ and $b(t)$ are two clusters in S. Further, by the definition of reconciled trees, $a(t) \neq t$, and $b(t) \neq t$. Thus, t is not a duplication node under the LCA mapping from T_r to S. On the other hand, since G is identical to $T_r|_{L(G)}$, we have that $a(g) \subset a(t), b(g) \subset b(t)$ or $a(g) subset b(t)$, $b(g) \subset a(t)$. Let $a(g)$ and $b(g)$ be mapped to t_1 and t_2, respectively, when G is considered as a subtree of T_r. By Lemma 4.5, $T_r(t_1) = T_r(G(a(g)), S(t_1))$ and $T_r(t_2) = T_r(G(b(g)), S(t_2))$. By induction, $t_{dup}(T_r(t_1), S(t_1)) = t_{dup}(G(a(g)), S(t_1))$ and $t_{dup}(T_r(t_2), S(t_2)) = t_{dup}(G(b(g)), S(t_2))$. Since $a(g) \subseteq t_1$ and $b(g) \subseteq t_2$, g is not a duplication node under the LCA mapping from G to S. Thus,

$$\begin{aligned} t_{dup}(G, S) &= t_{dup}(G(a(g)), S(a(s))) + t_{dup}(G(b(g)), S(b(s))) \\ &= t_{dup}(T_r(a(t)), S(a(s))) + t_{dup}(T_r(b(t)), S(b(s))) \\ &= t_{dup}(T_r, S). \end{aligned}$$

Case 2. $a(t) = b(t)$.

Then $a(t) = b(t) = t = s$. Thus a duplication happens at t under the LCA mapping from T_r to S. Since $a(t) = b(t)$, then either $a(g)$ is mapped to $a(t)$ or $b(g)$ is mapped to $b(t)$. Otherwise, $a(t)$ or $b(t)$ contains G as a subtree, which contradicts the fact that T_r is the reconciled tree of G with respect to S. Without loss of generality, we may assume that the former is true. Let $b(g)$ be mapped to t'. Note that $t' \subseteq b(t) = s$. Under the LCA mapping from G to S, $a(g)$ is mapped to s. Thus, by induction,

$$\begin{aligned} t_{dup}(T_r, S) &= 1 + t_{dup}(T_r(a(t)), S) + t_{dup}(T_r(b(t)), S) \\ &= 1 + t_{dup}(a(g), S) + t_{dup}(G(b(g)), S(t')) \\ &= t_{dup}(G, S). \end{aligned}$$

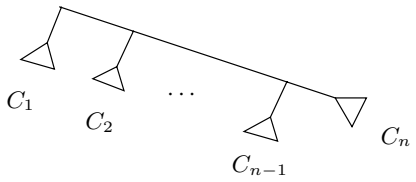

FIG. 13. *Connection of m gene trees in a right line tree.*

This proves Lemma 4.6. □

By Lemma 4.6, the problem OST III is a special case of the problem OST I in which each instance has only one gene tree. Unfortunately, such a problem is still NP-hard when a given gene tree is not a uniquely leaf-labeled tree.

THEOREM 4.7. *The decision version of OST* III *is NP-complete.*

Proof. Again, the problem is obviously in NP. To prove its NP-hardness, by Lemma 4.6, we need only to prove the following problem to be NP-hard:

Given a gene tree, find a species tree S with the minimum duplication cost $t_{dup}(G, S)$.

Given a class C of m gene trees with the same n uniquely labeled leaves, we construct a gene G by connecting all gene trees in C through a right line tree as shown in Figure 13. Since all gene trees in C have the same labeled leaves, we have that for any species tree S,

$$t_{dup}(G, S) = m - 1 + \sum_{1 \le i \le m} t_{dup}(G_i, S).$$

This finishes the reduction from an NP-hard problem OST I to the problem given above (see Remark 1 after Theorem 4.1). □

5. A heuristic method. We have proved that the problem of reconstructing an optimal species tree from gene trees is NP-hard. Therefore, there is unlikely an efficient algorithm for the problem. In this section, we will develop a heuristic method for it in a special case when all gene trees are uniquely leaf-labeled. Throughout this section, we will assume that trees are uniquely leaf-labeled without explicitly mentioning it.

5.1. A new metric. In this section, we introduce a new metric for measuring the similarity of two rooted full binary trees with uniquely labeled leaves based on the concept of duplications. Given two rooted full binary trees T_1 and T_2, in which each internal node has at least two children, we define the LCA mapping M from T_1 to T_2 as in section 2. We say a *duplication* happens at $x \in T_1$ under M if and only if for some child $c(x)$ of x, $M(c(x)) = M(x)$. We also use $t_{dup}(T_1, T_2)$ to denote the number of duplications occurring under the mapping M.

Let T be a rooted full binary tree. For any internal edge $e = (u, v)$, the *contraction tree* of T at e is the resulting tree after the removal of e and combining u and v into a new node p such that p is adjacent to all the neighbors of both u and v.

LEMMA 5.1. *The duplication cost satisfies the triangle inequality, i.e.,* $t_{dup}(T_1, T_3) \le t_{dup}(T_1, T_2) + t_{dup}(T_2, T_3)$ *for any three rooted full binary trees* T_1, T_2, *and* T_3 *with same uniquely labeled leaves.*

Proof. Let M_{ij} denote the LCA mapping from T_i to T_j. Now let T_1' be the resulting tree from T_1 by contracting all edges (u, v) such that $M_{12}(u) = M_{12}(v)$. Furthermore, let M_{12}' be the mapping from T_1' to T_2. We prove the following facts.

Fact 1. For any $m \in T_1'$, $M_{12}'(m) = m$. Thus, $t_{dup}(T_1', T_2) = 0$.

Proof. It follows from the definition of T_1'. □

Fact 2. $t_{dup}(T_1, T_3) \leq t_{dup}(T_1, T_2) + t_{dup}(T_2, T_3)$ if $t_{dup}(T_1', T_3) \leq t_{dup}(T_2, T_3)$.

Proof. Under the mapping M_{13}, a duplication happens at a node $n \in T_1$ if and only if $M_{13}(n) = M_{13}(c(n))$ for some child $c(n)$ of n. Let D denote the set of such duplication nodes in T_1 under M_{13}. We divide D into two disjoint subsets:

$$D_1 = \{n \in D \mid M_{12}(n) = M_{12}(c(n))\}$$

and

$$D_2 = \{n \in D \mid M_{12}(n) \neq M_{12}(c(n))\}.$$

Obviously, $|D_1| \leq t_{dup}(T_1, T_2)$ since any node in D_1 is also a duplication node under M_{12}. Furthermore, by the definition of T_1', $|D_2| \leq t_{dup}(T_1', T_3)$ since any node in D_2 is a duplication under the LCA mapping from T_1' to T_3. Hence, $t_{dup}(T_1, T_3) = |D_1| + |D_2| \leq t_{dup}(T_1, T_2) + t_{dup}(T_1', T_3) \leq t_{dup}(T_1, T_2) + t_{dup}(T_2, T_3)$ if $t_{dup}(T_1', T_3) \leq t_{dup}(T_2, T_3)$. This concludes the proof of Fact 2. □

Let $M_{12}'(n) = p$ and $M_{12}'(c(n)) = q$. Then, by Fact 1, $n = p$ and $c(n) = q$. If $M_{13}(n) = M_{13}(c(n))$, then all nodes in the path from $M_{23}(p)$ and $M_{23}(q)$ are mapped to the same node in T_3. This implies that $t_{dup}(T_1', T_3) \leq t_{dup}(T_2, T_3)$ and so, by Fact 2, $t_{dup}(T_1, T_3) \leq t_{dup}(T_1, T_2) + t_{dup}(T_2, T_3)$. This finishes the proof of Lemma 5.1. □

Now we define a new similarity measure between two rooted full binary trees as

$$d(T_1, T_2) = \frac{t_{dup}(T_1, T_2) + t_{dup}(T_2, T_1)}{2}.$$

Since the duplication cost is computable in linear time [34], the measure $d(.,.)$ is also efficiently computable. Further, it satisfies the three metric axioms.

PROPOSITION 5.2. *For any three full binary trees T_1, T_2, and T_3 with the same uniquely labeled leaves, $d(.,.)$ satisfies the following properties:*

(1) $d(T_1, T_2) = 0$ *if and only if* $T_1 = T_2$;

(2) $d(T_1, T_3) \leq d(T_1, T_2) + d(T_2, T_3)$ *for any* T_2;

(3) $d(T_1, T_2) = d(T_2, T_1)$.

In what follows, we call $d(.,.)$ the *symmetric duplication cost*. Interestingly, the symmetric duplication cost is closely related to the NNI distance for full binary trees, which was introduced independently in [19] and [27]. An NNI operation swaps two subtrees that are separated by an internal edge (u, v) as illustrated in Figure 14. The *NNI distance*, $D_{NNI}(T_1, T_2)$, between two full binary trees T_1 and T_2 is defined as the minimum number of NNI operations required to transform one tree into the other.

PROPOSITION 5.3. *For any species trees T_1 and T_2, $d(T_1, T_2) \leq D_{NNI}(T_1, T_2)$.*

Proof. Suppose T_1 is converted into T_2 by one NNI operation. Then, we can easily verify that $d(T_1, T_2) = 1$. Thus, $d(T_1, T_2) \leq D_{NNI}(T_1, T_2)$. Since $d(.,.)$ satisfies the triangle inequality, the result holds in general also. □

We now prove the following NP-completeness result.

THEOREM 5.4. *The decision version of finding an optimal species tree from a set of gene trees is NP-complete under the symmetric duplication cost.*

Proof. Obviously, it is in NP. In section 4.1, we have shown that OST I is NP-complete even for all gene trees with the same uniquely labeled leaves. Moreover, we may even assume that the duplication cost between any two gene trees is at least 2.

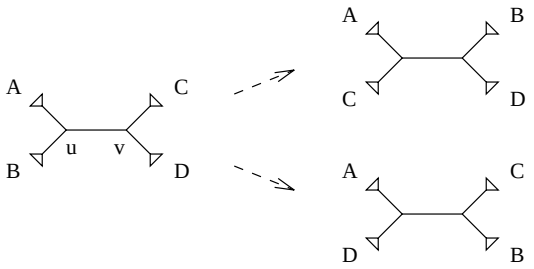

FIG. 14. *The two possible NNI operations on an internal edge* (u, v).

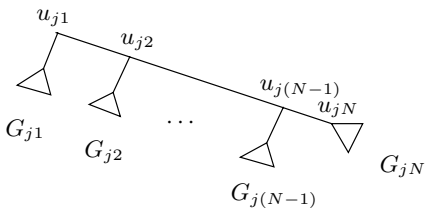

FIG. 15. *The tree* G'_j *of Theorem* 5.4.

We reduce this special case of OST I to the problem of finding an optimal species tree from gene trees under the symmetric duplication cost. Given an instance of OST I $I_1 = \{G_1, G_2, \ldots, G_n\}$ where each G_i is leaf uniquely labeled, and for any $i \neq j$, $L(G_i) = L(G_j)$ and $t_{dup}(G_i, G_j) \geq 2$. Assume that the leaf label set is $L = \{l_1, l_2, \ldots, l_m\}$ for each gene tree. For any species tree S with leaf label set L, if $S \neq G_i$ for any i, $1 \leq i \leq n$, then $t_{dup}(S, G_i) \geq 1$ for any i. If $S = G_i$ for some i in the range from 1 to n, then $t_{dup}(S, G_j) \geq 2$ for any $j \neq i$. Thus, for any species tree S with leaf label set L,

$$\sum_{j=1}^{n} t_{dup}(S, G_j) \geq n. \tag{7}$$

Let $N = 3n^2$. We introduce mN new labels l_{ik}, $1 \leq i \leq m$ and $1 \leq k \leq N$. For any j $(1 \leq j \leq n)$ and k $(1 \leq k \leq N)$, we construct G_{jk} from G_j by replacing the leaf l_i by l_{ik} for every i, $1 \leq i \leq m$. Let G'_j be the tree $L(G_{j1}, G_{j2}, \ldots, G_{jN})$ defined in Figure 15. Note that G'_j is a tree with mN labeled leaves. Finally, let $I_2 = \{G'_1, G'_2, \ldots, G'_n\}$. In order to finish the reduction, we now prove that I_1 has a solution with cost at most d if and only if I_2 has a solution with cost less than $(\frac{d+n}{2} + \frac{1}{4})N$.

Suppose S is a solution for I_1 with cost d. Let S' be the tree obtained from S by replacing each leaf l_i by a line tree $L(l_{i1}, l_{i2}, \ldots, l_{iN})$. Then it is easy to see that $t_{dup}(G_{jk}, S') = t_{dup}(G_j, S)$. Thus, $t_{dup}(G'_j, S') \leq t_{dup}(G_j, S)N + N$. Furthermore, since $t_{dup}(L(l_{i1}, l_{i2}, \ldots, l_{iN}), G'_k) = 0$, and S' has $n-1$ internal nodes that are not in $L(l_{i1}, l_{i2}, \ldots, l_{iN})$ for any i, $t_{dup}(S', G'_j) \leq n-1$. Therefore, the symmetric duplication cost of the solution S' for I_2 is

$$\sum_{i=1}^{n} \frac{t_{dup}(S', G'_j) + t_{dup}(G'_j, S')}{2} \leq \frac{1}{2}(dN + nN + n(n-1)) < \left(\frac{d+n}{2} + \frac{1}{4}\right) N.$$

Conversely, assume that the optimal solution for I_1 has duplication cost at least

$d+1$. Suppose S is a solution of I_2. For any $1 \le k \le N$, let $A_k = \{l_{ik} | 1 \le i \le m\}$, $S_k = S|_{A_k}$, and let u_k be the LCA of u_{jk} in S, where u_{jk}'s are the nodes in G'_j as shown in Figure 15. Note that u_k does not depend on the choice of j. Obviously, $u_N \subseteq \cdots \subseteq u_2 \subseteq u_1$. Assume that there are h indices k's ($1 \le k \le N-1$) satisfying $u_{k+1} \subset u_k$. Let these indices be $k_1, k_2, \ldots, k_h$. Then for any $k \ne k_t$ ($t = 1, 2, \ldots, h$), $1 \le k \le N-1$, u_{jk} is a duplication node in the mapping from G'_j to S. Hence, we have that

$$t_{dup}(G'_j, S) \ge \sum_{k=1}^{N} t_{dup}(G_{jk}, S) + N - 1 - h. \tag{8}$$

We use h_j to denote the number of duplications that occur on one of the nodes u_{k_1}, u_{k_2}, ..., u_{k_h} under the LCA mapping from S to G'_j. Let j' be the index that minimizes h_j over all j from 1 to n and let $h' = h - h_{j'}$. Assume that $u_{r_1}, u_{r_2}, \ldots, u_{r_{h'}}$ are the h' nonduplication nodes in the mapping from S to $G'_{j'}$. We have that $\{r_1, r_2, \ldots, r_{h'}\} \subseteq \{k_1, k_2, \ldots, k_h\}$ and $r_1 < r_2 < \cdots < r_{h'}$. Let $A = \bigcup_{t=1}^{h'} A_{r_t}$; then it is easy to verify that in the tree $S|_A$, for any $1 \le s \le h'$, $A_{r_s} \cap LCA(\bigcup_{t=s+1}^{h'} A_{r_t}) = \emptyset$. Thus,

$$t_{dup}(S, G'_j) \ge h_j + t_{dup}(S|_A, G'_j) \ge h - h' + \sum_{t=1}^{h'} t_{dup}(S_{r_t}, G_{jr_t}). \tag{9}$$

Combining formulae (7), (8), and (9), we have

$$\begin{aligned}
&\sum_{j=1}^{n} \left[t_{dup}(G'_j, S) + t_{dup}(S, G'_j) \right] \\
&\quad \ge \sum_{k=1}^{N} \sum_{j=1}^{n} t_{dup}(G_{jk}, S) + n(N - 1 - h') + \sum_{t=1}^{h'} \sum_{j=1}^{n} t_{dup}(S_{r_t}, G_{jr_t}) \\
&\quad \ge (d + n + 1)N - n.
\end{aligned}$$

Thus we know that for any solution of I_2, the cost is at least $\frac{(d+n+1)N-n}{2} \ge (\frac{d+n}{2} + \frac{1}{4})N$. □

5.2. A heuristic method for finding species trees. Although finding an optimal species tree from gene trees is NP-hard for the symmetric duplication cost $d(.,.)$, we have the following approximation result.

THEOREM 5.5. *There is a polynomial-time approximation of ratio* 2 *to the problem of finding an optimal species tree from gene trees with the symmetric duplication cost* $d(.,.)$.

Proof. Given an input of n gene trees $G_1, G_2, \ldots, G_n$, we compute $\sum_{i \ne j}^{n} d(G_i, G_j)$ for each $j \le n$ and output G_j with the minimum cost $\sum_{i \ne j}^{n} d(G_i, G_j)$ as the species tree. We now prove that the output species tree has at most twice the optimal symmetric duplication cost. Assume that G_1 is the output and S is an optimal species tree. Then

$$\begin{aligned}
\sum_{i \le n} d(G_i, G_1) &\le \frac{\sum_{i \le n} \sum_{j \le n} d(G_i, G_j)}{n} \\
&\le \frac{\sum_{i \le n} \sum_{j \le n} (d(G_i, S) + d(G_j, S))}{n} \\
&\le 2 \sum_{i \le n} d(G_i, S).
\end{aligned}$$

This proves Theorem 5.5. □

In general, the optimal species tree for a set of gene trees under the symmetric duplication cost is different from ones under the duplication and mutation costs. However, these trees should be quite similar to each other intuitively. Hence, based on Theorem 5.5, we propose the following heuristic method for the problem.

Search Paradigm

Input: Gene tree $G_1, G_2, \ldots, G_n$.

1. Find a gene tree $T' = T_k$ with the minimum symmetric duplication cost $\sum_{i \le n} d(T_i, T_k)$.
2. Search for the optimal species tree starting from T' using NNI, CP, or alternate NNI and CP.

Here cut and paste (CP) is also known as subtree pruning and regrafting [30]. According to the experimental research conducted by Page and Charleston [24], the best choice seems to be alternating between the NNI and CP method in step 2 of our heuristic method.

We have extensively tested our heuristic method and compared it with the algorithm that starts the search from a random tree. The latter was implemented in Page's package GeneTree Version 1.0. When running Page's algorithm, we start from a random tree and search near-optimal species trees using the method of alternating NNI and CP. We also use the method of alternating NNI and CP to do the search in our algorithm. When there are less than 10 species, and gene trees in each data set are chosen randomly, both algorithms perform well. They produce quickly species trees with optimal duplication costs. However, when there are over 15 species, and gene trees in a data set are closely related, which is usually true for practical molecular data, our algorithm performs much better. We have conducted 22 tests. We generated a set of gene trees as follows: (a) Generate a random tree R using an algorithm of Rémy [1, 26]; (b) repeatedly generate a tree by randomly choosing up to 10 NNI operations and applying these operations on R. The results are listed in Table 2 except for three unfinished tests in which the algorithm of searching from a random tree took over one hour and was stopped before finishing, but our algorithm finished within half a minute. Our algorithm found species trees with better duplication costs in all the cases and took much fewer CP and NNI operations (and hence much less time) to get the solution. We used a Pentium MMX-233 personal computer. In each of the 22 tests, our algorithm finished in less than half a minute, while the search-from-a-random-tree algorithm took more than one hour for 6 tests.

6. A general reconstructing problem. There is a large family of genes each having several distinct copies in the studied species. In order to derive a species tree that truly reflects the evolution of species, one needs full knowledge about which copies of the gene are comparable. This is usually impossible until a careful study of the species has been done. However, one may have different confidences in different genes. Hence, it is natural to propose the following general problem. We use I^+ to denote the set of positive integers and let m be any similarity measure between gene and species trees.

General Optimal Species Tree (GOST).

INSTANCE: A set of n gene trees $G_1, G_2, \ldots, G_n$, to each tree a confidence value $c_i \in I^+$ is associated.

QUESTION: Find a species tree S with the minimum cost $\sum_{i=1}^{n} c_i m(G_i, S)$.

TABLE 2

R = the algorithm that starts the search with a random tree, SP = our search paradigm. The last column contains the numbers of NNI/CP operations used by the two algorithms.

Clearly, GOST is NP-hard under the duplication cost and the mutation cost. For the NNI distance, the same conclusion also holds.

THEOREM 6.1. *The decision version of GOST is NP-complete for the NNI distance.*

Proof. We reduce the problem of computing NNI distance between two trees (see [3]) to GOST. Given are two binary trees T_1 and T_2 with n leaves. By applying an NNI operation to T_1, there are as many as $2n-2$ different resulting trees. Let T_3 be such a tree, i.e., $d_{NNI}(T_3, T_1) = 1$. We consider the following instance I of GOST:

$$I = \{T_1, T_2, T_3, c_1 = 2, c_2 = 2, c_3 = 1\}.$$

Let S be an optimal species tree for I. Then one can easily verify that $S = T_3$ if and only if $d_{NNI}(T_1, T_2) = d_{NNI}(T_1, T_3) + d_{NNI}(T_3, T_2)$. Note that the NNI distance

$d_{NNI}(T_1, T_2)$ is at most $n \log n + 2n$ [17]. If GOST is solved in polynomial time, we can compute $d_{NNI}(T_1, T_2)$ using an efficient search as follows. For each T_3 such that $d_{NNI}(T_1, T_3) = 1$, compute the optimal species tree S for the instance I defined above. If $S = T_3$, then we use T_3 to replace T_1, compute $d_{NNI}(T_3, T_2)$ inductively, and output $1 + d_{NNI}(T_3, T_2)$. This finishes the reduction and hence the proof. □

Note that the approximation algorithm in Theorem 5.5 cannot be generalized to GOST. Therefore, it is challenging to develop polynomial-time algorithms with good approximation factors for GOST under the various similarity measures.

7. Further research. Further studies on our topics in relation with parametric complexity classes have been carried out recently by Fellows et al. We refer the reader to [6, 7]. We end the paper with a list of open questions.

1. Is the definition of reconciled tree in section 2.4 identical to the one defined by Page (the smallest tree satisfying the three properties listed in section 2.4)?
2. Study the complexity of approximating the problems OST I, OST II, and OST III. Is it possible to develop efficient polynomial-time approximation algorithms for these problems?
3. Develop efficient polynomial-time approximation algorithms for GOST defined in section 6 under the various measures studied here.

THE GENERAL STRUCTURE OF EDGE-CONNECTIVITY OF A VERTEX SUBSET IN A GRAPH AND ITS INCREMENTAL MAINTENANCE. ODD CASE*

YEFIM DINITZ† AND ALEK VAINSHTEIN‡

Abstract. Let $G = (V, E)$ be an undirected graph, S be a subset of its vertices, $\mathfrak{C}_S$ be the set of minimum edge-cuts partitioning S, and λ_S be the cardinality of such a cut. We suggest a graph structure, called the *connectivity carcass* of S, that represents both cuts in $\mathfrak{C}_S$ and the partition of V by all these cuts; its size is $O(\min\{|E|, \lambda_S|V|\})$. In this paper we present general constructions and study in detail the case λ_S odd; the specifics of the case λ_S even are considered elsewhere. For an adequate description of the connectivity carcass we introduce a new type of graph: locally orientable graphs, which generalize digraphs. The connectivity carcass consists of a locally orientable quotient graph of G, a cactus tree (in case λ_S odd, just a tree) representing all distinct partitions of S by cuts in $\mathfrak{C}_S$, and a mapping connecting them. One can build it in $O(|S|)$ max-flow computations in G. For an arbitrary sequence of u edge insertions not changing λ_S, the connectivity carcass can be maintained in time $O(|V| \min\{|E|, \lambda_S|V|\} + u)$. For two vertices of G, queries asking whether they are separated by a cut in $\mathfrak{C}_S$ are answered in $O(1)$ worst-case time per query. Another possibility is to maintain the carcass in $O(|S| \min\{|E|, \lambda_S|V|\} + u)$ time, but to answer the queries in $O(1)$ time only if at least one of the vertices belongs to S.

Key words. edge-connectivity, minimum cuts, graph structures, incremental maintenance, dynamic algorithms

1. Introduction.

Connectivity problems play an important role in applications of graph theory in computer science and have been extensively studied. In particular, much attention has been given to edge-connectivity problems. A pair of vertices s and t of an undirected graph $G = (V, E)$ is said to be k(-*edge*)-*connected* if there exist k edge-disjoint paths between them (equivalently, there is no k'-cut, $k' \leqslant k - 1$, separating s and t). The k-connectivity is an equivalence relation, and its equivalence classes are called k-*connectivity classes*. It is known that the system of globally minimum cuts and connectivity classes formed by them in a graph is represented by a *cactus tree*, i.e., a graph whose blocks are edges and cycles [DKL] (for a brief description in English see [NV, NGM]); it is just a tree if the size of globally minimum cuts is odd. On the other hand, the lattice of all (s, t)-minimum cuts for fixed vertices s and t is represented by all closed sets of some directed acyclic graph (dag) with one source and one sink [PQ].[1] Both these data structures can be maintained efficiently

[1]This fact was discovered independently by A. Karzanov (personal communication, 1977).

under edge insertions (see [DW] for the first one and, e.g., [I] for the second). In [DV1] we have suggested a new structure, which is a natural generalization of both the aforementioned representations. This data structure represents all minimum cuts of G partitioning a fixed vertex subset and the corresponding partition of this subset into its connectivity classes; besides, it represents the partition of V by all these cuts. Our structure admits efficient incremental maintenance as well.

In this paper we describe general constructions and provide a detailed analysis of the odd case, that is, of the case when the cardinality of the cuts in question is odd. This allows us to introduce all the main ideas while avoiding certain technical difficulties. For a brief analysis of the general case, see [DV1, DV2]; a detailed analysis will be given elsewhere.

A well-known model for pairwise minimum cuts in a graph is the Gomory–Hu tree [GH]. It represents one minimum (x, y)-cut for any pair of vertices x, y, which is far from being sufficient for the purpose of incremental maintenance. Indeed, if the newly inserted edge increases the value of the single minimum (x, y)-cut represented by the Gomory–Hu tree, one cannot tell whether the size of minimum (x, y)-cuts remains the same or increases.

One of the goals of connectivity studies is to provide tools for fast answering connectivity queries in dynamic graphs, such as "Are vertices u and v k-connected?" or "Show k-cuts separating u and v." An important problem of this type is maintaining the hierarchy of the k-connectivity classes, $k \leqslant l$; the corresponding incremental algorithms (that allow insertions of edges to G) are presented in [WT] for $l = 2$, [GI] for $l = 3$, and [DW] for $l = 4$. We hope that our data structure can play the crucial role in solving this problem for arbitrary l. Indeed, take for a vertex subset a $(k-1)$-connectivity class, then its connectivity subclasses are just k-connectivity classes of G. The totality of these subclasses gives the partition of V into k-classes. Thus, it suffices to maintain our data structures for all $(k-1)$-classes of the graph, $k \leqslant l$. Observe that when an edge insertion causes merging of some $(k-1)$-classes, their new connectivity structures must be merged as well. The analysis of this merge is beyond the scope of the present paper; the case $l = 4$ is handled in [DW]. So, the results cover the "local" part of the work on the maintenance of the hierarchy of connectivity classes for a general l.

Another application of connectivity structures is augmentation problems of the type: given a graph, add the minimum number of edges so as to increase the connectivity of the whole graph to a prescribed value. The cactus structure of minimum cuts was employed essentially in [NGM, Be] to develop clear and fast schemes and algorithms for graph augmentation. One can suppose that the suggested generalization of this structure to locally minimum cuts will help to improve the results in this area.

Finally, the analysis of the connectivity structure of a vertex subset in a graph can arise itself in an application. For example, let us consider an interconnection network $\mathcal{N}$ whose nodes are terminals and auxiliary intermediate stations. Then it is natural to define the connectivity structure of $\mathcal{N}$ as the connectivity structure of the set of terminals in $\mathcal{N}$. As an illustration, consider the network with the terminals A, B, and C shown on Figure 1.1; the 3-cuts shown by dashed lines are the minimum cuts partitioning $\{A, B, C\}$, but there exist also two irrelevant 2-cuts and one irrelevant 3-cut.

Let us consider a vertex subset S and the set of all minimum S-cuts, that is, cuts of G that partition S and have the minimum cardinality, λ_S, among such cuts; λ_S is said to be the *connectivity* of S. Two such cuts are called equivalent if they partition

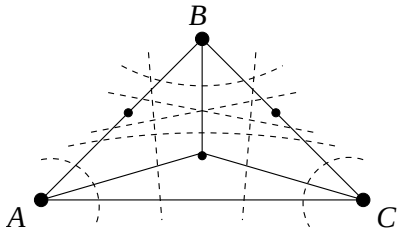

FIG. 1.1. *Minimum cuts in an interconnection network.*

S in the same way. We prove that the system of all such partitions of S, and thus also all the $(\lambda_S + 1)$-connectivity classes of S, is represented by a cactus tree $\mathcal{H}_S$ (called the skeleton), similarly to the representation of [DKL]. These partitions are defined by cuts of $\mathcal{H}_S$ almost bijectively. In the odd case the skeleton is just a tree, and the representation of the partitions by its cuts is a bijection.

Each family of equivalent minimum S-cuts is represented, similarly to [PQ], by cuts of a two-terminal dag of a special type, called a strip, which is defined up to the reversal of all its edges. Such a strip is obtained from G by certain contractions; in what follows we identify each vertex of the strip with the subset of V contracted into this vertex. We show that these strips agree on intersections in the following sense. First, if two nonterminal vertices of two strips intersect (as subsets of V), then these vertices coincide. Thus, the total partition of V by all minimum S-cuts subdivides only the two terminal vertices of each strip. We denote by $\mathcal{F}_S$ the graph obtained from G by contraction of each part of this total partition into a single vertex. Second, let two vertices of two strips coincide; then these vertices have, in a sense, the same set of incident edges. It turns out that the two 2-partitions of this set into incoming and outcoming edges in both strips coincide as unordered 2-partitions. As a result, at each vertex of $\mathcal{F}_S$ there arises a unique distinguished unordered 2-partition of the set of incident edges (called the inherent partition). The graph $\mathcal{F}_S$ with the inherent partitions at its vertices we call the flesh; it represents the entire family of minimum S-cuts. In this paper we extend to $\mathcal{F}_S$ methods used for dags in the case $|S| = 2$.

In order to build appropriate tools for analyzing $\mathcal{F}_S$, we introduce and study a special type of graphs: undirected graphs with a 2-partition of the set of incident edges at each vertex; we call them locally orientable graphs. In general such a graph cannot be oriented globally, but still preserves certain properties of digraphs. An analogue of an oriented path in a locally orientable graph is a path that agrees with inherent partitions (called a coherent path); we consider reachability along coherent paths. For graphs satisfying a certain natural restriction on cyclic coherent paths one can define the notions of reachability cones and strongly connected components, and adjust depth-first search (DFS) to scanning such graphs and finding these components. These techniques apply to the flesh since it satisfies even a stronger restriction: all its coherent paths are simple (thus, $\mathcal{F}_S$ is, in a sense, acyclic).

Finally, to each vertex of $\mathcal{F}_S$ we assign the set of families of equivalent minimum S-cuts in whose strips this vertex is nonterminal. The corresponding cuts of $\mathcal{H}_S$ define a subset of edges in $\mathcal{H}_S$ (called the projection π_S of the vertex); it turns out to be a path. The structure consisting of the skeleton, the flesh, and the projection mapping is called the *connectivity carcass of* S.

The connectivity carcass allows to answer readily several types of queries. The query asking whether two given vertices in S are $(k + 1)$-connected is answered just

by checking whether they are mapped into the same node of $\mathcal{H}_S$ or by checking whether they are contained in the same vertex of $\mathcal{F}_S$. In the latter way one can check also whether two arbitrary vertices of G are separated by a minimum S-cut. A minimum S-cut separating two vertices of which at least one belongs to S is defined immediately in terms of their projections. The same query in the general case may require, in addition, to combine such a cut with a reachability cone of one of the given vertices. For any two subsets S_1, S_2 of S, the corresponding strip of minimum S-cuts separating S_1 from S_2 is obtained by a certain contraction of the flesh defined by the projection mapping. The orientations of the edges in this strip are induced by the inherent partitions at the vertices of the flesh.

The connectivity carcass can be constructed by a polynomial algorithm. This is possible since it is "glued" naturally from (s,t)-strips of type [PQ], $s,t \in S$, s fixed (because of their "coincidences on intersections").

When considering incremental dynamics of the connectivity carcass, we assume that the cardinality of minimum S-cuts does not change under edge insertions; if such a change occurs, we say that the connectivity carcass vanishes. As a matter of fact, there arises a new system of larger minimum S-cuts, but this transition is beyond the scope of dynamic considerations in this paper.

Upon inserting a new edge into G, all the three components of the carcass change accordingly, and all the changes are of a contractive nature (provided λ_S does not change). The change of the graph of the flesh consists in contracting several vertices into a single new vertex. In particular, the endpoints U_1 and U_2 of the image of the new edge in $\mathcal{F}_S$, and all the vertices that can be visited by a coherent path between U_1 and U_2, "fall" into the new vertex. The other flesh vertices that are contracted are defined in terms of projections and reachability. The inherent partitions remain the same, except for the new flesh vertex, where the inherent partition is glued naturally from those of constituting vertices, or becomes trivial in case it was trivial for at least one of the constituting vertices. The change of the skeleton consists in contracting edges and "squeezing" cycles in the path-of-edges-and-cycles connecting the projections of U_1 and U_2 in the cactus tree $\mathcal{H}_S$; in the odd case it is just an ordinary path, and all of its edges are contracted. The projection of the new flesh vertex is $\pi_S(U_1) \cap \pi_S(U_2)$. The set of the other flesh vertices for which the projection changes is defined by their reachability from U_1 and U_2. From the projection of such a vertex, certain parts of the sets $\pi_S(U_1) \setminus \pi_S(U_2)$ or $\pi_S(U_2) \setminus \pi_S(U_1)$ are deleted.

The incremental algorithm [DV1] for maintaining the connectivity carcass is built according to the above scheme. In particular, it maintains the reachability cones of units, and thus involves, as a subproblem, incremental maintenance of transitive closures. The complexity of this algorithm is $O(|V| \min\{|E|, \lambda_S|V|\} + u)$, where u is the number of edge insertions (it is assumed that all of them preserve the connectivity of S); therefore, we do not exceed the complexity of best known algorithms for maintenance of the transitive closure (see [I, LL]). Each query asking whether two given vertices are separated by a minimum S-cut is answered in $O(1)$ worst-case time; such a cut itself can be shown in $O(|V|)$ amortized time. The dag representation of all minimum S-cuts separating any two subsets of S can be obtained in $O(|E|)$ amortized time. (For a comparison, in [GN] such a representation for an arbitrary pair of one-element subsets is constructed in $O(|V| \cdot |E|)$ time.)

The complexity of maintenance can be reduced at the expense of an increase in the reaction time for certain queries: we guarantee the same $O(1)$ worst-case time only in the cases when at least one of the vertices in question belongs to S. To

avoid the time-consuming maintenance of reachability cones, we suggest (see [DV2]) maintaining, instead of the actual flesh, a weaker contraction of the initial flesh, called the preflesh; the actual flesh can be obtained from the preflesh by contraction of its strongly connected components. The skeleton, the preflesh, and the projection mapping are maintained incrementally in time $O(|S|\min\{|E|,\lambda_S|V|\}+|V|\log|V|+u)$ for an arbitrary sequence of u edge insertions preserving the connectivity of S. The only increase of the reaction time, to $O(|E|)$ worst case, arises for the separation query in the case when the vertices in question both do not belong to S and have the same projection; the cut query in this situation is answered within the same $O(|E|)$ time.

As a corollary, we can simultaneously maintain the connectivity carcasses for all parts $S_1,\dots,S_r$ of an arbitrary partition of V in $O(|V|\min\{|E|,\lambda_S|V|\}+r|V|\log|V|+ru)$ time. Certain more delicate considerations extend this complexity bound (with the same overhead and even cheaper updates) to the "local" part of the work on the maintenance of the hierarchy of k-connectivity classes, $k\leqslant l$, mentioned above. The crucial observation is that when an edge (v,w) is added to G, the totality of connectivity carcasses for all k-connectivity classes, $k\leqslant l-1$, changes if and only if v and w belong to different l-classes. It turns out that the complexity of this local work is $O(|V|\min\{|E|,\lambda_S|V|\}+r|V|\log|V|+u)$, where r is the number of $(l-1)$-connectivity classes.

The first part of the paper treats the general case (λ_S arbitrary). In section 2 we give basic definitions and concepts. In section 3 we introduce locally orientable graphs and study their properties. In section 4 we consider a number of simple cases to gain intuition and to prove several basic lemmas. In section 5 we define the flesh (for the general case) and the skeleton (for the odd case only) and state their properties. In the rest of the paper λ_S is assumed to be odd. In section 6 we define the projection and present further properties of the connectivity carcass. In section 7 we describe the transformations of the connectivity carcass under the insertion of an edge to G. In section 8 we describe algorithms for construction and incremental maintenance of the connectivity carcass and for answering the queries.

The results of this paper were published in a preliminary form in [DV1, DV2].

2. Basic definitions and properties. In this paper we consider connected undirected graphs $G=(V,E)$, $|V|\geqslant 2$, without loops and possibly with parallel edges. We assume that these properties are preserved under vertex contractions; that is, we delete the obtained loops, but keep all the parallel edges. As usually, we denote $|V|$ by n and $|E|$ by m. For each ordered 2-partition $\mathcal{P}=(V_\mathcal{P},\bar{V}_\mathcal{P})$, $\bar{V}_\mathcal{P}=V\setminus V_\mathcal{P}$, of the vertex set V we define its edge-set $E_\mathcal{P}$ as the set of edges whose ends lie in distinct parts of $\mathcal{P}$. An ordered 2-partition $\mathcal{C}$ is said to be a *cut* of G if no proper subset of $E_\mathcal{C}$ coincides with $E_\mathcal{P}$ for some other 2-partition $\mathcal{P}$. The sets $V_\mathcal{C}$ and $\bar{V}_\mathcal{C}$ are called the *sides* of $\mathcal{C}$; we say that a vertex $v\in V$ lies *inside* $\mathcal{C}$ if $v\in V_\mathcal{C}$, and *outside* $\mathcal{C}$ if $v\in\bar{V}_\mathcal{C}$. For any cut $\mathcal{C}$, the opposite cut $\bar{\mathcal{C}}$ is defined by $V_{\bar{\mathcal{C}}}=\bar{V}_\mathcal{C}$, $\bar{V}_{\bar{\mathcal{C}}}=V_\mathcal{C}$; we say that $\bar{\mathcal{C}}$ is obtained from $\mathcal{C}$ by *flipping*. Let $\mathcal{C}$ and $\mathcal{C}'$ be two cuts such that $V_\mathcal{C}\subseteq V_{\mathcal{C}'}$; we say that $\mathcal{C}'$ *dominates* $\mathcal{C}$ and write $\mathcal{C}\preceq\mathcal{C}'$. If the inclusion $V_\mathcal{C}\subset V_{\mathcal{C}'}$ is strict, we write $\mathcal{C}\prec\mathcal{C}'$.

For any two cuts $\mathcal{C}$ and $\mathcal{C}'$, denote by $\mathcal{C}\cap\mathcal{C}'$ the 2-partition $(V_\mathcal{C}\cap V_{\mathcal{C}'},\bar{V}_\mathcal{C}\cup\bar{V}_{\mathcal{C}'})$, and by $\mathcal{C}\cup\mathcal{C}'$ the 2-partition $(V_\mathcal{C}\cup V_{\mathcal{C}'},\bar{V}_\mathcal{C}\cap\bar{V}_{\mathcal{C}'})$. Observe that the 2-partitions $\mathcal{C}\cap\mathcal{C}'$ and $\mathcal{C}\cup\mathcal{C}'$ are not necessarily cuts; however, if they are, then $\mathcal{C}\cap\mathcal{C}'\preceq\mathcal{C}\preceq\mathcal{C}\cup\mathcal{C}'$ and $\mathcal{C}\cap\mathcal{C}'\preceq\mathcal{C}'\preceq\mathcal{C}\cup\mathcal{C}'$. As usually, the *cardinality* $c(\mathcal{C})=c(V_\mathcal{C},\bar{V}_\mathcal{C})$ of a cut $\mathcal{C}$ is defined to be the size of its edge-set $E_\mathcal{C}$; clearly, $c(\bar{\mathcal{C}})=c(\mathcal{C})$. The notion of cardinality is extended naturally to arbitrary 2-partitions of V and, moreover, to arbitrary pairs of

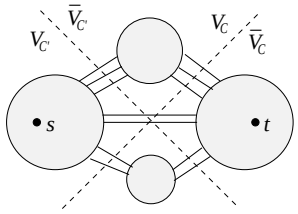

FIG. 2.1. *Two intersecting S-mincuts.*

disjoint subsets of V: if $X_1, X_2 \subset V$, $X_1 \cap X_2 = \varnothing$, then $c(X_1, X_2)$ stands for the number of edges with one end in X_1 and the other in X_2.

Let S be a subset of V; we denote by σ the cardinality of S. Any cut $\mathcal{C}$ defines a 2-partition $(S_\mathcal{C}, \bar{S}_\mathcal{C})$ of S, with $S_\mathcal{C} = V_\mathcal{C} \cap S$, $\bar{S}_\mathcal{C} = \bar{V}_\mathcal{C} \cap S$. A cut $\mathcal{C}$ is said to be an *S-cut* if both $S_\mathcal{C}$ and $\bar{S}_\mathcal{C}$ are nonvoid. For $S = \{a, b\}$, we speak of (a, b)-cuts instead of $\{a, b\}$-cuts to keep the usual notation. It is easy to see that the minimum cardinality among 2-partitions dividing S is equal to that among S-cuts; we denote it by λ_S. Moreover, each 2-partition of minimum cardinality λ_S dividing S is an S-cut. In this paper we are interested only in S-cuts of cardinality λ_S; we call them minimum S-cuts, or *S-mincuts*. The following basic property of S-mincuts (see Figure 2.1) is used extensively throughout the paper.

LEMMA 2.1. *Let $\mathcal{C}$ and $\mathcal{C}'$ be two arbitrary S-mincuts such that both $V_\mathcal{C} \cap V_{\mathcal{C}'} \cap S$ and $\bar{V}_\mathcal{C} \cap \bar{V}_{\mathcal{C}'} \cap S$ are nonempty. Then*

(i) $c(V_\mathcal{C} \cap \bar{V}_{\mathcal{C}'}, \bar{V}_\mathcal{C} \cap V_{\mathcal{C}'}) = 0$;

(ii) $c(V_\mathcal{C} \cap V_{\mathcal{C}'}, V_\mathcal{C} \cap \bar{V}_{\mathcal{C}'}) = c(V_\mathcal{C} \cap \bar{V}_{\mathcal{C}'}, \bar{V}_\mathcal{C} \cap \bar{V}_{\mathcal{C}'})$, $c(V_\mathcal{C} \cap V_{\mathcal{C}'}, \bar{V}_\mathcal{C} \cap V_{\mathcal{C}'}) = c(\bar{V}_\mathcal{C} \cap V_{\mathcal{C}'}, \bar{V}_\mathcal{C} \cap \bar{V}_{\mathcal{C}'})$.

Proof. (i) We assume that $\mathcal{C} \neq \mathcal{C}'$, since otherwise the assertion is trivial. Let s and t be two arbitrary vertices in $V_\mathcal{C} \cap V_{\mathcal{C}'} \cap S$ and $\bar{V}_\mathcal{C} \cap \bar{V}_{\mathcal{C}'} \cap S$, respectively. Then both $\mathcal{C}$ and $\mathcal{C}'$ are (s, t)-mincuts, and hence, by [FF, Chap. 1, Corollary 5.3], every edge e between $V_\mathcal{C} \cap \bar{V}_{\mathcal{C}'}$ and $V_{\mathcal{C}'} \cap \bar{V}_\mathcal{C}$ must be both free of any maximal (s, t)-flow and saturated by it.

(ii) By (i), for any maximal (s, t)-flow $c(V_\mathcal{C} \cap V_{\mathcal{C}'}, V_\mathcal{C} \cap \bar{V}_{\mathcal{C}'})$ is the flow entering $V_\mathcal{C} \cap \bar{V}_{\mathcal{C}'}$, and $c(V_\mathcal{C} \cap \bar{V}_{\mathcal{C}'}, \bar{V}_\mathcal{C} \cap \bar{V}_{\mathcal{C}'})$ is the flow leaving $V_\mathcal{C} \cap \bar{V}_{\mathcal{C}'} X \cap \bar{Y}$. These two quantities are equal by the flow conservation law. The second equality is proved in the same way. □

The following observation, though trivial, is important: for any two S-mincuts $\mathcal{C}_1$ and $\mathcal{C}_2$, at least one of the pairs $\mathcal{C}_1, \mathcal{C}_2$ and $\mathcal{C}_1, \bar{\mathcal{C}}_2$ satisfies the conditions of Lemma 2.1.

Two S-cuts are said to be S-equivalent if they define the same 2-partition of S. Equivalence classes of S-mincuts are called *bunches*. Evidently, if one replaces each cut of a bunch by the opposite cut, then one again gets a bunch, which is said to be opposite to the initial one. The following statement is an immediate corollary of Lemma 2.1.

FACT 2.2. *Let $\mathcal{C}$ and $\mathcal{C}'$ be two S-mincuts satisfying the conditions of Lemma* 2.1. *Then*

(i) *both $\mathcal{C} \cap \mathcal{C}'$ and $\mathcal{C} \cup \mathcal{C}'$ are S-mincuts;*

(ii) *let $\mathcal{C}''$ be an S-mincut S-equivalent to $\mathcal{C}'$; then $\mathcal{C} \cap \mathcal{C}''$ and $\mathcal{C} \cup \mathcal{C}''$ are S-mincuts S-equivalent to $\mathcal{C} \cap \mathcal{C}'$ and $\mathcal{C} \cup \mathcal{C}'$, respectively.*

In particular, the intersection and the union of two S-equivalent S-mincuts are cuts from the same bunch as well.

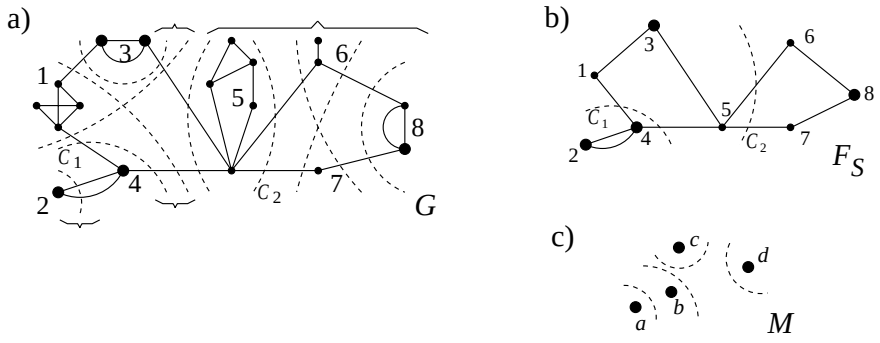

FIG. 2.2. *S-mincuts, the graph $\mathcal{F}_S$, and inducing of cuts and bunches.*

Let S_1 and S_2 be two disjoint subsets of S. An S-mincut is said to be an (S_1, S_2)-*mincut* if it keeps S_1 and S_2 on different sides. It follows immediately from Fact 2.2(i) that the intersection of all (S_1, S_2)-mincuts having S_1 inside is again an (S_1, S_2)-mincut. We call it the S_1-*tight* (S_1, S_2)-mincut.

Two vertices of G are said to be S-equivalent if they are not separated by any S-mincut. Equivalence classes of vertices are called S-units, or simply *units*. Evidently, the unit containing a given vertex is just the inner side of the intersection of all S-mincuts having this vertex inside. We denote by $\mathcal{F}_S$ the quotient graph obtained from G by contracting all the vertices of the same unit. The vertices of $\mathcal{F}_S$ are naturally called units. Each S-mincut induces naturally a cut of $\mathcal{F}_S$ separating the same units; in what follows we do not distinguish between these two cuts.

Observe that, in general, S is partitioned by the set of all S-mincuts into subsets $S_1, S_2, \ldots, S_r$, and r can be less than σ. This situation is handled in the following lemma.

LEMMA 2.3. (i) *Contract each S_i, $1 \leqslant i \leqslant r$, to a supervertex and denote the set of supervertices by $\bar{S}$. Then $\bar{S}$-mincuts and S-mincuts coincide up to the above contraction*; *in particular*, $\mathcal{F}_S = \mathcal{F}_{S'}$.

(ii) *Fix an arbitrary vertex v_i in each S_i, $1 \leqslant i \leqslant r$, and denote $S' = \{v_1, \ldots, v_r\}$. Then the sets of S'-mincuts and S-mincuts coincide*; *in particular*, $\mathcal{F}_S = \mathcal{F}_{S'}$.

Proof. (i) Follows immediately from definitions.

(ii) Indeed, since $S' \subseteq S$, each S'-cut is an S-cut, and hence either $\lambda_{S'} > \lambda_S$, or $\lambda_{S'} = \lambda_S$ and each S'-mincut is an S-mincut. On the other hand, any S-mincut separates some pair (S_i, S_j) and thus separates v_i from v_j. Therefore it is also an S'-cut, and moreover an S'-mincut, as required. □

Let $f : V \to M$ be a mapping to an arbitrary set M. For any $W \subseteq V$, we denote by $f(W)$ the set $\{f(w) : w \in W\}$. We say that a 2-partition $\mathcal{P}$ of M *f-induces a cut* $\mathcal{C}$ if $V_{\mathcal{C}} = f^{-1}(M_{\mathcal{P}})$. Similarly, given a mapping $g : S \to M$, we say that $\mathcal{P}$ *g-induces a bunch* of S-cuts if $S_{\mathcal{C}} = g^{-1}(M_{\mathcal{P}})$ for any cut $\mathcal{C}$ in this bunch.

To illustrate the above notions, let us consider the graph G presented on Figure 2.2(a). Large black circles denote vertices in S; thus $\lambda_S = 2$. All the ten S-mincuts are shown by dashed lines. They fall into four bunches consisting of 1, 2, 2, and 5 cuts, respectively, marked by braces. The vertices of G fall into eight units marked by numbers. The quotient graph $\mathcal{F}_S$ is presented on Figure 2.2(b). The quotient mapping f takes all the vertices of a unit i to the vertex i of $\mathcal{F}_S$. Each S-mincut is f-induced by a unique cut of $\mathcal{F}_S$ (e.g., see cuts $\mathcal{C}_1$ and $\mathcal{C}_2$ in Figures 2.2(a) and (b)).

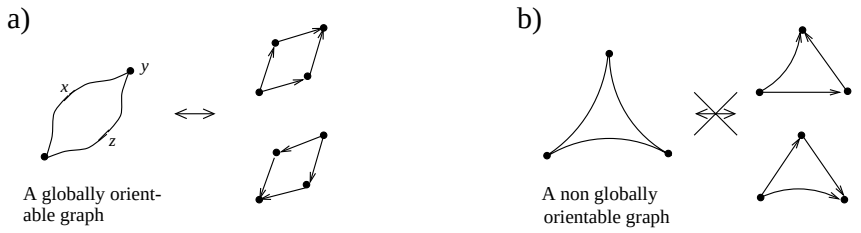

FIG. 3.1. *Local and global orientability.*

Let us consider also a four-element set $M = \{a, b, c, d\}$ and the mapping $g : S \to M$ that takes the vertices of S belonging to the units 2, 3, 4, 8 to a, c, b, d, respectively. The four 2-partitions of M shown in Figure 2.2(c) g-induce the four bunches of S-mincuts in G. Observe that all the above constructions are valid also for the set S' obtained by deleting from S any of the two vertices in unit 3.

3. Locally orientable graphs.

3.1. General locally orientable graphs. Recall that in the case $|S| = 2$ the quotient graph $\mathcal{F}_S$ possesses the structure of a dag, up to the reversal of all its edges. In general, $\mathcal{F}_S$ has a more sophisticated structure; however, as is shown in this paper, one can think of $\mathcal{F}_S$ as being glued from simpler dag-like objects of the above type. The basic local property of $\mathcal{F}_S$ is that the edges incident to any vertex are subdivided in a unique way into two groups. This subdivision is inherited from the subdivision into the edges leaving and entering the same vertex in the corresponding dags.

In this section we introduce and study general graphs equipped with this additional local structure, which are in a sense intermediate between undirected and directed graphs. We further impose on these graphs additional restrictions and arrive at certain important properties similar to those known for directed graphs. These properties support the detailed analysis of $\mathcal{F}_S$ carried on in subsequent sections.

Let v be an arbitrary vertex of an undirected graph. The *star* of v is the set E_v of edges incident to v. Assume that a certain unordered 2-partition of E_v is fixed; the parts of this 2-partition are called the two *sides* of the star. If both sides of E_v are nontrivial (nonempty), then v is called a *stretched* vertex; otherwise (when one of the sides coincides with E_v and the other is empty) v is called a *terminal*. A graph is said to be *locally orientable* if a 2-partition of the star into two sides is fixed at each of its vertices. In other words, a locally orientable graph is a pair $(G; \mathcal{E})$, where $G = (V, E)$ is an undirected graph and $\mathcal{E}$ is a mapping that assigns to each vertex $v \in V$ an unordered 2-partition of E_v. We say that $(G; \mathcal{E})$ *overlies* the initial graph G, and that G *underlies* the locally orientable graph $(G; \mathcal{E})$.

In particular, for any vertex v of an arbitrary directed graph, the partition of arcs incident to v into incoming and outcoming defines a 2-partition of E_v in the underlying undirected graph. Thus, for any digraph D, there exists a canonically defined locally orientable graph, which overlies the underlying undirected graph of D. A locally orientable graph $(G; \mathcal{E})$ is called *globally orientable* if one can direct the edges of G in such a way that for any vertex v all the edges entering v form one side of E_v defined by $\mathcal{E}$, while all the edges leaving v form its other side. Figure 3.1 provides two examples of locally orientable graphs of which one is globally orientable, while the other is not. Here and in what follows stretched vertices are denoted by rectangles to visualize the corresponding 2-partitions; terminals are denoted by circles. Globally

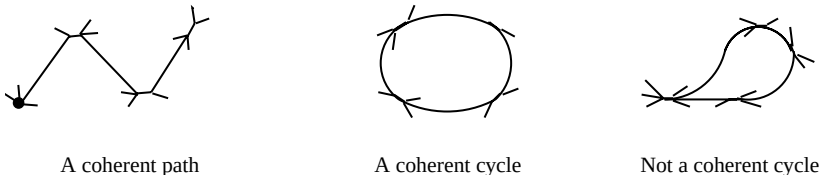

FIG. 3.2. *Coherence of paths and cycles.*

orientable graphs are essentially equivalent to directed graphs in the following sense.

LEMMA 3.1. *Given a connected globally orientable graph, the overlying directed graph is restored uniquely up to the global reversal of arcs.*

Proof. Let $\vec{G}_1$ and $\vec{G}_2$ be two digraphs overlying a given locally orientable graph G. Let V^+ be the subset of vertices at which the ordered 2-partitions of the star into incoming and outcoming arcs in $\vec{G}_1$ and $\vec{G}_2$ coincide, and let V^- be the subset of vertices at which they are opposite. Evidently, (V^+, V^-) is a partition of V. Assume that both its parts are nonempty. Since G is connected, it contains an edge between vertices $v^+ \in V^+$ and $v^- \in V^-$. Assume, without loss of generality (w.l.o.g.), that the corresponding arc in $\vec{G}_1$ leaves v^+ and enters v^-. Then the corresponding arc in $\vec{G}_2$ must leave both of them, a contradiction. Thus either $V^- = \varnothing$ and $\vec{G}_1 \cong \vec{G}_2$, or $V^+ = \varnothing$ and $\vec{G}_2$ is opposite to $\vec{G}_1$. □

The following construction provides a criterion for the global orientability of a locally orientable graph G. (We do not use this criterion in what follows.) Let us split each vertex v of G and its star into the two vertices v_1 and v_2 whose stars are exactly the sides at v and add the auxiliary edge (v_1, v_2); the obtained graph we denote G'.

PROPOSITION 3.2. *A locally orientable graph G is globally orientable if and only if G' is bipartite.*

Proof. Let G be globally orientable and $\vec{G}$ be its overlying digraph. Let us transform $\vec{G}$ into $\vec{G}'$ similarly to the above transformation; evidently, $\vec{G}'$ overlies G'. The partition $(\{v_1 : v \in V\}, \{v_2 : v \in V\})$ shows that G' is bipartite.

Now let G' be bipartite with the partition (V^*, V^{**}). Let us direct all edges from V^* to V^{**}. The contraction of all auxiliary edges results in a digraph overlying G. It is consistent with the 2-partitions at vertices since for each $v \in V$ the corresponding vertices v_1 and v_2 belong to different parts, i.e., arcs only leave v_1 and only enter v_2, or vice versa. □

According to Lemma 3.1, locally orientable graphs are a generalization of directed graphs. Some concepts of digraphs have their natural analogues for this generalization. A path $(v_0, e_1, v_1, e_2, \ldots, e_r, v_r)$ in a locally orientable graph is said to be *coherent* if for any of its inner vertices v_i, $1 \leqslant i \leqslant r-1$, the edges e_i and e_{i+1} belong to the opposite sides of the star of v_i (see Figure 3.2). Clearly, the inverses of any coherent path, any single edge path, and any single vertex path are coherent paths. Observe that each coherent path can be extended beyond its endpoint, provided it is not a terminal. Coherent paths are natural analogues of directed paths in digraphs. In particular, a coherent path in a globally orientable graph corresponds to a directed path in the overlying digraph or to the inverse of such a path.

For an arbitrary locally orientable graph, all vertices and edges of coherent paths beginning at a vertex v are called *reachable* from v. All these vertices and edges form

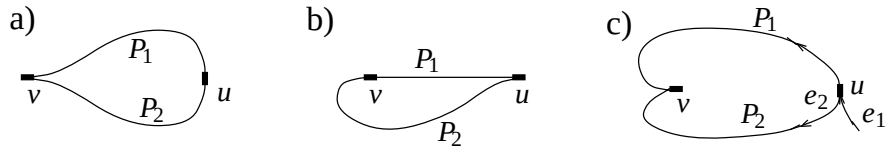

FIG. 3.3. *Cases in the proof of Lemma* 3.4.

the *reachability subgraph* of v. Observe that the reachability relation on vertices is symmetric (though not transitive: see vertices x, y, z in Figure 3.1(a)). Therefore, the notion of mutual reachability of two vertices is well defined.

We call a 2-partition $\mathcal{P}$ of the vertex set of a locally orientable graph (in particular, its cut) *transversal* if any coherent path intersects the corresponding edge-set $E_{\mathcal{P}}$ at most by one edge. Thus, if both endpoints of a coherent path lie on the same side of a transversal cut, then all of the path lies on the same side of this cut. Observe that the edge-set of a transversal 2-partition intersects at most one side of the star of any vertex. Moreover, the following statement can be proved easily.

FACT 3.3. *Let $\mathcal{P}_1$ and $\mathcal{P}_2$ be two transversal 2-partitions of the vertex set of a locally orientable graph such that $V_{\mathcal{P}_1} \cap V_{\mathcal{P}_2}$ is a single stretched vertex v. Then the intersections of the star of v with the edge-sets of $\mathcal{P}_1$ and $\mathcal{P}_2$ are exactly the two sides of this star.*

3.2. Coherent locally orientable graphs. A cyclic coherent path (for which $v_0 = v_r$ and $r > 1$) is called a *coherent cycle* if the edges e_r and e_1 belong to the opposite sides at v_0 (see Figure 3.2). A locally orientable graph is called *coherent* if each its cyclic coherent path is a coherent cycle. Coherent locally orientable graphs possess the following remarkable property.

LEMMA 3.4. *The reachability subgraph of any vertex of a coherent locally orientable graph is globally orientable.*

Proof. To construct a global orientation of the reachability subgraph of v we proceed as follows. Let us choose a side of the star of v. Moving along any coherent path starting at v and leaving v from this side, we direct all its edges from v. Similarly, moving along any coherent path starting at v and leaving v from the opposite side, we direct all its edges to v.

Let us prove the following statement: if two paths P_1 and P_2 from v to an arbitrary vertex u leave v from the same side (from the opposite sides), then they enter u at the same side (at the opposite sides). Assume to the contrary that P_1 and P_2 leave v from the same side and enter u at the opposite sides (see Figure 3.3(a)). Then the cyclic coherent path composed of P_1 and the inverse of P_2 is not a coherent cycle. Similarly, if P_1 and P_2 leave v from the opposite sides and enter u at the same side, then the cyclic coherent path composed of the inverse of P_2 and P_1 is not a coherent cycle (see Figure 3.3(b)).

Assume now that in our construction some edge e acquires two opposite orientations via paths P_1 and P_2. Evidently, the behavior of these paths at an arbitrary endpoint of e distinct from v contradicts to the above statement. Thus, the orientation of edges is well defined. Finally, to prove its consistency with the initial orientability structure we have to ensure that if two edges e_1, e_2 incident to a vertex u are oriented to and from u, respectively, then they are at the opposite sides of u. For $u = v$ it is evident. For $u \neq v$, we have to consider four cases depending on the types of the paths P_1 and P_2 that defined the orientations of the edges e_1, e_2, respectively. For

example, let both P_1 and P_2 leave v from the side opposite to the one chosen in the construction and let e_1 and e_2 be oriented as in Figure 3.3(c). Then P_2 enters u via e_2 while P_1 enters u via an edge preceding e_1 in P_1. Thus P_2 and P_1 enter u at the opposite sides, a contradiction with the above statement. The three other cases are handled in the same way. □

According to Lemmas 3.1 and 3.4, one can construct in an obvious way a version of the DFS that starts from an arbitrary vertex v and scans all the vertices and edges reachable from v in the same direction (i.e., by paths leaving v from the same side).

For a coherent locally orientable graph, the relation "two vertices belong to the same coherent cycle" is symmetric and transitive; the subgraphs induced by its equivalence classes are naturally called strongly connected components. It is easy to see that strongly connected components intersecting a reachability subgraph lie entirely in this subgraph and correspond bijectively to the strongly connected components of its overlying digraph. Hence, we can execute any DFS-based linear algorithm for finding strongly connected components on any reachability subgraph.

An analogue of a dag is an *acyclic* locally orientable graph, the one without cyclic coherent paths; thus, it is coherent. In particular, the underlying graph of a dag is acyclic in the above sense. As in the proof of Lemma 3.4, it follows from the acyclicity that for any two coherent paths joining v_1 and v_2, their initial edges leave v_1 from the same side. Thus, the set of vertices reachable from v_1 splits into two *reachability cones* corresponding to the sides of its star. (If v_1 is a terminal, one of the cones is trivial.) It is easy to see that if v_2 belongs to a reachability cone $\mathcal{R}$ of v_1, then one of the reachability cones of v_2 contains v_1 while the other lies strictly inside $\mathcal{R}$. (This property may be regarded as a weak analogue of transitivity.) Acyclicity implies that each coherent path can be extended beyond each of its endpoints up to a terminal. As a corollary, each nontrivial reachability cone of a vertex contains at least one terminal distinct from this vertex.

3.3. Strips. A locally orientable graph is called *balanced* if for any stretched vertex the two sides of its star have equal cardinalities. In this subsection we study balanced acyclic two-terminal locally orientable graphs. It is shown that such graphs are essentially identical to dags used in the analysis of (s,t)-mincuts. In fact, the quotient graph $\mathcal{F}_S$ in the general case has all the above properties except for one: it has more than two terminals (see section 5). To study this sophisticated object we use the results presented in this subsection.

LEMMA 3.5. *Any acyclic two-terminal locally orientable graph is globally orientable.*

Proof. By Lemma 3.4, it is enough to prove that the reachability subgraph of a terminal in such a graph coincides with the entire graph. Each vertex or edge is a coherent path; therefore, it can be extended to a coherent path between two terminals. By the acyclicity, these terminals are distinct, and the result follows. □

According to this Lemma, properties of an acyclic two-terminal locally orientable graph G are similar to those of its overlying dag $\vec{G}$. In particular, the following statements concerning transversal cuts are true.

FACT 3.6. (i) *The transversal cuts of G underlie the cuts of $\vec{G}$ in which all arcs are directed from the part containing the source to the part containing the sink.*

(ii) *Any transversal 2-partition of G is a (transversal) cut separating the terminals.*

(iii) *A reachability cone of any vertex in G defines a transversal cut; it is the intersection of all transversal cuts such that both this vertex and the terminal that*

belongs to this cone lie inside them.

An acyclic two-terminal globally orientable graph is called a *strip* (of width w) if all its transversal cuts are of the same cardinality w. Observe that the degree of a terminal in a strip equals its width (since the 2-partition isolating this terminal is a transversal cut).

Let s and t be the terminals and v be a vertex of a strip. We label the sides of the 2-partition and the cones at v by s and t; the cones are denoted $\mathcal{R}_s(v)$ and $\mathcal{R}_t(v)$. Thus, any two coherent paths $(u_1, \dots, u_2) \in \mathcal{R}_x(u_1)$ and $(u_2, \dots, u_3) \in \mathcal{R}_x(u_2)$, $x = s$ or t, can be concatenated into a coherent path $(u_1, \dots, u_2, \dots, u_3) \in \mathcal{R}_x(u_1)$.

Strip Lemma. (i) *An acyclic two-terminal locally orientable graph is a strip if and only if it is balanced.*

(ii) *There exists at most one strip for a fixed underlying graph and a fixed pair of terminals.*

Proof. (i) Let G be a balanced acyclic locally orientable graph with two terminals s and t. By Lemma 3.5, G is globally orientable. Let $\vec{G}$ be the overlying digraph of G in which s is the source and let $\mathcal{C}$ be a transversal cut of G such that $s \in V_{\mathcal{C}}$. We consider the difference Δ between the sum of outdegrees (in $\vec{G}$) for all vertices in $V_{\mathcal{C}}$ and the sum of their indegrees. On one hand, since G is balanced and $t \notin V_{\mathcal{C}}$, Δ equals the outdegree of s. On the other hand, since each internal arc of $V_{\mathcal{C}}$ contributes 1 to both sums and all external arcs are directed outside (by Fact 3.6(i)), Δ equals the cardinality of $E_{\mathcal{C}}$. Thus $c(\mathcal{C})$ equals the outdegree of s for any transversal cut $\mathcal{C}$.

Let now G be a strip and $\vec{G}$ be its overlying dag with the source s and the sink t. Let v be an arbitrary nonterminal vertex and let $\mathcal{R}$ be the reachability cone of v in $\vec{G}$. Both 2-partitions $(\mathcal{R}, V \setminus \mathcal{R})$ and $(\mathcal{R} \setminus v, (V \setminus \mathcal{R}) \cup v)$ are transversal since any directed path can only enter $\mathcal{R}$ (or $\mathcal{R} \setminus v$) but not leave it. By Fact 3.6(ii), they are cuts. Their cardinalities differ by the difference between the indegree and the outdegree of v. Since both cardinalities are equal, the indegree and outdegree at v are equal as well.

(ii) The statement is evident for graphs with two vertices; hence, we assume that there exists a vertex $v \neq s, t$. Let us consider a strip G with a source s and the sink t. It is easy to see that the deletion of s from G yields new terminals. Indeed, the one-vertex coherent path v can be extended up to terminals in both directions; these terminals are distinct since the graph is acyclic. As it was shown in the proof of Lemma 3.4, all the deleted edges incident to an arbitrary vertex belong to the same side of the vertex. Hence, for any new terminal exactly half of incident edges are deleted, and for any other vertex strictly less than half (a characterization in terms of the underlying graph). Let us prove that the contraction of the new terminals implies a strip. The obtained graph is evidently balanced and two-terminal. Assume that there exists a cyclic coherent path in it. Evidently, it starts and ends at the new terminal and thus can be extended to a cyclic coherent path starting and ending at s in the initial strip, a contradiction. Finally, the initial strip can be restored uniquely from the strip obtained.

Assume to the contrary that assertion (ii) is not valid. Then there exists a minimal counterexample: a graph with the minimal number of vertices giving rise to two distinct strips. Let us execute with these strips the above procedure. According to the characterization mentioned, the resulting undirected graphs coincide. Thus, by the minimality of the counterexample, the resulting strips coincide as well. By the remark at the end of the previous paragraph, the same holds for the initial strips, a contradiction. □

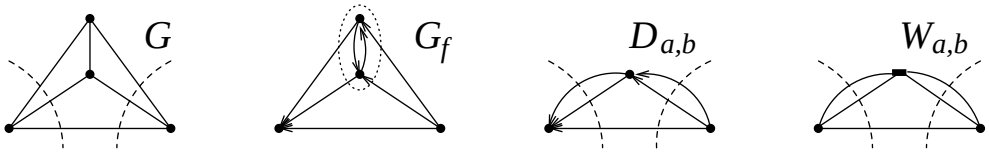

FIG. 3.4. *Construction of the* (a, b)*-strip.*

The concept of a strip allows us to reformulate and refine the main result of [PQ] on the representation of all minimum cuts between two vertices of a graph. Let us consider an undirected graph G and an arbitrary pair of its vertices a, b. Assume f is a maximal flow from a to b in G, and G_f is the corresponding residual graph. The result of the contraction of each strongly connected component of G_f to a new supervertex is a dag $D_{a,b}$ not depending on f. The corresponding quotient mapping is denoted by $\delta_{a,b}$, and the underlying locally orientable graph of this dag by $\mathcal{W}_{a,b}$ (see Figure 3.4).

THEOREM 3.7. *Let G be an undirected graph and a, b be a pair of its vertices. Then the graph $\mathcal{W}_{a,b}$ overlies $\mathcal{F}_{\{a,b\}}$, is a strip, and its transversal cuts correspond bijectively to the minimum (a, b)-cuts of G via the $\delta_{a,b}$-inducing.*

Proof. Recall that a vertex subset X in an arbitrary dag is said to be closed if no other vertices can be reached from this subset, or, equivalently, if no arc goes from X to $\bar{X}$. By [PQ] the $\delta_{a,b}$-inducing provides a bijection between the minimum (a, b)-cuts of G and the 2-partitions of type {a closed set of $D_{a,b}$, its complement}. According to Fact 3.6(i), the 2-partitions of the above type overlie exactly the transversal cuts of $\mathcal{W}_{a,b}$. Since all minimum (a, b)-cuts of G have the same cardinality, so do all the transversal cuts of $\mathcal{W}_{a,b}$, and hence $\mathcal{W}_{a,b}$ is a strip. It follows from the above discussion that the partition of V into the vertices of $\mathcal{W}_{a,b}$ is a refinement of the partition into the vertices of $\mathcal{F}_{\{a,b\}}$. To prove that they, in fact, coincide, it is sufficient to show that each vertex U of $\mathcal{W}_{a,b}$ is separated from all other vertices by transversal cuts. Indeed, by Fact 3.6(iii), these cuts are just the two cuts defined by reachability cones of U. □

Remark. Observe that natural analogues of the above construction and of Theorem 3.7 are valid for directed graphs.

The strip $\mathcal{W}_{a,b}$ will be referred to as the (a, b)-strip, and its vertices as (a, b)-units, or units of $\mathcal{W}_{a,b}$. Obviously, $\mathcal{W}_{b,a}$ coincides with $\mathcal{W}_{a,b}$ and $\delta_{b,a} = \delta_{a,b}$. The above constructions and results can be extended easily to the case of minimum cuts separating two disjoint vertex subsets A and B: it is enough to contract A and B into new supervertices. The corresponding (A, B)-strip is denoted by $\mathcal{W}_{A,B}$ and the quotient mapping by $\delta_{A,B}$.

LEMMA 3.8. *Let u be a vertex of G and $U \neq \delta_{a,b}(b)$ be the corresponding (a, b)-unit. The contraction of the reachability cone of U in $\mathcal{W}_{a,b}$ containing the terminal $\delta_{a,b}(a)$ gives the $(\{a, u\}, b)$-strip; its width is equal to the width of the initial strip $\mathcal{W}_{a,b}$.*

Proof (see Figure 3.5). It is easy to see that the contraction of a side of a transversal cut in an acyclic locally orientable graph preserves acyclicity. Therefore, by Fact 3.6(iii) and the Strip Lemma, the above contraction yields a strip $\mathcal{W}$. Since the terminal $\delta_{a,b}(b)$ remains untouched, the width of $\mathcal{W}$ equals that of $\mathcal{W}_{a,b}$.

By part (ii) of the Strip Lemma, it is enough to prove now that the underlying graph of $\mathcal{W}$ coincides with that of $\mathcal{W}_{\{a,u\},b}$. Since all $(\{a, u\}, b)$-cuts are (a, b)-cuts,

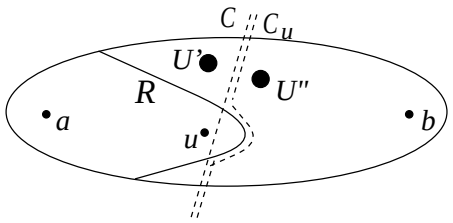

FIG. 3.5. *To the proof of Lemma* 3.8.

we can study them (more exactly, their images) in $\mathcal{W}_{a,b}$. First, by Fact 3.6(iii), the reachability cone $\mathcal{R}$ in question coincides with the $(\{a,u\},b)$-unit containing $\{a,b\}$. Second, let U' and U'' be two (a,b)-units not belonging to $\mathcal{R}$ and let $\mathcal{C}$ be an (a,b)-cut separating them. Evidently, the union of $\mathcal{C}$ and the cut defined by $\mathcal{R}$ is an $(\{a,u\},b)$-cut $\mathcal{C}_u$ separating U' and U''. □

Observe that for an arbitrary vertex subset S, the set of all minimum S-cuts is the union of the sets of minimum (a,b)-cuts for certain pairs of vertices $a,b \in S$. It is natural to ask whether it is possible to glue the corresponding (a,b)-strips together to form a single object. The main finding of this paper is that such an object exists: it is $\mathcal{F}_S$ with a canonical structure of local orientability defined by these (a,b)-strips.

4. Simple cases.

4.1. Generalities. To make our ideas more intuitive, we consider in this section several simple cases. The word "case" refers to the structure of partitions of S by S-mincuts; an example of such a structure is shown in Figure 2.2(c). From this point of view, the simplest possible cases arise when S is divided (by all S-mincuts together) into two or three parts.

Assume that S is divided into two parts S_1 and S_2. By Lemma 2.3(i), we can consider these parts as supervertices a and b and thus reduce this case to the situation when $S=\{a,b\}$. It is convenient to represent this situation by the "skeleton" graph shown in Figure 4.1(a). In a similar way, the case when S is divided into three parts is reduced to the situation when $S=\{a,b,c\}$ and any one of these vertices is separated from any other one by an S-mincut. Clearly, from the three possible types of S-mincuts, $(a,\{b,c\})$, $(b,\{a,c\})$, and $(c,\{a,b\})$, at least two must exist. So we have two subcases: the asymmetric, when exactly two types of S-mincuts are present, and the symmetric, when there are present all three of them. As before, we represent these subcases by certain "skeleton" structures. The asymmetric subcase is represented by the path (a,b,c) (provided we assume that there are no $(b,\{a,c\})$-cuts), and the symmetric subcase by the 3-star with terminals a, b, c (see Figures 4.1(b) and (c)). Observe that the 1-cuts of all these skeleton structures (they are shown by dashed lines in Figure 4.1) correspond bijectively to distinct partitions of S by minimum S-cuts in the original graph.

In addition, in the last subsection we consider the case when S is divided into an arbitrary number of parts, but the corresponding skeleton structure is just a path.

The definitions and results of this section can be regarded as prototypes of definitions and results for the general case presented in sections 5–7. Sometimes the proofs are omitted; this means that a more general result is proved in a subsequent section.

4.2. A two-element subset *S*. From the static point of view, the case $\sigma=2$ is covered completely by Theorem 3.7; recall that for $S=\{a,b\}$ one has $\mathcal{F}_S=\mathcal{W}_{a,b}$.

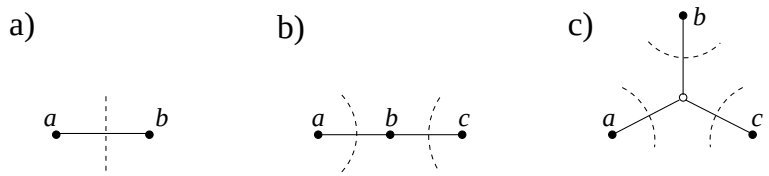

FIG. 4.1. *Skeleton structures.*

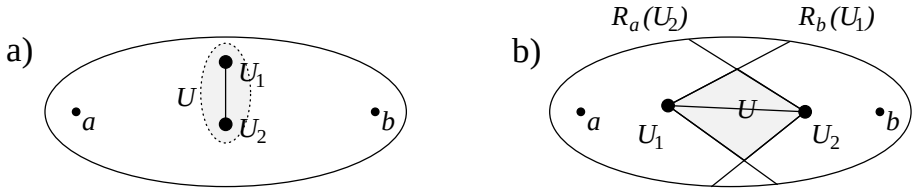

FIG. 4.2. *Dynamics of* $\mathcal{F}_{\{a,b\}}$.

Let us turn to dynamics. In what follows, we put a hat over any notation (e.g., $\widehat{\mathcal{R}}_c$, or $\widehat{\mathcal{F}}_S$) to denote the corresponding object after edge insertion. Recall that the units of $\mathcal{F}_S$ are defined as the strongly connected components of the graph G_f, where f is a maximum flow from a to b in G. Since we restrict ourselves to the case of a fixed value of (a,b)-mincuts, we may use the *same* flow f for the entire dynamic process. Hence, we can maintain the graph G_f fixing local changes. Namely, the insertion of a new edge (u_1,u_2) implies the addition of two arcs (u_1,u_2) and (u_2,u_1) to G_f. Moreover, one can maintain the dag $D_{a,b}$ of the strongly connected components of G_f as follows. Let U_1,U_2 be the components containing u_1,u_2, respectively. The new dag $\widehat{D}_{a,b}$ is obtained from the current one by adding arcs (U_1,U_2) and (U_2,U_1) and shrinking the new strongly connected component containing both U_1 and U_2. This transformation can be easily extended to the underlying strip $\mathcal{W}_{a,b}$ as follows.

If $U_1=U_2$, then there are no changes in $\mathcal{W}_{a,b}$. Otherwise, U_1 and U_2 are contracted to a new unit $U^{\rm new}$.

If U_1 and U_2 are not mutually reachable in $\mathcal{W}_{a,b}$, then there are no other changes in $\mathcal{W}_{a,b}$ (see Figure 4.2(a)). Otherwise, assume w.l.o.g. that $U_2\in\mathcal{R}_b(U_1)$ and $U_1\in\mathcal{R}_a(U_2)$; then $\mathcal{R}_b(U_1)\cap\mathcal{R}_a(U_2)$ (that is, the set of all the units and edges of all the paths between U_1 and U_2) is contracted into $U^{\rm new}$ as well (see Figure 4.2(b)).

If both U_1 and U_2 are terminals, then the system of S-mincuts vanishes. If exactly one of them is a terminal, then $U^{\rm new}$ is the corresponding terminal in the new strip. If both U_1 and U_2 are stretched, then $U^{\rm new}$ is stretched as well, and the side of the 2-partition at $U^{\rm new}$ labeled by a (resp., b) is glued from the sides of the 2-partitions at all the contracted units labeled by the same letter (except for the internal edges of the contracted subgraph).

Observe that the dag of the strongly connected components is exactly the object maintained by algorithms [I, LL], with the time complexity $O(mn)$. Evidently, any such algorithm can be easily modified to maintain a strip, with the same complexity.

As was mentioned in the previous subsection, the above description covers also a more general situation, when σ is arbitrary, but all the S-mincuts divide S in the same way into two subsets S_1 and S_2. Recall that by Lemma 2.3 in this case $\mathcal{F}_S=\mathcal{W}_{S_1,S_2}=\mathcal{W}_{s_1,s_2}=\mathcal{F}_{\{s_1,s_2\}}$ for any $s_1\in S_1$, $s_2\in S_2$.

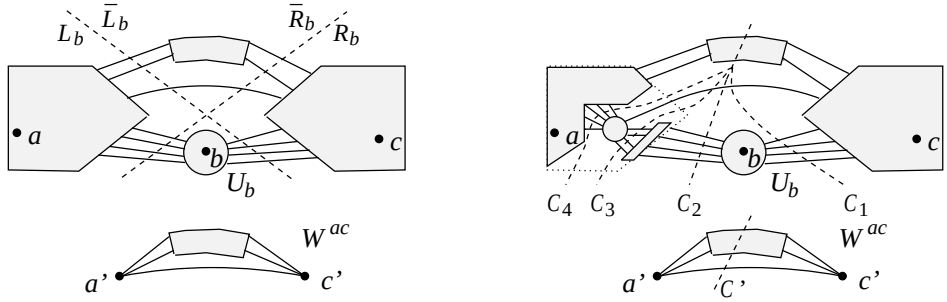

FIG. 4.3. *Structure of $\mathcal{F}_{\{a,b,c\}}$ in the asymmetric case.*

4.3. A three-element subset S: The asymmetric subcase. The smallest nontrivial case, from the static point of view, is $S = \{a, b, c\}$ and any two of these vertices are separated by an S-mincut. In this subsection we consider the asymmetric subcase; we assume w. l. o. g. that there are no $(b, \{a, c\})$-cuts. Thus, every S-mincut is an (a, c)-cut, and vice versa. Therefore, the entire family of S-mincuts is represented by the strip $\mathcal{W}_{a,c}$; in particular, (a, c)-units coincide with S-units. We define the structure of local orientability on the graph $\mathcal{F}_{\{a,b,c\}}$ by keeping that of $\mathcal{W}_{a,c}$ at all the units, except for the unit U_b containing b, which is now regarded as a terminal. Since $\mathcal{W}_{a,c}$ is acyclic and balanced, and turning a vertex to a terminal does not extend the set of coherent paths, we see that $\mathcal{F}_{\{a,b,c\}}$ is acyclic and balanced as well. Besides, we see that all S-mincuts of G are transversal cuts in $\mathcal{F}_{\{a,b,c\}}$; observe that the converse is not true; see, e.g., the cut that separates U_b from all the other units.

We denote by $(L_b, \bar{L}_b)$ the $\{a, b\}$-tight $(\{a, b\}, c)$-mincut (for the definition see section 2 immediately after Fact 2.2). Similarly, $(R_b, \bar{R}_b)$ is the $\{b, c\}$-tight $(\{b, c\}, a)$-mincut (see Figure 4.3(a)). Observe that according to Lemma 2.1(i), there are no edges between $L_b \cap R_b$ and $\bar{L}_b \cap \bar{R}_b$.

In our next statement we summarize other properties of the cuts $(L_b, \bar{L}_b)$ and $(R_b, \bar{R}_b)$.

LEMMA 4.1. (i) *L_b and R_b are the two reachability cones of the unit U_b in $\mathcal{W}_{a,c}$, and hence $L_b \cap R_b$ coincides with this unit.*

(ii) *The sides of the star of U_b in $\mathcal{W}_{a,c}$ are induced in $\mathcal{F}_{\{a,b,c\}}$ by edge-sets of $(L_b, \bar{L}_b)$ and $(R_b, \bar{R}_b)$.*

(iii) *The contraction of L_b in $\mathcal{F}_{\{a,b,c\}}$ gives $\mathcal{W}_{b,c}$, the contraction of R_b in $\mathcal{F}_{\{a,b,c\}}$ gives $\mathcal{W}_{a,b}$.*

Proof. (i) The proof follows from Fact 3.6(iii).

(ii) The proof follows from (i) and Fact 3.3.

(iii) The proof follows from Lemma 3.8. □

Evidently, either U_b is a separating vertex of $\mathcal{F}_{\{a,b,c\}}$, or $\mathcal{F}_{\{a,b,c\}} \setminus U_b$ is connected. In the latter case we build from $\mathcal{F}_{\{a,b,c\}}$ a locally orientable graph $\mathcal{W}^{ac}$ by deleting all the vertices of U_b and contracting $L_b \cap \bar{R}_b$ to the terminal a' and $\bar{L}_b \cap R_b$ to the terminal c' (see Figure 4.3(a)). (Informally, $\mathcal{W}^{ac}$ is the common part of $\mathcal{W}_{a,b}$ and $\mathcal{W}_{b,c}$ in $\mathcal{F}_{\{a,b,c\}}$.) An S-mincut $\mathcal{C}$ of G that separates $L_b \cap \bar{R}_b$ from $\bar{L}_b \cap R_b$ and thus generates an (a', c')-mincut $\mathcal{C}'$ in $\mathcal{W}^{ac}$ we call an *extension* of $\mathcal{C}'$.

LEMMA 4.2. (i) *The graph $\mathcal{W}^{ac}$ is a strip of width $\lambda' = \lambda_S - \frac{1}{2} \deg U_b < \frac{1}{2}\lambda_S$.*

(ii) *All of its transversal cuts, and only they, are extendible to S-mincuts.*

(iii) *If a 2-partition of $L_b \cup R_b$ enters an extension of some transversal cut of*

FIG. 4.4. *Dynamics of $\mathcal{F}_{\{a,b,c\}}$ in the asymmetric case.*

$\mathcal{W}^{ac}$, *then it enters some extension of any such cut.* (*Informally, all transversal cuts of $\mathcal{W}^{ac}$ are interchangeable in S-mincuts.*)

Proof. (i) Observe that deletion of vertices does not give rise to new coherent paths; thus, it preserves the acyclicity of a locally orientable graph. For the same reason, any transversal 2-partition induces a transversal 2-partition in the new graph. Since the contraction of a side of a transversal 2-partition preserves acyclicity, $\mathcal{W}^{ac}$ is an acyclic two-terminal balanced locally orientable graph. Hence, it is a strip by part (i) of the Strip Lemma. It is easy to see, applying Lemma 2.1, that $\lambda_S = c(L_b, \bar{L}_b) = \deg a' + \frac{1}{2}\deg U_b$. Since $\lambda' = \deg a'$, we get $\lambda' = \lambda_S - \frac{1}{2}\deg U_b$. Assume that $\lambda' \geqslant \frac{1}{2}\lambda_S$. Then $\deg U_b \leqslant \lambda_S$, which means that $(L_b \cap R_b, \bar{L}_b \cup \bar{R}_b)$ is a 2-partition of cardinality at most λ_S separating b from $\{a, c\}$, a contradiction.

(ii) Let us denote by $\mathcal{W}'$ the graph obtained from $\mathcal{F}_{\{a,b,c\}}$ by deleting U_b. By (i), any transversal cut $(Z, \bar{Z})$ of $\mathcal{W}^{ac}$ has cardinality λ' and generates a 2-partition $(X, \bar{X})$ of the same cardinality in $\mathcal{W}'$. By Lemma 2.1, the edge-set of the 2-partition $(X \cup U_b, \bar{X})$ in $\mathcal{F}_{\{a,b,c\}}$ has exactly by $\frac{1}{2}\deg U_b$ more edges, i.e., $\lambda' + \frac{1}{2}\deg U_b = \lambda_S$ edges. Thus, it is a cut and is an extension of $(Z, \bar{Z})$.

Conversely, let $(X, \bar{X})$ be an S-mincut separating $L_b \cap \bar{R}_b$ from $\bar{L}_b \cap R_b$. It generates a 2-partition of cardinality λ' in $\mathcal{W}'$ and a 2-partition of the same cardinality separating a' and c' in $\mathcal{W}^{ac}$. Thus, it is a λ'-cut separating a' and c', i.e., a transversal cut.

(iii) Since there are exactly two such partitions, namely, $((L_b \cap \bar{R}_b) \cup U_b, \bar{L}_b \cap R_b)$ and $(L_b \cap \bar{R}_b, (\bar{L}_b \cap R_b) \cup U_b)$, one can proceed exactly as in the proof of (ii). □

Remark. Observe that Lemma 4.2 remains true for a more general definition of an extension, in which $\mathcal{C}$ is required only to separate the ends of all edges between $L_b \cap \bar{R}_b$ and $\bar{L}_b \cap \bar{R}_b$ that lie in $L_b \cap \bar{R}_b$ and the ends of all edges between $\bar{L}_b \cap \bar{R}_b$ and $\bar{L}_b \cap R_b$ that lie in $\bar{L}_b \cap R_b$. Such a definition would allow us to consider, for example, the cuts $\mathcal{C}_3$ and $\mathcal{C}_4$ on Figure 4.3(b) as extensions of $\mathcal{C}'$, while according to the current definition, the only extensions of $\mathcal{C}'$ are $\mathcal{C}_1$ and $\mathcal{C}_2$. However, in what follows we do not consider such a generalization of the notion of extension.

Dynamics of $\mathcal{F}_{\{a,b,c\}}$ in the asymmetric subcase are induced by those of $\mathcal{F}_{\{a,c\}} = \mathcal{W}_{a,c}$ (see section 4.2) straightforwardly, except for the case when U_b, and possibly some other units, is contracted to U^{new}. Let us consider this case; it occurs when $U_b \in \mathcal{R}_c(U_1) \cap \mathcal{R}_a(U_2)$, up to flipping of U_1 and U_2 (see Figure 4.4). The only specifics in this case is that U^{new} becomes a new terminal (in fact, $\widehat{U}_b$).

Remark. To translate the definition of the contracted set into the terms of $\mathcal{F}_{\{a,b,c\}}$, one has to take into account that a coherent path in $\mathcal{W}_{a,c}$ is either a coherent path in $\mathcal{F}_{\{a,b,c\}}$, or a concatenation of two coherent paths: a path to U_b in L_b and a path from U_b in R_b. Under this translation, the above condition on U_b is equivalent to $U_1 \in \mathcal{R}_a(U_b) = L_b$ and $U_2 \in \mathcal{R}_c(U_b) = R_b$.

There is a special situation when not only U_b but U_a as well is contracted to U^{new}; this occurs when $U_1 = U_a$ (see Figure 4.4(b)). In this situation the asymmetric

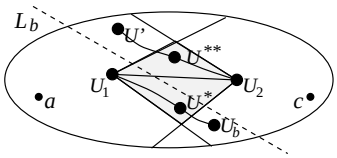

FIG. 4.5. *To the proof of Lemma* 4.3.

three-element case degenerates, and we arrive at the case considered at the end of section 4.2; that is, $\mathcal{F}_{\{a,b,c\}}$ becomes equal to $\mathcal{W}_{\{a,b\},c} = \mathcal{F}_{b,c} = \mathcal{F}_{a,c}$. Evidently, U_a above can be replaced by U_c.

Finally, if $\{U_1, U_2\} = \{U_a, U_b\}$, then the system of S-mincuts vanishes.

As we see, the reduction of the three-element case to the two-element case is defined via subsets L_b and R_b. Let us consider the dynamics of L_b (those of R_b are similar) in the case when $\mathcal{F}_{\{a,b,c\}}$ does not degenerate.

LEMMA 4.3. *The set L_b is extended if and only if $U_1 \in L_b$ and $U_2 \notin L_b$ (up to flipping of U_1 and U_2). The new part of $\widehat{L}_b$ is the union of units U' such that $U' \in \mathcal{R}_a(U_2)$ and $U' \notin L_b$.*

Proof. The "if" part of the first statement is trivial, since U_2 is added to L_b.

Let U' be a new unit in $\widehat{L}_b$ and let $(U', \dots, U^{\text{new}}, \dots, U_b)$ be a coherent path in $\widehat{\mathcal{W}}_{a,c}$; clearly, it lies entirely in $\widehat{\mathcal{R}}_c(U')$. Its edges form two coherent paths in $\mathcal{F}_{\{a,b,c\}}$: $(U', \dots, U^*) \in \mathcal{R}_c(U')$ and $(U^{**}, \dots, U_b) \in \mathcal{R}_c(U^{**})$ (see Figure 4.5). Since U' is new in $\widehat{L}_b$, we have $U^* \neq U^{**}$, and thus the statement holds for the case when U^{new} contains only U_1 and U_2. Otherwise we may assume w.l.o.g. that $U^*, U^{**} \subset U^{\text{new}} = \mathcal{R}_c(U_1) \cap \mathcal{R}_a(U_2)$. Hence in $\mathcal{W}_{a,c}$ there exist coherent paths $(U^*, \dots, U_2) \in \mathcal{R}_c(U^*)$ and $(U_1, \dots, U^{**}) \in \mathcal{R}_c(U_1)$. The first of them does not contain U_b by assumption, and thus $(U', \dots, U^*, \dots, U_2)$ is a coherent path in $\mathcal{F}_{\{a,b,c\}}$. Therefore, $U_2 \in L_b$ would imply $U' \in L_b$ in a contradiction to the assumption that U' is new in $\widehat{L}_b$. The path $(U_1, \dots, U^{**}, \dots, U_b)$ does not contain U_b twice (as a coherent path in $\mathcal{W}_{a,c}$), and thus is a coherent path in $\mathcal{F}_{\{a,b,c\}}$; hence, $U_1 \in L_b$. The assertion follows. ∎

4.4. A three-element subset S: The symmetric subcase. Assume now that all types of $\{a,b,c\}$-cuts exist in G. Let $\mathcal{C}_x = (V_x, \bar{V}_x)$ be the $\{y,z\}$-tight $(\{y,z\}, x)$-mincut (Figure 4.6(a)); here and in what follows $x, y, z \in \{a,b,c\}$, $x \neq y \neq z$. As usual, these three 2-partitions define the following eight subsets of V: $V^{\varnothing} = V_a \cap V_b \cap V_c$; $V^a = \bar{V}_a \cap V_b \cap V_c$; $V^b = V_a \cap \bar{V}_b \cap V_c$; $V^c = V_a \cap V_b \cap \bar{V}_c$; $V^{ab} = \bar{V}_a \cap \bar{V}_b \cap V_c$; $V^{bc} = V_a \cap \bar{V}_b \cap \bar{V}_c$; $V^{ac} = \bar{V}_a \cap V_b \cap \bar{V}_c$; $V^{abc} = \bar{V}_a \cap \bar{V}_b \cap \bar{V}_c$. These subsets are called *cells*.

The following statement is crucial for the rest of our results (see Figure 4.6(b)).

3-STAR LEMMA. (i) $V^{abc} = \varnothing$.

(ii) *Vertices of V^{xy} can be adjacent only to vertices of V^{xy}, V^x, V^y; besides, $c(V^{xy}, V^x) = c(V^{xy}, V^y)$.*

Proof. Let us consider the cut $\mathcal{C}^{x,xy} = \mathcal{C}_z \cap \bar{\mathcal{C}}_x = (V^x \cup V^{xy}, V \setminus (V^x \cup V^{xy}))$. Since both $\mathcal{C}_z$, $\mathcal{C}_x$ are minimum (x,z)-cuts, the cut $\mathcal{C}^{x,xy}$ is a minimum (x,z)-cut as well, and hence $c(\mathcal{C}^{x,xy}) = \lambda_S$. Similarly, $\mathcal{C}^{y,xy} = \mathcal{C}_z \cap \bar{\mathcal{C}}_y = (V^y \cup V^{xy}, V \setminus (V^y \cup V^{xy}))$ is a minimum (y,z)-cut with $c(\mathcal{C}^{y,xy}) = \lambda_S$. Therefore, both $\mathcal{C}^{x,xy}$ and $\mathcal{C}^{y,xy}$ are minimum (x,y)-cuts. According to Lemma 2.1(i), there are no edges between V^{xy} and $V \setminus (V^x \cup V^{xy} \cup V^y)$, and, moreover, $c(V^{xy}, V^x) = c(V^{xy}, V^y)$, so assertion (ii) is proved.

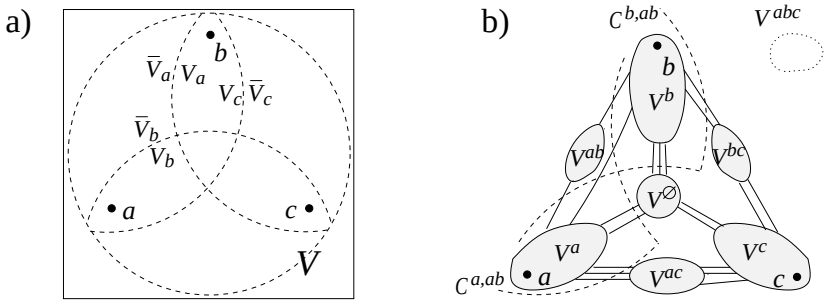

FIG. 4.6. *Structure of $\mathcal{F}_{\{a,b,c\}}$ in the symmetric case.*

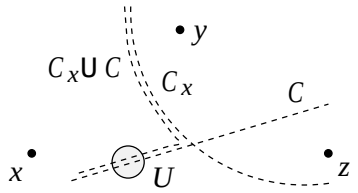

FIG. 4.7. *To the proof of Lemma* 4.4(i).

We know already that there are no edges between V^{abc} and V^{xy}. By Lemma 2.1(i) applied to the minimum (x,y)-cuts $\mathcal{C}_x$ and $\mathcal{C}_y$, we get that there are no edges between $V^{xy} \cup V^{abc}$ and $V^z \cup V^\varnothing$. So, there are no external edges incident to V^{abc} at all. Since the initial graph is connected, we thus get $V^{abc} = \varnothing$. □

Properties of the cuts $\mathcal{C}_x$ are similar to those of the cuts $(L_b, \bar{L}_b)$ and $(R_b, \bar{R}_b)$ (see section 4.2). In particular, the first statement below can be regarded as an analogue of Lemma 4.1(iii).

LEMMA 4.4. (i) *Contraction of the inner side V_x of $\mathcal{C}_x$ in $\mathcal{F}_{\{a,b,c\}}$ gives the underlying undirected graph of the strip $\mathcal{W}_{\{y,z\},x}$.*

(ii) *Every unit, except for $V^\varnothing$, corresponds in this way to a vertex in either one or two strips.*

(iii) *For every unit $U \neq V^\varnothing$, the 2-partitions of its star induced by the 2-partitions at the corresponding vertices in these strips coincide.*

Proof. (i) Since all $(\{y,z\},x)$-mincuts are S-mincuts and $\mathcal{C}_x$ is the $\{y,z\}$-tight $(\{y,z\},x)$-mincut, the result of the contraction still represents all $(\{y,z\},x)$-mincuts. Therefore, the only thing we have to prove is that no $(\{y,z\},x)$-unit distinct from the contracted one can be divided by an S-mincut. Indeed, let U, to the contrary, be such a unit and $\mathcal{C}$ be an S-mincut dividing U. W.l.o.g. we can assume that $\mathcal{C}$ is an $(z,\{x,y\})$-cut containing z inside; recall that z lies also inside $\mathcal{C}_x$ (see Figure 4.7). Then $\mathcal{C}_x \cup \mathcal{C}$ is a $(\{y,z\},x)$-mincut dividing U, a contradiction.

(ii) The proof follows from (i) immediately.

(iii) Assume w.l.o.g. that U lies in V^{xy}. According to (i) and (ii), U is a unit in the strips $\mathcal{W}_{\{y,z\},x}$ and $\mathcal{W}_{\{x,z\},y}$. By Lemma 3.8, both these strips are contractions of the same strip $\mathcal{W}_{x,y}$. Moreover, in both cases U is not a contracted unit, so local orientations at U in both cases are inherited from $\mathcal{W}_{x,y}$, and thus coincide. □

Let us assign to every unit, except for $V^\varnothing$, the 2-partition of its star defined in

Lemma 4.4(iii), and to $V^{\varnothing}$ the trivial 2-partition. Then $\mathcal{F}_{\{a,b,c\}}$ becomes a locally orientable graph. Evidently, the contraction of $\mathcal{F}_{\{a,b,c\}}$ described in Lemma 4.4(i) yields now the strip $\mathcal{W}_{\{y,z\},x}$ itself. One can say, thus, that all the strips $\mathcal{W}_{\{y,z\},x}$ "are glued" into the aggregate structure $\mathcal{F}_{\{a,b,c\}}$ because they "coincide on intersections."

LEMMA 4.5. (i) *The locally orientable graph $\mathcal{F}_{\{a,b,c\}}$ is balanced and acyclic.*

(ii) *Each S-mincut is transversal in $\mathcal{F}_{\{a,b,c\}}$.*

Proof. (i) Evidently, $\mathcal{F}_{\{a,b,c\}}$ is balanced, since the 2-partition at each nonterminal unit is inherited from a strip. Let us prove its acyclicity. Indeed, let there exist a cyclic coherent path P. By the definition, any two units lying on P are separated by an S-mincut. However, this cut fails to be transversal, since its edge-set has at least two edges in common with P. Thus, (i) follows from (ii).

(ii) First, let us observe that a coherent path in $\mathcal{F}_{\{a,b,c\}}$ that enters V^x cannot leave it. Indeed, the 2-partition $(V^x, \bar{V}^x)$ can be represented as $\mathcal{C}^{x,xy} \cap \mathcal{C}^{x,xz}$ (see the proof of the 3-Star Lemma) and is thus a minimum $(x, \{y,z\})$-cut. Therefore, a coherent path in $\mathcal{F}_{\{a,b,c\}}$ that enters and leaves V^x yields in $\mathcal{W}_{x,\{y,z\}}$ a coherent path that intersects at least twice the edge-set of the transversal cut $(V^x, \bar{V}^x)$, a contradiction.

Now let $\mathcal{C}$ be an S-mincut contradicting the claim, and let P be a coherent path intersecting $E_{\mathcal{C}}$ at least twice. Assume w.l.o.g. that $\mathcal{C}$ is an $(x, \{y,z\})$-cut; then it is represented as a transversal cut in $\mathcal{W}_{x,\{y,z\}}$. If the path P lies entirely in $V^x \cup V^{xy} \cup V^{xz}$, then it is represented as a coherent path in $\mathcal{W}_{x,\{y,z\}}$, a contradiction. Thus, by part (ii) of the 3-Star Lemma, P must enter either $V^{\varnothing}$, or V^y, or V^z. However, $V^{\varnothing}$ is a terminal, and a path entering V^y or V^z cannot leave them. Hence, in this case the contraction takes P to a coherent path in $\mathcal{W}_{x,\{y,z\}}$, and we are done. □

Therefore, an arbitrary undirected graph with three distinguished vertices in the symmetric case, as well as in the asymmetric one, defines canonically an acyclic balanced locally orientable graph $\mathcal{F}_{\{a,b,c\}}$.

Remark. Recall that a strip can be considered as a general graph model of a two-ended object of a constant width. In a sense, the locally orientable graph $\mathcal{F}_{\{a,b,c\}}$ with the structure given by Figure 4.6(b) represents a general *three-ended object of a constant width.*

The following statement stems from the proof of Lemma 4.5.

FACT 4.6. *Any intercell coherent path in $\mathcal{F}_{\{a,b,c\}}$ belongs to one of the following four types*: V^x-V^{xy}; V^x-V^{xy}-V^y; V^x-V^y; V^x-$V^{\varnothing}$.

According to Lemma 4.1(i) and (ii), in the asymmetric subcase one can reconstruct the strip $\mathcal{W}_{a,c}$ starting from $\mathcal{F}_{\{a,b,c\}}$ and using the cuts $(L_b, \bar{L}_b)$ and $(R_b, \bar{R}_b)$. In a similar way, in the symmetric subcase one can obtain each of the three strips $\mathcal{W}_{x,y}$ by a contraction of $\mathcal{F}_{\{a,b,c\}}$ defined in terms of the cuts $\mathcal{C}_x$.

LEMMA 4.7. *Let us contract $V_y \cap V_z$ in $\mathcal{F}_{\{a,b,c\}}$ and assign to the contracted unit the 2-partition of its star into the edges crossing the cuts $\mathcal{C}_y$ and $\mathcal{C}_z$, respectively. The result is the strip $\mathcal{W}_{y,z}$.*

Proof (to visualize the statement and the proof observe that $V_y \cap V_z = V^{\varnothing} \cup V^x$, see Figure 4.6). Let us denote by $\mathcal{W}$ the locally orientable graph defined in the statement of the lemma. (It is well defined due to part (ii) of the 3-Star Lemma.) We consider the two following ways of constructing the strip $\mathcal{W}_{\{x,z\},y}$. First, we take the strip $\mathcal{W}_{y,z}$ and, according to Lemma 3.8, contract the cone of x (more exactly, of the unit U_x containing x) that contains z. Second, we take $\mathcal{F}_{\{a,b,c\}}$ and contract the inner part V_y of the cut $\mathcal{C}_y$ (see Lemma 4.4(i)). Since both ways yield the same result, we

conclude that all units $U \in V^y \cup V^{yx} \cup V^{yz}$ in $\mathcal{W}_{y,z}$ and $\mathcal{F}_{\{a,b,c\}}$ coincide, as well as the 2-partitions at these units. Proceeding in the same way with the strip $\mathcal{W}_{\{x,y\},z}$, we get the coincidence for all units, except for U_x in $\mathcal{W}_{y,z}$ and $V_y \cap V_z$, which is a single unit in $\mathcal{W}$; thus, $U_x = V_y \cap V_z$. Observe that, on one hand, the two sides of U_x in $\mathcal{W}$ are just the intersections of its star with the edge-sets of the cuts $\mathcal{C}_y$ and $\mathcal{C}_z$. On the other hand, by Fact 3.6(iii), these two cuts correspond to the cones of U_x in $\mathcal{W}_{y,z}$ via our contraction mapping. Thus, the 2-partitions at U_x in the two graphs coincide as well, and the proof is completed. □

Similarly to the asymmetric case, one can build a locally orientable graph $\mathcal{W}^{xy}$, $x, y \in \{a, b, c\}$, $x \neq y$, by deleting from $\mathcal{F}_{\{a,b,c\}}$ all the vertices of $V^{\varnothing} \cup V^z \cup V^{xz} \cup V^{yz}$, $z \neq x, y$, and contracting V^x and V^y to terminals. (Informally, $\mathcal{W}^{ab}$, $\mathcal{W}^{bc}$, and $\mathcal{W}^{ac}$ are the common parts of all three strips $\mathcal{W}_{a,b}$, $\mathcal{W}_{b,c}$, and $\mathcal{W}_{a,c}$.) An S-mincut $\mathcal{C}$ of G that separates V^x from V^y, and thus generates a cut $\mathcal{C}'$ in $\mathcal{W}^{xy}$ separating its terminals, we call an *extension* of $\mathcal{C}'$ (compare with the definition preceding Lemma 4.2). The following statement is an analogue of Lemma 4.2.

LEMMA 4.8. (i) *The graphs $\mathcal{W}^{xy}$ are strips of width $\lambda^{xy} \leqslant \frac{1}{2}\lambda_S$.*

(ii) *All their transversal cuts, and only they, are extendible to S-mincuts.*

(iii) *Each pair of transversal cuts of $\mathcal{W}^{xy}$ and $\mathcal{W}^{xz}$, $z \neq x, y$, has a mutual extension to a minimum $(x, \{y, z\})$-cut.*

(iv) *If a 2-partition of $V \setminus V^{xy}$ enters an extension of some transversal cut of $\mathcal{W}^{xy}$, then it enters some extension of any such cut.* (*Informally, all transversal cuts of this strip are interchangeable in S-mincuts.*)

Proof. (i) Observe that, according to Lemma 4.7, one can construct $\mathcal{W}^{xy}$ in a similar way starting from $\mathcal{W}_{x,y}$. Therefore, the proof of Lemma 4.2(i) applies with minor changes: the assumption $\lambda^{xy} > \frac{1}{2}\lambda_S$ implies the existence of a 2-partition of cardinality less than λ_S separating z from $\{x, y\}$.

(ii) The "all" part of the assertion is proved exactly as in Lemma 4.2. To prove the "only" part we consider an arbitrary cut $\mathcal{C}$ separating V^x from V^y. Assume, w.l.o.g., that $\mathcal{C}$ is an $(x, \{y, z\})$-cut containing x inside. Replacing $\mathcal{C}$ by $\mathcal{C} \cup \mathcal{C}_y$ we arrive to the case considered in the proof of Lemma 4.2(ii).

(iii) It follows easily from the proof of Lemma 4.2(ii) that any transversal cut $\mathcal{C}'_1$ of $\mathcal{W}^{xy}$ can be extended to an $(x, \{y, z\})$-cut $\mathcal{C}_1$ of $\mathcal{F}_{\{a,b,c\}}$. Then $\tilde{\mathcal{C}}_1 = \mathcal{C}_1 \cap \mathcal{C}_z$ is a minimum (x, z)-cut, as the intersection of minimum (x, z)-cuts. Observe that $\tilde{\mathcal{C}}_1$ is an $(x, \{y, z\})$-cut. Similarly, starting from a transversal cut $\mathcal{C}'_2$ of $\mathcal{W}^{xz}$ we find an $(x, \{y, z\})$-cut $\tilde{\mathcal{C}}_2$. Their union is evidently a mutual extension of $\mathcal{C}'_1$ and $\mathcal{C}'_2$. Observe that $\tilde{\mathcal{C}}_1 \cup \tilde{\mathcal{C}}_2$ is the unique mutual extension of $\mathcal{C}'_1$ and $\mathcal{C}'_2$, since by definition, each such extension contains V^x inside and $V^{\varnothing} \cup V^y \cup V^z \cup V^{yz}$ outside.

(iv) Let $\mathcal{C}$ be an extension of some transversal cut of $\mathcal{W}^{xy}$ and let $\mathcal{C}'_1$ be an arbitrary transversal cut of $\mathcal{W}^{xy}$. Assume w.l.o.g. that both x and $V^{\varnothing}$ lie inside $\mathcal{C}$. Recall that $\mathcal{C}^{y,xy}$ defined in the proof of the 3-Star Lemma is a minimum (x, y)-cut. Therefore, $\tilde{\mathcal{C}} = \mathcal{C} \cap \bar{\mathcal{C}}^{y,xy}$ is also a minimum (x, y)-cut. On the other hand, similarly to the proof of Lemma 4.2(ii), there exists an extension $\mathcal{C}_1$ of $\mathcal{C}'_1$ such that $V^x \cup V^{xz}$ lies inside $\mathcal{C}_1$ and $V^y \cup V^{yz} \cup V^{\varnothing} \cup V^z$ outside it. The cut $\tilde{\mathcal{C}} \cup \mathcal{C}_1$ is thus an extension of $\mathcal{C}'_1$ (since $\bar{\mathcal{C}}$ is an extension of the cut separating the unit U_x in $\mathcal{W}^{xy}$), and it partitions $V \setminus V^{xy}$ in the same way as $\mathcal{C}$. □

Let us analyze the incremental dynamics of $\mathcal{F}_S$ in the symmetric subcase. Since $\mathcal{F}_S$ is glued from the strips $\mathcal{W}_{x,\{y,z\}}$ (or their extensions $\mathcal{W}_{x,y}$), it suffices to study the dynamics of these strips. According to section 4.2, insertion of an edge (u_1, u_2) modifies each of the strips in such a way that all the units, as well as the canonical

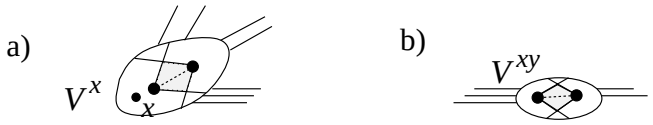

FIG. 4.8. *Dynamics of $\mathcal{F}_{\{a,b,c\}}$ in the symmetric case,* I.

2-partitions of their stars, remain the same except for the units contracted into the new one (containing both u_1 and u_2). Hence, by Lemma 4.4, the same holds for the locally orientable graph $\mathcal{F}_S$. According to the same lemma, if for some strip $\widehat{\mathcal{W}}_{x,\{y,z\}}$ the single new unit is not the terminal containing y and z, then it coincides with the new unit U^{new} of $\mathcal{F}_S$. The same is true if for some strip $\widehat{\mathcal{W}}_{x,y}$ the new unit is not the unit containing z.

In the description of incremental dynamics of $\mathcal{F}_S$ we make use of the partition into the cells V^x, V^{xy}, $V^{\varnothing}$. Therefore, to be self-contained, we have to describe the changes in the cells; note that it suffices for this to clear up the dynamics of the sets V_x.

Below we consider all the nine distinct possibilities to insert a new edge (u_1, u_2), $u_1 \in U_1$, $u_2 \in U_2$, with respect to the cell partition.

Case 1. If $U_1 = U_2$ (in particular, $U_1 = U_2 = V^{\varnothing}$), then $\mathcal{F}_S$ evidently remains the same.

Case 2. If U_1 and U_2 belong to the same set V^{xy} (see Figure 4.8(a)), we can trace the dynamics in any of $\mathcal{W}_{x,\{y,z\}}$, $\mathcal{W}_{\{x,z\},y}$, and $\mathcal{W}_{x,y}$. Clearly, the definition of the contracted unit U^{new} (see section 4.2) can be translated straightforwardly into terms of $\mathcal{F}_S$: U^{new} results from the contraction of U_1, U_2, and the units and edges on the coherent paths between U_1 and U_2 (all of them belong to V^{xy}). Since the contracted unit in the modified strip is nonterminal, this contraction is the only change in $\mathcal{F}_S$. Note that the changes are localized in V^{xy} and can be traced also in $\mathcal{W}^{xy}$.

Case 3. Similarly, if $U_1, U_2 \in V^x$ (see Figure 4.8(b)), we can trace the changes in any of the strips $\mathcal{W}_{x,\{y,z\}}$, $\mathcal{W}_{x,y}$, or $\mathcal{W}_{x,z}$ to define U^{new} in the same way. It is easy to show that the changes are localized in V^x.

In all the above cases all the cuts $\mathcal{C}_a$, $\mathcal{C}_b$, $\mathcal{C}_c$ remain the same, and thus the partition into cells is stable.

Case 4. Let now $U_1 \in V^x$, $U_2 \in V^{xy}$ (see Figure 4.9(a)). As in the previous two cases, the new unit U^{new} can be defined via $\mathcal{W}_{x,\{y,z\}}$, $\mathcal{W}_{x,y}$, or $\mathcal{W}_{x,z}$. The strip $\mathcal{W}_{x,y}$ can be used also for establishing the dynamics of the set V_y via Lemma 4.3; in terms of this lemma, it is the set L_z. By the same lemma, the new part of $\widehat{V}_y$ is $V' = \mathcal{R}_x(U_2) \setminus V_y$. Another way is to use $\mathcal{W}_{\{x,z\},y}$, where the set V_y forms the terminal U_{xz} containing x and z; then the new part of $\widehat{V}_y = \widehat{U}_{yz}$ is $\mathcal{R}_x(U_2) \setminus U_{yz}$. It follows from Fact 4.6 that V' is contained in V^{xy} and coincides with the cone of U_2 in $\mathcal{W}^{xy}$ in the direction to the terminal containing x, minus this terminal. From the dynamics of $\mathcal{W}_{x,\{y,z\}}$ and $\mathcal{W}_{z,\{x,y\}}$, respectively, it is clear that the sets V_x and V_z do not change. Therefore, all the cells are stable except for $\widehat{V}^x = V^x \cup V'$ and $\widehat{V}^{xy} = V^{xy} \setminus V'$.

Case 5. If $U_1 \in V^{xz}$, $U_2 \in V^{xy}$ (see Figure 4.9(b)), we can use strips $\mathcal{W}_{x,\{y,z\}}$, $\mathcal{W}_{x,y}$, and $\mathcal{W}_{x,z}$ for determining U^{new}. In this case, there are no coherent paths between U_1 and U_2; hence, $U^{\text{new}} = \{U_1, U_2\}$. Using strips $\mathcal{W}_{x,y}$ and $\mathcal{W}_{x,z}$, respectively,

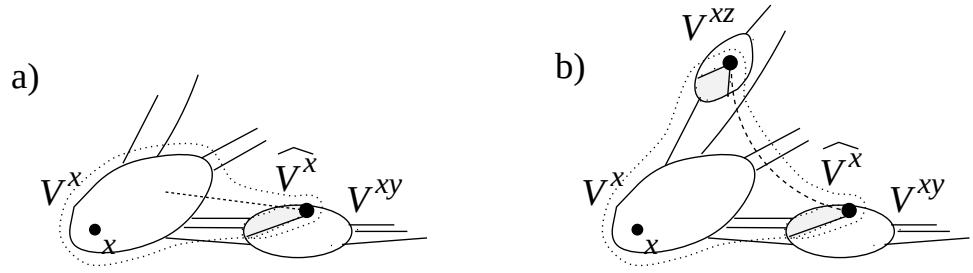

FIG. 4.9. *Dynamics of* $\mathcal{F}_{\{a,b,c\}}$ *in the symmetric case,* II.

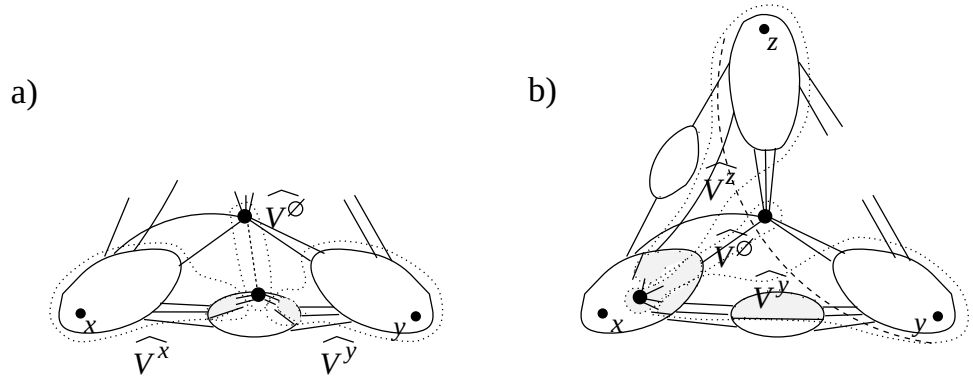

FIG. 4.10. *Dynamics of* $\mathcal{F}_{\{a,b,c\}}$ *in the symmetric case,* III.

in the same way as $\mathcal{W}_{\{x,z\},y}$ in the previous case, we establish that $\widehat{V}_y = V_y \cup \mathcal{R}_x(U_2)$ and $\widehat{V}_z = V_z \cup \mathcal{R}_x(U_1)$. Therefore, $\widehat{V}^x = V^x \cup \mathcal{R}_x(U_1) \cup \mathcal{R}_x(U_2)$, while V^{xy} and V^{xz} are cut down correspondingly.

Case 6. If $U_1 = V^\varnothing$, $U_2 \in V^{xy}$ (see Figure 4.10(a)), we use the strip $\mathcal{W}_{x,y}$. Once again $U^{\text{new}} = \{U_1, U_2\}$. Both V_x and V_y grow to $V_x \cup \mathcal{R}_x(U_2)$ and $V_y \cup \mathcal{R}_y(U_2)$, respectively. Therefore, $\widehat{V}^x = V^x \cup \mathcal{R}_x(U_2) \setminus U_2$, $\widehat{V}^x = V^x \cup \mathcal{R}_x(U_2) \setminus U_2$, and $\widehat{V}^\varnothing = V^\varnothing \cup U_2$.

Case 7. If $U_1 \in V^x$, $U_2 = V^\varnothing$ (see Figure 4.10(b)), we consider the strip $\mathcal{W}_{x,\{y,z\}}$ with terminals U_x, $x \in U_x$, and $U_{yz} = V_x$, $y, z \in U_{yz}$, $V^\varnothing \subset U_{yz}$. By section 4.2, the cone $\mathcal{R}_{yz}(U_1)$ is added to U_{yz}, resulting in $\widehat{V}_x = V_x \cup \mathcal{R}_{yz}(U_1)$. Evidently, strips $\mathcal{W}_{\{x,z\},y}$ and $\mathcal{W}_{\{x,y\},z}$ do not change; hence V_y and V_z are stable. Using the sets $\widehat{V}_x$, $\widehat{V}_y = V_y$, and $\widehat{V}_z = V_z$ in accordance to the definition of a cell, we get $U = \widehat{V}^\varnothing = V^\varnothing \cup (V^x \cap \mathcal{R}_{yz}(U_1))$, $\widehat{V}^y = V^y \cup (V^{xy} \cap \mathcal{R}_{yz}(U_1))$, $\widehat{V}^z = V^z \cup (V^{xz} \cap \mathcal{R}_{yz}(U_1))$, and each one of V^x, V^{xy}, V^{xz} is lessened by the corresponding part of $\mathcal{R}_{yz}(U_1)$.

A special subcase occurs when $U_1 = U_x$. Then $\mathcal{W}_{x,\{y,z\}}$ vanishes, and we arrive at the asymmetric case for $\mathcal{F}_{\{y,x,z\}}$. In terms of section 4.3, $\widehat{U}_x = V_x \cup V^\varnothing$, $\widehat{L}_x = V_z$, $\widehat{R}_x = V_y$, $\widehat{V}_{yz} = V_{yz}$, and $\widehat{\mathcal{W}}_{yz} = \mathcal{W}_{yz}$.

Case 8. The case $U_1 \in V^x$, $U_2 \in V^{yz}$ (see Figure 4.11(a)) is equivalent to a composition of the two previous cases: apply the transformation of Case 6 and the transformation of Case 7 with x replaced by y.

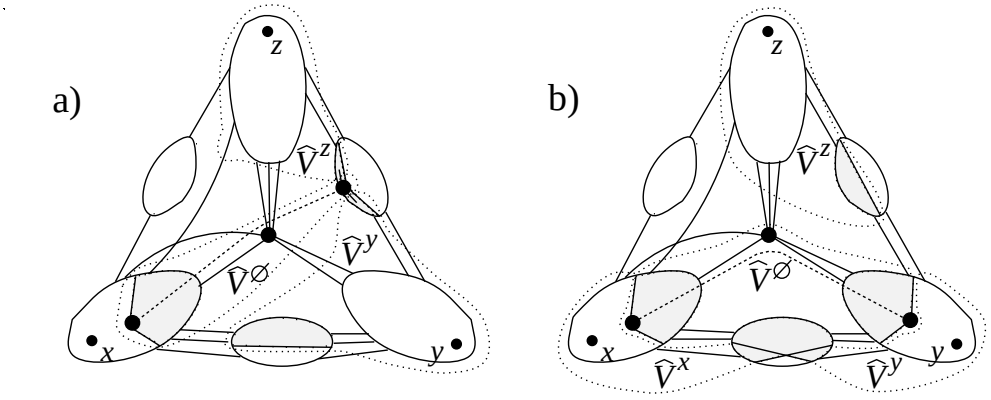

FIG. 4.11. *Dynamics of* $\mathcal{F}_{\{a,b,c\}}$ *in the symmetric case,* IV.

To see this, assume first that $V^\varnothing \neq \varnothing$ and choose an arbitrary vertex $w \in V^\varnothing$. Then the transformation of $\mathcal{F}_{\{a,b,c\}}$ equals the sum of the transformations caused by adding *two* edges: (u_1, w) and (w, u_2). Indeed, addition of each one of these edges affects only one of the strips $\mathcal{W}_{yz}$ and $\mathcal{W}_{x,\{y,z\}}$, and their dynamics are exactly the same as in Cases 6 and 7, respectively.

The case $V^\varnothing = \varnothing$ can be reduced to the previous one by the following trick. We add to G a new vertex w and three new edges (a, w), (b, w), (c, w). It is easy to see that S-mincuts of the new graph G^* correspond bijectively to S-mincuts of G; more precisely, $(X, \bar{X})$ corresponds to $(X, \bar{X} \cup \{w\})$ if and only if $|X \cap S| = 1$. Hence, all the cells of $\mathcal{F}^*_{\{a,b,c\}}$ coincide with the corresponding cells of $\mathcal{F}_{\{a,b,c\}}$ except for $(V^*)^\varnothing = \{w\}$. Since $(V^*)^\varnothing$ is now nonvoid, the transformation taking $\mathcal{F}^*_{\{a,b,c\}}$ to $\widehat{\mathcal{F}}^*_{\{a,b,c\}}$ is exactly as described above; to obtain $\widehat{\mathcal{F}}_{\{a,b,c\}}$ it suffices just to delete w.

Case 9. The last case occurs when $U_1 \in V^x$, $U_2 \in V^y$ (see Figure 4.11(b)). It can be considered as a composition of two Case 7's: apply the transformation of Case 7 as described and the same transformation with x replaced by y. In this situation the two transformations are not independent: their joint action forces the set $V' = V^{xy} \cap \mathcal{R}_{yz}(U_1) \cap \mathcal{R}_{xz}(U_2)$ to be added to both V_x and V_y and thus to move from V^{xy} to $V^\varnothing$. The validity of the above description can be observed in the same way as in the previous case; the two edges added in this case are the edges between U_1 and $V^\varnothing$ and between $V^\varnothing$ and U_2.

The only special subcase not yielded by double application of Case 7 occurs if $U_1 = U^x$, $U_2 = U^y$. It results in vanishing of both strips $\mathcal{W}_{x,\{y,z\}}$ and $\mathcal{W}_{y,\{x,z\}}$, and thus leads to degeneration of $\mathcal{F}_{\{a,b,c\}}$ to $\widehat{\mathcal{W}}_{\{x,y\},z} = \widehat{\mathcal{F}}_{x,z} = \widehat{\mathcal{F}}_{y,z}$; evidently, $\widehat{\mathcal{W}}_{\{x,y\},z}$ coincides with $\mathcal{W}_{\{x,y\},z}$.

4.5. An arbitrary subset S with the path structure. Let $S = \{a = b_0, b_1, \ldots, b_{r-1}, b_r = c\}$; assume that there exist exactly r distinct partitions of S by S-mincuts and each of them is of the form $(\{a, b_1, \ldots, b_{i-1}\}, \{b_i, \ldots, b_{r-1}, c\})$, $1 \leqslant i \leqslant r$. This means that the skeleton structure (in the sense defined in section 4.1) for this case is the path $(a, b_1, \ldots, b_{r-1}, c)$ (see Figure 4.12). Similarly to the case of the path (a, b, c) (section 4.3), all S-mincuts are represented by the (a, c)-strip $\mathcal{W}_{a,c}$. We define the structure of local orientability on the graph $\mathcal{F}_S$ by keeping that of $\mathcal{W}_{a,c}$ at all the units, except for the units U_{b_i} containing b_i, $1 \leqslant i \leqslant r-1$, which are now regarded as

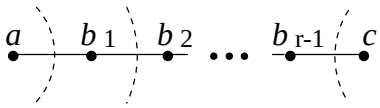

FIG. 4.12. *Path skeleton structure.*

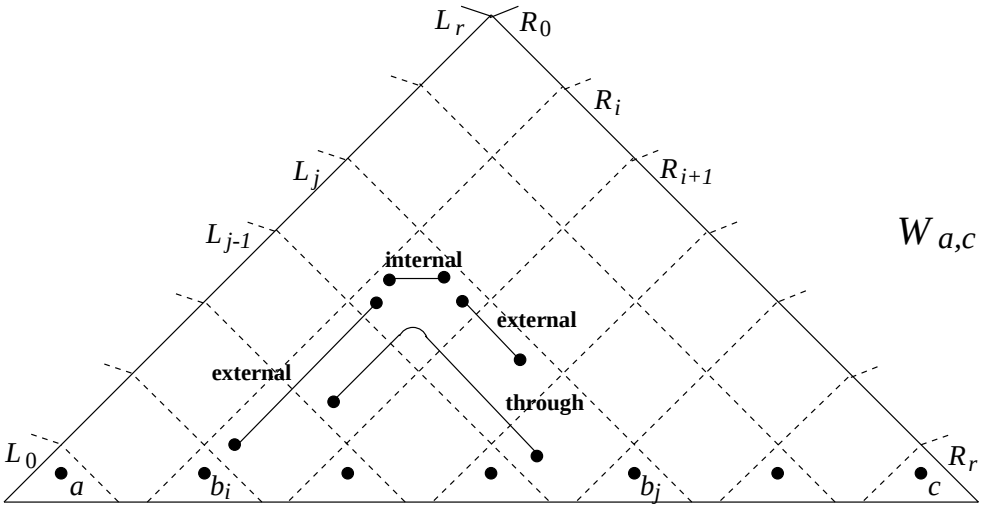

FIG. 4.13. *Cell structure for the path case.*

terminals. As in section 4.3, $\mathcal{F}_S$ is acyclic and balanced and all S-mincuts of G are transversal cuts in $\mathcal{F}_S$.

For each i, $0 \leqslant i \leqslant r-1$, let $(L_i, \bar{L}_i)$ be the $\{a, b_1, \ldots, b_i\}$-tight $(\{a, b_1, \ldots, b_i\}, \{b_{i+1}, \ldots, b_{r-1}, c\})$-mincut. Similarly, for each i, $1 \leqslant i \leqslant r$, let $(R_i, \bar{R}_i)$ be the $\{c, b_{r-1}, \ldots, b_i\}$-tight $(\{c, b_{r-1}, \ldots, b_i\}, \{b_{i-1}, \ldots, b_1, a\})$-mincut. Besides, we define L_r and R_0 to be the entire set of units of $\mathcal{F}_S$. The properties of the cuts $(L_i, \bar{L}_i)$ and $(R_i, \bar{R}_i)$ are similar to those of $(L_b, \bar{L}_b)$ and $(R_b, \bar{R}_b)$ (see Lemma 4.1) and of $\mathcal{C}_x$ (see Lemma 4.4(i) and Lemma 4.7). We omit the proof, since it is similar to that of Lemma 4.1; for illustration, see Figure 4.13.

LEMMA 4.9. (i) *For any pair i, j, $0 \leqslant i < j \leqslant r$, one has $L_i \subset L_j$ and $R_i \supset R_j$.*

(ii) *For any i, $0 \leqslant i \leqslant r$, L_i and R_i are the reachability cones of the unit U_{b_i} in $\mathcal{W}_{a,c}$, and hence $L_i \cap R_i$ coincides with this unit.*

(iii) *The sides of the star of U_{b_i} in $\mathcal{W}_{a,c}$ are induced in $\mathcal{F}_S$ by edge-sets of $(L_i, \bar{L}_i)$ and $(R_i, \bar{R}_i)$.*

(iv) *For any pair i, j, $0 \leqslant i < j \leqslant r$, the contraction of L_i and R_j in $\mathcal{F}_S$ into two terminals gives $\mathcal{F}_{\{b_i, \ldots, b_j\}}$.*

By Lemma 4.9(iii), the strip $\mathcal{W}_{a,c}$ can be restored from $\mathcal{F}_S$. Observe that the sets $\{b_i, \ldots, b_j\}$, $i < j$, have the path structure similar to that of S. Therefore, by Lemma 4.9(iii) and (iv), the strips $\mathcal{W}_{b_i, b_j}$ can be restored from $\mathcal{F}_S$ as well. A unit which is not contracted to a terminal in the construction described in Lemma 4.9(iv) is said to be *distinguished* by $\mathcal{W}_{b_i, b_j}$.

The two nested families $\{L_i\}$ and $\{R_i\}$ define a cell structure on the set of units.

Namely, the *cell* Q^{ij}, $0 \leqslant i \leqslant j \leqslant r$, is defined as the intersection $(L_j \setminus L_{j-1}) \cap (R_i \setminus R_{i+1})$, where $L_{-1} = R_{r+1} = \varnothing$ (compare with the definition preceding the 3-Star Lemma). Observe that Q^{ii} is exactly the unit containing b_i. Part (iv) of Lemma 4.9 implies that the units of the same cell are distinguished by the same "partial" strips $\mathcal{W}_{b_p,b_q}$. More exactly, the following statement holds.

LEMMA 4.10. *The units of the cell Q^{ij} are distinguished by the strip $\mathcal{W}_{b_p,b_q}$ if and only if the paths $(b_i,\dots,b_j)$ and $(b_p,\dots,b_q)$ in the skeleton structure have at least one common edge.*

Proof. According to (iv) above, to obtain $\mathcal{W}_{b_p,b_q}$ we contract the cells Q^{ij} with $j \leqslant p$ or $i \geqslant q$, and the assertion follows. □

Edges between cells and, generally, mutual reachability of their units are subject to the following restriction.

LEMMA 4.11. *Let U_1 and U_2 be mutually reachable in $\mathcal{F}_S$, $U_l \in Q^{i_l,j_l}$, $l = 1, 2$, and $i_1 < i_2$. Then*

(i) $j_1 \leqslant j_2$;

(ii) *if U_1 is a stretched unit and U_3 lies in the same reachability cone of U_1 as U_2, $U_3 \in Q^{i_3,j_3}$, then $i_1 \leqslant i_3$ and $j_1 \leqslant j_3$.*

Proof. (i) Assume that $i_1 < i_2$, $j_2 < j_1$, and there exists a coherent path P_2 between U_1 and U_2. Evidently, U_1 is not a terminal. Let us extend P_2 behind U_1 up to a terminal U_{b_p}. W.l.o.g. we may assume that $p > i_1$ (the case $p < j_1$ is treated in the same way). Let us consider the S-mincut $(X, \bar{X})$ with $X = L_{j_1} \cap \bar{R}_{i_1+1}$. Evidently, the endpoints U_2 and U_{b_p} of the extended path lie outside this cut, while an intermediate unit U_1 lies inside this cut. So, the extended path intersects the transversal cut $(X, \bar{X})$ at least twice, a contradiction.

(ii) Let U_{b_p} be as above. From (i) we get immediately that either $p \geqslant j_1$ or $p \leqslant i_1$. If $p \geqslant j_1$, then we set $i = \min\{i_2, j_1\}$; now both U_{b_p} and U_2 belong to R_i, while U_1 does not (since $i_1 < i_2$), a contradiction. Hence, $p \leqslant i_1$.

Let us now extend a coherent path P_3 between U_1 and U_3 behind U_3 up to a terminal U_{b_q}. (Since U_3 is not necessarily a stretched unit, it may happen that $U_{b_q} = U_3$.) Observe that P_3 can be extended up to U_{b_p}; we denote the obtained coherent path by P_3'. Once more we get from (i) that either $q \geqslant j_1$ or $q \leqslant i_i$. If $q \leqslant i_1$, then the endpoints U_{b_q} and U_{b_p} of P_3' belong to L_{i_1}, while its intermediate unit U_1 does not, a contradiction. Hence, $q \geqslant j_1$.

Assume now that $i_3 < i_1$; in this case $U_3 \neq U_{b_q}$. Let us consider the part of P_3' between U_1 and U_{b_q}. Both its endpoints belong to R_{i_1}, while its intermediate unit U_3 does not, a contradiction.

Assume now that $i_3 = i_1$ and $j_3 < j_1$; again we have $U_3 \neq U_{b_q}$. Let us consider the same path as in the previous case. Both its endpoints do not belong to L_{j_3}, while its intermediate unit U_3 does, a contradiction.

Therefore, $i_1 = i_3$ implies $j_1 \leqslant j_3$. Finally, $i_1 < i_3$ implies the same inequality. □

Remark. Observe that the first assertion of the above lemma can be regarded as a generalization of Lemma 2.1(i).

Let us now extend the definition of the cell structure to the edges of $\mathcal{F}_S$. Let $e = (U_1, U_2)$ be an edge of $\mathcal{F}_S$, and assume that $U_1 \in Q^{i_1 j_1}$ and $U_2 \in Q^{i_2 j_2}$. We put $i = \min\{i_1, i_2\}$, $j = \max\{j_1, j_2\}$, and say that e belongs to the cell Q^{ij}. Observe that by Lemma 4.11 there are three types of edges belonging to a cell Q^{ij}: internal (both endpoints belong to Q^{ij}), external (one endpoint belongs to Q^{ij} and the other one either to $Q^{ij'}$, $i \leqslant j' < j$, or to $Q^{i'j}$, $i < i' \leqslant j$), and through (one endpoint belongs

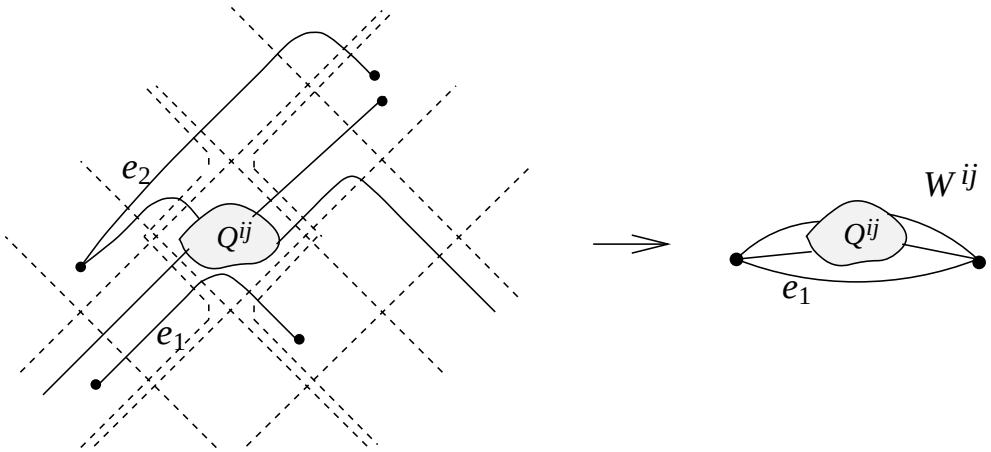

FIG. 4.14. *To the definition of the strip* $\mathcal{W}^{ij}$.

to $Q^{ij'}$, $i \leqslant j' < j$, and the other one to $Q^{i'j}$, $i < i' \leqslant j$); for an illustration, see Figure 4.13.

This definition can be justified as follows. Insert a dummy vertex u into the edge e, thus dividing it into e_1 and e_2. Evidently, if an S-mincut $(X, \bar{X})$ of the initial graph is crossed by e, then upon insertion of u it is replaced by two S-mincuts of the modified graph: $(X \cup \{u\}, \bar{X})$ and $(X, \bar{X} \cup \{u\})$. Conversely, let $(Y, \bar{Y})$, $u \in \bar{Y}$, be an S-mincut of the modified graph crossed, say, by e_1. Then $(Y \cup \{u\}, \bar{Y} \setminus \{u\})$ is another S-mincut of the modified graph, and it is crossed by e_2. Finally, if an S-mincut is not crossed by e, then it remains intact in the modified graph, and vice versa. It follows from the above discussion that the only difference between the initial $\mathcal{F}_S$ and the modified one is the new unit U that consists of the single dummy vertex u and belongs to the cell Q^{ij}; U, together with the incident edges $e_1 = (U_1, U)$ and $e_2 = (U_2, U)$, replaces the edge e in $\mathcal{F}_S$. This dummy unit, in a sense, represents the edge e, and thus justifies the above definition. Observe that this definition is stable with respect to insertion of dummy vertices. Namely, if e belongs to the cell Q^{ij}, then both e_1 and e_2 belong to the same cell.

For any pair i, j, $0 \leqslant i \leqslant j \leqslant r$, excluding cases $i = j = 0$ and $i = j = r$, we build from $\mathcal{F}_S$ a locally orientable graph $\mathcal{W}^{ij}$ with the set of nonterminals Q^{ij} (see Figure 4.14). We delete $\bigcup\{Q^{pq} : p < i \leqslant j < q\}$ and $\bigcup\{Q^{pq} : i < p \leqslant q < j\}$. (Observe that by Lemma 2.1 there are no edges between Q^{ij} and the deleted sets.) Next, we contract the sets $\bigcup\{Q^{pq} : p \leqslant i,\ q \leqslant j,\ (p,q) \neq (i,j)\}$ and $\bigcup\{Q^{pq} : p \geqslant i,\ q \geqslant j,\ (p,q) \neq (i,j)\}$ into two terminals a' and c'. Finally, we delete the edges between a' and c' that do not belong to Q^{ij}. Observe that this definition is consistent with the definition of $\mathcal{W}^{ac}$ given in section 4.3 ($\mathcal{W}^{02}$, in our new notation), because all the edges between a' and c' in $\mathcal{F}_{\{a,b,c\}}$ belong to Q^{02}. Evidently, all the edges that belong to Q^{ij} participate in $\mathcal{W}^{ij}$. Besides, each external edge participates in one more such graph, and each through edge in two more such graphs. Extensions of cuts of $\mathcal{W}^{ij}$ to S-mincuts are defined similarly to the case analyzed in section 4.3. The following statement is an analogue of Lemmas 4.2 and 4.8.

LEMMA 4.12. (i) *The graph* $\mathcal{W}^{ij}$ *is a strip of width* λ^{ij}; *if* $j = i$, *then* $\lambda^{ij} > \lambda_S/2$, *while if* $j \geqslant i + 2$, *then* $\lambda^{ij} < \lambda_S/2$.

(ii) *All its transversal cuts, and only they, are extendible to* S*-mincuts.*

(iii) *For any sequence* $i_1 < i_2 < \cdots < i_l \leqslant j_l < \cdots < j_2 < j_1$, *any set of* l *transversal cuts of* $\mathcal{W}^{i_1j_1}, \ldots, \mathcal{W}^{i_lj_l}$ *has a mutual extension to an* S*-cut. Moreover, if* $j_l \geqslant i_l + 2$, *then* $\lambda^{i_1j_1} + \cdots + \lambda^{i_lj_l} < \lambda_S/2$.

(iv) *Let* $i_1 < i_2 < \cdots < i_l \leqslant j_l < \cdots < j_2 < j_1$ *and let a* 2*-partition of* $V \setminus \{Q^{i_1j_1} \cup \cdots \cup Q^{i_lj_l}\}$ *enter a mutual extension of a set of transversal cuts of* $\mathcal{W}^{i_1j_1}, \ldots, W^{i_lj_l}$. *Then it enters some mutual extension of any set of such cuts.* (*Informally, all sets of transversal cuts for such a sequence of strips are interchangeable in* S*-mincuts.*)

Proof. (i) The fact that $\mathcal{W}^{ij}$ is a strip is proved similarly to Lemma 4.2(i) taking into account that the sets $X_a = \bigcup\{Q^{pq} : p \leqslant i,\ q \leqslant j,\ (p,q) \neq (i,j)\}$ and $\bar{X}_c = \bigcup\{Q^{pq} : p \geqslant i,\ q \geqslant j,\ (p,q) \neq (i,j)\}$ define transversal cuts $\mathcal{C}_a = (X_a, \bar{X}_a)$ and $\mathcal{C}_c = (X_c, \bar{X}_c)$ (shown by a double line on Figure 4.14). The inequality for the case $j = i$ follows from the fact that the cardinality of the cut $(U_{b_i}, V \setminus U_{b_i})$ exceeds λ_S. In the case $j \geqslant i + 2$ we see that all the edges of $\mathcal{F}_S$ incident to a'-type terminals in the strips $\mathcal{W}^{ij}$ and $\mathcal{W}^{i+1,i+1}$ belong to the edge-set of $\mathcal{C}_a$. Therefore, $\lambda^{ij} + \lambda^{i+1,i+1} \leqslant c(\mathcal{C}_a) = \lambda_S$. Since $\lambda^{i+1,i+1} > \lambda_S/2$, we are done.

(ii) Let X_a and $\bar{X}_c$ be defined as above. Given any transversal cut $\mathcal{C}' = (a' \cup Z, \bar{Z} \cup c')$ of $\mathcal{W}^{ij}$, let us consider the edge-set of the 2-partition $\mathcal{C} = (X_a \cup Z, \bar{Z} \cup \bar{X}_a)$ of V. As compared with the edge-set of $\mathcal{C}_a$, it loses the edges between X_a and Z and gets the edges between Z and $\bar{Z} \cup \bar{X}_c$. However, the same holds for the cut $\mathcal{C}'$ as compared with the cut of $\mathcal{W}^{ij}$ that separates a'. Since, by (i), the cuts in the second pair have equal cardinalities, the same is true for the first pair. Thus $\mathcal{C}$ is a minimum S-cut.

Conversely, let $(X, \bar{X})$ be an S-mincut separating X_a from $\bar{X}_c$. By the same reasons as above, it generates a 2-partition of cardinality λ^{ij} in $\mathcal{W}^{ij}$ that is a minimum (i.e., transversal) cut of $\mathcal{W}^{ij}$.

(iii) Let $\mathcal{C}'_k$ be a transversal cut of $\mathcal{W}^{i_kj_k}$, $1 \leqslant k \leqslant l$. Denote by $\mathcal{C}_k$ the extension of $\mathcal{C}'_k$ defined as in the proof of (ii) and consider the S-mincut $\mathcal{C} = \mathcal{C}_1 \cup \cdots \cup \mathcal{C}_l$. Inequalities $i_1 < i_2 < \cdots < i_l \leqslant j_l < \cdots < j_2 < j_1$ guarantee that $\mathcal{C}$ is an extension for any of the $\mathcal{C}'_k$ and hence is a mutual extension of the whole set $\{\mathcal{C}'_1, \ldots, \mathcal{C}'_k\}$. The same inequalities guarantee that no edge is counted more than once in the sum $\lambda^{i_1j_1} + \cdots + \lambda^{i_lj_l}$; the rest of the proof of the inequality $\lambda^{i_1j_1} + \cdots + \lambda^{i_lj_l} < \lambda_S/2$ follows the proof of (i).

(iv) Assume that $l = 1$. Let $\mathcal{C}_0$ be an extension of some transversal cut of $\mathcal{W}^{i_1j_1}$ and let $\mathcal{C}'$ be an arbitrary transversal cut of $\mathcal{W}^{i_1j_1}$. Take $\bar{X}_c$ as above and put $X^*_c = X_c \setminus Q^{i_1j_1}$; then $\mathcal{C}^* = (X^*_c, \bar{X}^*_c)$ is an S-mincut. Now define the cut $\mathcal{C}$ of G as in the proof of (ii); then $(\mathcal{C}_0 \cap \mathcal{C}^*) \cup \mathcal{C}$ is an extension of $\mathcal{C}'$ that divides $V \setminus Q^{i_1j_1}$ in the same way as $\mathcal{C}_0$. For $l > 1$ the proof applies with evident minor changes. □

Dynamics of $\mathcal{F}_S$, $S = \{a = b_0, \ldots, b_r = c\}$, in the case of the path structure are induced by those of $\mathcal{F}_{\{a,c\}} = \mathcal{W}_{a,c}$, in the same way as it was done for $\mathcal{F}_{\{a,b,c\}}$ in the asymmetric subcase (see section 4.3). To be more precise, let $U_1 \in Q^{i_1j_1}$, $U_2 \in Q^{i_2j_2}$ (we may assume w.l.o.g. that $j_1 \leqslant j_2$); we call i_k, j_k the *coordinates* of U_k, $k = 1, 2$. Certain elements of S "fall inside" U^{new} when $j_1 \leqslant i_2$; in this case U^{new} is a terminal and it contains all the b_k such that $j_1 \leqslant k \leqslant i_2$ (see Figure 4.15(a)).

Concerning the dynamics of the sets L_k (those of R_k are similar), Lemma 4.3 can be generalized as follows.

LEMMA 4.13. *The sets* L_k, $j_1 \leqslant k < j_2$, *and only they, are extended* (*at least by* U_2). *The new part of* $\widehat{L}_k$ *is the union of the units* $U' \in Q^{i'j'}$ *such that* $j' > k$ *and* $U' \in \mathcal{R}_a(U_2)$.

The proof of Lemma 4.13 is similar to that of Lemma 4.3 (see Figure 4.15(b)).

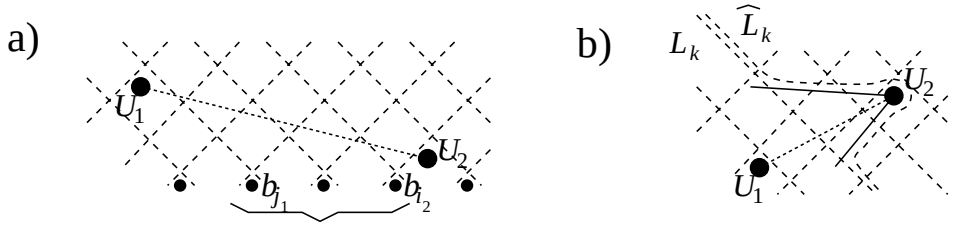

FIG. 4.15. *Dynamics in the case of the path structure.*

In the case when $U^{\rm new}$ is not a terminal, its new cell and the new cells of the other units can be defined via the characterization of the sets $\widehat{L}_k$, $\widehat{R}_l$ given in Lemma 4.13. We use the following notation. Let $j_{\min} = \min\{j_1, j_2\}$ and $i_{\max} = \max\{i_1, i_2\}$. The unit $U(j)$ is the one of U_1, U_2 with the j-coordinate not less than that of the other one, and $U(i)$ is the one of them with the i-coordinate not greater than that of the other one.

COROLLARY 4.14. (i) *The new unit $U^{\rm new}$ belongs to the cell $\widehat{Q}^{i_{\max} j_{\min}}$.*

(ii) *Let a unit $U' \in Q^{ij}$ move to the cell $\widehat{Q}^{i^* j^*}$.*

If $j > j_{\min}$ and $U' \in \mathcal{R}_a(U(j))$, then $j^* = j_{\min}$, otherwise $j^* = j$.

If $i < i_{\max}$ and $U' \in \mathcal{R}_c(U(i))$, then $i^* = i_{\max}$, otherwise $i^* = i$.

Moreover, an analogue of Corollary 4.14 is valid also in the case when $U^{\rm new}$ is a terminal if we previously merge the cells with the identified indices in the range $[j_1, \ldots, i_2]$.

5. The flesh and the skeleton of the connectivity carcass.

5.1. The system of units, or the flesh of the connectivity carcass. Let us consider an arbitrary bunch $\mathcal{B}$ of S-cuts, and let $(S_{\mathcal{B}}, \bar{S}_{\mathcal{B}})$ be the corresponding partition of S (see section 2 for all the necessary definitions). In fact, $\mathcal{B}$ is the set of all minimum $(S_{\mathcal{B}}, \bar{S}_{\mathcal{B}})$-cuts; thus the structure of $\mathcal{B}$ can be represented by the strip $\mathcal{W}_{S_{\mathcal{B}}, \bar{S}_{\mathcal{B}}}$. For brevity, in what follows this strip is denoted by $\mathcal{W}_{\mathcal{B}}$, the corresponding quotient mapping by $\delta_{\mathcal{B}}$, and the units of $\mathcal{W}_{\mathcal{B}}$ are called $\mathcal{B}$-units. Therefore, the following statement holds.

FACT 5.1. *Any bunch of S-cuts $\mathcal{B}$ is represented by the strip $\mathcal{W}_{\mathcal{B}}$ and the mapping $\delta_{\mathcal{B}}$ so that the $\delta_{\mathcal{B}}$-inducing provides a bijection between the transversal cuts of $\mathcal{W}_{\mathcal{B}}$ and the S-cuts in $\mathcal{B}$.*

Evidently, for the bunch $\bar{\mathcal{B}}$ of cuts opposite to cuts in $\mathcal{B}$, the strip $\mathcal{W}_{\bar{\mathcal{B}}}$ coincides with $\mathcal{W}_{\mathcal{B}}$.

By the definition, the partition of V into S-units is a refinement of its partition into $\mathcal{B}$-units. The following statement shows that only the two terminal $\mathcal{B}$-units can be refined.

LEMMA 5.2. *Each nonterminal $\mathcal{B}$-unit is an S-unit.*

Proof. The proof is similar to that of Lemma 4.4(i). Let U be a nonterminal $\mathcal{B}$-unit subdivided by an S-mincut $\mathcal{C}$. Evidently, there exist vertices $x \in S_{\mathcal{B}}$ and $y \in \bar{S}_{\mathcal{B}}$ separated by $\mathcal{C}$; assume w.l.o.g. that x lies inside $\mathcal{C}$. By the definition of $\mathcal{B}$-units, the bunch $\mathcal{B}$ contains cuts $\mathcal{C}_1$ and $\mathcal{C}_2$ separating $S_{\mathcal{B}}$ from U and U from $\bar{S}_{\mathcal{B}}$, respectively. Observe that all the three cuts $\mathcal{C}$, $\mathcal{C}_1$, and $\mathcal{C}_2$ are minimum (x, y)-cuts. Let us consider the cut $\mathcal{C}_1 \cup (\mathcal{C} \cap \mathcal{C}_2)$. It contains $S_{\mathcal{B}}$ inside, contains $\bar{S}_{\mathcal{B}}$ outside, and thus belongs to $\mathcal{B}$. However, it subdivides U, a contradiction. ∎

In what follows we say that the S-units described in Lemma 5.2 are *distinguished* by the bunch $\mathcal{B}$ or by the bunch strip $\mathcal{W}_{\mathcal{B}}$ (compare with the definition preceding Lemma 4.10).

By the definition, the star of any nonterminal vertex of the locally orientable graph $\mathcal{W}_{\mathcal{B}}$ is partitioned into two sets of equal cardinality. Thus, by Lemma 5.2, the star of the corresponding vertex of $\mathcal{F}_S$ is halved. The crucial observation is that the arising 2-partition does not depend on the choice of $\mathcal{B}$ (see Lemma 4.4(iii) for a particular case of the same statement).

LEMMA 5.3. *If an S-unit is distinguished by several bunch strips, then the 2-partitions of its star in all these strips coincide.*

Proof. Let U be an S-unit distinguished by bunches $\mathcal{B}$ and $\mathcal{B}'$. W.l.o.g., the 2-partition $(S_{\mathcal{B}'}, \bar{S}_{\mathcal{B}'})$ divides $S_{\mathcal{B}}$. Therefore, for any $x \in \bar{S}_{\mathcal{B}}$ one can choose $y \in S_{\mathcal{B}}$ separated from x by this 2-partition. Similarly to the proof of Lemma 4.4(iii), both strips $\mathcal{W}_{\mathcal{B}}$ and $\mathcal{W}_{\mathcal{B}'}$ are contractions of the same strip $\mathcal{W}_{x,y}$. (In this case Lemma 3.8 is used repeatedly.) Hence, the 2-partitions at U in these strips are inherited from $\mathcal{W}_{x,y}$ and thus coincide. □

Let us provide $\mathcal{F}_S$ with a canonical structure of a locally orientable graph (see definitions in section 3). To the star of any S-unit distinguished by at least one bunch strip we assign the partition into sides indicated in Lemma 5.3. To the star of any other unit we assign the trivial 2-partition. These 2-partitions are said to be *inherent*. The quotient graph $\mathcal{F}_S$ endowed with the structure of a locally oriented graph as described above is said to be the *flesh* of the connectivity carcass of S.

As for general locally orientable graphs, the units of the former type are called stretched, and those of the latter type, terminals. In addition, a unit is called *heavy* if it intersects S. Observe that only terminal units (but, in general, not all of them) can be heavy. Below we prove several basic properties of $\mathcal{F}_S$.

In what follows we illustrate certain general concepts on the graph shown in Figure 5.1(a). Large black circles denote vertices in S; several S-mincuts are shown by dashed lines; nontrivial S-units are encircled by dotted lines. The corresponding flesh is presented in Figure 5.1(b).

According to the definitions above, $\mathcal{F}_S$ is obtained by "gluing together" all the bunch strips. Conversely, each bunch strip can be reconstructed from $\mathcal{F}_S$ with the help of contractions. Indeed, let $\mathcal{B}$ be an arbitrary bunch of S-mincuts. The intersection of all cuts in $\mathcal{B}$ is called the *tight* cut of $\mathcal{B}$; the union of all cuts in $\mathcal{B}$ is called the *loose* cut of $\mathcal{B}$. (Evidently, each of them separates a terminal of $\mathcal{W}_{\mathcal{B}}$ from all other units.) Observe that the tight cut of $\mathcal{B}$ is just the $S_{\mathcal{B}}$-tight $(S_{\mathcal{B}}, \bar{S}_{\mathcal{B}})$-mincut (for the definition, see section 2 immediately after Fact 2.2), while the loose cut of $\mathcal{B}$ is the opposite of the $\bar{S}_{\mathcal{B}}$-tight $(\bar{S}_{\mathcal{B}}, S_{\mathcal{B}})$-mincut. The following statement is a generalization of Lemma 4.1(iii) and Lemma 4.4(i).

LEMMA 5.4. *For any bunch $\mathcal{B}$, the strip $\mathcal{W}_{\mathcal{B}}$ is obtained from $\mathcal{F}_S$ by contracting all the units inside the tight cut of $\mathcal{B}$ and all the units outside the loose cut of $\mathcal{B}$ into terminals.*

Proof. The proof follows immediately from Lemmas 5.2 and 5.3 (for details, see the proof of Lemma 4.4(i)). □

Parts (i) and (ii) of the next statement provide a generalization of Lemma 4.5.

THEOREM 5.5. (i) *The flesh $\mathcal{F}_S$ is a balanced acyclic locally orientable graph.*

(ii) *Each S-mincut is transversal in $\mathcal{F}_S$.*

(iii) *Let $\tilde{n}$ and $\tilde{m}$ be the numbers of vertices and edges of $\mathcal{F}_S$, respectively. Then $\tilde{n} \leqslant n$, $\tilde{m} \leqslant m$, $\tilde{m} = O(\lambda_S \tilde{n})$.*

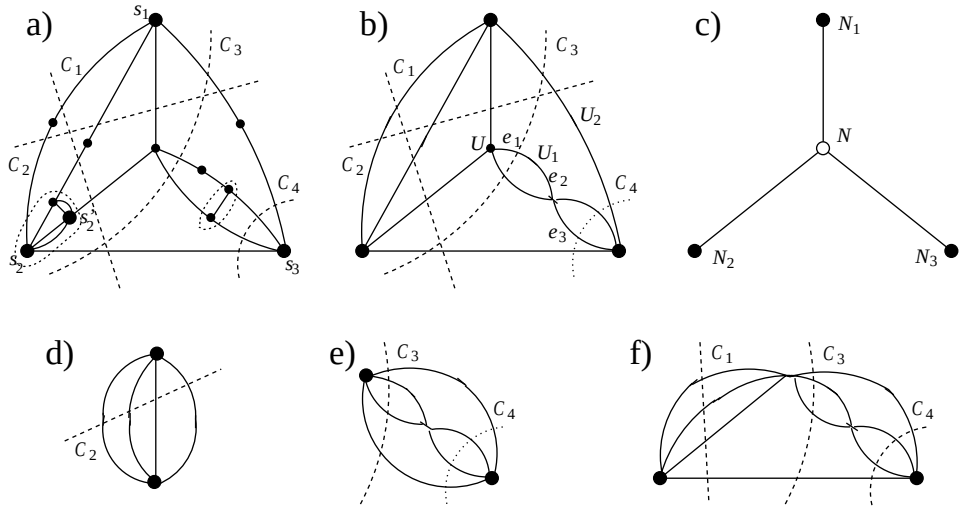

FIG. 5.1. *Connectivity carcass of a graph and its contractions to strips.*

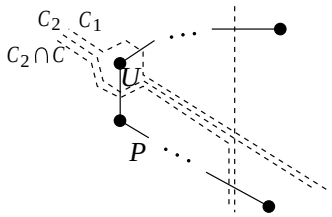

FIG. 5.2. *To the proof of Theorem* 5.5.

Proof. (i) The fact that $\mathcal{F}_S$ is balanced is clear, since inherent partitions at stretched units of $\mathcal{F}_S$ come from those in bunch strips (see Lemma 5.3). Acyclicity of $\mathcal{F}_S$ follows from part (ii) of this theorem exactly in the same way as in the proof of Lemma 4.5.

(ii) Assume to the contrary that the claim is violated by some pair G, S and the corresponding flesh $\mathcal{F}_S$. Then there exists a minimal counterexample, namely, an S-mincut $\mathcal{C}$ and a coherent path P in $\mathcal{F}_S$ such that P intersects the edge-set of $\mathcal{C}$ at least twice and the number of units in P is minimal among all such pairs $\mathcal{C}, P$ (see Figure 5.2). By minimality, the endpoints of P lie outside $\mathcal{C}$, and all the inner units of P lie inside $\mathcal{C}$ (up to flipping of $\mathcal{C}$). Let U be an arbitrary inner unit of P; since P is a coherent path, U is a stretched unit. Therefore, there exists a bunch that distinguishes U. Let $\mathcal{C}_1$ be the S-mincut in this bunch defined by a cone $\mathcal{R}$ of U in the corresponding strip and $\mathcal{C}_2$ be the S-mincut in this bunch defined by $\mathcal{R} \setminus U$. Up to taking the other cone of U, we may assume that both pairs $\mathcal{C}_1, \mathcal{C}$ and $\mathcal{C}_2, \mathcal{C}$ satisfy the conditions of Lemma 2.1. Thus, by Fact 2.2, both $\mathcal{C}_1 \cap \mathcal{C}$ and $\mathcal{C}_2 \cap \mathcal{C}$ are S-mincuts; moreover, they belong to the same bunch and their inner parts differ exactly by U.

Let us traverse P from an endpoint up to U and take the edge entering U and the

next edge of P. By Fact 3.3, exactly one of the above edges intersects the edge-set of $\mathcal{C}_2 \cap \mathcal{C}$; let U' be the other endpoint of this edge. Since U' lies inside $\mathcal{C}_2 \cap \mathcal{C}$, it lies inside $\mathcal{C}$ as well, and thus cannot be an endpoint of P. Let P' be the subpath of P leaving U by the edge (U, U') and ending at the corresponding endpoint of P. Since both U and this endpoint of P lie outside $\mathcal{C}_2 \cap \mathcal{C}$, the pair $\mathcal{C}_2 \cap \mathcal{C}, P'$ contradicts the minimality of the pair $\mathcal{C}, P$.

(iii) The first two inequalities are evident. Let us show that $\tilde{m} \leqslant \lambda_S(\tilde{n}-1)$. Since any two units are separated by an S-mincut, the size of a minimum cut between them in $\mathcal{F}_S$ is at most λ_S. Let us consider the Gomory–Hu tree of $\mathcal{F}_S$ (see [GH]). Recall that its vertices correspond bijectively to the units, and thus any of its edges defines a cut of $\mathcal{F}_S$. By [GH], this cut is a minimum cut between some two units, and hence its size is at most λ_S. Since there are $\tilde{n}-1$ such cuts and each edge of $\mathcal{F}_S$ takes part in at least one of them, their total number $\tilde{m}$ does not exceed $\lambda_S(\tilde{n}-1)$, as required. □

The flesh can be considered, in a sense, as a generalization of a strip. By the way, at early stages we called our structure "branching dag." The meaning of such a nickname will become more clear in the next subsection (see also section 4.4).

5.2. The system of bunches, or the skeleton of the connectivity carcass: Odd case. For the case $S = V$, the S-mincuts are the (globally) minimum cuts of G, and any bunch consists of exactly one S-mincut. Recall (see the introduction) that the structure of all minimum cuts of G is represented by a cactus tree (see [DKL]); if the graph connectivity is odd, it is, in fact, a tree. The construction is based on the Crossing Lemma [Bi, DKL]. A generalization of this lemma to the S-mincuts and the existence of a cactus tree representation of all 2-partitions of S by S-mincuts were stated (without proof) independently in [Na, W93] (see also [DV1]). The generalization of the lemma is straightforward (see below); for a proof of the existence of a cactus tree representation, see [DN, Nu].

As usual, two 2-partitions of a set are called crossing if they divide the set into four nonvoid parts. We consider a more delicate notion: two S-cuts $\mathcal{C}$ and $\mathcal{C}'$ (which are 2-partitions of V) are said to be S-crossing if they divide S into four nonvoid parts.

S-Crossing Lemma. *Let $\mathcal{C}$ and $\mathcal{C}'$ be S-crossing S-mincuts; then*

(i) $c(V_{\mathcal{C}} \cap V_{\mathcal{C}'}, V_{\mathcal{C}} \cap \bar{V}_{\mathcal{C}'}) = c(V_{\mathcal{C}} \cap \bar{V}_{\mathcal{C}'}, \bar{V}_{\mathcal{C}} \cap \bar{V}_{\mathcal{C}'}) = c(\bar{V}_{\mathcal{C}} \cap \bar{V}_{\mathcal{C}'}, \bar{V}_{\mathcal{C}} \cap V_{\mathcal{C}'}) = c(\bar{V}_{\mathcal{C}} \cap V_{\mathcal{C}'}, V_{\mathcal{C}} \cap V_{\mathcal{C}'}) = \lambda_S/2$;

(ii) $c(V_{\mathcal{C}} \cap V_{\mathcal{C}'}, \bar{V}_{\mathcal{C}} \cap \bar{V}_{\mathcal{C}'}) = c(V_{\mathcal{C}} \cap \bar{V}_{\mathcal{C}'}, \bar{V}_{\mathcal{C}} \cap V_{\mathcal{C}'}) = 0$.

Hence, the 2-partitions $\mathcal{C} \cap \mathcal{C}'$, $\mathcal{C} \cap \bar{\mathcal{C}}'$, $\bar{\mathcal{C}} \cap \bar{\mathcal{C}}'$, $\bar{\mathcal{C}} \cap \mathcal{C}'$ are S-mincuts as well.

The proof coincides with that of the Crossing Lemma, with an additional observation that in our case all 2-partitions involved are actually S-cuts.

It follows immediately from part (i) of the S-Crossing Lemma that for λ_S odd there are no S-crossing S-mincuts. Let us show that whenever this S-crossing-free property holds, we can represent the system of bunches of S-mincuts by a tree (for an example, see Figure 5.1(c)). Recall that each bunch is uniquely characterized by the corresponding 2-partition of S; let us concentrate on these 2-partitions. Observe that the S-crossing-free property for S-mincuts is equivalent to the crossing-free property for these 2-partitions of S (i.e., that no two such 2-partitions are crossing).

Theorem 5.6. *For any set X and any crossing free family F of 2-partitions of X,*

(i) *there exist a unique tree $\mathcal{H}$ with the node set $\mathcal{N}$ and a mapping $\varphi : X \to \mathcal{N}$ such that φ-inducing provides a bijection between the cuts of $\mathcal{H}$ and the 2-partitions*

in F;

(ii) *the size of $\mathcal{H}$ is linear in the number of subsets that X is cut into by the members of F.*

This statement can be considered as folklore; however, for a proof see [DW, section 4.1].

COROLLARY 5.7. *For any $G = (V, E)$ and any $S \subseteq V$ with the S-crossing-free property the system of bunches of S-mincuts is represented by a tree, which we denote by $\mathcal{H}_S$; its node set is denoted by $\mathcal{N}_S$. The corresponding mapping $S \to \mathcal{N}_S$ is denoted by φ_S; the bunches of S-mincuts correspond bijectively to the cuts of $\mathcal{H}_S$ via φ_S-inducing. Moreover, the cardinality of $\mathcal{N}_S$ is linear in the number of $(\lambda_S + 1)$-connectivity classes in S.*

The tree $\mathcal{H}_S$ is said to be the *skeleton* of the connectivity carcass of the set S. Its edges are called *structural edges* (to distinguish them from the edges of the graph G). Any cut of $\mathcal{H}_S$ is defined by a single structural edge.

Observe that the image $\varphi_S(S)$ does not necessarily coincide with $\mathcal{N}_\mathcal{S}$. The nodes N for which $\varphi_S^{-1}(N) = \varnothing$ are called *empty* nodes (e.g., node N on Figure 5.1(c)). It follows from the construction that the degree of each empty node is at least three. It is easy to see that the preimages of the nonempty nodes in $\mathcal{N}_\mathcal{S}$ are exactly the classes of $(\lambda_S + 1)$-connectivity in S.

By Corollary 5.7, for any S with λ_S odd, the system of bunches of S-mincuts is represented by the skeleton $\mathcal{H}_S$, which is a tree. For λ_S even, this is also the case if the S-crossing-free property holds. In general, analogues of Theorem 5.6 and Corollary 5.7 are valid, in which the tree is replaced by a cactus tree. It means that each bunch is represented by a cut of this cactus tree, which is defined either by a structural edge not belonging to any cycle, or by a pair of structural edges belonging to the same cycle. For details see [DV1].

In the rest of the paper we assume that the skeleton is a tree, thus completely covering the odd case.

6. Structure and properties of the connectivity carcass.

6.1. Tight cuts. Let ε be an arbitrary structural edge of $\mathcal{H}_S$ and N be one of its endpoints. By Theorem 5.6, this edge defines two mutually opposite bunches of S-mincuts; these two bunches are represented by a strip (see Fact 5.1), which we denote $\mathcal{W}(\varepsilon)$. (For example, Figures 5.1(d) and (e) show the strips $\mathcal{W}(N, N_1)$ and $\mathcal{W}(N, N_3)$, respectively.) Consider the cut of $\mathcal{H}_S$ corresponding to ε and containing N inside. The intersection of all S-mincuts of the bunch represented by this cut of $\mathcal{H}_S$ is the tight cut of this bunch. This cut is said to be the *N-tight cut in direction ε* and is denoted by $\mathcal{C}(N, \varepsilon)$ (e.g., the cut $\mathcal{C}_3$ on Figure 5.1(a) is the N-tight cut in direction (N, N_1)).

A *path* in $\mathcal{H}_S$ is an alternating sequence of distinct nodes and structural edges; we consider the opposite sequence as the same path traversed in the opposite direction. The unique path between two arbitrary nodes M, N of the skeleton is denoted by $[M, N]$. For any two structural edges ε' and ε'' there exists a unique path that starts by one of them and ends by the other one; we denote this path by $[\varepsilon', \varepsilon'']$.

It turns out that tight cuts are monotonous along paths in the skeleton. More precise, the following generalization of Lemma 4.9(i) holds; it makes use of the domination relation $\prec$ between cuts defined at the beginning of section 2.

LEMMA 6.1. *For any path $P = (N_0, \varepsilon_1, N_1, \ldots, \varepsilon_r, N_r)$ in the skeleton $\mathcal{H}_S$, $r \geqslant 2$, one has $\mathcal{C}(N_0, \varepsilon_1) \prec \mathcal{C}(N_{r-1}, \varepsilon_r)$.*

Proof. Observe that the sets $S \cap V_{\mathcal{C}(N_0,\varepsilon_1)}$ and $S \cap V_{\mathcal{C}(N_{r-1},\varepsilon_r)}$ are nonempty, since the cuts in question are S-cuts. Moreover, $S \cap V_{\mathcal{C}(N_0,\varepsilon_1)}$ is contained in $S \cap V_{\mathcal{C}(N_{r-1},\varepsilon_r)}$, since both sets are φ_S-preimages of subtrees of $\mathcal{H}_S$ and the subtree of the former is contained in that of the latter; the set inclusion is strict since the partitions of S by distinct bunches are distinct.

Let a and b be arbitrary vertices in $S \cap V_{\mathcal{C}(N_0,\varepsilon_1)}$ and $S \cap \bar{V}_{\mathcal{C}(N_r,\varepsilon_r)}$, respectively. Both $\mathcal{C}(N_0,\varepsilon_1)$ and $\mathcal{C}(N_{r-1},\varepsilon_r)$ are minimum (a,b)-cuts, so their intersection $\mathcal{C}$ is a minimum (a,b)-cut as well. By the set inclusion proved above, the cut $\mathcal{C}$ belongs to the bunch defined by ε_1, and thus coincides with $\mathcal{C}(N_0,\varepsilon_1)$, since the latter cut is tight. This coincidence, together with the strict inclusion $S \cap V_{\mathcal{C}(N_0,\varepsilon_1)} \subset S \cap V_{\mathcal{C}(N_{r-1},\varepsilon_r)}$, implies the assertion of the lemma. □

COROLLARY 6.2. *For any path $P = (N_0, \varepsilon_1, N_1, \ldots, \varepsilon_r, N_r)$ in the skeleton $\mathcal{H}_S$, $r \geqslant 2$, one has $V_{\mathcal{C}(N_0,\varepsilon_1)} \cap V_{\mathcal{C}(N_r,\varepsilon_r)} = \varnothing$ and $V_{\mathcal{C}(N_1,\varepsilon_1)} \not\subseteq V_{\mathcal{C}(N_{r-1},\varepsilon_r)}$.*

Remark. Let ε' and ε'' be two arbitrary structural edges and $\mathcal{C}'$ and $\mathcal{C}''$ be two tight cuts in directions ε' and ε'', respectively. Observe that Lemma 6.1 and Corollary 6.2 cover all the possible choices for $\mathcal{C}'$ and $\mathcal{C}''$.

6.2. Reconstruction of pairwise strips. According to Lemma 5.4, one can obtain the strip representation for any bunch of S-mincuts just by a contraction of $\mathcal{F}_S$. This fact holds also in a more general situation, when one is interested in the strip representation $\mathcal{W}_{s_1,s_2}$ for an arbitrary pair of vertices $s_1, s_2 \in S$, or, more generally, in the strip $\mathcal{W}_{S_1,S_2}$ for an arbitrary pair of disjoint subsets $S_1, S_2 \subset S$, provided the cardinality of (S_1,S_2)-mincuts equals λ_S. Observe that in this case the (S_1,S_2)-mincuts, which are represented by $\mathcal{W}_{S_1,S_2}$, are exactly the S-mincuts separating S_1 from S_2. In this subsection we describe the contractions of $\mathcal{F}_S$ that give the corresponding strips. The reader can use for illustration Figure 5.1(d) ($S_1 = \{s_1\}$, $S_2 = \{s_2, s_2', s_3\}$), Figure 5.1(e) ($S_1 = \{s_3\}$, $S_2 = \{s_1, s_2\}$), Figure 5.1(f) ($S_1 = \{s_2\}$, $S_2 = \{s_3\}$).

Let T_1 and T_2 be two edge-disjoint subtrees of $\mathcal{H}_S$. The *link* of T_1 and T_2 is defined as the unique path with one endpoint in T_1 and the other one in T_2 and having no edges in common with T_1 and T_2. We denote the link of T_1 and T_2 by $\mathcal{L}(T_1,T_2)$. Observe that the link of two distinct nodes M and N is just the path $[M,N]$, the link of two distinct edges ε' and ε'' extended by these edges themselves gives exactly the path $[\varepsilon',\varepsilon'']$, and the link of two subtrees intersecting by a node is this very node.

Let S_1 and S_2 be disjoint subsets of S. By Theorem 5.6, a bunch of S-mincuts separates S_1 from S_2 if and only if the deletion of the corresponding edge of $\mathcal{H}_S$ produces two subtrees containing $\varphi_S(S_1)$ and $\varphi_S(S_2)$, respectively. Let $\mathcal{T}(S_1)$ and $\mathcal{T}(S_2)$ be the minimal subtrees of the tree $\mathcal{H}_S$ containing $\varphi_S(S_1)$ and $\varphi_S(S_2)$, respectively. For brevity, we write $\mathcal{L}(S_1,S_2)$ instead of $\mathcal{L}(\mathcal{T}(S_1),\mathcal{T}(S_2))$. The following statement follows easily from Theorem 5.6 and Lemma 6.1.

FACT 6.3. (i) *If $\mathcal{T}(S_1) \cap \mathcal{T}(S_2) \neq \varnothing$, then there are no S-mincuts separating S_1 from S_2.*

(ii) *Otherwise, the edges of $\mathcal{H}_S$ corresponding to the bunches of S-mincuts separating S_1 from S_2 form the link $\mathcal{L}(S_1,S_2)$.*

(iii) *Under the assumptions of* (ii), *let N_1 be the endpoint of $\mathcal{L}(S_1,S_2)$ lying in $\mathcal{T}(S_1)$ and ε_1 be the edge of $\mathcal{L}(S_1,S_2)$ incident to N_1. Then the S_1-tight (S_1,S_2)-mincut coincides with the N_1-tight cut in direction ε_1.*

Now we can prove the main result of this subsection, which is a generalization of Lemma 4.1(i),(ii), Lemma 4.7, and Lemma 4.9 (ii)–(iv). For an illustration, see Figure 6.1.

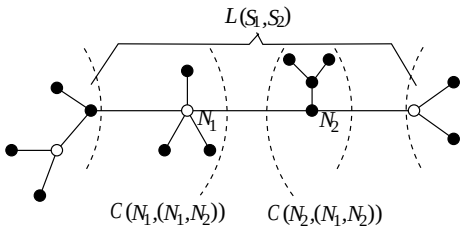

FIG. 6.1. *To the proof of Theorem* 6.4.

THEOREM 6.4. *Let S_1 and S_2 be two subsets of S such that $\mathcal{T}(S_1) \cap \mathcal{T}(S_2) = \varnothing$. The strip $\mathcal{W}_{S_1,S_2}$ is obtained as follows.*

The underlying graph of $\mathcal{W}_{S_1,S_2}$ is obtained from $\mathcal{F}_S$ by contractions of certain subsets of units to a single heavy unit. These subsets correspond bijectively to the nodes of the link $\mathcal{L}(S_1, S_2)$. The subset U_N that corresponds to a node N is equal to the intersection of the inner sides of N-tight cuts in directions of the edges of $\mathcal{L}(S_1, S_2)$ incident to N.

The inherent partition at any noncontracted unit remains the same. The inherent partition at a new unit U_N is induced by the edge-sets of the N-tight cuts defining U_N.

Proof. Let us delete all the edges of the path $\mathcal{L}(S_1, S_2)$. The trees of the forest thus obtained correspond bijectively to the nodes of $\mathcal{L}(S_1, S_2)$: a node N corresponds to the tree $\mathcal{T}_N$ that contains N. Denote by Σ_N the inverse image of the set of all the nodes of $\mathcal{T}_N$ under the mapping φ_S. Observe that Σ_N is a nonempty subset of S. Indeed, if N is an endpoint of the link, then Σ_N is just the intersection of a side of a certain S-mincut with S and is thus nonempty. If N is an inner node of the link, then $\Sigma_N = \varnothing$ would imply that the cuts of $\mathcal{H}_S$ defined by the two structural edges incident to N φ_S-induce the same 2-partition of S, in contradiction to Theorem 5.6 (compare with the proof of Lemma 6.1). Besides, by Fact 6.3(ii), the S-mincuts separating S_1 from S_2 do not divide Σ_N. Therefore, in any case all the set Σ_N lies in a single heavy unit of the strip $\mathcal{W}_{S_1,S_2}$, which we denote by U'_N. Observe that if N is an endpoint of the link, then U'_N is a terminal of $\mathcal{W}_{S_1,S_2}$ (since Σ_N contains one of S_1 and S_2).

Let now N_1 and N_2 be two neighboring nodes in the link such that N_1 and $\varphi_S(S_1)$ lie on the same side of the edge (N_1, N_2) in $\mathcal{H}_S$. Let us consider the set of all $(S_1 \cup \Sigma_{N_1}, S_2 \cup \Sigma_{N_2})$-mincuts (all of them are represented in $\mathcal{W}_{S_1,S_2}$). It is easy to see that the subtrees $\mathcal{T}(S_1 \cup \Sigma_{N_1})$ and $\mathcal{T}(S_2 \cup \Sigma_{N_2})$ contain nodes N_1 and N_2, respectively. By Fact 6.3(ii), this set of cuts is represented by the strip $\mathcal{W}(N_1, N_2)$ defined by the structural edge (N_1, N_2). Therefore, by Lemma 3.8, to get the strip $\mathcal{W}(N_1, N_2)$, it is sufficient to contract the corresponding cones of the nodes U'_{N_1} and U'_{N_2} in $\mathcal{W}_{S_1,S_2}$.

By Facts 3.6(iii) and 6.3(ii) and Lemma 6.1, these cones are just the inner sides of the tight cuts $\mathcal{C}(N_1, (N_1, N_2))$ and $\mathcal{C}(N_2, (N_1, N_2))$, respectively. Since the intersection of the two opposite cones of any unit in a strip coincides with this unit, we thus get that the units U'_N constructed in the proof coincide with the sets U_N defined in the formulation of the theorem.

Observe that, by Lemma 5.4, one can obtain $\mathcal{W}(N_1, N_2)$ directly from $\mathcal{F}_S$ by contracting the inner sides of the same tight cuts $\mathcal{C}(N_1, (N_1, N_2))$ and $\mathcal{C}(N_2, (N_1, N_2))$. Therefore, there is a bijection between the units of $\mathcal{F}_S$ and $\mathcal{W}_{S_1,S_2}$ that lie between

pairs of the above-described tight cuts; moreover, this bijection preserves the inherent partitions. Let us consider the set of units in $\mathcal{W}_{S_1,S_2}$ that do not participate in that bijection. One can deduce from Lemma 6.1 and Corollary 6.2 that each such unit U lies either inside the tight cut $\mathcal{C}(N,(N,M))$, where N is an endpoint of the link and (N,M) belongs to the link, or in the intersection of the inner sides of the two tight cuts $\mathcal{C}(N,(N,N_1))$ and $\mathcal{C}(N,(N,N_2))$, where N is an inner node of the link and N_1 and N_2 are the neighbors of N in the link. In the first case, U is one of the terminal units of $\mathcal{W}_{S_1,S_2}$ (by Fact 6.3(iii)). In the second case, U lies in the intersection of the two opposite cones of the unit U_N in $\mathcal{W}_{S_1,S_2}$, and thus coincides with U_N. The claim concerning the inherent partition at U_N follows immediately from the above construction and Fact 3.3. □

Remarks. (1) Let us distinguish a subset of coherent paths in $\mathcal{F}_S$ by preventing their inner units from "falling inside" any unit U_N, $N \in \mathcal{L}(S_1,S_2)$. By the construction above, these paths correspond naturally to the coherent paths of $\mathcal{W}_{S_1,S_2}$ without inner units U_N, $N \in \mathcal{L}(S_1,S_2)$.

(2) Observe that for any path $P = (N_0,\varepsilon_1,\dots,\varepsilon_r,N_r)$ in $\mathcal{H}_S$, the link of the subsets of S lying inside $\mathcal{C}(N_0,\varepsilon_1)$ and $\mathcal{C}(N_r,\varepsilon_r)$ is exactly P, since there are no empty nodes of degree at most two in $\mathcal{H}_S$. The strip corresponding to these two subsets is denoted by $\mathcal{W}(P)$.

6.3. The projection mapping. Let U be an arbitrary unit of the flesh $\mathcal{F}_S$. We say that U is *projected* to an edge ε of the skeleton $\mathcal{H}_S$ if U is a nonterminal unit of $\mathcal{W}(\varepsilon)$ (for example, unit U_2 in Figure 5.1(b) is a stretched unit of the strip $\mathcal{W}(N_1,N)$ shown in Figure 5.1(d), and thus U_2 is projected to the edge (N_1,N)). In other words, U is projected to $\varepsilon = (N_1,N_2)$ if it lies outside the N_1-tight and N_2-tight cuts in direction ε.

THEOREM 6.5. (i) *For any stretched unit U of the flesh, the set $\pi_S(U)$ of structural edges to which U is projected is nonempty and is the edge-set of a path in the skeleton.*

(ii) *For any terminal unit U of the flesh, the set of structural edges to which U is projected is empty, and there exists a unique node $\pi_S(U)$ of the skeleton such that U belongs to all $\pi_S(U)$-tight cuts.*

Proof. (i) The set $\pi_S(U)$ is nonempty by the definition of a stretched unit. Let us show that there exists a path in the skeleton containing all the structural edges in $\pi_S(U)$. If there is only one such edge, then the statement is trivial; thus in what follows we assume that $|\pi_S(U)| \geqslant 2$. Let us take a path $P = (N_0,\varepsilon_1,N_1,\dots,N_{r-1},\varepsilon_r,N_r)$ that is inclusion-maximal among all paths with both end-edges in $\pi_S(U)$. Suppose, to the contrary, that there exists an edge $\varepsilon \in \pi_S(U)$ that does not belong to P (see Figure 6.2(a)). Then the link of ε and P meets P in an inner node N_i (otherwise P could be extended). We denote by ε' the edge of this link incident to N_i. By Lemma 6.1, U lies outside the cuts $\mathcal{C}(N_i,\varepsilon_i)$, $\mathcal{C}(N_i,\varepsilon_{i+1})$, and $\mathcal{C}(N_i,\varepsilon')$. However, this contradicts the following generalization of part (i) of the 3-Star Lemma.

LEMMA 6.6. *Let N be a node of $\mathcal{H}_S$, ε_1, ε_2, ε_3 be structural edges incident to N, $\mathcal{C}_i = \mathcal{C}(N,\varepsilon_i)$, $i \in \{1,2,3\}$. Then $\bigcap_i \bar{V}_{\mathcal{C}_i} = \varnothing$.*

Proof. Let us choose a vertex $s_i \in S$ in such a way that $s_i \in \bar{V}_{\mathcal{C}_i}$, $i = 1,2,3$. Vertices s_i are distinct, since they belong to inverse images (under φ_S) of disjoint subtrees of $\mathcal{H}_S$. Observe that $\mathcal{T}(\{s_j,s_k\})$ is a path containing both ε_j and ε_k, but not containing ε_i. Thus, by Fact 6.3(iii), the $\{s_j,s_k\}$-tight $(\{s_j,s_k\},s_i)$-mincut coincides with $\mathcal{C}_i$. Therefore, $\mathcal{C}_i$ is exactly the cut $\mathcal{C}_{s_i}$ as defined in section 4.4, and the assertion of the lemma follows from part (i) of the 3-Star Lemma. □

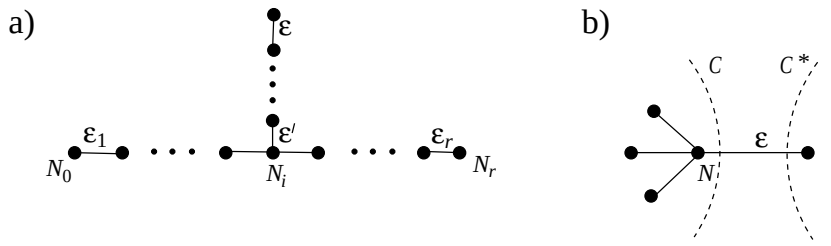

FIG. 6.2. *To the proofs of Theorem* 6.5 *and Lemma* 6.6.

Remark. Clearly, the remaining assertions of the 3-Star Lemma can be generalized to our case as well.

It remains to show that each edge $(N_{i-1}, \varepsilon_i, N_i)$ in P belongs to $\pi_S(U)$. Indeed, U lies outside both $\mathcal{C}(N_1, \varepsilon_1)$ and $\mathcal{C}(N_{r-1}, \varepsilon_r)$ and thus, by Lemma 6.1, outside both $\mathcal{C}(N_i, \varepsilon_i)$ and $\mathcal{C}(N_{i-1}, \varepsilon_i)$, as required.

(ii) Now let U be a terminal unit of the flesh. Then, for each structural edge ε, U lies inside exactly one of the two tight cuts in direction ε. Let us consider the collection $\mathcal{I}$ of all tight cuts that contain U inside and have inclusion-minimum inner sides. Let $\mathcal{C}'$ and $\mathcal{C}''$ be two arbitrary cuts in $\mathcal{I}$, ε' and ε'' be the corresponding structural edges, and let $[\varepsilon', \varepsilon''] = (N_0, \varepsilon', N_1, \ldots, N_{r-1}, \varepsilon'', N_r)$. Then, by Lemma 6.1 and the minimality of the cuts in question, one of the following possibilities holds: either $\mathcal{C}' = \mathcal{C}(N_0, \varepsilon')$ and $\mathcal{C}'' = \mathcal{C}(N_r, \varepsilon'')$ or $\mathcal{C}' = \mathcal{C}(N_1, \varepsilon')$ and $\mathcal{C}'' = \mathcal{C}(N_{r-1}, \varepsilon'')$.

In the first case, the tight cut $\mathcal{C}(N_1, \varepsilon')$ contains U inside (by Lemma 6.1), and thus both tight cuts in direction ε' contain U inside, a contradiction. In the second case, let us assume that there exists an edge $\varepsilon \in P(\varepsilon', \varepsilon'')$ distinct from ε' and ε''. Then, by Lemma 6.1 and the minimality of $\mathcal{C}'$ and $\mathcal{C}''$, both tight cuts in direction ε do not contain a terminal U inside, a contradiction. Therefore, $\mathcal{C}'$ and $\mathcal{C}''$ are tight cuts of the same node N ($N = N_1 = N_{r-1}$). One can prove easily that any other cut in $\mathcal{I}$ is also an N-tight cut.

Moreover, any N-tight cut belongs to $\mathcal{I}$. Indeed, assume that $\mathcal{C}$ is the N-tight cut in direction ε and $\mathcal{C} \notin \mathcal{I}$ (see Figure 6.2(b)). Denote by $\mathcal{C}^*$ the other tight cut in direction ε. Then U lies either inside $\mathcal{C}$ or inside $\mathcal{C}^*$. In the first case, there exists a cut in $\mathcal{I}$ dominated by $\mathcal{C}$. (For the definition of domination, see the beginning of section 2.) By the above reasoning, this cut is an N-tight cut, and we thus get two N-tight cuts with nested inner sides, which contradicts Corollary 6.2. In the second case, by Lemma 6.1, $\mathcal{C}^*$ is dominated by all the N-tight cuts except for $\mathcal{C}$, and thus by all the cuts in $\mathcal{I}$, which contradicts the minimality of these cuts. Therefore, we can set $\pi_S(U) = N$. □

Thus, the *projection* mapping π_S is defined, assigning to each unit U the path of Theorem 6.5 (observe that a single node is itself a path); the endpoints of this path are called the *coordinates* of U in $\mathcal{H}_S$ (compare with the definition preceding Lemma 4.13). For an example see Figures 5.1(b) and (c): the coordinates of the unit U_1 are N and N_3, those of U_2 are N_1 and N_3, and those of U are N and N.

The triple $(\mathcal{F}_S, \mathcal{H}_S, \pi_S)$ is called the *connectivity carcass* of S. According to Theorems 5.5(iii) and 5.6, its size is $O(\min\{\tilde{m}, \lambda_S \tilde{n}\}) = O(\min\{m, \lambda_S n\})$.

Let us consider a cut of the skeleton $\mathcal{H}_S$ defined by a structural edge and repre-

senting a bunch $\mathcal{B}$. If we delete this edge from the skeleton, it falls into two connected components $\mathcal{H}_S(\mathcal{B})$ and $\bar{\mathcal{H}}_S(\mathcal{B})$ containing $\varphi_S(S_{\mathcal{B}})$ and $\varphi_S(\bar{S}_{\mathcal{B}})$, respectively.

THEOREM 6.7. *The set of vertices lying inside the tight (resp., outside the loose) cut of $\mathcal{B}$ is the union of all units U of $\mathcal{F}_S$ such that $\pi_S(U) \subseteq \mathcal{H}_S(\mathcal{B})$ (resp., $\pi_S(U) \subseteq \bar{\mathcal{H}}_S(\mathcal{B})$).*

Proof. Let us denote by ε the structural edge corresponding to $\mathcal{B}$, and by N and $\bar{N}$ its endpoints lying in $\mathcal{H}_S(\mathcal{B})$ and $\bar{H}_S(\mathcal{B})$, respectively. Then the tight cut of $\mathcal{B}$ is $\mathcal{C}(N, \varepsilon)$, and the loose cut of $\mathcal{B}$ is $\bar{\mathcal{C}}(\bar{N}, \varepsilon)$. Now let U be an arbitrary unit of $\mathcal{F}_S$. If $\varepsilon \in \pi_S(U)$, then, by definition, U lies outside both $\mathcal{C}(N, \varepsilon)$ and $\mathcal{C}(\bar{N}, \varepsilon)$. Otherwise, $\varepsilon \notin \pi_S(U)$; by Theorem 6.5 we may assume w.l.o.g. that $\pi_S(U) \subseteq \mathcal{H}_S(\mathcal{B})$. Let us prove that U lies inside $\mathcal{C}(N, \varepsilon)$.

Assume to the contrary that this is not the case; then U lies inside $\mathcal{C}(\bar{N}, \varepsilon)$, since otherwise the projection of U would contain ε. If U is a stretched unit, then there exists a structural edge $\varepsilon' \in \pi_S(U) \subseteq \mathcal{H}_S(\mathcal{B})$. Let $[\varepsilon', \varepsilon] = (\bar{N}', \varepsilon', N', \ldots, N, \varepsilon, \bar{N})$. Then U lies outside $\mathcal{C}(N', \varepsilon')$ and inside $\mathcal{C}(\bar{N}, \varepsilon)$, in a contradiction to Lemma 6.1. Now let U be a terminal unit, and $N' = \pi_S(U) \subseteq \mathcal{H}_S(\mathcal{B})$ be its projection. We consider the link $(N', \varepsilon_1, \ldots, N)$ of N' and ε in $\mathcal{H}_S$. By Theorem 6.5(ii), U lies inside $\mathcal{C}(N', \varepsilon_1)$, which, by Lemma 6.1, contradicts to the fact that U lies outside $\mathcal{C}(N, \varepsilon)$. □

It follows readily from Theorem 6.7 that the projections of distinct terminal units are distinct. (It suffices to take for $\mathcal{B}$ the bunch of an arbitrary cut separating one of these units from the other.) Hence, π_S provides an *injection* of the set of terminal units into the set of nodes of $\mathcal{H}_S$.

Theorem 6.7 provides another point of view on the construction of Theorem 6.4.

COROLLARY 6.8. *A unit U_N is the union of all units U of $\mathcal{F}_S$ such that $\pi_S(U) \subseteq \mathcal{T}_N$. A unit U of $\mathcal{F}_S$ does not fall inside any unit U_N, $N \in \mathcal{L}(S_1, S_2)$, if and only if $\pi_S(U) \cap \mathcal{L}(S_1, S_2) \neq \varnothing$. A unit U_N is reachable from U in $\mathcal{W}_{S_1,S_2}$ if and only if N is not inner for $\pi_S(U) \cap \mathcal{L}(S_1, S_2)$.*

The following statement reveals an intimate relation between the projection of a stretched unit and its reachability cones. Let U be a stretched unit, $\mathcal{R}_1$ and $\mathcal{R}_2$ be the reachability cones of U, $\mathcal{N}_1$ and $\mathcal{N}_2$ be the sets of nodes that are the projections of the terminals belonging to $\mathcal{R}_1$ and $\mathcal{R}_2$, respectively, and $\mathcal{T}_1$ and $\mathcal{T}_2$ be the minimum subtrees of $\mathcal{H}_S$ containing $\mathcal{N}_1$ and $\mathcal{N}_2$, respectively. Observe that each reachability cone of U contains at least one terminal, and hence both $\mathcal{T}_1$ and $\mathcal{T}_2$ are nonempty.

THEOREM 6.9. *The projection of U coincides with the link of $\mathcal{T}_1$ and $\mathcal{T}_2$.*

Proof. Let ε be an arbitrary structural edge in the projection $\pi_S(U)$ and $\mathcal{B}$ be one of the two opposite bunches represented by ε. It is easy to see that all the terminals that belong to $\mathcal{R}_1$ lie inside the tight cut of $\mathcal{B}$, while those in $\mathcal{R}_2$ lie outside the loose cut of $\mathcal{B}$, up to flipping of $\mathcal{B}$. Hence, by Theorem 6.7, $\mathcal{T}_1 \subseteq \mathcal{H}_S(\mathcal{B})$ and $\mathcal{T}_2 \subseteq \bar{\mathcal{H}}_S(\mathcal{B})$. It follows immediately that the trees $\mathcal{T}_1$ and $\mathcal{T}_2$ are disjoint, and that $\pi_S(U) \subseteq \mathcal{L}(\mathcal{T}_1, \mathcal{T}_2)$.

Assume now that $\pi_S(U) \neq \mathcal{L}(\mathcal{T}_1, \mathcal{T}_2)$; then there exists a subpath $P = (N', \varepsilon', N, \varepsilon'', N'')$ of the link such that ε' belongs to $\pi_S(U)$, while ε'' does not. By Corollary 6.8, U_N is reachable from U in $\mathcal{W}(P)$. Hence, by the remark after Theorem 6.4, there exists a coherent path in $\mathcal{F}_S$ that leads from U to the intersection of the inner sides of $\mathcal{C}(N, \varepsilon')$ and $\mathcal{C}(N, \varepsilon'')$. Let us extend this path to a terminal U^* of $\mathcal{F}_S$ (see Figure 6.3).

If the extended path leaves the inner side of the N-tight cut in direction ε for some $\varepsilon \neq \varepsilon', \varepsilon''$, then it cannot return back, and, by Theorem 6.7, the projection of U^* lies in the subtree of $\mathcal{H}_S$ that is separated from N by ε. However, this projection belongs either to $\mathcal{T}_1$ or to $\mathcal{T}_2$, and hence one of the edges ε' and ε'' does not belong

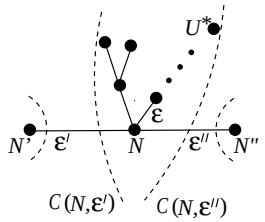

FIG. 6.3. *To the proof of Theorem* 6.9.

to $\mathcal{L}(\mathcal{T}_1, \mathcal{T}_2)$, a contradiction.

Otherwise, U^* lies inside all the N-tight cuts, and thus, by Theorem 6.5, it is projected to N, which gives the same contradiction as above. □

By Theorem 6.9, each of $\mathcal{T}_1$ and $\mathcal{T}_2$ contains exactly one coordinate of U. Therefore, we can label the reachability cones of any stretched unit (and thus the parts of the inherent partition) by its coordinates; the reachability cone of U that contains the terminals whose projections coincide with or lie "behind" the coordinate N is denoted by $\mathcal{R}_N(U)$. Moreover, we can now redenote the trees $\mathcal{T}_i$: the tree that contains N is denoted by $\mathcal{T}_N(U)$.

6.4. The cell structure. For any path in the skeleton with endpoints M and N we define the *cell* Q^{MN} as the set of units with the coordinates M, N (compare with definitions preceding the 3-Star Lemma and Lemma 4.10); by definition, the cell Q^{NM} coincides with Q^{MN}. A cell of type Q^{MM} is called *terminal*; it is either empty or consists of exactly one terminal unit (with projection M).

Let us introduce a visibility relation, which is, in a sense, a relaxation of the reachability relation studied in section 3. We say that a cell $Q^{M_2N_2}$ is *visible* from a nonterminal cell $Q^{M_1N_1}$ *in direction* N_1 if both $P_1 = [M_1, N_1]$ and $P_2 = [M_2, N_2]$ are subpaths of the same path P, so that $P = [M_1, N_2]$ or $P = [M_1, M_2]$. We denote this path P by $[P_1, P_2]$ (which is consistent with the previous use of notation $[\cdot, \cdot]$). It is easy to see that if $Q^{M_2N_2}$ is visible from $Q^{M_1N_1}$ in both directions, then $Q^{M_2N_2} = Q^{M_1N_1}$. The following statement, which is a generalization of Lemma 4.11, shows that the visibility relation is indeed a relaxation of the reachability relation.

THEOREM 6.10. *Let U_1 be a stretched unit with coordinates M_1 and N_1, $U_2 \in \mathcal{R}_{N_1}(U_1)$, and let Q_1 and Q_2 be the cells containing U_1 and U_2, respectively. Then Q_2 is visible from Q_1 in direction N_1.*

Proof. If U_2 is a terminal, then the assertion follows immediately from Theorem 6.9. Now let U_2 be a stretched unit with coordinates M_2 and N_2, and let w.l.o.g. $U_1 \in \mathcal{R}_{M_2}(U_2)$. Since $\mathcal{R}_{N_2}(U_2) \subseteq \mathcal{R}_{N_1}(U_1)$, we get $\mathcal{T}_{N_2}(U_2) \subseteq \mathcal{T}_{N_1}(U_1)$; hence the path $[N_1, N_2]$ lies entirely in $\mathcal{T}_{N_1}(U_1)$, and, by Theorem 6.9, intersects with $[M_1, N_1]$ exactly by N_1. Therefore, N_1 lies on $[M_1, N_2]$. Since U_2 is stretched, we can prove in a similar way that M_2 lies on $[M_1, N_2]$, as required. □

By Theorem 6.10, when we consider several units lying on the same coherent path, we may assume that their coordinates are named consistently. In other words, if $\pi_S(U_1) = [M_1, N_1]$, $\pi_S(U_2) = [M_2, N_2]$, and $U_2 \in \mathcal{R}_{N_1}(U_1)$, then we assume that U_1 belongs to $\mathcal{R}_{M_2}(U_2)$, and hence $[\pi_S(U_1), \pi_S(U_2)] = [M_1, N_2]$.

The following statement can be considered as the main relation between coherent

paths in the flesh and the skeleton.

COROLLARY 6.11. *Let U lie on a coherent path P from U_1 to U_2; then $M \in [M_1, M_2]$ and $N \in [N_1, N_2]$.*

Remark. It follows immediately from Corollary 6.11 that when one builds the strip $\mathcal{W}([M_1, N_2])$ (as described in Theorem 6.4), no intermediate unit of P is subject to contraction.

We now can extend the definition of the projection to the edges of $\mathcal{F}_S$, similar to what was done in section 4.5. Let $e = (U_1, U_2)$ be an edge of $\mathcal{F}_S$ and assume that $U_1 \in Q^{M_1N_1}$, $U_2 \in Q^{M_2N_2}$. We then say that the *projection* of e equals $[M_1, N_2]$; in other words, we define $\pi_S(U_1, U_2) = [\pi_S(U_1), \pi_S(U_2)]$. As in section 4.5, this definition can be justified by inserting a dummy vertex in the edge e; it is easy to see that the projection of the unit that contains such a vertex is exactly $[M_1, N_2]$. As before, there are three types of edges belonging to a cell Q^{MN}: internal (both endpoints belong to Q^{MN}), external (exactly one endpoint belongs to Q^{MN}), and through (both endpoints do not belong to Q^{MN}).

For any proper path $[M, N]$, $M \neq N$, we build from $\mathcal{F}_S$ a locally orientable graph $\mathcal{W}^{MN}$ with the set of nonterminals Q^{MN} (which may be as well empty). We delete all the cells nonvisible from Q^{MN} (observe that by Theorem 6.10 there are no edges between Q^{MN} and the deleted sets) and contract all the cells visible from Q^{MN} only in direction M and those visible only in direction N into two terminals $\tilde{M}$ and $\tilde{N}$, respectively. Finally, we delete all the edges between $\tilde{M}$ and $\tilde{N}$ that do not belong to Q^{MN}. An S-mincut $\mathcal{C}$ of G that separates the preimages of the terminals, and thus generates an $(\tilde{M}, \tilde{N})$-mincut $\tilde{\mathcal{C}}$ in $\mathcal{W}^{MN}$, is called an *extension* of $\tilde{\mathcal{C}}$ (compare with definitions preceding Lemmas 4.2 and 4.8). The following result is a generalization of Lemmas 4.2, 4.8, and 4.12.

THEOREM 6.12. (i) *The graph $\mathcal{W}^{MN}$ is a strip; moreover, if $[M, N]$ contains at least two structural edges, then its width λ^{MN} does not exceed $\lambda_S/2$.*

(ii) *All its transversal cuts, and only they, are extendable to S-mincuts. Such an extension can be found in any bunch corresponding to an edge in $[M, N]$ and in no other bunch.*

(iii) *Let $\{Q^{M_iN_i}\}$ be a set of pairwise nonvisible cells such that all the paths $[M_i, N_i]$ contain at least one common edge. Then any set of transversal cuts of $\mathcal{W}^{M_iN_i}$ has a mutual extension to an S-mincut. Moreover, if all the paths $[M_i, N_i]$ contain at least two common edges, then $\sum_i \lambda^{M_iN_i} \leqslant \lambda_S/2$.*

(iv) *If a 2-partition of $V \setminus \bigcup_i Q^{M_iN_i}$ enters a mutual extension of some sample of transversal cuts, one from each of $\mathcal{W}^{M_iN_i}$, then it enters some mutual extension of any such sample. (Informally, samples of transversal cuts of these strips are interchangeable in S-mincuts.)*

Proof. We start from the following general observation. Let $\varepsilon' = (M', N')$ be an arbitrary structural edge of $[M, N]$. (We assume that $[M, M']$ and $[N, N']$ do not intersect.) Let us consider the strip $\mathcal{W}(\varepsilon')$. Its terminals correspond naturally to M' and N'. Evidently, any unit of Q^{MN} remains stretched in $\mathcal{W}(\varepsilon')$; its cones and the sides of its star are labeled by M' and N'. Let $\mathcal{R}_{M'}$ denote the union over $U \in Q^{MN}$ of the cones $\mathcal{R}_{M'}(U)$ in $\mathcal{W}(\varepsilon')$; $\mathcal{R}_{N'}$ is defined similarly.

Let us delete $\bar{\mathcal{R}}_{M'} \cap \bar{\mathcal{R}}_{N'}$ and contract $\bar{\mathcal{R}}_{M'} \cap \mathcal{R}_{N'}$ and $\mathcal{R}_{M'} \cap \bar{\mathcal{R}}_{N'}$ into two new terminals $\tilde{M}'$ and $\tilde{N}'$, respectively. It is easy to see that each direct edge between $\tilde{M}'$ and $\tilde{N}'$ corresponds to a through edge in Q^{MN}; the converse is not true, since the endpoints of a through edge do not necessarily belong to $\mathcal{R}_{M'}$ or $\mathcal{R}_{N'}$. Thus, the number of direct edges between $\tilde{M}'$ and $\tilde{N}'$ does not exceed the number of through

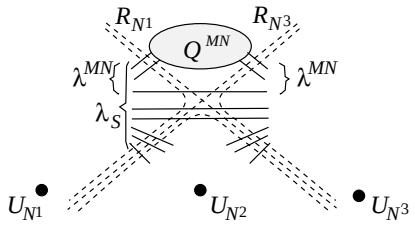

FIG. 6.4. *To the proof of inequality* $\lambda^{MN} < \lambda_S/2$.

edges in Q^{MN}. If it is strictly less, we add complementary direct edges in order to equalize these quantities. Let us denote the obtained locally orientable graph by $\tilde{\mathcal{W}}^{MN}$. We claim that $\tilde{\mathcal{W}}^{MN}$ coincides with $\mathcal{W}^{MN}$.

First of all, $Q^{MN} = \mathcal{R}_{M'} \cap \mathcal{R}_{N'}$. Indeed, the inclusion $Q^{MN} \subseteq \mathcal{R}_{M'} \cap \mathcal{R}_{N'}$ is trivial. On the other hand, if $U \in \mathcal{R}_{M'} \cap \mathcal{R}_{N'}$, then there exist $U', U'' \in Q^{MN}$ such that U lies on a coherent path from U' to U''. Hence, by Corollary 6.11, $\pi_S(U) = [M, N]$ and so $U \in Q^{MN}$.

Let us consider an arbitrary edge $e = (U, U^*)$ such that $U \in Q^{MN}$ and $U^* \notin Q^{MN}$. While constructing $\tilde{\mathcal{W}}^{MN}$ and $\mathcal{W}^{MN}$, this edge is not deleted (by Lemma 2.1 and Theorem 6.10, respectively) and goes from U to a terminal. In $\tilde{\mathcal{W}}^{MN}$ this terminal corresponds to the label of the side at U in $\mathcal{F}_S$ that contains e. By Theorems 6.7 and 6.10, the same holds true for $\mathcal{W}^{MN}$. Therefore, the stars of the corresponding terminals in $\tilde{\mathcal{W}}^{MN}$ and $\mathcal{W}^{MN}$ coincide, and thus these locally orientable graphs coincide as well.

(i) By the construction of $\tilde{\mathcal{W}}^{MN}$, it is a balanced acyclic two-terminal locally orientable graph; hence, by part (i) of the Strip Lemma, it is a strip.

Let $[M, N]$ contain at least two structural edges, and let N^1, N^2, N^3 be any three consequent nodes in $[M, N]$. We consider the strip $\mathcal{W}([N^1, N^3])$ and define the cones $\mathcal{R}_{N^1}$ and $\mathcal{R}_{N^3}$ in it and the strip $\tilde{\mathcal{W}}^{MN} \equiv \mathcal{W}^{MN}$ in the same way as above. By Theorem 6.10 and the construction of $\mathcal{W}([N^1, N^3])$ in Theorem 6.4, the contracted unit U_{N^2} belongs to $\bar{\mathcal{R}}_{N^1} \cap \bar{\mathcal{R}}_{N^3}$. Since $\mathcal{C}^1 = (\mathcal{R}_{N^1}, \bar{\mathcal{R}}_{N^1})$ and $\mathcal{C}^3 = (\mathcal{R}_{N^3}, \bar{\mathcal{R}}_{N^3})$ are S-mincuts, there are no edges between $\mathcal{R}_{N^1} \cap \mathcal{R}_{N^3}$ and $\bar{\mathcal{R}}_{N^1} \cap \bar{\mathcal{R}}_{N^3}$ (by Lemma 2.1). Next, since $\mathcal{C}^1 \cap \bar{\mathcal{C}}^3$ is an S-mincut, one has $c(\mathcal{R}_{N^1} \cap \bar{\mathcal{R}}_{N^3}, \bar{\mathcal{R}}_{N^1} \cap \bar{\mathcal{R}}_{N^3}) = \lambda_S - \lambda^{MN}$; similarly, $c(\bar{\mathcal{R}}_{N^1} \cap \mathcal{R}_{N^3}, \bar{\mathcal{R}}_{N^1} \cap \bar{\mathcal{R}}_{N^3}) = \lambda_S - \lambda^{MN}$ (see Figure 6.4). Hence, $c(\bar{\mathcal{R}}_{N^1} \cap \bar{\mathcal{R}}_{N^3}, \mathcal{R}_{N^1} \cup \mathcal{R}_{N^3}) = 2(\lambda_S - \lambda^{MN})$. However, since $U_{N^2} \cap S \neq \varnothing$, one has $c(\bar{\mathcal{R}}_{N^1} \cap \bar{\mathcal{R}}_{N^3}, \mathcal{R}_{N^1} \cup \mathcal{R}_{N^3}) \geqslant \lambda_S$. Thus $\lambda^{MN} < \lambda_S/2$, as required.

(ii) Existence of an extension for any $(M', N') \in [M, N]$ is proved in the same way as it was done in Lemma 4.12(ii), with the set X_a replaced by $\mathcal{R}_{M'} \cap \bar{\mathcal{R}}_{N'}$ and $\bar{X}_c$ by $\mathcal{R}_{N'} \cap \bar{\mathcal{R}}_{M'}$.

Any extension of a transversal cut of $\mathcal{W}^{MN}$ separates the preimages of $\tilde{M}$ from those of $\tilde{N}$ and hence the set of terminals "behind" M from the set of terminals "behind" N. By Fact 6.3(ii) and the second remark after Theorem 6.4, the bunch of such a cut must be defined by an edge in $[M, N]$.

(iii) Let $\varepsilon' = (M', N')$ be a common edge of all the $[M_i, N_i]$. We consider the strip $\mathcal{W}(\varepsilon')$ and build the sets $\mathcal{R}^i_{M'}$ and $\mathcal{R}^i_{N'}$ as above. Let $\mathcal{R}^*_{M'}$ be the union of $\mathcal{R}^i_{M'}$ over all i, and let $\mathcal{R}^*_{M'}$ be defined similarly. Let $e = (U, U^*)$ be an edge such that

$U \in Q^{M_iN_i}$, $U^* \notin Q^{M_iN_i}$, and $U^* \notin \mathcal{R}^i_{M'}$; then $U^* \notin \mathcal{R}^*_{M'}$. Indeed, assume to the contrary that $U^* \in \mathcal{R}^j_{M'}$, $j \neq i$; then, by Theorem 6.10, the cell $Q^{M_iN_i}$ is visible from $Q^{M_jN_j}$, a contradiction. The rest of the proof of the existence of a mutual extension is similar to that of Lemma 4.12(iii), as above. The inequality for $\sum_i \lambda^{M_iN_i}$ follows immediately from Lemma 4.12(iii) applied to the strip $\mathcal{W}(\cap_i[M_i, N_i])$. One should note, however, that some nodes of $(\cap_i[M_i, N_i])$ can be empty, and hence the inequality of type $\lambda_{ii} > \lambda_S/2$ for such a node is replaced by $\lambda_{ii} \geqslant \lambda_S/2$. As a consequence, we get a nonstrict inequality for $\sum_i \lambda^{M_iN_i}$.

(iv) The proof is similar to that of Lemma 4.12(iv). □

6.5. Other properties of the connectivity carcass. Assume that we are interested in pointing out an S-mincut separating two given vertices of G that lie in distinct units U_1 and U_2. The following statement is obtained easily.

LEMMA 6.13. (i) *Let $\pi_S(U_1)$ and $\pi_S(U_2)$ be distinct* nodes *of $\mathcal{H}_S$. Consider any cut of $\mathcal{H}_S$ separating them, and let $\mathcal{B}$ be any of the corresponding bunches. Then the tight and the loose cuts of $\mathcal{B}$ separate U_1 from U_2.*

(ii) *Let one of the projections, say, $\pi_S(U_1)$, contain a structural edge $\varepsilon_1 = (M_1, N_1)$, and let M, N be the coordinates of U_1 in the corresponding order. Then one of the sets $\mathcal{R}_M(U_1) \cup V^{\mathcal{C}(M_1,\varepsilon_1)}$ and $\mathcal{R}_N(U_1) \cup V^{\mathcal{C}(N_1,\varepsilon_1)}$ defines an S-mincut separating U_1 from U_2.*

Proof. (i) The proof follows from Fact 6.3(ii).

(ii) It is clear from the structure of $\mathcal{W}_{\varepsilon_1}$ that both sets mentioned define S-mincuts; on the other hand, their intersection is exactly $U_1 \neq U_2$, and the result follows. □

Consider now a pair s, t of non-(λ_S+1)-connected vertices in S. Let us decompose the connectivity carcass with respect to this pair.

Let $U_i = U_{N_i}$, $0 \leqslant i \leqslant k$, be the heavy units of $\mathcal{W}_{s,t}$, $s \in U_0$, $t \in U_k$ (see Theorem 6.4 for details); it is easy to prove that U_i are numbered according to any topological order of $\mathcal{W}_{s,t}$. For any i as above we put $\Sigma_i = S \cap U_i$ (which coincides with Σ_{N_i} defined in the proof of Theorem 6.4) and contract the set S in two different ways: S^i is obtained by contraction of $S \setminus \Sigma_i$ into a single vertex s^i, and $\tilde{S}$ is obtained by contraction of each of Σ_i into a single vertex $\tilde{s}_i$. The graphs G^i and $\tilde{G}$ are defined similarly as the results of the above two contractions applied to G. Note that the connectivity of $\tilde{S}$ in $\tilde{G}$ is exactly λ_S, while the connectivity of S^i in G^i can be greater than λ_S.

It can be shown easily that the connectivity carcass of $\tilde{S}$ in $\tilde{G}$ has the same type as one considered in section 4.5. Its skeleton is the path $[N_0, N_k]$ and its flesh is obtained from $\mathcal{W}_{s,t}$ by turning the heavy units U_i, $0 \leqslant i \leqslant k$, into terminals.

Let I denote the set of indices such that $\lambda_{S^i}(G^i) = \lambda_S$.

LEMMA 6.14. (i) *The skeleton $\mathcal{H}_S$ is obtained from the path $[N_0, N_k] = \mathcal{H}_{\tilde{S}}(\tilde{G})$ and the skeletons $\mathcal{H}_{S^i}(G^i)$, $i \in I$, by identifying N_i with the node $N^i = \varphi_{S^i}(s^i)$ of $\mathcal{H}_{S^i}(G^i)$.*

(ii) *The units of the flesh $\mathcal{F}_S$ are*

- *the units of $\mathcal{F}_{S^i}(G^i)$, $i \in I$, except for the unit U^i containing s^i;*
- *the nonheavy units of $\mathcal{W}_{s,t}$;*
- *the terminal units $U^{(i)} = U^i \cap V_{\mathcal{C}(N_i,(N_i,N_{i-1}))} \cap V_{\mathcal{C}(N_i,(N_i,N_{i+1}))} \neq \varnothing$, $i \in I$, and $U^{(i)} = V_{\mathcal{C}(N_i,(N_i,N_{i-1}))} \cap V_{\mathcal{C}(N_i,(N_i,N_{i+1}))} \neq \varnothing$, $i \notin I$ (for $i = 0$ and $i = k$ only one of the above two cuts is taken), if nonempty.*

Moreover, if a unit other than $U^{(i)}$ participates in a more than one flesh as above, then it participates in $\mathcal{F}_{\tilde{S}}(\tilde{G})$ and at most two of $\mathcal{F}_{S^i}(G^i)$.

(iii) *The projection of any unit other than $U^{(i)}$ is the concatenation of its projections in the connectivity carcasses that contain it.*

Proof. Observe that each S-mincut of G either partitions one of Σ_i, $i \in I$, and does not partition its complement in S or separates some of Σ_i from the others according to the skeleton $\mathcal{H}_S$. More exactly, each bunch of S-mincuts of G coincides either with a bunch of $\tilde{S}$-mincuts of $\tilde{G}$ or with a bunch of S^i-mincuts of G^i for some $i \in I$. This implies assertion (i).

Let U be a terminal unit of $\mathcal{F}_S$ corresponding to a node N of $\mathcal{H}_S$. Recall that U is the intersection of all N-tight cuts. If N belongs to the subtree $\mathcal{H}_i$ of $\mathcal{H}_S$ hanging on the path $[N_0, N_k]$ at N_i and $N \neq N_i$, then these cuts are the N-tight cuts of the connectivity carcass of S^i in G^i. Therefore, U is a terminal unit of this partial connectivity carcass. If $N = N_i$, $i \in I$, then all the N-tight cuts are of the same type, except for one or two cuts corresponding to the edges of $[N_0, N_k]$ incident to N_i. Clearly, U_i is a unit of $\mathcal{F}_S$ for any $i \notin I$. Thus we get assertion (ii) for terminals.

Let U be a stretched unit. It is distinguished by all bunches that correspond to the edges of its projection. The projection is contained either in one of $\mathcal{H}_i$, or in $\mathcal{H}_i \cup [N_0, N_k]$ for some i, or in $\mathcal{H}_i \cup [N_i, N_j] \cup \mathcal{H}_j$. The rest of assertion (ii) follows, as well as assertion (iii). □

7. Incremental transformations of the connectivity carcass.

7.1. Transformations of the components of the connectivity carcass. In this section we describe the transformations of all the three components of the connectivity carcass caused by insertion of a new edge (u_1, u_2) that preserves the value of λ_S. In what follows U_i stands for the unit containing u_i, Q_i for the cell containing U_i, and P_i for the projection $\pi_S(U_i)$, $i = 1, 2$. If $U_1 = U_2$, then the carcass does not change. So in what follows we assume that $U_1 \neq U_2$. If P_1 and P_2 are edge-disjoint, we denote by L_1 and L_2, respectively, the endpoints of the link $\mathcal{L} = \mathcal{L}(P_1, P_2)$. Otherwise, we set $\mathcal{L} = \varnothing$ and denote by $[M, N]$ the intersection of the projections; furthermore, in this case we assume w.l.o.g. that if $P_1 = [M_1, N_1]$ and $P_2 = [M_2, N_2]$, then the paths $[M_1, M_2]$ and $[N_1, N_2]$ do not intersect and $M \in [M_1, M_2]$, $N \in [N_1, N_2]$. In both cases we denote by $\mathcal{T}$ the minimal subtree of $\mathcal{H}_S$ containing both P_1 and P_2. Recall that we put a hat over any notation (e.g., $\widehat{\mathcal{H}}_S$ or $\widehat{\mathcal{F}}_S$) to denote the corresponding object after edge insertion.

The main concern of this section is to distinguish, in terms of the connectivity carcass, the S-mincuts that do not separate U_1 from U_2, since these are exactly the S-mincuts that are preserved under the insertion.

The transformations of the skeleton under edge insertion are as follows.

THEOREM 7.1. *If $\mathcal{L}$ contains at least one structural edge, then all the nodes and structural edges of $\mathcal{L}$ are contracted to a single new node; otherwise the skeleton remains the same.*

Proof. Let $\widehat{\mathcal{H}}_S$ be obtained from $\mathcal{H}_S$ by contraction of $\mathcal{L}$ into a new node N (or $\widehat{\mathcal{H}}_S = \mathcal{H}_S$ if $\mathcal{L}$ does not contain any edges). We define $\widehat{\varphi}_S$ as follows: $\widehat{\varphi}_S = \varphi_S$ if $\varphi_S \notin \mathcal{L}$, and $\widehat{\varphi}_S = N$ otherwise.

Let ε be an arbitrary structural edge in $\mathcal{H}_S$.

If $\varepsilon \notin \mathcal{T}$, then, by Theorem 6.7, both U_1 and U_2 lie in the same terminal of the strip $\mathcal{W}(\varepsilon)$. Hence, in this case the new edge does not affect any cut of this strip.

If $\varepsilon \in \mathcal{T}$, but $\varepsilon \notin \mathcal{L}$, then at least one of the units U_1 and U_2 is a stretched unit in $\mathcal{W}(\varepsilon)$. Hence, in this case at least one tight cut of $\mathcal{W}(\varepsilon)$ is not affected by the new edge, and thus the corresponding 2-partition of S is still an S-mincut.

Finally, if $\varepsilon \in \mathcal{L}$, then, by Theorem 6.7, U_1 and U_2 lie in distinct terminals of $\mathcal{W}(\varepsilon)$. Hence, in this case no cuts represented by $\mathcal{W}(\varepsilon)$ survive, and thus the corresponding 2-partition of S ceases to be an S-mincut.

Thus, by Theorem 5.6, $\widehat{\mathcal{H}}_S$ is indeed the skeleton of the graph $G \cup (u_1, u_2)$. □

The transformations of the flesh under edge insertion are as follows.

THEOREM 7.2. *The new flesh is obtained by contraction of a certain subset of units of $\mathcal{F}_S$ into a single new unit U^{new}. This subset contains*

(i) *U_1 and U_2;*

(ii) *all the units lying on coherent paths between U_1 and U_2;*

(iii) *all the units U such that $\pi_S(U) \subseteq \mathcal{L}$;*

(iv) *in the case when an endpoint K of P_i is the unique common point of P_i and $P_j \cup \mathcal{L}$, $i, j \in \{1, 2\}$, $i \neq j$, all the units U such that $U \in \mathcal{R}_K(U_i)$ and $\pi_S(U) \subseteq P_i \cup \mathcal{L}$.*

Proof. First, let us prove the following statement concerning the initial graph G.

CLAIM A. *If a unit U satisfies at least one of the conditions of Theorem* 7.2, *then any S-mincut that separates U_1 from U separates also U_1 from U_2.*

Indeed, if $U = U_2$, then the claim is trivial.

Let U belong to a coherent path between U_1 and U_2. Let $\mathcal{C}$ be an S-mincut that separates U_1 from U but fails to separate U_1 from U_2; then we get a coherent path with both endpoints on one side of $\mathcal{C}$ and an intermediate unit U on the other side, a contradiction.

Let $\pi_S(U) \subseteq \mathcal{L}$, and let $\mathcal{C}$ be an S-mincut separating U_1 from U. By Theorem 6.7, the structural edge ε representing $\mathcal{C}$ in $\mathcal{H}_S$ lies either in $\mathcal{L}$ or in P_1. If $\varepsilon \in \mathcal{L}$, then U_1 and U_2 are separated by any cut represented by ε (see the proof of Theorem 7.1). If $\varepsilon \in P_1$, then U_1 is a stretched unit of $\mathcal{W}(\varepsilon)$, while both U and U_2 lie in the same terminal of $\mathcal{W}(\varepsilon)$, and the claim follows.

Assume now that an endpoint K of P_1 is the unique common point of P_1 and $P_2 \cup \mathcal{L}$, and besides, $U \in \mathcal{R}_K(U_1)$ and $\pi_S(U) \subseteq P_1 \cup \mathcal{L}$. Let $\mathcal{C}$ and ε be as in the previous case; then, by Theorem 6.7, ε belongs to $P_1 \cup \mathcal{L}$. If $\varepsilon \in \mathcal{L}$, we proceed as above. If $\varepsilon \in P_1 \cap \pi_S(U)$, then both U_1 and U are stretched units of $\mathcal{W}(\varepsilon)$. Moreover, U_2 lies in one of the terminals of $\mathcal{W}(\varepsilon)$, and, by Theorem 6.10, U lies in the cone of U_1 containing this terminal. Thus, $\mathcal{C}$ separates U_1 from U_2. If ε lies in P_1, but not in $\pi_S(U)$, then, by Theorem 6.10, both U and U_2 lie in the same terminal of $\mathcal{W}(\varepsilon)$, and again $\mathcal{C}$ separates U_1 from U_2.

Finally, if an endpoint K of P_2 is the unique common point of P_2 and $P_1 \cup \mathcal{L}$, and besides, $U \in \mathcal{R}_K(U_2)$ and $\pi_S(U) \subseteq P_2 \cup \mathcal{L}$, one has to interchange the roles of U_1 and U_2 in the above reasoning.

Therefore, Claim A is proved, and as an immediate corollary we get that all the units listed in Theorem 7.2 are indeed contracted into a single new unit.

Let us now prove another statement concerning the initial graph G.

CLAIM B. *If a unit U violates all the conditions of Theorem* 7.2 *and $U' \neq U$ is an arbitrary unit, then there exists an S-mincut that separates U from U' and does not separate U_1 from U_2.*

Indeed, let $P = \pi_S(U)$, let Q be the cell containing U, and assume first that U is a stretched unit.

Suppose that there exists a structural edge $\varepsilon \in P$ that does not belong to $\mathcal{T}$. Then U is a stretched unit in $\mathcal{W}(\varepsilon)$, while both U_1 and U_2 lie in the same terminal of $\mathcal{W}(\varepsilon)$ (by Theorem 6.7). Therefore, any S-mincut that separates U from U' in $\mathcal{W}(\varepsilon)$ satisfies the assertion of the claim.

From now on we may assume that P lies entirely in $\mathcal{T}$. By the assumptions of the Theorem, P does not lie entirely in $\mathcal{L}$; hence, there exists an edge $\varepsilon \in P$ that belongs (w.l.o.g.) to P_1. If ε belongs also to P_2, then all the three units U, U_1, and U_2 are stretched in $\mathcal{W}(\varepsilon)$. If U_1 and U_2 lie in the opposite cones of U in $\mathcal{W}(\varepsilon)$, then U lies on a coherent path from U_1 to U_2, which is prohibited by the assumptions of the claim. So, there exists a cone $\mathcal{R}$ of U in $\mathcal{W}(\varepsilon)$ that contains neither U_1 nor U_2. If $\mathcal{R}$ does not contain U' as well, then the cut of $\mathcal{W}(\varepsilon)$ defined by $\mathcal{R}$ satisfies the assertion of the claim. Otherwise, we use instead of $\mathcal{R}$ the cone $\mathcal{R}'$ of U' in $\mathcal{W}(\varepsilon)$ that is contained in $\mathcal{R}$.

If $\varepsilon \notin P_2$, then in $\mathcal{W}(\varepsilon)$ both U and U_1 are stretched, while U_2 lies in a terminal. Let $\mathcal{R}$ be the cone of U in $\mathcal{W}(\varepsilon)$ that contains the other terminal. If U_1 does not belong to $\mathcal{R}$, then the cut of $\mathcal{W}(\varepsilon)$ defined by $\mathcal{R}$ (or by $\mathcal{R}'$, as above, if $U' \in \mathcal{R}$) satisfies the assertion of the claim.

Now let $U_1 \in \mathcal{R}$; this means, in particular, that U belongs to some cone of U_1 in $\mathcal{W}(\varepsilon)$, and thus in $\mathcal{F}_S$, say, $U \in \mathcal{R}_K(U_1)$. By Theorem 6.10, this means that Q is visible from Q_1 in direction K. Therefore, if ε_1 is the edge of P_1 incident to K, then $\varepsilon_1 \in P$. If $\varepsilon_1 \in P_2$, we proceed in the same way as above; so, we may assume that $\varepsilon_1 \notin P_2$. Let us consider the strip $\mathcal{W}(\varepsilon_1)$. Both U and U_1 are stretched in $\mathcal{W}(\varepsilon_1)$; moreover, U lies in a cone $\mathcal{R}_1$ of U_1, while U_2 lies in a terminal. If this terminal does not belong to $\mathcal{R}_1$, we consider the cone $\mathcal{R}$ of U that lies inside $\mathcal{R}_1$. It is easy to see that the cut of $\mathcal{W}(\varepsilon_1)$ defined by $\mathcal{R}$ (or by $\mathcal{R}'$, as above, if $U' \in \mathcal{R}$) satisfies the assertion of the claim.

Finally, let the terminal containing U_2 in $\mathcal{W}(\varepsilon)$ lie in $\mathcal{R}_1$. It follows immediately from Theorem 6.7 that in this case K is the unique common point of P_1 and $P_2 \cup \mathcal{L}$. By the assumptions of the claim, P does not lie entirely in $P_1 \cup \mathcal{L}$; hence, there exists an edge ε_2 of P such that $\varepsilon_2 \in P_2$. Evidently, in $\mathcal{W}(\varepsilon_2)$ both U and U_2 are stretched, while U_1 lies in a terminal. Let U lie outside the cone of U_2 in $\mathcal{W}(\varepsilon_2)$ that contains this terminal, and let $\mathcal{R}$ be the cone of U in $\mathcal{W}(\varepsilon_2)$ that contains the other terminal; then the cut of $\mathcal{W}(\varepsilon_2)$ defined by $\mathcal{R}$ (or by $\mathcal{R}'$, as above, if $U' \in \mathcal{R}$) satisfies the assertion of the claim. Otherwise, we use the same reasoning as above to see that one of the endpoints of P_2 is the unique common point of P_2 and $P_1 \cup \mathcal{L}$, and hence $\mathcal{T}$ is just a path. Therefore, Q_1 and Q_2 are visible from Q in opposite directions. Thus, the coherent path from U_1 to U in $\mathcal{W}(\varepsilon_1)$ can be concatenated with a coherent path from U to U_2 in $\mathcal{W}(\varepsilon_2)$, and we get that U lies on a coherent path from U_1 to U_2, in a contradiction with the assumptions of the claim.

Assume now that U is a terminal unit, and let $P' = \pi_S(U')$. Observe that P from now on is a node of $\mathcal{H}_S$.

If $P \cap P' = \varnothing$, then, by the assumptions of the claim, there exists a structural edge ε that belongs to the link of P and P' and does not lie in $\mathcal{L}$. Evidently, the units U and U' lie in the opposite terminals of the strip $\mathcal{W}(\varepsilon)$. On the other hand, the units U_1 and U_2 cannot lie in the opposite terminals in such a strip. Therefore, one of the tight cuts in direction ε satisfies the assertion of the claim.

Now let $U' = U_1$ and P be a node of P_1. If P is not an endpoint of P_1, then at least one of the two P-tight cuts in directions of the edges of P_1 incident to P does not contain U_2 (otherwise P would belong to $\mathcal{L}$). If P is an endpoint of P_1, then the P-tight cut in direction of the edge of P_1 incident to P does not contain U_2 (for the same reason as above).

This completes the proof of Claim B, since if U' is stretched and satisfies the assumptions of the claim, then we can use the same reasoning as above interchanging

the roles of U and U', whereas if U' violates the assumptions of the claim, then any cut that separates U from U_1 separates also U from U', by Claim A.

As an immediate corollary of Claim B we get that all the units not listed in Theorem 7.2 remain uncontracted, and thus the Theorem is proved. □

The transformations of the projections under edge insertion are as follows.

THEOREM 7.3. (i) *The projection of* U^{new} *is either the new node obtained by the contraction of* $\mathcal{L}$ (*if* $\mathcal{L}$ *contains at least one structural edge*), *or* $P_1 \cap P_2$ *otherwise.*

(ii) *The intersection with* $\mathcal{L}$ *is deleted from the projection of any noncontracted unit.*

(iii) *For each unit* $U \in \mathcal{R}_{N_1}(U_1)$, *the common part of* $\pi_S(U)$ *and the path between* M_1 *and* M (*or* L_1) *is deleted from* $\pi_S(U)$. *Similar transformations are applied to* $\mathcal{R}_{M_1}(U_1)$, $\mathcal{R}_{N_2}(U_2)$, $\mathcal{R}_{M_2}(U_2)$.

Proof. Assume first that U is an arbitrary stretched unit of the initial graph, and let ε be an arbitrary structural edge of $\pi_S(U)$.

If $\varepsilon \notin \mathcal{T}$, then both U_1 and U_2 lie in the same terminal of $\mathcal{W}(\varepsilon)$, and thus the new edge does not affect any cut of $\mathcal{W}(\varepsilon)$. Hence, ε is preserved in the new projection of U.

If $\varepsilon \in \mathcal{L}$, then U_1 and U_2 lie in the opposite terminals of $\mathcal{W}(\varepsilon)$, and thus all the cuts of $\mathcal{W}(\varepsilon)$ do not survive. Hence, ε is deleted from the new projection of U.

If $\varepsilon \in P_1 \cap P_2$, then both U_1 and U_2 are stretched units of $\mathcal{W}(\varepsilon)$. Therefore, both tight cuts of $\mathcal{W}(\varepsilon)$ remain unaffected by the new edge, and hence ε is preserved in the new projection of U.

The only remaining case is when ε belongs to exactly one of the P_1 and P_2; assume w.l.o.g. that $\varepsilon \in [M_1, K]$, where $K = M$ if $P_1 \cap P_2 \neq \varnothing$, and $K = L_1$ otherwise. Then U_1 is a stretched unit of $\mathcal{W}(\varepsilon)$, while U_2 lies in the terminal of $\mathcal{W}(\varepsilon)$ that belongs to $\mathcal{R}_{N_1}(U_1)$ (or, more exactly, to the cone of U_1 in $\mathcal{W}(\varepsilon)$ that lies in $\mathcal{R}_{N_1}(U_1)$). Therefore, if $U \notin \mathcal{R}_{N_1}(U_1)$, then ε is preserved in the new projection of U, while otherwise it is deleted from the new projection.

Assume now that U is a terminal of $\mathcal{F}_S$; evidently, the new edge cannot convert it to a stretched unit, and thus all we have to do is to establish that the new projection of U cannot shift.

By Theorem 6.5(ii), U lies in the intersection of all the K-tight cuts, where $K = \pi_S(U)$. It follows easily from Theorem 7.1 that if ε is incident to K and $\varepsilon \notin \mathcal{L}$, then the new K-tight cut in direction ε dominates the old one. Therefore, if $K \notin \mathcal{L}$, or $K = \mathcal{L}$, then K remains to be the projection of U in the new skeleton.

Finally, let $K \in \mathcal{L}$ and $K \neq \mathcal{L}$; we denote by ε_i and ε_i' the edges of the path $[K, L_i]$ incident to K and L_i, respectively ($i = 1, 2$). By Lemma 6.1, any L_i-tight cut, except for the L_i-tight cut in direction ε_i', dominates the K-tight cut in direction ε_i. By Theorem 7.1, all the edges incident to L_i except for ε_i' are preserved in the new skeleton, and are incident to its new node. Evidently, the tight cut of the new node in any of these directions dominates the L_i-tight cut in the same direction. Thus, the U^{new} lies in the intersection of all the tight cuts of the new node. □

Remark. It follows from Theorems 7.2 and 7.3 that if a unit must be contracted, then its new projection obtained formally via Theorem 7.3 coincides with that of U^{new}.

Finally, let us describe the transformation of the inherent 2-partition under edge insertion.

THEOREM 7.4. (i) *The inherent* 2*-partitions at noncontracted units remain the same.*

(ii) *If $P_1 \cap P_2$ does not contain any edges, then the inherent 2-partition at U^{new} is trivial. Otherwise, the inherent 2-partition for U^{new} is glued from those for contracted units. Namely, the part of the star of U_1 labeled by N_1 (resp., M_1) is glued with that for U_2 labeled by N_2 (resp., M_2). For other units, two parts are glued together if the corresponding reachability cones contain the same unit out of U_1 and U_2.*

Proof. (i) Follows immediately from Theorem 7.3, since the 2-partition at a unit U of the flesh is either trivial or inherited from the 2-partition at the same unit of any strip $\widehat{\mathcal{W}}(\varepsilon)$, $\varepsilon \in \pi_S(U)$.

(ii) The first part follows immediately from Theorem 7.3.

Let $P_1 \cap P_2$ now contain at least one edge ε. By Lemma 5.3, it is enough to prove the statement for the 2-partition at U in the strip $\widehat{\mathcal{W}}(\varepsilon)$. It follows from Theorems 7.1–7.3 that to get $\widehat{\mathcal{W}}(\varepsilon)$ from $\mathcal{W}(\varepsilon)$ one has just to insert the edge (U_1, U_2) into $\mathcal{W}(\varepsilon)$ and to transform it accordingly. This transformation was already considered in section 4.2, so the statement follows. □

7.2. Local reachability cones. The transformations of the connectivity carcass described in Theorems 7.2 and 7.3 are formulated in terms of reachability cones. Therefore, to maintain the carcass, we need to maintain the cones as well. However, reachability cones in an acyclic locally orientable graph behave in a more complicated way than those in a dag. In particular, insertion of an edge may cause a reduction of a reachability cone. Indeed, if a stretched unit belonging to a cone is contracted into a terminal (see Theorem 7.2), then any coherent path passing through this unit cannot be traced behind it in the modified flesh. To avoid these difficulties, we introduce a simpler structure, called a local reachability cone, which preserves all the useful properties of reachability cones but is easier to handle.

Let $\mathcal{R}$ be a reachability cone of an arbitrary unit U. We define the *local reachability cone* $\mathcal{R}^{\mathrm{loc}}$ as the set of units $U' \in \mathcal{R}$ such that $\pi_S(U) \cap \pi_S(U')$ contains at least one edge. (In particular, the local cone of a terminal is empty.) One can check easily that local reachability cones of U are obtained from the corresponding reachability cones of U in the strip $\mathcal{W}(\pi_S(U))$ by deleting the terminals. Observe that reachability cones in the assumptions of Theorems 7.2 and 7.3 can be replaced by the corresponding local reachability cones.

Indeed, for any unit U whose projection is changed according to Theorem 7.3(iii), the intersection $\pi_S(U) \cap P_1$ contains at least one edge, and hence such a unit belongs to $\mathcal{R}^{\mathrm{loc}}_{N_1}(U_1)$ (or, similarly, to $\mathcal{R}^{\mathrm{loc}}_{M_1}(U_1)$, $\mathcal{R}^{\mathrm{loc}}_{N_2}(U_2)$, or $\mathcal{R}^{\mathrm{loc}}_{M_2}(U_2)$).

The units U distinguished by condition (iv) of Theorem 7.2 satisfy $U \in \mathcal{R}_K(U_i)$ and $\pi_S(U) \subseteq P_i \cup \mathcal{L}$. However, if $\pi_S(U) \cap P_i$ does not contain any edges, the latter inclusion implies $\pi_S(U) \subseteq \mathcal{L}$, and hence U is already distinguished by condition (iii). Otherwise $\pi_S(U) \cap P_i$ contains at least one edge, and this together with the former inclusion implies $U \in \mathcal{R}^{\mathrm{loc}}_K(U_i)$.

Finally, let us consider the units distinguished by condition (ii) of Theorem 7.2. Evidently, these units form the intersection of the two reachability cones $\mathcal{R}(U_1)$ and $\mathcal{R}(U_2)$. (For the sake of simplicity, we do not specify the labels of the cones.) Let us prove that it suffices to consider only the units lying in the intersection $\mathcal{R}^{\mathrm{loc}}(U_1) \cap \mathcal{R}^{\mathrm{loc}}(U_2)$. Indeed, if $\mathcal{R}(U_1) \cap \mathcal{R}(U_2) = \varnothing$, then $\mathcal{R}^{\mathrm{loc}}(U_1) \cap \mathcal{R}^{\mathrm{loc}}(U_2) = \varnothing$, and the assertion is trivial. Otherwise, by Theorem 6.10, the minimum tree containing P_1 and P_2 is a path, and the projection of any unit $U \in \mathcal{R}(U_1) \cap \mathcal{R}(U_2)$ belongs to this path. If $\pi_S(U)$ intersects both P_1 and P_2 at least by an edge, then $U \in \mathcal{R}^{\mathrm{loc}}(U_1) \cap \mathcal{R}^{\mathrm{loc}}(U_2)$. If $\pi_S(U)$ intersects both P_1 and P_2 at most by a node, then $\pi_S(U) \subseteq \mathcal{L}$, and U is distinguished by condition (iii) of Theorem 7.2. Finally, if $\pi_S(U)$ intersects at least

by an edge exactly one of P_1 and P_2, then the assumptions of Theorem 7.2(iv) are satisfied, and U is distinguished by condition (iv).

8. Construction and incremental maintenance of the connectivity carcass.

8.1. Construction of the connectivity carcass. We build the connectivity carcass by a recursive algorithm based straightforwardly on Lemma 6.14; in what follows we use the notation of this lemma.

First of all, we choose an arbitrary vertex $s \in S$ and find maximal flows from s to all the other vertices $t \in S$; this allows us to define λ_S as the minimal value of these flows. All the vertices $t \in S$ such that the value of a maximal flow from s to t exceeds λ_S are contracted together with s; in what follows s denotes this new vertex. We then choose an arbitrary one of the remaining vertices of S (denoted by t) and execute the following procedure.

We build the strip $\mathcal{F} = \mathcal{W}_{s,t}$, as explained in section 3.3. To build the skeleton $\mathcal{H} = \mathcal{H}_{\tilde{S}}(\tilde{G})$ we find a topological order of the units in $\mathcal{F}$. Let $U_0 \ni s, U_1, \ldots, U_k \ni t$ be the heavy units in this order; we define $\mathcal{H}$ as a k-edge path $(N_0, N_1, \ldots, N_k)$, $k \geqslant 1$.

To find the corresponding projections $\pi = \pi_{\tilde{S}}$, we execute DFS in $\mathcal{F}$ in direction U_k first from U_{k-1}, then from U_{k-2}, and so on up to U_0. In any such execution we assign N_i as a coordinate to the units found from U_i and backtrack each time when we discover a unit already visited in the previous search. To get the other coordinate we repeat the same process in direction U_0 first from U_1, then from U_2, and so on up to U_k.

Next, for each i, $0 \leqslant i \leqslant k$, we turn the unit U_i into a terminal. If U_i contains vertices of S distinct from s and t, we do the following. We build the set S' by taking all the vertices of S that do not belong to U_i, together with s and t, if they are not yet included in S'. We contract all the vertices of S' into a new vertex s^i, thus obtaining the new graph G^i and the new set S^i in it. We then scan the vertices t' in $S^i \setminus s^i$ and find a maximum flow from s^i to t'. If its value exceeds λ_S, then we just contract t' to s^i. Otherwise, we stop scanning and build the connectivity carcass $(\mathcal{H}^i, \mathcal{F}^i, \pi^i)$ of S^i in G^i by a recursive execution of the same procedure, with $s = s^i$, $t = t'$. This carcass is then merged with the current triple $(\mathcal{H}, \mathcal{F}, \pi)$, as follows.

The skeleton $\mathcal{H}$ is merged with $\mathcal{H}^i$ by identifying the node $N_i \in \mathcal{H}$ with the node $\pi^i(s^i) \in \mathcal{H}^i$.

The new terminal unit corresponding to N_i is built according to Lemma 6.14; it participates in $\mathcal{F}_S$ if the result is a nonempty set.

To merge the partitions of V into units of $\mathcal{F}$ and $\mathcal{F}^i$ we assume that each vertex $v \in V$ knows its units $U(v)$ and $U^i(v)$, and each unit knows its cardinality. Now, for each $v \in V$ we check the units $U(v)$ and $U^i(v)$. If their cardinalities are equal, we concatenate their projections into the new projection of $U(v)$ and cancel $U^i(v)$. Otherwise, we set the new $U(v)$ to be the smallest of the two units involved, preserve its projection, and cancel the other unit.

Notice that the sets $S^i \setminus s^i$, $0 \leqslant i \leqslant k$, do not intersect since they belong to the disjoint vertex sets U_i, respectively.

The above-described algorithm implies the following result (the proof is omitted).

THEOREM 8.1. *The connectivity carcass of an arbitrary vertex subset S can be constructed in time dominated by the complexity of $2\sigma - 2$ max-flow computations in G.*

8.2. Incremental maintenance of the connectivity carcass. Let n be the number of vertices in the initial graph G, $\tilde{\sigma} \leqslant \sigma$ be the number of (λ_S+1)-connectivity classes in S, $\tilde{n} \leqslant n$ be the initial number of flesh units, $\tilde{m} \leqslant m$, $\tilde{m} = O(\lambda_S \tilde{n})$, be the initial number of flesh edges.

We maintain the connectivity carcass under an arbitrary sequence of updates (edge insertions) not changing the connectivity of S and queries "Are vertices $v, w \in G$ separated by an S-mincut?" denoted by $\mathrm{Sep}(v, w)$, "Show an S-mincut separating $v, w \in G$," denoted by $\mathrm{Cut}(v, w)$, and "Construct the strip $\mathcal{W}_{S_1,S_2}$ for $S_1, S_2 \subset S$," denoted by $\mathrm{Strip}(S_1, S_2)$.

In order to maintain the connectivity carcass efficiently, we propose to keep track of the projections represented by the coordinates and of certain parts of reachability cones specified below. It follows from the discussion in section 7.2 that instead of a reachability cone $\mathcal{R}$ it suffices to maintain any partial subcone of $\mathcal{R}$ that contains the corresponding local reachability cone $\mathcal{R}^{\mathrm{loc}}$; we will maintain and use a certain subcone of this type named $\mathcal{R}^{\mathrm{part}}$. By Lemma 3.4, any reachability cone $\mathcal{R}$ of an arbitrary unit W, and hence $\mathcal{R}^{\mathrm{part}}$, is globally orientable. Since it is acyclic, it can be treated in the same way as a dag. In what follows we assume that W is the source in this dag. Following [I], we represent $\mathcal{R}^{\mathrm{part}}$ by a directed spanning tree rooted at W and make use of the following reachability vector of length $\tilde{n}$. Each entry of the vector takes one of the three values to distinguish the following situations: the unit is currently contained in $\mathcal{R}^{\mathrm{part}}$; the unit was never contained in $\mathcal{R}^{\mathrm{part}}$; the unit was previously deleted from $\mathcal{R}^{\mathrm{part}}$. At the initial moment we set $\mathcal{R}^{\mathrm{part}} = \mathcal{R}$; the initialization takes $O(\tilde{n}\tilde{m})$ time for all the cones together.

The skeleton is represented as follows. First, we fix an arbitrary node of the skeleton and make it the root. Second, we attach to each node a single auxiliary leaf bearing the same name. When an edge from a child to its parent is contracted, the new node acquires the name of the parent; observe that only edges of the skeleton are contracted. It follows easily by induction that at any moment the names of the auxiliary leaves attached to each skeleton node are exactly the names of the original nodes contracted into this node. The projection of any unit U is represented by the pair of auxiliary leaves corresponding to the coordinates of U; in fact, the actual projection is the path between the parents of these two leaves.

To handle the obtained rooted tree we make use of the compressed tree data structure proposed in [W92]. This data structure allows us to perform an arbitrary sequence of w nearest common ancestor (NCA) and parent queries and edge contractions in $O(w + t \log^2 t)$ time, where t is the size of the initial tree. In our case this means that we can perform NCA and parent queries in $O(1)$ amortized time with an overhead of $O(\tilde{\sigma} \log^2 \tilde{\sigma})$, since by Theorem 5.6 the size of the skeleton is $O(\tilde{\sigma})$.

The set of units is represented with the help of the standard union-find technique (see [AHU]) that allows us to perform an arbitrary sequence of w operations in $O(w + t \log t)$, where t is the size of the initial set. In our case this means that we can perform find operations in $O(1)$ worst-case time with an overhead of $O(\tilde{n} \log \tilde{n})$. Each side of a unit W is represented as a linked list of edges, and the whole such list is labeled by the corresponding coordinate of W.

When a new edge is inserted, it takes $O(1)$ worst-case time to locate the units U_1 and U_2 containing its endpoints. The nontrivial case, when U_1 and U_2 are distinct, can occur at most $\tilde{n}$ times (since this causes the contraction of these units). For each nontrivial case, we do the following.

On the first stage we analyze the relative position of the projections $\pi_S(U_1)$ and

$\pi_S(U_2)$. If they are edge-disjoint, we find their link and, according to Theorem 7.1, contract the edges of the link. Otherwise, we find their intersection and establish the correspondence between the endpoints of the intersection and the endpoints of the projections (see the beginning of section 7.1 for details). It is easy to check that in order to find the link or the intersection of two projections, and to establish the latter correspondence, it suffices to apply a constant number of NCA and parent queries. Since we spend $O(1)$ amortized time for each of $O(\tilde{n})$ queries with an overhead of $O(\tilde{\sigma}\log^2\tilde{\sigma})$ (covering all contractions), the total time for the first stage is $O(\tilde{\sigma}+\tilde{n}+\tilde{\sigma}\log^2\tilde{\sigma}) = O(\tilde{n}+\tilde{\sigma}\log^2\tilde{\sigma})$.

On the second stage we change the projections. By Theorem 7.3(i), we assign to U^{new} either the contracted node of the skeleton or the path $\pi_S(U_1)\cap\pi_S(U_2)$. Evidently, the total cost of such an assignment is $O(\tilde{n})$. Further, since projections are represented by coordinates, contractions in the skeleton do not imply explicit changes in this representation. Thus, projection changes prescribed by Theorem 7.3(ii) do not require any time.

Finally, to find units whose coordinates must be changed according to Theorem 7.3(iii), we execute DFS in the spanning tree of each of the four partial cones involved and backtrack each time when we reach a unit whose projection no more intersects a certain path in the skeleton; see Theorem 7.3(iii) for details (e.g., for the case of $\mathcal{R}_{N_1}(U_1)$ this path is either $[M_1, M]$ or $[M_1, L_1]$). The validity of such a backtracking is justified by Theorem 6.10. It is easy to see that all the operations performed on the second stage, other than the analysis of the relative position of two paths in the skeleton, require $O(1)$ amortized time per unit. The latter analysis can be performed in $O(1)$ amortized time per unit as well by means of NCA and parent queries as above.

To estimate the total amount of time required by projection changes in this case, let us assign a weight to each edge in the flesh. The weight of an edge is equal to the sum of the lengths of the projections of its endpoints. (The length of a projection is just the number of structural edges in it.) Observe that each time when an edge is scanned, the projection of its tail is truncated. Hence, the length of the projection of the tail strictly decreases, and the same occurs to the weight of the edge considered. Since the initial weight of each edge is $O(\tilde{\sigma})$, we see that the overall number of projection changes is $O(\tilde{\sigma}\tilde{n})$, and that of edge scans is $O(\tilde{\sigma}\tilde{m})$. Thus, the total amount of work on the second stage is $O(\tilde{n}+\tilde{\sigma}\tilde{n}+\tilde{\sigma}\tilde{m}+\tilde{\sigma}\log^2\tilde{\sigma}) = O(\tilde{\sigma}\tilde{m})$.

The contractions in the flesh are performed on the third stage. Evidently, the total cost of contractions described in Theorem 7.2(i) is $O(\tilde{n}\log\tilde{n})$. The set of units that must be contracted according to Theorem 7.2(ii) is the intersection of two opposite local reachability cones (see the discussion in section 7.2); to find these units we just scan the reachability vectors of the corresponding partial cones. Since each contraction itself takes $O(\log\tilde{n})$ amortized time, the total amount of time for contractions in this case is $O(\tilde{n}^2+\tilde{n}\log\tilde{n}) = O(\tilde{n}^2)$.

To find the units that must be contracted according to Theorem 7.2(iii) and (iv), we scan all the units and check for each of them whether its new projection coincides with this of the contracted unit (see the remark after Theorem 7.3). This takes $O(1)$ amortized time per unit (by using a constant number of parent queries) and thus $O(\tilde{n})$ time for the whole scan. Each contraction itself takes $O(\log\tilde{n})$ amortized time. Since each occurrence of this case leads to a contraction in the skeleton, the total number of such occurrences is $O(\tilde{\sigma})$. Hence, the total amount of work in this case is $O(\tilde{\sigma}\tilde{n}+\tilde{n}\log\tilde{n}+\tilde{\sigma}\log^2\tilde{\sigma}) = O(\tilde{\sigma}\tilde{n}+\tilde{n}\log\tilde{n})$.

To find the 2-partition at the new unit, provided it is stretched, we establish the correspondence between the labels at the sides of the stars involved and concatenate the corresponding linked lists. This can be done in $O(\tilde{n}+\tilde{\sigma}\log^2\tilde{\sigma})$ time with the same technique as above.

On the fourth stage we change partial reachability cones. Let $\mathcal{R}^{\text{part}}$ be a partial cone of some unit W. As it was described above, $\mathcal{R}^{\text{part}}$ is represented by a spanning tree rooted at W and the three-valued reachability vector. Since the set of the contracted units is already known, we scan the corresponding entries of the reachability vector and find the list $L(\mathcal{R}^{\text{part}})$ of the units in $\mathcal{R}^{\text{part}}$ that should be contracted. Since each unit is contracted at most once, the total amount of work for these scans is $O(\tilde{n}^2)$. If the list $L(\mathcal{R}^{\text{part}})$ is empty, the cone $\mathcal{R}^{\text{part}}$ is not changed. Otherwise we proceed as follows (see the proof of Theorem 8.2 for support).

If U^{new} is a terminal, we just delete all the units belonging to $L(\mathcal{R}^{\text{part}})$, together with their subtrees, from the tree representing $\mathcal{R}^{\text{part}}$, and change the reachability vector accordingly. Since each unit is deleted at most once from each tree, and the total number of trees is $O(\tilde{n})$, the total amount of work in this case is $O(\tilde{n}^2)$.

If U^{new} is not a terminal, we do the following. For each unit U belonging to the list $L(\mathcal{R}^{\text{part}})$ and distinct from W, we check whether its parent belongs to the list; if it does, we contract the edge from U to its parent, and if not, we mark this edge. If there are marked edges, we identify all their tails into a new unit W' and delete all marked edges except for an arbitrary one. Finally, if exactly one of U_1 and U_2 (say, U_1) never belonged to $\mathcal{R}^{\text{part}}$, the other one (in our case, U_2) belongs to $\mathcal{R}^{\text{part}}$, and $\pi_S(W)\cap(\pi_S(U_1)\cap\pi_S(U_2))$ contains at least one edge, we add a certain subtree to $\mathcal{R}^{\text{part}}$ by identifying its root with W', if defined, or with W otherwise. To obtain this subtree we execute DFS in the spanning tree of the corresponding partial cone of U_1 and backtrack each time when we get to a unit that belongs to $\mathcal{R}^{\text{part}}$ or was previously deleted from $\mathcal{R}^{\text{part}}$. Clearly, the total amount of work in this case is proportional to the number of edge operations, that is, contractions, marking and deletions of edges currently in $\mathcal{R}^{\text{part}}$, and scans of edges currently not in $\mathcal{R}^{\text{part}}$. Each edge in $\mathcal{R}^{\text{part}}$ is contracted or marked and deleted at most once. Besides, each time when $\mathcal{R}^{\text{part}}$ is updated, at most one edge is marked and not deleted. Finally, each scan turns an edge currently not in the entire cone $\mathcal{R}$ to an edge in $\mathcal{R}$. Moreover, such an edge never belonged to $\mathcal{R}$ before, and hence each edge is scanned at most once. Therefore, the total number of edge operations is $O(\tilde{n}\tilde{m})$.

To find whether two vertices of G are separated by an S-mincut, it suffices to find the corresponding units (in $O(1)$ worst-case time) and to check whether they do not coincide. If this is the case, the partition of S corresponding to such a cut can be obtained via Lemma 6.13 using Theorem 6.7. Finding a cut of the skeleton separating two given nodes and finding an edge of a projection takes $O(1)$ amortized time (with the help of NCA queries). To find a tight cut as in Lemma 6.13(ii), we check for all units the inclusion of Theorem 6.7 in $O(1)$ amortized time per unit.

To obtain the strip $\mathcal{W}_{S_1,S_2}$ of Theorem 6.4 we execute $O(|S_1|+|S_2|)$ NCA queries to check whether $\mathcal{T}(S_1)\cap\mathcal{T}(S_2)=\varnothing$, and if this is the case, to find the link $\mathcal{L}(S_1,S_2)$. Next, for each unit U we check whether its projection intersects the path $\mathcal{L}(S_1,S_2)$ by an edge. If this is not the case, a few NCA queries give us the endpoint $N\in\mathcal{L}(S_1,S_2)$ of the link of $\mathcal{L}(S_1,S_2)$ and $\pi_S(U)$. The unit U belongs to the contracted subset corresponding to N. To obtain the orientation, it suffices to execute DFS by coherent paths from any terminal unit of the strip.

The complexity of the above-described algorithm is given by the following statement.

THEOREM 8.2. *The connectivity carcass of an arbitrary vertex subset S can be maintained in $O(\tilde{n}\tilde{m}+u+q_{\text{sep}}+q_{\text{cut}}\tilde{n}+q_{\text{strip}}\tilde{m})$ time for an arbitrary sequence of u edge insertions preserving the value of λ_S, q_{sep} queries $\text{Sep}(v,w)$, q_{cut} queries $\text{Cut}(v,w)$, and q_{strip} queries $\text{Strip}(S_1,S_2)$. Moreover, each query $\text{Sep}(v,w)$ can be answered in $O(1)$ worst-case time.*

Proof. It follows from the discussion above that the only thing one has to check is that partial reachability cones are maintained properly, that is, that at any moment they remain intermediate between local reachability cones and ordinary ones. Since for a terminal both the local cone and its partial cone maintained by the algorithm are trivial, we assume from now on that W is a stretched unit and remains stretched in the modified flesh.

It is convenient to use the same notation as in section 7, that is, $P_1=[M_1,N_1]$ and $P_2=[M_2,N_2]$ are the projections of U_1 and U_2, respectively; if U^{new} is stretched, then $[M,N]$ is their intersection (it contains at least one edge), the paths $[M_1,M_2]$ and $[N_1,N_2]$ are disjoint, and $M\in[M_1,M_2]$, $N\in[N_1,N_2]$. Besides, $\widehat{\pi}_S(U)$ stands for the modified projection of U, provided U exists in the modified flesh, or for the projection of U^{new} otherwise. In the latter case U is one of the units constituting U^{new}, and hence is implicitly contained in it as a set of vertices, which justifies our notation. In the same sense, we say that a cone is increased upon edge insertion if the set of vertices that constitute its units increases.

Let us prove first the following statement.

LEMMA 8.3. *If an edge insertion takes a unit U out of a local cone $\mathcal{R}^{\text{loc}}$ of W, then U will never belong to $\mathcal{R}^{\text{loc}}$ again.*

Proof. We prove, moreover, that if $U\in\mathcal{R}^{\text{loc}}$ and $U\notin\widehat{\mathcal{R}}^{\text{loc}}$, then already $\widehat{\pi}_S(W)$ and $\widehat{\pi}_S(U)$ intersect at most by a node; since the projections can only shrink upon edge insertions, this would mean that U never belongs to $\mathcal{R}^{\text{loc}}$ again. Assume to the contrary that $\widehat{\pi}_S(W)$ and $\widehat{\pi}_S(U)$ intersect at least by an edge. Then $U\notin\widehat{\mathcal{R}}^{\text{loc}}$ can occur only if U^{new} is a terminal and each coherent path from W to U in $\mathcal{F}_S$ passes through at least one unit that constitutes this terminal. Let U' be such an intermediate unit on a coherent path from W to U, and let $\widehat{\pi}_S(U')=N'$. It follows immediately from Theorem 6.10 that $\widehat{\pi}_S(W)$ and $\widehat{\pi}_S(U)$ belong to distinct branches of $\widehat{\mathcal{H}}_S$ hanging at N', so they intersect at most by a node, a contradiction. ∎

Remark. Observe that the monotonicity property of Lemma 8.3 does not hold for the cone $\mathcal{R}(W)$ itself. For example, let G be a graph shown on Figure 8.1(a). Assume that $S=\{x,y,z\}$; then $\mathcal{F}_S$ is as shown on Figure 8.1(b), and hence $U\in\mathcal{R}(W)$. Upon insertion of the edge (v,y) the flesh changes as shown on Figure 8.1(c); here $U\notin\mathcal{R}(W)$. Finally, upon subsequent insertion of the edge (y,u) the flesh changes as shown on Figure 8.1(d), and again $U\subset U''\in\mathcal{R}(W)$.

It follows immediately from Lemma 8.3 that when maintaining $\mathcal{R}^{\text{part}}$, one does not need to include in it anew the units that were previously deleted from it.

Observe that exactly the same reasoning proves that if U^{new} is a terminal, then the whole subtree rooted at any unit in $L(\mathcal{R}^{\text{part}})$ does not belong to the corresponding $\widehat{\mathcal{R}}^{\text{loc}}$. Thus, the case when the new unit is a terminal is completed.

Assume now that U^{new} is stretched; clearly, in this case $\mathcal{R}$ is not decreased. First of all, observe that if $U',U''\in L(\mathcal{R}^{\text{part}})$ and there exists a coherent path from W to U'' passing through U', then all the units on this path lying between U' and U'' belong to $L(\mathcal{R}^{\text{part}})$ as well. Indeed, let U be such a unit, and consider an arbitrary

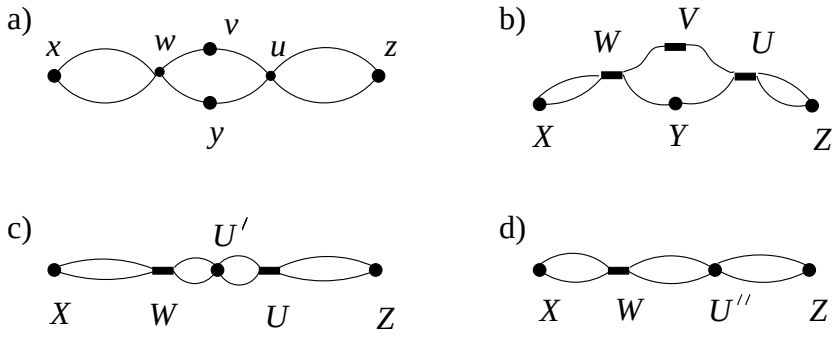

FIG. 8.1. *Nonmonotonicity of reachability cones.*

S-mincut separating U, say, from U'. It follows immediately from Theorem 5.5(ii) that the same S-mincut separates also U' from U'', and hence it no more exists after the edge insertion. Therefore, U is contracted into U^{new} as well. This means that the units in $L(\mathcal{R}^{\text{part}})$ form a set of subtrees in the tree representing $\mathcal{R}^{\text{part}}$ in such a way that no root of a subtree is a descendant of another root. It follows immediately that the contraction-marking-deletion-identifying procedure described in the algorithm is well defined, and that the tree thus obtained represents the part of $\widehat{\mathcal{R}}^{\text{part}}$ containing all the vertices constituting $\mathcal{R}^{\text{part}}$, and thus $\mathcal{R}^{\text{loc}}$. Clearly, if $\mathcal{R}^{\text{loc}}$ does not increase, we are done.

Let us consider the case when $\mathcal{R}^{\text{loc}}$ is increased. Evidently, this happens if and only if the new unit belongs to $\widehat{\mathcal{R}}^{\text{loc}}$ and at least one of U_1 and U_2 (say, U_1) does not belong to $\mathcal{R}^{\text{loc}}$. Let us prove the following statement.

LEMMA 8.4. *The conditions $U^{\text{new}} \in \widehat{\mathcal{R}}^{\text{loc}}$ and $U_1 \notin \mathcal{R}^{\text{loc}}$ are equivalent to the following three: $U_1 \notin \mathcal{R}^{\text{part}}$, $U_2 \in \mathcal{R}^{\text{part}}$, and $\pi_S(W) \cap (P_1 \cap P_2)$ contains at least one edge.*

Proof. Indeed, $U^{\text{new}} \in \widehat{\mathcal{R}}^{\text{loc}}$ implies that $\widehat{\pi}_S(W) \cap (P_1 \cap P_2)$ contains at least one edge, therefore, the same is true for $\pi_S(W) \cap (P_1 \cap P_2)$ (since projections can only shrink). Next, if $\pi_S(W) \cap (P_1 \cap P_2)$ contains at least one edge and $U_1 \notin \mathcal{R}^{\text{loc}}$, then $U_1 \notin \mathcal{R}$; indeed, $U_1 \in \mathcal{R}$ would imply together with $U_1 \notin \mathcal{R}^{\text{loc}}$ that $\pi_S(W)$ intersects P_1 at most by a node, a contradiction. Clearly, $U_1 \notin \mathcal{R}$ implies $U_1 \notin \mathcal{R}^{\text{part}}$. The same reasoning with U_1 replaced by U_2 shows that if $U_2 \notin \mathcal{R}^{\text{part}}$, then $U_2 \notin \mathcal{R}$. Finally, to get the condition $U_2 \in \mathcal{R}^{\text{part}}$, it remains to rule out the case $U_1, U_2 \notin \mathcal{R}$. It follows easily from Theorem 7.2 that the units constituting U^{new} are, apart from U_1 and U_2, exactly those lying on coherent paths between U_1 and U_2. Therefore, $U_1, U_2 \notin \mathcal{R}$ together with $U^{\text{new}} \in \widehat{\mathcal{R}}^{\text{loc}}$ would imply the existence of a unit $U \in \mathcal{R}$ lying on such a path; hence, extending a coherent path from W to U behind U we can get either to U_1 or to U_2, a contradiction.

In the other direction, $U_1 \notin \mathcal{R}^{\text{part}}$ implies $U_1 \notin \mathcal{R}^{\text{loc}}$ and $U_2 \in \mathcal{R}^{\text{part}}$ implies $U^{\text{new}} \in \widehat{\mathcal{R}}$. By Theorem 7.3, any edge contained in $\pi_S(W) \cap (P_1 \cap P_2)$ is contained also in $\widehat{\pi}_S(W) \cap (P_1 \cap P_2)$, and hence, the existence of an edge in the former intersection together with $U^{\text{new}} \in \widehat{\mathcal{R}}$ implies $U^{\text{new}} \in \widehat{\mathcal{R}}^{\text{loc}}$. □

In fact, in the algorithm, instead of checking condition $U_1 \notin \mathcal{R}^{\text{part}}$, we check whether U_1 has never belonged to $\mathcal{R}^{\text{part}}$. Indeed, if U_1 currently does not belong to $\mathcal{R}^{\text{part}}$ but has belonged to it previously, then by Lemma 8.3 we do not need to include U_1 into $\widehat{\mathcal{R}}^{\text{part}}$.

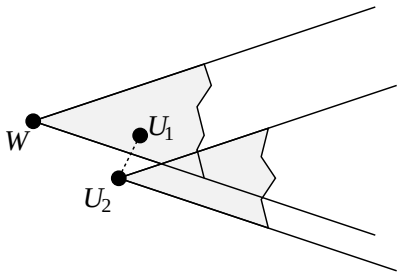

FIG. 8.2. *To the dynamics of* $\mathcal{R}^{\text{part}}$.

Let us describe now the additional units acquired by $\widehat{\mathcal{R}}^{\text{loc}}$. Assume w.l.o.g. that the cones of W under consideration are in direction N_2. (By Theorem 6.10 this makes sense, since $U_2 \in \mathcal{R}^{\text{part}}$.) Let us prove that all the additional units belong to $\mathcal{R}^{\text{loc}}_{N_1}(U_1)$ (see Figure 8.2). Indeed, all such units evidently belong to $\mathcal{R}_{N_1}(U_1)$. If $U \in \mathcal{R}_{N_1}(U_1)$ but $U \notin \mathcal{R}^{\text{loc}}_{N_1}(U_1)$, then $\pi_S(U)$ does not have edges in common with $\pi_S(U_1)$ and lies behind N_1 with respect to M_1. However, by Theorem 7.3(iii), the part of $\pi_S(W)$ lying behind N_1 with respect to M_1 is deleted in the modified carcass. Hence, $\widehat{\pi}_S(W)$ intersects $\widehat{\pi}_S(U)$ at most by a node, and thus $U \notin \widehat{\mathcal{R}}^{\text{loc}}$. The backtracking rule in the cone $\mathcal{R}^{\text{loc}}_{N_1}(U_1)$ is justified by Lemma 8.3. □

8.3. Maintenance of the cell structure. As one can easily see from the description of the algorithm in section 8.2, the most time-consuming problem is to maintain the flesh, namely, the distribution of the vertices of the initial graph among units and reachability between units. Below we propose a less detailed, cell-oriented approach. It allows us to reduce the complexity of maintenance at the expense of an increase in the reaction time for certain separation queries: we guarantee the same $O(1)$ worst-case time only in the cases when at least one of the vertices in question belongs to S. To avoid the time-consuming maintenance of reachability cones, we suggest to maintain, instead of the actual flesh, a weaker contraction of the initial flesh, called the *preflesh*; the actual flesh can be obtained from the preflesh by contraction of its strongly connected components. At any moment the partition of V into units represented by our data structure (henceforth, *preunits*) is, in a sense, intermediate: it is a refinement of the true partition, while the initial partition is a refinement of this partition. Though this approach does not guarantee the proper distribution of vertices among units, it keeps track of the distribution of vertices of G among cells.

More exactly, upon inserting a new edge we execute all the contractions as prescribed only if the resulting unit is a terminal; otherwise, we contract only the two preunits containing the endpoints of the inserted edge, as described in Theorem 7.2(i). Thus, the preflesh can be not acyclic but is a coherent locally orientable graph, and the true units are just its strongly connected components. Besides, we maintain only the 2-partitions at the preunits, but not reachability cones of any kind. The set of the preunits, the 2-partitions at each one of them, and the skeleton are represented in the same way as in the previous algorithm.

The preliminary stage of the new algorithm (distinguishing between trivial and nontrivial edge insertions) almost coincides with that of the previous one and has the same complexity $O(u)$. The only difference is that we locate not the units, but the

preunits U_1^p and U_2^p that contain the endpoints of the new edge.

The first stage of the new algorithm (update of the skeleton) coincides literally with that of the previous one and has the same complexity $O(\tilde{n} + \tilde{\sigma}\log^2\tilde{\sigma})$.

The only difference on the second stage (update of projections) is related to the case of units whose coordinates must be changed according to Theorem 7.3(iii). Instead of scanning the cones, we scan the two reachability subgraphs of U_1^p and U_2^p. It is done by executing a DFS four times (in both directions for both preunits) with backtracking each time when we reach a preunit whose projection no longer intersects a certain path in the skeleton. It is easy to see that all the reasoning involving weights of edges remains valid in this case; hence the total amount of work on the second stage is $O(\tilde{\sigma}\tilde{m})$.

The third stage of the new algorithm (update of the preflesh) is somewhat different from the corresponding stage of the previous one. If the new unit (and thus the new preunit) is not a terminal, we contract only the preunits U_1^p and U_2^p. The 2-partition at the new preunit is maintained exactly as in the previous algorithm with the help of labels, and the total amount of time for this case is $O(\tilde{n}\log\tilde{n} + \tilde{\sigma}\log^2\tilde{\sigma})$.

If the new unit (and thus the new preunit) is a terminal, we just contract all the preunits whose new projection coincides with the projection of the new terminal (see the remark after Theorem 7.3). Thus, the total amount of time in this case is $O(\tilde{\sigma}\tilde{n} + \tilde{n}\log\tilde{n} + \tilde{\sigma}\log^2\tilde{\sigma}) = O(\tilde{\sigma}\tilde{n} + \tilde{n}\log\tilde{n})$.

To find whether two vertices of G are separated by an S-mincut, we find the corresponding preunits (in $O(1)$ worst-case time). If they coincide, then such a cut does not exist. Otherwise, we check their projections. If the projections differ, then such a cut exists and is a cell cut. To find it we analyze the projections of all the preunits and verify the inclusion of Theorem 6.7. This can be done in $O(\tilde{n})$ amortized time by means of NCA queries as in the previous algorithm.

If the projections coincide, then the two preunits belong to the same nonterminal cell. In this case we do not know at once whether a cut in question exists or not; thus we answer both queries simultaneously. According to Lemma 6.13, the work to be done is split into two parts. One of them consists of finding a certain cell cut and is done exactly in the same way as in the previous case and within the same time. The other part is to find a certain reachability cone of one of our preunits. It is done by scanning the reachability subgraph of this preunit. Since, unlike the previous algorithm, we have no special data structure supporting reachability cones, this is done similarly to the scanning on the second stage. Thus, the time for both queries in this case is $O(\tilde{m})$.

Finally, to obtain the strip $\mathcal{W}_{S_1,S_2}$ of Theorem 6.4 we proceed exactly as in the previous algorithm and get this strip up to contractions of strongly connected components. To get the true strip, we replace the ordinary DFS used in the previous algorithm for obtaining orientations by the extended DFS that also finds and contracts strongly connected components. The total time remains the same.

We thus get the following result.

THEOREM 8.5. *The cell structure of the connectivity carcass of an arbitrary vertex subset S can be maintained in $O(\tilde{\sigma}\tilde{m} + \tilde{n}\log\tilde{n} + u + q\tilde{m})$ time for an arbitrary sequence of u edge insertions preserving the value of λ_S and q queries* $\mathrm{Sep}(v,w)$, $\mathrm{Cut}(v,w)$, $\mathrm{Strip}(v,w)$. *Moreover, if at least one of the vertices v, w is in S, or v and w belong to distinct cells, then the query* $\mathrm{Sep}(v,w)$ *can be answered in $O(1)$ worst-case time, and the query* $\mathrm{Cut}(v,w)$ *in $O(\tilde{n})$ amortized time.*

FORMAL-LANGUAGE-CONSTRAINED PATH PROBLEMS*

CHRIS BARRETT†, RIKO JACOB‡, AND MADHAV MARATHE†

Abstract. Given an alphabet Σ, a (directed) graph G whose edges are weighted and Σ-labeled, and a formal language $L \subseteq \Sigma^*$, the *formal-language-constrained shortest/simple path* problem consists of finding a shortest (simple) path p in G complying with the additional constraint that $l(p) \in L$. Here $l(p)$ denotes the unique word obtained by concatenating the Σ-labels of the edges along the path p. The main contributions of this paper include the following:

(1) We show that the formal-language-constrained shortest path problem is solvable efficiently in polynomial time when L is restricted to be a context-free language (CFL). When L is specified as a regular language we provide algorithms with improved space and time bounds.

(2) In contrast, we show that the problem of finding a simple path between a source and a given destination is NP-hard, even when L is restricted to fixed simple regular languages and to very simple classes of graphs (e.g., complete grids).

(3) For the class of treewidth-bounded graphs, we show that (i) the problem of finding a regular-language-constrained simple path between source and destination is solvable in polynomial time and (ii) the extension to finding CFL-constrained simple paths is NP-complete.

Our results extend the previous results in [*SIAM J. Comput.*, 24 (1995), pp. 1235–1258; *Proceedings of the* 76*th Annual Meeting of the Transportation Research Board*, 1997; and *Proceedings of the* 9*th ACM SIGACT-SIGMOD-SIGART Symposium on Database Systems*, 1990, pp. 230–242]. Several additional extensions and applications of our results in the context of transportation problems are presented. For instance, as a corollary of our results, we obtain a polynomial-time algorithm for the best k-similar path problem studied in [*Proceedings of the* 76*th Annual Meeting of the Transportation Reasearch Board*, 1997]. The previous best algorithm was given by [*Proceedings of the* 76*th Annual Meeting of the Transportation Research Board*, 1997] and takes exponential time in the worst case.

1. Introduction.

In many path-finding problems arising in diverse areas, certain patterns of edge/vertex labels in the labeled graph being traversed are allowed/preferred, while others are disallowed. Thus, the feasibility of a path is determined by (i) its length (or cost) under well-known measures on graphs such as distance, and (ii) its associated label. The acceptable label patterns can be specified as a formal language. For example, in transportation systems with mode options for a traveler to go from source to destination, the mode selection and destination patterns of an itinerary that a route will seek to optimize can be specified by a formal language. The problem of finding label-constrained paths also arises in other application areas such as production distribution network, VLSI design, databases queries [MW95, AMM97], etc. Here, we study the problem of finding shortest/simple paths in a network subject to certain formal language constraints on the labels of the paths obtained. We

illustrate the type of problems studied here by discussing prototypical application areas.

1.1. Intermodal route planning. Our initial interest in the problem studied in this paper came from our work in the TRANSIMS[1] project at the Los Alamos National Laboratory. We refer the reader to [TR+95a, AB+97, TR+95b] for a detailed description of this project.

As a part of the intermodal route planning module of TRANSIMS, our goal is to find feasible (near optimal) paths for travelers in an intermodal network (a network with several mode choices, such as train, car, etc.) subject to certain mode-choice constraints. The mode choices for each traveler are obtained by either processing the data from the microsimulation module or by certain statistical models built from real life survey data. We refer the reader to Ben-Akiva and Lerman [BaL] for a detailed discussion and references on the theory of discrete choice analysis as applied to transportation science. The following example illustrates a prototypical problem arising in this context.

Example 1. We are given a directed labeled, weighted graph G. The graph represents a transportation network with the labels on edges representing the various modal attributes (e.g., a label t might represent a rail line). Suppose we wish to find a shortest route from s to d for a traveler. This is the ubiquitous shortest path problem. But now we are also told that the traveler wants to go from s to d using the following modal choices: either he walks to the train station, then uses trains, and then walks to his destination (office), or he would like to go all the way from home to office in a car. Using t to represent trains, w to represent walking, and c to represent a car, the traveler's mode choice can be specified as $w^+t^+w^+ \cup c^*$, where $\cup, +$, and $*$ denote the usual operators used to describe regular languages.

1.2. Searching the Web. Browsing the Web to find documents of interest as well as searching a database using queries can be interpreted as graph traversals in a certain graph. From this viewpoint, one views the Web (database) as a directed (undirected), labeled graph—the nodes are URL sites (text) and the edges are hyperlinks. A query for finding a particular URL site, for instance, proceeds by browsing the network by following links and searching by sending information retrieval requests to "index servers." A serious problem that arises in the context of using pattern-matching-based search engines is that the queries cannot exploit the topology of the document network. For example, as pointed out in [Ha88],

> Content search ignores the structure of a hypermedia network. In contrast, structure search specifically examines the hypermedia structure for subnetworks that match a given pattern.

We refer the reader to the work of [MW95, AMM97, Ha88] for a more thorough discussion on this topic. A recent paper by Abiteboul and Vianu [AV99] also discusses how regular expression constrained path queries can be used to query the Web. The following example is essentially from [AMM97].

Example 2. Let G be a graph describing a hypertext document. Suppose we want to search for job opportunities for software engineers. We first query an index server to find pages that mention the keywords "employment job opportunities" and then, from each of these pages, we could follow the local paths of lengths 0, 1, or 2 to find pages that contain the keywords "software engineer." We can state the above problem

[1] TRANSIMS is an acronym for the Transportation Analysis and Simulation System. See http://transims.tsasa.lanl.gov for details.

as finding labeled paths in G with constraints on the admissible labelings. We refer to [AMM97] for a number of additional interesting queries that can be formulated in such a framework.

2. Problem formulation. The problems discussed in the above examples can be formally described as follows: Let $G(V, E)$ be an (un)directed graph. Each edge $e \in E$ has two attributes—$l(e)$ and $w(e)$. $l(e)$ denotes the label of edge e. In this paper, the label is drawn from a (fixed) finite alphabet Σ. The attribute $w(e)$ denotes the weight of an edge. Here, we assume that the weights are nonnegative integers. Most of our positive results can in fact be extended to handle negative edge weights also (if there are no negative cycles). A path p of length k from u to v in G is a sequence of edges $\langle e_1, e_2, \ldots, e_k \rangle$, such that $e_1 = (u, v_1)$, $e_k = (v_{k-1}, v)$, and $e_i = (v_{i-1}, v_i)$ for $1 < i < k$. A path is *simple* if all the vertices in the path are distinct. Given a path $p = \langle e_1, e_2, \ldots, e_k \rangle$, the weight of the path is given by $\sum_{1 \le i \le k} w(e_i)$ and the label of p is defined as $l(e_1) \cdot l(e_2) \cdots l(e_k)$. In other words the label of a path is obtained by concatenating the labels of the edges on the path in their natural order. Let $w(p)$ and $l(p)$ denote the weight and the label of p, respectively.

DEFINITION 1 (formal-language-constrained shortest path). *Given an (un)directed labeled, weighted graph G, a source s, a destination d, and a formal language (regular, context-free, context-sensitive, etc.) L, find a shortest (not necessarily simple) path p in G such that $l(p) \in L$.*

DEFINITION 2 (formal-language-constrained simple path). *Given an (un)directed labeled, weighted graph G, a source s, a destination d, and a formal language (regular, context-free, context-sensitive, etc.) L, find a shortest simple path p in G such that $l(p) \in L$.*

For the rest of the paper we denote the formal-language-constrained shortest path problem restricted to regular, context-free, and context-sensitive languages by REG-ShP, CFG-ShP, and CSG-ShP, respectively. Similarly, we denote the formal-language-constrained simple path problem restricted to regular, context-free, and context-sensitive languages by REG-SiP, CFG-SiP, and CSG-SiP, respectively.

In general we consider the input for these problems to consist of a description of the graph (including labeling and weights) together with the description of the formal language as a grammar. By restricting the topology of the graph and/or the syntactic structure of the grammar, we get modifications of the problems. If we claim a statement to be true "for a *fixed* language," we refer to the variant of the problem, where the input consists of the graph only, whereas the language is considered to be part of the problem specification.

Note that in unlabeled networks with nonnegative edge weights, a shortest path between s and d is necessarily simple. This need not be true when we wish to find a shortest path subject to an additional constraints on the set of allowable labels. As a simple example, consider the graph $G(V, E)$ that is a simple cycle on four nodes. Let all the edges have weight 1 and label a. Now consider two adjacent vertices x and y. The shortest path from x to y consists of a single edge between them; in contrast a shortest path with label $aaaaa$ consists of a cycle starting at x and the additional edge (x, y).

3. Summary of results. We investigate the problem of formal-language-constrained path problems. A number of variants of the problem are considered and both polynomial-time algorithms as well as hardness results (NP-, PSPACE-hardness, undecidability) are proved. Two of the NP-hardness results are obtained by combining the simplicity of a path with the constraints imposed by a formal language. We

FIG. 1. *Summary of results on formal-language-constrained simple/shortest paths in contrast to the word recognition problems. LT, RL, CFL, CSL denote locally testable, regular, context-free, and context-sensitive languages, respectively. For regular languages, the time bounds hold for regular expressions with the operators* $(\cup, \cdot, *, 2)$. *FP states that the problem can be computed in deterministic polynomial time, even if the language specification is part of the input. The superscripts in the table and the corresponding text tell where the result is proven.*

believe that the techniques used to prove these results are of independent interest. The main results obtained in the paper are summarized in Figure 1 and include the following:

(1) We show that CFG-ShP has a polynomial-time algorithm. For REG-ShP with operators $(\cup, \cdot, *)$, we give polynomial-time algorithms that are substantially more efficient in terms of time and space. The polynomial-time solvability holds for the REG-ShP problem, when the underlying regular expressions are composed of $(\cup, \cdot, *, 2)^2$ operators. We also observe that the extension to regular expressions over operators $(\cup, \cdot, *, -)$ is PSPACE-hard.

(2) In contrast to the results for shortest paths, we show that the problem finding any *simple* paths between a source and a given destination is NP-hard, even when restricted to a very simple, fixed locally testable regular language (see section 6.2 for details) and very simple graphs (undirected grid graphs).

(3) In contrast to the results in (1) and (2) above, we show that for the class of treewidth-bounded graphs, (i) the REG-SiP is solvable in polynomial time, but (ii) CFG-SiP problem is NP-complete, even for a fixed deterministic linear context-free language (CFL). The easiness proof can be extended to one-way-log-space recognizable languages. It uses a dynamic programming method, although the tables turn out to be quite intricate.

(4) Finally, we investigate complexity of problems CSG-ShP and CSG-SiP. Using simple reductions and, in contrast to the complexity results in (1) and (2), we show that (i) CSG-SiP is PSPACE-complete but (ii) CSG-ShP is *undecidable* even for a fixed language.

(5) As an application of the theory developed here, we provide a polynomial-time algorithm for a number of basic problems in transportation science. In

[2]Operator $\square^2$ or simply 2 stands for the square operator. R^2 denotes $R \cdot R$.

section 7 we consider two examples, namely, the BEST k-SIMILAR PATH and the TRIP CHAINING problem.

The results mentioned in (1)–(4) provide a tight bound on the computational complexity (P versus NP) of the problems considered, given the following assumptions: The inclusions of classes of formal languages "finite $\subset$ locally testable" and "regular $\subset$ deterministic linear context-free" are tight, i.e., there is no natural class of languages "in between" these classes. Furthermore in this paper grid-graphs are considered to be the "easiest" class of graphs that do not have a bounded treewidth.

Preliminary versions of the algorithms outlined here have already been incorporated in the route planning module of TRANSIMS. In [JMN98] we conduct an extensive empirical analysis of these and other basic route-finding algorithms on realistic traffic network.

4. Related work. We refer the reader to the monograph by Huckenbeck [Hu97] for a comprehensive survey on path problems. References [TR+95a, AB+97, TR+95b] provide a detailed account of the TRANSIMS project. Regular-expression-constrained simple path problems were considered by Mendelzon and Wood [MW95]. The authors investigate this problem in the context of finding efficient algorithms for processing database queries (see [CMW87, CMW88, MW95]). A recent paper by Abiteboul and Vianu describes further results on related problems [AV99]. Yannakakis [Ya90, Ya95] in his keynote talk has independently outlined some of the polynomial-time algorithms given in section 5. Romeuf [Ro88] also independently considered some of the problems discussed in section 5. However, the emphasis in [Ya90] was on database theory and Romeuf [Ro88] considered only regular languages. Online algorithms for finding regular-expression-constrained paths are given in [BKV91]. Our work on finding formal-language-constrained shortest paths is also related to the work of Ramalingam and Reps [RR96]. The authors were interested in finding a minimum-cost derivation of a terminal string from one or more nonterminals of a given context-free grammar. The problem was first considered by Knuth [Ku77] and is referred to as the *grammar problem*. [RR96] gives an incremental algorithm for a version of the grammar problem and as corollaries obtain incremental algorithms for single-source shortest path problems with positive edge weights. We close this section with the following additional remarks:

(1) To our knowledge this is the first attempt at using formal language theory in the context of modeling mode/route choices in transportation science.

(2) The polynomial-time algorithms and the hardness results presented here give a boundary on the classes of graphs and queries for which polynomial-time query evaluation is possible. In [MW95] the authors state that

> Additional classes of queries/dbgraphs for which polynomial-time evaluation is possible should be identified ....

Our results significantly extend the known hardness as well as easiness results in [MW95] on finding regular-expression-constrained simple paths. For example, the only graph theoretic restriction considered in [MW95] was acyclicity. On the positive side, our polynomial-time algorithms for regular-expression-constrained simple path problems when restricted to graphs of bounded treewidth are a step toward characterizing graph classes on which the problem is easy. Specifically, it shows that for graphs with fixed-size recursive separators, the problems is easy. Examples of graphs that can be cast in this framework include chordal graphs with fixed clique size, outer planar graphs, series parallel graphs, etc. (see [Bo92] for other examples).

(3) The basic techniques extend quite easily (with appropriate time performance

bounds) to solve other (regular-expression-constrained) variants of shortest path problems. Two notable examples that frequently arise in transportation science and can be solved are (i) multiple-cost shortest paths [Ha92, BAL97] and (ii) time-dependent shortest paths [OR90]. These extensions are briefly outlined in section 7.

The rest of the paper is organized as follows. Section 4.1 contains preliminary results and basic definitions. In section 5, we present efficient algorithms for grammar-constrained shortest path problems (namely, REG-SHP and CFG-SHP). Section 6 contains our hardness/easiness results for simple paths. Section 7 outlines several extensions and applications of our basic results.

4.1. Basic definitions. We recall the basic concepts in formal language and graph theory. Additional basic definitions on topics related to this paper can be found in [HU79, GJ79, AHU, CLR, HRS76, Pa94, Ta81]. For the rest of the paper, we use $|I|$ to denote the size of an object I represented using binary notation.

DEFINITION 3. *Let Σ be a finite alphabet disjoint from $\{\varepsilon, \phi, (,), \cup, \cdot, *\}$. A regular expression R over Σ is defined as follows:*

(1) *The* empty string *"ε," the* empty set *"ϕ," and, for each $a \in \Sigma$, "a" are atomic regular expressions.*
(2) *If R_1 and R_2 are regular expressions, then $(R_1 \cup R_2)$, $(R_1 \cdot R_2)$, and $(R_1)^*$ are compound regular expressions.*

DEFINITION 4. *Given a regular expression R, the language (or the set) defined by R over Σ and denoted by $L(R)$ is defined as follows:*

(1) $L(\varepsilon) = \{\varepsilon\}$; $L(\phi) = \phi$; $\forall a \in \Sigma: L(a) = \{a\}$.
(2) $L(R_1 \cup R_2) = L(R_1) \cup L(R_2) = \{\, w \mid w \in L(R_1) \text{ or } w \in L(R_2) \,\}$.
(3) $L(R_1 \cdot R_2) = L(R_1) \cdot L(R_2) = \{\, w_1 w_2 \mid w_1 \in L(R_1) \text{ and } w_2 \in L(R_2) \,\}$.
(4) $L(R^*) = \bigcup_{k=0}^{\infty} L(R)^k$, *where* $L(R)^0 = \{\varepsilon\}$ *and* $L(R)^i = L(R)^{i-1} \cdot L(R)$.

DEFINITION 5. *A* nondeterministic finite automaton *(NFA) is a 5-tuple $M = (S, \Sigma, \delta, s_0, F)$, where*

(1) *S is a finite nonempty set of states;*
(2) *Σ is the input alphabet (a finite nonempty set of letters);*
(3) *δ is the* state transition function *from $S \times (\Sigma \cup \{\varepsilon\})$ to the power set of S;*
(4) *$s_0 \in S$ is the initial state;*
(5) *$F \subseteq S$ is the set of accepting states.*

If there is an $s \in S$ such that $\delta(s, \varepsilon)$ is a nonempty subset of S, then the automaton M is said to have ε-transitions. If M does not have any ε-transitions and $\forall\ s \in S$ and $\forall\ a \in \Sigma$ the set $\delta(s, a)$ has at most one element, then δ can be regarded as a (partial) function from $S \times \Sigma$ to S and M is said to be a *deterministic finite automaton* (DFA).

The extended transition function δ^* from $S \times \Sigma^*$ is defined in a standard manner. The size of M denoted by $|M|$ is defined to be equal to $|S||\Sigma|$.

DEFINITION 6. *Let $M = (S, \Sigma, \delta, s_0, F)$ be an NFA. The* language accepted *by M denoted $L(M)$ is the set*

$$L(M) = \{\, w \in \Sigma^* \mid \delta^*(s_0, w) \cap F \neq \phi \,\}.$$

A string w is said to be accepted by the automaton M if and only if $w \in L(M)$.

DEFINITION 7. *A* context-free grammar *(CFG) G is a quadruple (V, Σ, P, S), where V and Σ are disjoint nonempty sets of* nonterminals *and* terminals*, respectively, $P \subset V \times (V \cup \Sigma)^*$ is a finite set of* productions*, and S is the* start symbol*. A CFG G is said to be* linear *if at most one nonterminal appears on the right-hand side of any of its productions.*

DEFINITION 8 (see[Bo88, AL+91]). *Let $G = (V, E)$ be a graph. A* tree-decomposition *of G is a pair $(\{X_i \mid i \in I\}, T = (I, F))$, where $\{X_i \mid i \in I\}$ is a family of subsets of V and $T = (I, F)$ is a tree with the following properties:*

(1) $\bigcup_{i \in I} X_i = V$.
(2) *For every edge $e = (v, w) \in E$, there is a subset X_i, $i \in I$, with $v \in X_i$ and $w \in X_i$.*
(3) *For all $i, j, k \in I$, if j lies on the path from i to k in T, then $X_i \bigcap X_k \subseteq X_j$.*

The treewidth *of a tree-decomposition $(\{X_i \mid i \in I\}, T)$ is $\max_{i \in I} |X_i| - 1$. The treewidth of G is the minimum treewidth of a tree decomposition.*

5. Shortest paths. In this section, we present polynomial-time algorithms for the problems REG-SHP and CFG-SHP.

5.1. Algorithm for REG-SHP and extensions. In this subsection, we will describe our algorithms for regular expression constrained shortest path problems. We note that regular expressions over $(\cup, \cdot, *)$ can be transformed into equivalent NFAs in $O(n)$ time [AHU], where n represents the size of the regular expression. Thus for the rest of this subsection we assume that the regular expressions are specified in terms of an equivalent NFA.

The basic idea behind finding shortest paths satisfying regular expressions is to construct an auxiliary graph (the product graph) combining the NFA denoting the regular expression and the underlying graph. We formalize this notation in the following.

DEFINITION 9. *Given a labeled directed graph G, a source s, and a destination d, define the NFA $M(G) = (S, \Sigma, \delta, s_0, F)$ as follows:*

(1) *$S = V$; $s_0 = s$; $F = \{d\}$;*
(2) *Σ is the set of all labels that are used to label the edges in G; and*
(3) *$j \in \delta(i, a)$ if and only if there is an edge (i, j) with label a.*

Note that this definition can be used to interpret an NFA as a labeled graph as well.

DEFINITION 10. *Let $M_1 = (S_1, \Sigma, \delta_1, p_0, F_1)$ and $M_2 = (S_2, \Sigma, \delta_2, q_0, F_2)$ be two NFAs. The product NFA is defined as $M_1 \times M_2 = (S_1 \times S_2, \Sigma, \delta, (p_0, q_0), F_1 \times F_2)$, where $\forall a \in \Sigma$, $(p_2, q_2) \in \delta((p_1, q_1), a)$ if and only if $p_2 \in \delta_1(p_1, a)$ and $q_2 \in \delta_2(q_1, a)$.*

It is clear that $L(M_1 \times M_2) = L(M_1) \cap L(M_2)$. Algorithm RE-Constrained-Short-Paths outlines the basic steps for solving the problem and uses the cross product construction mentioned above.

THEOREM 11. *The algorithm RE-Constrained-Short-Paths computes the exact solution for the problem* REG-SHP *with nonnegative edge weights in time $O(T(|R||G|))$. Here $T(n)$ denotes the running time of a shortest path algorithm on a graph with n nodes.*

Proof. For the correctness of the algorithm observe the following: Consider a shortest path q^* in G of cost $w(q^*)$ that satisfies the regular expression R. This path and the accepting sequence of states in the NFA imply a path q' of the same cost between (s_0, s) to (f, d) for some $f \in F$. So we know that the sought path is considered. Conversely, for each path τ in $M(G) \times M(R)$ of cost $w(\tau)$ that begins on a starting state and ends on a final state, the projection of τ to the nodes of G yields a path of same cost in G from s to d that satisfies the regular expression R.

To calculate the running time of the algorithm, observe that the size of $M(R) \times M(G)$ is $O(|R||G|)$. As the overall running time is dominated by step 4, we obtain $O(T(|R||G|))$ as a bound. ∎

ALGORITHM RE-CONSTRAINED-SHORT-PATHS:

- *Input:* A regular expression R, a directed labeled weighted graph G, a source s, and a destination d.
- 1. Construct an NFA $M(R) = (S, \Sigma, \delta, s_0, F)$ from R.
  2. Construct the NFA $M(G)$ of G.
  3. Construct $M(G) \times M(R)$. The length of the edges in the product graph is chosen to be equal to the corresponding edges in G.
  4. Starting from state (s_0, s), find a shortest path to the vertices (f, d), where $f \in F$. Denote these paths by p_i, $1 \le i \le w$. Also denote the cost of p_i by $w(p_i)$.
  5. $C^* := \min_{p_i} w(p_i)$; p^*: $w(p^*) = C^*$.
     (If p^* is not uniquely determined, we choose an arbitrary one.)
- *Output:* The path p^* in G from s to d of minimum length subject to the constraint that $l(p) \in L(R)$.

5.2. Extensions: Other regular expressions. We consider two possible extensions for the problem REG-SHP, namely, allowing the additional operators for taking the complement $(-)$ and for squaring an expression (2).

THEOREM 12. *Shortest path in the complement of an NFA or a regular expression over* $(\cup, \cdot, *)$ *is PSPACE-hard.*

Proof. Let R be such a regular expression. The question of deciding if the complement of $L(R)$ is empty (regular expression nonuniversality) is known to be PSPACE-complete (see [GJ79, problems AL1 and AL9]). Given an instance of such a problem we create a graph G with one node v. There is a loop from v to v for each symbol in the alphabet. The existence of a path from v to v with the label in the complement of the language $(\Sigma^* - L(R))$ is equivalent to the existence of such a word. □

This immediately implies the following corollary.

COROLLARY 13. REG-SHP *for regular expressions over* $(\cup, \cdot, *, -)$ *is PSPACE-hard.*

It is easy to see that regular expressions consisting of operators from $(\cup, \cdot, *, 2)$ can be represented by CFGs with rules of the form $A \to BB$. This observation together with the results of the next section (section 5.3) yields the following corollary.

COROLLARY 14. REG-SHP *for regular expressions over* $(\cup, \cdot, *, 2)$ *can be solved in polynomial time.*

5.3. Algorithm for CFG-SHP. We now extend our results in section 5.1 to obtain polynomial-time algorithms for CFL-constrained shortest path problems. Beside the applicability of the algorithm, this result stands in contrast to the hardness of simple-path problems even for a single fixed regular expression.

The algorithm for solving CFG-constrained shortest paths is based on dynamic programming. Hence we will first investigate the structure of an optimal shortest path from s to d in the graph G that is labeled according to the CFG R. Assume that R is in Chomsky normal form, i.e., all rules of the form $C \to AB$ or $C \to a$ (see [HU79] for details). Consider any such shortest path p with $l(p) = a_1 a_2 \cdots a_m$. One important property of any CFG is that nonterminals are expanded independently. In the case of a Chomsky normal form, the derivation forms a binary tree, which means that the

label of p can be decomposed into two parts l_1 and l_2 such that $l(p) = l_1 l_2$, $S \to AB$, $A \xrightarrow{*} l_1$, and $B \xrightarrow{*} l_2$.

With this structure in mind let us define the quantity $D(i, j, A)$ as the shortest path distance from i to j subject to the constraint that the label on this path can be derived starting from the nonterminal A.

These values are well defined and fulfill the following recurrence:

$$D(i,j,A) = \min_{(A \to BC) \in R} \min_{k \in V} \Big(D(i,k,B) + D(k,j,C) \Big), \tag{1}$$

$$D(i,j,a) = \begin{cases} w(i,j) & \text{if } l((i,j)) = a, \\ \infty & \text{otherwise.} \end{cases} \tag{2}$$

Observation 15. *These equations uniquely determine the function D and immediately imply a polynomial-time dynamic programming algorithm.*

Proof. Consider the case that D and D' satisfy the above recurrence but are different. Then there must be a smallest witness of this fact $a = D(i, j, X)$ and $b = D'(i, j, X)$, and $a \neq b$. Let us assume $a > b$ and consider the smallest such b. As the definition (2) is unambiguous, we know that $X = A$ is a nonterminal. As b is minimal, it is finite and satisfies (1). This implies that there must exist the witnesses $e = D(i, k, B)$ and $f = D(k, j, C)$ that establish $b = e + f$ as their sum. As all lengths in the graph are positive, both e and f are smaller than b. By the choice of a and b we know that $e = D'(i, k, B)$ and $f = D'(k, j, C)$, implying with (1) the contradiction $a \leq e + f = b$.

This discussion immediately implies a dynamic programming approach to compute the table of D. Starting with the values for links in the network, we fill the table with increasing values. This can be done with a Bellman–Ford-type algorithm. This algorithm will finally set at least one entry in the table per round. The execution time is bound by the square of the number of entries in the table times the amount of time needed to compute the two minima in (1). This is polynomial, namely, $O(|V|^5|N|^2|R|^2)$ with V being the vertices of the graph, N the nonterminals, and R the rules of the grammar in Chomsky normal form.

Another way of implementing this is to set the table by filling in the smallest values first. There a heap is used to hold the current estimates on entries, and the smallest one is finally put in the table generating or changing estimates. This implies one extract-min operation and up to $2|V||R|$ update operations for every entry. Using Fibonacci–Heaps (see [CLR] for an analysis), this sums up to $O(|V|^2|N| \cdot (\log(|V|^2|N|) + 2|V||R|))$, that is, $O(|V|^3|N||R|)$. ∎

A naive adaptation of a Floyd–Warshall-type algorithm fails, because we cannot split an optimal path in two optimal subsolutions at an arbitrary node of the path. The splitting in the above dynamic programming works only because it is done in accordance with the grammar.

6. Simple paths. Next we investigate the complexity of finding formal-language-constrained simple paths. For the ease of exposition, we present our results for directed, multilabeled graphs. The following lemma shows how to extend these results to undirected and unilabeled graphs.

Lemma 16.

(1) REG-SiP *on directed, multilabeled grids can be reduced to* REG-SiP *on directed grids.*

(2) REG-SiP *on directed grids can be reduced to* REG-SiP *on undirected grids.*

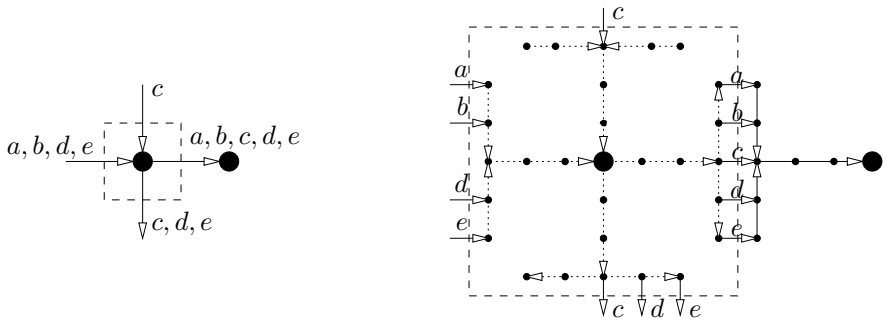

FIG. 2. *Example for replacing multilabels. All the dotted edges "inside" are labeled with* v. *Only the connection to the right is completely depicted.*

(3) *For all* $k \geq 1$, CFG-SIP *on directed graphs of treewidth* k *can be reduced to* CFG-SIP *on undirected graphs of the same treewidth.*

Proof. (1) Applying the changes illustrated in Figure 2 to all nodes of a multilabeled grid G, we obtain an unilabeled grid G'. G' is part of a grid roughly $|\Sigma|^2$ times larger than the original one. Furthermore, the alphabet needs to be extended by two symbols, one for inaccessible edges and one, the symbol v, for the edges "inside" the extended nodes.

The regular language L is replaced by the regular language L' defined as follows:

$$L' = \{\ w \in (\Sigma \cup \{v\})^* \mid w = v^* x_1 v^* x_2 v^* \cdots v^* x_n v^* \ \text{ and } \ x_1 x_2 \cdots x_n \in L\ \}.$$

Now paths in the new instance (G', L') are in one-to-one correspondence to paths in the original instance (G, L).

(2), (3) It is well known (see, for example, [HU79]) that regular and CFLs are closed under substitution. Let $\Sigma = \{a, b, \ldots, z\}$ be an alphabet. Then $\Sigma' = \{a', b', \ldots, z'\}$ is a marked copy of this alphabet. Substitution with the homomorphism $a \mapsto aa'$, $\forall\ a \in \Sigma$ yields the following: If $L \subseteq \Sigma^*$ is regular, the language

$$L' = \{\ w \in (\Sigma \cup \Sigma')^* | w = x_1 x_1' x_2 x_2' \cdots x_n x_n' \ \text{ and } \ x_1 x_2 \cdots x_n \in L\ \}$$

is also regular. Let G be the original graph. The directed edges in G labeled with a get replaced by two consecutive edges labeled with a and a', introducing a new node.

In this situation paths in G' complying with L' are in a one-to-one correspondence to paths in G complying with L. It is straightforward to extend the weight function on the edges to preserve the weights of paths. Additionally relative path length (in number of edges used) are preserved.

The proof of (2) follows from the fact that the resulting G' can be embedded in a grid using a new symbol $v \notin (\Sigma \cup \Sigma')$ as label.

For (3) let T be a tree-decomposition of treewidth k. If $k = 1$, the graph itself is a tree and replacing edges by paths of length 2 does not change the treewidth. Otherwise let T be a tree-decomposition of width $k > 1$. For every new node we create a new set of the tree-decomposition consisting of the new node and the endpoints of the edge it splits. This set is included in the tree of the decomposition by attaching it to the set that covered the split edge. As $k > 1$, sets of cardinality 3 cannot change the treewidth, yielding a new tree-decomposition of width k. ∎

6.1. Finite languages.

DEFINITION 17. *A language L is called* finite *if there are only finitely many words in L.*

Finite languages are considered one of the smallest subclasses of the regular languages.

THEOREM 18. *For any* fixed *finite language L the problem* REG-SIP *can be solved in polynomial time.*

Proof. Let k be the maximum length of a word in L. Considering all k-tuples of nodes, and checking if they form the sought path, yields a polynomial-time algorithm of running time $O(n^k)$. □

THEOREM 19. *Let $\mathcal{C}$ be a graph class (such as planar, grid, etc.) such that the* HAMILTONIAN PATH *problem is* NP*-hard when restricted to $\mathcal{C}$. Then the problem* REG-SIP *is* NP*-hard when restricted to $\mathcal{C}$ and (free) finite languages.*

Proof. Consider a fixed class of graphs $\mathcal{C}$ for which the HAMILTONIAN PATH problem is NP-hard. Then given an instance G of the HAMILTONIAN PATH problem in which $G \in \mathcal{C}$, with n nodes, we construct an instance G_1 of the regular-expression-constrained simple path problem by labeling all the edges in G by a. We now claim that there is a Hamiltonian path in G if and only if there is a simple path in G_1 that satisfies a^{n-1}, i.e., the constraining language is chosen to be the finite language $L = \{a^{n-1}\}$. □

6.2. Hardness of REG-SIP. Before formally stating the theorem and the proof we present the overall idea. We perform a reduction from 3-SAT. It will be easy to verify that the reduction can be carried out in polynomial time (logarithmic space).

Our encoding of a satisfiability question naturally decomposes into two parts. The first is to choose an assignment; the second is to check whether this assignment satisfies the given formula. Choosing the assignment will correspond to choosing a certain part of the path. The 3-CNF formula will be checked clause by clause. This requires access to the value of a variable more than once. Here this is achieved by forcing sufficiently many subpaths to be similar (in the sense that they stand for the same assignment). These "copies" of the assignment can then be used to check whether the underlying assignment satisfies the 3-CNF formula. This is now a local task, as there is one copy of the assignment for every clause.

In order to achieve sufficiently many similar copies of the assignment, the following *beads and holes argument* will be useful: Think of $n + 1$ holes forming a straight line and n beads between every two of them. Each bead is allowed to fall in one of the two holes adjacent to it. Moreover, we allow at most one bead in each hole. The state of the system after the beads fall down in the holes is a description of the contents of each hole. By reporting which hole is free, the state of the beads and holes system is described completely; since all beads left of the free hole fell in the left hole and the remaining beads fell into the right hole. We additionally know that there exists a set of at least $n/2$ consecutive beads that fell in the same direction.

The construction presented enforces an overall snake-like path, which goes up and down several times. This is schematically depicted in Figure 3. Figure 4 provides additional details about the construction and will be described in what follows. At this point it is sufficient to note that nodes on a vertical dotted line will be referred to as nodes on a column, and vertices on each horizontal dotted line will be referred to as nodes on a level (or a row). For the case of n levels (variables) and m columns the following statements provide an overall outline of the proof:

(1) Every column of the rotated grid (depicted in Figure 4) represents a member

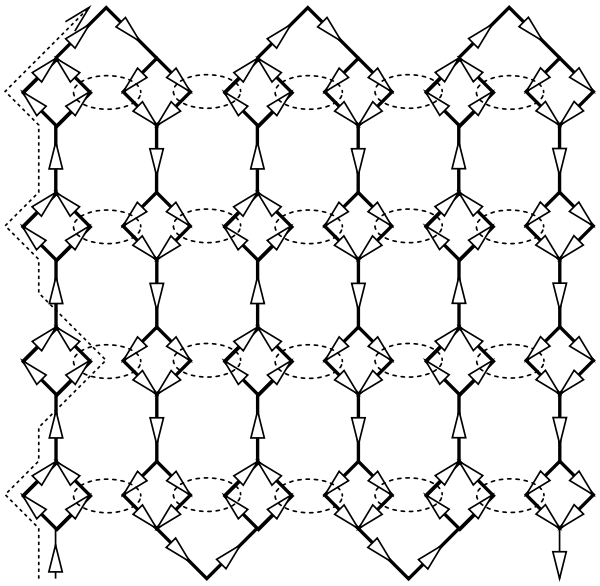

FIG. 3. *Overall shape of all feasible paths; the dotted circles stand for nodes to be identified. One possible leg in the first column is depicted as a dashed line.*

of an extended sequence of clauses. Any feasible path from S to D will use all of the column nodes. Such a path naturally decomposes into subpaths which span an entire column and are called legs.

(2) The shape of a leg uniquely corresponds to an assignment; for this, levels of the rotated grid are identified with variables.

(3) Identically shaped legs do not interfere with neighboring columns.

(4) Let p be one fixed feasible path, i.e., a path that consists of m legs, as many as there are columns. Such a path visits every node but precisely n variable nodes, one per level. Therefore, the shape of the legs of p cannot change too often (following the beads and holes argument), which in turn ensures that there will be a lot of similar legs.

(5) On each column the labeling together with the language allows us to check that the assignment represented by the leg satisfies a clause (of the extended set of clauses). For this we use three symbol of the alphabet to stand for the three literals of the clause.

We will prove the theorem for multilabeled directed grid-graphs. Lemma 16 implies that the result holds for unilabeled undirected grid graphs.

THEOREM 20. *The* REG-SIP *problem is* NP*-hard for complete multilabeled directed grids and a* fixed *regular expression.*

Proof. We present a reduction from the problem 3-SAT, which is well known to be NP-complete; see, for example, [GJ79].

Given a 3-SAT formula we construct a labeled complete directed grid, such that there exists a path from the start vertex to the destination vertex, that complies with a fixed (independent of the formula) regular expression, if and only if the formula is satisfiable.

Let $F = (X, C)$ be a 3-CNF formula, $X = \{x_1, x_2, x_3, \ldots, x_n\}$ the set of variables, and $C = \{c_1, c_2, c_3, \ldots, c_m\}$ the set of clauses.

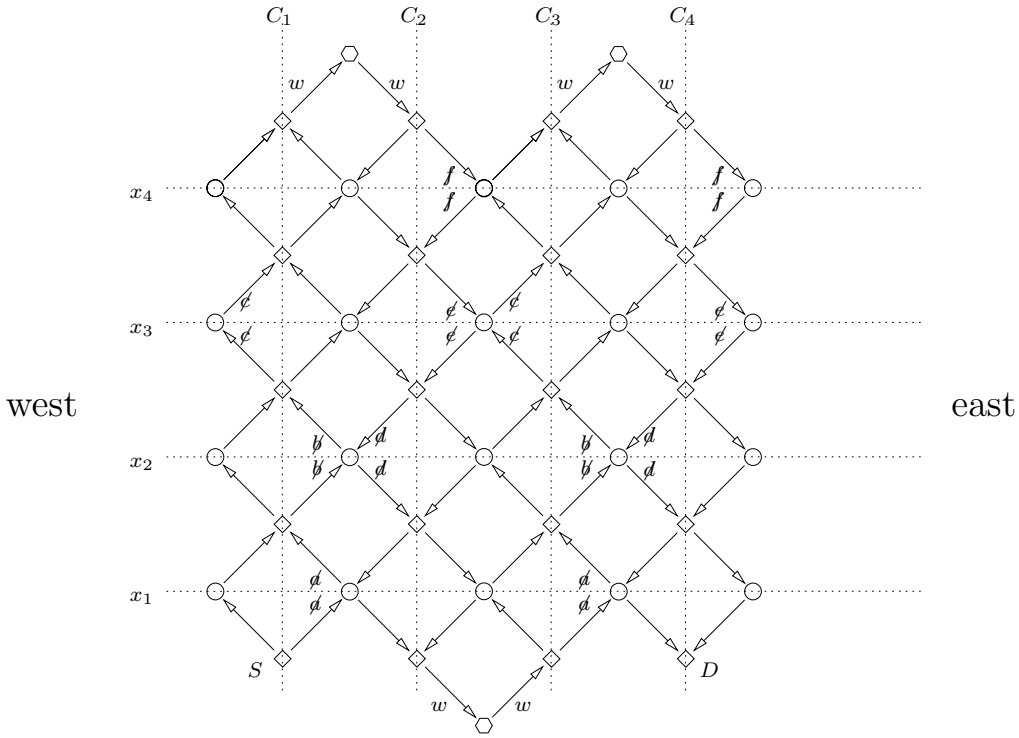

FIG. 4. *Graph corresponding to the formula* $(x_1 \vee x_2 \vee \neg x_3) \wedge (\neg x_2 \vee x_3 \vee x_4)$*, west-true, east-false, in general upward edges are labeled* a*,* b*, and* c*, downward edges are labeled* d*,* e*, and* f*. The label* $\not{c}$ *in the figure states that the corresponding edge is not labeled with* a *(by this deviating from the general rule). For simplicity the additional* $4 = (4+2)-2$ *repetitions of the basic clause-sequence are omitted.*

For the beads and holes argument we need $n + 2$ repetitions of the sequence of clauses. To do this, we construct an extended sequence $d_1, \ldots, d_M$ of clauses that consists of exactly $n+2$ copies of the original sequence of clauses ($M = m(n+2)$). It is important that the ordering of the basic sequence remains unchanged between different copies. This extended sequence of clauses is used in what follows for constructing the graph.

We will describe a grid rotated by 45 degrees against the coordinate system that we use to define levels (i.e., rows) and columns. There are three different types of vertices: (i) clause-vertices, (ii) variable-vertices, and (iii) join-vertices. The layout of these vertices is illustrated in Figure 4 by means of an example. The coordinate system essentially has for every clause C_i a vertical line with the name of the clause and for every variable x_i a horizontal line named by the variable. These lines are shown as dotted lines in Figure 4. The vertices of the grid lie in the middle of the so-formed line-segments. Clause-vertices lie on dotted vertical (clause-)lines and are drawn as rhombuses. Variable vertices lie on horizontal (variable-)lines and are drawn as circles. There are additional bottom and top lines of join-vertices that are drawn as hexagons. It is easy to see that this grid is part of a complete square grid with $(M + n + 2)^2$ nodes.

To simplify the description we assume that M is even. For the rest of the proof, by a slight abuse of notation, we use the phrase edges incident on a vertex v to mean both

the incoming and outgoing edges that have v as one of the endpoints. The start node S is the lowermost clause-node on C_1, the destination node D the lowermost clause-node on C_M. To achieve paths of the snake-like form depicted in Figure 3, we direct all edges incident on a clause-vertex on an odd-numbered column upward and all edges incident on a clause-vertex lying on even-numbered columns downward. This orientation is depicted in Figure 4. In order to enforce the overall shape of admissible paths, we label the edges incident on join-vertices with w. Furthermore, with important exceptions to be described later, upward edges are in general multilabeled with a, b, and c, where as downward edges are in general multilabeled with d, e, and f. Let us define the regular expression

$$R = \Big((a^* \cup b^* \cup c^*)ww(d^* \cup e^* \cup f^*)ww\Big)^*(a^* \cup b^* \cup c^*)ww(d^* \cup e^* \cup f^*)$$

and the corresponding language $L = L(R)$.

The final construction will have some of the labels removed; this only makes the set of feasible paths smaller. The following proposition summarizes a key property of the above construction.

PROPOSITION 21. *Let P be a simple path in the described graph from S to D complying with the regular language L. Then the following holds:* (i) *P can be partitioned into a set of legs and* (ii) *there exist m consecutive legs that have identical shape.*

Proof. (i) Call every subpath labeled with $w(d^+ \cup e^+ \cup f^+)w$ or $w(a^+ \cup b^+ \cup c^+)w$ a leg. Here $x^+ := x^*x$ is the usual shorthand used in regular expressions. As the label of P is in the given regular language, this defines a partitioning of P into M subpaths L_i. Because of the labeling of the grid, all legs have one endpoint at the lower join level and one at the upper join level. Because of this all L_i have the same length. Additionally every second vertex of a leg is a clause-node, and all these clause-nodes are in the same column. As we traverse a leg from the low-numbered end to the high-numbered end, we deviate from the vertical line passing through variable-vertices on the way. The sequence of deviations (east/west) defines the *shape* of the leg. The shape of a leg is used to infer an assignment to the variables as discussed later.

(ii) As P is simple, every node of the grid is visited at most once by P. As a result the shapes of two neighboring legs L_i and L_{i+1} are not independent. If L_i deviates at (variable-)level j to the east, L_{i+1} may not deviate to the west on that level. As there are $(M+1)n$ variable-vertices in the grid and Mn variable-vertices on P, there are exactly n variable-vertices not used by P. An averaging argument yields that there must exist m consecutive columns of variable-vertices that are all used by P. This implies that all legs in that range must have identical shape. □

These m legs will be used as multiple copies of an encoding of an assignment of truth values to the variables. The removing of some of the labels of the graph will allow us to enforce the semantics of the clauses. Given the shape of a leg we use the following rule (denoted rule **R**) to infer an assignment to the variables:

(R) If the shape deviates on level x_i to the west (east), we assign x_i the truth value TRUE (FALSE).

Note that we have m legs with identical shapes and thus we have a consistent assignment to the variables across clauses. The constraining regular expression and appropriate labels to the edges also have to ensure that the following holds. The

leg corresponding to each C_i can only have shapes such that the corresponding assignment to the variables using rule **R** makes C_i true. For an odd-numbered clause $C_{2k+1} \equiv (u_1 \vee u_2 \vee u_3)$, we remove labels from the graph in the following way: If $u_1 = x_i$ (resp., $u_1 = \neg x_i$) we remove the label a from both the edges incident on the variable-vertex x_i that is to the east (resp., west) of the column C_{2k+1}. For u_2 (resp., u_3) the label b (resp., c) is removed in the same way on the level corresponding to the variable of the literal. For even-numbered clauses d, e, and f take the role of a, b, and c.

PROPOSITION 22. *Let L_k be a leg of a path in G from S to D on column C_k complying with L and let A be the assignment corresponding to the shape of L_k using rule* **R**. *Then the labeling of L_k can be chosen to be of the form $wxx \dots xxw$ with $x \in \{a, b, c, d, e, f\}$ if and only if A evaluates C_k to TRUE.*

Proof. Let A evaluate C_k to TRUE. Then at least one of the literals of C_k is TRUE. We can choose the x accordingly (for example, $x = a$ if it is the first literal and k is odd). On the level corresponding to this positive (resp., negative) literal the path deviates to the west (resp., east), and can thus be labeled with x; independent of its shape, L_k can be labeled with x on all other levels.

Conversely, if the leg is labeled in $wxx \dots xxw$, we can focus on the literal of the clause corresponding to x (for example, the first literal if $x = a$). As the labeling at the level of that variable is available only in the correct direction, A must evaluate the clause to true. □

This completes the construction of the graph. We now prove the correctness of the reduction.

Suppose there exists a satisfying assignment A to the formula. Then we choose the shape of the path from S to D in the snake-like fashion with the additional property that we deviate to the west on level x_j if x_j is set to TRUE by A; otherwise we deviate to the east. Since A is a satisfying assignment, each clause contains at least one literal that is set true by A. So we choose the labeling on all legs L_k of the path in column C_k corresponding to this literal of C_k. This yields a simple path that complies with L.

Conversely, let there be a simple path from S to D complying with L. By Proposition 21, we know that the path has m consecutive legs of the same shape corresponding to an assignment A. By construction of the extended sequence of clauses and Proposition 22 we know that A satisfies all of the original clauses. So the formula is satisfiable. □

In fact this result stays valid for a smaller class of infinite regular languages.

DEFINITION 23 (see [Str94]). *A language L is called locally testable if there exists a k and a finite set S such that*

$$w \in L \iff (\forall v <_k w : v \in S).$$

Here $v <_k w$ stands for the fact that v is a subword of length k of w.

COROLLARY 24. *The* REG-SIP *problem is* NP*-hard for a complete multilabeled directed grid and a fixed locally testable language.*

Proof. In the proof of Theorem 20 the constraining regular language can be replaced by the regular language L defined as follows:

$$L = \left\{ v \in \Sigma^* \;\middle|\; x_1 x_2 <_2 v \to \Big(x_1 \in \{a, b, c, d, e, f\} \to x_2 = x_1 \vee x_2 = w\Big) \right\}.$$

This condition is equivalent to stating that any sequence of $y \in \{a, b, c, d, e, f\}$ may be ended only by a w. Starting from the first symbol in the word, L guarantees

that this single symbol is repeated until the next w. The labeling of the grid ensures that this w is at the top join-vertex between the columns C_1 and C_2. There the simplicity enforces another w and it follows inductively that L enforces the snake-like shape of the path as well as the uniform labeling of the legs. So it is as strong as the language used in the proof of Theorem 20.

It should be noted that Lemma 16 cannot be applied immediately in this situation. Nevertheless the result of the corollary extends. This is easy to verify using a slight modification of the graph proposed in the proof of Lemma 16 and a modification of the language. This makes use of the fact that the directionality can readily be omitted and that constructions of the form $x_i = y \rightarrow x_{i+5} = y$ are also expressible in locally testable languages. □

Note that the result of Theorem 20 immediately extends to other graph classes.

COROLLARY 25. *Let $\mathcal{C}$ be a class of graphs such that $\forall\ k > 0$ there is an instance $\mathcal{I} \in \mathcal{C}$ that contains as a subgraph a $(k \times k)$-mesh and both the graph and the subgraph are computable in time polynomial in k; then the* REG-SIP *problem is* NP*-hard for $\mathcal{C}$.*

Thus the REG-SIP *problem is* NP*-hard even for* (i) *complete cliques,* (ii) *interval graphs,* (iii) *chordal graphs,* (iv) *complete meshes,* (v) *complete hypercubes,* (vi) *permutation graphs.*

6.3. Hardness of CFG-SIP. We show that CFG-SIP, the problem of finding a simple path complying with a CFL, is NP-hard even on graphs with bounded treewidth. Before formally stating the proof, we give the overall idea. We present a reduction from 3-SAT (see, e.g., [GJ79] for definition). The basic idea is to have a path consisting of two subpaths. The first subpath uniquely chooses an assignment and creates several identical copies of it. The second subpath checks one clause at every copy of the assignment and can only reach the destination if the assignment satisfies the given formula.

Consider the language $L = \{w\#w^R\$w\#w^R \cdots w\#w^R | w \in \Sigma^*\}$. As is standard, w^R denotes the reverse of string w. At the heart of our reduction is the crucial observation that L can be expressed as the intersection of two CFLs L_1 and L_2. Consider $L_1 = \{\, w_0\#w_1\$w_1^R\#w_2\$w_2^R t \cdots w_k\$w_k^R\#w_{k+1} \,|\, w_i \in \Sigma^* \,\}$ and $L_2 = \{\, v_1\#v_1^R\$v_2\#v_2^R \cdots v_k\#v_k^R \,|\, v_i \in \Sigma^* \,\}$. To see that $L = L_1 \cap L_2$, observe that $w_0 = v_1,\ v_1^R = w_1$, and $\forall\ i,\ w_i^R = v_{i+1}, v_{i+1}^R = w_{i+1}$, establishing that $v_i = v_{i+1}$ holds $\forall\ i$, and thus $L = L_1 \cap L_2$.

Now, imagine w representing an assignment to the variables of a 3-CNF formula with a fixed ordering of the variables. For every clause of the formula, we create a copy of this assignment. L is used to ensure that all these copies are consistent, i.e., identical.

Note that we have two basic objects for performing the reduction—a CFG and a labeled graph. We will specify L_1 as a CFG and use the labeled graph and simple paths through the graph to implicitly simulate L_2. Recall that there is a straightforward deterministic pushdown automaton M for accepting L_2. Our graph will consist of an "upward chain" of vertices and a "downward chain" of vertices along with a few additional vertices. The upward chain will simulate the behavior of M when it pushes w on the stack. The "downward chain" will then simulate popping the contents of the stack and verifying that they match w^R. We will call such a gadget a "tower" as an analogy to the stack of M.

We now describe the proof in detail. For the purposes of simplicity, we prove the results for directed graphs; the extension to undirected graphs follows with Lemma 16.

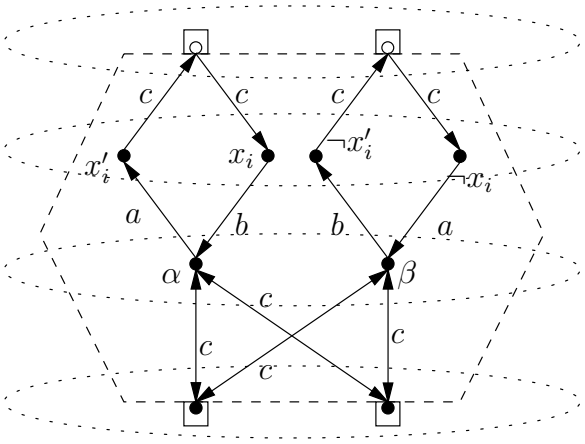

FIG. 5. *The gadget H_i used to implement the tower, forcing the assignment to be spread consistently over the graph. Dashed ellipses denote the so-called level sets.*

THEOREM 26. *The* CFG-SIP *problem is* NP-hard*, even for graphs of constant treewidth and a fixed deterministic CFL.*

Proof. Reduction from 3-SAT. Let $F(X, C)$ be a 3-CNF formula, where $X = \{x_1, \ldots, x_n\}$ denotes the set of variables and $C = \{c_1, \ldots, c_m\}$ denotes the set of clauses. Corresponding to F, we create an instance $G(V, E_1 \cup E_2)$ of CFG-SIP as follows. We will describe the reduction in two parts—first the subgraph (V, E_1) and then the subgraph (V, E_2).

The subgraph (V, E_1) is constructed as follows: Corresponding to each clause c_j, we have a tower T^j. It consists of n "simple-path stack-cell" gadgets H for each variable one. This basic gadget is depicted in Figure 5.

Consider a simple path p from one of the bottom nodes (marked by a square in the figure) to one of the top nodes. Because of the labels of this gadget, we can define the *signature* y of this path by $l(p) = cyc$ with $y \in \{a, b\}$. Let q be another simple path that has no vertex in common with p, starts at one of the top nodes, and ends in one of the bottom nodes. Then we can again properly define the signature z of this path by $l(q) = czc$.

Because of the nodes α and β, the signatures are identical, i.e., $y = z$. Furthermore, if p uses the node x_i', the node x_i is not used at all, and q has to use the node $\neg x_i$. Similarly, if p uses the node $\neg x_i'$, the node $\neg x_i$ is not used at all, and q has to use the node x_i.

These gadgets are now composed to form towers T^j, by identifying the top terminal nodes of H_i^j with the bottom terminal nodes of H_{i+1}^j. The tower has four levels corresponding to every variable. We call this a *floor* of the tower. The bottom of the tower T^j is connected to the bottom of the tower T^{j+1}. The start vertex is connected to the bottom of the tower T^1. These connections are depicted in Figure 6. Before we describe the remaining edges, we discuss the properties of a tower.

Consider a tower T^j and a simple path r labeled according to $(c(a \cup b)c)^* \# (c(a \cup b)c)^*$ that starts at one bottom vertex and reaches the other bottom vertex. Such a path has the following important properties:

(1) The path r consists of two simple subpaths p and q separated by an edge labeled with $\#$. p starts at the bottom of the tower and is labeled according to the regular expression $(c(a \cup b)c)^*$. On every floor it uses exactly one of the nodes $\{x_i', \neg x_i'\}$,

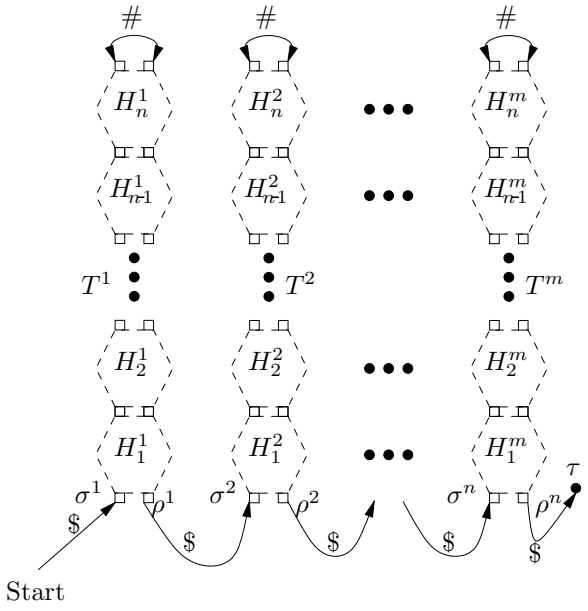

FIG. 6. *Assembling the gadgets, building the graph* G_1.

thus realizing an assignment to the variables of X. This assignment uniquely corresponds to the labeling of this path.

(2) The constraints of *simplicity* and the direction of edges imply that q has the following structure: it starts at the unused top vertex, is labeled with $l(q) = l(p)^R$, avoids already-used nodes, and reaches the unvisited bottom vertex. Furthermore q is *uniquely* determined given p.

(3) Note that for each variable x_i, the simple path r visits exactly one of the nodes in $\{x_i, \neg x_i\}$. If the path reflects an assignment in which x_i is true, then x_i is unused and $\neg x_i$ is used, and vice versa. These free nodes will be used in the second part of the reduction to verify that the chosen assignment is indeed satisfying F.

We now assemble the towers to form the graph G_1 depicted in Figure 6.

PROPOSITION 27. *Any simple path in* G_1 *starting at the start node* s *and reaching the intermediate node* τ*, with the constraint that the labeling belongs to* $\$((c(a \cup b)c)^*\#(c(a \cup b)c)^*\$)^*$*, generates the language*

$$L_2 = \{\, \$w_1\#w_1^R\$w_2\#w_2^R\$ \cdots w_n\#w_n^R\$ \mid w_i \in (c(a \cup b)c)^* \,\}.$$

Proof. The statement follows from the above. □

We now choose the constraining CFL for the path from s to τ to be

$$L_1 = \{\, \$w_1\#w_2\$w_2^R\#w_3\$w_3^R\# \ldots w_{k-1}\$w_{k-1}^R\#w_k\$ \mid k \in \mathbb{N}, w_i \in (c(a \cup b)c)^* \,\}$$

The following important lemma follows from Proposition 27 and the definition of L_1.

LEMMA 28.

(1) *Proposition* 27 *enforces that in every tower the used and unused nodes can be uniquely interpreted as an assignment to the variables of* X.
(2) L_1 *enforces that these assignments are consistent across two consecutive towers.*

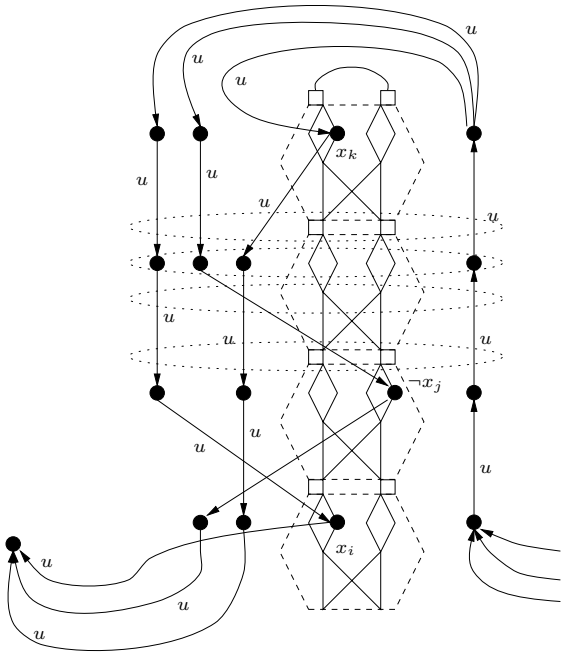

FIG. 7. *One tower of the second part of the graph, according to the clause* $(x_i \vee \neg x_j \vee x_k)$.

We now describe the subgraph (V, E_2). The label of each edge in this subgraph is u. The subgraph is composed of m subgraphs $D_1 \cdots D_m$, the subgraph D_i corresponding to clause c_i, depicted in Figure 7. Every D_i basically consists of four simple chains. The first one goes up the tower. There it splits into three downward directed paths. Each of them corresponds to a literal of c_i. The node in the tower T_i corresponding to that literal is used as part of the path. At the very bottom the three paths are joined and connected to D_{i-1}. At the boundaries D_0 is replaced by d and D_{m+1} by τ. This completes the description of the graph $G(V, E_1 \cup E_2)$.

The instance of CFG-SIP consists of the graph $G(V, E_1 \cup E_2)$ and the constraining CFL $L = L_1 \cdot u^*$. This forces the path to go through every tower using edges in $G(V, E_1)$, visit vertex τ, and then use the edges of $G(V, E_2)$ to reach d.

We now prove the correctness of the reduction. Suppose, there exists a satisfying assignment for F. Then we choose the path from s through all the towers to τ accordingly. For the remaining path to d we use the fact that for every clause of F at least one literal is true. Choosing the downward-directed subpath according to this literal we can complete a simple path to d. By construction, the label of this path complies with the CFG.

Conversely suppose there exists a simple path in G from s to d satisfying the labeling constraint. The alternation of # and \$ in L enforces that such a path visits every tower, then the vertex τ, and finally the destination. In this situation we can define an assignment A according to the path in the first tower. By Lemma 28, and the path's being simple, we know that A is consistently represented in all the towers. The second part of the path shows that A is a satisfying assignment for F.

Finally it is easy to verify that G has a constant treewidth. For this we describe a tree decomposition of the graph. The up to four nodes of one level in a gadget H_i

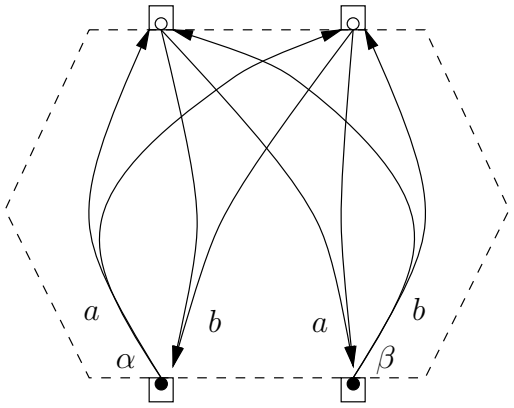

FIG. 8. *The smaller gadgets replacing the H_i used in the original construction. a stands for a_1, a_2, a_3; b for b_1, b_2, b_3. To encode the clauses some of these labels get removed, as in the proof of Theorem* 20.

and the up to four nodes of the path D_i form so-called level-sets. Two neighboring level-sets together, and two bottom level-sets of neighboring towers, respectively, form a set of the tree-decomposition. Additional sets for s, d, and τ with all the adjacent nodes are needed. This shows that the treewidth is bounded by 16. □

Actually the result of Theorem 26 can be extended to obtain the following.

COROLLARY 29. CFG-SIP *is* NP*-hard when restricted to graphs of treewidth* 3 *and a fixed* linear, deterministic *CFG.*

Proof. The proof is similar to the proof of Theorem 26, and thus we describe only the necessary modifications needed to prove the corollary. First we can replace the second part of the graph, used to verify that the assignment satisfies the formula. This is done as in the proof of Theorem 20, by replacing a (and b) by three symbols a_1, a_2, and a_3 (b_1, b_2, b_3). We modify the language such that for the context-free part all a_i are equivalent and all b_i are equivalent. Then we add a regular component to the language (take the intersection), enforcing that on one leg all the indices have to be identical. By removing certain labels we can make sure that in every tower one clause is tested.

Since we do not need the free nodes anymore, the gadget H_i depicted in Figure 5 can be replaced by a much smaller one, depicted in Figure 8. Note that replacing parallel directed links by disjoint paths of length 2 does not increase the treewidth in this situation. The additional nodes and edges can be covered in a tree-decomposition by some more leaf-sets of size 3. This does not increase the width of the tree-decomposition. In total the treewidth of the modified construction is reduced to 3.

Taking a new alphabet symbol x we define the language $H = \{\ wxw^P\#v | w \in L_1, v \in (\Sigma - \{\#\})^*\ \}$. It is easy to see that H can be specified by a linear CFG if L_1 is a regular language. Here w^P is defined to be the reverse of w with bottom marker \$ and top marker # exchanged. We take L_1 to be a regular language that forces the path to use the top marker of every tower. It is sufficient to argue that the proof of Theorem 26 can be modified such that the constraining CFL can be replaced by H.

For this we double the sequence of variables, introducing a new set of variables $\{x'_i = x_{2n-i+1}\}$ yielding the extended sequence $x_1, x_2, \ldots, x_n, x'_n, x'_{n-1}, \ldots, x'_1$. The new variables are used only while constructing the towers, but not for the evaluation

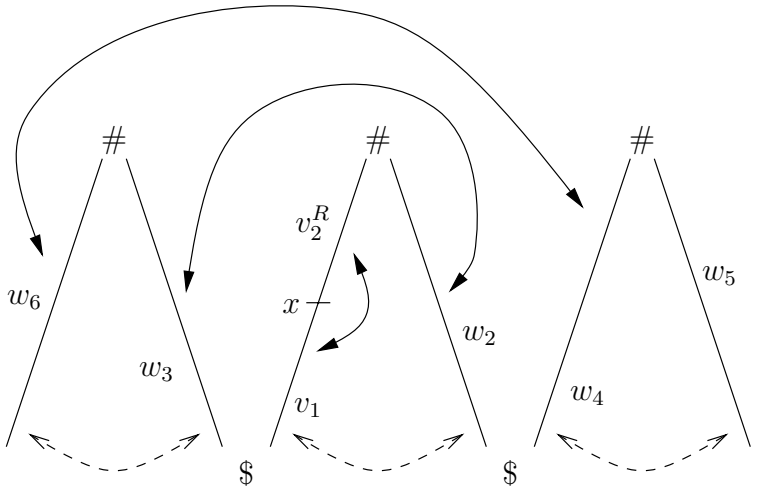

FIG. 9. *Schematic labeling of the path; $w_1 = v_1 v_2^R$; solid arrows stand for correspondence enforced by the language, dashed arrows for correspondence resulting from the graph.*

of clauses. Additionally we have to incorporate the middle marker x into the graph. Assuming the number of clauses m is odd, this means that we modify the tower $m/2$ at the level of the lowermost gadget $H_{n+1}^{m/2}$ created for the new variable x'_n. In this gadget we replace both upward edges by paths of length 2. The upper edge gets the original label, the lower edge gets labeled with x.

The proof of correctness consists of showing that the new H ensures a single assignment is represented by all the subpaths in the towers. This can be shown inductively from the middle symbol x outwards. The way the information is spread is depicted in Figure 9. The induction starts with the fact that the signature w_1 of the upward path in tower $m/2$ is forced by H to comply with $v_1 = v_2^R$, leading to the definition $w_1 = v_1 v_2^R$, with the property $w_1 = w_1^R$. So we do not have to distinguish between w_1 and w_1^R. Then the graph enforces $w_2 = w_1$, H enforces $w_3 = w_2$, and so on. This establishes that all the (lower halves of the) signatures are identical. The remaining part of the proof follows the details given for Theorem 26 closely. □

Note that the language H in the proof of Theorem 26 can also be accepted by a deterministic log-space-bounded Turing machine having a two-way input tape.

6.4. Algorithm for REG-SIP on graphs of bounded treewidth. In contrast to the above NP-hardness results we show that for graphs of bounded treewidth the problem REG-SIP is solvable in polynomial time. The class of treewidth-bounded graphs includes interval graphs and chordal graphs with *bounded clique size*, complete meshes, with fixed length or width, outer planar graphs, series parallel graphs, etc. We refer the reader to [AC+93, AL+91, Bo88, Bo92, BL+87] for other polynomial-time-solvable problems for treewidth-bounded graphs. This easiness result, along with the hardness result in the preceding section, also implies that these results are in a sense the best possible. We will use the notion of a nice tree-decomposition discussed in [Bo92].

DEFINITION 30. *A tree-decomposition $\langle \{ X_i \mid i \in I \}, T = (I, F) \rangle$ is* nice *if one can choose a root r in the tree such that*

- *T is a binary tree;*

- *if i is a leaf, then $|X_i| = 1$ (start node);*
- *if i has two children j and k, then $X_i = X_j = X_k$ (join node);*
- *if i has one child j, then there exists a vertex v such that either*
  - *$X_i = X_j \setminus \{v\}$ (forget node), or*
  - *$X_i = X_j \cup \{v\}$ (introduce node).*

We use the fact, that there exists always a nice tree-decomposition of optimal width (treewidth), and that it can be constructed in linear time [Bo92].

THEOREM 31. *The* REG-SIP *problem is solvable in polynomial time on treewidth-bounded graphs*

Proof. Given a treewidth-bounded graph G along with a nice tree-decomposition $T(I, F)$, we describe an algorithm that computes tables of (partial) shortest simple paths in a bottom-up fashion in T. Specifically, we have one table for every set X_i corresponding to the node i of T. We describe the entries of these tables and how to compute the values (i) for leaf sets and (ii) for internal nodes from the values in the tables of the child node(s). Since the number of values computed, as well as the number of tables, is polynomial in the size of G, this yields a polynomial-time algorithm.

The complicated task is to keep track of the simplicity of the path or, more precisely, the nodes used by the partial solutions represented by entries of the table. We have an entry for each type of path going through the set of nodes to which the table is attached. Since these sets are separators in G it is not necessary to keep the complete information about possible paths "behind" the separator. For the remainder of this section, we use k to denote the treewidth of the tree-decomposition T. In the following, for a set X_j corresponding to a node i in T we give a characterization of the distinct subsolutions that need to be maintained.

First we introduce the notion of an "atom": a simple path in the already "visited" part of the graph. An atom is characterized by

(1) a node in X_j the path starts;
(2) the state the automaton is in before reading in the label of the path;
(3) a node in X_j the path ends;
(4) the state of the automaton after having read in the label of the path.

We accept the special situation of one-node paths, i.e., indices with identical nodes and states.[3] There are two special "half" atoms standing for a beginning segment and an end segment of the path: There we have a node and a state identifying the end node of a simple path that starts at the source, such that its label can lead the automaton to the specified state. Similarly, for the end segment of a path we have a node and a state such that the labeling along the path gets the automaton from this state to an accepting state at the sink. Thus the subsolutions are completely described by

> the $O(k)$ atoms plus the two special half atoms together with a set of other used nodes in X_i.

We only need to allow the atoms to be empty, meaning that they do not denote any path. Noting that the total number of ways to partition a set of size k is $k^{O(k)}$ leads to an upper bound of $(2k \cdot |NFA|)^{O(k)}$ for the number of entries in the tables[4] which is polynomial in the size of the NFA for fixed treewidth k.

Note that the entry in the table where both of the special half atoms are empty stands for a complete solution in the already visited part of the graph. For every type

[3] Here we could actually account for ε moves in the automaton if we choose to.
[4] We have not attempted to optimize the size of the tables.

of partial solutions we maintain the total length of the shortest partial solution.

We now describe the tables more formally. For the leaf sets consisting of a single node v the table is easy to compute. It has entries with value 0 for the following partial solutions:

- $s \neq v \neq d$ for all states i: the length 0 path v-v, with start and end states i, no additional nodes used.
- $v = s$ the length 0-path from s to v ending in the initial state.
- $v = d$ for all accepting states $f \in F$: the length 0-path from v to d beginning in state f.

In order to compute the tables in a bottom-up fashion in T, we need to consider three possible cases depending on the type of nodes in T. Let i be a node in T.

i **is a join node:** (1) Letting j and l be the children of i, we know that $X_i = X_j = X_l$. Combine a partial solution stored in the table associated j with a partial solution stored in the table associated with l. For all pairs of types of partial solutions check if they can be combined to form another partial solution (no commonly used nodes, matching boundary node and state of the partial solution, respecting special cases for source and destination subpaths). Create the new type and compute the value of the combined solution. If the type does not yet exist in the table or the newly computed value is smaller than the old table entry, update the table entry. This is justified by the observation that the described subsolutions associated with j and k are disjoint except at the set of separator nodes X_i.

(2) Keep the componentwise min of the tables: for all types of partial solutions (their descriptions match as the two sets of the decomposition are identical), keep the smaller value. If the solution according to a type does not exist, we assume its value to be infinity. (This can also be seen as (1), where we combine the entry with an "empty subsolution" of cost 0 from the left and from the right and then choose the better one.)

i **is a forget node:** Let v be the node removed from the set in the nice tree-decomposition. We discard all partial solutions that contain a path with endpoint v. In all partial solutions, we delete v in the set of used nodes. For the resulting identical subsolutions we keep the one with minimum value.

i **is an introduce node:** Let v be the new node, e_i the edges between v and nodes in the set of the child.

(1) Set up the new node. Copy all known partial solutions. Create new partial solutions by combining all known with all solutions created according to the rules stated above for leaf sets of the form $\{v\}$.

(2) Include the incident edges one by one. Consider all possible new paths using this edge.

The correctness of the algorithm follows by noting the following:

(1) Given an entry in the root of the table for the existence of a path p of a given length, we can easily find such a path recursively from subsolutions associated with the children of the root.

(2) Conversely, let p be one of the optimal (shortest) solutions. Let X_r be the set associated with the root of T. Assume that r is a join node and let l and w be the left and right children. The argument for the other two cases is similar and thus omitted. It is easy to see that the path p can be broken into two paths p_1 and p_2 (p_2 could be empty) such that p_1 is a subsolution maintained at l and p_2 is subsolution maintained at w. □

The following generalization of the previous result holds.

COROLLARY 32. *Let L be a fixed language decidable by a one-way input tape,* log*-space-bounded nondeterministic Turing machine (NDTM). Then the problem of finding a shortest simple path from source to destination according to L is solvable in polynomial time on treewidth bounded graphs.*

Proof. The length of a simple path in the graph is bounded by n. The number of configurations of an NDTM using $\log n$ tape cells is polynomial in n. No other configurations of the machine can be used while recognizing a word of length smaller than or equal to n. As the machine reads the input tape in one direction only, we can create an NFA with states representing configuration that (i) decides L for words of length $\leq n$ and (ii) has a size polynomial in n. Using the algorithm in the proof of Theorem 31 with NFA M, we can compute the sought path in polynomial time. □

Note that $a^n b^n c^n$ and all languages accepted by pushdown automata having only one stack-symbol are examples of such languages.

6.5. Algorithm for acyclic graphs. Another well-known situation in which shortest simple paths are feasible is for acyclic graphs. This stems from the fact that all paths in an acyclic graph are simple and by this the shortest and the shortest simple path always coincide. This, together with the results of section 5, yields the following result.

COROLLARY 33. *The problem* CFG-SIP *is solvable in polynomial time on directed acyclic graphs.*

Making use of the fact that the length of a simple path is bounded by the size of the graph, we get the following.

COROLLARY 34. *The problem of finding a shortest simple simple from source to destination in a directed acyclic graph according to a formal language L is solvable in polynomial time if there exists a polynomial time computable CFL R of size polynomial in n with the following property:*

$$x \in \Sigma^*,\ |x| \leq n :\ \ (x \in L \leftrightarrow x \in L(R)).$$

7. Extensions and applications. In this section, we briefly discuss extensions and applications of our results to problems in transportation science. For many of these applications, it is possible to devise dynamic-programming-based methods to solve the problems; our aim is to convey the applicability of the general methodology proposed here.

7.1. Node labels and trip chaining. Consider the problem where the nodes have labels, instead of the edges and the constraint is on the concatenated node labels of a path. Easy transformations of the input show that all the results we develop for the edge-labeled case are also true for the node-labeled case. We can transform this kind of instance into an edge-labeled one by the following steps: The network stays the same, the edges get labeled with a new symbol. Every node gets an additional loop attached. This loop gets the label(s) of the node. Then the language has to be extended such that (i) exactly every second symbol has to be the new edge symbol and (ii) the word without the edge symbols is in the original language. It is easy to see that regular and context-free languages are closed under this operation. This shows, that easiness results for edge label constraints imply easiness results for node label constraints. If we have an edge-labeled graph, we split the edges and insert a node with the edge label, and label all the old nodes with one new symbol. The language has

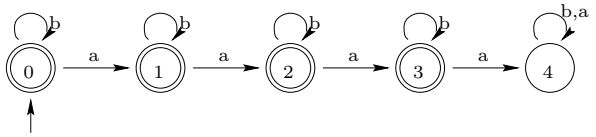

FIG. 10. *Automaton used to count shared links, accepting if less than* 4.

to be extended as above. This construction transfers edge-label-constrained hardness results to node-label-constrained results.

The node label extensions turn out to be useful in modeling transportation-related problems. In many transportation applications (e.g., TRANSIMS) one needs to find paths for travelers who need to visit a fixed sequence of location types. For instance, we might want to find a shortest path from home to home that visits some locations, e.g., ATM–gas station–supermarket–post office, in this particular order, but with the freedom to choose one of the several ATMs (gas stations, etc.) in the city. Problems of this type are referred to in the transportation literature as *trip chaining* problems. The problem cannot be solved by direct application of Dijkstra's shortest path algorithm to find best paths between two consecutive subdestinations and concatenating these paths. By treating each destination type as a node label and constructing a simple regular expression, we can select places for the subdestinations and find shortest path in networks that satisfy the precedence constraints using the polynomial result discussed in this paper.

7.2. Finding alternatives to shortest paths. There has been considerable interest in algorithms for variations of shortest paths (see [AMO93, Ta81, HNR68, OR90, Ha92, BAL97]). For example, in a recent paper by Scott, Pabon-Jimenez, and Bernstein [SJB97], the authors consider the following problem: given a graph G, a shortest path SP in G, and an integer parameter, find the shortest path $SP1$ in G that has at most k links in common with SP. Call this the BEST k-SIMILAR PATH problem. In [SJB97], the authors present an integer linear program formulation of the problem and present a heuristics based on Lagrangian relaxation. It can be verified that the heuristic takes exponential time in the worst case. Quoting [SJB97], *"The link overlap constraint thus makes finding the best path much more difficult (i.e., shortest path problems with a single constraint are* NP*-hard)"*; thus suggesting that the BEST k-SIMILAR PATH problem is likely to be NP-hard. Here we show that this problem is solvable in time $T(k|G|)$, where $T(n)$ denotes the time taken to find a shortest path on a graph with n vertices. This substantially improves upon the exponential-time algorithm given in [SJB97]. Our approach for solving the problem is based on using our algorithm for regular-expression-based shortest paths. The approach uses the fact that, given a k and symbol $a \in \Sigma$, the language consisting of all words $w \in \Sigma^*$ with no more than k occurrences of the symbol a in them is regular. Given a graph G, a shortest path SP in G and an integer parameter k, we perform the following steps:

(1) Label the edges on the shortest paths by a and all the other edges in G by b.
(2) Construct an NFA M that accepts all strings that have no more than k occurrences of a. The corresponding automaton M is shown in Figure 10 (and happens to be deterministic).
(3) Find a shortest path in G with the constraint that its label is in $L(M)$.

The proof of correctness is straightforward. We note that in this particular case, we in fact always get a simple path, since we can always remove a loop from a path without increasing its length or acceptability of the shorter string.

7.3. Handling left-turn and U-turn penalties. Suppose we are told that in our road network there is additional cost incurred when we take certain left turns. This is a common scenario in transportation science and is referred to as turn penalties [HM95]. This is not an unlikely scenario. In fact the current Dallas Fort Worth case study has exactly this situation. Specifically, several left turns in the study area are prohibited, which amounts to saying that the cost of taking that edge if it is a left turn is ∞. Moreover, the infrastructure change that is proposed for the case study intends to make a series of left turns illegal near the area of Valley View Mall and the Galleria.

A well-known reduction from the original problem to the problem of finding a shortest path in a modified network (see [AMO93] for details) can be used to solve this problem. (The basic idea is to replace each intersection by a clique of size 4. A slightly more complicated subgraph is required for directed graphs.) Instead of giving a penalty to a turn, suppose we wish to find a path in which we do not take more than, say, k left turns. This variant of the problem cannot be solved by a direct application of Dijkstra's algorithm, but is amenable to an efficient solution using the formal language approach. To do this we again replace each intersection by a clique of size 4 and then add appropriate labels to each of these edges. We then construct an automaton, which accepts strings that contain at most k labels corresponding to left turns. This can be constructed along the lines of the k-SIMILAR PATH problem. The rest of the details are straightforward. Now consider a more complicated query in which we wish to find a path such that the number of left turns is a small fraction of the total number of edges. It is easy to see that this can be written as a CFG and thus again can be solved efficiently.

7.4. Time-dependent networks and multicriteria shortest paths. In several transportation applications, it is desirable to solve shortest path problems on networks in which the edge weights are a function of time. In [OR90] Orda and Rom consider this type of problem for various waiting policies and function classes. One of their basic algorithms is a dynamic programming on functions. Combining this with our results, we obtain a polynomial-time algorithm for CFL-constrained shortest paths in time-depending networks.

As a final application, consider bicriteria and in general multicriteria shortest path problems. For instance, we might have two different weight functions on each edge a function $c(e)$ that captures the cost of using that edge and a function $t(e)$ that captures the time it takes to traverse the edge. The aim of the bicriteria shortest path problem aims at finding a minimum cost path from a source s to a destination d, that obeys a given budget bound B on the time taken to go from s to d. This problem has been studied extensively in the literature (see [MRS+95] and the references therein). Given that the cross product construction simply constructs multiple copies of the basic graph, it is easy to design a polynomial-time approximation scheme for the bicriteria shortest path problem subject to labeling constraints. The idea is a straightforward combination of the ones outlined here and those used for designing approximation schemes for the basic bicriteria problem.

7.5. Other formal languages. As expected, attempts to extend the polynomial-time algorithms to more general grammars such as the context-sensitive grammars fail to yield polynomial-time results. Intuitively, the hardness of the problems is due to the fact that *emptiness* and *recognition problems* for context-sensitive grammars are undecidable and PSPACE-complete, respectively.

Consider the problem for context-sensitive grammars. It is easy to show that

the problem (CSG-SHP) is undecidable even for a fixed log-space decidable context-sensitive language. It is easy to see that the language

$$L = \left\{ w\#^i \mid w \in \{0,1\}^*,\ \text{TM}(w) \text{ halts on an empty input using space } \log i \right\}$$

is context sensitive. It is in fact log-space computable. It is also straightforward to see that

$$L' = \{w \mid \exists i\ w\#^i \in L\}$$

is another way of stating the halting problem and is thus undecidable.

Showing that we can use CSG-SHP to decide L' establishes that CSG-SHP is itself undecidable. For $w \in \{0,1\}^*$ we construct a directed chain labeled according to w with start s and end d. We additionally put a loop from d to d labeled with $\#$. The fixed constraining language is L. Now $w \in L'$ is equivalent to the existence of a (in general not simple) path from s to d in this graph. Note that this graph is nearly a tree.

In contrast, the CSG-SIP is PSPACE-complete. Membership in PSPACE follows by observing that a simple path in a graph $G(V, E)$ can have at most $|V|$ nodes. Thus a space-bounded NDTM [HU79] can guess a simple path p and then verify that $l(p) \in L(M)$, where M is the context-sensitive grammar. The hardness is shown by reducing the problem of deciding if $w \in L(M)$ to finding a simple path in a directed chain that is labeled according to w. Let s and t denote the two endpoints of this chain. Then there is a path from s to t whose labels are in $L(R)$ if and only if $w \in L(R)$. Similar extensions hold for other formal languages. Note that for this argument the context-sensitive language can be fixed to represent an arbitrary PSPACE-complete problem.

8. Conclusions. In this paper, we have presented a general approach for modeling and solving a number of problems that seek to find paths subject to certain labeling constraints. The model was shown to be particularly useful in understanding and solving transportation science problems. The results in this paper provide a fairly tight characterization of the complexity of these problems, varying the type of considered path, the underlying grammar, and allowed graph classes. For a number of nontrivial cases this completely characterizes the boundary between easy and hard cases. Our results can also be seen investigating tradeoffs between (i) economy of descriptions of languages used to describe labeling constraints and (ii) the efficient solvability of the corresponding problems.

In [BK+99, JBM99, JMN98], we have obtained a number of additional theoretical as well as empirical results on related topics. Specifically in [JBM99], we show how applying our results on finding REG-SHP in time-dependent networks can be used to solve a number of additional problems arising in transportation science. In [BK+99, JMN98], we have carried out a detailed experimental analysis to validate the suitability of extensions of the algorithm suggested here on realistic transportation networks. We refer the reader to the Web site http://transims.tsasa.lanl.gov for comprehensive information about TRANSIMS and related documents.

The results presented here raise a number of questions for further investigation. First, it would be of interest to characterize the class of fixed regular (context-free) languages for which the regular-expression-constrained simple path problems are solvable in polynomial time. It would also be of interest to provide natural formulation of other label-constrained subgraph problems. For example, what is a natural way

to specify labeling constraints for spanning trees of a graph? A number of possible ways present themselves; the aim is to find ways that are both natural and useful in modeling practical problems.

Acknowledgments. We want to thank Harry Hunt III, Sven Krumke, Alberto Mendelzon, S. S. Ravi, R. Ravi, Dan Rosenkrantz, M. Yannakakis, Hans-Christoph Wirth, Stephen Eubank, Kai Nagel, Terence Kelly, Robert White, and Brian Bush for several useful discussions, pointers to related literature, and suggested improvements in the course of writing this paper. We also thank the anonymous referee for a careful reading of the manuscript and a number of helpful comments on the earlier draft.

A FAST GENERAL METHODOLOGY FOR INFORMATION-THEORETICALLY OPTIMAL ENCODINGS OF GRAPHS*

XIN HE†, MING-YANG KAO‡, AND HSUEH-I LU§

Abstract. We propose a fast methodology for encoding graphs with information-theoretically minimum numbers of bits. Specifically, a graph with property π is called a *π-graph*. If π satisfies certain properties, then an n-node m-edge π-graph G can be encoded by a binary string X such that (1) G and X can be obtained from each other in $O(n \log n)$ time, and (2) X has at most $\beta(n)+o(\beta(n))$ bits for any continuous superadditive function $\beta(n)$ so that there are at most $2^{\beta(n)+o(\beta(n))}$ distinct n-node π-graphs. The methodology is applicable to general classes of graphs; this paper focuses on planar graphs. Examples of such π include all conjunctions over the following groups of properties: (1) G is a planar graph or a plane graph; (2) G is directed or undirected; (3) G is triangulated, triconnected, biconnected, merely connected, or not required to be connected; (4) the nodes of G are labeled with labels from $\{1, \ldots, \ell_1\}$ for $\ell_1 \leq n$; (5) the edges of G are labeled with labels from $\{1, \ldots, \ell_2\}$ for $\ell_2 \leq m$; and (6) each node (respectively, edge) of G has at most $\ell_3 = O(1)$ self-loops (respectively, $\ell_4 = O(1)$ multiple edges). Moreover, ℓ_3 and ℓ_4 are not required to be $O(1)$ for the cases of π being a plane triangulation. These examples are novel applications of small cycle separators of planar graphs and are the only nontrivial classes of graphs, other than rooted trees, with known polynomial-time information-theoretically optimal coding schemes.

1. Introduction.

Let G be a graph with n nodes and m edges. This paper studies the problem of *encoding* G into a binary string X with the requirement that X can be *decoded* to reconstruct G. We propose a fast methodology for designing a coding scheme such that the bit count of X is information-theoretically optimal. Specifically, a function $\beta(n)$ is *superadditive* if $\beta(n_1)+\beta(n_2) \leq \beta(n_1+n_2)$. A function $\beta(n)$ is *continuous* if $\beta(n + o(n)) = \beta(n) + o(\beta(n))$. For example, $\beta(n) = n^c \log^d n$ is continuous and superadditive, for any constants $c \geq 1$ and $d \geq 0$. The continuity and superadditivity are closed under additions. A graph with property π is called a *π-graph*. If π satisfies certain properties, then we can obtain an X such that (1) G and X can be computed from each other in $O(n \log n)$ time, and (2) X has at most $\beta(n)+o(\beta(n))$ bits for any continuous superadditive function $\beta(n)$ so that there are at most $2^{\beta(n)+o(\beta(n))}$ distinct n-node m-edge π-graphs. The methodology is applicable to general classes of graphs; this paper focuses on planar graphs.

A *conjunction* over k groups of properties is a boolean property $\pi_1 \wedge \cdots \wedge \pi_k$, where π_i is a property in the ith group for each $i = 1, \ldots, k$. Examples of suitable π for our methodology include every conjunction over the following groups:

F1. G is a planar graph or a plane graph.
F2. G is directed or undirected.
F3. G is triangulated, triconnected, biconnected, merely connected, or not required to be connected.
F4. The nodes of G are labeled with labels from $\{1, \ldots, \ell_1\}$ for $\ell_1 \leq n$.
F5. The edges of G are labeled with labels from $\{1, \ldots, \ell_2\}$ for $\ell_2 \leq m$.
F6. Each node of G has at most $\ell_3 = O(1)$ self-loops.
F7. Each edge of G has at most $\ell_4 = O(1)$ multiple edges.

Moreover, ℓ_3 and ℓ_4 are not required to be $O(1)$ for the cases of π being a plane triangulation. For instance, π can be the property of being a directed unlabeled biconnected simple plane graph. These examples are novel applications of small cycle separators of planar graphs [12, 11]. Note that the rooted trees are the only other nontrivial class of graphs with a known polynomial-time information-theoretically optimal coding scheme, which encodes a tree as nested parentheses using $2(n-1)$ bits in $O(n)$ time.

Previously, Tutte proved that there are $2^{\beta(m)+o(\beta(m))}$ distinct m-edge plane triangulations where $\beta(m) = (\frac{8}{3} - \log_2 3)m + o(m) \approx 1.08m + o(m)$ [17] and that there are $2^{2m+o(n)}$ distinct m-edge n-node triconnected plane graphs that may be nonsimple [18]. Turán [16] used $4m$ bits to encode a plane graph G that may have self-loops. Keeler and Westbrook [10] improved this bit count to $3.58m$. They also gave coding schemes for several families of plane graphs. In particular, they used $1.53m$ bits for a triangulated simple G, and $3m$ bits for a connected G free of self-loops and degree-1 nodes. For a simple triangulated G, He, Kao, and Lu [5] improved the bit count to $\frac{4}{3}m + O(1)$. For a simple G that is triconnected and thus free of degree-1 nodes, they [5] improved the bit count to at most $2.835m$ bits. This bit count was later reduced to at most $\frac{3\log_2 3}{2}m + O(1) \approx 2.378m + O(1)$ by Chuang et al. [2]. These coding schemes all take linear time for encoding and decoding, but their bit counts are not information-theoretically optimal. For labeled planar graphs, Itai and Rodeh [6] gave an encoding of $\frac{3}{2}n \log n + O(n)$ bits. For unlabeled general graphs, Naor [14] gave an encoding of $\frac{1}{2}n^2 - n \log n + O(n)$ bits.

For applications that require query support, Jacobson [7] gave a $\Theta(n)$-bit encoding for a connected and simple planar graph G that supports traversal in $\Theta(\log n)$ time per node visited. Munro and Raman [13] improved this result and gave schemes to encode binary trees, rooted ordered trees, and planar graphs. For a general planar G, they used $2m + 8n + o(m+n)$ bits while supporting adjacency and degree queries in $O(1)$ time. Chuang et al. [2] reduced this bit count to $2m + (5 + \frac{1}{k})n + o(m+n)$ for any constant $k > 0$ with the same query support. The bit count can be further reduced if only $O(1)$-time adjacency queries are supported, or if G is simple, triconnected, or triangulated [2]. For certain graph families, Kannan, Naor and Rudich [8] gave schemes that encode each node with $O(\log n)$ bits and support $O(\log n)$-time testing of adjacency between two nodes. For dense graphs and complement graphs, Kao, Occhiogrosso, and Teng [9] devised two compressed representations from adjacency lists to speed up basic graph search techniques. Galperin and Wigderson [4] and Papadimitriou and Yannakakis [15] investigated complexity issues arising from encoding a graph by a small circuit that computes its adjacency matrix.

Section 2 discusses the general encoding methodology. Sections 3 and 4 use the

methodology to obtain information-theoretically optimal encodings for various classes of planar graphs. Section 5 concludes the paper with some future research directions.

2. The encoding methodology. Let $|X|$ be the number of bits in a binary string X. Let $|G|$ be the number of nodes in a graph G. Let $|S|$ be the number of elements, counting multiplicity, in a multiset S.

FACT 1 (see [1, 3]). *Let $X_1, X_2, \ldots, X_k$ be $O(1)$ binary strings. Let $n = |X_1| + |X_2| + \cdots + |X_k|$. Then there exists an $O(\log n)$-bit string χ, obtainable in $O(n)$ time, such that given the concatenation of $\chi, X_1, X_2, \ldots, X_k$, the index of the first symbol of each X_i in the concatenation can be computed in $O(1)$ time.*

Let $X_1 + X_2 + \cdots + X_k$ denote the concatenation of $\chi, X_1, X_2, \ldots, X_k$ as in Fact 1. We call χ the *auxiliary binary string* for $X_1 + X_2 + \cdots + X_k$.

A graph with property π is called a *π-graph*. Whether two π-graphs are *distinct* or *indistinct* depends on π. For example, let G_1 and G_2 be two topologically non-isomorphic plane embeddings of the same planar graph. If π is the property of being a planar graph, then G_1 and G_2 are two indistinct π-graphs. If π is the property of being a planar embedding, then G_1 and G_2 are two distinct π-graphs. Let α be the number of distinct n-node π-graphs. Clearly it takes $\lceil \log_2 \alpha \rceil$ bits to differentiate all n-node π-graphs. Let $\text{index}_\pi(G)$ be an $\lceil \log_2 \alpha \rceil$-bit indexing scheme of the α distinct π-graphs.

Let G_0 be an input n_0-node π-graph. Let $\lambda = \log\log\log(n_0)$. The encoding algorithm $\text{encode}_\pi(G_0)$ is merely a function call $\text{code}_\pi(G_0, \lambda)$, where the recursive function $\text{code}_\pi(G, \lambda)$ is defined as follows:

```
function code_π(G, λ)
{
  if |G| = O(1) or |G| ≤ λ then
    return index_π(G)
  else
  {
    compute π-graphs G_1, G_2, and a string X, from which G can be recovered;
    return code_π(G_1, λ) + code_π(G_2, λ) + X;
  }
}
```

Clearly, the code returned by algorithm $\text{encode}_\pi(G_0)$ can be decoded to recover G_0. For notational brevity, if it is clear from the context, the code returned by algorithm $\text{encode}_\pi(G_0)$ (respectively, function $\text{code}_\pi(G, \lambda)$) is also denoted $\text{encode}_\pi(G_0)$ (respectively, $\text{code}_\pi(G, \lambda)$).

Function $\text{code}_\pi(G, \lambda)$ *satisfies the separation property* if there exist two constants c and r, where $0 \le c < 1$ and $r > 1$, such that the following conditions hold:

P1. $\max(|G_1|, |G_2|) \le |G|/r$.
P2. $|G_1| + |G_2| = |G| + O(|G|^c)$.
P3. $|X| = O(|G|^c)$.

Let $f(|G|)$ be the time required to obtain $\text{index}_\pi(G)$ and G from each other. Let $g(|G|)$ be the time required to obtain G_1, G_2, X from G, and vice versa.

THEOREM 2.1. *Assume that function $\text{code}_\pi(G, \lambda)$ satisfies the separation property and that there are at most $2^{\beta(n)+o(\beta(n))}$ distinct n-node π-graphs for some continuous superadditive function $\beta(n)$.*

1. *$|\text{encode}_\pi(G_0)| \le \beta(n_0) + o(\beta(n_0))$ for any n_0-node π-graph G_0.*
2. *If $f(n) = 2^{n^{O(1)}}$ and $g(n) = O(n)$, then G_0 and $\text{encode}_\pi(G_0)$ can be obtained from each other in $O(n_0 \log n_0)$ time.*

Proof. The theorem holds trivially if $n_0 = O(1)$. For the rest of the proof we assume $n_0 = \omega(1)$, and thus $\lambda = \omega(1)$. Many graphs may appear during the execution of $\text{encode}_\pi(G_0)$. These graphs can be organized as nodes of a binary tree T rooted at G_0, where (i) if G_1 and G_2 are obtained from G by calling $\text{code}_\pi(G, \lambda)$, then G_1 and G_2 are the children of G in T, and (ii) if $|G| \le \lambda$, then G has no children in T. Further consider the multiset S consisting of all graphs G that are nodes of T. We partition S into $\ell+1$ multisets $S(0), S(1), S(2), \ldots, S(\ell)$ as follows. $S(0)$ consists of the graphs G with $|G| \le \lambda$. For $i \ge 1$, $S(i)$ consists of the graphs G with $r^{i-1}\lambda < |G| \le r^i\lambda$. Let $G_0 \in S(\ell)$, and thus set $\ell = O(\log \frac{n_0}{\lambda})$.

Define $p = \sum_{H \in S(0)} |H|$. We first show

$$|S(i)| < \frac{p}{r^{i-1}\lambda} \tag{1}$$

for every $i = 1, \ldots, \ell$. Let G be a graph in $S(i)$. Let $S(0, G)$ be the set consisting of the leaf descendants of G in T; for example, $S(0, G_0) = S(0)$. By condition P2, $|G| \le \sum_{H \in S(0,G)} |H|$. By condition P1, no two graphs in $S(i)$ are related in T. Therefore $S(i)$ contains at most one ancestor of H in T for every graph H in $S(0)$. It follows that $\sum_{G \in S(i)} |G| \le \sum_{G \in S(i)} \sum_{H \in S(0,G)} |H| \le p$. Since $|G| > r^{i-1}\lambda$ for every G in $S(i)$, inequality (1) holds.

Statement 1. Suppose that the children of G in T are G_1 and G_2. Let $b(G) = |X| + |\chi|$, where χ is the auxiliary binary string for $\text{code}_\pi(G_1, \lambda) + \text{code}_\pi(G_2, \lambda) + X$. Let $q = \sum_{i \ge 1} \sum_{G \in S(i)} b(G)$. Then $|\text{encode}_\pi(G_0)| = q + \sum_{H \in S(0)} |\text{code}_\pi(H, \lambda)| \le q + \sum_{H \in S(0)} (\beta(|H|) + o(\beta(|H|)))$. By the superadditivity of $\beta(n)$, $|\text{encode}_\pi(G_0)| \le q + \beta(p) + o(\beta(p))$. Since $\beta(n)$ is continuous, Statement 1 can be proved by showing $p = n_0 + o(n_0)$ and $q = o(n_0)$ below.

By condition P3, $|X| = O(|G|^c)$. By Fact 1, $|\chi| = O(\log |G|)$. Thus, $b(G) = O(|G|^c)$, and

$$q = \sum_{i \ge 1} \sum_{G \in S(i)} O(|G|^c). \tag{2}$$

Now we regard the execution of $\text{encode}_\pi(G_0)$ as a process of growing T. Let $a(T) = \sum_{H \text{ is a leaf of } T} |H|$. At the beginning of the function call $\text{encode}_\pi(G_0)$, T has exactly one node G_0, and thus $a(T) = n_0$. At the end of the function call, T is fully expanded, and thus $a(T) = p$. By condition P2, during the execution of $\text{encode}_\pi(G_0)$, every function call $\text{code}_\pi(G, \lambda)$ with $|G| > \lambda$ increases $a(T)$ by $O(|G|^c)$. Hence

$$p = n_0 + \sum_{i \ge 1} \sum_{G \in S(i)} O(|G|^c). \tag{3}$$

Note that

$$\sum_{i \ge 1} \sum_{G \in S(i)} |G|^c \le \sum_{i \ge 1} (r^i\lambda)^c p/(r^{i-1}\lambda) = p\lambda^{c-1} r \sum_{i \ge 1} r^{(c-1)i} = p\lambda^{c-1} O(1) = o(p). \tag{4}$$

By (3) and (4), we have $p = n_0 + o(p)$, and thus $p = O(n_0)$. Therefore $\sum_{i \ge 1} \sum_{G \in S(i)} |G|^c = o(n_0)$. By (2) and (3), $p = n_0 + o(n_0)$ and $q = o(n_0)$, finishing the proof of Statement 1.

Statement 2. By conditions P1 and P2, $|H| = \Omega(\lambda)$ for every $H \in S(0)$. Since $\sum_{H \in S(0)} |H| = p = n_0 + o(n_0)$, $|S(0)| = O(n_0/\lambda)$. Together with (1), we know

$|S(i)| = O(\frac{n_0}{r^i\lambda})$ for every $i = 0, \ldots, \ell$. By the definition of $S(i)$, $|G| \leq r^i\lambda$ for every $i = 0, \ldots, \ell$. Therefore G_0 and $\text{encode}_\pi(G_0)$ can be obtained from each other in time

$$\frac{n_0}{\lambda} O\left(f(\lambda) + \sum_{1 \leq i \leq \ell} r^{-i} g(r^i\lambda)\right).$$

Clearly $f(\lambda) = 2^{\lambda^{O(1)}} = 2^{o(\log\log n_0)} = o(\log n_0)$. Since $\ell = O(\log n_0)$ and $g(n) = O(n)$, $\sum_{1 \leq i \leq \ell} r^{-i} g(r^i\lambda) = \sum_{1 \leq i \leq \ell} \lambda = O(\lambda \log n_0)$, and Statement 2 follows. □

Sections 3 and 4 use Theorem 2.1 to encode various classes of graphs G. Section 3 considers plane triangulations. Section 4 considers planar graphs and plane graphs.

3. Plane triangulations. A *plane triangulation* is a plane graph, each of whose faces has size exactly 3. For any plane triangulation P with n nodes, m edges, and f faces, Euler's formula ensures that $n - m + f = 2$ even if P contains self-loops and multiple edges. One can then obtain $m = 3n - 6$. Therefore every n-node plane triangulation, simple or not, has exactly $3n - 6$ edges.

In this section, let π be an arbitrary conjunction over the following groups of properties of a plane triangulation G: F2, F6, and F7, where ℓ_3 and ℓ_4 are not required to be $O(1)$. Our encoding scheme is based on the next fact.

FACT 2 (see [12]). *Let H be an n-node m-edge undirected plane graph, each of whose faces has size at most d. We can compute a node-simple cycle C of H in $O(n + m)$ time such that*

- *C has at most $2\sqrt{dn}$ nodes; and*
- *the numbers of H's nodes inside and outside C are at most $2n/3$, respectively.*

Let G be a given n-node π-graph. Let G' be obtained from the undirected version of G by deleting the self-loops. Clearly each face of G' has size at most 4. Let C' be a cycle of G' having size at most $4\sqrt{n}$ guaranteed by Fact 2. Let C consist of the edges of G corresponding to the edges of C' in G'. Note that C is not necessarily a directed cycle if G is directed. Since G' does not have self-loops, $2 \leq |C| \leq 4\sqrt{n}$. If $\ell_4 \geq 2$, then $|C|$ can be 2. Let G_{in} (respectively, G_{out}) be the subgraph of G formed by C and the part of G inside (respectively, outside) C. Let x be an arbitrary node on C.

G_1 is obtained by placing a cycle C_1 of three nodes outside G_{in} and then triangulating the face between C_1 and G_{in} such that a particular node y_1 of C_1 has degree strictly lower than the other two. Clearly this is feasible even if $|C| = 2$. The edge directions of $G_1 - G_{\text{in}}$ can be arbitrarily assigned according to π.

G_2 is obtained from G_{out} by (1) placing a cycle C_2 of three nodes outside G_{out} and then triangulating the face between C_2 and G_{out} such that a particular node y_2 of C_2 has degree strictly lower than the other two, and (2) triangulating the face inside C by placing a new node z inside of C and then connecting it to each node of C by an edge. Note that (2) is feasible even if $|C| = 2$. Similarly, the edge directions of $G_2 - G_{\text{out}}$ can be arbitrarily assigned according to π.

Let u be a node of G. Let v be a node on the boundary $B(G)$ of the exterior face of G. Define $\text{dfs}(u, G, v)$ as follows. Let w be the counterclockwise neighbor of v on $B(G)$. We perform a depth-first search of G starting from v such that (1) the neighbors of each node are visited in the counterclockwise order around that node, and (2) w is the second visited node. A numbering is assigned the first time a node is visited. Let $\text{dfs}(u, G, v)$ be the binary number assigned to u in the above depth-first search. Let $X = \text{dfs}(x, G_1, y_1) + \text{dfs}(x, G_2, y_2) + \text{dfs}(z, G_2, y_2)$.

LEMMA 3.1.

1. *G_1 and G_2 are π-graphs.*
2. *There exists a constant $r > 1$ with $\max(|G_1|, |G_2|) \leq n/r$.*
3. *$|G_1| + |G_2| = n + O(\sqrt{n})$.*
4. *$|X| = O(\log n)$.*
5. *G_1, G_2, X can be obtained from G in $O(n)$ time.*
6. *G can be obtained from G_1, G_2, X in $O(n)$ time.*

Proof. Statements 1–5 are straightforward by Fact 2 and the definitions of G_1, G_2, and X. Statement 6 is proved as follows. It takes $O(n)$ time to locate y_1 (respectively, y_2) in G_1 (respectively, G_2) by looking for the node with the lowest degree on $B(G_1)$ (respectively, $B(G_2)$). By Fact 1, it takes $O(1)$ time to obtain $\mathrm{dfs}(y_1, G_1, x)$, $\mathrm{dfs}(y_2, G_2, x)$, and $\mathrm{dfs}(y_2, G_2, z)$ from X. Therefore x and z can be located in G_1 and G_2 in $O(n)$ time by depth-first traversal. Now G_{in} can be obtained from G_1 by removing $B(G_1)$ and its incident edges. The cycle C in G_{in} is simply $B(G_{\mathrm{in}})$. Also, G_{out} can be obtained from G_2 by removing $B(G_2)$, z, and their incident edges. The C in G_{out} is simply the boundary of the face that encloses z and its incident edges in G_2. Since we know the positions of x in G_{in} and G_{out}, G can be obtained from G_{in} and G_{out} by fitting them together along C by aligning x. The overall time complexity is $O(n)$. ∎

THEOREM 3.2. *Let G_0 be an n_0-node π-graph. Then G_0 and $\mathrm{encode}_\pi(G_0)$ can be obtained from each other in $O(n_0 \log n_0)$ time. Moreover, $|\mathrm{encode}_\pi(G_0)| \leq \beta(n_0) + o(\beta(n_0))$ for any continuous superadditive function $\beta(n)$ such that there are at most $2^{\beta(n)+o(\beta(n))}$ distinct n-node π-graphs.*

Proof. Since an n-node π-graph has $O(n)$ edges, there are at most $2^{O(n \log n)}$ distinct n-node π-graphs. Thus, there exists an indexing scheme $\mathrm{index}_\pi(G)$ such that $\mathrm{index}_\pi(G)$ and G can be obtained from each other in $2^{|G|^{O(1)}}$ time. The theorem follows from Theorem 2.1 and Lemma 3.1. ∎

4. Planar graphs and plane graphs. In this section, let π be an arbitrary conjunction over the following groups of properties of G: F1, F2, F3, F6, and F7. Clearly an n-node π-graph has $O(n)$ edges.

Let G be an input n-node π-graph. For the cases of π being a planar graph rather than a plane graph, let G be embedded first. Note that this is only for the encoding process to be able to apply Fact 2. At the base level, we still use the indexing scheme for π-graphs rather than the one for embedded π-graphs. As shown below, the decoding process does not require the π-graphs to be embedded.

Let G' be obtained from the undirected version of G by (1) triangulating each of its faces that has size more than 3 such that no additional multiple edges are introduced, and then (2) deleting its self-loops. Let C' be a cycle of G' guaranteed by Fact 2. Let C consists of (a) the edges of G corresponds to the edges of C' in G', and (b) the edges of C' that are added into G' by the triangulation. (C is not necessarily a directed cycle of a directed G.) Let G_C be the union of G and C. Let G_{in} (respectively, G_{out}) be the subgraph of G_C formed by C and the part of G_C inside (respectively, outside) C. Let $C = x_1 x_2 \cdots x_\ell x_{\ell+1}$, where $x_{\ell+1} = x_1$. By Fact 2, $\ell = O(\sqrt{n})$.

LEMMA 4.1. *Let H be an $O(n)$-node $O(n)$-edge graph. There exists an integer k with $n^{0.6} \leq k \leq n^{0.7}$ such that H does not contain any node of degree k or $k-1$.*

Proof. Assume for a contradiction that such a k does not exist. It follows that the sum of degrees of all nodes in H is at least $(n^{0.6} + n^{0.7})(n^{0.7} - n^{0.6})/4 = \Omega(n^{1.4})$. This contradicts the fact that H has $O(n)$ edges. ∎

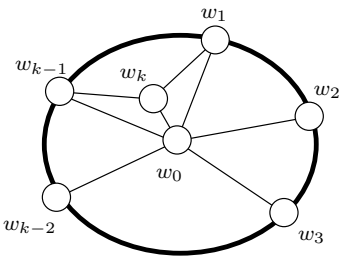

FIG. 1. *A k-wheel graph W_k.*

Let W_k, with $k \geq 3$, be a *k-wheel graph* defined as follows. As shown in Figure 1, W_k consists of $k+1$ nodes $w_0, w_1, w_2, \ldots, w_{k-1}, w_k$, where $w_1, w_2, \ldots, w_k, w_1$ form a cycle. w_0 is a degree-k node incident to each node on the cycle. Finally, w_1 is incident to w_{k-1}. Clearly W_k is triconnected. Also, w_1 and w_k are the only degree-4 neighbors of w_0 in W_k. Let k_1 (respectively, k_2) be an integer k guaranteed by Lemma 4.1 for G_{in} (respectively, G_{out}). Now we define G_1, G_2, and X as follows.

G_1 is obtained from G_{in} and a k_1-wheel graph W_{k_1} by adding an edge (w_i, x_i) for every $i = 1, \ldots, \ell$. Clearly for the case of π being a plane graph, G_1 can be embedded such that W_{k_1} is outside G_{in}, as shown in Figure 2(a). Thus, the original embedding of G_{in} can be obtained from G_1 by removing all nodes of W_{k_1}. The edge directions of $G_1 - G_{\text{in}}$ can be arbitrarily assigned according to π.

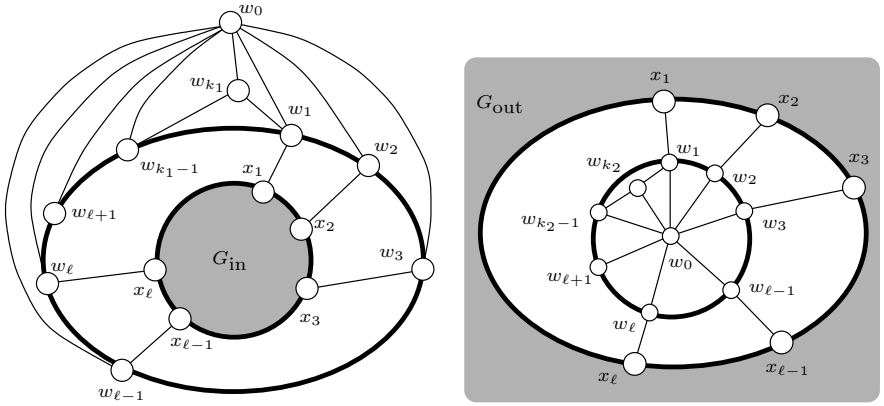
G_2 is obtained from G_{out} and a k_2-wheel graph W_{k_2} by adding an edge (w_i, x_i) for every $i = 1, \ldots, \ell$. Clearly for the case of π being a plane graph, G_2 can be embedded such that W_{k_2} is inside C, as shown in Figure 2(b). Thus, the original embedding of G_{out} can be obtained from G_2 by removing all nodes of W_{k_2}. The edge directions of $G_2 - G_{\text{out}}$ can be arbitrarily assigned according to π.

Let X be an $O(\sqrt{n})$-bit string which encodes k_1, k_2, and whether each edge (x_i, x_{i+1}) is an original edge in G, for $i = 1, \ldots, \ell$.

LEMMA 4.2.

1. *G_1 and G_2 are π-graphs.*
2. *There exists a constant $r > 1$ with $\max(|G_1|, |G_2|) \leq n/r$.*
3. *$|G_1| + |G_2| = n + O(n^{0.7})$.*
4. *$|X| = O(\sqrt{n})$.*
5. *G_1, G_2, X can be obtained from G in $O(n)$ time.*
6. *G can be obtained from G_1, G_2, X in $O(n)$ time.*

Proof. Since W_{k_1} and W_{k_2} are both triconnected, and each node of C has degree at least 3 in G_1 and G_2, statement 1 holds for each case of the connectivity of the input π-graph G. Statements 2–5 are straightforward by Fact 2 and the definitions of G_1, G_2, and X. Statement 6 is proved as follows. First of all, we obtain k_1 from X. Since G_{in} does not contain any node of degree k_1 or $k_1 - 1$, w_0 is the only degree-k_1 node in G_1. Therefore it takes $O(n)$ time to identify w_0 in G_1. w_{k_1} is the only degree-3 neighbor of w_0. Since $k_1 > \ell$, w_1 is the only degree-5 neighbor of w_0. w_2 is the common neighbor of w_0 and w_1 that is not adjacent to w_{k_1}. From now on, w_i, for each $i = 3, 4, \ldots, \ell$, is the common neighbor of w_0 and w_{i-1} other than w_{i-2}. Clearly, $w_1, w_2, \ldots, w_\ell$ and thus $x_1, x_2, \ldots, x_\ell$ can be identified in $O(n)$ time. G_{in} can now be obtained from G_1 by removing W_{k_1}. Similarly, G_{out} can be obtained from G_2 and X by deleting W_{k_1} after identifying $x_1, x_2, \ldots, x_\ell$. Finally, G_C can be recovered by fitting G_{in} and G_{out} together by aligning $x_1, x_2, \ldots, x_\ell$. Based on X, G can then be



(a) G_1 (b) G_2

FIG. 2. *G_1 and G_2. The gray area of G_1 is G_{in}. The gray area of G_2 is G_{out}.*

obtained from G_C by removing the edges of C that are not originally in G. □

Remark. In the proof for statement 6 of Lemma 4.2, identifying the degree-k_1 node (and the k_1-wheel graph W_{k_1}) does not require the embedding for G_1. Therefore the decoding process does not require the π-graphs to be embedded. This is different from the proof of Lemma 3.1.

THEOREM 4.3. *Let G_0 be an n_0-node π-graph. Then G_0 and* $\text{encode}_\pi(G_0)$ *can be obtained from each other in $O(n_0 \log n_0)$ time. Moreover,* $|\text{encode}_\pi(G_0)| \leq \beta(n_0) + o(\beta(n_0))$ *for any continuous superadditive function $\beta(n)$ such that there are at most $2^{\beta(n)+o(\beta(n))}$ distinct n-node π-graphs.*

Proof. Since there are at most $2^{O(n \log n)}$ distinct n-node π-graphs, there exists an indexing scheme $\text{index}_\pi(G)$ such that $\text{index}_\pi(G)$ and G can be obtained from each other in $2^{|G|^{O(1)}}$ time. The theorem follows from Theorem 2.1 and Lemma 4.2. □

5. Concluding remarks. For brevity, we left out F4 and F5 in sections 3 and 4. One can verify that Theorems 3.2 and 4.3 hold even if π is a conjunction over F1 through F7 including F4 and F5.

The coding schemes given in this paper require $O(n \log n)$ time for encoding and decoding. An immediate open question is whether one can encode some graphs other than rooted trees in $O(n)$ time using information-theoretically minimum number of bits. It would be of significance to determine whether the tight bound of the number of distinct π-graphs for each π is indeed continuous superadditive.

EFFICIENTLY CONSTRUCTING THE VISIBILITY GRAPH OF A SIMPLE POLYGON WITH OBSTACLES*

SANJIV KAPOOR† AND S. N. MAHESHWARI†

Abstract. This paper describes an output-sensitive scheme to construct the visibility graph of a simple polygon with m obstacles and n vertices in optimal $O(|E| + T + m \log n)$ time where $|E|$ is the size of the visibility graph and T is the time required to triangulate the simple polygon with obstacles. We use a partition of the space into regions called corridors which eases the efforts of the construction. Our algorithms are simple and the data structures used are only linked lists.

Key words. simple polygon, obstacles, visibility graph, triangulation, linked lists, output-sensitive

1. Introduction.

The visibility graph, $GVIS = (V, E)$, of a simple polygon with m obstacles is a graph where the vertices in set V, $|V| = n$, are the vertices of the simple polygon with obstacles and the edge set, E, is defined as follows: $(u, v) \in E$ iff u and v can be connected to each other by a line segment that does not intersect any edge or vertex of the simple polygon or obstacle. Such an edge is referred to as a *visibility edge*. We refer to the simple polygon with obstacles as a *polygonal structure*. The visibility graph is a fundamental structure in computational geometry. It has a number of applications including being a graph in which the shortest distance between any pair of vertices in the polygonal structure can be found using standard graph algorithms [AAG+86]. While in recent developments algorithms for the shortest path problem use a continuous version of Dijkstra's algorithm, the visibility graph approach still provides for simple and efficient solutions [KM88, KMM97] which are optimal when the number of obstacles is $O(\sqrt{n})$.

Since the visibility graph has size $O(n^2)$, algorithms for this problem will require $O(n^2)$ time in the worst case. In fact, worst case time optimal algorithms are well known for this problem [AAG+86, Wel85, GM91]. Other related results may be found in [Her89, OW88]. In this paper we describe an algorithm which requires time $O(|E| + T + m \log n)$, where E is the edge set of the visibility graph and T is the time required for triangulating the simple polygon with obstacles. An $O(n \log n)$ worst case bound on T is well known [PS85]. However, when the number of obstacles is small improvements are possible. A bound of $O(n + m \log^{1+\epsilon} m)$ [BYC94] is known for the triangulation problem when there are $O(m)$ obstacles.

We note that a scheme requiring $O(|E| + n \log n)$ steps for solving this problem has also been discovered by [GM91]. The algorithm developed here appears simpler and uses less complicated data structures.

Our development is as follows: The algorithm first partitions the space into subregions which we call corridors. We describe this in section 2. The visibility graph of corridors is easy to determine in linear time. We show how to do this in section 3. We

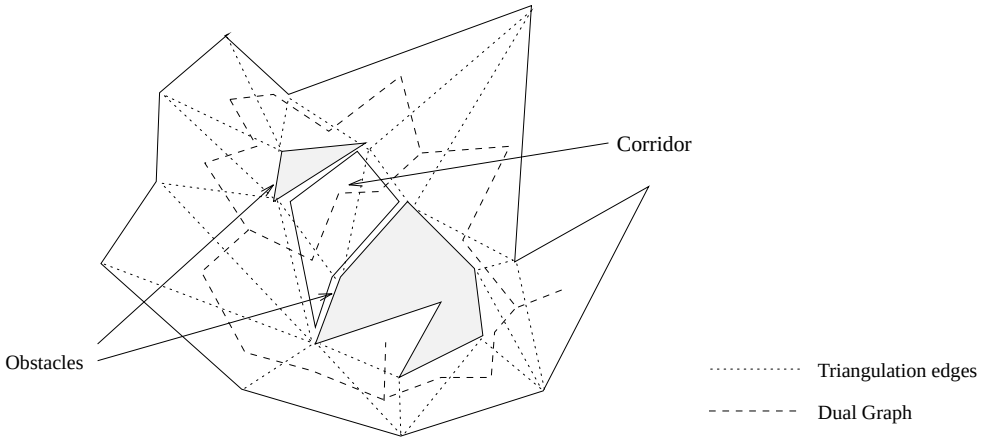

FIG. 1. *Partition.*

then show how to extend this construction to the case of a general polygonal structure in section 4.

2. Corridor structure. In this section we will consider the triangulation of the polygonal structure and extract from it regions which we call corridors. This partition of the space into corridors has been used before in a shortest path algorithm [KM88].

Consider an arbitrary triangulation of the simple polygon with obstacles.

The triangulation partitions the space into triangular regions. We consider the dual graph $G_d = (V_d, E_d)$ obtained by assigning vertices to the regions and edges between a pair of vertices if the two corresponding triangles share an edge. Let $v \in V_d$ be a vertex. The region corresponding to v is denoted by $T(v)$. Furthermore, let $e = (v_1, v_2)$ be an edge in the dual graph. The triangulation edge that separates the triangles, $T(v_1)$ and $T(v_2)$, is defined to be $D(e)$, the edge dual to e. $T(v_1)$ and $T(v_2)$ are termed adjacent triangles (Figure 1).

We next partition the dual graph into paths called C-paths. We define a 2-path in G_d to be a simple path in which all internal vertices, if they exist, are of degree 2. A C-path is a 2-path of maximal length. Each such C-path, P, defines a corridor, $\mathcal{C}$, as follows: $\mathcal{C}(P) = \cup_{a \in P} T(a)$, degree $(a) = 2$ or 1, i.e., the region formed by the union of the sequence of triangles corresponding to the vertices of degree 2 and degree 1, if they exist, of P. A corridor is a simple polygon.

We consider the general case, when the path P starts and ends at vertices of degree 3. The corridor $\mathcal{C}(P)$ has two sides comprising edges which are edges of the polygonal structure. There are also two bounding edges which form the corridor end. These edges are triangulation edges which separate the corridor from the other regions. A corridor may also simply be an edge as we see below.

When an endpoint of the path P has degree 1, the corresponding corridor end has a degenerate bounding edge, (u, v) with $u = v$. The last triangle in the corridor comprises two edges of the polygonal structure. And there is no adjacent corridor at this corridor end.

Corridors are connected to each other by triangles called junctions. These junctions correspond to vertices with degree 3 in the dual graph, G_d. A corridor may be connected either to other corridors through a junction at a corridor end or to none. These corridors are called adjacent corridors. The case when the corridor is connected

to exactly one other corridor through a junction occurs when both the bounding edges of the other corridor form two of the three edges of the junction triangle.

Note that a corridor may be degenerate. Consider when two degree 3 vertices u and v are adjacent. The edge $D(e)$, dual to $e = (u, v)$, is said to form a degenerate corridor. The corridor consists of a single (triangulation) edge alone which serves as the two bounding edges. The two vertices are degenerate sides of the corridor.

Given a triangulation, the partitioning of the polygonal region into corridors and junctions can be achieved in $O(n)$ time. This is done by identifying the degree 3 and degree 1 vertices in the dual graph. Each C-path which connects a degree 3 or degree 1 vertex to another degree 3 or degree 1 vertex defines a corridor.

2.1. Definitions. We need the following definitions.

We define the corridor distance, $dist(u, v)$, between two vertices u and v of the polygonal structure in a corridor, $\mathcal{C}(P)$, to be the minimum number of edges required to be traversed in $P \in G_d$ to reach a triangle containing u from another triangle containing v. More precisely, $dist(u, v)$ is the minimum number of edges required to be traversed in P to reach a vertex $b \in G_d$ from another vertex $a \in G_d$ such that $u \in T(a)$ and $v \in T(b)$.

Given points u, v, and w, we will let $\angle(u, v, w)$ represent the smaller angle (less than 180 degrees) formed at v by the line segments (v, u) and (v, w). An angle $\angle(u, v, w)$ is defined to be inside a corridor if the corridor contains a sector, $S(u, v, w)$, of a circle in the plane defined as follows: $S(u, v, w) = B(v, \epsilon) \cap Cone(u, v, w)$ where ϵ is a sufficiently small constant, $B(v, \epsilon)$ is the circle of radius ϵ centered at v, and $Cone(u, v, w)$ is the cone in the plane with vertex v and angle $\angle(u, v, w)$ with the sides defined by the lines containing the line segments (v, u) and (v, w).

Given a list L and elements (pointers) a and b of (into) L, suppose a precedes b in a list L. This will be indicated by $a \preceq_L b$. And if a succeeds b in the list, L, then we shall represent this by $a \succeq_L b$. Use of L will be eliminated wherever understood.

3. Constructing the visibility diagram of a corridor. In this section we show how to construct the visibility diagram for the set of vertices in a corridor. We consider only nondegenerate corridors.

Let P be a C-path in G_d. Let $\mathcal{C}(P)$ be the corresponding corridor with two bounding edges $U = (a, b)$ and $B = (p, q)$ and two sides, (i) S_1, which connects a to p using edges of the polygonal structure, and (ii) S_2, which connects b to q. We let the sequence of degree 1 and 2 vertices of the path P be $p_1, p_2, \ldots, p_k$ and let the triangles, corresponding to the vertices on the path, be $T_1, T_2, \ldots, T_k$. Note that $T_i = T(p_i)$.

To construct the visibility diagram for the corridor, we traverse the corridor from one boundary, say, $U = (a, b), a \in S_1, b \in S_2$, called the upper boundary, to the other boundary, B, the bottom boundary, i.e., the vertices of the corridor are processed in order of increasing corridor distance from the vertices on the bounding edge, U. The basic attempt is to construct a list for the current vertex, v, that contains vertices visible to v from among the vertices already considered in the corridor. This suffices to construct all the visibility edges since each visibility edge, (u, v), v being at greater corridor distance than u from the boundary U, is constructed once when v is processed. Two lists are constructed for each vertex v, one list for each of the two sides of the corridor. Each such list is called a visibility list. The lists are sorted in the order that the visible vertices occur along the sides of the corridor, i.e., by decreasing value of the distance $dist(u, w)$, $u \in \mathcal{C}, w \in U$, or, equivalently, by increasing value of $dist(v, u), u \in C$.

For a vertex, v, the visibility list comprising vertices visible to v on side S_1 is $LIST_1(v)$ and that comprising vertices visible to v on side S_2 is $LIST_2(v)$. We let $T_1 = (a, b, v_1)$. v_1 is the first vertex to be considered in the corridor. $LIST_1(v_1)$ contains a and $LIST_2(v_1)$ contains b. The algorithm next considers another vertex obtained from the triangle T_2 adjacent to T_1 in the corridor C. T_2 adds one new vertex. This vertex is adjacent to v_1 via a triangulation or a corridor edge. The visibility list of the new vertex is constructed and this process is repeated for successive vertices. We describe the general step next.

Let v_i be the vertex and T_i the triangle to be considered at the ith step. v_i is contained in triangle T_i which also contains v_{i-1}, the last vertex considered. Assume without loss of generality (w.l.o.g.) that v_i is on side S_1. Let $u_1 \dots u_k = v_i$ be the vertices on side S_1 already considered by the algorithm and let $w_1 \dots w_l$ be the vertices on side S_2 already considered up to this step.

First we describe how to build $LIST_1(v_i)$. The first vertex visible to v_i is u_{k-1} on side S_1. From u_{k-1} we will obtain the next visible vertex, say, u_j. Considering vertices along the corridor would involve traversing too many useless (invisible) vertices. We thus use the vertices on the visibility lists of u_{k-1} itself, taking care not to traverse this list more than a constant number of times.

We find u_j by traversing $LIST_1(u_{k-1})$ to find the highest indexed vertex v such that $\angle(v, u_{k-1}, v_i)$ is an angle inside the corridor, if it exists. This vertex is the vertex in $\{u_1 \dots u_{k-2}\}$ closest to v_i on side S_1, which may be visible to v_i. Note that if no such angle is found, then no visible vertex u_j exists. The vertex satisfying the above angle property is a candidate for addition to the visibility list of v_i.

Let this candidate be called v_q. Suppose v_q is visible. The next vertex on $LIST_1(v_i)$ is obtained from v_q. Again we find the highest indexed vertex in $LIST_1(v_q)$, v, such that the $\angle(v, v_q, v_i)$ is an angle inside the corridor and we determine its visibility. This is repeated until we find a candidate which is not visible or the end of the corridor is reached.

To determine if the candidate v_q is visible or not, note that the vertex will be invisible only if (v_i, v_q) intersects an edge on S_2. At least one such edge, say, e_t, will be visible from v_i and in fact the vertex of the intersected edge furthest from v_i, say, v_t, satisfies $dist(v_t, v_i) < dist(v_q, v_i)$. This is because the sequence of triangles in the corridor which starts from a triangle containing v_i and ends at a triangle containing v_q includes the triangle containing e_t. Note that in fact the edge which obstructs the visibility has an endpoint which either is in $LIST_2(v_i)$ or is a candidate for addition to $LIST_2(v_i)$.

In the algorithm below, $LIST_1(v_i)$ and $LIST_2(v_i)$ are built simultaneously. At each step we maintain two candidates to be added, one to each list. When both candidates are present then the candidate closer to u_k is added to the appropriate list. If only one candidate is present, then it is added to the appropriate list provided it is visible. The next candidate for the updated list is computed from the visibility list of the candidate added. This process is repeated either until the end of the corridor is reached or until no candidate is available.

We can now detail our algorithm. It is assumed that v_i is on side S_1.

ALGORITHM CORRVIS(C).

{ Corridor C has a boundary $(a = v_0, b = v_{-1})$ and comprises triangle $T_1 \dots T_k$. }

$i \leftarrow 0$;

Repeat

$i \leftarrow i + 1$;

```
Pick vertex v_i, adjacent to v_{i-1}, in triangle T_i = (v_{i-1}, v_j, v_i), j ≤ i − 2;
If v_{i-1} is on side S_1 then
        begin
        LIST_1(v_i) ← v_{i-1}; can_2 ← v_{i-2}
        end
else
        begin
        LIST_1(v_i) ← v_{i-2}; can_2 ← v_{i-1}
        end;
Repeat
        vis ←last vertex added to visibility lists of v_i;
        If vis is in LIST_1(v_i) then
                can_1 ← CANDIDATE(v_i, vis)
        else can_2 ← CANDIDATE(v_i, vis);
        If Both can_1 and can_2 exist then
                If dist(can_1, v_i) ≤ (can_2, v_i) then
                   Add can_1 to LIST_1(v_i)
                else Add can_2 to LIST_2(v_i)
        else    If can_1 exists and is visible to v_i then
                   Add can_1 to LIST_1(v_i)
                else If can_2 exists and is visible to v_i then
                        Add can_2 to LIST_2(v_i);
        Until (no more candidates are added to the lists);
Until (no more triangles left);
```

Next we describe two procedures used in the above algorithm. The first procedure determines if a candidate *can* is visible to vertex v_i. The second procedure, $CANDIDATE(v_i, vis)$, generates the candidate following vis which may be added to the visibility list of v_i that contains vis. The procedure may not return with a candidate if vis is the last vertex in the visibility list of v_i.

3.1. Determining visibility. Let can_1 and can_2 be the two candidates at time step t. Let $u_1, u_2 \ldots u_l$ be the vertices in $LIST_1(v_i)$ and let $w_1, w_2 \ldots w_r$ be the vertices in $LIST_2(v_i)$. Assume that there is a coordinate frame centered at v_i. Let α_j be the angle that (v_i, u_j) makes with the x-axis, and let β_j be the angle that (v_i, w_j) makes with the x-axis. We assume w.l.o.g. that $LIST_1(v_i)$ is being constructed in a clockwise fashion and $LIST_2(v_i)$ in a counterclockwise fashion. $LIST_1$ and $LIST_2$ are defined to overlap if $\exists p, q, 1 \le p, q \le r$ and $\exists j, k, 1 \le j, k \le l$ such that $[\beta_p, \beta_q] \cap [\alpha_j, \alpha_k] \neq \emptyset$. If such an overlap occurs, then one of the vertices in (u_p, u_q, w_j, w_k), say, u_q, is not visible from v_i since it is blocked by an edge on side S_2.

To determine visibility the following cases arise:

(1) Both can_1 and can_2 exist. Then the closer of the two vertices is visible to v_i.
(2) Suppose can_1 exists but can_2 does not. Let w' be the candidate generated for the visibility list, $LIST_2(v_i)$, when the last vertex w_r was added to it. w' may not have existed. In this case it suffices to check if $LIST_1(v_i)$, with the candidate can_1 added to it, overlaps with $LIST_2(v_i)$. If it does, then can_1 is not visible. If w' existed, then can_1 is not visible and will not exist since w' is not visible (see proof of Lemma 3.1 below).
(3) Suppose can_2 exists and can_1 does not. This case is symmetric to the previous case.

Note that candidates are added to the visibility lists for v_i in order of increas-

ing distance from v_i. We formally prove the correctness of the above procedure for computing the visibility.

LEMMA 3.1. *The candidate visible to v_i, from among can_1 and can_2, is correctly computed.*

Proof. We show the correctness of the procedure in the three cases that arise when determining can_1 and can_2.

Consider the first case. In this case since both can_1 and can_2 exist the candidate closer to v_i, say, can_1, is visible. The proof is by contradiction: Suppose not. Then can_1 is obstructed due to the overlap of $LIST_1(v_i)$ appended with can_1 and $LIST_2(v_i)$. But then no candidate at greater corridor distance than can_1 will be visible from the last vertex, t, in $LIST_2(v_i)$. Since can_2 is generated from $LIST_2(t)$ and must be visible from t, this is a contradiction.

In the second case, if w' does not exist, then there is no vertex, w', on side S_2 such that w' is visible to w_r and $\angle(v_i, w_r, w')$ is an angle less than 180 degrees inside the corridor. Thus only vertices in $LIST_2(v_i)$ can obstruct the visibility of the candidate, can_1, from v_i. This is determined correctly.

Alternatively suppose w' exists. Then since it is not a candidate currently, it has already been determined that w' is not visible due to an obstruction by an obstacle edge on side S_1. This implies that any vertex, v, such that $dist(v, v_i) > dist(w', v_i)$ and $\angle(v, u_j, v_i)$ is an angle inside the corridor, u_j being the last vertex in the current list $LIST_1(v_i)$, is not visible to v_i and to u_j. As candidates are considered in order of increasing distance from v_i, $dist(can_1, v_i) > dist(w', v_i)$ and thus can_1 is not visible to v_i and cannot exist.

The third case is symmetric to the first. □

3.2. Next candidate computation. To find the next vertex which is a candidate for the visibility list of v after a vertex vis has been added, we employ a scheme which generates the next candidate by a simple scan of the visibility list at vis. To do so we associate a constant number of pointers with each of the visibility lists of every vertex whose visibility lists have been built up. We next show that the lists will be scanned once only by a pointer, throughout the construction, thus ensuring efficient generation of candidates.

We need the following property and definitions: We let $U = (u_1, u_2)$ be the upper bounding edge of a corridor C.

DEFINITION. *A vertex a* occurs before *a vertex b on side, S, of corridor, C, with respect to bounding edge U, if $dist(a, u_1) < dist(b, u_1)$.*

Henceforth, we assume that the scan direction and starting boundary are fixed. Note that the visibility lists at a vertex, v, are ordered so that a vertex y follows x in the list if $dist(x, v) \leq dist(y, v)$.

LEMMA 3.2 (property monotonicity). *Let a and b be vertices of corridor C such that a occurs before b. Let u be a vertex visible to both a and b such that $dist(u, u_1) < dist(a, u_1) \leq dist(b, u_1)$. Let P_a and P_b be the pointer positions in $LIST_1(u)$ (or in $LIST_2(u)$ as appropriate) which give the next candidates for addition to the visibility list $LIST_1$ (or $LIST_2$) of a and b. If a and b are on side $S_1(S_2)$, then*

- *$P_a \succeq P_b$ ($P_a \preceq P_b$) in $LIST_1(u)$ if u is on S_1, and*
- *$P_a \preceq P_b$ ($P_a \succeq P_b$) in $LIST_2(u)$ if u is on S_2.*

Proof. We assume that a, b, and u are on S_1. The next candidate vertex for addition to $LIST_1$ of a or b is obtained by the first vertex, v_a or v_b, visible to u such that the angle $\angle(v_a, u, a)$ or $\angle(v_b, u, b)$ is an angle inside the corridor. Consider the straight line rays (a, u) and (b, u) with origin a and b, respectively. Let the rays strike

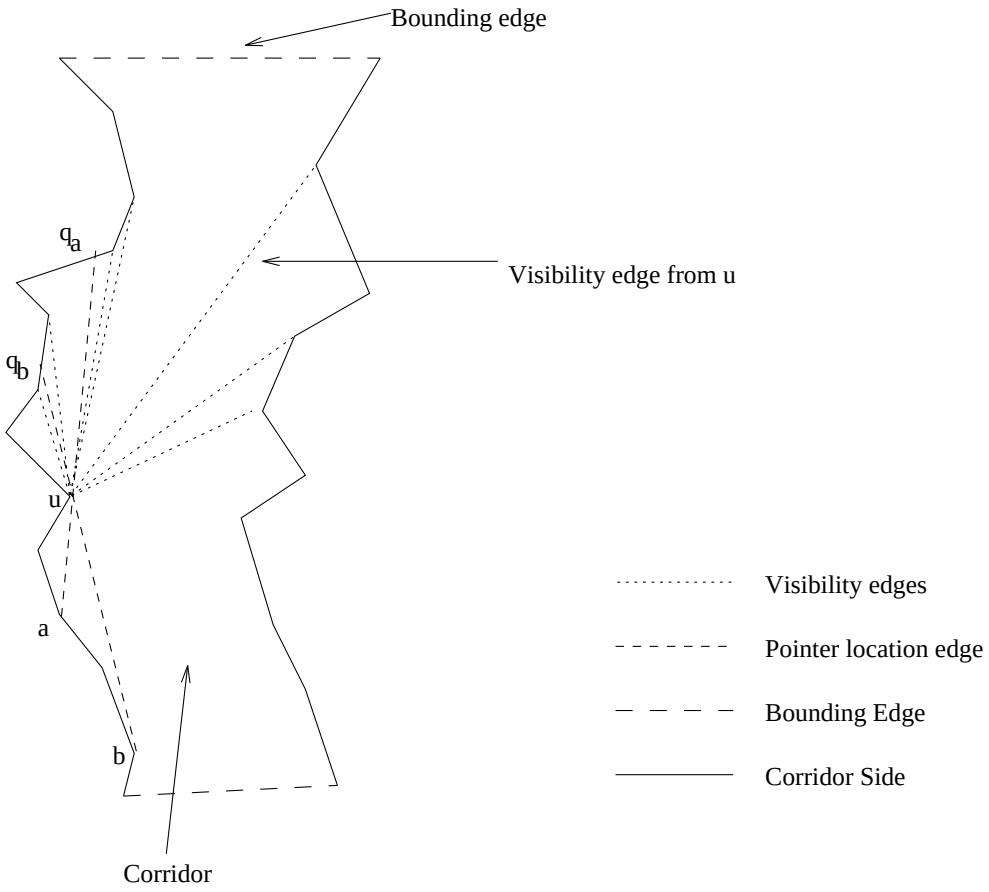

FIG. 2. *Order in a corridor.*

the side S_1 at q_a and q_b. The next candidate, $v_a(v_b)$, for $a(b)$ is the first vertex in $LIST_1(u)$ after the point $q_a(q_b)$ on S_1. Since q_b is closer to u than q_a the property follows. A symmetric proof applies in the other cases. (See Figure 2.) □

We use this property as follows: There are two pointers associated with a list, say, $LIST_1(u)$, at a vertex u on side S_1 of a corridor C. The first pointer, p_1, generates candidates for vertices on side S_1 whereas the second one, p_2, generates candidates for vertices on side S_2. Initially, the pointer p_1, associated with a list of u, is at one end of the list. Note again that the list is ordered by increasing distance of the visible vertices from u. The pointer, p_1, associated with the list at vertex u points to the candidate which is generated for $LIST_1(v)$, using the list $LIST_1(u)$, when u is added to the visibility list of v. The next time u is added to the visibility list of some other vertex, say, w, further along the corridor and on the same side, S_1, the pointer moves from its current position in $LIST_1(u)$ to generate the candidate for w. Since vertices are considered in order of their increasing distance from the bounding edge, for construction of the visibility lists, the monotonicity property of the position of the pointers (Lemma 3.2) ensures that the direction of movement of the pointer, p_1, is monotone and thus the list is scanned once only by the pointer, p_1, to generate candidates for all the vertices on side S_1 in the corridor. The same property is true

for p_2 when generating candidates for vertices in S_2 using $LIST_1(u)$, except that the list is traversed by this pointer in a direction opposite to that of p_1. Thus we have the following.

LEMMA 3.3. *Let $v \in C$. The visibility lists $LIST_1(v)$ and $LIST_2(v)$ are traversed only once to generate candidates for vertices in C.*

3.3. Correctness and time complexity. We show the following lemma.

LEMMA 3.4. *The visibility graph, $GVIS(V, E)$, where V is the set of vertices of a triangulated corridor, is correctly generated in $O(|E|)$ time.*

Proof. We first show correctness of the algorithm, CorrVis(C). It suffices to show that for a given vertex v_i, the visibility lists are correctly computed given the visibility lists of vertices which occur before v_i in the corridor. We show that $LIST_1(v_i)$ is correctly computed. The construction of $LIST_2(v_i)$ is symmetric and the correctness follows by a similar argument.

Assume that v_i is not on the boundary of the corridor. If it is, then the visibility list is the null list which is trivially constructed. To prove that $LIST_1(v_i)$ is correctly computed, we use induction on the distance $dist(v_i, vis)$ where $vis \in LIST_1(v_i)$ or $LIST_2(v_i)$. For the base case note that the vertex adjacent to v_i at distance 1 is trivially in $LIST_1(v_i)$. Suppose all visible vertices at distance $\leq k$ have been added to $LIST_1(v_i) \cup LIST_2(v_i)$. Consider the closest vertex, v, visible to v_i at distance greater than k from v_i. Assume w.l.o.g. that $v \in LIST_1(v_i)$. The vertex, v, is in the visibility list of vertex v' such that $dist(v_i, v') \leq k$ and v' is the vertex prior to v in $LIST_1(v_i)$. To prove this, consider the triangle $T = (v, v_i, v')$. If v is not visible to v', then (v', v) is intersected by an edge e of side S_1 but no edge of S_1 intersects (v_i, v) and (v_i, v'). Thus $\exists$ a vertex v'' on side S_1 such that $dist(v_i, v'') > dist(v_i, v')$, which is inside T and visible to v_i. This contradicts the choice of v'. Thus v will be generated as a candidate when v' is added to $LIST_1(v_i)$. Moreover, the visibility of the candidate is correctly determined as Lemma 3.1 proves. This completes the induction step.

To prove the time complexity note that, by Lemma 3.3, each visibility list is traversed once only while generating candidates for visibility lists of other vertices. Moreover, visibility of a candidate is checked in constant time since the last vertices in the two lists together with the candidate suffice to determine when an overlap occurs. Visibility list construction thus requires time $O(|\cup_{v \in C}(LIST_1(v) \cup LIST_2(v))|) = O(|E|)$. □

4. Visibility in a simple polygon with obstacles. To construct the visibility diagram of a simple polygon among obstacles we investigate the properties of the visibility lists of a point v in the polygonal structure. We need the following definitions.

Let $SC = C_1, C_2 \ldots C_k$ be a sequence of corridors such that (s.t.) C_{i+1} is adjacent to C_i via junction J_i, i.e., both corridors have a bounding edge in the triangle corresponding to the junction J_i, $\forall i, 1 \leq i \leq k-1$. Let $V_{SC} = \{v | v \in G_d \ \& \ T(v) \in [\cup_i C_i] \cup \mathcal{J}\}$ where $\mathcal{J} = \{J_1, J_2, \ldots, J_{k-1}\}$ and $E_{SC} \subset E$ is the set of edges induced by V_{SC}. The vertices and edges in V_{SC} and E_{SC} form a path $P_{SC} \in G_d$.

Similar to the previous section the corridor distance between two vertices v_1 and v_2, $dist(v_1, v_2)$, along a sequence of corridors SC is the minimum number of edges required to be traversed on the path, P_{SC}, to reach a triangle containing v_1 from a triangle containing v_2.

We assume a rectangular coordinate system $\mathcal{L}$ on the plane.

In the visibility diagram of a simple polygon with obstacles since the visible vertices may belong to different corridors there is no induced ordering on the vertices

themselves. However, the set of vertices visible to v can be partitioned such that with each partition is associated a sequence of corridors. In this section we show that the visible vertices can be arranged in a tree, called the visibility tree. We then show how to construct these trees for all the vertices in the polygonal structure in time proportional to the number of visibility edges.

4.1. Visibility trees. Let v be a vertex in a corridor C. Let $U = (a, b)$ and $B = (p, q)$ be the two bounding edges of the corridor. And let $VIS_B(v)$ be the set of vertices visible to v through edge B, where a vertex is defined to be visible through edge B if the visibility edge $(v, v'), v' \in VIS_B(v)$, intersects B. Suppose each visibility edge is labeled by the sequence of corridors which it traverses to reach vertex v. This labeling partitions the set of visibility edges in $VIS_B(v)$, with edges that traverse the same sequence of corridors being in one partition. Note that all the visibility edges in a partition are in the same corridor. The edges in a partition can be ordered and will be shown in fact to be constructed by a procedure similar to that in the previous section. We represent the partition of the set of visibility edges in $VIS_B(v)$ by a tree called a visibility tree and termed $TVIS_B(v)$. We will describe the construction of this tree below. All vertices visible to v can be divided into two sets, $VIS_U(v)$ and $VIS_B(v)$, and for each set a visibility tree will be constructed.

We now show how to construct the tree, $TVIS_B(v)$. At the root, r, of $TVIS_B(v)$ are two lists $LIST_1$ and $LIST_2$ which store, in order, vertices u of C on the two sides S_1 and S_2 that are visible to v and with corridor distance to v, $dist(u, v)$, less than $dist(p, v)$ and $dist(q, v)$, respectively. These vertices are termed to lie in between v and B. The root has at most two sons. With each son is associated a corridor which contains vertices visible to v through B. The two sons are ordered from left to right in increasing order of the angle of visibility edges from v to visible vertices in each of the two corridors. The angle is measured in, say, the counterclockwise direction in a coordinate system parallel to $\mathcal{L}$ and centered at vertex v. Assume w.l.o.g. that the angle between (p, v) and (q, v) is less than π in the counterclockwise direction. The angle of a visibility edge (v, p') is measured relative to (v, p), i.e., by $\angle(p, v, p')$. The ordering obtained is called an angle ordering. A similar ordering is defined for $TVIS_U(v)$. In this tree the sons are ordered again by increasing angle order. The angles are measured in the counterclockwise direction in a coordinate system parallel to $\mathcal{L}$ and fixed at vertex v. The angle of a visibility edge (v, b') is measured relative to (v, b), i.e., by $\angle(b', v, b)$.

W.l.o.g. we restrict our attention to $TVIS_B(v)$. The corridors at the sons of the root of $TVIS_B(v)$ are chosen so as to contain the closest vertex visible to v through B. Note that these corridors are not necessarily adjacent to C via the junction triangle, T, containing edge B. Since a vertex may belong to one or two corridors, the node has at most two sons. Let C_1 and C_2 be the two corridors. Each of the sons has two lists which contain, in order, the vertices on each of the two sides of the corridor, say, C_1, that are visible to v such that the corresponding visibility edges cross triangles in C_1 and intersect B. The visibility edges to the vertices in the corridor at the left son precede the visibility edges to the vertices in the corridor at the right son. Note that the corridors at the two sons could be the same. However, the lists of visible vertices stored at the left son are disjoint from the lists at the right son. This relationship of sons of a node in the tree to their parent node, as illustrated for the root node, is repeated recursively.

In general, a node p in the tree $TVIS_B(v)$ is associated with a corridor C_p, a bounding edge $B(p)$ of C_p, and at most two lists, $LIST_1(C_p)$ and $LIST_2(C_p)$. Note

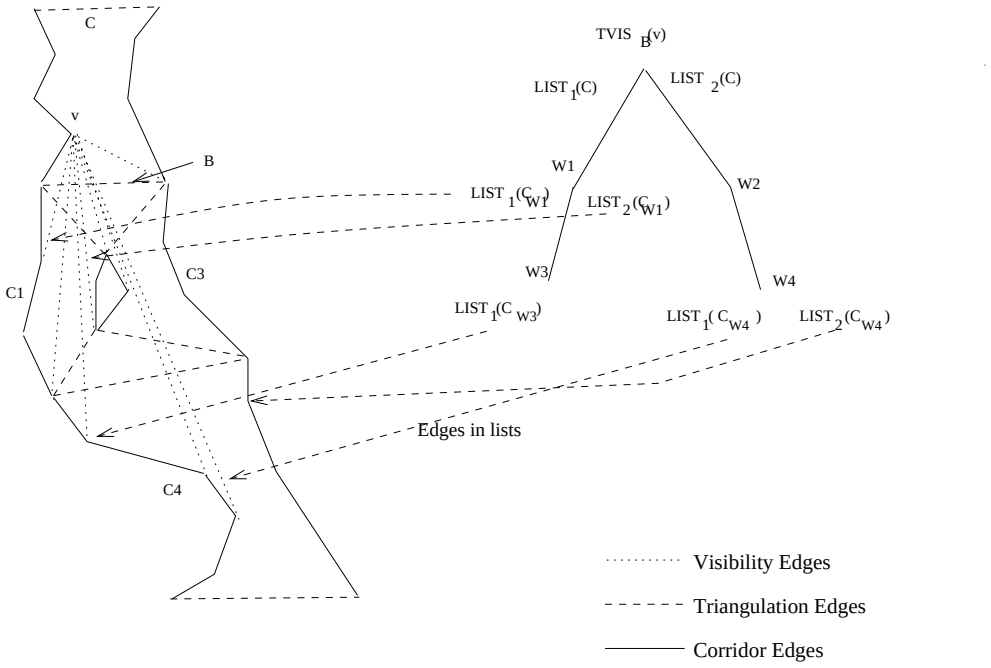

FIG. 3. *Visibility tree.*

that C_p may not be adjacent to the corridor, C', associated with the parent of p. In this case there is a unique sequence of corridors which connects C' to C_p. This is the sequence of corridors traversed by the visibility edge to the vertex closest to v in C_p. We term the sequence which connects C' with C_p as $AC(p)$. We let $SC(path(p))$ be the sequence of corridors, not including C_p, which are associated with or connect corridors corresponding to nodes on $path(p)$ from p to the root node of $TVIS_B(v)$, i.e., $SC(path(p)) = AC(p)C_{p_1}AC(p_1)C_{p_2}AC(p_2)\ldots AC(p_k)$, where p_k is the root of the tree $TVIS_B(v)$, and $p_1, p_2 \ldots$ are the nodes on the path from p to the root.

We consider vertices, w, in C_p that are visible to v such that the visibility edge, $(w, v), w \in C_p$, intersects $B(p)$ and the triangles in the sequence of corridors $SC(path(p))$. C_p has two sides. Assume w.l.o.g. that visible vertices on side S_1 occur before than visible vertices on side S_2, the vertices being ordered by angle ordering. $LIST_1(C_p)$ is the list of vertices on side S_1 of C_p, visible to v, such that the visibility edge, $(v_i, v), v_i \in LIST_1(C_p)$, intersects $B(p)$ and the triangles in the sequence of corridors $SC(path(p))$. Similarly, $LIST_2(C_p)$ is the list of nodes on side S_2 of the corridor C_p visible to v through $B(p)$ and the same sequence of corridors, $SC(path(p))$ (Figure 3). As in the previous section the vertices in the lists are ordered according to increasing corridor distance from v.

Moreover, let $son(p)$ be either one of the two possible sons of p. Associated with $son(p)$ is a corridor C_{son} and a bounding edge $B(son)$ which contains the closest visible vertex to v through $B(son)$ and the sequence $SC(path(son(p)))$. $son(p)$ contains $LIST_1(C_{son})$ and $LIST_2(C_{son})$.

The following lemma shows the usefulness of this tree.

LEMMA 4.1. *Let v be in corridor C. Let B be a bounding edge of C. At the root of $TVIS_B(v)$ are stored all vertices visible to v in corridor C and lying in between*

v and B. Every other vertex visible to v is stored at a node in $TVIS_B(v)$ s.t., at node $w \in TVIS_B(v)$, are stored all vertices visible to v having the property that the corresponding visibility edge intersects B and $B(w)$ and traverses the corridor sequence $SC(path(w))$.

Proof. The first part of the lemma follows from the definition of $TVIS_B(v)$. To prove the second part first note that a vertex stored in a list at a node in $TVIS_B(v)$ satisfies the required property by construction.

Second, we show that every visible vertex is stored at the correct node w in $TVIS_B(v)$. Consider a vertex, v_w, in a corridor C_w, visible to v through B.

We prove by induction on the distance of v_w from v that v_w is present in either $LIST_1$ or $LIST_2$ at a node w, with an associated bounding edge $B(w)$ and a corridor C_w, in $TVIS_B(v)$ s.t. this vertex is visible through a corridor sequence $CS = SC(path(w))$ and boundary $B(w)$. For the base case, the construction procedure adds the closest vertex from the same corridor, C. Assume that the hypothesis is true for vertices at distance at most k from v. Consider the vertex v_w in C_w which is at distance greater than k from v. Suppose $CS = C_1 \dots C_q$ is the sequence of corridors intersected by the edge (v, v_w) where C_1 is the first corridor traversed after the boundary B. W.l.o.g. assume that C_q, the last corridor in the sequence CS, has a vertex visible to v. By the induction hypothesis, a node q in $TVIS_B(v)$ corresponding to C_q exists.

First consider the case when v_w is the first vertex in corridor C_w that is visible to v through the sequence CS and $B(w)$. Since v_w is the closest vertex visible to v through the sequence CS and since q exists, the definition of $TVIS_B(v)$ ensures that a node corresponding to C_w will be present in the tree as a son of q and v_w will be contained in a list at that node. Since $CS = SC(path(w))$ the edge (v, v_w) has the required property that it intersects $B, B(w)$, and $SC(path(w))$. Note that if v_w is a vertex in a junction triangle, then it is part of two corridors and q will have two sons.

Alternatively, vertices from C_w already exist at the node w and v_w is added to a list at C_w in order of its distance from v according to the description of the visibility tree.

This completes the induction step. □

We can list all the vertices visible to v through edge B by enumerating the lists at the nodes of $TVIS_B(v)$. We describe an algorithm *L-Traversal* for doing so below. In the algorithm, r is the node in the tree being currently visited and r_l and r_r are the left and right sons, respectively.

ALGORITHM L-TRAVERSAL (r).

begin

Output $LIST_1(C_r)$;
L-Traversal(r_l);
L-Traversal(r_r);
Output $LIST_2(C_r)$ in reverse order;

end.

Here C_r is the corridor associated with node r. The procedure is called with the root of $TVIS_B(v)$ as parameter.

Note that if w is a node in $TVIS_B(v)$, then all vertices in the lists associated with nodes in the left subtree at w are output before the vertices in the lists associated with nodes in the right subtree at w. It is easy to see the following claim which shows an ordering of the visibility edges by angle.

LEMMA 4.2. *An L-traversal of $TVIS_B(v)$ lists, in increasing angle order, all the*

vertices visible to v through edge B of corridor C.

We note the following fact about $TVIS_B(v)$. A corridor may be associated with more than one node in the tree since sections of the same corridor may be visible to v but through different sequences of corridors (see Figure 3 where $C_{w3} = C_{w4} = C_4$) or through different boundary edges. However, each vertex appears only once in the tree.

To summarize, the sets of all visible vertices are stored in trees. For each vertex v, in corridor C with bounding edges U and B, are constructed two trees $TVIS_U(v)$ and $TVIS_B(v)$ which store vertices visible to v through U and B, respectively.

4.2. Constructing $TVIS_B(v)$. Next we describe how to construct $TVIS_B(v)$. We start with building the visibility lists at the root of $TVIS_B(v)$. Let C be the corridor containing v. After building the visibility list for C, one or two sons of the root node are created, each corresponding to a corridor containing the closest visible vertex to v through the bounding edge, B. Visibility lists are built for these corridors and the process is repeated with the addition of sons associated with available corridors.

In the next section we detail the construction of the visibility list for a corridor C_w at a node w in $TVIS_B(v)$ and subsequent generation of children nodes and the first vertex of the visibility lists at each child node. We outline the methodology: At each step we maintain at most two candidates from C_w, one each for addition to the two visibility lists, $LIST_1(C_w)$ and $LIST_2(C_w)$. A vertex p is added to $LIST_1(C_w)$ or to $LIST_2(C_w)$, as applicable, at the tree node w in $TVIS_B(v)$ as follows:

1. If both candidates exist, then p is the closest vertex, visible to v, among the two candidates from C_w.
2. If only one candidate exists, then p is that candidate provided it is visible.

As in the previous section, visibility is determined from the candidates and the current visibility lists, $LIST_1(C')$ and $LIST_2(C')$ where C' is either C_w or a corridor at the parent of w in $TVIS_B(v)$.

4.3. Obtaining candidates and constructing visibility edges. We detail the maintenance of two candidates for addition to the lists at the node w, corresponding to C_w, in $TVIS_B(v)$. The initial candidates at the root of $TVIS_B(v)$ are obtained from the vertices adjacent to v in the corridor, C. Suppose a vertex q is added to $LIST_1(C_w)$ from among the candidates. A new candidate needs to be obtained. This candidate is obtained from the visibility tree of q in corridor C_w. Let X be the bounding edge of the present corridor, C_w, containing q through which the visibility has to be further extended. Using a scan of $LIST_1(C_r)$, where $r = w$ is the root node of $TVIS_X(q)$, the first vertex l, referred to by can^*, which is a candidate for addition to $LIST_1$ as a vertex visible to v, is determined. Note that edges are ordered by their corridor distance. There are two cases: If l exists and is in the same corridor, then it forms the next candidate for $LIST_1(C_w)$. Alternatively, l may not exist in the same corridor.

Suppose the candidate does not exist in the same corridor. Then a new candidate is to be obtained from another corridor. However, the construction of the other list $LIST_2(C_w)$ may not have finished. A candidate is obtained for the construction of this list and added to $LIST_2(C_w)$ so that the resultant list does not overlap with $LIST_1(C_w)$. We assume that given a vertex q in corridor C, the two lists of vertices in C visible to q are present. This construction is performed as preprocessing for all the corridors using the algorithm in the previous section. When construction of both $LIST_1(C_w)$ and $LIST_2(C_w)$ finishes, new candidates from other corridors are to be obtained.

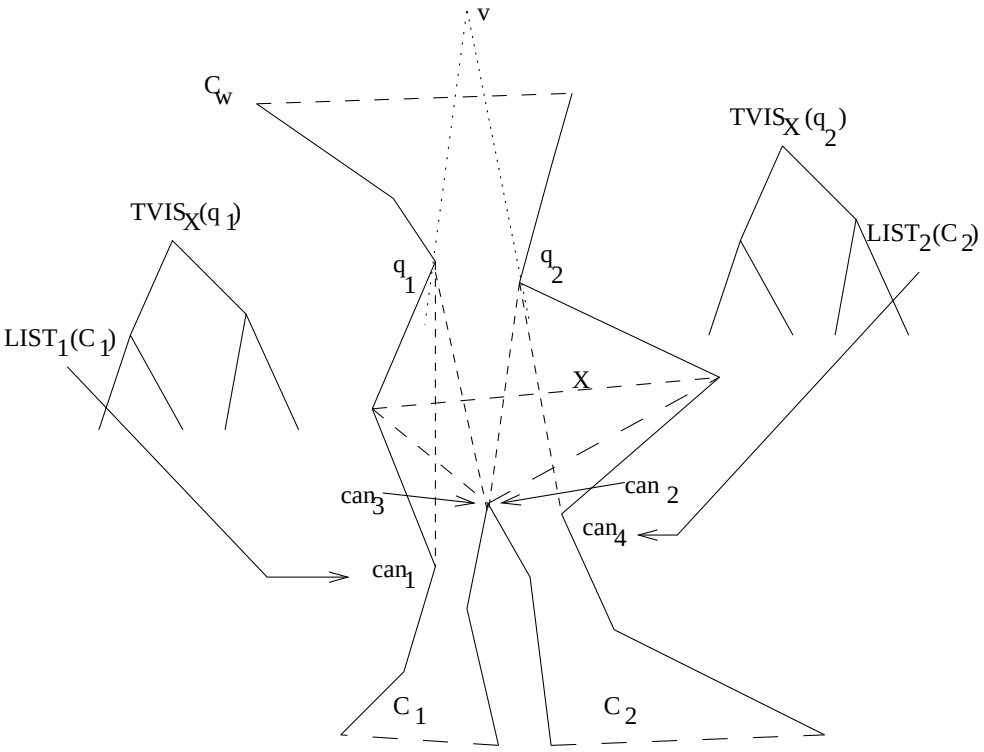

FIG. 4. *Candidate generation.*

Let q_1 and q_2 be the two vertices last added to $LIST_1(C_w)$ and $LIST_2(C_w)$, respectively. It may be that one of these lists, say, $LIST_2(C_w)$, is empty. In this case q_2 is chosen to be the vertex last added to a $LIST_2$ at the first ancestor node of w in the tree $TVIS_B(v)$, which contains a vertex in the list $LIST_2$ at that node. We let $C(q_1)$ and $C(q_2)$ be the corridors containing q_1 and q_2, respectively.

The following scheme, termed *Find-next*, is adopted to find candidates and extend the visibility tree in the adjacent corridors.

4.3.1. Description of procedure *Find-next*. Let t_1 be the node of $TVIS_{X1}(q_1)$ such that vertices visible through bounding edge X_1 are to be found from the corridors associated with the sons of that node. Initially, t_1 is the root node. And let t_2 be a node of $TVIS_{X2}(q_2)$ such that vertices visible through bounding edge X_2 are to be found from the corridors associated with the sons of that node. Again, initially t_2 is the root node. We assume w.l.o.g. that both the left and right sons of t_1 and t_2 exist. We generate two candidates can_1 and can_2 from $LIST_1(C_{left(t_1)})$ and $LIST_1(C_{right(t_1)})$. And two other candidates can_3 and can_4 come from $LIST_2(C_{left(t_2)})$ and $LIST_2(C_{right(t_2)})$. These candidates are obtained by finding the first vertex in the corresponding list that may be visible to v (Figure 4). The candidates may or may not exist. A candidate is visible if there exists a visibility edge which traverses, unobstructed, the sequence $SC(Path(w))$ as well as the corridor C_w. The visibility of can_1 and can_2 is determined by checking that each is not obstructed by the last candidate entered into $LIST_2(C(q_2))$ and the visibility of can_3 and can_4 is determined by checking that each is not obstructed by the last

candidate in $LIST_1(C(q_1))$. Such a visible candidate is termed r-visible. This check for visibility ignores that a candidate may be obstructed by some other candidate.

The following property is easy to see.

LEMMA 4.3. *The closest r-visible candidate from among can_1, can_2, can_3, and can_4 is visible from v.*

We next describe how to determine the closest r-visible candidate and extend the construction of the visibility tree. We need the following definition.

DEFINITION. $dist(C, v)$, C a corridor and v a vertex, is the corridor distance of the vertex in C closest to v.

Let c_m be the candidate closest to v among the visible candidates can_1, can_2, can_3, and can_4. c_m will be used as can^* to further construct the tree $TVIS_B(v)$. The following cases arise.

Case 1. c_m is can_1 in corridor C'. In this case add a tree node, w', corresponding to corridor C'. Next, candidates can be generated for $LIST_1(C')$ and $LIST_2(C')$. The first candidate for $LIST_2$ may be found from C'. If no candidate is available from C', then the first candidate for $LIST_2$ will be found from a descendant corridor. Note that a sibling of w' in the tree cannot exist. This follows by contradiction. Suppose it did. Then the vertex at the junction of the corridors, corresponding to the left and right sons, would be visible and thus can_1 would not be the closest candidate, c_m.

Case 2. c_m is can_2 in corridor C''. If this candidate vertex is a junction vertex, then two tree nodes at the two sons of the current tree node are constructed. Each node corresponds to a corridor containing can_2. Alternatively, one son of the current tree node is constructed. Note that in the second case can_1 does not exist. In the first case, let C' and C'' be the two corridors obtained. Candidates for $LIST_1$ and $LIST_2$ in both corridors are generated. This is done by using the left son of t_1 to obtain the first candidate available for $LIST_1(C')$ and by using the left son of t_2 to obtain the first candidate for $LIST_2(C')$. Similarly the lists at the right sons of t_1 and t_2 are used to obtain the first candidates for $LIST_1(C'')$ and $LIST_2(C'')$, respectively. These candidates are then used to generate other candidates at greater corridor distance. In the second case, the lists in the corridor containing can_2, say, C'', are generated similarly as above.

Case 3. The candidate is can_3. Again if the vertex is a junction vertex, then two sons are constructed. Otherwise, one son is constructed. Candidates for $LIST_1$ and $LIST_2$ in the corridors constructed are obtained as in the previous case.

Case 4. The candidate c_m is can_4. This case is symmetric to the first case and one tree node is added as a son of the current tree node.

Finally, consider the case when candidates can_1 and can_2 either do not exist or are not r-visible. Then we show how to determine a node in $TVIS_{X1}(q_1)$ such that visible vertices are to be found from the corridors associated with the sons of that node. This node is used to update t_1.

We have three cases (Figure 5).

Case (i). If can_1 does not exist and can_2 is not r-visible due to overlap with $LIST_2(C(q_2))$, then t_1 is updated to be the left son of t_1 in $TVIS_{X1}(q_1)$ or its descendants. This is because no vertex can be visible through the corridor associated with the right son since can_2 itself is obstructed by a vertex in $LIST_2(C(q_2))$.

Case (ii). If can_2 also does not exist, then t_1 is updated to become the right son since no vertex can become a candidate from the corridor associated with the left son of t_1 or its descendants.

Case (iii). If can_1 exists and is not visible again due to overlap with $LIST_2(C(q_2))$,

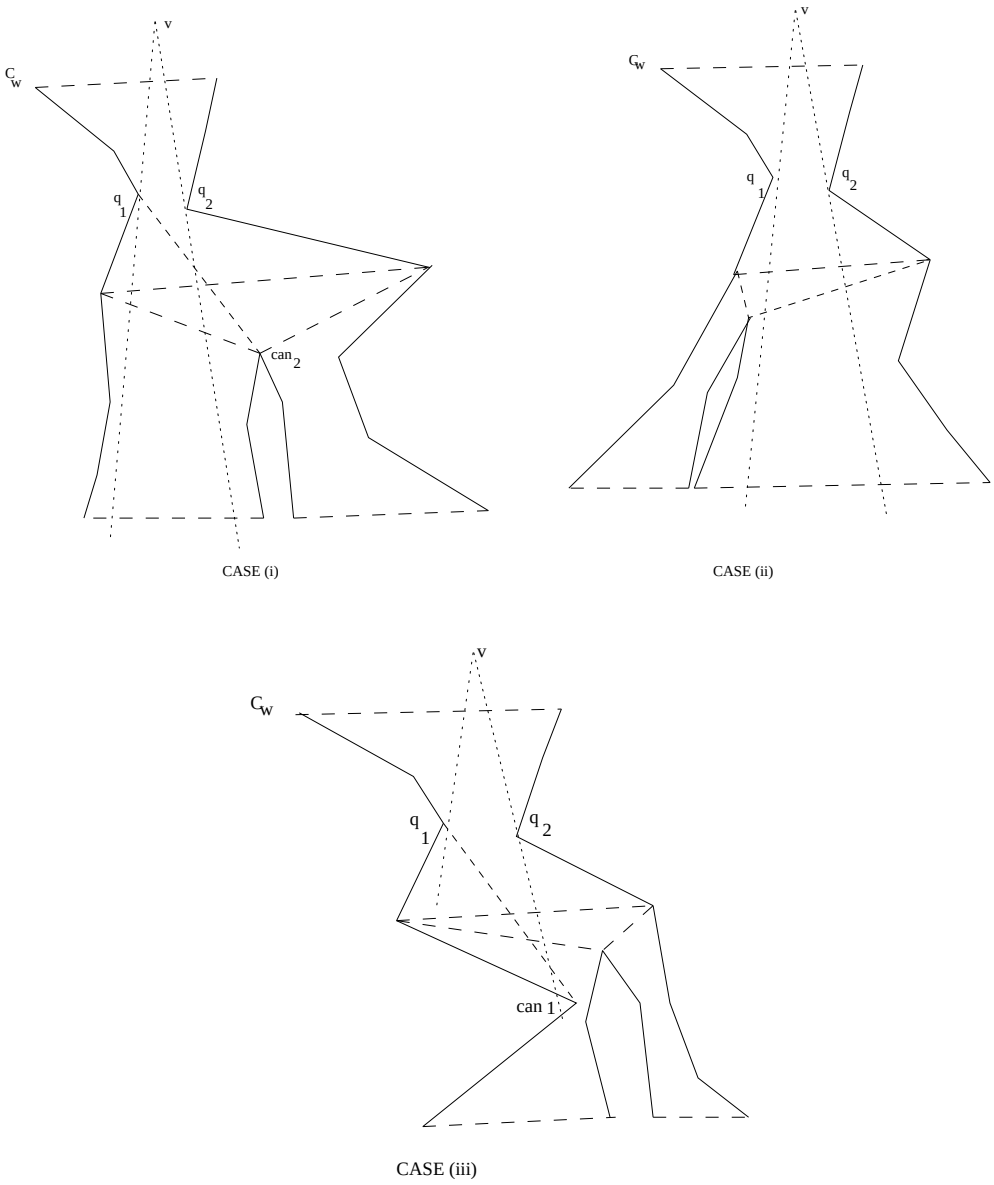

FIG. 5.

then processing need not continue.

A similar procedure is used to update t_2 if both can_3 and can_4 either do not exist or are not r-visible. We call the entire procedure described above *Find-new*.

We obtain the following lemma.

LEMMA 4.4. *Given a pair of nodes, t_1 and t_2, in two visibility trees, $TVIS_{X1}(q_1)$ and $TVIS_{X2}(q_2)$, respectively, the procedure Find-new correctly does one of the following:*

(1) *Finds the closest visible candidate, can^*, from the corridors at the sons of t_1 and t_2 and generates sons at node w of $TVIS_B(v)$;*

(2) *updates t_1 and t_2 in the two trees from among the sons of t_1 and t_2 such that the visible vertex closest to v is in a corridor at a descendant node of the updated t_1 and t_2;*

(3) *determines that no visible vertex exists at a descendant node of t_1 or t_2.*

Find-new is applied repeatedly to obtain candidates or to determine if the processing stops.

This describes procedure *Find-next*. Thus procedure *Find-next* finds the closest visible candidate from the corridors at descendant nodes of t_1 and t_2 and generates sons of w in $TVIS_B(v)$ or determines that no visible vertex exists at a descendant node of t_1 or t_2.

Furthermore, note the following. Suppose that can_1 exists. Then can_1 as well as can_2, if can_2 exists, can be found in time proportional to the time required to find can_1 in $LIST_1(left(t_1))$ or at descendant nodes. This is so because in this case can_2 will be a vertex of a junction triangle. Similarly, if can_4 exists, the time required to find can_3 and can_4 is proportional to the time required to find can_4.

For an efficient algorithm we will not implement procedure *Find-next* as above. We will detail an efficient procedure to determine the closest visible candidates later in the section. The algorithm will use linked lists and pointers to detect the closest visible vertex.

Finally, note that at a vertex the algorithm may not be able to obtain a candidate for its visibility list since the candidates may not be currently present. The availability of the visibility lists depends on the sequence in which vertices are considered by the overall algorithm for building visibility lists. However, if all the candidates required were available, the following lemma shows that the lists are correctly built.

LEMMA 4.5. *Suppose vertices in visibility lists are available when required for computation of candidates. Then $TVIS_B(v)$ is correctly computed.*

Proof. The proof is by induction on the size of $TVIS_B(v)$. The base case, when $TVIS_B(v)$ has one node, is trivially true since the vertices adjacent to v in C, of which there is at least one, are in the visibility list at the root of $TVIS_B(v)$. Assume that the tree is correctly built when there are k vertices in the visibility tree of v. Let w be the tree node at which the vertex prior to the $(k+1)$st vertex, in L-Traversal order, exists. Consider additions to the visibility lists, $LIST_1(C_w)$ and $LIST_2(C_w)$. If the $(k+1)$st candidate is in the same corridor, then by a proof similar to the proof of Lemma 3.1 addition to the visibility lists is correctly done.

Thus consider the case when there are no candidates in corridor C_w. Note that $LIST_1(C_w)$ or $LIST_2(C_w)$ may be empty. Let v_1 be the last vertex added to $LIST_1$ at w or an ancestor node, if $LIST_1(C_w)$ is empty. And let v_2 be the last vertex added to $LIST_2$ at w or at an ancestor node. Candidates are to be obtained from the corridors at the descendants of the root node in $TVIS_{B'}(v_1)$ and $TVIS_{B''}(v_2)$, B' and B'' being bounding edges. We let t_1 and t_2 be the root nodes of $TVIS_{B'}(v_1)$ and $TVIS_{B''}(v_2)$, respectively. Let v_c be the closest vertex visible to v through C_w. We prove by induction on the corridor distance between v_c and C_w that this candidate and the corridors at the sons of the node corresponding to w will be correctly added. For the base case, consider the case when the vertex v_c is at distance 1 from C_w, i.e., $dist(C_w, v_c) = 1$. The vertex v_c must be either in $LIST_1(y)$, where y is one of $left(t_1)$ or $right(t_1)$, or in $LIST_2(z)$, where z is one of $left(t_2)$ or $right(t_2)$. Let C_{lw} and C_{rw} be the corridors adjacent to C_w. If the closest vertex is in the junction between the three corridors, then two sons are added to the node w, one corresponding to C_{lw} and the other to C_{rw}. If the closest vertex is not the vertex in the junction, then one node

is added since only one adjacent corridor may have visible vertices. If both do, then the vertex at the junction will also be visible. This is determined in the procedure above as shown in Lemma 4.4

For the induction step, suppose that $dist(C_w, v_c) = j$ and further assume that if $dist(C_w, v_c) < j$, then the vertex and the corridors at the sons of w have been correctly determined and v_c obtained. We consider the corridors C_{lw} and C_{rw} adjacent to C_w above. Suppose v_c is in one of these corridors or in the closest corridor from among the set $\mathcal{C} = \{C_{left(t_1)}, C_{right(t_1)}, C_{left(t_2)}, C_{right(t_2)}\}$. Then, by Lemma 4.4, we are done since the son corresponding to the corridor will be added when $c_m = v_c$, the closest visible vertex in the corridors at the sons of t_1 and t_2, is determined. Otherwise, we need to determine the corridor through which the closest vertex is visible. This is achieved in the above procedure, *Find-next*, by determining a corridor, say, $C' \in \mathcal{C}$, which does not contain v_c but through which vertices are visible. The correctness of the determination of C' follows from Lemma 4.4. Candidates are generated from the sons of the tree node which is in $TVIS_{B'}(v_1)$ and $TVIS_{B''}(v_2)$ and corresponds to the corridor C'. Since $dist(C', v_c) < j$ we can, by induction, conclude that the procedure *Find-next*, when applied recursively, correctly determines the vertex, v_c, and the corridor or corridors which are to be associated with the son or sons, respectively, of the tree node $w \in TVIS_B(v)$.

This also completes the induction step to show that $TVIS_B(v)$ is correctly generated. □

Each vertex added to $TVIS_B(v)$ uses the visibility tree at v, $TVIS_U(v)$, where U is the other bounding edge of the corridor containing v, to further construct its visibility tree. The vertices from $TVIS_B(v)$ are considered in order of their occurrence in the L-Traversal of $TVIS_B(v)$ for construction of visibility edges using v. This is done to ensure efficiency.

We next consider the possibility that candidates are not available. Let us consider the case when a candidate for the visibility tree of a vertex v is to be obtained from $LIST_1(C)$ at a node associated with corridor C in $TVIS_X(q)$, the visibility tree of a vertex q. If the candidate is not present in the list, then v is put in a list associated with the vertex q, $WAITLIST_1(q)$. This list contains the vertices whose candidates have to be obtained from $LIST_1(C)$ for some C, in $TVIS_X(q)$.

When vertices are added to the visibility list of q, a candidate for each vertex in $WAITLIST_1(q)$ is generated if possible.

A similar situation arises when a candidate for v is to be obtained from $LIST_2(C)$ for some C in $TVIS_X(q)$. $WAITLIST_2(q)$ is a list which contains v when the candidate for v is not present.

We note the following property of the visibility lists.

LEMMA 4.6 (property sort). *Let v_1 and v_2 be two vertices added to $LIST_1(C_1)(LIST_2(C_1))$ for a corridor C_1 in tree $TVIS_B(v)$. Then v_1 and v_2 are added to the visibility list in the same order as they occur in the visibility list, $LIST_1(C_1)(LIST_2(C_1))$, i.e., in order of increasing corridor distance from v.*

Proof. We use induction on the maximum corridor distance between v and the vertices to be added. The basis of induction is easily established since when the corridor distance is 1 then there is only one vertex to be considered. Assume that v_1 is closer to v than v_2 is. And let the corridor distance between v and v_2 be k or greater. Next suppose that the claim is true for distances less than or equal to $k-1$. We show that v_1 and v_2 become candidates for the visibility list of v in that order.

Suppose v_2 occurs immediately after v_1 in the visibility list of v. Then v_2 will

be generated as a candidate *after* v_1 has been added to the visibility list of v since procedure *Find-next* determines the closest candidate for a list at every step. Alternatively, suppose there is some other vertex, say, $w \in C_1$, s.t. $dist(v_1, v) < dist(w, v) < dist(v_2, v)$. If more than one vertex satisfies this property then let w be the vertex closest to v_2. By induction, w occurs as a candidate for the visibility list of v after v_1 and since v_2 will be obtained from w, v_2 becomes a candidate after v_1. □

Using this property we next show that the visibility trees can be built in time proportional to the sizes of all the trees. There are two kinds of pointers associated with each vertex q. One kind is used to construct the tree and the other kind is used to generate candidates.

The movements of the first kind of pointer require $O(E)$ time, given the candidates, since by **Property Sort**, vertices are added in order for each corridor. We next consider the complexity of generating candidates.

4.4. Generating r-visible candidates. There are two cases in the generation of candidates. In one case, the candidates are generated from already constructed lists. In the second case, candidates are generated for vertices which are in some $WAITLIST$. As the vertices are added to the visibility list of a vertex, say, q, with respect to one direction along the corridor, C, containing q, candidates are generated for vertices visible to q in the other direction and occurring in $WAITLIST_1(q)$ and $WAITLIST_2(q)$. The ordering in which vertices are added to $WAITLIST$s will be the ordering in an L-Traversal of $TVIS_U(q)$ when candidates are to be generated from $TVIS_B(q)$ where U and B are the bounding edges of the corridor C. We assume that the visibility edges are visited in sorted angle order.

We show below that, as in the case of a simple corridor, the generation of candidates requires linear time. In order to generate can_1, can_2, can_3, and can_4 we will generate two kinds of candidates. From the first kind, can_h and can_i, we will obtain can_1 and can_2. From the second kind, can_j and can_k, we will obtain can_3 and can_4, respectively. Consider a sequence of vertices for which a candidate is generated from the visibility list in $TVIS_B(q)$, B a bounding edge. We show below that as in the case of simple corridors the direction of the pointer movement required to generate candidates is monotone.

Let q be a vertex with visibility trees $TVIS_B(q)$ and $TVIS_U(q)$, B and U being bounding edges. Let a and b be vertices visible to q through edge U. Let $q \in LIST_1(C_w)$ or $LIST_2(C_w)$, where C_w is a corridor at node $w \in TVIS_X(a)$, and let $q \in LIST_1(C_y)$ or $LIST_2(C_y)$, where C_y is a corridor at node $y \in TVIS_Y(b)$ for some bounding edges X and Y. Note that C_w and C_y are the same corridor.

Let $P1_a$ be the position of the candidate c_a in $TVIS_B(q)$, which gives can_h, the first kind of candidate, and which is the first candidate which follows q in some $LIST_1$ in $TVIS_X(a)$. The candidate c_a may be required to be added, as can_h, in an L-Traversal to $LIST_1$ of corridor C_w or of a corridor at the left or only son of w in $TVIS_X(a)$. Let $P1_b$ be the position of the candidate c_b in $TVIS_B(q)$ which is the first candidate following q, in some $LIST_1$ in $TVIS_Y(B)$. This candidate may be required for addition, as can_h, to $LIST_1$ of C_y or of a corridor at the left or only son of y in $TVIS_Y(b)$. Similarly, let $Q1_a$ and $Q1_b$ be the positions of d_a and d_b, which give can_i, the first kind of candidate if one exists, in $TVIS_B(q)$. The candidates d_a and d_b may be required to be added, as can_i, to $TVIS_X(a)$ and $TVIS_Y(b)$, respectively. In fact d_a and d_b are the first candidates following q in a L-Traversal which may be required to be added to $LIST_1$ at the right sons of $TVIS_X(a)$ and $TVIS_Y(b)$, respectively.

The following property, the proof of which is similar to Lemma 3.2 and hence

omitted, is stated next.

LEMMA 4.7. *If a follows $b, a \neq b$ in an L-Traversal of $TVIS_U(q)$, then*

- *$P1_a \succeq_{LIST_1} P1_b (Q1_a \succeq_{LIST_1} Q1_b)$ when $c_a(d_a)$ and $c_b(d_b)$ are in a $LIST_1$ at a node $v \in TVIS_B(q)$;*
- *alternatively, c_b (d_b) may be found at a node which is a predecessor of c_a (d_a) in an L-Traversal of $TVIS_B(q)$.*

The candidates found above are related to can_1 and can_2 and are required to be obtained using procedure *Find-next* as follows. Consider the case that the candidate is not in the current corridor C_w or C_y. Suppose can_1 exists at the left son of the current node w or y. Then can_h is can_1 and if can_i exists it is can_2. Note that in this case can_i is a vertex at a junction.

Alternatively, suppose can_1 does not exist at the left son of the current node w or y. In the first case, if no vertex is visible at the left son or a descendant of the left son of the current node in $TVIS_B(q)$, can_h, if it exists, is can_2. Otherwise, if a vertex is visible at the left son or a descendant of the left son of the current node, then, if can_i exists, can_i is can_2.

A similar property is true for pointer positions of the candidates for $LIST_2$ in $TVIS_X(a)$ and $TVIS_Y(b)$. In this case can_j and can_k are the two candidates to be found and are analogous to can_h and can_i. Let $P2_a$ be the position of the candidate e_a in $TVIS_B(q)$, which is the first candidate of the second kind, called can_k, following q to be added to a $LIST_2$ in $TVIS_X(a)$. This candidate may be required to be added in an L-Traversal to $LIST_2$ of C_w or a corridor at the right or only son of w in $TVIS_X(a)$. Similarly let $P2_b$ be the position in the tree of the candidate e_b in $TVIS_B(q)$ which is the first candidate following q, for addition to $LIST_2$ of $TVIS_Y(b)$. The candidate is added to C_y or a corridor at the right or only son of y in $TVIS_Y(b)$. Similarly, let $Q2_a$ and $Q2_b$ be the positions of another second kind of candidate can_j, if it exists, in $TVIS_B(q)$, termed f_a and f_b, respectively, which are the first candidates following q which may be added in an L-Traversal to $LIST_2$ at the left sons of $TVIS_X(a)$ and $TVIS_Y(b)$, respectively.

LEMMA 4.8. *If a follows $b, a \neq b$ in an L-Traversal of $TVIS_U(q)$, then*

- *$P2_b \succeq_{LIST_2} P2_a (Q2_b \succeq_{LIST_2} Q2_a)$ when $e_a(f_a)$ and $e_b(f_b)$ are in a $LIST_2$ at a node $v \in TVIS_B(q)$;*
- *alternatively, e_b (f_b) may be found at a node which is a predecessor of e_a (f_a) in an L-Traversal of $TVIS_B(q)$.*

We next show how the above properties ensure that a linear scan of lists at nodes in $TVIS_B(q)$ suffices to generate candidates for all points having q in their visibility list. Suppose we have just constructed a visibility edge from a vertex v to a vertex q in a corridor C. Assume that $q \in LIST_1(C)$. To extend the visibility tree of v, we need to obtain either one or two candidates for $LIST_1$ from the visibility tree $TVIS_B(q)$ for some B. To obtain the candidates from q we use the pointer positions when the candidates were last generated for a vertex v' which was added to the visibility list of q immediately preceding the addition of v. The following procedure is used to generate candidates can_h and can_i.

Let P_1 be the position of the pointer used to generate can_h for v' at a node x in the tree $TVIS_B(q)$. Let C_x be the corridor corresponding to node x. We now show how to find a candidate can^* from which the two candidates can_h and can_i will be obtained. The search for can^* starts with the current position of P_1, say, in $LIST_1(C_x)$, and proceeds linearly along the list, $LIST_1$, at node x and other nodes as would an L-Traversal of the tree $TVIS_B(q)$. The search stops having found the first

candidate vertex in a $LIST_1$ in the L-Traversal. There are two cases. Either can^* is found or not.

- *can^* exists.* Assume that $v \neq v'$. Further suppose that can^* is found at node y in the tree. We let can_h be can^*. Next we need to find can_i. There are two subcases. Either the node at which the candidate can_i for v' was found, if at all, is on the path, $path(y, root)$, from y to the root, $root$, of $TVIS_B(q)$, or it is not on $path(y, root)$.

  In the first subcase let w be the node. The search for can_i proceeds along the path from w to the root, i.e., along $path(w, root)$. This search for can_i requires considering the vertices at the junction triangles connecting adjacent corridors along the tree path. Let x' be a node on the path. Then a junction triangle connects the three corridors associated with x', $left(x')$, and $right(x')$. The vertex common to $C(left(x'))$ and $C(right(x'))$, called $vcr(x')$, is checked to be a candidate for can_i provided $right(x') \notin path(w, y)$. The search stops at the last node z on the path, $path(w, root)$ s.t. $vcr(z)$ is a candidate. (See Figure 6.)

  Alternatively, when can_i for v' was not on $path(y, root)$, the search for can_i proceeds as above along the path from y to the root. Note that in this case the previous node at which the candidate can_i for v' was found occurred prior to nodes on the path in an inorder traversal of the tree $TVIS_B(q)$.

  We now consider the case when $v = v'$. In this case, the candidate can_h previously found for v' has not been used. If can_i, found previously, also has not been used, then no new candidate need be discovered. If it has been used, then can_i is updated. Let $y \in TVIS_B(q)$ be the node at which can_h for v' was discovered. And let $w \in TVIS_B(q)$ be the node at which can_i for v' was discovered. Let z be the first descendant node of w on $path(w, y)$ with a right son not on $path(w, y)$. Then can_i is the vertex common to $C(left(z))$ and $C(right(z))$.
- *can^* does not exist.* Suppose that can^* was not found. Then neither can_h nor can_i can exist since a scan of $LIST_1$ at nodes obtained by an L-Traversal of the tree would have found can_h or can_i.

A symmetric procedure is also applied for the search for can_j and can_k. We repeat the details for completion. Let P_2 be the position of the pointer used to generate can_j for v at a node w in the tree $TVIS_B(q)$. We now show how to find a candidate can^* from which the two candidates can_j and can_k will be obtained. The search for can^* starts with the current position of P_2, say, in $LIST_2(C_x)$, and proceeds linearly along the list, $LIST_2$, at node x and other nodes as would an L-Traversal of the tree $TVIS_B(q)$. The search stops having found the first vertex which is a candidate in a $LIST_2$ of $TVIS_B(q)$. There are two cases. Either can^* is found or not.

- *can^* exists.* Assume that $v \neq v'$. Further suppose that can^* is found at node y in the tree. We let can_j be can^*. Next we need to find can_k. There are two subcases. Either the node at which the candidate can_k for v' was found, if it exists at all, is on the path from y to the root, $path(y, root)$, or not.

  In the first subcase let w be the node. The search for can_k proceeds along the path from w to y, i.e., along $path(w, y)$. This search for can_k requires considering the vertices at the junction triangles connecting adjacent corridors along the tree path. Let x' be a node on the path. Then the junction triangle connects the three corridors associated with x', $left(x')$, and $right(x')$. The vertex common to $C(left(x'))$ and $C(right(x'))$, called $vcl(x')$, is checked to

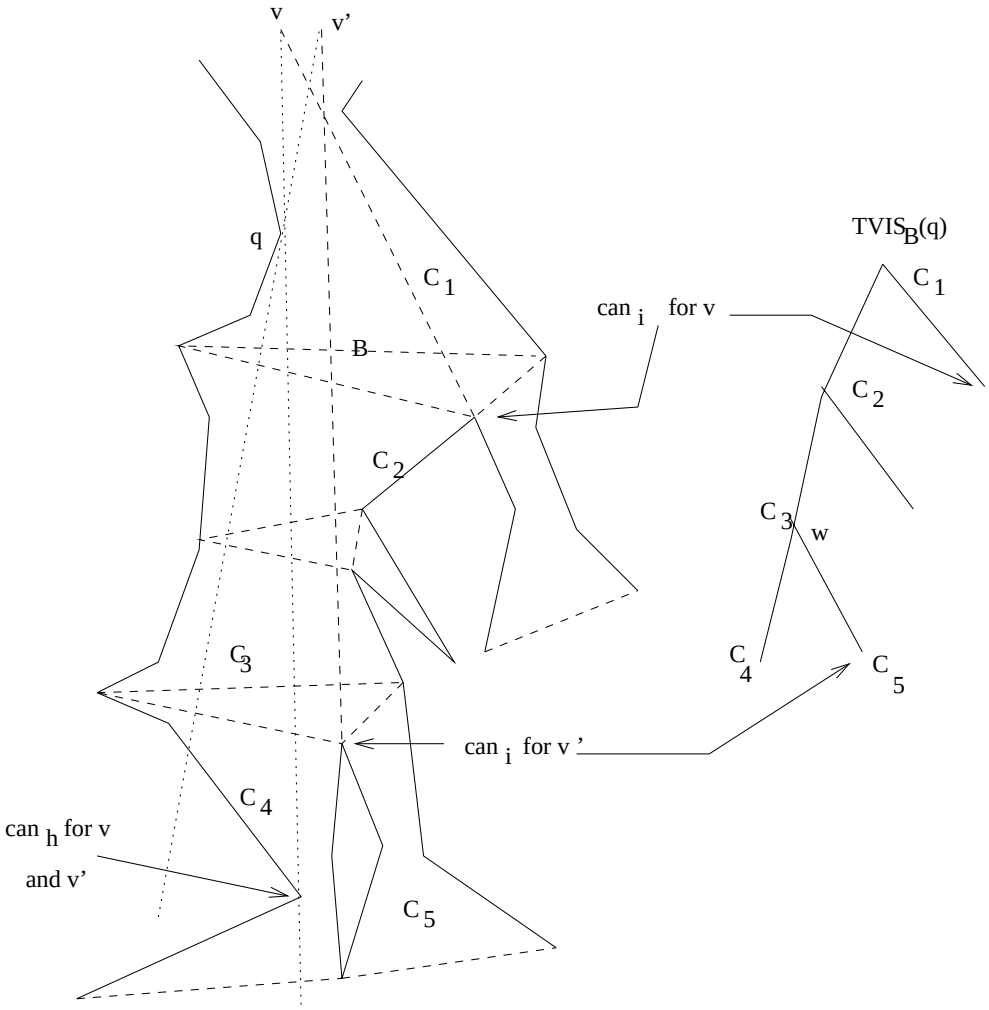

FIG. 6. *Searching for candidates can_h and can_i.*

be a candidate for can_k provided $left(x') \notin path(w, y)$. The search stops at the last node z on the path, $path(w, root)$, s.t. $vcl(z)$ is a candidate.

Alternatively, when can_k for v' was not on $path(y, root)$, the search for can_k proceeds as above along the path from y to the root. Note that in this case the previous node at which the candidate can_k for v' was found occurred prior to nodes on the path in an in-order traversal of the tree $TVIS_B(q)$.

Next suppose that $v = v'$. In this case, the candidate can_j previously found for v' has not been used. If can_k, found previously, also has not been used, then no new candidate need be discovered. If it has been used, then can_k is updated. Let $y \in TVIS_B(q)$ be the node at which can_j for v' is discovered. And let $w \in TVIS_B(q)$ be the node at which can_k for v' was discovered. Let z be the first descendant node of w on $path(w, y)$ with a left son not on $path(w, y)$. Then can_k is the vertex common to $C(left(z))$ and $C(right(z))$.

- *can^* does not exist.* Suppose that can^* was not found. Then neither can_j nor can_k can exist since a scan of $LIST_2$ at nodes obtained by an L-Traversal of the tree would have found can_j or can_k.

The closest candidate from among can_h, can_i, can_j, and can_k will give the candidate to extend the visibility tree of v as described in procedure *Find-next*.

LEMMA 4.9. *The candidates can be correctly generated in time linear in the size of the visibility trees.*

Proof. Consider a vertex q in corridor C with bounding edges U and B. We only consider generation of candidates which lead to the addition of new nodes in the visibility trees. Candidates along a corridor are easily determined as shown in the previous section. We prove the claim for the generation of the candidates can_h and can_i for vertices in $TVIS_U(q)$ from the lists $LIST_1$ at nodes in $TVIS_B(q)$. We will assume that candidates are generated for the vertices in $TVIS_U(q)$ in the same order as they occur in an L-Traversal of $TVIS_U(q)$. A similar analysis holds when the vertices are considered in reverse order of the L-Traversal. The proof for the generation of the candidates can_j and can_k from lists $LIST_2$ is similar.

The candidates can_h and can_i are generated using a pointer. Initially the pointer is at the beginning of the list of vertices obtained from $LIST_1(C = C_w), w \in TVIS_B(q)$, when the visible vertices are scanned in an L-Traversal of the tree. At the generic step there are two cases. Either the vertex, v, for which a candidate is to be found is different from the vertex, say, v', for which a candidate is found at the previous step or it is the same.

First, consider the case when the vertex is different. The pointer P_1 which generates can_h may move from its current position. By Lemma 4.7 this movement is monotone. We next show that can_i is correctly determined. If can_h and can_i exist, then can_i is a junction vertex since then both the visibility lists $LIST_1$ and $LIST_2$ are nonempty at the left and right sons, respectively, of the current node, called *curr*, in $TVIS_{B'}(v)$, where B' is a bounding edge. The tree node at which can_i exists is to be determined. First note that all junction vertices, which are candidates, occur consecutively along the path. Also, by Lemma 4.7, the position of the node at which can_i is obtained comes after its previous position in an L-Traversal of $TVIS_B(q)$. Thus it suffices to consider the path $path(w, root)$ or $path(y, root)$ where y is the node at which can_h is found and w is the node at which the can_i candidate for the vertex v' was found.

Next, consider the case when the vertices are the same, i.e., $v' = v$. In this case the position of can_h does not change. Let this position be at node y. can_i may have been added to a visibility list and used. Let *vcan* be the node at which can_i is found. Since can_i is added to a visibility list at the right son of the current node, *curr*, in $TVIS_{B'}(v)$ where B' is a bounding edge, candidates for addition to lists at the descendants of the left son are required. can_h is one candidate which may be added to a visibility list at the left son or a descendant node of the left son. To determine can_i it suffices to consider junction vertices at nodes which are proper descendants of the node *vcan* with their right son not on the path to y. This is because the junction vertices at these nodes are candidates and the junction vertex at the first such descendant is can_i. This path, P_s, is traversed only once for successive determination of candidates can_i for vertex v when can_i is used but can_h is not used as a candidate. Eventually the corridor containing can_h will be reached and either can_h will be used or it will be determined that the visibility subtree of v cannot be extended further. The time for traversing this path, P_s, is charged to the initial traversal which determined the

position of can_i when a candidate for v was computed.

Thus the lists in a tree, $TVIS_B(q)$, can be traversed in linear time to determine candidates for vertices visible to q through the other bounding edge of the corridor C. The lemma follows. □

Finally note that the determination of a candidate for a vertex u at q occurs only after candidates are determined for other vertices before u in an L-Traversal of the lists in the visibility tree $TVIS_B(q)$, B a bounding edge. Since vertices have to wait for candidates in $WAITLIST$s, there is a possibility of a deadlock. To avoid deadlock we adopt the following simple strategy.

4.5. Avoiding deadlock. We consider two directions, UP and $DOWN$. A visibility edge (u, v) corresponding to vertex v in the visibility list at u is assumed to be directed from u to v. The same edge is assumed to be directed from v to u when u occurs in the visibility list of v. A directed edge (u, v) is in the direction UP if $y(v) \geq y(u)$ and in the direction $DOWN$ if $y(u) > y(v)$. We partition the edges in the visibility tree $TVIS_B(u)$ into two sets. One set is the set of edges in the direction $DOWN$, termed $TDVIS_B(u)$, and the other in the direction UP, termed $TUVIS_B(u)$. A candidate for a vertex in $TUVIS_U(u)$ is obtained from $TDVIS_B(u)$ and $TUVIS_B(u)$ where U and B are the bounding edges of corridor C containing u. A candidate for a vertex in $TDVIS_U(u)$ is similarly obtained. A symmetric procedure applies when candidates are to be found for vertices in $TVIS_B(u)$.

The lists $TUVIS_B(u)$ and $TDVIS_B(u)$ are constructed by the procedure described above in the previous sections. We require candidates to start the construction. The first candidate for $TUVIS_B(u), u \in C$, through a bounding edge B, is obtained by finding the edge which a horizontal ray crossing B, in the direction of increasing x, strikes the polygonal structure. The endpoint of this edge above the ray gives the required first candidate. This first candidate can be found for all vertices simultaneously by a horizontal sweep through the corridors. Given the list of horizontal rays emanating through a bounding edge, each ray starting at a vertex in the corresponding corridor, the rays which traverse without obstruction a given corridor, C', which is adjacent to the current one via a junction, can be computed in $O(\log n)$ steps. The rays emanating from vertices in C' can be appended to the rays which traverse C' in time linear in the size of C'. In general, given a set of rays entering a corridor, C', through a bounding edge, U, the rays that emanate from the other bounding edge, B, can be obtained by using binary search to eliminate rays that strike the convex hull of any of the two sides of the corridor. Moreover, the rays that originate from a side, say, S_1, of C' can be obtained by a linear scan, which starts at the bounding edge U and eliminates rays obstructed by the edges on the corridor sides. The corridor processing requires $O(\log n + C'_r)$ where C'_r is the number of rays that originate from C'. Given that there are $O(m)$ corridors the sweep requires $O(m \log n + n)$ steps. The sweep details are similar to the sweep in [KM] which sweeps using the corridor structure to construct a restricted set of visibility edges. A similar sweep gives the first candidates in $TDVIS_B(u), u \in C$, and B a bounding edge, for all vertices u in the polygonal structure.

4.6. Correctness. The correctness of the scheme is obtained from the following properties.

LEMMA 4.10. (1) *The visibility lists $LIST_1(C)$ and $LIST_2(C)$ are correctly built in sorted order at a tree node.*

(2) *The nodes of $TVIS_B(v)$ are correctly generated.*

Proof. First, assume that all the required visibility lists are present. The proof of (1) is similar to the proof of Lemma 3.4.

To prove (2) we show that the visibility tree is correctly built. If candidates are available, then the correctness follows from Lemma 4.5.

We thus remove the assumption that the visibility lists containing the required candidates are present. We need to show that the algorithm is not deadlocked. For this purpose we consider the following rank function on visibility edges. Let u and v be vertices in corridors with bounding edges $B1, U1$ and $B2, U2$, respectively. Let v be a visible vertex in $TUVIS_{B1}(u)$ and u be a visible vertex in $TDVIS_{B2}(v)$. Let $prev(v)$ be the vertex prior to v in $TUVIS_{B1}(u)$ and let $prev(u)$ be the vertex prior to u in $TDVIS_{B2}(v)$. Note that the vertices are ordered by an L-Traversal of the visibility tree.

We let $v' = prev(v)$. We define $\text{rank}(u, v) = \max(r(u, v), r(v, u))$, where

- $r(u, v) = 1 + \text{rank}(u, v')$ when v is not visible to v';
- $r(u, v) = \text{rank}(u, v') + \text{rank}(v', v)$ when v is visible to v';
- $\text{rank}(u, v) = 1$ when v is the first vertex in the L-Traversal of the visibility tree of u.

The *rank* function is well defined since the rank $\text{rank}(u, v)$, $v \in TUVIS_{B1}(u)$, depends only on the rank of a vertex w above u, i.e., with $y(w) > y(u)$.

We prove by induction on the rank of edge (u, v) that when at time t a candidate is to be generated for v from $TVIS_{U1}(u)$, then $TVIS_{B1}(u)$ contains v as well as all vertices in the tree prior to v. Also at this step $TVIS_{B2}(v)$ contains u and all vertices prior to u.

Basis step. When the rank of an edge (u, v) is 1 the claim is trivially true since both vertices u and v are added as the first vertex in each other's visibility lists by the initial construction.

Induction step. Suppose that the induction hypothesis is true for all edges with rank $< k$. Consider an edge (u, v) with rank k. Let v' be $prev(v)$ in $TDVIS_{B1}(u)$, $v \in TDVIS_{B1}(u)$, and let u' be $prev(u)$ in $TUVIS_{B2}(v)$, $u \in TUVIS_{B2}(v)$. Since (u, v') has rank less than k, when a candidate for u is to be generated u has already been added to the visibility list of $TUVIS_{B'}(v')$, B' a bounding edge, and all vertices prior to u have been added to $TUVIS_{B'}(v')$. Similarly v is in a visibility list at $TDVIS_{B''}(u')$, B'' a bounding edge, and all vertices prior to v have also been added. When v is considered as a candidate for the visibility list of u after v', v' and all vertices prior to v' in $TDVIS_{B1}(u)$ have been added. And similarly u' and all vertices prior to u' also are present in $TUVIS_{B2}(v)$. The algorithm will thus generate the candidate v for addition to the visibility list of u and the candidate u for addition to the visibility list of v using vertices already in the visibility lists at u' and v', respectively. The conditions for the generation of candidates are satisfied as shown above. Thus v will be added to $TDVIS_{B1}(u)$ and u will be added to $TUVIS_{B2}(v)$. And all vertices prior to v and u have been added to $TDVIS_{B1}(u)$ and $TUVIS_{B2}(v)$, respectively. This completes the induction step.

The algorithm is thus never deadlocked.

The lemma follows. □

We have thus shown that the algorithm correctly builds the visibility lists.

Since the data structures used in the algorithm are lists which store the visibility edges at each node of the visibility trees, the space requirement is linear in the number of visibility edges and vertices in the polygonal structure. Together with the analysis of the time complexity in the previous section we obtain the last theorem.

THEOREM 4.11. *GVIS(V,E), the visibility graph of V, the set of vertices of a simple n-vertex polygon with m obstacles, can be correctly constructed in time $O(\mid E \mid + T + m \log n)$ and $O(E)$ space, where $\mid E \mid$ is the number of edges in the visibility graph and T is the time required to triangulate the polygon with obstacles.*

5. Conclusions. We may note that the algorithm presented above does not use sorting but only a triangulation of the polygonal structure.

The corridor structure used in this algorithm for partitioning the polygonal structure has been used for another algorithm to construct a restricted visibility graph, $G_s = (V, E_s)$, which contains shortest path information [KM]. In this graph common tangents between the corridor chains, where a corridor chain is a convex chain enclosing a side of a corridor, are required. The common tangents from a corridor chain, CH_C, in C through a bounding edge B to other corridor chains, can be stored in a tree structure, called $TANVIS_B(CH_C)$, similar to $TVIS_B(v), v \in C$. With each node of the tree are associated a corridor chain, say, $CH_{C'}$, and a tangent common to both corridor chains, CH_C and $CH_{C'}$, if there is a visible common tangent. The tangents are constructed using the trees for other corridor chains and the sides of the corridors as in the algorithm presented above. The crucial property is a monotonicity property of the position of the tangents in the corridors as well as at the nodes of the tree $TANVIS_B(CH_C)$. This holds when the corridor chains, for which tangents are to be constructed using CH_C, are considered in an in-order traversal of $TANVIS_U(CH_C)$, where U is the other bounding edge of C. This monotonicity property ensures that each tree will be scanned once during the construction of all the tangents in the restricted graph. Also each vertex in the corridor is scanned once to construct the tangents. The above outlines an extension of the scheme, described above in the paper, for constructing the restricted visibility graph in $O(|E_s| + T + m \log n)$ time.

Finally, we would like to thank the referees for their helpful comments on the manuscript.

OPTIMAL WORST CASE FORMULAS COMPARING CACHE MEMORY ASSOCIATIVITY*

HÅKAN LENNERSTAD† AND LARS LUNDBERG‡

Abstract. In this paper we derive a worst case formula comparing the number of cache hits for two different cache memories. From this various other bounds for cache memory performance may be derived.

Consider an arbitrary program P which is to be executed on a computer with two alternative cache memories. The first cache is set-associative or direct-mapped. It has k sets and u blocks in each set; this is called a (k, u)-cache. The other is a fully associative cache with q blocks—a $(1, q)$-cache.

We derive an explicit formula for the ratio of the number of cache hits $h(P, k, u)$ for a (k, u)-cache compared to a $(1, q)$-cache for a worst case program P. We assume that the mappings of the program variables to the cache blocks are optimal.

The formula quantifies the ratio

$$\inf_P \frac{h(P, k, u)}{h(P, 1, q)},$$

where the infimum is taken over all programs P with n variables. The formula is a function of the parameters n, k, u, and q only. Note that the quantity $h(P, k, u)$ is NP-hard.

We assume the commonly used LRU (least recently used) replacement policy, that each variable can be stored in one memory block, and that each variable is free to be mapped to any set.

Since the bound is decreasing in the parameter n, it is an optimal bound for all programs with at most n variables. The formula for cache hits allows us to derive optimal bounds comparing the access times for cache memories. The formula also gives bounds (these are not optimal, however) for any other replacement policy, for direct-mapped versus set-associative caches, and for programs with variables larger than the cache memory blocks.

Key words. cache memory, fully associative cache, set-associative cache, direct-mapped cache, 0, 1-matrices, performance bound, extremal matrices

1. Introduction.

Cache memories reduce the memory access time in computer systems; an excellent survey can be found in [20]. The hardware budget is, however, limited in terms of gates, routing, etc., when designing cache memories. This hardware budget can be used in different ways, e.g., one can include different amounts of associative memories thus yielding a fully associative, set-associative, or direct-mapped cache. Due to the limited hardware budget, using associative memories reduces the number of storage elements in the cache. Moreover, the access time usually increases with increasing associativity. Consequently, trade-offs between the access time, the degree of associativity, and the number of storage elements are of interest. Such design trade-offs are difficult. One aspect here is the implementation cost of associative memories as compared to the storage elements. This ratio depends on the implementation technique [17].

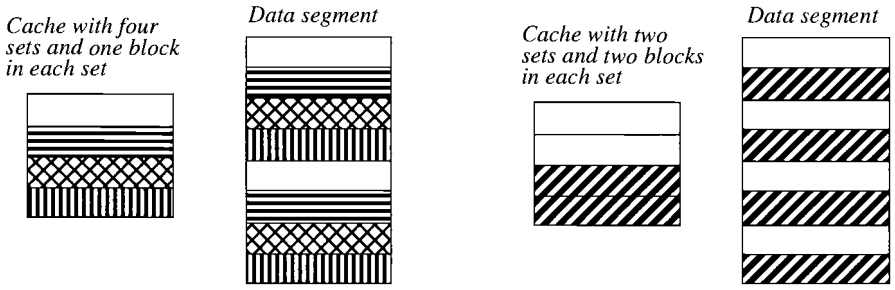

FIG. 1. *A direct-mapped and a set-associative cache with two sets for a data segment of size* 8.

Another aspect is the maximum difference in hit ratio between small fully associative caches and larger set-associative or direct-mapped caches. Calculating the maximum hit ratio decrease when reducing the number of storage elements is not difficult, i.e., in the worst case scenario the hit ratio may drop to zero. This can best be understood by considering a loop with a large number of iterations. (The definition of a loop can be obtained from any textbook on introductory computer programming.) In each loop iteration we access the same n variables. If we use the LRU or FIFO replacement policies [21] and reduce the number of cache blocks from n to $n-1$, the cache hit ratio will drop from 100 percent to zero. Estimating the maximum hit ratio increase when increasing the degree of associativity and decreasing the total number of storage elements is, however, nontrivial. Figure 1 illustrates two cases of different associativity.

A problem with direct-mapped caches and caches with a limited degree of associativity, i.e., a limited set size, is that the performance for certain access patterns may be seriously impaired due to collisions. Consider a direct-mapped cache and a loop with a large number of iterations. Two different variables are accessed in the loop. If these two variables are mapped to the same set, there will be collisions, and each variable reference will result in a cache miss. However, if we consider a system with a degree of associativity larger than or equal to two, no collisions will occur; with the exception of the initial references, all references to the two variables result in cache hits.

If the variables can be mapped independently of each other, the compiler or programmer may detect the collisions and try to map the variables to different sets. However, in some cases the number of collisions will increase when the set size decreases, even when using the best possible mapping of variables to sets. This can be understood with the aid of the example below.

Consider a program with three loops, each containing a large number of iterations. In loop one, variables A and B are accessed repeatedly. In loop two, variables B and C are accessed, and in loop three, variables A and C are accessed. Only one variable can be allocated in a block. Consider also a small cache system with two blocks. This system can be arranged in one of two ways: direct-mapped or fully associative. In the direct-mapped case, at least two of the variables A, B, and C are mapped to the same set. As a result, at least one of the three loops results in a large number of collisions, even when using the best possible mapping of variables to sets. In the fully associative case, there will be no collisions.

In this paper we establish several comparisons of cache memory performance, all derived from one basic optimal formula. The main part of the report is focused on this

particular formula. It is an optimal upper bound on the maximum relative increase of cache hits when using a fully associative cache as compared to a set-associative or direct-mapped cache. In section 9 we show that the result can also be used for comparing set-associative caches with direct-mapped caches. We assume that the compiler, or programmer, is free to map variables to any arbitrary cache set. In some cases, e.g., for different elements in large variables such as arrays and matrices, this is obviously not true. In section 9, however, we will demonstrate that the results are indeed valid for a large number of real cases, including many programs which access large variables. From an applied point of view, section 3, which presents the formula, and section 9, which presents various applications and extensions of the main formula, are the most important sections.

The present paper is part of a series of reports on optimal worst case bounds in computer science contexts. We have also derived optimal bounds for static versus dynamic allocation of parallel programs [7, 9], for cluster versus dynamic allocation [8], for all programs with a specified parallelism [10], for the worst case performance drop at memory reorganization [11], and for the cluster execution time for a program P only knowing one or more execution times for P, executed with dynamic allocation and any schedule [12, 13]. We have also obtained optimal performance bounds on the gain of permitting dynamic allocation of communication channels in distributed processing [14]. All these reports provide optimal bounds for NP-hard quantities [2]. In the present report we consider the NP-hard problem of finding an optimal mapping for a certain program P with a (k, u)-cache, i.e., a mapping maximizing the number of cache hits. We provide a formula for this number for worst case programs.

The method in all the reports consists of two steps:

1. Successive elimination of unnecessary programs, leading to a subset of all programs. This set contains at least one extremal (worst case) program and allows matrix representation of the remaining programs.
2. In the remaining set of programs—sometimes regarded as matrices—those where all possible rows occur equally frequently are proven to be extremal. Here we have obtained a formulation which is sufficiently simple to allow the derivation of explicit formulas.

The first step is, of course, application-dependent to a higher degree than the second. In the present report, the first step is taken care of in sections 2–6, while sections 7 and 8 deal with the second step. Section 9 gives different applications and generalizations of the results. Section 10 contains a short discussion of the results in relation to existing research. Section 11 displays plots of the formula as well as an application which takes memory access times into consideration.

2. Problem definition and notation. A data cache is defined by five parameters: the number of sets, the number of blocks in each set, the block size, the replacement policy within a set, and the update policy to main memory. We focus here on two parameters: the number of cache sets and the number of blocks in each set. A cache with k sets containing u blocks each is denoted as (k, u)-cache. In some reports, this cache configuration is referred to as a u-way set-associative cache with k sets. A *mapping* maps each variable in a program onto a specific memory address and thus to a specific cache set. During the complete execution each variable will be stored on this address. Thus a mapping can be thought of as a partition of the variables into k sets.

If u equals one, the cache is direct-mapped. If k equals one, the cache is fully associative. It is well known [5] that with a fixed number of blocks, the hit ratio is

higher, or at least equal, with a fully associative cache than with a direct-mapped cache. The left part of Figure 1 shows a $(4, 1)$-cache, and the right part shows a $(2, 2)$-cache for a data segment of size 8.

In this study, the results are valid for any block size (for further details see the discussion in section 9.4). However, all blocks are of the same size. We are only interested in the hit ratio, i.e., the percentage of all memory references that can be handled by the cache. The hit ratio is unaffected by the update policy, e.g., write-through or copy-back. The update policy is thus of no importance in this study.

In cache memory systems, code references are much easier to handle than data references. In this report, we only consider data references. When the code references are ignored, the execution of the program P can be regarded as a sequence of $m(P)$ references to n different program variables. All variables are stored in the data segment. We assume that the data segment is infinitely large, and that the compiler or programmer is free to map any variable onto any block. This assumption is discussed in section 9. We also assume that all memory words in a variable are stored in the same block. We only consider variables which are referenced at least once, and hence $n \leq m(P)$.

The only limit on the size of the program variables is that no variable should exceed one cache memory block. This restriction is discussed and to a large extent removed in section 9. Several small variables may be mapped to the same cache block. If a variable in one block is transferred to, or from, the cache, all other variables mapped to the same block are transferred simultaneously. In Theorem 2.2, we show that we may in the remainder of the report consider only the case of having exactly one variable mapped to each block.

No initial storing is assumed; the first referenced block will thus be stored in the cache without replacing any other variable. We assume that the LRU [16] replacement policy is used within each set. This means that if a cache set is full and a variable mapped to this set is referenced which is not in the cache, then the variable—together with other variables mapped to the same block—replaces the least recently referenced block in the cache set. This is a reasonable replacement policy which has been used in some machines [6] as well as in other studies (e.g., see [5] and [19]). We discuss other replacement policies in section 9.

If the number of sets exceeds one, different mappings of variables to memory addresses may result in different hit ratios. Consider, for example, a direct-mapped cache and a program which repeatedly accesses two variables in a loop. If these two variables are mapped to the same set, each access will result in a cache miss. If, however, the two variables are mapped to different sets, there would be no cache misses, apart from the initial references. A mapping which for a particular program P results in a maximal number of hits is referred to as an *optimal mapping* for P. The number of hits for a program P, using an optimal mapping and a (k, u)-cache, is denoted $h(P, k, u)$. The number of hits for a program P with an arbitrary mapping A is denoted by $h(A, P, k, u)$. Hence, if A_1 is an optimal mapping for the program P, $h(A_1, P, k, u) = h(P, k, u)$.

Some of the memory references that can be handled by the $(1, q)$-cache may lead to misses using the (k, u)-cache, at least for some values on n, k, q, and u. References which are hits using the $(1, q)$-cache but misses using the (k, u)-cache are referred to as *extra misses*. We now consider a mapping which, using a (k, u)-cache, minimizes the number of extra misses. Using this mapping, the number of extra misses for a certain program P is denoted $em(P, k, u, q)$. The number of extra misses with a specific

mapping A is denoted by $em(A, P, k, u, q)$. In mathematical language, all possible mappings are all possible partitions of the n variables in k sets. We summarize as follows.

DEFINITION 2.1. *Given a program P, we denote the maximal number of hits and the minimal number of extra misses as follows:*

$$h(P, k, u) = \max_A h(A, P, k, u),$$

and

$$em(P, k, u, q) = \min_A em(A, P, k, u, q).$$

Note that $h(P, k, u)$ and $em(P, k, u, q)$ may be realized with different mappings. The problem of finding an optimal mapping using a (k, u)-cache is NP-hard (see [2, problems P01 and P02], for example).

We next prove that in the interest of worst case estimates, we need only to consider programs where each variable is the size of one block. Note that in this case $h(A_1, P, 1, q) = h(A_2, P, 1, q)$ for any mappings A_1 and A_2. As a result, we need no notation of mappings in conjunction with the quantity $h(P, 1, q)$. In the following theorem, n-programs denote programs with n variables.

THEOREM 2.2.

$$\inf_{n\text{-programs } P} \frac{h(P, k, u)}{h(P, 1, q)} = \inf_{n\text{-programs } P \text{ with blocksized variables only}} \frac{h(P, k, u)}{h(P, 1, q)}.$$

Proof. Consider any program P with n variables in which some variables are mapped to the same block when using an optimal mapping for a $(1, q)$-cache. Suppose that the variables $i_1, i_2, \ldots, i_j$ are mapped to the same block. Then there is another program P', which has none of the variables $i_1, i_2, \ldots, i_j$, but a new variable i_0. The size of i_0 equals the sum of the sizes of the variables $i_1, i_2, \ldots, i_j$, and each reference to $i_1, i_2, \ldots, i_j$ in P is replaced by a reference to i_0 in P'. Since all variables mapped to the same block are transferred to and from the cache simultaneously, we have $h(P, 1, q) = h(P', 1, q)$.

Next consider a (k, u)-cache. By the construction the mappings of the variables of P' can be regarded as those mappings of the variables of P where the variables $i_1, i_2, \ldots, i_j$ are mapped to the same block. In addition, for each mapping A' of the variables of P', there is a mapping A of the variables of P so that $h(A', P', k, u) = h(A, P, k, u)$. Hence

$$h(P', k, u) = \max_{A'} h(A', P', k, u) \leq \max_A h(A, P, k, u) = h(P, k, u).$$

Thus

$$\frac{h(P', k, u)}{h(P', 1, q)} \leq \frac{h(P, k, u)}{h(P, 1, q)}.$$

By repeating this argument we obtain a program P'' where no variables are mapped to the same block, and where

$$\frac{h(P'', k, u)}{h(P'', 1, q)} \leq \frac{h(P, k, u)}{h(P, 1, q)}.$$

We also increase the size of each variable in P'' to equal the size of one block. Clearly this also preserves the inequality.

Denote the number of variables of the program P'' by y; obviously, $y < n$. We next construct a program P''' with n variables by adding one reference each to $n - y$ new variables as the $n-y$ last references in the program P''. Each new variable is the same size as one block. The $n - y$ last references in the program P''' are all misses in any cache and with any mapping since the first reference to a block is always a miss. Hence we can also obtain an optimal mapping from an optimal mapping of the program P'' by adding the new variables to any block. Hence $h(P'', 1, q) = h(P''', 1, q)$, and $h(P'', k, u) = h(P''', k, u)$.

Given any program P with n variables, we can thus construct a program P''' with n variables, where each variable is the size of one block, and where

$$\frac{h(P''', k, u)}{h(P''', 1, q)} \leq \frac{h(P, k, u)}{h(P, 1, q)}. \qquad \square$$

We also need the quantity $eh(A, P, k, u, q)$, the extra hits. This is the number of memory references for P which are misses with a $(1, q)$-cache but hits using a (k, u)-cache, when using a mapping A. We clearly have the following relation.

LEMMA 2.3. $h(A, P, k, u) - h(P, 1, q) = eh(A, P, k, u, q) - em(A, P, k, u, q)$.

The significance of the results is based on the calculation of an explicit formula for the following function.

DEFINITION 2.4.

$$r(n, k, u, q) = \max_P \frac{em(P, k, u, q)}{h(P, 1, q)},$$

where the maximum is taken over all programs P with n variables.

The formula for $r(n, k, u, q)$ is presented in Theorem 3.2.

3. Main results. Our first result states that the formula for

$$\max_P em(P, k, u, q)/h(P, 1, q)$$

can be used to obtain optimal worst case estimates for the hit ratio comparing the two caches. Here we thus obtain an optimal bound on the NP-hard quantity $h(P, k, u)$.

THEOREM 3.1.

(i) *The worst case ratio of cache hits comparing two caches is given by*

$$\inf_P \frac{h(P, k, u)}{h(P, 1, q)} = 1 - r(n, k, u, q),$$

where the infimum is taken over all programs P with n variables.

(ii) *Consider a program P with n variables, and suppose that the hit ratio $h(P, 1, q)/m(P)$ for P with a $(1, q)$-cache is known. In this case, an optimal estimate of the hit ratio for the program P using a (k, u)-cache is given by*

$$\inf_P \frac{h(P, k, u)}{m(P)} = (1 - r(n, k, u, q)) \frac{h(P, 1, q)}{m(P)}.$$

The proof of Theorem 3.1 is given at the end of this section. The function $1 - r(n, k, 1, k)$, which compares a direct-mapped cache to a fully associative cache, is plotted in section 11.2.

The formula for $r(n,k,u,q)$ is given in the following theorem.

THEOREM 3.2. *Suppose that n,k,u and q are positive integers, and denote $I = \lfloor \frac{n-i}{k-1} \rfloor$ and $J = n - i - (k-1)\lfloor \frac{n-i}{k-1} \rfloor = (n-i) mod (k-1)$.*

Then, if $n \le ku$ or $u \ge q$, $r(n,k,u,q) = 0$. If $ku < q$ and $ku < n$, then $r(n,k,u,q) = 1$. In the remaining cases we may compute the value of $r(n,k,u,q)$ as

$$r(n,k,u,q) = \frac{1}{q\binom{n}{q}} \min_{i=\lceil n/k \rceil, \lceil nu/q \rceil, \lceil nu/q \rceil + 1, \ldots, n} \left(\sum_{j=u+1}^{\min(q,i)} j \binom{i}{j} \binom{n-i}{q-j} + J \sum_{j=u+1}^{\min(q,I+1)} j \binom{I+1}{j} \binom{n-I-1}{q-j} + (k-1-J) \sum_{j=u+1}^{\min(q,I)} j \binom{I}{j} \binom{n-I}{q-j} \right),$$

or as

$$r(n,k,u,q) = 1 - \frac{1}{q\binom{n}{q}} \max_{i=\lceil n/k \rceil, \lceil nu/q \rceil, \lceil nu/q \rceil + 1, \ldots, n} \left(\sum_{j=1}^{\min(u,i)} j \binom{i}{j} \binom{n-i}{q-j} + J \sum_{j=1}^{\min(u,I+1)} j \binom{I+1}{j} \binom{n-I-1}{q-j} + (k-1-J) \sum_{j=1}^{\min(u,I)} j \binom{I}{j} \binom{n-I}{q-j} \right).$$

By counting terms in the sums it is easily seen that the first formula has fewer terms if and only if

$$\min(q,i) - \min(u,i) + J(\min(q,I+1) - \min(u,I+1)) + (k-1-J)(\min(q,I) - \min(u,I)) \ge ku.$$

That is, for $q \ge 2u$, the first formula is computationally most efficient, and if u is close to 1, the second is favorable.

This theorem is proved in section 8.

We also prove that the function r is increasing.

LEMMA 3.3. *For any $n > 0$, $r(n,k,u,q) \le r(n+1,k,u,q)$.*

By this lemma, which is proved in section 8, a bound for a large n is valid as a bound for all programs with at most n variables. We thus have the following more n-independent version of Theorem 3.1(i).

THEOREM 3.4. *The worst case ratio of cache hits comparing two caches is given by*

$$\inf_P \frac{h(P,k,u)}{h(P,1,q)} = 1 - r(n,k,u,q),$$

where the infimum is taken over all programs P with at most n variables.

We will next describe the results for specific programs (Theorem 3.9) from which the general results of Theorems 3.1 to 3.4 follow. These also have some interest in

their own right. Below, we describe the complete programs: these are extremal for the ratio $\max_P em(P,k,u,q)/h(P,1,q)$ and essential in the calculation of the formula.

As discussed previously, a program can be represented by a sequence of m integers, each between 1 and n, where each integer occurs at least once since each variable is referenced at least once. In this sequence, each entry represents one memory reference, and its value denotes the variable which is referenced.

When executed using a $(1,q)$-cache, the program induces a sequence of states for the cache. Our results are based on an analysis of this sequence of states. We will next describe its representation briefly—the full description is given in section 6.

For any given program P we initially add n references, one reference to each of the n variables, in the same order as they are initially referenced in the program P. This gives the program P' with $m(P') = m(P) + n$. Note that if $n > q$, we add n misses using a $(1,q)$-cache.

For any reference in the program P' after the initial n references, the state of the cache is described by a so-called (q,n)-hit vector. This vector contains one entry for each variable; the content describes whether the variable is in the cache or not. There are $n-q$ 0's for variables not in the cache. Variables in the cache are denoted by "1," except the least recently referenced variable in the cache, which is represented by "q" at the corresponding position.

The program P is represented by a matrix $M(P)$ having as rows all induced (q,n)-hit vectors of P' which represent hits using a $(1,q)$-cache. If $n > q$, P' has at least $n+1$ initial misses, i.e., the number of rows of the matrix $M(P)$ is less than $m(P)$. Obviously there exist $q\binom{n}{q}$ different (q,n)-hit vectors.

The raison d'etre for the (q,n)-hit vectors is that we represent enough information for our purpose, and that any collection of (q,n)-hit vectors represents a program (Theorem 6.12). Therefore, results about programs can be derived by studying collections of (q,n)-hit vectors. The main part of section 6 is devoted to establishing the fact that the problem can be studied using the (q,n)-hit vector representation.

DEFINITION 3.5. *A program P is complete if all $q\binom{n}{q}$ possible (q,n)-hit vectors are equally frequent in the matrix $M(P)$.*

THEOREM 3.6. *All complete programs are extremal for the ratio $em(P,k,u,q)/h(P,1,q)$, i.e., for each complete program P we have*

$$em(P,k,u,q)/h(P,1,q) = \max_{P'} em(P',k,u,q)/h(P',1,q).$$

Here the maximum is taken over all programs P' with the same number of variables as P.

The main part of the report is devoted to proving the correctness of this theorem. In parallel with this we prove the usefulness of the (q,n)-hit vector description.

We next consider optimal mappings of the n variables onto the k sets. A mapping where each set contains either $\lfloor n/k \rfloor$ or $\lceil n/k \rceil$ variables is called a uniform mapping. A mapping where one set has i variables, where $i > \lceil n/k \rceil$, and the other $k-1$ sets have $\lfloor (n-i)/(k-1) \rfloor$ or $\lceil (n-i)/(k-1) \rceil$ variables is called a quasi-uniform mapping.

We prove the following theorem, which is essential in order to compute the Theorem 3.2 formula.

THEOREM 3.7. *For any complete program P there is an optimal mapping which is either uniform or quasi-uniform.*

In section 7 we prove that, practically speaking, complete programs may have any hit ratio. We in fact prove that the set of possible hit ratios for complete programs is dense in the interval $(0,1)$.

LEMMA 3.8. *For any number $H, 0 \le H \le 1$, and for any $\epsilon > 0$, there is a complete program P such that*

$$\left| \frac{h(P,1,q)}{m(P)} - H \right| < \epsilon.$$

We conclude this section by showing how Theorem 3.1 follows once Theorem 3.6 and Lemma 3.8 have been established.

THEOREM 3.9.

(i) *For any program P with n variables, we have*

$$h(P,1,q)(1 - r(n,k,u,q)) \le h(P,k,u).$$

(ii) *For any complete program P with n variables, we have*

$$h(P,1,q)(1 - r(n,k,u,q)) \le h(P,k,u) < m(P) - h(P,1,q)r(n,k,u,q).$$

Proof. Given a program P, use A_0 and A_1 to denote optimal mappings for the number of cache hits and for the number of extra misses, respectively. From Lemma 2.3 we then obtain

$$\begin{aligned} h(P,k,u) = h(A_0,P,k,u) &\ge h(A_1,P,k,u) \\ &\ge h(P,1,q) - em(A_1,P,k,u,q) = h(P,1,q) - em(P,k,u,q). \end{aligned}$$

Hence

$$h(P,k,u) \ge h(P,1,q) - em(P,k,u,q).$$

By invoking $r(n,k,u,q) \ge em(P,k,u,q)/h(P,1,q)$ the inequality in (i) follows.

The right inequality for complete programs follows from the relation

$$h(A,P,k,u) + em(A,P,k,u,q) < m(P).$$

To the left we here have all hits and a subset of the misses when using a (k,u)-cache, and to the right we have all memory references. Only the misses which are also misses with a $(1,q)$-cache are not represented. Since the initial reference is a miss for both caches, a strict inequality is valid. By taking optimal mappings A_0 and A_1 as before we get

$$\begin{aligned} h(A_0,P,k,u) < m(P) - em(A_0,P,k,u,q) &\le m(P) - em(A_1,P,k,u,q) \\ &= m(P) - em(P,k,u,q). \end{aligned}$$

Now, by invoking Theorem 3.6, for complete programs P we have $r(n,k,u,q) = em(P,k,u,q)/h(P,1,q)$; the right inequality follows. □

Proof of Theorem 3.1(i). By taking $h(P,1,q)/m(P)$ arbitrarily close to 1, Theorem 3.1(i) follows immediately from Lemma 3.8, Theorem 3.6, and Theorem 3.9.

4. Method overview. The results in section 3 are established when we have proved the following facts for complete programs.

1. Complete programs are extremal: Theorem 3.6.
2. The formula in Theorem 3.2 is valid for complete programs. Part of this is to establish that a complete program has an optimal mapping which is uniform or quasi-uniform (Theorem 3.7).

3. There are complete programs with any hit ratio: Lemma 3.8.

In order to derive a mathematical formula for $r(n, k, u, q)$ for all positive integers n, k, q, and u, we start by taking care of trivial cases of integers n, k, q, and u (section 5). For the nontrivial cases, we successively take away uninteresting sets of programs with the argument that if a program which is removed is extremal, then there is another program which is also extremal and which is not removed. Thus we always keep at least one program which is extremal for the problem.

We next represent the sequence of states for a $(1, q)$-cache which is induced by the program P with a sequence of so-called (q, n)-state vectors. This vector describes the state of the cache and thus contains enough information about the history of P to decide whether the next reference is a hit or a miss.

We have seen that the minimum of the ratio $h(P, k, u)/h(P, 1, q)$ can be obtained by calculating the maximum of $em(P, k, u, q)/h(P, 1, q)$. For this ratio, the $(1, q)$-cache misses are uninteresting and they are not represented in the sequence of (q, n)-state vectors. By frequent use of this flexibility, i.e., by adding $(1, q)$-cache misses in certain ways, it is possible to prove that any arbitrary sequence of (q, n)-state vectors represents a valid program. Theorem 6.9 thus states that, starting with any (q, n)-state vector, one can add $(1, q-1)$-cache misses so that the next hit occurs at any other state for the $(1, q-1)$-cache.

With the aid of Theorem 6.11 we can always add cache misses so that the next hit always references the variable which in this time cycle is the least recently referenced one. This allows the representation to be further simplified into so-called (q, n)-hit vectors. The aim of section 6 is Theorem 6.12. Using this theorem, it becomes valid to consider arbitrary sequences of (q, n)-hit vectors.

In section 7, complete programs are defined and studied. In this section, Theorems 3.6 and 3.7 and Lemma 3.8 are proved. The proof of Theorem 3.6 consists of the so-called duplication argument, which is a cornerstone in [7, 8, 9, 10, 11, 12, 13, 14].

The calculation of the explicit formula, Theorem 3.2, is made in section 8. In section 9 the applicability of the results is discussed, and section 10 concludes the paper. Section 11 displays some graphics related to the results.

Figures 2 and 3 present the logical structure of the theorems and lemmas needed to establish Theorems 3.1 and 3.2.

5. Trivial cases.

THEOREM 5.1. *If $n \leq ku$, then $r(n, k, u, q) = 0$.*

Proof. If $n \leq ku$, then all variables can be contained within a cache with k sets each containing u blocks. As a result, there will be no extra misses for the (k, u)-cache. □

THEOREM 5.2. *If $ku < q$ and $ku < n$, then $r(n, k, u, q) = 1$.*

Proof. From the definition of $r(n, k, u, q)$ it is obvious that $r(n, k, u, q) \leq 1$ for any values of n, k, q, and u.

If $ku < q$, it is possible to write a program P which repeatedly accesses a set of variables requiring q blocks of memory space. Since we use the LRU replacement policy, we will obtain a cache-miss for every reference using the (k, u)-cache. For the $(1, q)$-cache we will, however, obtain no misses after the first iteration. By increasing the number of such iterations, it is possible to make the ratio $em(P, k, u, q)/h(P, 1, q) > 1 - \epsilon$ for any $\epsilon > 0$. Thus $\sup em(P, k, u, q)/h(P, 1, q) = 1$. □

THEOREM 5.3. *If $u \geq q$, then $r(n, k, u, q) = 0$.*

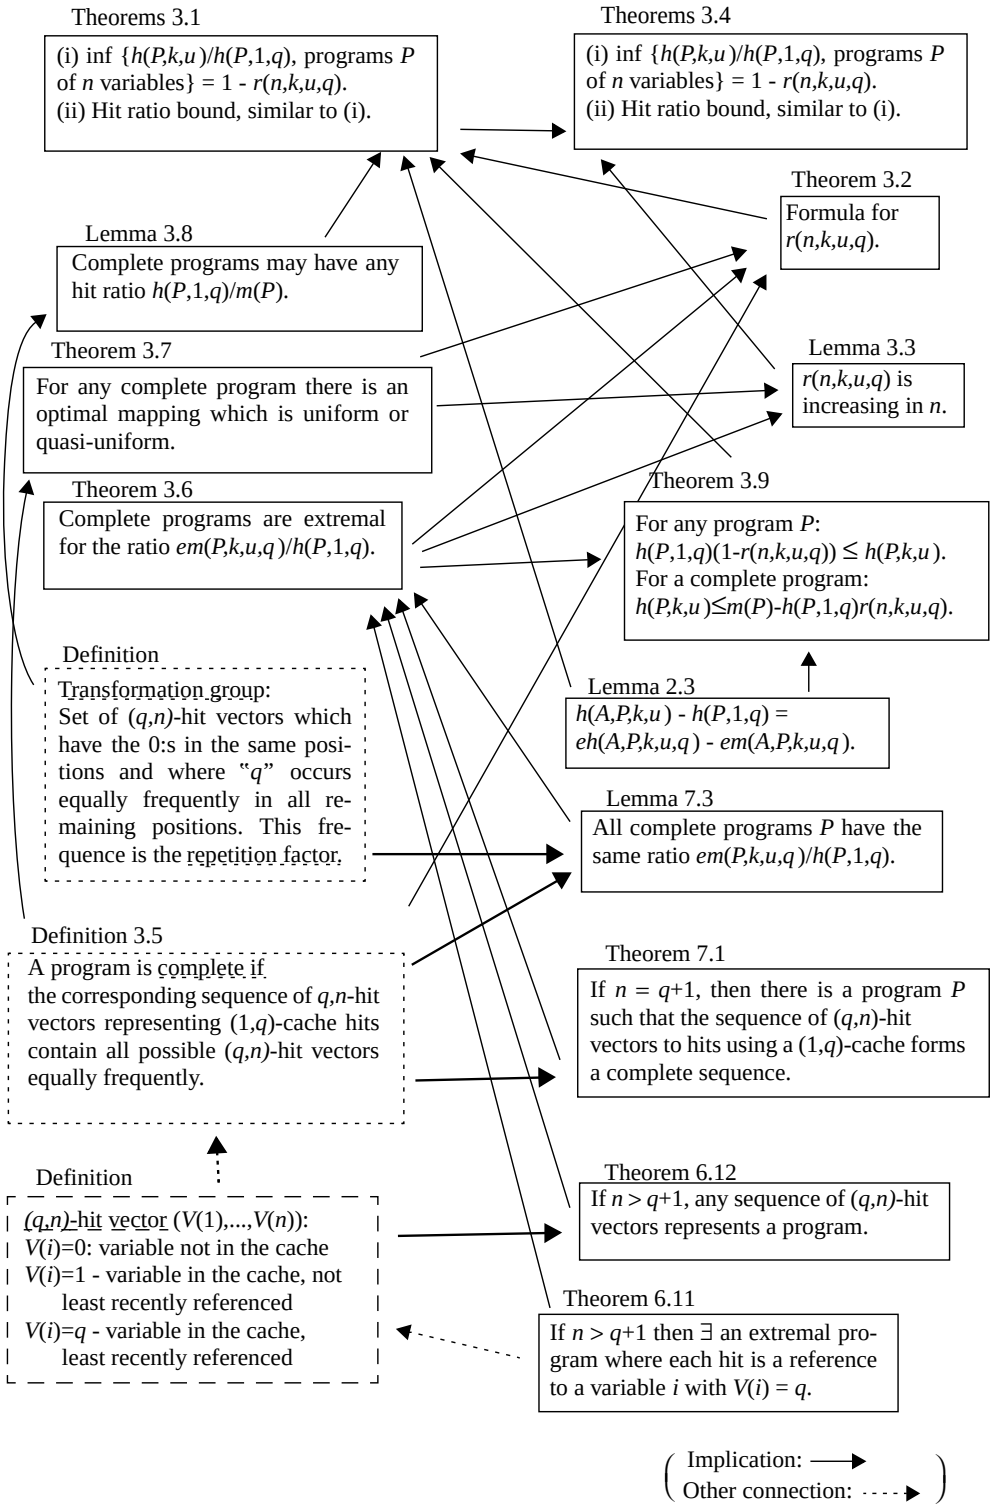

FIG. 2. *Logical structure outside section* 6 *(excluding the proofs in section* 9*).*

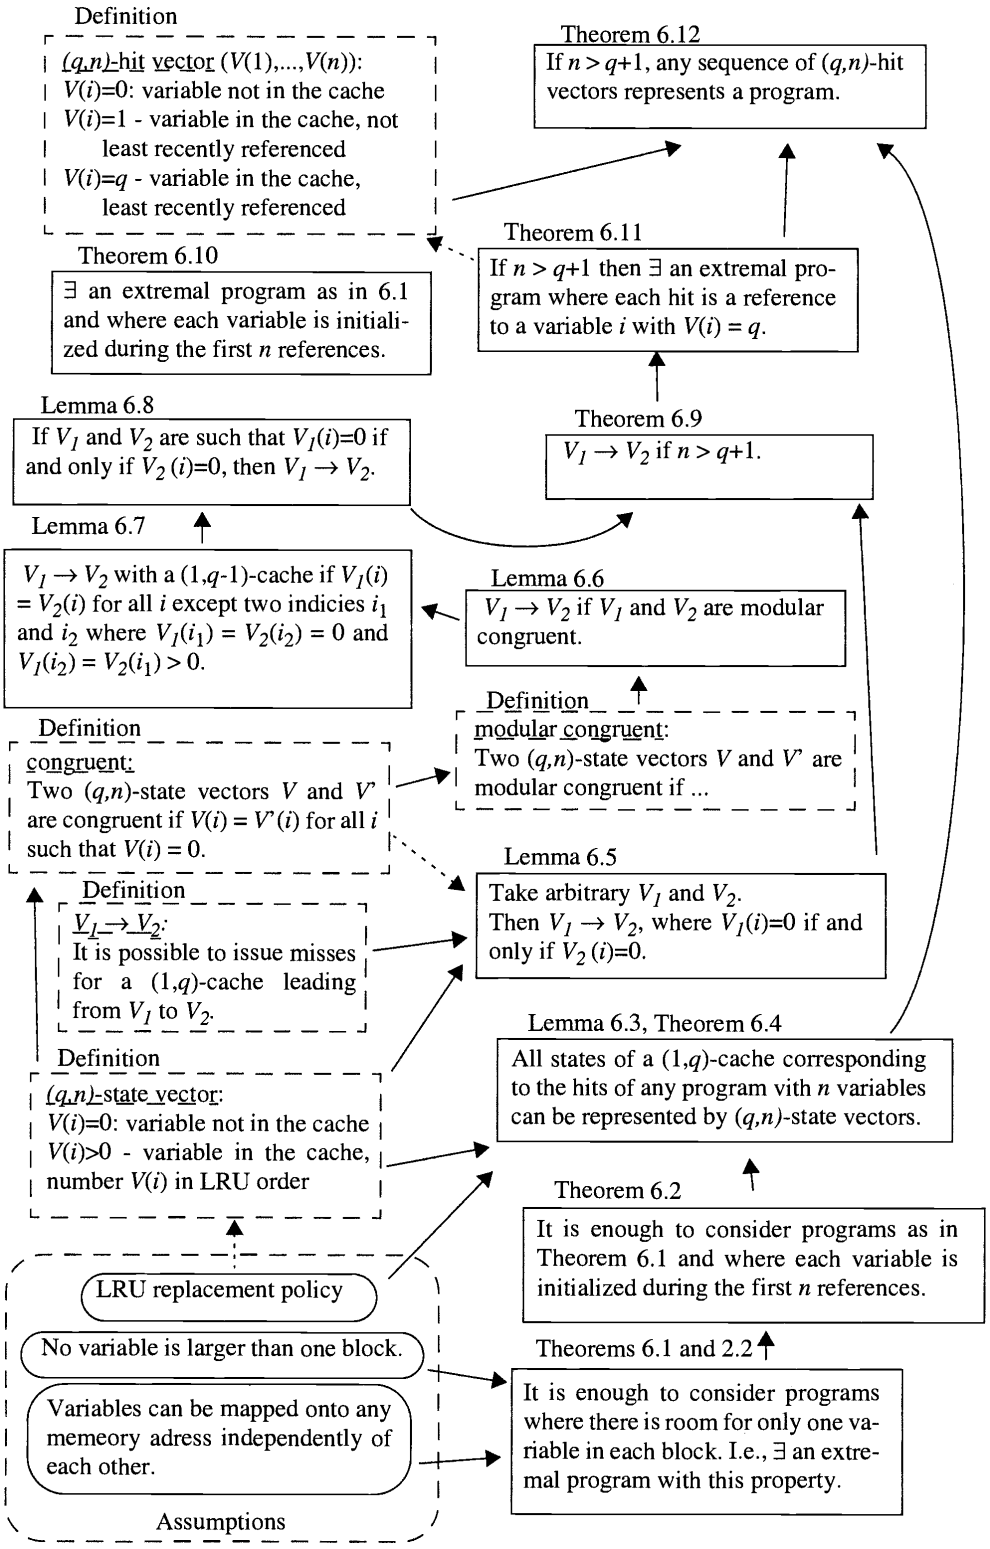

FIG. 3. *Logical structure of section* 6.

Proof. If $u \geq q$, then each set in the (k, u)-cache is larger than the set in the $(1, q)$-cache. Consequently, using the LRU replacement policy, no extra misses can occur. ∎

Having isolated the trivial cases above, we assume that $n > ku \geq q > u$ in the rest of this paper, unless otherwise stated. In addition, "extremal programs" will, unless otherwise stated, denote programs which maximize the quantity $em(P, k, u, q)/h(P, 1, q)$.

6. From programs to (q, n)-hit vectors.

THEOREM 6.1. *For any values of n, k, u, and q, there is at least one extremal program such that each variable occupies exactly one block.*

Proof. The only difference in the above statement compared to that in Theorem 2.2 is that here we wish to maximize $em(P, k, u, q)/h(P, 1, q)$, whereas in that proof we want to minimize $h(P, k, u)/h(P, 1, q)$. It is easily seen that the same proof also works for this theorem. ∎

There are thus extremal programs which have room for exactly one variable in each block. From now on we consider only such programs.

Since there are n variables in the program, we know that there will be at least n cache misses because each variable will be referenced at least once. The first reference to a variable, which always results in a miss, is referred to as the initial reference.

THEOREM 6.2. *Consider an arbitrary extremal program P and denote the first referenced variable by i_1, the second referenced variable by i_2, and so on. Then consider a program P' which is identical to P, with the exception that a sequence of n memory references to variables $i_1, i_2, \ldots, i_n$ in this order has been added at the start of the program. Then P' is also an extremal program.*

Proof. Since we are considering the case when $n > q$, the number of hits using a $(1, q)$-cache is the same for P and P'. That is, memory reference number r in P results in a miss using a $(1, q)$-cache if and only if memory reference number $r + n$ in P' results in a miss using a $(1, q)$-cache. Recall that we use the LRU replacement policy. Hence $h(P, 1, q) = h(P', 1, q)$.

Consider memory reference number r_2 in program P and denote the referenced variable by i. If r_2 results in a hit using a $(1, q)$-cache, then there is another reference r_1 which also accesses variable i, such that $r_1 < r_2$ and there are no references to variable i between r_1 and r_2. The sequence of memory references between r_1 and r_2 completely determines if r_2 will result in a miss using a (k, u)-cache, i.e., this sequence determines if an extra miss will occur. Obviously this sequence corresponds to the sequence $r_1 + n$ to $r_2 + n$ in P'. As a result, the number of extra misses is the same for P and P', i.e., $em(P, k, u, q)/h(P, 1, q) = em(P', k, u, q)/h(P', 1, q)$. Consequently, if P is an extremal program, P' is also an extremal program. ∎

Hence there are extremal programs which have no hits during the n first memory references using a $(1, q)$-cache. From now on we consider only such programs.

A (q, n)-state vector V defines the variables currently stored in a $(1, q)$-cache and the order in which they have been referenced. V has one entry for each variable. If variable i is not in the cache, then $V(i) = 0$. Otherwise $V(i)$ denotes the number of variables referenced since variable i was referenced last, including variable i. Hence if variable i is the most recently accessed variable, $V(i) = 1$. If it is the second most recently accessed variable, $V(i) = 2$, and so on (see Figure 4). Hence after the first n memory references, the (q, n)-state vector consists of the q first positive integers and $n - q$ zeros. As discussed before, the LRU replacement policy is used.

Clearly, a (q, n)-state vector has n entries and contains each of the first q positive integers exactly once, and $n - q$ zeros. If a reference to variable j is a cache miss, and

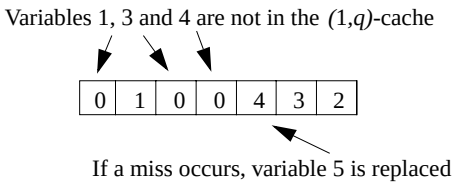

FIG. 4. *A (q,n)-state vector where $q=4$ and $n=7$.*

$V(i)=q$, then variable i is replaced in the cache. We then set $V(i)=0$, increment all positive integers, and set $V(j)=1$. If the reference to variable j is a hit, we increment all entries which are smaller than $V(j)$ and then set $V(j)=1$. Figure 4 shows a (q,n)-state vector for the case when $q=4$ and $n=7$.

We are interested in the ratio $em(P,k,u,q)/h(P,1,q)$ for extremal programs. When using a $(1,q)$-cache there are no hits during the first n memory references. Therefore, we do not consider the n first memory references, i.e., we assume that there are always q nonzero entries in a (q,n)-state vector. The numbering of the (q,n)-state vectors is chosen so that the (q,n)-state vector number r describes the state of the cache immediately before reference r in the program.

Now consider a mapping A of the n variables to k sets. Each mapping can be regarded as a partition of the first n positive integers in k sets A_j; mapping A is thus the sets $A_1,\ldots,A_k$.

LEMMA 6.3. *Consider a (k,u)-cache, a mapping A, and a (q,n)-state vector V corresponding to reference r in a program P. Assume that $i_0 \in A_\alpha$.*

Then the variable i_0 is not in the (k,u)-cache at reference r in program P if and only if there are j variables i_j, which are also mapped to A_α, such that $0<V(i_j)<V(i_0)$ and $j \geq u$.

Proof. This is a direct consequence of the definition of the (q,n)-state vector, Theorem 6.2, and of the fact that the LRU replacement policy is used. □

The next theorem states that a (q,n)-state vector contains enough information about the history of the program for our purposes.

THEOREM 6.4. *If the (q,n)-state vector after r references and the mapping of variables to sets are known, then it is possible to determine from this information whether reference r is an extra miss or not.*

Proof. Consider a (q,n)-state vector V, a mapping A, and a reference to a variable i_0. If $V(i_0)>0$, no miss will occur using a $(1,q)$-cache. This is a direct consequence of the definition of the (q,n)-state vector.

Assume that $i_0 \in A_\alpha$ using the (k,u)-cache and there are j variables i_j, which are also mapped onto A_α. In this case, the previous lemma guarantees that if $0<V(i_j)<V(i_a)$ and $j \geq u$, a cache miss will occur using the (k,u)-cache and mapping A.

Consequently, if the (q,n)-state vector and the mapping of variables to memory blocks are known, it is possible to determine if an extra miss will occur. □

Our next aim is to prove that any sequence of (q,n)-state vectors represents the sequence of $(1,q)$-hits for some program (Theorem 6.9). This allows us to consider arbitrary sequences of (q,n)-state vectors.

Two (q,n)-state vectors V and V' are said to be *congruent* if $V(i)=V'(i)$ for all i such that $V(i)=0$.

LEMMA 6.5. *For two arbitrary (q,n)-state vectors V_1 and V_2, it is possible to*

generate a sequence of memory references such that, starting from V_1, we reach a state vector which is congruent with V_2 without producing any hits using a $(1, q)$-cache.

Proof. Generate a reference to the first variable i (the variables are enumerated in some fixed arbitrary order) for which $V_1(i) = 0$ and $V_2(i) \neq 0$, thereby producing a new (q, n)-state vector V'. If V' and V_2 are not congruent, we again issue a reference to a variable i, where $V'(i) = 0$ and $V_2(i) \neq 0$. This procedure can be repeated until we reach a vector V' which is congruent with V_2.

For the sequence of memory references generated in this way there are no hits using a $(1, q)$-cache. □

Consider two congruent (q, n)-state vectors V and V'. The q indexes i_j for which $V(i_j) \neq 0$ are enumerated in such an order that $V(i_1) = 1, V(i_2) = 2, \ldots, V(i_q) = q$. V and V' are *modular congruent* if there is an integer x: $V(i_j) = ((V'(i_j)+x) \bmod q)+1$ for all $j : 1 \leq j \leq q$.

LEMMA 6.6. *For two modular congruent (q, n)-state vectors V_1 and V_2, it is possible to generate a sequence of memory references such that, starting from V_1, we reach V_2 without producing any hits using a $(1, q-1)$-cache.*

Proof. If we issue a reference to the variable $i_q : V_1(i_q) = q$, we will obtain a new state vector V_1' which is modular congruent to V_1. This reference will also clearly be a miss when using a $(1, q-1)$-cache. By repeating this kind of reference, we can generate any vector V which is modular congruent to V_1 without producing any hits when using a $(1, q-1)$-cache. □

Two (q, n)-state vectors V_1 and V_2 are *quasi-identical* if $V_1(i) = V_2(i)$ for all i except two indexes i_a and i_b so that $V_2(i_a) = 0, V_2(i_b) > 0, V_1(i_a) = V_2(i_b)$, and $V_1(i_b) = V_2(i_a)$.

LEMMA 6.7. *For two quasi-identical (q, n)-state vectors V_1 and V_2, it is possible to generate a sequence of memory references, such that, starting from V_1, we reach V_2 without producing any hits using a $(1, q-1)$-cache.*

Proof. Consider two state vectors V_1' and V_2' which are modular congruent with V_1 and V_2, respectively. V_1' and V_2' have been chosen so that $V_1'(i_b) = q$ and so that V_1' and V_2' are also quasi-identical. By issuing one reference to the variable i_a with $V_2'(i_a) = q$ we obtain V_2'' which is modular congruent to V_2'.

From Lemma 6.6 we know that it is possible to generate a sequence of memory references, such that, starting from V_1, it is possible to reach V_1' without producing any hits using a $(1, q-1)$-cache. From V_1' we obtain V_2'' by issuing a reference to variable i_a. Since $V_1'(i_a) = 0$, this reference leads to a miss using a $(1, q-1)$-cache. Again, Lemma 6.6 guarantees that, starting from V_2'', it is possible to generate a sequence of memory references such that we reach V_2 without producing any hits using a $(1, q-1)$-cache. □

LEMMA 6.8. *For two congruent (q, n)-state vectors V_1 and V_2, it is possible to generate a sequence of memory references so that, starting from V_1, we reach V_2 without producing any hits using a $(1, q-1)$-cache.*

Proof. Assume that $V_1(z) = V_2(z) = 0$, and that $V_2(i_j) = j$ for all $j : 1 \leq j \leq q$. In this case, the algorithm below reaches $V_1' = V_2$, starting from V_1, without generating any hit using a $(1, q-1)$-cache.

1. Let $j = q$ and let V_j' be modular congruent to V_1 such that $V_j'(i_q) = q$.
2. If $j = 1$, the algorithm terminates; else let $j = j - 1$.
3. If $V_{j+1}'(i_j) = j$, then $V_j' = V_{j+1}'$ and go to 2.
4. Go to state X_j, which is quasi-identical with V_{j+1}', i.e., $X_j(i) = V_{j+1}'(i)$ for all $i : 1 \leq i \leq n$ except that $X_j(i_j) = V_{j+1}'(z) = 0$ and $X_j(z) = V_{j+1}'(i_j) = t$

$(t < j)$.

5. Go to state X'_j, which is quasi-identical with X_j, i.e., $X'_j(i) = X_j(i)$ for all $i : 1 \leq i \leq n$ except that $X'_j(i_y) = Xj(i_j) = 0$ and $X'_j(i_j) = X_j(i_y) = j$, i.e., i_y is the index for which $X_j(i_y) = j$.
6. Go to state V'_j, which is quasi-identical with X'_j, i.e., $V'_j(i) = X'_j(i)$ for all $i : 1 \leq i \leq n$ except that $V'_j(z) = X'_j(i_y) = 0$ and $V'_j(i_y) = X'_j(z) = t$, n.b. V'_j is congruent with V_1 and V_2.
7. Go to 2.

The above algorithm guarantees that $V'_1(i) = V_2(i)$ for all $i : j \leq i \leq n$. Moreover, Lemma 6.7 guarantees that there will be no hits using a $(1, q-1)$-cache during steps 4, 5, and 6 in the above algorithm. □

THEOREM 6.9. *If $n > q+1$, it is possible to go from any (q,n)-state vector V_1 to any other (q,n)-state vector V_2 without producing any hits in a $(1,q)$-cache.*

Proof. This follows immediately from Lemmas 6.5 and 6.8. □

For the moment, we are considering only cases in which $n > q+1$. The case when $n = q+1$ will be handled later. As discussed previously, a program can be represented by the sequence of memory references, with associated (q,n)-state vectors, which corresponds to hits using a $(1,q)$-cache. From Theorem 6.9 we know that if $n > q+1$, each (q,n)-state vector in this sequence is completely independent of any other vector in the sequence.

THEOREM 6.10. *Consider a mapping A and two memory references r_1 and r_2, both referring to the same variable x. Denote the (q,n)-state vectors corresponding to r_1 and r_2 by V_1 and V_2, respectively. Assume that these vectors are such that $0 < V_1(x) = p < q, V_2(x) = q$, and $V_2(i) = V_1(i)$, when $V_1(i) < p$; otherwise $V_2(i) = V_1(i) - 1$ for all $i \neq x$. Assume also that reference r_1 is a miss using a (k,u)-cache and a mapping A. Then reference r_2 is also a miss using a (k,u)-cache and the mapping A.*

Proof. From Lemma 6.3 we know that if reference r_1 leads to a miss using a (k,u)-cache and mapping A, then there are i variables z_i, which are mapped to the same set as x, such that $0 < V(z_i) < V(x) = p$ and $i \geq u$. We also know that $V_2(i) = V_1(i)$, when $V_1(i) < p$. Consequently, at reference r_1 the same z_i variables are mapped to the same set as x. Under these conditions, Lemma 6.3 tells us that reference r_2 will result in a cache miss. □

THEOREM 6.11. *If $n > q+1$, there exists an extremal program such that each hit using a $(1,q)$-cache is a reference to the variable for which the corresponding entry in the (q,n)-state vector equals q.*

Proof. Consider a program P and its induced sequence of (q,n)-state vectors. If a reference r occurs to a variable i with $V(i) < q$, it is possible to use Theorem 6.9 to add memory references immediately before reference r so that $V'(i) = q$, where V' is the new (q,n)-state vector preceeding reference r. If this is done for all i such that $V(i) < q$, we obtain a new program P' which has the same number of hits using a $(1,q)$-cache: $h(P,1,q) = h(P',1,q)$. It remains to check that the number of extra misses does not decrease. Using Theorem 6.9 it is possible to add memory references in such a way that V' fulfills all conditions in Theorem 6.10, with no new hits. It then follows from Theorem 6.10 that all extra misses in P are also extra misses in P'. If sequences of memory references are added in this way at each spot where a reference r occurs to a variable i with $V(i) < q$, then from the program P we obtain a program P' where each hit is a reference to a variable i with $V(i) = q$, and $em(P,k,u,q)/h(P,1,q) = em(P',k,u,q)/h(P',1,q)$. □

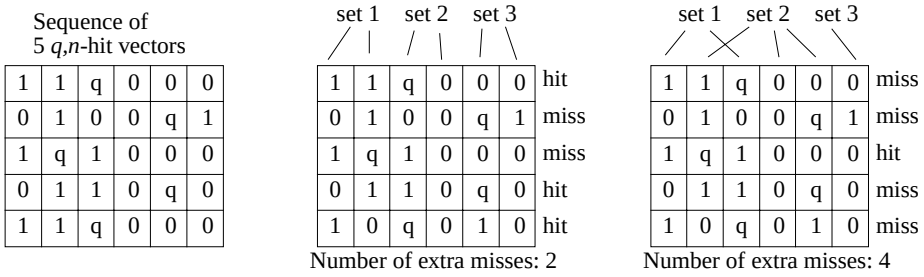

FIG. 5. *Two mappings of the same program with a* $(3,1)$*-cache, compared to a* $(1,3)$*-cache.*

From now on we will consider only programs for which each hit using a $(1,q)$-cache is a reference to the variable for which the corresponding entry in the current (q,n)-state vector equals q. There is at least one extremal program within this set. The ratio $em(P,k,u,q)/h(P,1,q)$ is, however, unchanged if all (q,n)-state vectors corresponding to misses using a $(1,q)$-cache are deleted—both quantities in the ratio deal with $(1,q)$-cache hits. It is clear that each arbitrary sequence of (q,n)-state vectors represents a program of this kind, with all misses removed. Hence we may look for extremal programs among the set of arbitrary sequences of (q,n)-state vectors.

Now consider a fixed mapping A, i.e., a partition of the variables in k sets consisting of u variables in each set. Our aim is to find how many of the (q,n)-state vectors result in a miss for a (k,u)-cache; this is the number of extra misses. Each reference to a variable i corresponds to an entry equaling q in the current (q,n)-state vector, $V(i)=q$. We know that the variable i is discarded using a (k,u)-cache if the number of variables $j : V(j) > 0$ belonging to this partition set is larger than u. This is a necessary and sufficient condition for an extra miss. Since we are thus only interested in whether a certain entry in a (q,n)-state vector is $0, q$, or some value between 0 and q, we can further simplify our notation. In a (q,n)-state vector "0," "1," and "q" are left unchanged, but all other integers are replaced by "1." As a result, each vector has one "q," $q-1$ "1," and $n-q$ "0." Such a vector is referred to as a (q,n)-hit vector. This vector also contains enough information to be able to decide whether an extra miss occurs or not.

In the following discussion we will often represent a program as a matrix which has (q,n)-hit vectors as rows. Again, only the hits are represented—all (q,n)-hit vectors representing misses with a $(1,q)$-cache are deleted.

Since a program has by definition $h(P,1,q)$ hits using a $(1,q)$-cache, we obtain an $h(P,1,q) \times n$ matrix. Figure 5 shows a program for which there are five cache hits using a $(1,3)$-cache, i.e., $h(P,1,q)=5$. The program has six variables. The first cache hit that occurs is a reference to variable number three. When this hit occurs, variables number one and two are also in the cache.

The example in Figure 5 shows that if the mapping of variables to sets is known, it is possible to determine if the memory reference corresponding to a certain (q,n)-hit vector will result in a miss using a (k,u)-cache or not. Remember, we are interested in the mapping of variables to sets resulting in a minimum number of misses using a (k,u)-cache. The figure also shows that the number of extra misses depends on the mapping.

The problem of calculating $r(n,k,u,q) = \max_P em(P,k,u,q)/h(P,1,q)$ for all programs P with n variables can now be formulated as the problem of finding a sequence of (q,n)-hit vectors for which the ratio obtained when dividing the minimum

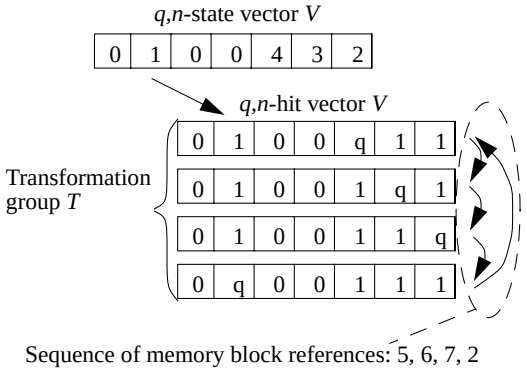

FIG. 6. *A transformation group T.*

number of misses for the sequence, when using a (k, u)-cache, with the length of the sequence is maximal.

The following theorem follows from Theorems 6.11 and 6.4. It summarizes the aim of the present section of reformulating the problem into arbitrary sequences of (q, n)-hit vectors.

THEOREM 6.12. *If $n > q + 1$, any sequence of (q, n)-hit vectors represents a program.*

It is obvious that any program with n variables corresponds to a sequence of (q, n)-hit vectors, as described before Definition 3.5.

7. Complete programs. There are $q\binom{n}{q}$ distinct (q, n)-hit vectors. A program for which the corresponding sequence of (q, n)-hit vectors contains exactly x copies of each distinct vector is referred to as a complete program; x is referred to as the *repetition factor*. Such a sequence of (q, n)-hit vectors is referred to as a complete sequence.

A set of q (q, n)-hit vectors forms a *transformation group* if all zeros are positioned at the same entries in all vectors and if the "q" is positioned differently in all vectors. Consequently, there are $x\binom{n}{q}$ transformation groups in a complete program.

Figure 6 shows a (q, n)-state vector V and the corresponding (q, n)-hit vector V. The figure also shows the transformation group T, in which V is a member. The arrows on the right side of the figure correspond to a sequence of four memory references, where the first reference is to a variable mapped to block 5, the second is to a variable mapped to block 6, the third to block 7, and the fourth to block 2. These four memory references go through all (q, n)-hit vectors in T exactly once, reaching (q, n)-hit vector V again after the fourth memory reference. With a $(1, 4)$-cache, none of the four memory references would result in a cache miss.

So far, we have considered only the case when $n > q + 1$. This is because if $n = q+1$, we cannot guarantee that there is a program corresponding to any arbitrary sequence of (q, n)-hit vectors (see Theorem 6.12). In the next theorem, however, we will show that there are complete programs even when $n = q + 1$.

THEOREM 7.1. *If $n = q + 1$, then there is a program P such that the sequence of (q, n)-hit vectors corresponding to hits using a $(1, q)$-cache forms a complete sequence.*

Proof. We are going to describe a complete program P with $n = q + 1$ variables.

The program P starts by generating the $n - 1$ memory references $2, 3, \ldots, q + 1$. This gives cache misses only, and the (q, n)-hit vector $V = (0, q, 1, \ldots, 1, 1)$. The

following q references are references to the variables $2, 3, \ldots, q+1$ in this order. By the definition of transformation groups we then clearly issue cache hits such that we go through all (q,n)-hit vectors in the transformation group T of V exactly once, returning finally to V.

Having done this we generate a memory reference to variable 1. This issue gives a miss and a new (q,n)-hit vector V' belonging to a different transformation group T', where $V'(1) = 0$. Again, we generate a sequence of q memory references, such that we go through all (q,n)-hit vectors in T' exactly once, finally returning to V' with no misses when using a $(1,q)$-cache. This procedure is repeated until we have produced all the $q+1$ different transformation groups.

Clearly the cache hits in the program P correspond to all possible (q,n)-hit vectors, and each (q,n)-hit vector occurs once. Consequently, P is a complete program for the case where x is one. Note that by repeating the $(q+1)^2$ memory references it is possible to obtain a complete program for any positive integer value of x. □

Proof of Lemma 3.8. Consider a complete program P for which the hits occur in such order that (q,n)-hit vectors belonging to the same transformation group are listed consecutively. If $h(P,1,q)/m(P) > H$, we add y cache misses at the end of the program, thus obtaining a new program P' which is also complete since only cache hits are involved in the definition of complete programs.

$$\frac{h(P',1,q)}{m(P')} = \frac{h(P,1,q)}{m(P)+y}.$$

If $h(P,1,q)/m(P) < H$, we consider another complete program P' where we have increased the repetition factor from x to x', still with (q,n)-hit vectors belonging to the same transformation group listed consecutively. Since only hits occur within a transformation group, we introduce no new misses. Let $\alpha = \frac{x'}{x}$. It is clear that by denoting the misses using a $(1,q)$-cache, $b(P) = m(P) - h(P,1,q)$, and $\alpha = \frac{x'}{x}$ we get

$$\frac{h(P',1,q)}{m(P')} = \frac{\alpha h(P,1,q)}{\alpha h(P,1,q) + b(P)}.$$

Hence we can increase the ratio so it is arbitrarily close to 1. By repeating the two techniques it is possible to find a complete program which has a hit ratio arbitrarily close to H. □

LEMMA 7.2. *Consider a complete program P. The variables in P include i_1 and i_2. If $A(i_1) = S_1$ (variable i_1 is mapped onto set S_1) and $A(i_2) = S_2$, and there is another mapping A' which is identical to A except $A'(i_1) = S_2$ and $A'(i_2) = S_1$, then the number of extra misses is the same for mappings A and A'.*

Proof. Obviously, the number of misses using a (k,u)-cache for vectors V where $V(i_1) = V(i_2)$ is the same for mappings A and A'. The symmetry of complete sequences guarantees that all (q,n)-hit vectors V in P, for which $V(i_2) \neq V(i_1)$, can be grouped into pairs (V,V'), such that $V(i) = V'(i)$, with the exception of $V(i_1) = V'(i_2)$ and $V(i_2) = V'(i_1)$. If and only if V results in a miss for mapping A using a (k,u)-cache, then V' results in a miss for mapping A' using a (k,u)-cache. Similarly, if and only if V results in a miss for mapping A' using a (k,u)-cache, then V' results in a miss for mapping A using a (k,u)-cache. Consequently, the number of extra misses is the same for A and A'. □

LEMMA 7.3. *All complete programs P with n variables have the same ratio $em(P,k,u,q)/h(P,1,q)$.*

Proof. Obviously, the ratio $em(P,k,u,q)/h(P,1,q)$ is not affected by the order in which the (q,n)-hit vectors are listed in the sequence corresponding to the complete program. The only potentially significant difference between two complete programs is thus the repetition factor x. Creating x copies of each row increases both the number of extra misses $em(P,k,u,q)$ and the number of hits using a $(1,q)$-cache $h(P,1,q)$ with the factor x. As a result, the ratio $em(P,k,u,q)/h(P,1,q)$ is not affected by x, i.e., all complete programs P with n variables have the same ratio $em(P,k,u,q)/h(P,1,q)$. □

Proof of Theorem 3.7. Lemma 7.3 and Theorem 3.6 allow us to consider a complete program of $q\binom{n}{q}$ rows. All references in one transformation group corresponding to a certain set will generate extra misses if the number of nonzeros in that set is larger than u; we otherwise obtain no extra misses. One transformation group will therefore contribute with i extra misses for each partition set where the number of nonzeros is $i > u$; the contribution is otherwise zero.

Consider two sets A_1 and A_2 in a mapping A, applied to a complete program P. The program may be represented by a matrix with $q\binom{n}{q}$ rows; the mapping may then also be referred to as a partition. The sets A_1 and A_2 are size n_1 and n_2, respectively, where $n_1 - n_2 \geq 2$. We will next move one variable from the larger set A_1 to the smaller set A_2, thereby producing the partition A'. If we denote the transferred column by c, we can write $A_1' = A_1 \backslash \{c\}$ and $A_2' = A_2 \cup \{c\}$. A' and A have all other partition sets in common.

We will next study under what conditions we have

$$em(A',P,k,u,q) \leq em(A,P,k,u,q).$$

If we replace A by A', the number of extra misses will not change at rows where the cth column contains a zero. However, at each row of P where we have 1 at column c, and we also have exactly u nonzeros in A_2 and do not have u nonzeros in the rest of A_1, the number of extra misses will increase by $u+1$. Here we have added the extra misses for all permutations in the same transformation group. Similarly, in a row where we have exactly u nonzeros in A_1' and do not have u nonzeros in A_2, the number of extra misses will decrease by $u+1$. Since P contains each permutation exactly once, with the aid of elementary combinatorics we may count these changes and we obtain

$$\begin{aligned} em(A',P,k,u,q) = {} & em(A,P,k,u,q) \\ & + (u+1)\left(\binom{n_2}{u}\binom{n-n_2-1}{q-u-1} - \binom{n_1-1}{u}\binom{n-n_1}{q-u-1}\right). \end{aligned}$$

Let $f(l) = \binom{l}{u}\binom{n-l-1}{q-u-1}$. So the contribution to the number of extra misses if one column is moved from A_1 to A_2, where $|A_1| = n_1$ and $|A_2| = n_2$, is

$$em(A',P,k,u,q) - em(A,P,k,u,q) = (u+1)(f(n_2) - f(n_1-1)).$$

We may now easily calculate for which l the function $f(l)$ is increasing or decreasing. We get

$$\begin{aligned} f(l) - f(l-1) &= \binom{l}{u}\binom{n-l-1}{q-u-1} + \binom{l-1}{u}\binom{n-l}{q-u-1} \\ &= \left(\frac{l}{l-u} - \frac{n-l}{n-l-q+u+1}\right)\binom{l-1}{u}\binom{n-l-1}{q-u-1} \end{aligned}$$

$$= \frac{l(n-l-q+u+1)-(l-u)(n-l)}{(l-u)(n-l-q+u+1)} \binom{l-1}{u} \binom{n-l-1}{q-u-1}$$
$$= \frac{-lq+l+un}{(l+1-u)(n-l-q+u)} \binom{l-1}{u} \binom{n-l-1}{q-u-1}.$$

We can conclude that $f(l)-f(l-1) \geq 0$ if and only if $l \leq \frac{un}{q-1}$. Since $q \leq ku$, we have $\frac{un}{q-1} \geq \frac{n}{k}\frac{q}{q-1} \geq \frac{n}{k}$. We therefore have a critical size $\frac{un}{q-1}$ for l which is higher than n/k. Of course, in a uniform partition, the partition sets have size $\lfloor n/k \rfloor$ and $\lceil n/k \rceil$.

Hence, if $n_2 < n_1 - 1 \leq \frac{un}{q-1}$, the number of extra misses will decrease if we move a column from a larger to a smaller set.

On the other hand, if $n_2 > n_1 - 1 \geq \frac{un}{q-1}$, the number of extra misses will decrease if, conversely, we move a column from a smaller to a larger set.

We will next repeat the argument by successively decreasing the number of extra misses by transferring columns between partition sets. We then finally obtain a uniform, or a quasi-uniform partition, which we may see as follows.

If all blocks in the starting partition are smaller than the critical size $\frac{un}{q-1}$, we apply the argument repeatedly to move columns from larger to smaller sets, thereby finally obtaining a uniform partition.

If one block is larger than the critical size, we apply the argument to pairs of the other blocks. We again move columns from larger to smaller sets, giving a quasi-uniform partition.

If the starting partition has two or more sets which are larger than the critical size, we apply the argument to a pair where both blocks are larger than the critical size. We then instead move columns from the smallest set to the largest. This argument is repeated for the same pair, until the smallest set is smaller than the critical size.

If there are still two or more blocks larger than the critical value, we apply this procedure to another such pair. Ultimately, we will have only one set which is larger than the critical size. This is handled as described above.

Consequently, our only candidates for optimal partitions are the uniform partitions, which have partition set sizes

$$\left(\left\lceil \frac{n}{k} \right\rceil, \dots, \left\lceil \frac{n}{k} \right\rceil, \left\lfloor \frac{n}{k} \right\rfloor, \dots, \left\lfloor \frac{n}{k} \right\rfloor \right),$$

together with the quasi-uniform partitions, defined by partition set size sequence

$$\left(i, \left\lceil \frac{n-i}{k-1} \right\rceil, \dots, \left\lceil \frac{n-i}{k-1} \right\rceil, \left\lfloor \frac{n-i}{k-1} \right\rfloor, \dots, \left\lfloor \frac{n-i}{k-1} \right\rfloor \right),$$

where $i = \max(\lceil n/k \rceil + 1, \lceil \frac{un}{q-1} \rceil), \dots, n$.

The quasi-uniform partitions have the size of one set larger or equal to the critical value $\frac{un}{q-1}$ but larger than $\lceil n/k \rceil$; while the other $k-1$ sets are as equally sized as possible. □

Numerical calculation shows that in most cases a uniform partition is optimal if the parameters are moderately large. For example, if all four parameters are at most 10, there are only three cases where a uniform partition is not optimal: $(n,k,u,q) = (9,7,1,7), (10,7,1,7)$, and $(10,8,1,8)$.

Proof of Theorem 3.6. Consider a sequence of (q,n)-hit vectors corresponding to an arbitrary program P_0 (see Figure 7), and take a mapping A_0 which is optimal for

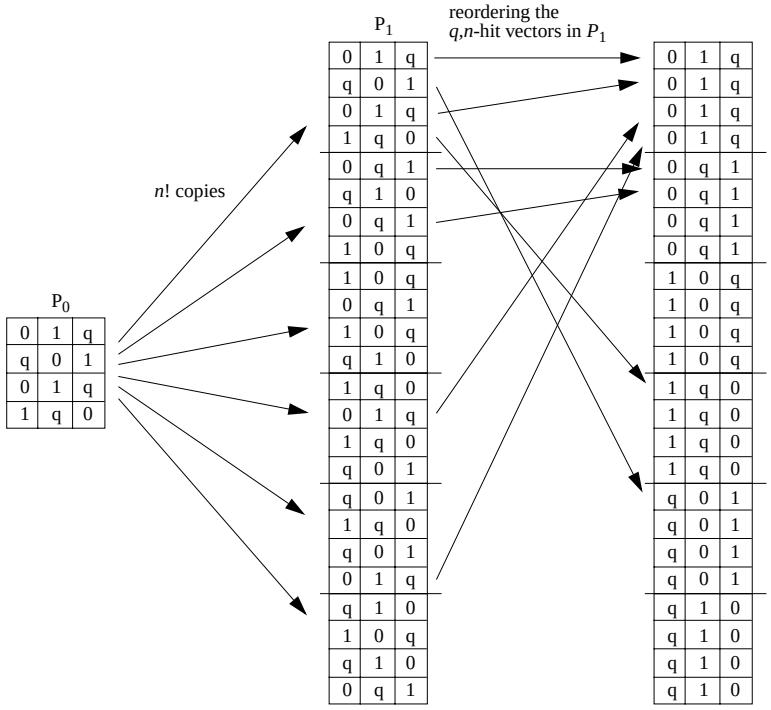

FIG. 7. *Creating a complete program P_1 from an arbitrary program P_0.*

the program P_0. Let A_1 be an optimal mapping for a complete program defined by n and q. We then clearly have

$$\frac{em(P_0,k,u,q)}{h(P_0,1,q)} = \frac{em(A_0,P_0,k,u,q)}{h(P_0,1,q)} \leq \frac{em(A_1,P_0,k,u,q)}{h(P_0,1,q)}.$$

As discussed previously, the (q,n)-hit vectors form a $h(P_0,1,q) \times n$ matrix; in the example in Figure 7 we have $h(P_0,1,q) = 4$ and $n = 3$.

We next duplicate the program P_0 in $n!$ copies, where each copy corresponds to one of the $n!$ permutations of the n columns in the $h(P_0,1,q) \times n$ matrix. The copies are concatenated, resulting in a sequence of (q,n)-hit vectors of the length $n!h(P_0,1,q)$. This sequence corresponds to a program P_1. It is clear that P_1 is a complete program (see the version of P_1 furthest to the right in Figure 7).

The mapping A_1 on each of the $n!$ permutations of the columns of P_0 can now be alternatively regarded as mappings $A_{1,i}, i = 1,\ldots,n!$, on the program P_0. Now fix the mapping A_1 to be such that $em(A_1,P_0,k,u,q) \leq em(A_{1,i},P_0,k,u,q)$ for all $i = 1,\ldots,n!$.

Then $em(A_1,P,k,u,q)$ is also a lower bound of the mean value of the quantities $em(A_{1,i},P_0,k,u,q)$. Since the sum of these is $em(A_1,P_1,k,u,q)$, we obtain

$$\begin{aligned}\frac{em(A_1,P_0,k,u,q)}{h(P_0,1,q)} &\leq \frac{1}{n!}\sum_{i=1}^{n!}\frac{em(A_{1,i},P_0,k,u,q)}{h(P_0,1,q)} \\ &= \frac{em(A_1,P_1,k,u,q)}{n!h(P_0,1,q)} = \frac{em(A_1,P_1,k,u,q)}{h(P_1,1,q)}.\end{aligned}$$

In addition, we know from Lemma 7.3 that all complete programs P with n variables have the same ratio $em(P,k,u,q)/h(P,1,q)$. From this we know that for an arbitrary program P_0,

$$\frac{em(P_0,k,u,q)}{h(P_0,1,q)} \le \frac{em(A_1,P_1,k,u,q)}{h(P_1,1,q)} = \frac{em(P_1,k,u,q)}{h(P_1,1,q)},$$

where P_1 is complete. Hence complete programs are extremal. □

8. Calculating $r(n,k,u,q)$.

Proof of Theorem 3.2. By Theorems 5.1, 5.2, and 5.3 we know that if $n \le ku$ or $u \ge q$, then $r(n,k,u,q) = 0$; and if $ku < q$ and $ku < n$, then $r(n,k,u,q) = 1$. In the remaining part of the proof we disregard such cases.

Consider a complete program P. We represent the program by a 0,1-matrix and assume no repetitions, i.e., P has $\binom{n}{q}$ rows. Each row in the matrix corresponds to a transformation group. We may reconstruct the transformation group by copying the row in q copies and replacing the ith nonzero with "q" in the ith copy for $i = 1,\dots,q$.

Now apply a partition A on P, and consider a specific row in P. The 1's which are in partition sets where there are $u+1$ 1's or more will result in extra misses. The cache set can only handle u variables, and the worst case program implies that the variables are referenced cyclically, resulting in only extra misses.

On the other hand, 1's which are in a set with u 1's or less will give no extra misses. Here the cache set can contain all the variables.

Assume that the ith partition set A_i of the partition A has w_i columns. How many rows (permutations) have j 1's in A_i?

Since P contains one copy of each possible permutation of q 1's in n positions, it is an easy combinatorial task to give an exact answer to this question. There are $\binom{w_i}{j}$ different ways of distributing these 1's in A_i, and there are $\binom{n-w_i}{q-j}$ different ways of distributing the other $q-j$ 1's in the remaining $n-w_i$ positions. We obtain extra misses only if $j \ge u+1$, and then we obtain j extra misses. The contribution to the number of extra misses from the ith set is thus

$$\sum_{j=u+1}^{\min(q,w_i)} j \binom{w_i}{j} \binom{n-w_i}{q-j}.$$

By adding the contributions from all sets, we get two alternative formulas for $r(n,k,u,q)$ with any partition A:

$$\begin{aligned} r(n,k,u,q) &= \frac{1}{q\binom{n}{q}} \min_A \left(\sum_{i=1}^{k} \sum_{j=u+1}^{\min(q,w_i)} j \binom{w_i}{j} \binom{n-w_i}{q-j} \right) \\ &= 1 - \max_A \frac{1}{q\binom{n}{q}} \sum_{i=1}^{k} \sum_{j=1}^{\min(u,w_i)} j \binom{w_i}{j} \binom{n-w_i}{q-j}. \end{aligned}$$

Essentially, in the first form we count the number of 1's which appear. In the second form, we count the number of 1's which do not appear and subtract this number from the total number of 1's, which is $q\binom{n}{q}$.

Using Theorem 3.7, we may invoke the set sizes of uniform and quasi-uniform partitions. Hence, by inserting in the above formula

$$(w_1,\dots,w_k) = \left(i, \left\lceil \frac{n-i}{k-1} \right\rceil, \dots, \left\lceil \frac{n-i}{k-1} \right\rceil, \left\lfloor \frac{n-i}{k-1} \right\rfloor, \dots, \left\lfloor \frac{n-i}{k-1} \right\rfloor \right),$$

where $i = \lceil n/k \rceil, \max(\lceil n/k \rceil + 1, \lceil \frac{un}{q-1} \rceil), \ldots, n$, we obtain the formula in Theorem 3.2. Since we have at most three set sizes, $i, \lceil \frac{n-i}{k-1} \rceil$, and $\lfloor \frac{n-i}{k-1} \rfloor$, we obtain only three terms in the sum. □

Proof of Theorem 3.4. Suppose that P_0 is a complete matrix and A_0 is an optimal mapping for P_0. Hence

$$r(n,k,u,q) = \max_{\text{programs } P \text{ with } n \text{ variables}} \frac{em(P,k,u,q)}{h(P,1,q)} = \frac{em(P_0,k,u,q)}{h(P_0,1,q)} = \frac{em(A_0,P_0,k,u,q)}{h(P_0,1,q)}.$$

We next construct a program P_1 by adding to program P_0 a new variable, of size exactly one block, as the very last reference. Since this variable is not referenced before, it is a miss using any cache. Hence we can obtain an optimal mapping A_1 to the program P_1 by adding the new variable to any set. The program P_1 has $n+1$ variables but may not be optimal. Thus

$$\frac{em(P_0,k,u,q)}{h(P_0,1,q)} = \frac{em(P_1,k,u,q)}{h(P_1,1,q)} \leq \max_{\text{programs } P \text{ with } n+1 \text{ variables}} \frac{em(P,k,u,q)}{h(P,1,q)} = r(n+1,k,u,q). \quad \square$$

9. Discussion. In this section we discuss the practical implications of the results as well as the assumptions on which they are based. Subsection 9.1 demonstrates how our results can be used for obtaining a bound on the worst case performance. In subsection 9.2 we discuss how the results can be used for comparing set-associative caches with direct-mapped caches, or other set-associative caches. In the remaining subsections we discuss some of the restrictions and assumptions in the definition of the problem. More specifically, in subsection 9.3 we discuss how replacement policies other than LRU would affect our results. Subsection 9.4 discusses the restriction that each variable must fit in one cache block. This discussion shows that the results obtained can be used also for programs with large variables. In subsection 9.5 we discuss large scientific programs which manipulate large matrices in different ways, e.g., matrix multiplication and addition.

9.1. Applying the results. The results reported here make it possible to obtain optimal worst case bounds on the cache hit ratio for set-associative and direct-mapped caches. This can best be understood by considering the following example.

Consider a program P, with n variables, for which we have obtained a certain hit ratio X using a $(1,q)$-cache. Now we are interested in the hit ratio Y for P using an optimal mapping of variables to memory addresses for a different cache organization—a (k,u)-cache—such that $q < ku$ and $u < q$. We know that $X \leq h(P,1,q)/m(P)$ and that $Y = h(P,k,u)/m(P)$. Consequently, we know from Theorem 3.1(ii) that $X(1 - r(n,k,u,q)) \leq Y$. One practical implication of this is that if we should obtain a hit ratio which is smaller than $X(1-r(n,k,u,q))$ using a (k,u)-cache, then we know that the mapping of variables to memory addresses is not optimal. Generally we do not know if $X = h(P,1,q)/m(P)$ or not, and Theorem 3.1(ii) gives an optimal lower bound on $h(P,k,u)/m(P)$. Consequently, based on the information we have the lower bound on Y is optimal.

In the above example the results were used for evaluating the performance (hit ratio) of one particular program P. However, it is also possible to use our results when

evaluating different cache architectures, e.g., $r(100, k, u, q)$ tells us how much worse a hit ratio we may obtain for a (k, u)-cache compared to a $(1, q)$-cache for programs with 100 variables or less (Lemma 3.3 shows that $r(n, k, u, q)$ is an increasing function of n). However, the results can also be used for more complex scenarios. Consider, for example, two cache memory systems: in system one we have a $(1, 20)$-cache, and in system two we have a $(20, 2)$-cache. The main memory access time is the same in both cases, and the access time for the $(1, 20)$-cache is eight times faster than a main memory access; the access time for the $(20, 2)$-cache is, on the other hand, ten times faster than a main memory access, i.e., the $(20, 2)$-cache is slightly faster than the $(1, 20)$-cache.

Let M be the access time for one memory reference on the main memory, and let C denote the access time on the cache memory. For a program P with length L and hit ratio H on system one we obtain the total access time (AT).

$$AT(P) = L(CH + M(1 - H)) = L(M - (M - C)H).$$

Let H' be the hit ratio with system two. From Theorem 3.1 we know that $H(P)(1 - r(n, k, u, q)) \leq H'(P) \leq 1$. Lower and upper bounds of the ratio $AT_2(P)/AT_1(P)$ when using caches with access times C_1 and C_2, respectively, follow:

$$\frac{C_2/C_1}{M/C_1 - (M/C_1 - 1)H} \leq \frac{AT_2(P)}{AT_1(P)} \leq \frac{M/C_1 - (M/C_1 - C_2/C_1)H(1 - r(100, k, u, q))}{M/C_1 - (M/C_1 - 1)H}.$$

In section 11.3 the bounds $f_1(H)$ and $f_2(H)$, respectively, are plotted as a function of the program parameter H when system one is a $(1, 20)$-cache with $M/C_1 = 8$, and system two is a $(20, 2)$-cache with $M/C_2 = 10$, i.e., $C_2/C_1 = 1.25$. Here we consider programs with 100 variables or less, and we thus need $r(100, 20, 2, 20) = 0.1652$. The functions $f_1(H)$ and $f_2(H)$ are interesting when we want to compare the two cache organizations.

9.2. Comparing set-associative and direct-mapped caches. Consider two set-associative cache memories. Cache M_1 is a (k, uc_1)-cache, and M_2 is a (kc_2, u)-cache. We assume that $c_1 \geq 1$ and $c_2 \geq 1$.

THEOREM 9.1.

$$\frac{h(P, kc_2, u)}{h(P, k, uc_1)} \geq 1 - r(nk, c_2, u, c_1)$$

for all programs P with n variables.

Proof. We first consider an arbitrary program P with n variables and an optimal mapping A_1 for M_1, i.e., we have $h(A_1, P, k, uc_1) = h(P, k, uc_1)$. We then construct another program P' with $n' = nk$ variables and a mapping A_1'. P' is identical to P with the exception that $n' - n$ references to the $n' - n$ new variables are added at the end of the program; one reference is added for each new variable. Mapping A_1 is used to define a mapping A_1'. Mapping A_1' is identical to A_1 for the n original variables. The remaining $n' - n$ variables are mapped in such a way that the number of variables in each set equals n. The mapping of the variables $n' - n$ does not affect the number of hits since the references to these variables are initial references, which are always cache misses according to LRU policy. As a result, $h(A, P, k, uc_1) = h(A', P', k, uc_1)$ using any mapping A, and $h(P, kc_2, u) = h(P', kc_2, u)$.

P' can be viewed as the sum of k interleaved programs P_i', $i = 1, \ldots, k$. A program P_i' contains the references to the variables in set i $(1 \leq i \leq k)$ in M_1 using mapping A_1'.

We then consider a mapping A_2 for M_2 such that variables which are mapped to set i in A_1' $(1 \le i \le k)$ are mapped to one of the c_2 sets $i + kj$ $(j = 0, \ldots, c_2 - 1)$ in A_2. For instance, if $k = 2$ and $c_2 = 2$, then all variables mapped to set zero in A_1' are mapped to sets zero or two in A_2, and all variables mapped to set one in A_1' are mapped to sets one or three in A_2.

The mapping A_2 defines, of course, a mapping of the variables in the set i in A_1', i.e., the variables of the program P_i'. Denote this submapping of A_2—the mapping of the variables of P_i' only—by $A_{2,i}$. Using this mapping, each of the k sets in M_1 can be treated as a fully associative cache for P_i' containing uc_1 blocks. This is compared to a (c_2, u)-cache. Using Theorem 3.1 and Lemma 3.3 we have

$$\frac{h(P_i', c_2, u)}{h(P_i', 1, uc_1)} \ge 1 - r(nk, c_2, u, uc_1)$$

for all programs P_i'.

For any two positive sequences $a_1, \ldots, a_n$ and $b_1, \ldots, b_n$ we have $\sum_i a_i / \sum_i b_i \ge \min_i a_i/b_i$. Hence,

$$\frac{\sum_{i=1}^{k} h(P_i', c_2, u)}{\sum_{i=1}^{k} h(P_i', 1, uc_1)} \ge 1 - r(nk, c_2, u, uc_1).$$

The subprograms P_i' were constructed from the optimal mapping A_1' for the program P'. It thus follows that

$$h(P', k, uc_1) = \sum_{i=1}^{k} h(P_i', 1, uc_1) = \sum_{i=1}^{k} h(A_1', P_i', 1, uc_1).$$

The mapping A_2 is not usually optimal; hence

$$h(P', kc_2, u) \ge h(A_2, P', kc_2, u) = \sum_i h(P_i', c_2, u).$$

It follows that

$$\frac{h(P, kc_2, u)}{h(P, k, uc_1)} \ge 1 - r(nk, c_2, u, uc_1)$$

for all programs P with n variables. □

9.3. Other replacement policies. In this paper we have used the LRU replacement policy throughout. In this subsection we will, however, show that some of the results can be applied to systems with other replacement policies.

Consider a fully associative cache, i.e., a $(1, q)$-cache, and a direct-mapped cache, i.e., a $(k, 1)$-cache.

THEOREM 9.2.

(i) *With any replacement policy we have*

$$\frac{h(P, k, 1)}{h(P, 1, q)} \ge 1 - r(n, k, 1, q)$$

for all programs P with n variables. We assume the same replacement policy for the $(1, q)$-cache and the $(k, 1)$-cache.

(ii) *Consider a program P with n variables and suppose that the hit ratio $h(P,1,q)/m(P)$ for P with a $(1,q)$-cache is known. For all replacement policies then*

$$\frac{h(P,k,1)}{m(P)} \geq (1 - r(n,k,1,q))\frac{h(P,1,q)}{m(P)}.$$

Proof. Consider a hit in the $(1,q)$-cache. We now temporarily redefine the (q,n)-hit vectors. We denote by q the variable which, according to the present replacement policy, is next to be excluded from the cache in the case of a cache miss. The variables marked with "1" are the remaining variables in the cache.

Now the same proofs can be used for showing that complete programs represent the worst case scenario when comparing a direct-mapped cache with a fully associative cache. We do not know, however, if it is possible to obtain a sequence of (q,n)-hit vectors corresponding to a complete program. Consequently, Theorem 9.2 follows from Theorem 3.1 and the fact that the complete program is still the worst case program when comparing a fully associative cache to a direct-mapped cache. In contrast to Theorem 3.1, however, the bound is not necessarily optimal. □

9.4. Large variables. In some cases, one variable may be too large to fit within one cache block. Examples of such variables are strings, records, and arrays which are accessed sequentially. (We will discuss matrices separately in the next subsection.) Accesses to such large variables consist of a number of clustered accesses to the different blocks in which the variable is contained.

THEOREM 9.3. *Consider programs P with n large variables, each consisting of v blocks. These blocks are mapped to consecutive memory addresses. Each access to one of these variables results in a sequence of accesses to the v blocks.*

(i)
$$\frac{h(P,k,u)}{h(P,1,q)} \geq 1 - r(n, \lfloor k/v \rfloor, u, \lceil q/v \rceil)$$

for all programs P with n variables, each variable consisting of v blocks.

(ii) *Suppose that the hit ratio $h(P,1,q)/m(P)$ for P with a $(1,q)$-cache is known. Then*

$$\frac{h(P,k,u)}{m(P)} \geq (1 - r(n, \lfloor k/v \rfloor, u, \lceil q/v \rceil))\frac{h(P,1,q)}{m(P)}.$$

Proof. Consider a $(1,q')$-cache, where $q' = v\lceil q/v \rceil$, and a (k',u)-cache, where $k' = v\lfloor k/v \rfloor$. Since $q' \geq q$ and $k' \leq k$, it is clear that $h(P,k,u)/h(P,1,q) \geq h(P,k',u)/h(P,1,q')$ for any program P. As a result, it is sufficient to show that

$$\frac{h(P,k',u)}{h(P,1,q')} \geq 1 - r(n, \lfloor k/v \rfloor, u, \lceil q/v \rceil) = 1 - r(n, k'/v, u, q'/v)$$

for all programs P with n variables with a size of v blocks each.

Consider the set of mappings for the $(1,q')$-cache where the first block in each variable is mapped to set i, where $i = 0, v, 2v, \ldots, k' - v - 1$. Let $h'(P,k',u)$ be the maximum number of cache hits for program P within this set of mappings. Obviously, $h'(P,k',u) \leq h(P,k',u)$. If we restrict ourselves to these mappings, we end up in a situation which is identical to having n one block variables and comparing a $(1,q'')$-cache to a (k'',u)-cache, where $q'' = q'/v = \lceil q/v \rceil$ and $k'' = k'/v = \lfloor k/v \rfloor$.

For such systems Theorem 3.1 guarantees the following.

(i) The worst case ratio of cache hits comparing two caches is given by

$$\inf_P \frac{h(P,k'',u)}{h(P,1,q')} = 1 - r(n,k'',u,q''),$$

where the infimum is taken over all programs P with n variables.

(ii) Consider a program P with n variables, and suppose that the hit ratio $h(P,1,q'')/m(P)$ for P with a $(1,q'')$-cache is known. Then an optimal estimate of the hit ratio for the program P using a (k'',u)-cache is given by

$$\inf_P \frac{h(P,k'',u)}{m(P)} = (1 - r(n,k'',u,q''))\frac{h(P,1,q'')}{m(P)}.$$

Consequently, Theorem 9.3 follows from Theorem 3.1 and the fact that

$$\begin{aligned} h(P,k,u)/h(P,1,q) &\geq h(P,k',u)/h(P,1,q') \\ &\geq h'(P,k',u)/h(P,1,q') = h(P,k'',u)/h(P,1,q'') \end{aligned}$$

for any program P with n variables consisting of v blocks. □

9.5. Scientific programs with large matrices. If the colliding variables are two elements in a large matrix, then the compiler can obviously not map them independently of each other. One scenario where these types of cache collisions occur are scientific applications, where large matrices are manipulated in different ways. In such programs, there are large loops that access rows, columns, diagonals, etc. Such loops contain long sequences of memory accesses for which the addresses are separated by a fixed distance called the *stride*. Some scientific applications are not well suited to cache memories, since the matrices are too large to fit into a cache. The bound is obviously valid (but not optimal) for such programs. In some cases, however, the access pattern can be adapted to cache memory systems, e.g., by dividing the computation into a number of steps and then accessing a limited part of the matrices in each step. In other cases, the matrix may be small enough to fit into the cache.

Consider a system with k cache sets of unit size and a program accessing a $b \times k$-matrix, i.e., a matrix with b rows and k columns, which is mapped row-by-row starting at memory address zero. This means that the ith element in each row is mapped to set i. As long as the program accesses each row sequentially, there are no collisions, i.e., there will be no cache misses after the first iteration through a row. If, however, the program accesses each column sequentially, there will be a collision on every access, i.e., for column j all memory accesses will be made to cache set j. As a result, there will be no cache hits when we iterate through a column.

It has been shown that these kinds of collisions can be handled by adding a number of dummy columns or, alternatively, dummy rows. By adding a dummy column in the example above, we can access a column sequentially with a minimum number of collisions [15]. Other access patterns, e.g., diagonals, can be handled in a similar way. However, for some combinations of access patterns some collisions always remain [15], i.e., if we eliminate the collisions for columns and diagonals, we may create conflicts for other access patterns.

We are interested in the minimum ratio $h(P,k,u)/h(P,1,q)$ for all programs P. It is clear that the minimum ratio occurs for programs with exactly q accesses in each loop. This is explained by the fact that, except for the initial misses, there will be no misses in the $(1,q)$-cache as long as the number of accesses in each iteration in the

loop is less than or equal to q. When the number of accesses in each loop iteration exceeds q there will be no hits at all using the $(1, q)$-cache. Clearly, the number of access conflicts per iteration is a nondecreasing function of the number of accesses in each loop iteration when using the (k, u)-cache.

By using the same kind of proof as in [15], we see that the worst case programs are the ones where all loops are equally long, and all strides occur equally frequently. For these kinds of programs we cannot improve the hit ratio for a (k, u)-cache by adding dummy columns. As a result, we know that the worst case program contains all combinations of the possible (bk, q)-hit vectors. (There are bk elements in the array, i.e., $n = bk$.) This is, in fact, the same kind of situation as for programs with any arbitrary access pattern and where we are free to map any variable to any address. However, in the case of matrices we obtain uniform partitions. Consequently, by disregarding the quasi-uniform partitions in the formula in Theorem 3.2 we obtain an optimal bound on programs containing large matrices. Disregarding quasi-uniform partitions has a very limited impact on $r(n, k, u, q)$. The limited possibility of mapping elements in an array independently of each other is thus almost completely compensated for by the fact that the array accesses must be separated by a fixed distance, i.e., by the stride.

Another, somewhat unusual, approach is to use nonlinear mapping functions. When ordinary linear mapping is used, every kth memory block is mapped to the same set. However, in some cases nonlinear mapping functions have been suggested [1, 18]. In such cases, the problem of optimally mapping variables to memory addresses is transformed into the problem of defining an optimal mapping function. In this case, different parts of large arrays can be mapped independently of each other.

10. Conclusions. The average behavior of set-associative caches has been studied extensively. One rule of thumb is that a $(k, 1)$-cache gives about the same hit ratio as a $(k/4, 2)$-cache [3]. On [3, p. 421] there is a table where the hit ratio using different cache sizes and different degrees of associativity is shown for a "typical" work load. A smaller version of the same table is also shown in [5]. These tables show that the hit ratio gain resulting from going from a $(k, 1)$-cache to a $(k/2, 2)$-cache is larger than the gain resulting from going from a $(k/2, 2)$-cache to a $(k/4, 4)$-cache; going from a $(k/4, 4)$-cache to a $(k/8, 8)$-cache results in an even smaller gain.

The plot in section 11.1 shows that the worst case scenarios behave rather differently to the average case scenarios. When $q << n$ (left side of the plot) we see that the maximum performance drop of using a $(k/2, 2)$-cache instead of a $(1, k)$-cache $(q = k)$ is smaller than the maximum performance drop of using a $(k, 1)$-cache instead of a $(1, k)$-cache. The plot also shows that the maximum performance drop of using a $(k/4, 4)$-cache instead of a $(1, k)$-cache $(q = k)$ is smaller than the maximum performance drop of using a $(k/2, 2)$-cache instead of $(1, k)$-cache. This is what one would intuitively expect. Quantifying the different worst case scenarios would not be possible, however, without the result presented here.

The plot in section 11.1 also shows that the worst case behavior is counter-intuitive (at least for us) and does not conform to the average case behavior when q is almost as large as n (right side of the plot). In this case the maximum performance drop of using a $(k/2, 2)$-cache instead of a $(1, k)$-cache $(q = k)$ is larger than the maximum performance drop of using a $(k, 1)$-cache instead of a $(1, k)$-cache and so on, i.e., the curves cross each other. In order to understand this we will consider the case when $n = 7$ and $q = k = 6$. In this case the worst case program corresponds to the following matrix of (q, n)-hit vectors.

q	1	1	1	1	1	0
1	q	1	1	1	1	0
1	1	q	1	1	1	0
1	1	1	q	1	1	0
1	1	1	1	q	1	0
1	1	1	1	1	q	0
q	1	1	1	1	0	1
1	q	1	1	1	0	1
1	1	q	1	1	0	1
1	1	1	q	1	0	1
1	1	1	1	q	0	1
1	1	1	1	1	0	q
q	1	1	1	0	1	1
1	q	1	1	0	1	1
1	1	q	1	0	1	1
1	1	1	q	0	1	1
1	1	1	1	0	q	1
1	1	1	1	0	1	q
q	1	1	0	1	1	1
1	q	1	0	1	1	1
1	1	q	0	1	1	1
1	1	1	0	q	1	1
1	1	1	0	1	q	1
1	1	1	0	1	1	q
q	1	0	1	1	1	1
1	q	0	1	1	1	1
1	1	0	q	1	1	1
1	1	0	1	q	1	1
1	1	0	1	1	q	1
1	1	0	1	1	1	q
q	0	1	1	1	1	1
1	0	q	1	1	1	1
1	0	1	q	1	1	1
1	0	1	1	q	1	1
1	0	1	1	1	q	1
1	0	1	1	1	1	q
0	q	1	1	1	1	1
0	1	q	1	1	1	1
0	1	1	q	1	1	1
0	1	1	1	q	1	1
0	1	1	1	1	q	1
0	1	1	1	1	1	q

Consider a $(6, 1)$-cache. The optimal mapping for this case is to map two variables to one set, and one variable to each of the five other sets. The number of extra misses in this case is 10. Then consider a $(3, 2)$-cache. The optimal mapping for this case is to map three variables to one set, and two variables to each of the other two sets. The number of extra misses in this case is 12. Consequently, the worst case program performs better on a $(6, 1)$-cache than on a $(3, 2)$-cache using the LRU replacement policy. In this case the worst case program is a program with seven variables and seven equally long loops, where each loop cyclically references six of the seven variables; each loop corresponds to one of seven possible ways of selecting six variables. One contribution of this study is that this kind of counter-intuitive behavior can be identified and indeed even quantified.

It is well known that one problem with direct-mapped (and set-associative) caches as compared to fully associative caches is that they exhibit an extremely poor worst case performance [4]. Without our results, however, it has not previously been possible to quantitatively compare the worst case behavior of direct-mapped and set-associative caches to fully associative caches. Section 11.2 displays a plot of this performance relation.

On [3, pp. 408–425] there is a very comprehensive discussion of the performance implications of various cache parameters, e.g., the LRU replacement policy outperforms random replacement, particularly for caches with relatively few blocks (up to a couple of thousand blocks). Moreover, the "optimal" block size increases with increasing cache size. Based on these observations it is reasonable to assume that large caches will have large blocks and that the LRU replacement policy is used within each set. Consequently, the LRU assumption made in this report is reasonable. The assumption that each variable can be mapped to one block becomes more reasonable for large cache blocks.

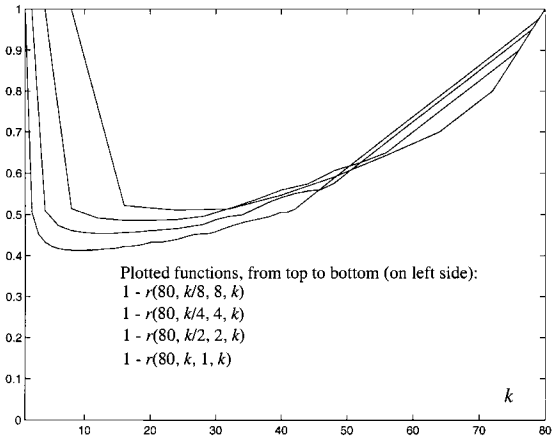
The discussion in section 9 shows that our results are applicable to a number of real scenarios. Moreover, the discussion in section 9 shows that a number of our assumptions with regard to the replacement policy, variable sizes, etc., can be relaxed, thus making the results applicable to a large number of cases.

11. Graphics section.

11.1. Increasing degree of associativity. This plot shows the worst case number of cache hits for four degrees of associativity, compared to full associativity. Here we compare only organizations with the same number of cache memory blocks. The worst case corresponds to the infinum

$$\inf_P \frac{h(P,k,u)}{h(P,1,q)} = 1 - r(80,k,u,q)$$

taken over programs of at most 80 variables.



Notes.

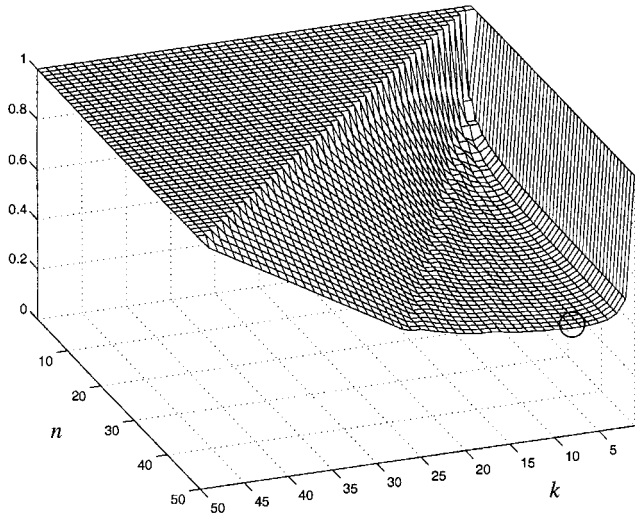
(1) The function r is defined only for integers—values representing noninteger arguments are plotted by linear interpolation.

(2) The improvement in a relative number of cache hits for worst case programs, as a function of the associativity, occurs fairly slowly. This is in accordance with [5]; see discussion in section 10.

(3) If the number of cache memory blocks (q) is close to the number of variables (n) (right side of the plot), less associativity can be favorable compared to more associativity with a constant number of cache memory blocks. In section 10 we describe programs which provide examples of this phenomenon.

11.2. Direct mapping versus full associativity. This plot shows the worst case hit ratio comparing a direct-mapped cache with a fully associative cache. The cache has k blocks, and programs of n variables are considered. The function plotted is

$$\inf_P \frac{h(P,k,1)}{h(P,1,k)} = 1 - r(n,k,1,k).$$

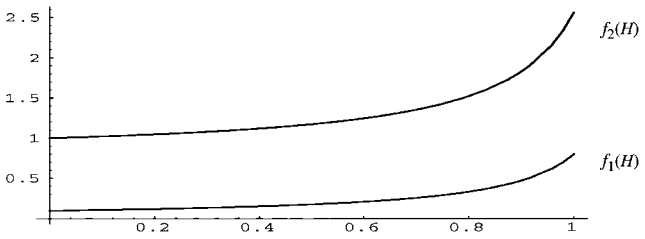


The minimum value for $1 - r(n,k,1,k)$ for n and k at most 50 is 0.4262 and occurs at $(n,k) = (50,8)$.

Suppose we want to compare a direct-mapped cache to a fully associative cache with equal number of cache blocks, and we are interested in the number of cache hits for programs with at most 50 variables. Then the ratio of cache hits in the two cases can vary more for different programs if we have eight memory blocks than any other number of cache blocks. If we have eight memory blocks in the cache, the ratio is in the worst case 0.4262.

11.3. Maximal and minimal access time. As described in section 9, estimates on cache hits can easily be transformed to estimates on access times. Consider a (20,2)-cache with cache access time 1/8; the main memory access time is normalized to 1. Denote the hit ratio for the program P on this system by H and the access time $A_1(H)$. Next the same program is to be executed on a (1,20)-cache with cache access time 1/10. Here optimal upper and lower bounds $f_1(H)$ and $f_2(H)$ for the access time $A_2(H)$ on the second system, relatively $A_1(H)$, are plotted.

$$f_1(H) = \frac{0.8}{8-7H} \le \frac{A_2(H)}{A_1(H)} \le \frac{8-5.635H}{8-7H} = f_2(H).$$



Notes.

(1) The lower bound is trivial, while the upper bound follows from Theorem 3.1. Both bounds are optimal, i.e., there are programs with any access time in the interval given by $f_1(H)$ and $f_2(H)$.

(2) Usually higher associativity results in slightly higher cache access time. If this relationship is known, i.e., if $C(k, u)$ is known, the above argument can be extended to provide optimal associativity in the sense of minimal access time for worst case programs.

MARKOV PAGING*

ANNA R. KARLIN†, STEVEN J. PHILLIPS‡, AND PRABHAKAR RAGHAVAN§

Abstract. This paper considers the problem of paging under the assumption that the sequence of pages accessed is generated by a Markov chain. We use this model to study the fault-rate of paging algorithms. We first draw on the theory of Markov decision processes to characterize the paging algorithm that achieves optimal fault-rate on any Markov chain. Next, we address the problem of devising a paging strategy with low fault-rate for a given Markov chain. We show that a number of intuitive approaches fail. Our main result is a polynomial-time procedure that, on any Markov chain, will give a paging algorithm with fault-rate at most a constant times optimal. Our techniques show also that some algorithms that do poorly in practice fail in the Markov setting, despite known (good) performance guarantees when the requests are generated independently from a probability distribution.

Key words. competitive analysis, paging, Markov chains, locality of reference

1. Introduction.

This paper considers the problem of paging in a two-level store under the assumption that the sequence of pages accessed (henceforth called the *reference string*) is generated by a Markov chain. Each page of virtual memory is represented by a state (or node) of the Markov chain M, whose transition probabilities p_{ij} specify the probability that an access to i is immediately followed by an access to j.

Sleator and Tarjan [19] initiated the worst-case study of paging, introducing a style of worst-case analysis that has come to be known as *competitive analysis* [12]. We wish to address some shortcomings of the traditional adversarial analysis of paging [19]. Borodin et al. [2] provided an important step toward bridging the gap between such worst-case analysis and reality by providing a model that captured the essential aspects of locality of reference in the reference string. Here we follow their lead and assume that the reference string is generated by a Markov chain (thereby removing the adversary's role).

We refer to on-line paging with the reference string generated by such a Markov chain as *Markov paging*. We focus on questions such as the following: Given a Markov chain, what is the best paging algorithm for reference strings generated by it and how can this algorithm be computed? Is there a simple algorithm that performs near-optimally on every Markov chain? Can Markov paging explain why some paging algorithms perform poorly in practice?

Some salient features of our work are the following:

- There is recent interest in the systems community in designing paging algorithms that adapt to the locality characteristics of a program [5, 15]. Thus insights derived from theoretical studies may have an impact on implementations.
- Markov paging, like the access graph model in [2, 10], offers a clean theoretical abstraction for locality of reference in a program. Unlike the models in [2, 10, 12, 19], there is no adversary generating the reference string, much as in a real program. Furthermore, certain simple properties of real programs—such as the fact that a data-dependent loop typically gets executed many times before exiting—can be modeled well.
- Practitioners study the *page-fault rate* for a program and a paging algorithm, rather than competitiveness. Page-fault rate has little meaning in an adversarial model but is eminently suited to a probabilistic model. In Markov paging, there is (as we shall see) a precise meaning to the page-fault rate of an algorithm as well as the best page-fault rate achievable on the Markov chain. Note that if each request is drawn independently from a probability distribution, the problem of devising the paging algorithm with lowest fault-rate has an easy solution [9].
- Markov paging enables us to provide a mathematical basis for the poor performance of certain paging algorithms (such as *random replacement* (RR) and *frequency count* (FC)). For example, the FC algorithm can be bad in the Markov paging setting, whereas one might think that on a probabilistic input this algorithm would perform well.
- Somewhat surprisingly, we find that several plausible approaches to devising paging algorithms will fail for Markov paging. For example, all *marking algorithms*, provably best in an adversarial model, suffer from page-fault rates that are far from optimal in Markov paging. This includes probabilistic versions of the FAR algorithm of [2, 10]. We also find that natural approximations of the optimal off-line paging algorithm MIN are far from optimal in Markov paging.
- We present an on-line paging algorithm that is computable in polynomial time and achieves a fault-rate within a constant times the best possible fault-rate on every Markov chain.

While our approach enables us to move away from competitive analysis toward a performance measure of greater interest to practitioners, two practical limitations of our work should be noted. First, in practical settings, page reference sequences may not be accurately modeled by a Markov chain in which pages are equated with chain states, since each page contains many memory locations. For example, a single page may have a number of basic blocks of code, and the next page to be referenced will depend on which basic block the program is currently in. Second, while the algorithm we present is polynomial-time computable, it requires the estimation and storage of commute times between pairs of pages of memory. The time and memory involved are considerable, so a simpler algorithm may be more applicable in practice.

1.1. Model. We have n pages that may be either in memory or on disk. Only k pages may be in memory at any time. An *on-line paging algorithm* is presented with a sequence of page requests. If the page currently requested is in memory, (a *hit*), no cost is incurred. However, if the page requested is not in memory (a *fault*), it must be fetched from the disk into memory for a unit cost. Furthermore, if there are already k pages in memory, one of the pages in memory must be evicted to make room for

the requested page. The decision of which page to evict must be made by the paging algorithm without detailed knowledge of future requests.

We now augment this basic model with a Markov source of references. Let M be an irreducible Markov chain whose state space is the set of n pages, and let A be an on-line paging algorithm. We define $f_A(M, k)$ to be the long-term frequency of faults incurred by A running on page request sequences generated by M and using a memory that can hold k pages. This is formalized in section 2. It is also shown in section 2 that there is an *optimal fault-rate* for every Markov chain M, which we denote by $f^*(M, k)$.

Note that we are not concerned here with the problem of inferring the Markov chain by observation of the page request sequence. We assume that the transition probabilities are already known. For example, they could be approximated to arbitrary accuracy by sampling a large enough initial prefix of the reference string.[1]

1.2. Related previous work. The underpinnings of competitive paging were laid in [12]. The literature of computer performance modeling and analysis contains related work, both theoretical and empirical. Denning [6] (and references therein) developed the *working set* model of program behavior for capturing locality of reference. Spirn [20] gives a comprehensive survey of models for program behavior. Franaszek and Wagner [9] studied a model in which every request is drawn independently from the same probability distribution. Shedler and Tung [18] and Lewis and Shedler [14] study paging in a Markov chain whose states represent *least recently used (LRU) stack distances*, a model convenient for studying the LRU paging algorithm. Denning and Spirn showed empirically that in order for a first-order Markov model to reasonably approximate real program behavior, it is necessary to separate data and instruction reference streams. Borodin et al. [2] and Irani, Karlin, and Phillips [10] have studied locality of reference in paging, though with an adversarial model.

Irani et al. [11] have studied other on-line problems when requests are independently drawn from a probability distribution. Vitter and Krishnan [21] considered the problem of prefetching into a cache when the reference string is generated by a Markov source (or mth-order Markov source). Under the assumption that there is always sufficient time to prefetch as many pages as wanted, Vitter and Krishnan show that data compression techniques can be used to obtain algorithms with optimal limiting page-fault rates.

1.3. Guided tour of the paper. Section 2 draws on the theory of Markov decision processes to characterize paging algorithms that achieve optimal fault-rate on any Markov chain. Theorem 2.1 shows that there is a memoryless, deterministic optimal on-line algorithm. Theorem 2.2 shows that there is a linear program that determines the optimal on-line algorithm, but this algorithm may have running time exponential in k. Section 3 shows that a number of plausible approaches for designing an efficient and provably good Markov paging algorithm will fail. Our main result, in section 4, gives an efficiently computable paging algorithm whose fault-rate is within a constant factor of the best possible on every Markov chain.

2. Markov decision theory and optimal paging. We begin by studying the relationship between page replacement policies and Markov decision theory [7].

A *Markov decision process* can be described as follows. Consider a discrete time Markov chain, whose state at time t is Y_t. After each observation of the system, one

[1] For this reason, the results we obtain assuming the Markov chain is known hold also in a limiting sense in the case where the Markov chain is not known.

of a set of possible actions is taken. Say that K_i is the set of actions possible when the system is in state i. Let A_t be the action taken at time t. A (possibly randomized) policy R is a set of functions $D_a(H_{t-1}, Y_t)$, where a is an action in K_{Y_t}, meaning that if H_{t-1} is the history of states and actions up to time $t-1$, and Y_t is the state at time t, then the probability action a is taken at time t is $D_a(H_{t-1}, Y_t)$. The actions can be such that they change the state of the system. We define this precisely by saying that $q_{ij}(a)$ is the probability of the system being in state j at the next instant, given that the system is in state i and action a is taken; i.e.,

$$Pr(Y_{t+1} = j \mid H_{t-1}, Y_t = i, A_t = a) = q_{ij}(a).$$

An additional set of parameters associated with a Markov decision process are costs: when the chain is in state i and action a is taken, a known cost w_{ia} is incurred.

Let $S_{R,T}$ be the expected cost of operating a system up to time T using policy R. ($S_{R,T} = \sum_{0 \le t \le T} \sum_j \sum_a P_R(Y_t = j, A_t = a) w_{ja}$.)

A standard cost criterion in Markov decision theory is to minimize the expected average cost per unit time, i.e., to find a policy R to minimize

$$\limsup_{T \to \infty} \frac{S_{R,T}}{T}. \tag{2.1}$$

We formalize the notion of expected faulted rate $f_A(M, k)$ of a paging algorithm A running on request sequences generated by the Markov chain M as follows. Let S be the state space of M (remember S is just the set of pages). Define the following augmented Markov chain whose state space is S'. A state in S' has two components: r and I. Here r is the most recent request, and I is a subset of S of size k representing the set of pages that are in memory immediately before servicing the request r.

When the system is in the state (r, I), and $r \notin I$, then there are k actions that can be taken by the on-line algorithm: for each $x \in I$, x can be evicted. The effect of the actions is described as follows. Suppose that p_{ij} are the transition probabilities of the underlying Markov chain. For each $r' \in S$,

$$Pr(Y_{t+1} = (r', I') \mid H_t, Y_t = (r, I), A_t = x) = p_{rr'},$$

where $I' = I \setminus \{x\} \cup \{r\}$.

When the system is in state (r, I) and $r \in I$, only the trivial action can be taken. The algorithm A is simply a policy for this Markov decision problem.

We set

$$w_{(r,I),a} = \begin{cases} 1 & \text{if } r \notin I, \\ 0 & \text{otherwise} \end{cases}$$

and define the expected fault rate $f_A(M, k)$ to be the expected average cost per unit time, as defined in (2.1) above.

The following two theorems instantiate basic results in Markov decision theory (see [7, Chapter 3, Theorem 2, and Chapter 6, Lemma 4]) to the case of Markov paging.

THEOREM 2.1. *For a given Markov chain there is an on-line page replacement policy that has minimum fault rate and is memoryless, time-invariant, and deterministic.*

Thus for the optimum algorithm, the decision of which page to evict on a fault depends only on the current request and the k pages in memory and is deterministic.

THEOREM 2.2. *The problem of computing the optimal on-line paging strategy on Markov chain M can be expressed as a linear programming problem in $n\binom{n}{k}$ variables.*

Note that this linear programming formulation gives us an algorithm for computing the optimal paging strategy on M whose running time may be exponential in k. We know of no technique to improve this upper bound, and this leads us to the study of efficiently computable strategies that approximate $f^*(M)$ well on every M. Note that when k is close to zero or to n, the linear program gives an efficient algorithm for computing the optimal on-line paging strategy. In fact, it is particularly instructive to consider the case $n = k + 1$, both for its own sake and because it has traditionally given good insights in paging [2, 8].

THEOREM 2.3. *When $n = k + 1$, for every M, there is an efficiently computable deterministic paging strategy that evicts only one of two fixed nodes ($k - 1$ pages are never evicted) whose fault-rate is at most $2f^*(M, k)$.*

Proof. Let G be the complete directed graph on n states, weighted by expected hitting times in M (the weight of edge (i, j) being $H_{i,j}$). For any memoryless, time-invariant, and deterministic algorithm, in any execution, the "hole" (the page that isn't in the memory) must eventually get into some cycle in G. Once in a cycle, the expected fault rate is just the reciprocal of the average edge weight around the cycle. Thus the optimal paging algorithm must use a *max mean cycle*. (See [13] for an algorithm to find a max mean cycle.) It follows that there is a cycle of length 2 that has page-fault rate at most twice optimal: just pick a pair (i, j) of adjacent vertices on a max mean cycle such that $H_{i,j}$ is at least the mean. Note that in the case that the chain is reversible, the mean hitting time around a cycle is independent of direction around the cycle, so there must be a cycle of length 2 with optimal page-fault rate. □

The following theorem compares the optimal on-line fault-rate to the optimal off-line fault-rate.

THEOREM 2.4. *The expected page-fault rate of the optimal on-line algorithm (OPT) is at most $O(\log k)$ times the expected page-fault rate of the optimal off-line algorithm (that sees the entire request string output by the Markov chain, then serves it optimally).*

This follows from the existence of an $O(\log k)$-competitive randomized paging algorithm [8], combined with the von Neumann minimax principle [16]. The bound is the best possible: when the Markov chain is the random walk on the $k + 1$ node complete graph K_{k+1}, any on-line algorithm has fault-rate $\Omega(\log k)$ times that of the optimal off-line algorithm [16].

3. Negative results. We begin this section by establishing that two algorithms that have been proposed and found to fare poorly in practice are far from optimal in Markov paging. Following this, we begin our quest for a simple, efficiently computable paging algorithm that has page-fault rate within a constant multiple of the best possible page-fault rate on every Markov chain. We show in this section that a number of intuitively "obvious" algorithms for Markov paging fail to achieve this goal and pave the way for our optimal algorithm in section 4. In all our negative results, $n = k + 1$; however, this is for simplicity of presentation only and can be generalized.

Remember that the hitting time $h_{x,y}$ from a state x in a Markov chain to another state y is defined to be the expected number of steps taken to first reach y starting from x, while the commute time $C_{x,y}$ is the expected number of steps to reach y from x and then return to x. We mention also that the commute time is related to the resistance [4], and thus the hitting times in most examples used here can be easily

computed by the electrically literate reader.

The RR paging algorithm will, on a fault, evict a random page in memory. Although optimal in the competitive setting against an adaptive on-line adversary [17], it performs relatively poorly in practice.

THEOREM 3.1. *There is a constant c such that for every $k > 2$, there is a Markov chain M for which $f_{RR}(M,k) \geq ckf^*(M,k)$.*

DEFINITION 3.2. *For positive integers a, b, the* lollipop graph $L(a,b)$ *is formed by attaching one end of a path through b nodes to a complete graph K_a on a nodes.*

Proof of Theorem 3.1. Let $n = k+1$, and let M be the Markov chain representing the simple random walk on $L(k-1,2)$. The maximum hitting time is $\Omega(k^2)$, say between nodes x and y. The algorithm that alternates its hole between x and y (as in Theorem 2.3) thus has a fault rate of $O(1/k^2)$, since the expected fault rate is $1/C_{x,y}$ by a result of renewal theory (see, for example, [7, p. 147]). Therefore $f^*(M,k)$ is $O(1/k^2)$. On the other hand, the expected time between faults incurred by RR is the average over all pairs of nodes x, y in the graph of the hitting time from x to y. This average is $O(k)$. □

The FC algorithm maintains, for each of the n pages, a count of the number of times that page has been accessed. On a fault, it evicts the page in memory that has been accessed least often. When every request is drawn independently from a probability distribution, FC converges to the optimal algorithm. However, it performs poorly in practice, since it ignores locality of reference. This is reflected by the fact that it is far from optimal in Markov paging (Theorem 3.3).

THEOREM 3.3. *There is a constant c such that for every $k > 2$, there is a Markov chain M for which $f_{FC}(M,k) \geq ckf^*(M,k)$.*

DEFINITION 3.4. *For positive integers a, b, the* forked lollipop graph $FL(a,b)$ *is formed from $L(a,b-1)$ by connecting two new nodes to the external end-node of the $(b-1)$-path.*

Proof of Theorem 3.3. Let $n = k+1$, and let M be the Markov chain representing the simple random walk on $FL(k/2,k/2)$. The two prongs have lowest stationary probability on this chain, so will eventually have the smallest frequency count in any request sequence. Thus FC will eventually alternate the "hole" (the node not in memory) between these two nodes. The expected time between faults incurred by FC is $O(k^2)$ (which is the expected hitting time from one prong to the other), whereas $f^*(M,k)$ is $O(1/k^3)$ (obtained by alternating the hole between one prong and a node in the clique). □

Next, we show that many algorithms that intuitively should perform well in Markov paging will in fact perform poorly on some Markov chains.

A class of on-line algorithms that one may expect to perform well are *marking algorithms*. Marking algorithms use a notion of *phases*. A *new page* is one that wasn't requested in the previous phase. A new phase begins with a request to a new page. When a page is requested, it is marked. As soon as k distinct pages are marked, the phase ends, and all pages become unmarked. A marking algorithm has the property that it never evicts a marked page.

It has been shown that there are optimal marking algorithms under competitive analysis for paging with locality of reference [2] as well as randomized paging algorithms (arbitrary request sequences) [8, 10]. Therefore, one might think that the same would hold when reference strings are generated from a Markov chain. The following theorem shows that our search for a good algorithm should exclude marking algorithms. The lower bound in the theorem cannot be improved, since there

is a marking algorithm A which is $O(\log k)$-competitive [8], and therefore there is a constant c such that $f_A(M,k) \le c(\log k) f^*(M,k)$ for any Markov chain M.

THEOREM 3.5. *There is a constant c such that for any $k > 2$, there is a Markov chain M for which $f_A(M,k) \ge c(\log k) f^*(M,k)$ for any marking algorithm A.*

Proof. Let M be the Markov chain corresponding to a simple random walk on the lollipop graph $L(k/2+1, k/2)$. Let y denote the node at the end of the path. A phase starts with a request at some vertex of the graph and ends just before all nodes in the graph have been requested. The last node to be requested starts a new phase. The important property of this Markov chain that defeats any marking algorithm is that once a node in the clique is requested, with high probability all the nodes in the clique will be requested before the node y is requested. Hence on average, almost half the phases will begin on y. By a standard argument, if a phase begins on y, any marking algorithm will incur an expected $\Omega(\log k)$ faults in the clique before the phase ends. Thus any marking algorithm will incur $\Omega(\log k)$ faults per phase on average. On the other hand, the on-line algorithm that alternately evicts a node in the clique and y will incur an average of one fault per phase. □

The optimal off-line algorithm for any reference string is commonly called MIN. MIN always replaces the page that will be requested furthest in the future. We now consider various on-line algorithms that mimic MIN on a Markov chain. The *maximum hitting time* (*MHT*) algorithm replaces, on a fault, that page in memory for which the *expected time* to the next request is the largest. Indeed, when the requests are drawn independently from a probability distribution, this algorithm performs well [9]; again, the locality of reference captured by Markov paging proves to be the undoing of this algorithm.

THEOREM 3.6. *For every $k > 10$, there is a Markov chain M on $k+1$ nodes and a constant c such that $f_{MHT}(M,k) \ge ckf^*(M,k)$.*

Proof. Consider the forked lollipop $G = FL(2k/3, k/3)$. Suppose that the Markov chain generating the reference string is the simple random walk on G.

If *MHT* is run on the reference string generated by this Markov chain, eventually one of the two prongs at the end of the path will be evicted. From either prong, the *MHT* is $4n^2/9$ to the other. On the other hand, the *MHT* from a prong to any node in the clique is $2n^2/9 + O(n)$. Thus the page not in memory (the "hole") will thereafter oscillate forever between the two prongs, so that $f_{MHT}(M,k)$ is $\Omega(1/k^2)$. The optimal algorithm will alternately evict a node in the clique and a prong with fault-rate $O(1/k^3)$. □

Let *LAST* be the algorithm that on a fault evicts the page that has the highest probability of being the last of the k pages in memory to be requested. An attractive variation on *LAST* is an algorithm we call max rank (*MR*) defined as follows. Suppose that at the time of a fault, S is the set of pages in memory. Then there is some permutation on S that describes the order in which these pages will subsequently be seen. For each page $i \in S$, and $1 \le j \le k$, let $p_i(j)$ be the probability that page i is the jth page in S that will be seen. Define the expected rank of page i, R_i to be $\sum_j j p_i(j)$. Then *MR* evicts the page $p \in S$ such that R_p is maximum.

THEOREM 3.7. *There is a constant c such that for any k* (i) *there is a Markov chain M such that $f_{LAST}(M,k) \ge ckf^*(M,k)$ and* (ii) *there is a Markov chain M such that $f_{MR}(M,k) \ge ckf^*(M,k)$.*

Proof. (i) Consider the Markov chain corresponding to the standard random walk on an undirected $k+1$ node cycle: all nodes are equally likely to be visited last. The following proof of this fact is credited by Broder [3], without further reference, to

Avrim Blum, Ernesto Ramos, and Jim Saxe, independently. Consider a point a on the cycle. Let its neighbors be b and c. Before visiting a, the walk will first visit one of its neighbors, say b. Given this fact, the probability that a is last is the probability that the walk will visit c, starting from b, before it visits a. This is clearly independent of the position of a.

Consequently, on a fault, $LAST$ might always evict the neighbor of the faulted node. Therefore, $LAST$ can have expected fault-rate $O(1/k)$ (since the expected time to hit a neighbor in a cycle is $O(k)$). On the other hand, the algorithm which alternates the hole between two antipodal points has an expected fault-rate of $O(1/k^2)$.

(ii) Consider a directed cycle on k nodes, with an extra node z that has edges to and from two antipodal nodes x and y. Let $p_{xz} = p_{yz} = p = 5/k$, and let $p_{zx} = p_{zy} = 1/2$. We show that starting from any node w on the cycle, the node of maximum rank is the node w^- that precedes w on the cycle. Indeed, the probability of avoiding half the cycle before hitting w^- by going through z is $p/2$, since the walk from w must reach z at the first chance (probability p), then can stay within $\{x, y, z\}$ for a while. The last time it leaves z before venturing outside $\{x, y, z\}$, it must move to whichever of x and y is closer to w^- (probability 1/2). The probability of avoiding half the cycle before hitting z is just p. Hence $R_{w^-} \geq k - 1 - \frac{p}{2}(\frac{k}{2} - 1)$, while $R_z \leq k - p(\frac{k}{2} - 1)$, and the former is larger for $k > 20$.

In contrast, the optimal on-line algorithm will evict z whenever there is a fault on the cycle. In this case, MR incurs $\Omega(k)$ times as many faults as the optimal on-line algorithm. □

Finally, an algorithm which is very close in spirit to our nearly optimal on-line algorithm of section 4 is the maximum commute time (MCT) algorithm. On a fault for page v, MCT evicts the page w in memory that maximizes the *commute time between v and w*.

THEOREM 3.8. *For every k, there is a Markov chain M for which $f_{MCT}(M, k) \geq kf^*(M, k)$.*

Proof. Consider the Markov chain corresponding to a directed cycle $k + 1$ nodes. Then every pair of nodes in the graph has the same commute time $(k+1)$. Therefore, on a fault at some node v, MCT might always evict the successor of v, incurring a fault on every request. Since the optimal on-line algorithm has a fault rate of $1/k$, the claim is proven. □

4. A provably good algorithm.

4.1. Description of the algorithm. The commute algorithm (CA) operates in phases. It keeps a window of the last $k + i$ requested pages, for some $0 \leq i \leq k$. (We assume $n \geq 2k$. For the case $n \leq 2k$, a simpler algorithm in the same spirit can be shown to have page-fault rate that is within a constant factor of optimal.) At the beginning of a phase the window is just the k most recently requested pages; these pages are resident in memory. When a "new" page p (one that hasn't been requested in the current or last phase) is requested, it is added to the window. The phase ends (and the window shrinks back to size k) when the $(k+1)$st distinct page is requested in the current phase. At that time, CA performs the minimum number of swaps necessary to ensure that the k most recently requested pages are again resident in memory, and the window again becomes the k most recently requested pages.

When the window contains $k + i$ pages, CA maintains a partial matching of i disjoint pairs of pages $\{(u_1, v_1), \ldots, (u_i, v_i)\}$. The commute algorithm maintains the following invariant:

For each j, $1 \le j \le i$, exactly one of u_j and v_j is in memory.

On a fault at u_j the page v_j is evicted, and vice versa. (Observe that *CA* is not a marking algorithm.) When a new page p is added to the window, it is paired with a page q that is in the window but not in the matching such that the commute time $C_{p,q}$ is maximized. The new pair is added to the partial matching, and may be involved in a single "switch," described below.

To describe the notion of a switch, we need some notation. For states a, b, u, v, we define the *relative distance* of the pair (a, b) to u to be

$$d[(a,b),u] = \frac{\min\{C_{a,u}, C_{b,u}\}}{C_{a,b}}.$$

Define also the relative distance of (a, b) to (u, v) to be

$$d[(a,b),(u,v)] = \min\{d[(a,b),u], d[(a,b),v]\} = \frac{\min\{C_{a,u}, C_{b,u}, C_{a,v}, C_{b,v}\}}{C_{a,b}}.$$

Intuitively, if $d[(a, b), u]$ is large, then both a and b are much further (in the commute time metric) from u than they are from each other. Similarly, if $d[(a, b), (u, v)]$ is large, then both a and b are much further from both u and v than they are from each other.

When a new pair (p, q) is added to the matching, *CA* does the following:

Case 1. If $d[(p, q), (u_j, v_j)] \le c_s$ for all j, then there is no switch: we service the fault at p by evicting q. Here c_s, the "constant for switching," is a suitably chosen constant; the reader can verify during the proof below that by choosing $c_s = 2$, all inequalities involving c_s hold.

Case 2 (switch). Otherwise, choose j so that $d[(p, q), (u_j, v_j)]$ is maximized, and replace the matched pairs (p, q) and (u_j, v_j) by (u_j, p) and (q, v_j). Service the fault at p by evicting whichever of u_j or v_j is in memory. This restores the invariant mentioned above.

In the upcoming proofs, we will distinguish one node in each pair, and therefore we may need to reverse the roles of u_ℓ and v_ℓ for some pairs, whether or not a switch has been done. The analysis below shows how this should be done.

As for the running time of *CA*, the complexity of computing the commute times in a Markov chain is polynomial in n. Therefore, with an initial preprocessing step that constructs the matrix of commute times, the complexity of running the algorithm *CA* is $O(k)$ per fault.

4.2. Analysis of the algorithm.

THEOREM 4.1. *There is a constant c such that for any Markov chain M and any k,*

$$f_{CA}(M,k) \le c f^*(M,k).$$

We prove the theorem by establishing a strict relationship between the pairs in the matching maintained by *CA*.

Consider one phase of the algorithm: let the rth subphase be the time when the window size is $k + r$. Let M_r and W_r be the matching and the set of pages in the window, respectively, during the rth subphase. Last, let V_{M_r} be the pages involved in M_r. Notice that $W_1 \subset W_2 \subset \cdots \subset W_k$ and $V_{M_1} \subset V_{M_2} \subset \cdots \subset V_{M_k}$. We will refer to one node in each pair (u_i, v_i) in M_r as *distinguished*. Without loss of generality the distinguished node will always be u_i.

We say that M_r is a *good* matching if the following hold:

1. For all pairs (u_i, v_i) and $(u_j, v_j) \in M_r$, $i \neq j$, $d[(u_i, v_i), u_j] \leq c_d$. Here c_d is the maximum allowable distance to distinguished nodes. The fact that u_j is involved in this condition, rather than v_j, is what makes u_j distinguished.
2. For each pair $(u_i, v_i) \in M_r$ and $a \in W_r \setminus V_{M_r}$, $d[(u_i, v_i), a] \leq c_u$. Here c_u is the maximum allowable distance to unmatched nodes.

The reader can verify during the proof that by choosing $c_u = 1$ and $c_d = 6$, all inequalities involving these constants hold.

We will be using the following facts about commute times.

LEMMA 4.2.

1. *Commute times satisfy the triangle inequality.*
2. $d[(a,b),c] \leq \frac{C_{a,c}}{C_{a,b}}$ *and* $d[(a,b),c] \leq \frac{C_{b,c}}{C_{a,b}}$.
3. $\frac{C_{a,c}}{C_{a,b}} \leq d[(a,b),c] + 1$ *and* $\frac{C_{b,c}}{C_{a,b}} \leq d[(a,b),c] + 1$.
4. $d[(a,b),c] \leq d[(a,b),d] + \frac{C_{c,d}}{C_{a,b}}$.
5. *If* $d[(x,y),z] \geq k_0$, $d[(a,b),x] \leq k_1$ *and* $d[(a,b),z] \leq k_2$, *then*

$$C_{x,y} \leq \frac{(k_1 + k_2 + 1)}{k_0} C_{a,b}.$$

Proof. Parts 1 and 2 follow immediately from the definition of commute time and relative distance. For part 3,

$$\frac{C_{a,c}}{C_{a,b}} \leq \frac{\min(C_{a,c}, C_{a,c} - C_{a,b}) + C_{a,b}}{C_{a,b}} \leq \frac{\min(C_{a,c}, C_{b,c})}{C_{a,b}} + 1 \leq d[(a,b),c] + 1,$$

where the second inequality follows from part 1. The other case is similar. For part 4,

$$d[(a,b),c] = \frac{\min(C_{a,c}, C_{b,c})}{C_{a,b}} \leq \frac{\min(C_{a,d}, C_{b,d}) + C_{d,c}}{C_{a,b}} = d[(a,b),d] + \frac{C_{d,c}}{C_{a,b}}.$$

Finally, part 5 follows from the application of part 2, part 1, and part 3 to give

$$C_{x,y} \leq \frac{C_{x,z}}{k_0} \leq \frac{(\min(C_{x,a}, C_{x,b}) + \max(C_{a,z}, C_{b,z}))}{k_0} \leq \frac{(d[(a,b),x] + d[(a,b),z] + 1)}{k_0} C_{a,b}.$$

Finally, use the fact that $d[(a,b),x] \leq k_1$ and $d[(a,b),z] \leq k_2$. ∎

LEMMA 4.3. *The matching maintained by CA is always good.*

Proof. The proof is by induction. Consider first the matching M_1 at the start of a phase: there is a single matched pair (p, q), consisting of a page p, whose request started the phase, and a page q that was chosen (out of the shrunk window of the k most recently requested pages) to maximize $C_{p,q}$. In this base case, the distinguished node can be chosen arbitrarily. Clearly, for $a \in W_r \setminus V_{M_1}$, we have $d[(p,q),a] \leq 1$.

Now suppose that M_r is a good matching; we will show that M_{r+1} is also good. We take q to be the distinguished node in the new pair. By the choice of q (maximizing $C_{p,q}$) and the assumption on M_r, M_{r+1} satisfies the following goodness conditions:

1. $d[(p,q),a] \leq c_u$ for any $a \in W_{r+1} \setminus V_{M_{r+1}}$.
2. For any pairs $(u_i, v_i), (u_j, v_j) \in M_r$, $d[(u_i, v_i), u_j] \leq c_d$, and for any $(u_i, v_i) \in M_r$ and $a \notin V_{M_{r+1}}$, $d[(u_i, v_i), a] \leq c_u$.
3. For each pair $(u_i, v_i) \in M_r$, $d[(u_i, v_i), q] \leq c_u$ since q was in the window but not in the matching.

There are two cases to consider, which follow.

Case 1. We did not switch. ($d[(p,q),(u_j,v_j)] \le c_s \ \forall j$.)
Remember that $d[(p,q),(u_i,v_i)] = \min(d[(p,q),u_i], d[(p,q),v_i])$. It might be that $d[(p,q),u_i] > c_d$. But in this case, $d[(p,q),v_i] \le c_s$, otherwise we would have switched. We show that for all pairs (u_j,v_j) in M_r, $d[(u_j,v_j),v_i] \le c_d$, so v_i can play the former distinguished role of u_i.
Let $(u_j,v_j) \in M_r$, $j \ne i$. We have

$$d[(u_j,v_j),v_i] \le d[(u_j,v_j),q] + \frac{C_{q,v_i}}{C_{u_j,v_j}} \le c_u + \frac{(c_s+1)C_{p,q}}{C_{u_j,v_j}},$$

where both inequalities follow from Lemma 4.2, the first from part 4 and the second from part 3. However, from part 5 of Lemma 4.2, since $d[(p,q),u_i] \ge c_d$, $d[(u_j,v_j),q] \le c_u$, and $d[(u_j,v_j),u_i] \le c_d$, it follows that

$$C_{p,q} \le \frac{c_u + c_d + 1}{c_d} C_{u_j,v_j}.$$

Substituting into the previous equation gives

$$d[(u_j,v_j),v_i] < c_u + \frac{(c_s+1)(c_u+c_d+1)}{c_d} \le c_d.$$

Case 2. We did switch the following.
Consider the new edges (p,u_j) and (q,v_j) (chosen so that $d[(p,q),(u_j,v_j)]$ is maximized). We show that p and q become distinguished vertices and that for some other pairs (u_k,v_k), v_k must become the distinguished vertex. The detailed proof that M_{r+1} is good follows.

We will need to use the following three inequalities:

- Since $d[(p,q),(u_j,v_j)] > c_s$,

$$C_{p,q} < \frac{\min\{C_{p,u_j}, C_{p,v_j}, C_{q,u_j}, C_{q,v_j}\}}{c_s}. \tag{4.1}$$

- From Lemma 4.2, part 5, since $d[(p,q),u_j] > c_s$ (because we switched), $d[(u_k,v_k),q] \le c_u$, and $d[(u_k,v_k),u_j] \le c_d$ (both because M_r was good), it follows that for any pair $(u_k,v_k) \in M_r$, $k \ne j$,

$$C_{p,q} < C_{u_k,v_k} \frac{c_u + c_d + 1}{c_s}. \tag{4.2}$$

- Last,

$$d[(p,q),(u_k,v_k)] \le d[(p,q),(u_j,v_j)]. \tag{4.3}$$

Many of the goodness conditions follow immediately from the goodness of M_r. The ones that require proof are described below, each with a derivation.

1. $d[(p,u_j),q] \le c_d$, and $d[(q,v_j),p] \le c_d$. This follows from (4.1).
2. $d[(p,u_j),a] \le c_u$ and $d[(q,v_j),a] \le c_u$ for any unmatched $a \in W_{r+1}$. For the first inequality, applying part 2 of Lemma 4.2, the fact that $C_{p,q} \ge C_{p,a}$ for all unmatched a, and (4.1) gives

$$d[(p,u_j),a] \le \frac{C_{p,a}}{C_{p,u_j}} \le \frac{C_{p,q}}{C_{p,u_j}} \le \frac{1}{c_s}.$$

Similarly, for the second inequality,

$$d[(q, v_j), a] \leq \frac{C_{q,a}}{C_{q,v_j}} \leq \frac{C_{q,p} + C_{p,a}}{C_{q,v_j}} \leq \frac{2}{c_s}.$$

3. For each pair $(u_k, v_k) \in M_r$, $k \neq j$, $d[(u_k, v_k), q] \leq c_d$ and $d[(u_k, v_k), p] \leq c_d$. The first inequality follows from the fact that M_r was good, so $d[(u_k, v_k), q] \leq c_u$. As for the second inequality,

$$\begin{aligned} d[(u_k, v_k), p] &\leq d[(u_k, v_k), q] + \frac{C_{p,q}}{C_{u_k,v_k}} \quad \text{(by part 4 of Lemma 4.2)}, \\ &\leq c_u + \frac{C_{p,q}}{C_{u_k,v_k}} \quad \text{(since } d[(u_k, v_k), q] \leq c_u\text{)} \\ &\leq c_u + \frac{c_u + c_d + 1}{c_s} \quad \text{(by (4.2))} \\ &\leq c_d. \end{aligned}$$

4. For each pair $(u_k, v_k) \in M_r$, either both $d[(p, u_j), u_k] \leq c_d$ and $d[(q, v_j), u_k] \leq c_d$ or v_k can become distinguished.
To prove this, assume that $d[(p, u_j), u_k] > c_d$. By assumption

$$C_{p,u_k} > c_d C_{p,u_j} \tag{4.4}$$

and from (4.1) above,

$$C_{p,q} < C_{p,u_j}/c_s. \tag{4.5}$$

Combining these two facts with part 3 of Lemma 4.2, we obtain

$$\begin{aligned} d[(p, q), u_k] &\geq \frac{C_{p,u_k}}{C_{p,q}} - \frac{C_{p,q}}{C_{p,q}} \\ &> \frac{c_d C_{p,u_j}}{C_{p,q}} - \frac{C_{p,u_j}}{c_s C_{p,q}} \\ &> (c_d - 1/c_s)\frac{C_{p,u_j}}{C_{p,q}}, \end{aligned}$$

and thus

$$d[(p, q), u_k] > d[(p, q), u_j]. \tag{4.6}$$

Therefore, by the choice of j,

$$d[(p, q), v_k] < d[(p, q), (u_j, v_j)]. \tag{4.7}$$

Therefore

$$\begin{aligned} C_{p,v_k} &\leq C_{p,q}(1 + d[(p, q), v_k]) \quad \text{(by part 4 of Lemma 4.2)} \\ &\leq C_{p,q}(1 + d[(p, q), u_j]) \quad \text{(by (4.7))} \\ &\leq C_{p,q} + C_{p,u_j} \\ &\leq C_{p,u_j}(1 + 1/c_2) \quad \text{(by (4.1))} \end{aligned}$$

so $d[(p,u_j),v_k] \le c_d$. The previous four lines of equations also establish that $d[(q,v_j),v_k] \le c_d$ by substituting q for p and v_j for u_j.
Now let $(u_l,v_l) \in M_r$. From (4.4) and (4.5) we have

$$\begin{aligned} C_{q,u_k} &\ge C_{p,u_k} - C_{pq} \\ &> (c_d - 1/c_s)C_{p,u_j} \\ &> (c_d - c_s/2)C_{p,u_j}. \end{aligned}$$

However,

$$\begin{aligned} C_{q,u_k} &\le C_{u_l,v_l}(1 + d[(u_l,v_l),q] + d[(u_l,v_l),u_k]) \\ &\le C_{u_l,v_l}(1 + c_u + c_d) \end{aligned}$$

and thus

$$C_{p,u_j} \le \frac{1 + c_u + c_d}{c_d - c_s/2} C_{u_l,v_l}. \tag{4.8}$$

We have

$$\begin{aligned} d[(u_l,v_l),v_k] &\le d[(u_l,v_l),q] + \frac{C_{p,q}(1 + d[(p,q),v_k])}{C_{u_l,v_l}} \\ &\le c_u + \frac{C_{p,q}(1 + d[(p,q),u_j])}{C_{u_l,v_l}} \quad \text{(by 4.7)} \\ &\le c_u + \frac{3C_{p,u_j}}{2C_{u_l,v_l}} \quad \text{(by 4.1)} \\ &\le c_d \quad \text{(by 4.8).} \qquad \square \end{aligned}$$

The following lemma shows why we are interested in relative distances.

LEMMA 4.4. *Let M be a Markov chain. Let u,v,h be three states in M, and let $\gamma = \Pr(h$ visited during a (u,v) commute$)$. Then*

$$\frac{C_{uv}}{C_{uh}} \ge \gamma \ge \frac{C_{uv}}{C_{uv} + C_{uh}}.$$

Proof. We use the following well-known proposition from renewal theory (see, for example, [7, p. 147]): Consider a Markov chain started in state i. Let $0 < S < \infty$ be a stopping time such that $X_S = i$. Let j be an arbitrary state. Then

$$E_i(\#\text{ of visits to } j \text{ before time } S) = \pi_j E_i(S),$$

where π_j is the stationary probability of state j and $E_i(X)$ is the expected value of random variable X when the chain is started in state i.

Let u,v,h be three states in M. Using the proposition, we obtain that

$$E_u(\#\text{ of visits to } h \text{ during a } (u,v) \text{ commute}) = \pi_h(E_u(T_v) + E_v(T_u)) = \pi_h C_{uv}. \tag{4.9}$$

Consider a random walk starting at u. Let p_1 be the probability that h is visited before v and let p_2 be the probability that h is first visited after v, but before a (u,v) commute has completed. Clearly $\gamma = p_1 + p_2$. Furthermore,

$$\begin{aligned} &E_u(\#\text{ of visits to } h \text{ during a } (u,v) \text{ commute}) \\ &\quad = p_1 E_h(\#\text{ of visits to } h \text{ during the time it takes to go from } h \text{ to } v \text{ to } u \text{ back to } h) \\ &\quad + p_2 E_h(\#\text{ of visits to } h \text{ during the time it takes to go from } h \text{ to } u \text{ and back to } h). \end{aligned}$$

Once again using the proposition, we obtain

$$\begin{aligned} &E_u(\#\text{ of visits to } h \text{ during a } (u,v) \text{ commute}) \\ &\quad = p_1\pi_h(E_h(T_v) + E_v(T_u) + E_u(T_h)) + p_2\pi_h(E_h(T_u) + E_u(T_h)). \end{aligned}$$

Combining this with (4.9), we obtain

$$C_{uv} = p_1(E_h(T_v) + E_v(T_u) + E_u(T_h)) + p_2 C_{uh}.$$

Since $(E_h(T_v) + E_v(T_u) + E_u(T_h)) \geq C_{uh}$, we obtain

$$\gamma \leq \frac{C_{uv}}{C_{uh}}.$$

On the other hand, $(E_h(T_v) + E_v(T_u) + E_u(T_h)) \leq C_{uv} + C_{uh}$, and thus

$$\gamma \geq \frac{C_{uv}}{C_{uv} + C_{uh}},$$

completing the proof of the theorem. □

We are ready to prove the main theorem.

Proof of Theorem 4.1. We show that *CA* incurs an expected number of faults, which is at most a constant times the expected number incurred by the *OPT*.

Let a *hole* of *OPT* be any page in W_r that *OPT* does not have in memory. We maintain a 1:1 mapping from pairs in the matching to holes of *OPT*, satisfying the following two properties:

- If h_i is the *OPT*-hole associated with pair (u_i, v_i) for some i, then $d[(u_i, v_i), h_i] = O(1)$.
- The mapping of pairs to holes is changed only when there is either an *OPT*-fault or a new pair is added to the matching. In both cases, the association changes for $O(1)$ pairs.

Say that an (x, y) *commute begins at time* t if (x, y) is a pair in the matching at time t (i.e., $(x, y) = (u_i, v_i)$ or $(x, y) = (v_i, u_i)$ for some i), *CA* had a fault on the most recent request, and the most recent request was at x. Let $T(x, y)$ be the set of times t such that an (x, y) commute begins at time t. Define a *new* node to be a node that is visited in the current phase but wasn't one of the nodes visited in the previous phase, and let G be the total number of new nodes seen in all phases in the request sequence.

The number of faults incurred by *CA* during a page request sequence, denoted $C(CA)$, satisfies

$$C(CA) = \left(\sum_{(x,y)} \sum_{t \in T(x,y)} 1 \right) + O(G),$$

where the last term comes from ensuring that the last k requests are in memory at the end of each phase.

Let $h(x, y, t)$ be the *OPT*-hole associated with pair (x, y) at time t for $t \in T(x, y)$. Let $X_{x,y,t}$ be the indicator random variable that is 1 if $t \in T(x, y)$ and $h(x, y, t)$ is requested during the (x, y) commute beginning at time t.

For $t \in T(x, y)$, let $t \in Q(x, y)$ if either $h(x, y, t)$ gets swapped to another pair or the phase containing t ends before the (x, y) commute starting at time t completes.

Otherwise let $t \in R(x, y)$. Let $C(OPT)$ be the number of faults incurred by OPT. For any page request sequence, we have

$$\sum_{(x,y)} \sum_{t \in R(x,y)} X_{x,y,t} \leq 2C(OPT)$$

since each OPT-fault can be accounted for at most twice, namely by an (x, y) commute and a (y, x) commute, for some pair (u_i, v_i).

The mapping of pairs to holes changes only if OPT incurs a fault or if a new pair is added to the matching, and then only $O(1)$ pairs are affected. A new pair is added to the matching only when a new node is visited. At most $2g$ commutes are in progress at the end of a phase, where g is the number of new nodes visited during the phase. Thus we have

$$\sum_{(x,y)} \sum_{t \in Q(x,y)} X_{x,y,t} = O(C(OPT) + G).$$

(Note that in fact $\sum_{(x,y)} \sum_{t \in Q(x,y)} 1 = O(C(OPT) + G)$.) Therefore,

$$\begin{aligned} \sum_{(x,y)} \sum_{t \in T(x,y)} X_{x,y,t} &= O(C(OPT) + G) \\ &= O(C(OPT) + k), \end{aligned}$$

where k is the number of pages that can be held in memory, since it is known [8] that any paging algorithm incurs $\Omega(G - k)$ faults.

Last, since $d[(x, y), h(x, y, t)] = O(1)$, by Lemma 4.4 there is a constant $p > 0$ such that for all u, v, t such that $t \in T(u, v)$,

$$E[X_{x,y,t}] \geq p.$$

Putting all this together, we obtain by linearity of expectations that

$$E[C(CA)] = O(E[C(OPT)] + k),$$

so the fault rate of CA is at most a constant factor greater than that of OPT.

It remains only to describe the mapping of pairs to holes.

At the beginning of a phase, the single matched pair is associated with any OPT-hole in the window—note that there is at least one. In general, if h_j is the hole associated with (u_j, v_j), we maintain the following invariant:

$$h_j \text{ is unmatched, or is } u_j, v_j, \text{ or } \{h_j, h_k\} = \{u_k, v_k\}, \text{ for some } k \neq j.$$

Notice that the invariant remains unchanged when the distinguished node in a pair changes. (In the case where $\{h_j, h_k\} = \{u_k, v_k\}$, for some $k \neq j$, and the designated node for pair $\{u_k, v_k\}$ changes, swapping h_j and h_k ensures that the invariant remains true.) The following procedure ensures that at any time h_j is changed, it is set to an unmatched node, or u_j, v_j, or u_k for some $k \neq j$, so $d[(u_j, v_j), h_j] = O(1)$, as required.

The first case to consider is when no switch was performed, and the pair (p, q) needs to find a hole $h(p, q)$. We have the following cases.

1. If $p = h_j$ for some j and $q = h_k$ for some k, then p becomes $h(p, q)$, h_k remains q, and we continue with (u_j, v_j) in place of (p, q).

2. If only one of p or q is associated with a pair, say $q = h(u_k, v_k)$, then q becomes $h(p, q)$, and we continue with (u_k, v_k).
3. At this point, there must be an OPT-hole that is unmatched because there are at least i holes total and only $i - 1$ pairs are associated with a hole. We consider three cases depending on what this unassociated OPT-hole is.
   (a) If the OPT-hole is unmatched, or is p or q, set $h(p, q)$ to this OPT-hole.
   (b) If the OPT-hole is u_k or v_k such that $h_k \in \{u_k, v_k\}$, set $h(p, q)$ to u_k and h_k to v_k.
   (c) If the OPT-hole is u_k or v_k such that $h_k \notin \{u_k, v_k\}$, set $h(p, q)$ to h_k and h_k to the unassociated OPT-hole.

The second case is when a switch was performed, producing pairs (p, u_j) and (q, v_j). In this case, we first unmatch h_j from (u_j, v_j) and then apply two steps according to the directions in the no-switch case above—first for (u_j, p) and then for (q, v_j).

When OPT incurs a fault at a hole h_j, the page is loaded into memory, so it is no longer a hole. The pair (u_j, v_j) then finds an unassociated OPT-hole as in the no-switch case above. This scheme satisfies the two required properties of the mapping from pairs to holes. □

Acknowledgment. We would like to thank the reviewers for extensive comments and excellent suggestions.

ASYMPTOTIC BEHAVIOR OF THE HEIGHT IN A DIGITAL SEARCH TREE AND THE LONGEST PHRASE OF THE LEMPEL–ZIV SCHEME*

CHARLES KNESSL† AND WOJCIECH SZPANKOWSKI‡

Abstract. We study the height of a *digital search tree* (DST) built from n random strings generated by an unbiased memoryless source (i.e., all symbols are equally likely). We shall argue that the height of such a tree is equivalent to the length of the longest phrase in the Lempel–Ziv parsing scheme that partitions a random sequence into n phrases. We also analyze the longest phrase in the Lempel–Ziv scheme in which a string of *fixed* length m is parsed into a *random* number of phrases. In the course of our analysis, we shall identify four natural regions of the height distribution and characterize them asymptotically for large n. In particular, for the region where most of the probability mass is concentrated, the asymptotic distribution of the height exhibits an exponential of a Gaussian distribution (with an oscillating term) around the most probable value $k_1 = \lfloor \log_2 n + \sqrt{2\log_2 n} - \log_2(\sqrt{2\log_2 n}) + \frac{1}{\log 2} - \frac{1}{2} \rfloor + 1$. More precisely, we shall prove that the asymptotic distribution of a DST is concentrated on either the one point k_1 or the two points $k_1 - 1$ and k_1, which actually proves (slightly modified) Kesten's conjecture quoted in [*Probab. Theory Related Fields*, 79 (1988), pp. 509–542]. Finally, we compare our findings for DST with the asymptotic distributions of the height for other digital trees such as tries and PATRICIA tries. We derive these results by a combination of analytic methods such as generating functions, Laplace transform, the saddle point method, and ideas of applied mathematics such as linearization, asymptotic matching, and the WKB method. Our analysis makes certain assumptions about the forms of some of the asymptotic expansions as well as their asymptotic matching. We also present detailed numerical verification of our results.

1. Introduction.

The heart of some universal data compression schemes is the parsing algorithm due to Lempel and Ziv [32] (cf. also [31]). It partitions a sequence into phrases (blocks) of variable sizes such that a new block is the shortest substring not seen in the past as a phrase. For example, the string 11001010001000100 is parsed into (1)(10)(0)(101)(00)(01)(000)(100). This parsing algorithm plays a crucial role in numerous applications such as efficient transmission of data discriminating between information sources, test of randomness, estimating the statistical model of individual sequences, and so forth. The parameters of interest in these applications are the number of phrases, the number of phrases of a given size, the size of a phrase, the length of a sequence built from a given number of phrases, the length of the longest phrase, etc. Some of them have already been analyzed (e.g., number of phrases [2, 13], the size of a typical phrase [15, 23]). Here we study the distribution of the longest phrase.

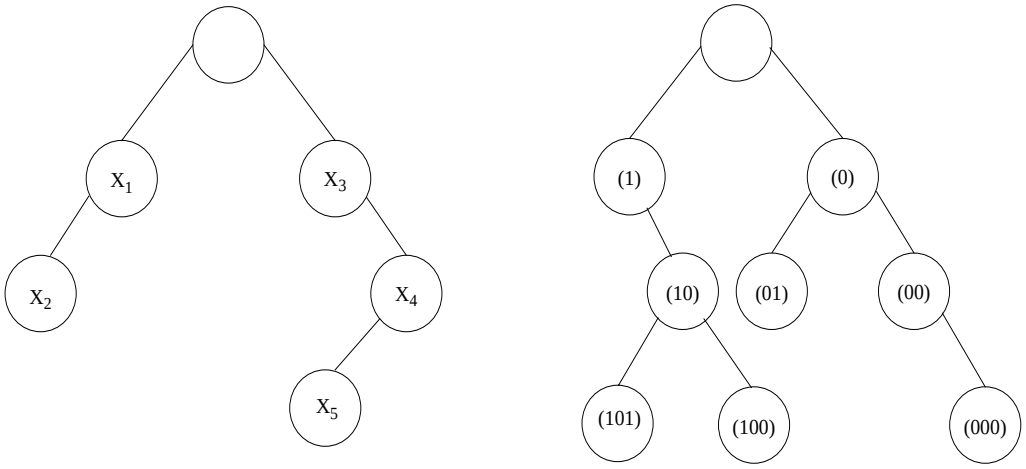

FIG. 1. *DST built from (left) five strings* $X_1 = 11100\ldots$, $X_2 = 11011\ldots$, $X_3 = 00110\ldots$, $X_4 = 00001\ldots$, $X_5 = 001011\ldots$*; (right) eight Lempel–Ziv phrases of the string* $11001010001000100\ldots$, *that is,* (1)(10)(0)(101)(00)(01)(000)(100).

The Lempel–Ziv parsing scheme can be efficiently implemented by a special digital tree called the *digital search tree* (DST). This finds myriad applications in computer science and telecommunications such as dynamic hashing, partial match retrieval of multidimensional data, searching and sorting, pattern matching, conflict resolution algorithms for broadcast communications, data compression, coding, security, genes searching, DNA sequencing, genome maps, and so forth. The DST is constructed as follows (cf. Figure 1). We consider n, possibly infinite, strings of symbols from a finite alphabet Σ (however, for simplicity we work only with the binary alphabet $\Sigma = \{0, 1\}$). The empty string is stored in the root, while the first string occupies the right or the left child of the root depending on whether its first symbol is "1" or "0." The remaining strings are stored in available nodes (that are directly attached to nodes already existing in the tree). The search for an available node follows the prefix structure of a string. The rule is simple: if the next symbol in a string is "1" we move to the right; otherwise we move to the left. The resulting tree has $n + 1$ internal nodes. The details can be found in [17] and [24].

The parsing scheme according to Lempel–Ziv with a *fixed* number, n, of phrases (cf. [11, 13, 23]) can be accomplished on the associated DST as follows: We consider an infinite sequence of binary symbols and partition it until we create the first n phrases. Assuming the first phrase is an *empty* one, we store it in the root of a DST, and all other phrases are stored in internal nodes. When a new phrase is created, the search starts at the root and proceeds down the tree as directed by the input symbols exactly in the same manner as in the DST construction. For example, for the binary alphabet, "0" in the input string means move to the left and "1" means proceed to the right. The search is completed when a branch is taken from an existing tree node to a new node that has not been visited before. Then an edge and a new node are added to the tree. Phrases created in such a way are stored directly in the nodes of the tree (cf. Figure 1).

We also study another model, called the *Lempel–Ziv model*, in which a string of *fixed* length m is parsed according to the Lempel–Ziv algorithm. We can again use

the associated DST to parse the string, but this time the number of phrases, M_m, and hence the number of nodes in the DST, is random. It is known (cf. [2, 32]) that the number of phrases $M_m \sim mh/\log m$ almost surely (a.s.) where h is the entropy of the source.

In this paper, we consider DSTs built over n randomly and independently generated strings of binary symbols. We assume that every symbol is equally likely, and thus we are within the framework of the so-called *symmetric Bernoulli* model. In other words, the strings are emitted by an *unbiased memoryless* source. Our interest lies in establishing the *asymptotic distribution* of the height, $\mathcal{H}_n$, for random DST. The height is the longest path in such trees, and its distribution is of considerable interest for several applications (e.g., the length of the longest phrase in the Lempel–Ziv scheme, maximum search time, and sorting).

We now summarize our main results. First of all, as a consequence of our analysis we prove that the average height of a DST built from n independent strings is $\mathbf{E}[\mathcal{H}_n] = \log_2 n + \sqrt{2\log_2 n} - \log_2(\sqrt{2\log_2 n}) + O(1)$. However, our main contribution lies in establishing the asymptotic distribution $\mathsf{Pr}\{\mathcal{H}_n \le k\}$ of the height as $n \to \infty$. In Theorem 2.1 we shall identify four natural regions of this distribution and characterize them asymptotically as n and k become large. In particular, we show that for the region where most of the probability mass is concentrated, the asymptotic distribution of the height exhibits an exponential of a Gaussian distribution (with an oscillating term) around the most probable value $k_1 = \lfloor \log_2 n + \sqrt{2\log_2 n} - \log_2(\sqrt{2\log_2 n}) + \frac{1}{\log 2} - \frac{1}{2} \rfloor + 1$. In fact, we shall prove that the asymptotic distribution of a DST is concentrated on either the one point k_1 or the two points $k_1 - 1$ and k_1. More precisely, we show the existence of certain subsequences of n such that the asymptotic distribution of the height concentrates only on k_1, or on k_1 and $k_1 - 1$. This proves (slightly modified) Kesten's conjecture quoted in Aldous and Shields [2, p. 538]. Finally, we obtain the asymptotic distribution of the length of the longest phrase in the Lempel–Ziv model (cf. Theorem 2.3).

Digital trees, that is, tries, PATRICIA tries, and DSTs, have been extensively analyzed in the past (cf. [2, 5, 6, 7, 8, 13, 14, 16, 17, 20, 22, 23, 24, 26, 27, 29, 30]). However, relatively little is known about the height of DSTs. An exception is the paper by Pittel [26] who proved that the height $\mathcal{H}_n \sim \log_2 n$ a.s. Later Aldous and Shields [2] improved Pittel's result to $\mathcal{H}_n \sim \log_2 n + \sqrt{2\log_2 n}$ a.s. No distributional result for the height is known to us. We fill this gap by presenting a complete characterization of the asymptotic distribution of the height.

Finally, we say a few words about our method of derivation and put our results in a larger perspective. From a mathematical view point, we study a nonlinear recurrence equation. The distribution $h_n^k = \mathsf{Pr}\{\mathcal{H}_n \le k\}$ satisfies recurrence (2.2) with the initial condition (2.3). We shall solve asymptotically this recurrence by methods of applied mathematics such as linearization, matched asymptotics, and the WKB method (cf. section 5.2). In passing, we mention that in a companion paper [19] we analyzed two similar recurrences: The so-called b-tries recurrence satisfies

$$h_n^{k+1} = 2^{-n} \sum_{i=0}^{n} \binom{n}{i} h_i^k h_{n-i}^k, \qquad k \ge 0,$$

with the initial condition $h_n^0 = 1$ for $n = 0, 1, 2, \ldots, b$ and $h_n^0 = 0$ for $n > b$. For

PATRICIA tries the distribution $h_n^k = \mathsf{Pr}\{\mathcal{H}_n^P \le k\}$ of the height $\mathcal{H}_n^P$ satisfies

$$h_n^{k+1} = 2^{-n+1} h_n^{k+1} + 2^{-n} \sum_{i=1}^{n-1} \binom{n}{i} h_i^k h_{n-i}^k, \quad k \ge 0,$$

with the initial conditions $h_0^0 = h_1^0 = 1$ and $h_n^0 = 0$ for $n \ge 2$. Surprisingly enough, although these recurrences resemble the DST recurrence, they lead to quite different solutions. The reader is referred to [19] for details.

The paper is organized as follows. In the next section, we present our main results for DSTs (cf. Theorem 2.1) and the Lempel–Ziv model (cf. Theorem 2.3). In section 3 we present detailed numerical results and discuss consequences of our findings. The proofs of these results are relegated to sections 4 and 5. These make certain assumptions about the forms of the asymptotic expansions and their matching.

2. Main results. We let $\mathcal{H}_n$ be the height of a DST and we denote its probability distribution by

$$h_n^k = \mathsf{Pr}\{\mathcal{H}_n \le k\}. \tag{2.1}$$

It satisfies the difference equation

$$h_{n+1}^{k+1} = \sum_{i=0}^{n} \binom{n}{i} 2^{-n} h_i^k h_{h-i}^k, \quad k \ge 0, \tag{2.2}$$

with the initial condition

$$h_0^0 = h_1^0 = 1; \quad h_n^0 = 0, \quad n \ge 2. \tag{2.3}$$

This follows from $\mathcal{H}_{n+1} = \max\{\mathcal{H}_i^{LT}, \mathcal{H}_{n-i}^{RT}\} + 1$, where $\mathcal{H}_i^{LT}$ and $\mathcal{H}_{n-i}^{RT}$ denote, respectively, the left subtree and the right subtree of sizes i and $n-i$, which happens with probability $2^{-n}\binom{n}{i}$. The root contains one string (or an empty string).

We can easily show that $h_n^k = 0$ for $n \ge 2^{k+1}$ (i.e., a balanced tree) and $h_n^k = 1$ for $k \ge n-1$ (i.e., a skewed tree). It therefore suffices to consider the range $k+2 \le n \le 2^{k+1} - 1$. We also note that the exponential generating function

$$H_k(z) = \sum_{n=0}^{\infty} \frac{h_n^k z^n}{n!} = \sum_{n=0}^{2^{k+1}-1} \frac{h_n^k z^n}{n!} = \sum_{n=0}^{k+1} \frac{z^n}{n!} + \sum_{n=k+2}^{2^{k+1}-1} h_n^k \frac{z^n}{n!} \tag{2.4}$$

satisfies

$$H'_{k+1}(2z) = H_k^2(z), \qquad k \ge 0, \tag{2.5}$$

with $H_0(z) = 1 + z$. Thus, for any k, the generating function $H_k(z)$ is a polynomial of degree $2^{k+1} - 1$ and the leading $k+2$ coefficients in this polynomial are the same as those in the Taylor series of e^z.

Below we give the exact expressions for h_n^k for a few values of n that are close to either k or 2^{k+1}:

$$h_n^{n-2} = 1 - 2^{-n^2/2} 2^{3n/2} 2^{-1}, \qquad n \ge 2; \tag{2.6}$$

$$h_n^{n-3} = 1 - (n-2) 2^{-n^2/2} 2^{5n/2} 2^{-3}, \qquad n \ge 4; \tag{2.7}$$

$$h_n^{n-4} = 1 - \left(\frac{n^2}{2} - \frac{5n}{2} + \frac{8}{3} - \frac{2}{3} 4^{5-n} \right) 2^{-n^2/2} 2^{7n/2} 2^{-6}, \quad n \ge 6; \tag{2.8}$$

and

$$h^k_{2^{k+1}-1} = (2^{k+1}-1)!2^{-k2^{k+1}}4^{2^k-1}\prod_{\ell=1}^{k}\left(\frac{1}{2^{\ell+1}-1}\right)^{2^{k-\ell}}, \qquad k \geq 0, \tag{2.9}$$

$$h^k_{2^{k+1}-2} = (\,2^{k+1}-2)!2^{-(2k+1)2^k}2^{3k+1} \times \prod_{\ell=1}^{k}\frac{1}{1-2^{-\ell}}\left[\prod_{m=1}^{\ell-1}(1-2^{-m-1})^{-2^{-m}}\right]^{2^{\ell-1}}, \quad k \geq 1. \tag{2.10}$$

We next consider the asymptotic limit $n \to \infty$. A singular perturbation analysis of the problem (2.2) shows that there are four cases of k that lead to different asymptotic expansions of h^k_n: $n \to \infty$ with $n-k$ fixed; $n,k \to \infty$ with $0 < k/n < 1$; $n,k \to \infty$ with $\xi = n2^{-k}$ fixed and $0 < \xi < 2$; and $n,k \to \infty$ with $2^{k+1} - n = O(1)$. We note that the last limit is only possible if n is close to a power of 2.

Using ideas of applied mathematics, such as linearization and asymptotic matching, we obtain the following results, listed in decreasing size of k/n. The derivation of these results is presented in sections 4 and 5, where we make certain assumptions about the forms of the asymptotic expansions, as well as the asymptotic matching between the various scales. In particular, the result in case (iii) (central regime) assumes a WKB expansion in the form (5.31) (cf. section 5 and [18, 21]).

THEOREM 2.1. *The distribution of the height for DSTs built from n independent strings generated by an unbiased memoryless source (and thus the length of the longest phrase in the Lempel–Ziv algorithm with a fixed number, n, of phrases) has the following asymptotic expansions:*

(i) FAR RIGHT-TAIL REGIME: $n,k \to \infty$, $n-k = j = O(1)$, $j \geq 2$,

$$\mathsf{Pr}\{\mathcal{H}_n > k\} = 1 - h^k_n \sim 2^{-j^2/2}2^{j/2}\frac{1}{(j-2)!}n^{j-2}2^{-n^2/2}2^{(j-1/2)n}. \tag{2.11}$$

(ii) RIGHT-TAIL REGIME: $n,k \to \infty$, $0 < k/n < 1$ *or* $\alpha \equiv 1/(1-k/n) = n/(n-k) \in (1,\infty)$,

$$1 - h^k_n \sim 2^{-k^2/2}2^{-k/2}F^k_n, \tag{2.12}$$

where

$$F^k_n = \frac{n^n}{(n-k)^{n-k}k^k}\frac{\sqrt{\pi n}(n-k)^{3/2}}{\sqrt{2}\ k^{5/2}}I(\alpha), \tag{2.13}$$

$$I(\alpha) = \frac{1}{\pi}\sum_{m=0}^{\infty}\frac{(-1)^m}{(\alpha-1)^m}\left[\prod_{\ell=1}^{m}(1-2^{-\ell})\right]^{-1}, \qquad \alpha > 2,$$

$$= \frac{1}{2\pi i}\int_{\frac{1}{2}-i\infty}^{\frac{1}{2}+i\infty}\frac{e^{z\log(\alpha-1)}}{\sin(\pi z)}\prod_{\ell=1}^{\infty}\exp\left(\frac{1-2^{\ell z}}{\ell(2^\ell-1)}\right)dz, \qquad \alpha > 1. \tag{2.14}$$

(iii) CENTRAL REGIME: *Under the WKB hypothesis discussed in section 5.2, for $n,k \to \infty$, $\xi = n2^{-k}$, ξ fixed and $0 < \xi < 2$, we have*

$$h^k_n \sim A(\xi)e^{-n\Phi(\xi)}, \tag{2.15}$$

$$A(\xi) = e^{-\xi\Phi'(\xi)-\Phi(\xi)}\sqrt{1+2\xi\Phi'(\xi)+\xi^2\Phi''(\xi)}. \tag{2.16}$$

By asymptotic matching (cf. section 5), we find that the function $\Phi(\xi)$ satisfies, for $\xi \to 2^-$,

$$\Phi(\xi) \sim \frac{1}{2}\log\left(\frac{e^2}{2C_0}\right) + \frac{1}{2}(2-\xi)\log(2-\xi) + \frac{1}{4}(\xi-2)\log(2C_0), \tag{2.17}$$

$$C_0 = \prod_{\ell=1}^{\infty}(1-2^{-\ell-1})^{-2^{-\ell}} = 1.20675\ldots, \tag{2.18}$$

and for $\xi \to 0^+$

$$\Phi(\xi) \sim 2^{-9/8}\frac{(\log 2)^{3/2}}{(\log\xi)^2}\xi^{1/2-1/\log 2}\exp\left(-\frac{[\log\xi - \log(-\log_2\xi)]^2}{2\log 2}\right) \times Q_*\left(\log_2\xi - \log_2(-\log_2\xi) + \frac{1}{2}\right). \tag{2.19}$$

Here $Q_*(z)$ is a periodic function of period one:

$$Q_*(z) = \frac{1}{\sqrt{2\pi}}\int_{-\infty}^{\infty} e^{-s^2/2}Q\left(z + \frac{is}{\sqrt{\log 2}}\right)ds,$$

where $Q(z)$ has the Fourier series

$$Q(z) = 2^{13/12}\prod_{\ell=1}^{\infty}(1-2^{-\ell})^{-1}\exp\left[-\frac{\pi^2}{3\log 2} - \sum_{m=1}^{\infty}\frac{\cos(2m\pi z)}{m\sinh(2\pi^2 m/\log 2)}\exp\left(-\frac{2\pi^2 m}{\log 2}\right)\right]. \tag{2.20}$$

An alternate representation is

$$Q(z) = \frac{e^{-\pi i z}}{\sin(\pi z)}e^{p(z)},$$

where

$$e^{p(z)} = e^{-(\log 2)z^2/2}e^{\pi i(z+\frac{3}{2})}2^{1/8}\left[\prod_{\ell=1}^{\infty}(1-2^{-\ell})^{-2}\right]\vartheta_1\left(\frac{i}{2}z\log 2\right)$$

and $\vartheta_1(u)$ is the Jacobi theta function defined by (cf. [3]*)*

$$\vartheta_1(u) = \vartheta_1(u|\tau) = 2\sum_{m=1}^{\infty}(-1)^{m+1}q^{(m-1/2)^2}\sin((2m-1)u) = 2q^{1/4}\sin(u)\prod_{m=1}^{\infty}(1-2\cos(2u)q^{2m}+q^{4m})(1-q^{2m}), \tag{2.21}$$

where $q = 1/\sqrt{2} = e^{\pi i\tau}$ with $\tau = (i\log 2)/(2\pi)$.

(iv) Left-tail regime: $n \to \infty$, $2^{k+1} - n = M = O(1)$, $M \geq 1$,

$$h_n^k \sim \frac{2\sqrt{\pi}}{(M-1)!}\left(\frac{2C_0}{e^2}\right)^{2^k}2^{(M-1/2)k}, \tag{2.22}$$

where C_0 is defined in (2.18).

Remark. We note that the leading term for h_n^k or $1-h_n^k$ is completely determined for cases (i), (ii), and (iv). However, for case (iii) the result involves the function $\Phi(\xi)$. We have not been able to determine Φ completely, except for its behaviors as $\xi \to 0$ and $\xi \to 2$. In section 3 we discuss the numerical computation of Φ and also give a refinement of (2.19). Our analytical results predict that Φ is finite at $\xi = 2$, with $\Phi(2) = 1-\log(\sqrt{2C_0}) = .559461\ldots$, but Φ' has a logarithmic singularity with $\Phi'(\xi) \sim -\log(\sqrt{2-\xi})$ as $\xi \to 2$. As $\xi \to 0^+$, (2.19) shows that Φ as well as all its derivatives vanish. The dominant term in the right side of (2.19) is $\exp[-(\log 2)(\log_2 \xi)^2/2]$. It is interesting to note that in [19] we obtained results analogous to (2.15) for b-tries and for PATRICIA trees. For b-tries the corresponding Φ satisfies $\Phi(\xi) \sim \xi^b/(b+1)!$ as $\xi \to 0$, so that this function has a zero of order b at $\xi = 0$. For the PATRICIA model the dominant term is the same as that for the DST model (i.e., $\log \Phi$ has the same leading term for the two models). More precisely, Φ in PATRICIA becomes

$$\Phi(\xi) \sim \frac{1}{2}\rho_0 e^{\varphi(\log_2 \xi)} \xi^{3/2} \exp\left(-\frac{\log^2 \xi}{2\log 2}\right), \qquad \xi \to 0^+,$$

where $\rho_0 \approx 1.73137$ and $\varphi(\cdot)$ is periodic with period one. However, by examining the second terms for $\log \Phi$ we see that Φ is flatter near $\xi = 0$ for the DST model. For both DST and PATRICIA, the function Φ shows oscillatory behavior as $\xi \to 0$, while this is not the case for b-tries.

Since $\Phi(\xi) > 0$ for $0 < \xi \le 2$ (see also the numerical results in section 3), h_n^k is exponentially small for cases (iii) and (iv), while for cases (i) and (ii) $1 - h_n^k$ is exponentially small. For case (i) $1 - h_n^k$ is (roughly) $O(2^{-n^2/2})$, for case (ii) $1 - h_n^k = O(2^{-k^2/2})$, while for cases (iii) and (iv) $h_n^k = O(e^{-n\Phi(\xi)})$. For a fixed large n, most of the probability mass occurs in that range of k where h_n^k changes from $h_n^k \approx 0$ to $h_n^k \approx 1$. We think of plotting h_n^k as a function of k so that (i) and (ii) apply in the right tail of the distribution while (iii) and (iv) apply in the left tail. The mass must thus be concentrated in the asymptotic matching region between cases (ii) and (iii). If we let $\xi \to 0$ sufficiently rapidly so that $n\Phi(\xi) \to 0$, then we can approximate (2.15) by $Ae^{-n\Phi} \sim 1 - n\Phi$ and then (ii) and (iii) asymptotically match, as is shown in section 5. We can also consider a limit where $n \to \infty$, $\xi \to 0$ with $n\Phi$ bounded, or even $n\Phi \to \infty$. Then (2.15) can be approximated by $e^{-n\Phi}$ or by $Ae^{-n\Phi}$, with Φ replaced by its expansion (2.19) as $\xi \to 0^+$.

We summarize our observations in the following corollary.

COROLLARY 2.2. *The asymptotic distribution of DST height is concentrated among the two points $k_1 - 1$ and k_1 where*

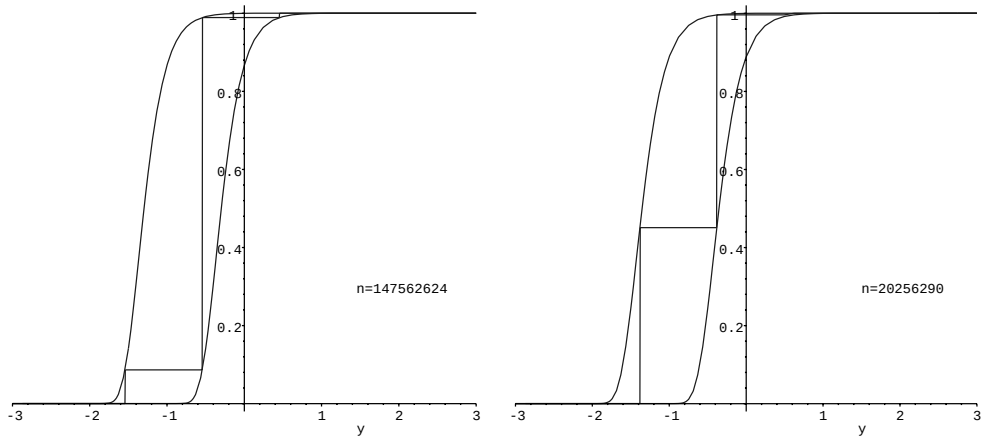
$$k_1 = k_1(n) = \left\lfloor \log_2 n + \sqrt{2\log_2 n} - \log_2(\sqrt{2\log_2 n}) + \frac{1}{\log 2} - \frac{1}{2} \right\rfloor + 1,$$

that is,

$$\mathsf{Pr}\{\mathcal{H}_n = k_1 - 1 \text{ or } k_1\} = 1 - o(1)$$

as $n \to \infty$. More precisely, (i) *there are subsequences n_i for which $\mathsf{Pr}\{\mathcal{H}_{n_i} = k_1\} = 1 - o(1)$ provided that*

$$\Delta(n_i) = \sqrt{2\log_2 n_i}\left\langle \log_2 n_i + \sqrt{2\log_2 n_i} - \log_2(\sqrt{2\log_2 n_i}) + \frac{1}{\log 2} - \frac{1}{2} \right\rangle - \frac{3}{2}\log_2(\sqrt{2\log_2 n_i}) \to \infty$$



(a) (b)

FIG. 2. *Asymptotic distributions for the heights of DSTs and their corresponding lower and upper bounds.*

as $i \to \infty$*;* (ii) *there are subsequences* n_i *for which* $\mathsf{Pr}\{\mathcal{H}_{n_i} = k_1 - 1 \text{ or } k_1\} = 1 - o(1)$ *provided that* $\Delta(n_i) = O(1)$.

Proof. To establish it we first simplify the expression in the matching region by setting

$$k_\ell = \left\lfloor \log_2 n + \sqrt{2\log_2 n} - \log_2(\sqrt{2\log_2 n}) + \frac{1}{\log 2} - \frac{1}{2} \right\rfloor + \ell \tag{2.23}$$
$$= \log_2 n + \sqrt{2\log_2 n} - \log_2(\sqrt{2\log_2 n}) + \frac{1}{\log 2} - \frac{1}{2} - \beta(n) + \ell,$$

where ℓ is an integer and

$$\beta(n) = \left\langle \log_2 n + \sqrt{2\log_2 n} - \log_2(\sqrt{2\log_2 n}) + \frac{1}{\log 2} - \frac{1}{2} \right\rangle. \tag{2.24}$$

Here $\langle x \rangle = x - \lfloor x \rfloor$ is the fractional part of x. By using (2.23) in $e^{-n\Phi}$ (with Φ replaced by (2.19)) and simplifying the expression for n large, we are led to

$$h_n^k \approx \exp\left(\frac{-Q_*}{2\sqrt{\log 2}} e^{\beta - \ell - 1/\log 2} 2^{\sqrt{2\log_2 n}(\beta-\ell) - (\beta-\ell)^2/2 - \frac{3}{4}\log_2(2\log_2 n)} \right), \tag{2.25}$$

where $Q_* = Q_*(\log_2 n - \log_2(\sqrt{2\log_2 n}) + 1/2)$ and $\beta = \beta(n)$ is as in (2.24). In (2.25) we write $\approx$ rather than $\sim$ since we neglected a factor $1 + O(1/\sqrt{\log n})$ in the exponent. Also, we note that $Q_*(z)$ is almost constant, with very small fluctuations, as explained below (2.29).

Now examine (2.25) for $\ell = 0$ and $\ell = 1$. If $0, < \beta < 1$ and $\ell = 0$, then h_n^k is small as $n \to \infty$. If $0 < \beta < 1$ and $\ell = 1$, h_n^k is close to one. This shows that for $0 < \beta(n) < 1$ the mass becomes concentrated at a single point as $n \to \infty$ (cf. Figure 2), corresponding to $\ell = 1$ in (2.23). It also follows from our analysis that the mean height is

$$\mathbf{E}[\mathcal{H}_n] = \log_2 n + \sqrt{2\log_2 n} - \log_2(\sqrt{2\log_2 n}) + O(1), \quad n \to \infty. \tag{2.26}$$

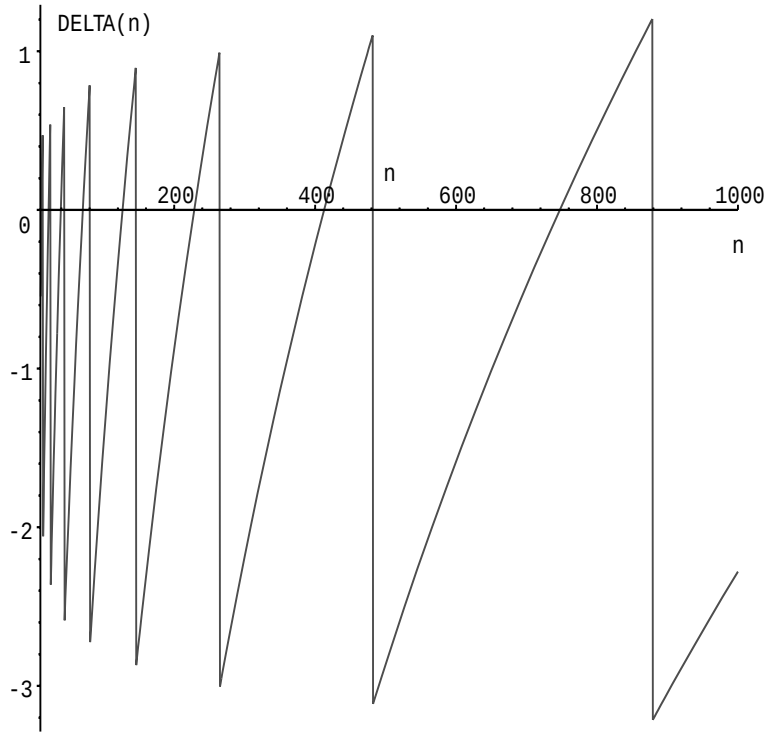


FIG. 3. *The function* $DELTA(n) = \Delta(n) = \beta(n)\sqrt{2\log_2 n} - 1.5\log_2\sqrt{2\log_2(n)}$ *versus* n.

In passing we recall that the first term of the above was already derived by Pittel [26], while the second term was established by Aldous and Shields [2]. In both cases the convergence is in probability sense.

We now show that one can find special sequences $n(i)$ such that $n(i) \to \infty$ as $i \to \infty$, and along these sequences there is probability mass concentrated at two points, corresponding to $\ell = 0$ and $\ell = 1$ in (2.23). We define

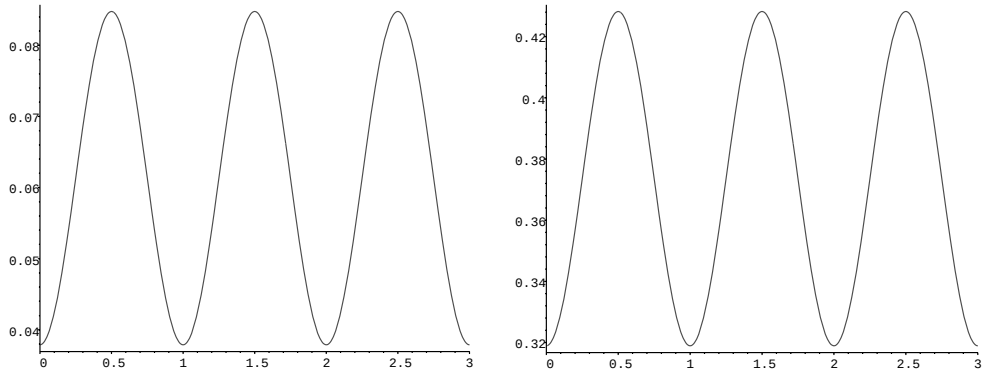
$$\Delta(n) = \beta(n)\sqrt{2\log_2 n} - \frac{3}{2}\log_2(\sqrt{2\log_2 n}) \tag{2.27}$$

and note that if $\Delta(n)$ is $O(1)$, then h_n^k in (2.25) is not asymptotically small at $\ell = 0$. We show in Figure 3 and more precisely in section 3 that we can find sequences $n(i)$ such that $\Delta(n(i))$ remains bounded, and in fact we can have $\Delta \to 0$ for some of these (cf. (3.13)). If we consider $n(i)$ with $\Delta(n(i)) \to 0$, then as $n \to \infty$ for $\ell = 0$ the right side of (2.25) asymptotically becomes

$$\exp\left[-\frac{Q_*}{2\sqrt{\log 2}}\exp\left(-\frac{1}{\log 2}\right)\right]. \tag{2.28}$$

This does not approach a limit as $n \to \infty$ due to the oscillatory behavior of $Q(z)$ and hence $Q_*(z)$. However, we show in section 4 that the nonconstant terms in the Fourier series for Q (to be precise, the series for $\log Q$) are *numerically* very small. Thus we can use the approximation resulting by using only the constant term, which yields

$$Q(z) \approx Q^0 = 2^{13/12}\left[\prod_{m=1}^{\infty}(1-2^{-m})^{-1}\right]\exp\left(-\frac{\pi^2}{3\log 2}\right) = .063716934676\ldots. \tag{2.29}$$



(a) (b)

FIG. 4. (a) *A plot of* $(Q(z) - 0.063716934676376354004922 00) \cdot 10^{24}$ *over three periods.* (b) *A plot of* $(Q_*(z) - 0.063716934676) \cdot 10^{12}$ *over three periods.*

Here $\approx$ means that $Q(z)$ is constant to the number of significant digits given in (2.29).

Now, $Q_*(z)$ is not the same as $Q(z)$. However, in Appendix A we derive the following alternate representation for $Q_*(z)$:

$$Q_*(z) = 2^{z^2/2}\sqrt{\frac{\log 2}{2\pi}}\left[\prod_{\ell=1}^{\infty}(1-2^{-\ell})^{-2}\right]\sum_{m=-\infty}^{\infty}\frac{(-1)^{m+1}2^{-m^2/2}2^{m/2}(2^{m-1/2}-2^{-m+1/2})}{2^{m-1/2}+2^{-m+1/2}+2^z+2^{-z}}. \tag{2.30}$$

We tabulate both $Q(z)$ and $Q_*(z)$ in Table 1 (cf. section 3) and sketch these functions in Figure 4. This shows that $Q_*(z)$ is also nearly constant with $Q_*(z) \approx Q_*^0 \approx .0637169$, which agrees with (2.29) to the accuracy given. Here Q_*^0 is the constant term of the Fourier series for $Q_*(z)$. Using (2.29) in (2.28) gives an estimate of the mass at $\ell = 0$ along sequences $n(i)$ that have $\Delta(n(i)) \to 0$. Note that $\Delta \to 0$ implies that $\beta \to 0$, in view of (2.27). In section 3 we test the accuracy of (2.28). □

We are now in a position to compare our results to the corresponding results for PATRICIA trees that we recently obtained in [19]. With regards to the average $\mathbf{E}[\mathcal{H}_n]$ given by (2.26) the first two terms are the same as for PATRICIA (see also Devroye [5]), but the third term for PATRICIA is $O(1)$, while for DST it is $O(\log\log n)$. Thus (2.26) shows that the improvement of the *DST trees over the PATRICIA tries* appears only at the third term in the asymptotics of $\mathbf{E}[\mathcal{H}_n]$. Since the coefficient of the $\log\log n$ term in (2.26) is negative, $\mathbf{E}[\mathcal{H}_n]$ is asymptotically smaller for DST. With respect to the limiting distribution in the central regime, both are of an exponential of a Gaussian type. However, the DST distribution function contains an additional term $O(\log\log n)$ in the double exponent. This additional term prohibits the limiting distribution for DST to be concentrated in some cases on k_1 and $k_1 + 1$, which does occur for PATRICIA height.

Finally, we shall discuss the Lempel–Ziv model in which a random string of *fixed* length, m, is partitioned into a random number, M_m, of phrases. We shall use the results of Theorem 2.1 to prove the asymptotic distribution of the longest phrase among the M_m random phrases. Let us first introduce for any $\varepsilon > 0$

$$\delta_m = \mathsf{Pr}\{M_m \notin [(1-\varepsilon)\mu(m), (1+\varepsilon)\mu(m)]\},$$

where $\mu(m) = m/\log_2 m$ (i.e., the typical number of phrases). It is known that $\delta_m \to 0$ as $m \to \infty$ (cf. [2, 13, 32]). In fact, a stronger result is known. Jacquet and Szpankowski [13] proved that $\delta_m = O(e^{-R\varepsilon\sqrt{m}})$ for some $R > 0$.

Now, we can formulate our second result.

THEOREM 2.3. *Consider the Lempel–Ziv model in which a fixed string of length m is parsed according to the Lempel–Ziv algorithm. Let $\mathcal{H}_m^{LZ}$ be the length of the longest phrase (among random number, M_m, of phrases), while $\mathcal{H}_n$ is still the height of a DST built from n independently generated strings, as studied in Theorem* 2.1. *Then for all $k \geq 0$ and $\varepsilon > 0$*

$$\mathsf{Pr}\{\mathcal{H}_{(1+\varepsilon)\mu(m)} \leq k\} - \delta_m \leq \mathsf{Pr}\{\mathcal{H}_m^{LZ} \leq k\} \leq \mathsf{Pr}\{\mathcal{H}_{(1-\varepsilon)\mu(m)} \leq k\} + \delta_m. \tag{2.31}$$

In particular,

$$\mathbf{E}[\mathcal{H}_m^{LZ}] = \log_2(m/\log_2 m) + \sqrt{2\log_2(m/\log_2 m)} - \frac{1}{2}\log_2\log_2(m/\log_2 m) + O(1), \tag{2.32}$$

and most of the probability mass is concentrated either at k_1^{LZ} or $k_1^{LZ} - 1$, where

$$k_1^{LZ} = \left\lfloor \log_2(m/\log_2 m) + \sqrt{2\log_2(m/\log_2 m)} - \frac{1}{2}\log_2\log_2(m/\log_2 m) + \frac{1}{\log 2} - 1 \right\rfloor + 1$$

for large m.

Proof. We proceed as follows

$$\begin{aligned}
\mathsf{Pr}\{\mathcal{H}_m^{LZ} \leq k\} &= \sum_{n\geq 0} \mathsf{Pr}\{\mathcal{H}_n \leq k,\ M_m = n\} \\
&\leq \delta_m + \sum_{(1-\varepsilon)\mu(m)\leq n\leq(1+\varepsilon)\mu(m)} \mathsf{Pr}\{\mathcal{H}_n \leq k,\ M_m = n\} \\
&\leq \delta_m + \mathsf{Pr}\{\mathcal{H}_{(1-\varepsilon)\mu(m)} \leq k\},
\end{aligned}$$

where the last inequality is a consequence of the fact that $\mathcal{H}_m^{LZ}$ is a nondecreasing sequence with respect to m. The lower bound of (2.31) can be proved in a similar manner. The rest is a simple consequence of (2.31). ∎

3. Discussion and numerical results. We shall discuss the accuracy of the various asymptotic results and also numerically calculate the hitherto undetermined function $\Phi(\xi)$. We begin by making some general comments on how to use the asymptotic formulae.

It is most natural to view the problem as starting with a fixed (large) n and then varying k. We let k^* be the minimum integer such that $2^{k+1} - 1 \geq n$. More precisely, we set

$$k^* = \begin{cases} \log_2(n+1) - 1 & \text{if} \quad n+1 = \text{ power of 2,} \\ \lfloor \log_2(n+1) \rfloor & \text{if} \quad n+1 \neq \text{ power of 2,} \end{cases} \tag{3.1}$$

and note that h_n^k is only nonzero for $k \geq k^*$. If, say, $n = 100$, we have $k^* = 6$. Then $2^{k^*+1} - n = 28$ so that we are probably out of the range where the M-scale expansion applies. For $k = k^*$ we have $\xi = n2^{-k} = 25/16$, and this is well within the range $0 < \xi < 2$, where Theorem 2.1(iii) applies. By increasing k to $k^* + 1$, $k^* + 2, k^* + 3, \ldots$, we obtain the values $25/32$, $25/64$, $25/128, \ldots$ for ξ, so that ξ

becomes small rapidly and it thus may be desirable to use the WKB approximation (cf. section 5) and further replace A and Φ by their small ξ expansions, which we have derived explicitly. When k further increases to a significant fraction of n (e.g., $k = 20$), then we should use the expansion (ii) of Theorem 2.1, which applies on the α-scale (where $\alpha = n/(n-k) > 1$). When k further increases to a value close to n, such as 95, we can use the expansion that applies for $j = n - k$ fixed (cf. Theorem 2.1(i)). Of course, for $k \geq n - 1$, we have $h_n^k = 1$.

If we start with $n = 127$, then $k^* = 6$, which correspond to $M = 1$ and $\xi = 127/64$. Thus for $k = k^*$ we can use the M-scale result (cf. Theorem 2.1(iv)), but increasing k to $k^* + 1 = 7$ puts us well within the region $0 < \xi < 2$, where Theorem 2.1(iii) applies. If $n = 128$, then $k^* = 7$ and $2^{k^*+1} - n = 128$. This corresponds to $M = 128$ and $\xi = 1$, and this indicates the ξ-scale result should be used. Since $\xi = 1$ is not close to either 0 or 2, we must use the numerical value of $\Phi(1)$.

We define k_1 by (2.23) with $\ell = 1$. According to our analysis, as $n \to \infty$ the probability mass should be concentrating at the single point k_1 or the two points $k_1 - 1$, k_1 (with the former being more likely). If $n = 100$, we have $k_1(100) = 10$ so that $k_1 - k^* = 4$, and hence the "left-tail" really consists of only the four points with $k = 6 - 9$.

In using the asymptotic results that involve the periodic functions $Q(z)$ and $Q_*(z)$, we approximate them by the numerical value in (2.29), which is correct to 11 significant digits for both of them. Figure 4 and Table 1 show that the oscillations in Q_* occur only in the 12th significant digit, while those in Q are even smaller, occurring in the 25th digit. From the Fourier series for Q given by (2.20) we can analytically estimate the oscillations by using only the term with $m = 1$ and approximating $\sinh(a)$ by $e^a/2$, which yields

TABLE 2

$$\frac{Q(z)}{Q_0} \approx 1 - 2e^{-2a}\cos(2\pi z), \qquad a = \frac{2\pi^2}{\log 2},$$
$$= 1 - 3.678\ldots(10^{-25})\cos(2\pi z).$$

We note that both Q and Q_* are symmetric about the midpoint $z = 1/2$ and achieve their maxima here.

We first discuss the accuracy of the expansion for M fixed, which corresponds to case (iv) of Theorem 2.1, as defined in section 2. In Table 2, we consider values of n that are of the form $2^{k+1} - 1$, or slightly smaller, and various M in the range 1 to 5. From the table we see that the asymptotic formula is highly accurate and that for larger k, we can allow M to be larger and still obtain good agreement. We recall that the error term in (2.22) is $O(2^{-k}) = O(n^{-1})$. The results in Table 2 suggest that the numerical coefficient of the correction term is fairly small.

We next consider the far right tail (cf. Theorem 2.1(i)), where h_n^k is close to one.

TABLE 4
Right-tail comparison.

n	k	α	$1-h_n^k$ (exact)	$1-h_n^k(2.12)$
16	12	4	$2.99991(10^{-22})$	$3.74045(10^{-22})$
20	15	4	$6.09591(10^{-34})$	$7.21250(10^{-34})$
24	18	4	$2.42022(10^{-48})$	$2.77231(10^{-48})$
28	21	4	$1.88363(10^{-65})$	$2.11079(10^{-65})$
32	24	4	$2.87538(10^{-85})$	$3.17143(10^{-85})$

In Table 3 we consider $10 \le n \le 25$ for $2 \le j \le 5$. We tabulate the exact values of $1-h_n^k$ and the result in (2.11). When $j=2$ the agreement is excellent for all n, as it should be since (2.6) shows that (2.11) is not only asymptotic but exact! However, for $j=3$ the error is about 25% when $n=10$; it decreases to below 10% when $n=25$. The situation becomes worse when j increases.

The correction term to (2.11) is $O(n^{-1})$. The data in Table 3 suggest that the numerical coefficient in the correction term is fairly large, and increases with j. This is certainly consistent with the exact results in (2.7) and (2.8), which show that the correction factor is of the form $1-2/n$ and $1-5/n$ for $j=3$ and $j=4$, respectively. Note also that if, say, $n=20$ and $j=5$, it is not a priori clear whether we should use the $j=O(1)$ result or that for $\alpha=n/j$ fixed.

In Table 4 we test the accuracy of (2.12). We fix $\alpha=n/(n-k)=4$ and consider $16 \le n \le 32$. Note that since $\alpha>2$, we can use the infinite sum in (2.13) to calculate the integral I, which yields $I(4)=.17398\ldots$. When $n=16$ the error is about 25% and decreases to 10% when $n=32$. While this is consistent with a correction term of $O(n^{-1})$, the data again suggest that the coefficient in the error term is fairly large, relative to one.

In obtaining the asymptotic results summarized in (2.11)–(2.22), we have written them in the simplest possible form. However, from our analysis we can easily generate results that are more uniform and more numerically accurate. By more uniform we mean they apply to larger ranges of k than those in (2.11)–(2.22). For example, in the right tail we find that

$$1-h_n^k \sim 2^{-k^2/2}2^{-k/2}\tilde{F}_j(n), \tag{3.2}$$

where $\tilde{F}_j(n)$ is given precisely by (4.15) of section 4. For j fixed and $n\to\infty$ (4.15) reduces to (2.11), for $\alpha=n/j>1$ and $n\to\infty$ it reduces to (2.12), and the analysis in section 4 shows that it applies even for $n\to\infty$ with $k/n\to 0$ as long as $k/\log_2 n=\nu>1$. Thus, the approximation holds anywhere in the right tail and we call $2^{-k^2/2}2^{-k/2}\tilde{F}_j(n)$ the "uniform right tail" (URT) approximation for $1-h_n^k$. In Table 5 we consider $n=10$, 20, 30, and 100 and various values of $k=n-j$. We decrease k until the exact value of $1-h_n^k$ exceeds .5 (i.e., $h_n^k<.5$). For $n=10$, Table 5 shows that for $k=8$ and $k=7$, the exact and URT results agree to 6 decimal places. As k decreases from 6 to 4, the error slowly increases, but remains under 2%. For $k=3$ we have $1-h_n^k>.5$, but even then URT is accurate to within 12%. By now we are well outside of the right tail. For $n=20$ and $k\ge 6$, URT is accurate to within .3% and agrees with the exact result to 6 decimal places for $k\ge 10$. When $k=5$ we have $1-h_n^k$ becoming $O(1)$, but still URT is accurate to within 5%. For $k=4$ the asymptotic result exceeds 1, but then we are clearly outside of the right tail. Similar trends are apparent for $n=30$ and $n=100$. Here we need only consider relatively

TABLE 5

	8	92	.115924	.122474
	7	93	.866855	>1

small values of k/n, since even here URT is accurate to 6 decimal places. We also note that in each data point in Table 5, URT *overestimates* $1-h_n^k$. This suggests that it may be an upper bound for $1-h_n^k$ (thus a lower bound for h_n^k) for points in the right tail.

Now we test the accuracy of the asymptotics for points where there is appreciable mass. According to our result, this corresponds to $k-\log_2 n \approx \sqrt{2\log_2 n}$. Our approximation here is that in (2.15) with $\Phi(\xi)$ replaced by its small ξ expansion (2.19). However, the analysis in section 4 shows that the error term in (2.19) is only smaller than the leading term by a factor $1/\log\xi$ (with possibly some $\log(-\log\xi)$ factors). While we could compute these, it proves more efficient to use the full result in (4.34) established in section 4. If we set $n2^{-k}=\xi$ in (4.34) we find that $2^{-k^2/2}2^{-k/2}\times$ (4.34) has the form $n\times$ [function of ξ], so that the matching condition in (5.40) may be refined to

$$\Phi(\xi)\sim\Phi_0(\xi),\qquad \xi\to 0^+, \tag{3.3}$$

where

$$\Phi_0(\xi)=\pi\xi\frac{1}{2\pi i}\int_{-i\infty}^{i\infty}\frac{2^{s(s-1)/2}Q(s)}{\Gamma(3-s)}e^{-s\log\xi}ds. \tag{3.4}$$

While the error in (2.19) is only about $1+O(1/|\log\xi|)$, we believe that in (3.3) the

error is about $1+O(\xi)$, though we have not explicitly calculated the correction. Now, (3.4) is much less insightful than (2.19), but it is much more accurate asymptotically and, as we show, numerically. The calculations in section 4 show that the leading term in a saddle point expansion of (3.4) as $\xi \to 0^+$ yields precisely (2.19). We also note that the integrand in (3.4) is an entire function of s, as both $Q(\cdot)$ and $1/\Gamma(\cdot)$ are.

In Appendix B we obtain the following representation for Φ_0 as an infinite sum:

$$\Phi_0(\xi) = \frac{1}{4\xi}\left[\prod_{\ell=1}^{\infty}(1-2^{-\ell})^{-2}\right]\sum_{m=-\infty}^{\infty}(-1)^{m+1}2^{-m^2/2}2^{5m/2}\exp(-2\xi 2^{-m}). \tag{3.5}$$

For any fixed $\xi > 0$ this sum converges very rapidly as $m \to \infty$, and even more rapidly as $m \to -\infty$, due to the exponential factor. It is thus useful for numerical calculations. The asymptotics as $\xi \to 0^+$ are difficult to obtain from (3.5), due to the alternating sum. However, we can easily see that $\Phi_0(\xi) = o(\xi^N)$ for all $N \geq 1$. Indeed, we expand the exponent in Taylor series and exchange the order of the two summations. We have

$$\sum_{m=-\infty}^{\infty}(-1)^{m+1}2^{-m^2/2}2^{5m/2}2^{-mL} = 0 \tag{3.6}$$

for any integer L, as can be seen by the antisymmetry of the summand with respect to the shift $m \to 5-2L-m$. It thus follows that Φ_0 vanishes to all algebraic orders as $\xi \to 0^+$. A rough estimate of the leading behavior can be obtained by noting that for $\xi \to 0^+$ the important terms in the sum are those where $\xi 2^{-m} = O(1)$ so that $m \approx \log_2 \xi$. There the magnitude of the summand is roughly $2^{-m^2/2} = \exp\left[-\frac{1}{2}(\log 2)(\log_2 \xi)^2\right]$, which is the same as the dominant factor in (2.19).

For numerical calculations we use (3.5) to approximate Φ and A in (2.15), for $\xi \to 0^+$. Setting $z_0 = \Phi_0(\xi)$,

$$z_1 = (\xi\Phi_0)'(\xi) = -\frac{1}{2}\left[\prod_{\ell=1}^{\infty}(1-2^{-\ell})^{-2}\right]\sum_{m=-\infty}^{\infty}(-1)^{m+1}2^{-m^2/2}2^{3m/2}\exp(-2\xi 2^{-m}) \tag{3.7}$$

and

$$z_2 = \xi(\xi\Phi_0)''(\xi) = \xi\left[\prod_{\ell=1}^{\infty}(1-2^{-\ell})^{-2}\right]\sum_{m=-\infty}^{\infty}(-1)^{m+1}2^{-m^2/2}2^{m/2}\exp(-2\xi 2^{-m}), \tag{3.8}$$

we thus obtain the asymptotic form of the (improved) WKB approximation as (cf. (2.15))

$$\sqrt{1+z_2}e^{-nz_0}e^{-z_1}. \tag{3.9}$$

We denote the above "refined" approximation by REF. In Table 6 we compare (3.9) to the exact values, for the few points where there is appreciable (numerical) mass. We also give the values of $\xi = n2^{-k}$, since (3.9) assumes that $\xi \to 0^+$. We consider n in the range $30 \leq n \leq 100$.

When $n = 40$ and $k = 5$ we have $\xi = 1.25$, and here (3.9) overestimates the true value by a factor of about 3. However, here we would not expect to be able to use the

TABLE 6
Refined approximation in the central regime.

	10	.098	1.0000	1.0000

small ξ approximation to (2.15), but rather should compute $\Phi(1.25)$ numerically and use this value instead. We will discuss the numerical computation of Φ shortly. When $k = 6$ we have $\xi = .625$ which is certainly not small, but nevertheless (3.9) is accurate to about 1%. For $k = 7, 8$, and 9 the two results agree to 3 or 4 decimal places. For each n we increased k until h_n^k is one to 4 decimal places. Note that by the time k reaches this value, we are fairly well in the right tail, and there we showed that URT is highly accurate.

As we increase n, Table 6 shows that REF is not accurate whenever $\xi \geq 1$, but gives reasonable approximations for $\xi \leq .8$ and is very good for $\xi \leq .5$. Thus the small ξ approximation to (2.15) in (3.9) is quite robust. The numerical computation of Φ is most difficult when ξ is small, so that the numerical and asymptotic methods complement each other, as is often the case in applied problems.

We note that it was essential that we used the refined approximation in (3.9), rather than the leading term result in (2.19), which we denote by $\Phi_{LT}(\xi)$. In Table 7 we compare the values of Φ_0 and Φ_{LT}, starting at $\xi = .1$ and decreasing to $\xi = 10^{-14}$. When $\xi = .1$ we have $\Phi_{LT}/\Phi_0 = 7.31$ and even if $\xi = 10^{-14}$, this ratio is 1.79, which

TABLE 7
Different approximations of $\Phi(\xi)$.

ξ	$\Phi_{LT}(\xi)$	$\Phi_0(\xi)$	Φ_{LT}/Φ_0
.1	$3.99(10^{-6})$	$5.45(10^{-7})$	7.31
10^{-2}	$3.58(10^{-15})$	$7.54(10^{-16})$	4.75
10^{-3}	$6.62(10^{-28})$	$1.78(10^{-28})$	3.72
10^{-4}	$2.95(10^{-44})$	$9.33(10^{-45})$	3.16
10^{-6}	$1.26(10^{-87})$	$4.94(10^{-88})$	2.55
10^{-8}	$5.12(10^{-145})$	$2.29(10^{-145})$	2.23
10^{-10}	$2.81(10^{-216})$	$1.38(10^{-216})$	2.03
10^{-12}	$2.62(10^{-301})$	$1.38(10^{-301})$	1.89
10^{-14}	$4.89(10^{-400})$	$2.73(10^{-400})$	1.79

is far from the theoretical value (=1) as $\xi \to 0^+$. When $\xi = 10^{-14}$, both values are about 10^{-400}. By now we are so far in the right tail that we would never use the WKB result in the first place.

Finally, we discuss the accumulation of the probability mass at one or two points as $n \to \infty$, as our results predict. We define ℓ and $\beta = \beta(n)$ as in (2.23). We clearly have $0 \le \beta < 1$. It proves easiest to discuss the limit $n \to \infty$ along subsequences $n(i)$ that correspond to β nearly constant.

If we take a fixed $0 < \beta < 1$, then (2.25) predicts that the masses at $\ell = 0, 1, 2$ (corresponding to $k = k_1 - 1, k_1, k_1 + 1$) are approximately

$$
\begin{aligned}
m_0 &\approx \exp\left[-\frac{Q_*}{2\sqrt{\log 2}} e^{-\frac{1}{\log 2}} \frac{2^{\beta\sqrt{2\log_2 n}} 2^{-\beta^2/2} e^{\beta}}{(2\log_2 n)^{3/4}}\right], \\
m_1 &\approx 1 - \frac{Q_*}{2\sqrt{\log 2}} e^{-\frac{1}{\log 2}} \frac{2^{(\beta-1)\sqrt{2\log_2 n}} 2^{-(\beta-1)^2/2} e^{\beta-1}}{(2\log_2 n)^{3/4}}, \\
m_2 &\approx \frac{Q_*}{2\sqrt{\log 2}} e^{-\frac{1}{\log 2}} \frac{2^{(\beta-1)\sqrt{2\log_2 n}} 2^{-(\beta-1)^2/2} e^{\beta-1}}{(2\log_2 n)^{3/4}}.
\end{aligned}
\tag{3.10}
$$

Here $m_0 = h_n^{k_1-1} - h_n^{k_1-2} \sim h_n^{k_1-1}$, $m_1 = h_n^{k_1} - h_n^{k_1-1} \sim h_n^{k_1} (\sim 1)$, and $m_2 = h_n^{k_1+1} - h_n^{k_1} \sim 1 - m_1$. Thus all the mass should concentrate at $k = k_1$ as long as β remains bounded from 0 and 1. Even as $\beta \to 1^-$ we will have $m_2 \to 0$ and $m_1 \to 1$, due to the factor $(\log n)^{-3/4}$ in m_2 and $1 - m_1$.

Next consider subsequences along which $\beta \to 0$. As before, we define $\Delta(n)$ by (2.27). Using (2.27) in (2.25) (or (3.10)) we find that if $n \to \infty$ in such a way that $\Delta(n)$ is bounded, then $h_n^{k_1-1}$ is $O(1)$ and < 1. Thus, for such sequences there is mass at two points, corresponding to $k = k_1 - 1$ and $k = k_1$.

To construct such sequences $\Delta(n)$ we consider the equation

$$
N + \frac{3}{2}\frac{\log_2(\sqrt{2\log_2 n})}{\sqrt{2\log_2 n}} = \log_2 n + \sqrt{2\log_2 n} - \log_2(\sqrt{2\log_2 n}) + \frac{1}{\log 2} - \frac{1}{2},
\tag{3.11}
$$

where N is an integer $N \ge 3$. For any N we can solve (numerically) the implicit relation (3.11) and generate a sequence of solutions, which we denote by $n_*(N)$. In view of the definition (2.24) of $\beta(n)$ we see that when $n = n_*(N)$ we have $\Delta(n) = 0$. Now, $n_*(N)$ is generally not an integer, but $\lfloor n_*(N) \rfloor$ or $\lfloor n_*(N) \rfloor + 1$ should correspond

to a local minimum of the sequence $|\Delta(n)|$. In Table 8 we compute the first few $n_*(N)$ and also give the sequence of local minima of $|\Delta(n)|$. We see that $\min|\Delta(n)|$ is the integer closest to $n_*(N)$ for all $3 \le N \le 15$. In Figure 4 we plot the sequence $\Delta(n)$. From (2.27) and the figure we see that the upper envelope grows (roughly) like $\sqrt{\log n}$ and the lower envelope like $-\log\log n$. The sequence increases, crosses zero, and then jumps back down. The jump corresponds to the fractional part β changing from 1^- to 0^+, which occurs by increasing n. The maxima of $\Delta(n)$ corresponds to $\beta \approx 1$, while the minima have $\beta \approx 0$. Note also that β is small at the minima of $|\Delta(n)|$.

We can easily solve (3.11) asymptotically as $N \to \infty$, and this yields the estimate

$$n_*(N) = 2^{\,N-\sqrt{2N}}\sqrt{2N}\,2^{3/2}e^{-1} \times \left[1 + \frac{\log 2}{\sqrt{2N}}\left(\frac{1}{2}\log_2(\sqrt{2N}) - 1\right) + O\left(\frac{\log N}{N}\right)\right]. \tag{3.12}$$

Using (3.12) to compute $\beta(n)$ and then $\Delta(n)$ for $N \to \infty$, we find that for $N \to \infty$ and $n - n_* = O(1)$

$$\Delta(n) \sim \frac{1}{n_*}(n - n_*)\left\{\frac{3}{4}\frac{\log_2(\sqrt{2\log_2 n_*})}{\log(n_*)} - \frac{3}{4\log 2}\frac{1}{\log(n_*)} + \frac{\sqrt{2}}{(\log 2)^{3/2}}\left(\sqrt{\log n_*} + \sqrt{\frac{\log 2}{2}} - \frac{1}{2\sqrt{\log n_*}}\right)\right\}. \tag{3.13}$$

This shows that as $n \to \infty$, $\Delta(n)$ is not only bounded but $\Delta(n) \to 0$ with (roughly) $\Delta(n_*(N)) = O(n^{-1})$. Thus, along sequences such as $n = \lfloor n_*(N)\rfloor$ or $n = \lfloor n_*(N)\rfloor + 1$, the mass m_0 should be

$$\exp\left[-\frac{Q_*}{2\sqrt{\log 2}}\exp\left(-\frac{1}{\log 2}\right)\right] \approx .990998897\ldots. \tag{3.14}$$

Even though this is *asymptotically* $O(1)$ and < 1, the small value of Q_* (cf. (2.29)) shows that *numerically* most of the mass will be at $k_1 - 1$, with the remaining mass at k_1. Expression (3.14) has some fluctuations, but these are very small in view of Table 1.

If we choose a sequence $n(i)$ such that $\beta(n) \to 1^-$, then the mass becomes concentrated at $\ell = 1$ ($k = k_1$), and the mass at $\ell = 2$ is

$$m_2 \sim \frac{Q_*}{2\sqrt{\log 2}}e^{-\frac{1}{\log 2}}\frac{1}{(2\log_2 n)^{3/4}}. \tag{3.15}$$

The right side of (3.15) approaches zero slowly, but in view of the small numerical value of $Q_* e^{-1/(\log 2)}\ 2^{-1}(\log 2)^{-1/2} \approx .009041857\ldots$, m_2 will be numerically small even for moderate values of n. We also note that choosing n to make $\beta \approx 1$ minimizes the mass at $\ell = 0$ ($k = k_1 - 1$). From an asymptotic point of view, the optimal way to choose $n(i)$ to get most rapid convergence to mass at the single point k_1 is to minimize $|\beta(n) - 1/2|$. This makes m_0 and m_2 both small. However, for moderate values of n, it is preferable to choose $\beta \approx 1$, in order that the factor $2^{\sqrt{2\log_2 n}}$ in the exponent in m_0 in (3.10) compensates for the numerically small value of Q_*. Thus for moderate n it is more essential to minimize m_0 rather than m_2 to obtain $m_1 \to 1$. For very large values of n it becomes desirable to minimize m_2, which requires $\beta \approx 0$ (but in such a way that $\Delta(n) \to -\infty$).

The numerical results in Table 6 show that for $k = 40$, 50, 60, 70, 80, 90, and 100, the most mass occurs, respectively, at $k = 6$, 7, 7, 7, 7, 8, and 8. The respective masses, obtained from $h_n^k - h_n^{k-1}$, are about .69, .57, .75, .69, .49, .64, and .75. The respective values of k_1 are 8, 9, 9, 9, 9, 10, and 10, so that the most mass is at $k_1 - 2$, not k_1! This apparent discrepancy, however, can easily be understood from the asymptotic analysis. In order to make the mass for $k \le k_1 - 2$ ($\ell \le -1$) about .1, even with an optimal value of $\beta \approx 1$, we need n large enough so that

$$.1 = \exp\left[-\frac{Q_*}{2\sqrt{\log 2}}\frac{1}{(2\log_2 n)^{3/4}}2^{2\sqrt{2\log_2 n}}2^{-2}e^{2-1/\log 2}\right]$$

so that $n \approx 22,123$. To make this mass .01, we need $n \approx 252,025$. To make the mass in the range $k \le k_1 - 1$ ($\ell \le 0$) .1 and .01 we need to have $n \approx 1.364(10^{10})$ and $n \approx 2.340(10^{12})$, respectively. This is well beyond the range of the values in Tables 2–6. Our asymptotic results predict that the mass should migrate from $k_1 - 2$ to $k_1 - 1$ and eventually to k_1, at least for values of β bounded away from zero. Note, however, that the numerical mass is well predicted by our asymptotic expansions, even for moderate values of n.

To better see the convergence of mass to one or two points, it is best to consider special subsequences $n(i)$ in order to avoid the oscillations caused by the appearance of $\beta(n)$. In Table 9, we consider the first few n which correspond to local minima of $|\Delta(n)|$, as given in Table 8. For these we give the exact masses $m_{-1} = h_n^{k_1-2} - h_n^{k_1-3}$, m_0 and m_1. As previously discussed the theory predicts that m_0 and m_1 will be close to .991 and .009. From Table 9 we see only that there is a gradual migration of mass from $k_1 - 2$ to $k_1 - 1$. However, even at $n = 127$ most of the mass is still at $k_1 - 2$.

In Table 10 we choose a sequence $n(i)$ so as to minimize $1 - \beta(n)$. This is the optimal way to "push" the mass out of $k = k_1 - 2$ and into $k = k_1$ for moderate n. The table clearly shows a gradual migration of mass from $k_1 - 2$ into $k_1 - 1$, and an increase of mass at k_1, though the latter is still below .05 when $n = 264$. Our asymptotic results predict that the migration from $k_1 - 1$ to k_1 along this subsequence would occur when $n \approx 10^{10}$, which is well beyond the range where it is feasible to do numerical calculations.

We conclude by discussing the numerical computation of $\Phi(\xi)$. We define

$$\Phi_{NUM}(\xi;k) \equiv -\frac{1}{n}\log(h_n^k), \qquad \xi = n2^{-k}.$$

Our results predict that for each fixed $0 < \xi \le 2$, $\Phi_{NUM}(\xi;k)$ should approach $\Phi(\xi)$ as $k \to \infty$. In Figure 5 we sketch Φ_{NUM} for $k = 6$. The limit function $\Phi(\xi)$ appears smooth except at $\xi = 0$ and $\xi = 2$, where our analytic results apply.

When $\xi = 2$ we have the theoretical value exactly, as $\Phi(2) = 1 - \log(\sqrt{2C_0}) = .55946\ldots$. Note that $n = 2^{k+1} - 1$ corresponds to $\xi = 2 - 2^{-k}$. In view of (2.17) we should have, as $k \to \infty$,

$$\Phi(2 - 2^{-k}) = \Phi(2) - \frac{k}{2}2^{-k} - \frac{1}{4}\log(2C_0)2^{-k} + o(2^{-k}). \tag{3.16}$$

In Table 11 we give $\Phi_{NUM}(2-2^{-k};k) = -\log(h^k_{2^{k+1}-1})/(2^{k+1}-1)$ for k in the range [2,7]. We compare Φ_{NUM} to both $\Phi(2)$ and the 3-term approximation in (3.16). This shows that Φ_{NUM} is indeed converging to the theoretical value.

To summarize, we have shown that the asymptotic results provide, on the whole, very good approximations to h_n^k. To achieve this, however, it is sometimes necessary to obtain more uniform and/or higher order results than those in (2.11)–(2.22). The accumulation of mass at $k = k_1$ is not in good agreement with the numerical results, but the asymptotics explain this and estimate the size of n necessary for the mass to migrate to k_1.

4. The right-tail analysis. In this section, we derive parts (i) and (ii) of Theorem 2.1, that is, the far right-tail approximation (2.11) and the right-tail asymptotic expansion (2.12).

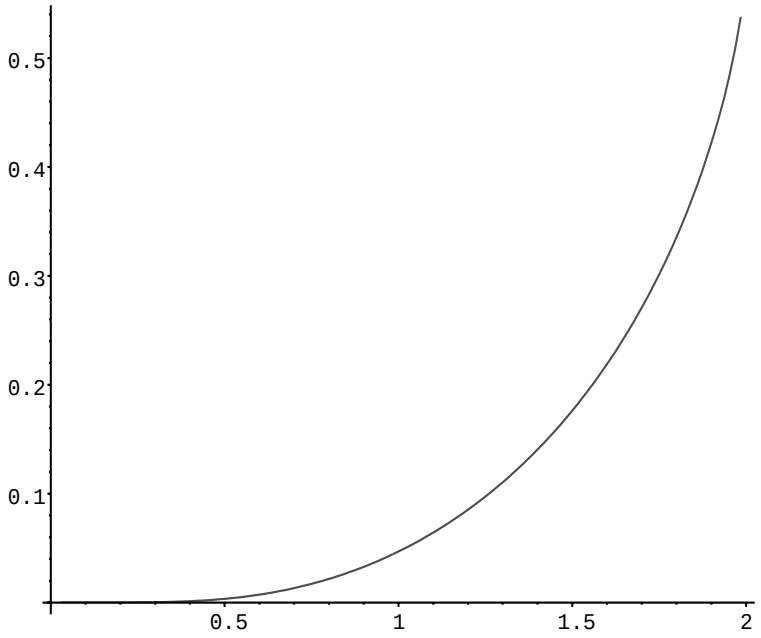

FIG. 5. *The functions* $\Phi_{NUM}(\xi;k)$ *versus* ξ *for* $k=6$.

4.1. The far right-tail analysis. Since we analyze h_n^k when the distribution is asymptotically close to one, it is convenient to set $j=n-k$ and

$$h_n^k = 1 - H_n^k, \qquad H_n^k = H_n^{n-j} = \mathcal{L}_j(n). \tag{4.1}$$

Using (4.1) in (2.2) we obtain

$$2^n\mathcal{L}_j(n+1) = 2\sum_{\ell=0}^{j-2}\binom{n}{\ell}\mathcal{L}_{j-\ell}(n-\ell) - \sum_{i=n-j+2}^{j-2}\binom{n}{i}\mathcal{L}_{i+j-n}(i)\mathcal{L}_{j-i}(n-i) \tag{4.2}$$

for $n \geq j$. Here we have multiplied (2.2) by 2^n and used the fact that $h_n^k = 1$ for $k \geq n-1$, which is equivalent to $\mathcal{L}_j(n) = 0$ for $j \leq 1$. We also note that if $k+1 \geq n$, $h_n^k = 1$ is an exact solution to (2.2), since every term in the sum lies in this range.

We have thus decomposed the nonlinear right side of (2.2) into a linear part and a nonlinear part, corresponding to the two sums in (4.2). For $n \geq 2j-3$ the second

sum is void and the equation is *exactly* linear. The initial condition (2.3) becomes

$$\begin{aligned} \mathcal{L}_j(j) &= 0, \qquad j = 0, 1, \\ \mathcal{L}_j(j) &= 1, \qquad j \geq 2. \end{aligned} \tag{4.3}$$

From (4.2) we can compute $\mathcal{L}_j(n)$ exactly for small values of $j \geq 2$. For example, setting $j = 2$ we obtain from (4.2), subject to $\mathcal{L}_2(2) = 1$,

$$\mathcal{L}_2(n) = 2^{-n^2/2} 2^{3n/2} 2^{-1}, \quad n \geq 2, \tag{4.4}$$

and this proves (2.6). Letting $j = 3$ in (4.2) we find that

$$\mathcal{L}_3(n) = \left(\frac{n}{8} - \frac{1}{4} \right) 2^{-n^2/2} 2^{5n/2}, \qquad n \geq 4, \tag{4.5}$$

which is equivalent to (2.7). Note that (4.5) remains valid if $n = 3$ since $\mathcal{L}_3(3) = 1$ by (4.3).

Next we discuss the asymptotics as $n \to \infty$. For any fixed j and $n \to \infty$, we can conclude that

$$\mathcal{L}_j(n) \sim 2^{-n^2/2} 2^{(j-1/2)n} n^{j-2} C(j). \tag{4.6}$$

To compute $C(j)$ we use (4.6) in (4.2) to obtain

$$\begin{aligned} 2^n C(j) \cdot (n+1)^{j-2} 2^{-n^2/2} 2^{-n} 2^{-1/2} 2^{(j-1/2)n} 2^{j-1/2} \\ \sim 2 \sum_{\ell=0}^{j-2} \binom{n}{\ell} C(j-\ell) (n-\ell)^{j-\ell-2} 2^{-(n-\ell)^2/2} 2^{(j-\ell-1/2)(n-\ell)}. \end{aligned} \tag{4.7}$$

Noting that $\binom{n}{\ell} n^{-\ell} \sim \frac{1}{\ell!}$ and $(n-\ell)^{j-\ell-2} \sim n^{j-2} n^{\ell}$ as $n \to \infty$ the leading terms in (4.7) yield

$$2^{j-1} C(j) = 2 \sum_{\ell=0}^{j-2} \frac{C(j-\ell)}{\ell!} 2^{\ell^2/2} 2^{\ell/2} 2^{-\ell j}, \qquad j \geq 2. \tag{4.8}$$

In view of (4.4) and (4.6) we have $C(2) = 1/2$. Solving (4.8) yields

$$C(j) = 2^{-j^2/2} 2^{j/2} \frac{1}{(j-2)!},$$

which completes the derivation of the asymptotic formula for $1 - h_n^k = H_n^k = \mathcal{L}_j(n)$ in (2.11).

4.2. The right-tail analysis. We next consider n and $j = n - k$ simultaneously large and such that $0 < k/n < 1$, so that we are in the range of Theorem 2.1(ii). We will show that the asymptotic relation (4.6) ceases to be valid if j is as large as $O(n)$. Note also that $j = n - k$ can be as large as $n - \log_2 n$. From our consideration of small values of j, it is easy to see that $F_j(n)$ has the form

$$F_j(n) = \tilde{F}_j(n) + O(\rho^n), \qquad n \geq 2j - 3, \tag{4.9}$$

where $\rho < 1$ and $\tilde{F}_j(n)$ is a polynomial of degree $j - 2$. The exponentially small term corresponds to terms that are $O(4^{-n}, 8^{-n}, 16^{-n}, \ldots)$, modulo some factors algebraic

in n, as $n \to \infty$. Our calculations also showed that $\tilde{F}_j(n)$ depends on the initial conditions (4.3) only through the value $\mathcal{L}_2(2) = 1$. We then used the fact that $\mathcal{L}_3(3) = 1$ to conclude that $c_1 = 0$, which implies that there are no terms of order $O(2^{-n})$ in the exponentially small term. Then the terms proportional to 4^{-n} are completely determined by the value of c_2, which follows from $\mathcal{L}_4(4) = 1$.

For the region $n/j > 2$ in the (j, n) plane the problem (4.2) is exactly linear. For $1 < n/j < 2$ the nonlinear terms are present, but as long as $\mathcal{L}_j(n)$ is asymptotically small (i.e., h_n^k is asymptotically close to 1), the nonlinear term is small compared to the linear term(s). Thus in the right tail we can drop the second sum in (4.2) and replace $=$ by $\sim$. Also, the exponentially small part of the solution $F_j(n)$ depends on the values of $F_j(n)$ when $n/j = 2$, which in turn depends on the initial condition(s) (4.3). The initial data propagates from $n/j = 1$ to the range $n/j > 2$ via the region where the nonlinear term is present. However, these terms are exponentially small compared to $\tilde{F}_j(n)$. This discussion shows that

$$F_j(n) \sim \tilde{F}_j(n) \tag{4.10}$$

as long as j is such that $\mathcal{L}_j(n)$ is asymptotically small.

We next compute $\tilde{F}_j(n)$ for arbitrary j and use the result to obtain the asymptotics of $\mathcal{L}_j(n)$ (and hence h_n^k) for $n, j \to \infty$ with n/j fixed and $n/j > 1$. This implies that $k, n \to \infty$ at the same rate and $0 < k/n < 1$.

Since $\tilde{F}_j(n)$ is a polynomial in n of degree $j-2$ we can write

$$\tilde{F}_j(n) = \binom{n}{j-2} + d_1(j)\binom{n}{j-3} + d_2(j)\binom{n}{j-4} + \cdots, \tag{4.11}$$

where the sum truncates after a finite number of terms. Here we have set $d_0(j) = 1$, which follows from (4.6). For a fixed j and $n \to \infty$ the successive terms in (4.11) are asymptotically smaller by factors of n^{-1}. However, we will show that this is no longer true if n and j are both large. Using (4.11) yields

$$\begin{aligned} 2^{j-2}\left[\binom{n+1}{j-2} + d_1(j)\binom{n+1}{j-3} + d_2(j)\binom{n+1}{j-4} + \cdots\right] \\ = \sum_{\ell=0}^{j-2}\binom{n}{\ell}\left[\binom{n-\ell}{j-\ell-2} + d_1(j-\ell)\binom{n-\ell}{j-\ell-3}\right. \\ \left. + d_2(j-\ell)\binom{n-\ell}{j-\ell-4} + \cdots\right]. \end{aligned} \tag{4.12}$$

Using the identities

$$\begin{aligned} \binom{n+1}{m} &= \binom{n}{m} + \binom{n}{m-1}, \\ \binom{n}{\ell}\binom{n-\ell}{j-\ell-m} &= \binom{n}{j-m}\binom{j-m}{\ell} \end{aligned}$$

and comparing coefficients of $\binom{n}{j-m}$ in (4.12) for $m \geq 2$, we are led to the recurrences

$$2^{j-2}[1 + d_1(j)] = \sum_{\ell=0}^{j-3} d_1(j-\ell)\binom{j-3}{\ell} \tag{4.13}$$

and

$$2^{j-2}[d_m(j)+d_{m+1}(j)] = \sum_{\ell=0}^{j-m-3} d_{m+1}(j-\ell)\binom{j-m-3}{\ell}, \quad m \geq 1. \tag{4.14}$$

From (4.13) it follows that $d_1(j) = -2$, which is independent of j. We then find from (4.14) that $d_m(j)$ is independent of j for all $m \geq 1$, and $d_m(j) = d_m$ satisfies

$$d_m + d_{m-1} = 2^{-m} d_m$$

so that $d_m = (-1)^m \prod_{N=1}^{m} \left(1-2^{-N}\right)^{-1}$ and hence

$$\tilde{F}_j(n) = \sum_{m=0}^{j-2} (-1)^m \binom{n}{j-2-m} \prod_{N=1}^{m} (1-2^N)^{-1}. \tag{4.15}$$

We can easily check that this agrees with our previous results for $2 \leq j \leq 4$.

Now consider the binomial coefficient in (4.15) in the limit $n, j \to \infty$ with m and $\alpha \equiv n/j$ fixed and α rational. Using Stirling's formula we obtain

$$\begin{aligned} \frac{n!}{(n+m-j+2)!}\frac{1}{(j-2-m)!} &\sim \frac{n!}{(n-j+2)!}\frac{1}{(n-j)^m}\frac{j^m}{(j-2)!} \\ &\sim \frac{n^n}{(n-j)^{n-j}j^j}\frac{j^{3/2}\sqrt{n}}{(n-j)^{5/2}}\left(\frac{1}{\alpha-1}\right)^m \frac{1}{\sqrt{2\pi}}. \end{aligned} \tag{4.16}$$

It follows that

$$\tilde{F}_j(n) \sim \frac{n^n}{(n-j)^{n-j}j^j}\frac{j^{3/2}\sqrt{n\pi}}{\sqrt{2}(n-j)^{5/2}} I(\alpha), \tag{4.17}$$

where

$$I(\alpha) \equiv \frac{1}{\pi}\sum_{m=0}^{\infty} \frac{(-1)^m}{(\alpha-1)^m}\left[\prod_{\ell=1}^{m}(1-2^{-\ell})\right]^{-1}. \tag{4.18}$$

The sum in (4.18) is absolutely convergent for $\alpha > 2$. We can extend its range of validity by writing the product as $\prod_{\ell=1}^{m}(\cdots) = \prod_{\ell=1}^{\infty}(\cdots)/\prod_{\ell=m+1}^{\infty}(\cdots)$ and subtracting $\prod_{\ell=1}^{\infty}(\cdots)$. The resulting sum will converge for $\alpha > 3/2$, but we will need to know the behavior of $\tilde{F}_j(n)$ as $n \to \infty$ for all $\alpha = n/j > 1$. Thus we need to obtain a different representation for $\tilde{F}_j(n)$, which will be more useful for asymptotic analysis.

We begin by considering the function

$$A(z) = \prod_{\ell=1}^{\infty} \exp\left(\frac{1-2^{\ell z}}{\ell(2^\ell-1)}\right), \qquad \Re(z) < 1. \tag{4.19}$$

From (4.19) we can easily show that $A(\cdot)$ satisfies the functional equation

$$A(z+1) = A(z)[1-2^z], \tag{4.20}$$

which can be used to analytically continue $A(\cdot)$ into the range $\Re(z) > 1$. Observe that

$$A(-m) = \prod_{N=1}^{m}(1-2^{-N})^{-1} = \prod_{\ell=1}^{\infty}\exp\left(\frac{1-2^{-m\ell}}{\ell(2^\ell-1)}\right).$$

Indeed, the above follows from

$$\prod_{\ell=1}^{\infty}\exp\left(\frac{1-2^{-m\ell}}{\ell(2^\ell-1)}\right)=\exp\left(\sum_{\ell=1}^{\infty}\frac{1}{\ell}2^{-\ell}\frac{1-2^{-\ell m}}{1-2^{-\ell}}\right)$$
$$=\exp\left(\sum_{N=1}^{m}\sum_{\ell=1}^{\infty}2^{-N\ell}\frac{1}{\ell}\right)$$
$$=\exp\left(-\sum_{N=1}^{m}\log(1-2^{-N})\right)=\prod_{N=1}^{m}(1-2^{-N})^{-1}.$$

Then, we can rewrite the sum in (4.15) as

$$\tilde{F}_j(n)=\sum_{\ell=0}^{j-2}(-1)^\ell e^{\pi ij}\binom{n}{\ell}A(\ell+2-j) \tag{4.21}$$
$$=\frac{n!}{2\pi i}(-1)^{n+j}\int_{\frac12-i\infty}^{\frac12+i\infty}\frac{\Gamma(z+j-n-2)}{\Gamma(z+j-1)}A(z)dz,$$

where $0<\Re(z)<1$ on the contour of integration. The last inequality is basically Rice's formula (cf. [7, 28]), but we can derive it directly. Indeed, in the region $\Re(z)<1$ the integrand has simple poles at $z=0,-1,\dots,-j+1,-j+2$ and $\mathrm{Res}[z=-m]=\frac{(-1)^{m-j+n}}{(j-m-2)!}\,\frac{A(-m)}{(n+m-j-2)!}$, $m\ge 0$, where $\mathrm{Res}[z=A]$ stands for the residue at A for the function under the integral. Next, we close the contour in the left half-plane and the integral is equal to the finite residue sum, which is the same as (4.15).

Noting that

$$\sum_{\ell=1}^{\infty}\frac{1-2^{\ell z}}{\ell(2^\ell-1)}=\sum_{\ell=1}^{\infty}\frac{2^{-\ell}}{\ell}\sum_{N=0}^{\infty}2^{-N\ell}-\sum_{\ell=1}^{\infty}\frac{2^{\ell(z-1)}}{\ell}\sum_{N=0}^{\infty}2^{-N\ell}$$
$$=-\sum_{N=0}^{\infty}\log(1-2^{-N-1})+\sum_{N=0}^{\infty}\log(1-2^{z-N-1}),$$

we find that the expression in (4.19) becomes

$$A(z)=\prod_{\ell=1}^{\infty}(1-2^{-\ell})^{-1}\prod_{m=1}^{\infty}(1-2^{z-m}), \tag{4.22}$$

which applies for all z, and thus gives the analytic continuation of (4.19) into the half-plane $\Re(z)>1$. Expression (4.22) also shows that $A(z)$ is an entire function, with zeros at $z=1,2,3,\dots$.

In order to find another representation for $A(z)$, we define $p(z)$ by the relation

$$A(z)=e^{-\pi iz}2^{z^2/2}2^{-z/2}e^{p(z)}\prod_{m=1}^{\infty}\exp\left(\frac{2^{-mz}}{m(1-2^{-m})}\right) \tag{4.23}$$

and we also note that for $\Re(z)>0$

$$\prod_{m=1}^{\infty}\exp\left(\frac{2^{-mz}}{m(1-2^{-m})}\right)=\prod_{m=0}^{\infty}\frac{1}{1-2^{-z-m}}. \tag{4.24}$$

Denoting the above product by $g(z)$, it satisfies $g(z+1) = g(z)(1-2^{-z})$ and $g(z) \sim 1$ as $z \to \infty$ with $\Re(z) > 0$. Using (4.23) in (4.20) then shows that $p(z+1) = p(z)$.

We next identify explicitly the periodic function $p(\cdot)$ in terms of the Jacobi elliptic theta function (cf. [3]):

$$\vartheta_1(u) = \vartheta_1(u|\tau) = 2q^{1/4}\sin(u)\prod_{m=1}^{\infty}(1-2\cos(2u)q^{2m}+q^{4m})(1-q^{2m}),$$

where $e^{\pi i\tau} = q$. Setting $q = 1/\sqrt{2}$ and $u = (i\log 2)z/2$ the above becomes

$$\vartheta\left(\frac{i}{2}(\log 2)z\right) = i2^{7/8}\left[\prod_{m=1}^{\infty}(1-2^{-m})\right]\sinh\left(\frac{\log 2}{2}z\right)\prod_{m=1}^{\infty}[1-2\cosh(z\log 2)2^{-m}+4^{-m}]$$

$$= i2^{-1/8}2^{z/2}(1-2^{-z})\prod_{m=1}^{\infty}(1-2^{-m})\prod_{m=1}^{\infty}(1-2^{z-m})\prod_{m=1}^{\infty}(1-2^{-z-m}). \tag{4.25}$$

Using (4.22), (4.24), and (4.25) in (4.23) we find that

$$e^{p(z)} = 2^{-z^2/2}e^{\pi iz}(-i)2^{1/8}\left[\prod_{m=1}^{\infty}(1-2^{-m})^{-2}\right]\vartheta_1\left(\frac{i}{2}(\log 2)z\right). \tag{4.26}$$

The periodicity of $p(z)$ in the real direction follows from the "quasi periodicity" of the theta function in the imaginary direction.

We return to the discussion of the asymptotics of $\tilde{F}_j(n)$ (cf. 4.21) for $n, j \to \infty$ with $\alpha > 1$. For z fixed and n, j large we have

$$\begin{aligned}\frac{\Gamma(z+j-n-2)}{\Gamma(z+j-1)} &= \frac{\pi}{\sin(\pi z)}\frac{(-1)^{n+j}}{\Gamma(n-j+3-z)}\frac{1}{\Gamma(z+j-1)}\\ &\sim \frac{\pi}{\sin(\pi z)}\frac{(-1)^{n+j}}{\Gamma(n-j+3)}\frac{1}{\Gamma(j-1)}\left(\frac{n}{j}-1\right)^z\\ &\sim \frac{(-1)^{n+j}}{\sin(\pi z)}\frac{1}{2}\frac{e^n}{(n-j)^{n-j}j^j}\frac{j^{3/2}}{(n-j)^{5/2}}(\alpha-1)^z.\end{aligned}$$

Here we used $\Gamma(N+z) \sim \Gamma(N)N^z$ for $N \to \infty$ and z fixed. Using the above in (4.21) and approximating $n!$ by Stirling's formula yields

$$\tilde{F}_j(n) \sim \frac{n^n}{(n-j)^{n-j}j^j}\frac{\sqrt{n}j^{3/2}}{(n-j)^{5/2}}\frac{\sqrt{\pi}}{\sqrt{2}}\frac{1}{2\pi i}\int_{\frac{1}{2}-i\infty}^{\frac{1}{2}+i\infty}\frac{(\alpha-1)^z}{\sin(\pi z)}A(z)dz, \tag{4.27}$$

which yields the second representation (2.14) for $I(\alpha)$ that appears in Theorem 2.1(ii). For $\alpha > 2$ we can close the integration contour in the left half-plane and recover (4.17). However, (4.27) applies for all $\alpha > 1$. To obtain (4.27) we took the large n limit of the integrand in (4.21). This can be justified using a dominated convergence argument.

4.3. Asymptotic matching for $\alpha \to 1^+$. For purposes of asymptotic matching, we will need to know the behavior of the approximation in (4.27) as $\alpha \to 1^+$. We first observe that since $A(z)$ is an entire function with zeros of $z = 1, 2, 3, \ldots$, the integrand in (4.27) is analytic for $\Re(z) > 0$. The asymptotics of the integral as $\alpha \to 1$ will be obtained by shifting the contour to the right. Since there are no singularities in the right half-plane, the asymptotics must be governed by a saddle point (cf. [4, 25]).

We use the representation (4.23) for $A(z)$ and note that the infinite product in (4.23) is $1+O(2^{-z})$ as $z\to\infty$ in the right half-plane. We thus write the integral in (4.27) as

$$J\equiv\frac{1}{2\pi i}\int_{\mathcal{B}}e^{-\lambda z}2^{z^2/2}2^{-z/2}Q(z)[1+O(2^{-z})]dz, \tag{4.28}$$

where $\mathcal{B}$ is any vertical contour with $\Re(z)>0$ and

$$Q(z)=\frac{e^{-\pi iz}}{\sin(\pi z)}e^{p(z)},\qquad \alpha-1=e^{-\lambda}. \tag{4.29}$$

The periodicity of $p(\cdot)$ implies that $Q(z+1)=Q(z)$ and $\alpha\to 1^+$ corresponds to $\lambda\to+\infty$.

For $\lambda\to\infty$ the integrand in (4.28) has a saddle point where

$$\frac{d}{dz}\left[-\lambda z+\frac{z^2}{2}\log 2-\frac{z}{2}\log 2\right]=z\log 2-\lambda-\frac{1}{2}\log 2=0.$$

Thus the saddle is at $z\approx\lambda/\log 2$ and we set

$$z=\frac{\lambda}{\log 2}+\frac{1}{2}+\zeta. \tag{4.30}$$

We now use (4.28)–(4.30) and obtain

$$J\sim e^{-\lambda/2}e^{-\lambda^2/(2\log 2)}2^{-1/8}\frac{1}{2\pi}\int_{-\infty}^{\infty}2^{-t^2/2}Q\left(\frac{\lambda}{\log 2}+\frac{1}{2}+it\right)dt \tag{4.31}$$

for $\lambda\to\infty$. By periodicity, the above integral is $O(1)$ in this limit. We use (4.31) in (4.27), set $j=n-k$, and expand the result for $k/n\to 0$. Noting that $e^{-\lambda/2}=\sqrt{k/(n-k)}\sim\sqrt{k/n}$ and $\lambda=\log(n/k)+O(k/n)$, we find that

$$\begin{aligned}\tilde{F}_j(n)\sim{}& e^{\,k\log n+k-k\log k}\frac{n^{3/2}}{k^2}\frac{2^{-9/8}}{\sqrt{\log 2}}Q_*\left(\log_2 n-\log_2 k+\frac{1}{2}\right)\\ &\times\exp\left[-\frac{1}{2\log 2}(\log n-\log k)^2\right],\end{aligned} \tag{4.32}$$

where

$$Q_*(z)=\frac{1}{\sqrt{2\pi}}\int_{-\infty}^{\infty}e^{-s^2/2}Q\left(z+\frac{is}{\sqrt{\log 2}}\right)ds. \tag{4.33}$$

It is important to note that (4.32) was obtained by first taking $n,j\to\infty$ with n/j fixed and then expanding the result for $n/j=\alpha\to 1$. Thus (4.32) applies for $k/n\to 0$, but we will shortly show that we also need $k/\log_2 n\to\infty$.

We next consider the limits $n\to\infty$ with $k-\log_2 n=O(1)$ and then $n\to\infty$ with $k/\log_2 n=\nu>1$. The first limit has no significance to the distribution h_n^k, since if $k=\log_2 n+O(1)$ we are no longer in the right tail and thus we cannot linearize (4.2). However, the function (4.15) is defined for *all* k. In section 5 we will show that the limit with $k/\log_2 n$ fixed >1 is important for the asymptotic matching between the left and right tails.

We return to the representation of $\tilde{F}_j(n)$ in (4.21) and set $z = n-j+s = k+s$. For k, n large and $s = O(1)$ we use $\Gamma(z+j-1) = \Gamma(n-1+s) \sim \Gamma(n+1)n^{-2}n^s = n!n^{s-2}$ and the approximation for $A(z)$ as $z \to \infty$. Then the asymptotic form of (4.21) is

$$\begin{aligned}(4.34)\quad \tilde{F}_j(n) &\sim \frac{1}{2\pi i}\int_{-i\infty}^{i\infty} \frac{\pi n^{2-s}}{\Gamma(3-s)} Q(s) \exp\left(\frac{\log 2}{2}(k+s)(k+s-1)\right) ds \\ &= \frac{1}{2\pi i}\pi 2^{k^2/2}2^{-k/2}n^2 \int_{-i\infty}^{i\infty} \frac{Q(s)}{\Gamma(3-s)} 2^{s^2/2}2^{-s/2}e^{(k\log 2 - \log n)s} ds,\end{aligned}$$

where the integral is $O(1)$ for $k = \log_2 n + O(1)$. If we use (4.34), we would find that $\mathcal{L}_j(n) = O(n)$, which corresponds to h_n^k large and negative!

Next we show that (4.34) asymptotically matches to (4.32) in an intermediate limit where $n, k \to \infty$ with $k/n \to 0$ but $k - \log_2 n \to \infty$. We also obtain an approximation to $\tilde{F}_j(n)$ that applies for $k/\log_2 n \in (1, \infty)$. We set $k = \nu \log_2 n$ with $\nu > 1$ and expand (4.34) for $n \to \infty$. To leading order, the saddle point equation for (4.34) is

$$\frac{d}{ds}\left[\frac{s^2}{2}\log 2 + (\nu-1)s\log n\right] = s\log 2 + (\nu-1)\log n = 0,$$

so the saddle is at $s \approx -(\nu-1)\log_2 n$.

Since this is asymptotically large, the factor $1/\Gamma(3-s)$ also affects the location of the saddle. For $s \to -\infty$ we thus approximate (cf. [1])

$$(4.35)\qquad \frac{1}{\Gamma(3-s)} = (-s)^{-5/2}\frac{1}{\sqrt{2\pi}}e^{s\log(-s)-s}\left(1 + O\left(\frac{1}{s}\right)\right).$$

Using (4.35) in (4.34) and expanding the integrand near the saddle $s = s_0 \equiv -(\nu-1)\log_2 n$ yields

$$\begin{aligned}(4.36)\quad \tilde{F}_j(n) \sim &\sqrt{\frac{\pi}{2}}2^{k^2/2}2^{-k/2}n^2\frac{1}{2\pi i}\int_{-i\infty}^{i\infty} Q(s)e^{F(s_0)}e^{F'(s_0)(s-s_0)}e^{F''(s_0)(s-s_0)^2/2} \\ &\times\ (-s)^{-5/2}\left[1 + O\left(\frac{1}{s}\right) + O\left(F'''(s_0)(s-s_0)^3\right)\right] ds,\end{aligned}$$

where

$$F(s) = -s + s\log(-s) + \frac{\log 2}{2}s^2 - \frac{\log 2}{2}s + (\nu-1)s\log n$$

so that

$$F'(s) = \log(-s) + (\log 2)s - \frac{1}{2}\log 2 + (\nu-1)\log n,$$

and hence $F'(s_0) = \log(-s_0) - (\log 2)/2$, $F''(s_0) = 1/s_0 + \log 2 \sim \log 2$. Setting $s = s_0 - \log_2(-s_0) + \frac{1}{2} + it$, the leading term for (4.36) becomes

$$\begin{aligned}\tilde{F}_j(n) \sim & \sqrt{\frac{\pi}{2}} 2^{k^2/2} 2^{-k/2} n^2 (-s_0)^{-2} e^{F(s_0)} \exp\left(-\frac{1}{2}(\log 2)[\log_2(-s_0)]^2\right) 2^{-1/8} \\ & \times \frac{1}{2\pi}\int_{-\infty}^{\infty} 2^{-t^2/2} Q\left(s_0 - \log_2(-s_0) + \frac{1}{2} + it\right) dt \\ & = \frac{2^{-9/8}}{\sqrt{\log 2}} (k - \log_2 n)^{-2} \exp\left(k\log n - \frac{1}{2}\frac{\log^2 n}{\log 2} + \frac{3}{2}\log n\right) \\ & \times \exp\left[-(k-\log_2 n)\log(k-\log_2 n) + k - \log_2 n - \frac{\log^2(k-\log_2 n)}{2\log 2}\right] \\ & \times Q_*\left(\log_2 n - \log_2(k-\log_2 n) + \frac{1}{2}\right), \end{aligned} \tag{4.37}$$

where $Q_*(z)$ is given by (4.33). Expression (4.37) holds in the limit $k, n \to \infty$ with $k/\log_2 n$ fixed and > 1. We can easily show that it matches to (4.32) in the intermediate limit where $k/n \to 0$, $k/\log_2 n \to \infty$. In this limit

$$\begin{aligned} -(k-\log_2 n)\log(k-\log_2 n) + k - \log_2 n - \frac{\log^2(k-\log_2 n)}{2\log 2} \\ = -k\log k + k + (\log_2 n)(\log k) - \frac{\log^2 k}{2\log 2} + O(1), \end{aligned}$$

so that (4.37) becomes the same as (4.32). This also shows that (4.32) applies only to the range where $k/\log_2 n \to \infty$. In order to asymptotically match the right and left tails, we shall need to use (4.37). We also note that if we multiply (4.37) by $2^{-k^2/2}2^{-k/2}$ (thus obtaining the corresponding approximation to $1 - h_n^k = H_n^k$), the result has the form $n \times$ [function of $(k - \log_2 n)$]. This is precisely what is needed in order to match to the WKB expansion that we will derive in section 5.

For $k, n \to \infty$ with $k/\log_2 n = \nu > 1$, we are still in the right tail. We can estimate the value of k where there is appreciable mass by using (4.37). We argue that when $H_n^k = 2^{-k^2/2}2^{-k/2}F_j(n)$ becomes $O(1)$ in n, then we are no longer in the tail. Since Q_* is clearly $O(1)$, this condition is equivalent to

$$\begin{aligned} & -\frac{k^2}{2}\log 2 - \frac{k}{2}\log 2 + k\log n + \frac{3}{2}\log n - \frac{1}{2}\frac{\log^2 n}{\log 2} - (k-\log_2 n)\log(k-\log_2 n) \\ & + k - \log_2 n - \frac{\log^2(k-\log_2 n)}{2\log 2} - 2\log(k-\log_2 n) = O(1). \end{aligned} \tag{4.38}$$

The largest terms in (4.38) are $-\frac{\log 2}{2}(k-\log_2 n)^2 + \log n$, which balance when $k - \log_2 n \sim \sqrt{2\log_2 n}$. This gives a rough argument that the mean $\mathbf{E}[\mathcal{H}_n]$ behaves as $\mathbf{E}[\mathcal{H}_n] - \log_2 n \sim \sqrt{2\log_2 n}$. A more careful analysis of (4.38) shows that the left side is $O(1)$ for

$$\begin{aligned} k = & \log_2 n + \sqrt{2\log_2 n} - \log_2(\sqrt{2\log_2 n}) + \frac{1}{\log 2} - \frac{1}{2} \\ & - \frac{3}{2}\frac{\log_2(\sqrt{2\log_2 n})}{\sqrt{2\log_2 n}} + O((\log n)^{-1/2}). \end{aligned} \tag{4.39}$$

We discussed the condition in (4.39) in more detail in section 3.

4.4. Another representation for $Q(z)$. We next obtain another representation for the periodic function $p(z)$ (and hence $Q(z)$), which involves a Fourier series that we need in some computations. We let $\tilde{A}(z)$ be a solution of (4.20) and set $\tilde{A}(z) = \exp[B(z)]$. Then $B(z)$ satisfies

$$B(z+1) - B(z) = \log(1 - 2^z). \tag{4.40}$$

Introducing the two-sided Laplace transform

$$B^*(s) = \int_{-\infty}^{\infty} B(z) e^{-sz} dz,$$

we find that

(4.41)

$$\begin{aligned}(e^s - 1)B^*(s) &= \int_{-\infty}^{\infty} \log(1 - 2^z) e^{-sz} dz \\ &= \int_{-\infty}^{0} \log(1 - 2^z) e^{-sz} dz + \int_0^{\infty} (\pm \pi i + \log(2^z - 1)) e^{-sz} dz \\ &= \int_0^{\infty} e^{sz} \log(1 - 2^{-z}) dz \pm \frac{\pi i}{s} + \frac{\log 2}{s^2} + \int_0^{\infty} e^{-sz} \log(1 - 2^{-z}) dz \\ &= \pm \frac{\pi i}{s} + \frac{\log 2}{s^2} + \sum_{\substack{m=-\infty \\ m \neq 0}}^{\infty} \frac{1}{m} \frac{1}{s - m \log 2},\end{aligned}$$

where both integrals converge in the strip $-\log 2 < \Re(s) < \log 2$, and the left side is analytic for $0 < \Re(s) < \log 2$. The standard inversion formula then yields

$$B(z) = \frac{1}{2\pi i} \int_{\frac{1}{2} - i\infty}^{\frac{1}{2} + i\infty} \frac{e^{sz}}{e^s - 1} \left[\frac{\log 2}{s^2} \pm \frac{\pi i}{s} + \frac{\pi}{s} \left(\cot\left(\frac{\pi s}{\log 2} \right) - \frac{\log 2}{\pi s} \right) \right] ds, \tag{4.42}$$

where $0 < \Re(s) < \log 2$ on the contour of integration. Here we have used the partial fractions expansion of $\cot(z)$ to evaluate the sum in (4.41).

The integrand $h(s)$ in (4.42) has a triple pole at $s = 0$, simple poles at $s = 2k\pi i$, $k = \pm 1, \pm 2, \ldots$, and simple poles where $s = \ell \log 2$, $\ell = \pm 1, \pm 2, \ldots$. To evaluate $B(z)$ as $z \to \infty$ we shift the contour to the left. A lengthy calculation shows that the residue at $z = 0$ is

$$\operatorname{Res}[h(s); s = 0] = \log 2 \left(\frac{z^2}{2} - \frac{z}{2} + \frac{1}{12} \right) \pm \pi i \left(z - \frac{1}{2} \right) - \frac{\pi^2}{3 \log 2}. \tag{4.43}$$

The residues along the imaginary axis combine with (4.43) to yield

$$\begin{aligned}B(z) = {} & \frac{\log 2}{2}(z^2 - z) \pm i\pi \left(z - \frac{1}{2} \right) + \frac{\log 2}{12} - \frac{\pi^2}{3 \log 2} \\ & + \sum_{\substack{m=-\infty \\ m \neq 0}}^{\infty} e^{2m\pi i z} \left[\pm \frac{1}{2m} - \frac{1}{2m} \coth\left(\frac{2\pi^2 m}{\log 2} \right) \right] + O(2^{-z})\end{aligned} \tag{4.44}$$

as $z \to \infty$. By shifting the contour to the right we find that $B(z) \sim -2^z$ as $z \to -\infty$.

We observe that $\tilde{A} = e^B$ and A in (4.19) (or (4.22)) are related by $\tilde{A}(z)/\tilde{A}(0) = A(z)$. For z real we have

$$\sum_{\substack{m=-\infty \\ m\neq 0}}^{\infty} \frac{1}{m} e^{2m\pi iz} = -2\pi i \left(\langle z \rangle - \frac{1}{2} \right),$$

where, to recall, $\langle z \rangle$ is the fractional part of z. By comparing (4.44) with (4.23) we find that

$$Q(z) = \frac{e^{-\pi iz}}{\sin(\pi z)} e^{p(z)} = \frac{1}{\sin(\pi z)} 2^{1/12} \exp\left(-\frac{\pi^2}{3\log 2} \pm i\pi \lfloor z \rfloor \right) \prod_{\ell=1}^{\infty} (1-2^{-\ell})^{-1} \times \exp\left[-\sum_{\substack{m=-\infty \\ m\neq 0}}^{\infty} \frac{e^{2m\pi iz}}{2m} \coth\left(\frac{2\pi^2 m}{\log 2} \right) \right]. \tag{4.45}$$

By periodicity it suffices to consider $0 < z < 1$. Writing

$$[\sin(\pi z)]^{-1} = e^{-\log(\sin \pi z)} = \exp\left[\log 2 + \frac{1}{2} \sum_{\substack{m=-\infty \\ m\neq 0}}^{\infty} \operatorname{sgn}(m) \frac{e^{2m\pi iz}}{m} \right]$$

($\operatorname{sgn}(x)$ is 1 for $x > 0$, -1 for $x < 0$, and 0 for $x = 0$) and noting that

$$\coth(am) - \operatorname{sgn}(m) = \frac{e^{-a|m|}}{\sinh(am)}, \qquad a > 0,$$

we find from (4.44), (4.25), and (4.26) that

$$Q(z) = 2^{13/12} \left[\prod_{\ell=1}^{\infty} (1-2^{-\ell})^{-1} \right] \exp\left[-\frac{\pi^2}{3\log 2} - \sum_{m=1}^{\infty} \frac{e^{-am}}{m \sinh(am)} \cos(2m\pi z) \right] = \frac{2^{-z^2/2 + z/2}(1-2^{-z})}{\sin(\pi z)} \prod_{m=1}^{\infty} (1-2^{-m})(1-2^{z-m})(1-2^{-z-m}), \tag{4.46}$$

where

$$a = \frac{2\pi^2}{\log 2}.$$

This coincides with the representation of $Q(z)$ given in Theorem 2.1(iii). From the Fourier series we see that $Q(z)$ is nearly constant since

$$\left| \sum_{m=1}^{\infty} \frac{e^{-am}}{m \sinh(am)} \cos(2m\pi z) \right| \leq \sum_{m=1}^{\infty} \frac{e^{-am}}{m \sinh(am)} = 3.678\ldots(10^{-25}).$$

To summarize the calculations, we have obtained the leading term for $1 - h_n^k$ for the limits (i) $n \to \infty$, $n-k = j = O(1)$, (ii) $n, k \to \infty$ with $0 < k/n = 1 - 1/\alpha < 1$, and (iii) $k, n \to \infty$ with $k/\log_2 n = \nu > 1$. The last corresponds to the "left-most" right-tail region. The third region involves correction terms that are $O(1/\log n)$, while the first two had correction terms $O(1/n)$. Thus we expect that the third case will result in the worst numerical agreement (this was discussed in more detail in section 3).

5. The left-tail and central-regime analyses. We analyze here the distribution when h_n^k is asymptotically small. Then we can no longer linearize (2.2). Whereas the right tail was treated using purely linear analysis, the left tail requires different techniques such as the WKB method and matched asymptotics.

5.1. The left-tail analysis. We first prove part (iv) of Theorem 2.1. We set $2^{k+1} - n = M$, $M \geq 1$, and first show how to compute h_n^k explicitly for small values of M. Since the generating function in (2.4) is a polynomial of degree $2^{k+1} - 1$ we isolate the two leading coefficients by writing

$$H_k(z) = a(k)z^{2^{k+1}-1} + b(k)z^{2^{k+1}-2} + \cdots + z + 1. \tag{5.1}$$

It follows that

$$H_k^2(z) = a^2(k)z^{2^{k+2}-2} + 2a(k)b(k)z^{2^{k+2}-3} + O(z^{2^{k+2}-4}) \tag{5.2}$$

and

$$\begin{aligned} H'_{k+1}(2z) = \frac{1}{2}\Big[\, & a\ (k+1)2^{2^{k+2}-1}(2^{k+2}-1)z^{2^{k+2}-2} \\ & + b(k+1)2^{2^{k+2}-2}(2^{k+2}-2)z^{2^{k+2}-3} + O(z^{2^{k+2}-4})\Big]. \end{aligned} \tag{5.3}$$

By using (2.5), (5.2), and (5.3) we obtain the recurrences

$$2^{2^{k+2}}(2^{k+2}-1)a(k+1) = 4a^2(k), \qquad a(0) = 1, \tag{5.4}$$

$$2^{2^{k+2}}(2^{k+2}-2)b(k+1) = 16a(k)b(k), \qquad b(0) = 1. \tag{5.5}$$

Equation (5.4) is nonlinear but (5.5) is linear, once we compute $a(k)$.

To solve (5.4) we set $a(k) = e^{\alpha(k)}$ to get

$$\alpha(k+1) - 2\alpha(k) = -\log\left[\frac{1}{4}2^{2^{k+2}}(2^{k+2}-1)\right]. \tag{5.6}$$

If $\alpha(k) = 2^k\tilde{\alpha}(k)$, then (5.6) becomes

$$\tilde{\alpha}(k+1) - \tilde{\alpha}(k) = -2^{-k-1}\log\left[\frac{1}{4}2^{2^{k+2}}(2^{k+2}-1)\right]. \tag{5.7}$$

We solve (5.7) subject to $\tilde{\alpha}(0) = 0$ to obtain

$$\alpha(k) = -2^k\sum_{\ell=0}^{k-1} 2^{-\ell-1}\log\left[\frac{1}{4}2^{2^{\ell+2}}(2^{\ell+2}-1)\right]. \tag{5.8}$$

Exponentiating (5.8) and some rearrangement yields

$$\begin{aligned} a(k) &= \prod_{\ell=1}^{k}\left(\frac{4}{2^{2^{\ell+1}}(2^{\ell+1}-1)}\right)^{2^{k-\ell}} \\ &= 2^{-k2^{k+1}}4^{2^k-1}\prod_{\ell=1}^{k}\left(\frac{1}{2^{\ell+1}-1}\right)^{2^{k-\ell}}. \end{aligned} \tag{5.9}$$

We next obtain the asymptotics of $a(k)$ as $k \to \infty$. We write

$$2^k \sum_{\ell=1}^{k} 2^{-\ell} \log(2^{\ell+1}-1) = (3\cdot 2^k - k + 3)\log 2 + 2^k \sum_{\ell=1}^{k} 2^{-\ell}\log(1-2^{-\ell-1})$$

so that

$$a(k) = 2^{-(2k+3)2^k} 2^{2^{k+1}+k+1} \left\{ \prod_{\ell=1}^{k} (1-2^{-\ell-1})^{-2^{-\ell}} \right\}^{2^k} \tag{5.10}$$
$$= 2^{-(2k+1)2^k} 2^{k+1} C_0^{2^k} [1+O(2^{-k})], \qquad k \to \infty,$$

where

$$C_0 = \prod_{\ell=1}^{\infty} (1-2^{-\ell-1})^{-2^{-\ell}}, \tag{5.11}$$

whose numerical value was given in (2.18) of section 2.

Since $h^k_{2^{k+1}-1} = (2^{k+1}-1)!a(k) = \Gamma(2^{k+1})a(k)$, we use Stirling's formula to get

$$h^k_{2^{k+1}-1} = 2\sqrt{\pi} 2^{k/2} \left(\frac{2C_0}{e^2}\right)^{2^k} [1+O(2^{-k})], \quad k \to \infty. \tag{5.12}$$

Using our result for $a(k)$ in (5.5) and solving the linear recurrence yields

$$b(k) = \prod_{\ell=1}^{k} \frac{8a(\ell-1)}{2^{2^{\ell+1}}(2^\ell-1)}. \tag{5.13}$$

Using the (exact) expression for $a(k)$ in (5.10) in (5.13), and noting that

$$\prod_{\ell=1}^{k} \frac{8\cdot 2^\ell}{2^{2^{\ell+1}}(2^\ell-1)} 2^{-(\ell+1/2)2^\ell} 2^{2^\ell} = 8^k 2^{1-(2k+1)2^k} \prod_{\ell=1}^{k} \left(\frac{1}{1-2^{-\ell}}\right),$$

we obtain

$$b(k) = 2^{-(2k+1)2^k} 2^{3k+1} \prod_{\ell=1}^{k} \left(\frac{1}{1-2^{-\ell}} \left(\prod_{j=1}^{\ell-1} (1-2^{-j-1})^{-2^{-j}} \right)^{2^{\ell-1}} \right). \tag{5.14}$$

We write the double product in (5.14) as

$$\prod_{\ell=1}^{k} C_0^{2^{\ell-1}} \frac{1}{1-2^{-\ell}} \left(\prod_{j=\ell}^{\infty} (1-2^{-j-1})^{2^{-j}} \right)^{2^{\ell-1}} \sim C_0^{2^k-1} C_1, \qquad k \to \infty, \tag{5.15}$$

where C_0 is given in (5.11) and

$$C_1 = \prod_{\ell=1}^{\infty} \left(\frac{1}{1-2^{-\ell}} \prod_{j=\ell}^{\infty} (1-2^{-j-1})^{2^{\ell-j-1}} \right).$$

In view of (5.15) we have

$$b(k) \sim 2^{-(2k+1)2^k} 2^{3k+1} C_0^{2^k-1} C_1, \quad k \to \infty, \tag{5.16}$$

and then $h^k_{2^{k+1}-2} = (2^{k+1}-2)!b(k)$ has the expansion

$$h^k_{2^{k+1}-2} \sim \frac{C_1}{C_0}\sqrt{\pi} 2^{3k/2} \left(\frac{2C_0}{e^2}\right)^{2^k}, \quad k \to \infty. \tag{5.17}$$

The constant C_1 may be simplified by noting that

$$\begin{aligned} C_1 &= \prod_{\ell=1}^{\infty} \frac{1}{1-2^{-\ell}} \left[\prod_{m=1}^{\infty} (1-2^{-m-\ell})^{2^{-m}}\right] \\ &= \left[\prod_{\ell=1}^{\infty} \frac{1}{1-2^{-\ell}}\right] \left(\prod_{N=2}^{\infty} \left[\prod_{m=1}^{N-1} (1-2^{-N})^{2^{-m}}\right]\right) \\ &= \left[\prod_{N=2}^{\infty} (1-2^{-N})^{1-2^{1-N}}\right] \left[\prod_{\ell=1}^{\infty} \frac{1}{1-2^{-\ell}}\right] \\ &= 2\prod_{N=2}^{\infty} (1-2^{-N})^{-2^{1-N}} \\ &= 2C_0. \end{aligned}$$

Hence, $h^k_n \sim 2\sqrt{\pi} 2^{3k/2} (2C_0 e^{-2})^{2^k}$ for $k \to \infty$ if $n = 2^{k+1}-2$.

Next we solve the recurrence (2.2) for $M = O(1)$ and $n \to \infty$, thus proving Theorem 2.1(iv). We change variables from (n,k) to (M,k) with $n = 2^{k+1} - M$ and

$$h^k_n = G(M,k) = G(2^{k+1}-n,k). \tag{5.18}$$

We replace k by $k-1$ in (2.2) and note that

$$\begin{aligned} h^k_{n+1} &= G(2^{k+1}-n-1,k) = G(M-1,k), \\ h^{k-1}_i &= G(2^k - i, k-1) = G\left(\frac{M}{2} + \frac{n}{2} - i, k-1\right). \end{aligned}$$

Thus (2.2) becomes, in terms of G and M,

$$G(M-1,k) = \sum_{i=0}^{n} \binom{n}{i} 2^{-n} G\left(\frac{M}{2} + \frac{n}{2} - i, k-1\right) G\left(\frac{M}{2} - \frac{n}{2} + i, k-1\right). \tag{5.19}$$

But $G = 0$ for $M \le 0$ (i.e., $n \ge 2^{k+1}$) so that the sum in (5.19) may be truncated over the range $(n-M)/2 < i < (n+M)/2$. Then setting $i = \ell + (n-M)/2$ we have

$$G(M-1,k) = \sum_{\ell=1}^{M-1} \binom{n}{\ell + (n-M)/2} 2^{-n} G(\ell, k-1) G(M-\ell, k-1). \tag{5.20}$$

The expression in (5.20) is still exact. For $n, k \to \infty$ with $M = O(1)$, we have

$$\binom{n}{i} 2^{-n} = \sqrt{\frac{2}{\pi n}} [1 + O(n^{-1})] = \frac{2^{-k/2}}{\sqrt{\pi}} [1 + O(2^{-k})],$$

so in this range we replace (5.20) by the asymptotic relation

$$G(M-1,k) \sim \frac{2^{-k/2}}{\sqrt{\pi}} \sum_{\ell=1}^{M-1} G(\ell,k-1)G(M-\ell,k-1). \tag{5.21}$$

Setting $M=1$, replacing $\sim$ by $=$, and solving (5.21) for $G(1,k)$ yields

$$G(1,k) \sim 2\sqrt{\pi}2^{k/2}A_0^{2^k}, \tag{5.22}$$

where A_0 is an undetermined constant. Setting $M=2$ in (5.21) and using (5.22) leads to

$$\frac{G(2,k)}{G(2,k-1)} \sim \frac{2}{\sqrt{\pi}}2^{-k/2}G(1,k-1) \sim 2\sqrt{2}A_0^{2^{k-1}}, \tag{5.23}$$

so that

$$G(2,k) \sim 2\sqrt{\pi}B_0 2^{3k/2}A_0^{2^k}, \tag{5.24}$$

where B_0 is another constant. We have scaled the factor $2\sqrt{\pi}$ out of the constant for convenience. Proceeding inductively we find that for general M

$$G(M,k) \sim 2\sqrt{\pi}B_0^{M-1}2^{(M-1/2)k}A_0^{2^k}\mathcal{G}(M), \quad k\to\infty. \tag{5.25}$$

Using (5.25) in (5.21) we find that

$$\mathcal{G}(M-1) = 4\cdot 2^{-M}\sum_{\ell=1}^{M-1}\mathcal{G}(\ell)\mathcal{G}(M-\ell) \tag{5.26}$$

with $\mathcal{G}(2)=1$. Thus, $\mathcal{G}(M)=1/(M-1)!$, which yields

$$G(M,k) \sim \frac{2\sqrt{\pi}}{(M-1)!}B_0^{M-1}2^{(M-1/2)k}A_0^{2^k}. \tag{5.27}$$

It remains only to determine A_0 and B_0. But our exact analysis for $M=1$ and $M=2$ shows, in view of (5.10) and (5.17) (with $C_1/C_0=2$), that

$$A_0 = \frac{2C_0}{e^2}, \quad B_0 = 1. \tag{5.28}$$

We have thus derived the result in (2.22) of Theorem 2.1(iv). We conclude by noting that the range $M=O(1)$ corresponds to the "left-most" tail of the distribution, and that for $n\to\infty$ the condition $M=O(1)$ can be satisfied only when n is close to a power of 2.

5.2. The central-regime analysis. We next analyze the scale $k,n\to\infty$ with $k-\log_2 n = O(1)$. We thus set $\xi = n2^{-k}$ and

$$h_n^k = F(\xi;n) = F(n2^{-k};n). \tag{5.29}$$

We consider the range $0<\xi<2$ and note that as $\xi\to 2^-$ we are approaching the scale $M=O(1)$, which we just analyzed. We have $k-\log_2 n = -\log_2\xi$ so that $k-\log_2 n\to\infty$ corresponds to $\xi\to 0^+$. For any fixed $\xi>0$ we are still in the left

tail as the mass is concentrated where $k - \log_2 n \sim \sqrt{2\log_2 n}$, which corresponds to $\xi \approx 2^{-\sqrt{2\log_2 n}}$, which is small.

We comment that the ξ-scale also arises in related models. We have previously shown in [19] that for tries, b-tries, and PATRICIA trees, the limit $n, k \to \infty$ with ξ fixed is important to the asymptotic analysis. We note that

$$h_{n+1}^k = F((n+1)2^{-k}; n+1) = F\left(\xi + \frac{\xi}{n}; n+1\right)$$

and

$$h_i^{k-1} = F(i2^{-k+1}; i) = F\left(\frac{2i}{n}\xi; i\right).$$

Using the above in (2.2), after replacing k by $k-1$, we obtain

$$F\left(\xi + \frac{\xi}{n}; n+1\right) = \sum_{i=0}^{n} \binom{n}{i} 2^{-n} F\left(\frac{2i}{n}\xi; i\right) F\left(2\left(1 - \frac{i}{n}\right)\xi; n-i\right). \tag{5.30}$$

We analyze (5.30) by a WKB-type expansion (cf. [10]). That is, we seek an asymptotic solution of (5.30) in the form

$$F(\xi; n) = e^{-n\Phi(\xi)}\left[A(\xi) + \frac{1}{n}A^{(1)}(\xi) + O(n^{-2})\right]. \tag{5.31}$$

The above may be viewed as a generalized saddle-point expansion. For simpler models, such as tries and b-tries, we can obtain exact expressions for the corresponding distributions. These usually involve Cauchy integrals that can be asymptotically evaluated by the saddle-point method. This then leads to an expansion of the form (5.31) for fixed ξ. Note that for b-tries ξ takes on values in the range $[0, b]$ and for PATRICIA trees the range is $[0, 1]$. For more difficult models, which cannot be or have not been solved exactly, we must try to obtain the asymptotic expansion directly from the equations, such as (2.2). This generally requires making an *ansatz*, such as (5.31).

Setting $x = i/n$ and $y = \sqrt{n}(x - 1/2) = \sqrt{n}(i/n - 1/2)$ and using Stirling's formula, we have

$$\binom{n}{i} 2^{-n} \sim \frac{e^{nf_0(x)}}{\sqrt{2\pi n x(1-x)}}, \qquad 0 < x < 1, \tag{5.32}$$

where $f_0(x) = -\log 2 - x\log x - (1-x)\log(1-x)$. For y fixed (5.32) simplifies to the Gaussian

$$\binom{n}{i} 2^{-n} = \sqrt{\frac{2}{\pi n}} e^{-2y^2}[1 + O(n^{-1})]. \tag{5.33}$$

We use (5.31) in (5.30) and expand for large n, which yields

$$e^{-n\Phi(\xi)} \cdot e^{-(\xi\Phi)'(\xi)}[A(\xi) + O(n^{-1})] = \sum_{i=0}^{n} \frac{e^{nf_0(i/n)}}{\sqrt{2\pi n}} \sqrt{\frac{n^2}{i(n-i)}}$$
$$\times \exp\left(-n\left[\frac{i}{n}\Phi\left(\frac{2i}{n}\xi\right) + \left(1 - \frac{i}{n}\right)\Phi\left(2\left(1 - \frac{i}{n}\right)\xi\right)\right]\right) A\left(\frac{2i}{n}\xi\right) A\left(2\left(1 - \frac{i}{n}\right)\xi\right).$$

Note that near the endpoints in the sum in (5.30), i and $n-i$ may not be large so that the expansion (5.31) does not apply. However, the major contribution to the sum comes from the range $i = n/2 + O(\sqrt{n})$. We approximate the sum in (5.34) by an integral via Euler–Maclaurin to get

(5.34)
$$e^{-n\Phi(\xi)} \cdot e^{-(\xi\Phi)'(\xi)}[A(\xi) + O(n^{-1})] \sim \frac{\sqrt{n}}{\sqrt{2\pi}} \int_0^1 \frac{e^{nf_0(x)}}{\sqrt{x(1-x)}} A(2x\xi)A(2(1-x)\xi)e^{-n[x\Phi(2\xi x)+(1-x)\Phi(2\xi(1-x))]}dx.$$

By symmetry, the major contribution must come from the midpoint $x = 1/2$. Setting

$$g(t) = t\Phi(2\xi t) + (1-t)\Phi(2\xi(1-t))$$

we have $g(1/2) = \Phi(\xi)$, $g'(1/2) = 0$, and

$$g''\left(\frac{1}{2}\right) = 8\xi\Phi'(\xi) + 4\xi^2\Phi''(\xi).$$

Setting $x = 1/2 + y/\sqrt{n}$ and expanding the integral by Laplace's method yields, to leading order,

$$e^{-n\Phi(\xi)}e^{-(\xi\Phi)'(\xi)}A(\xi) = \frac{1}{\sqrt{2\pi}} \frac{2\sqrt{2\pi}}{\sqrt{4 + g''(1/2)}} e^{-n\Phi(\xi)}A^2(\xi).$$

Thus the exponential factors cancel and we have

$$A(\xi) = [1 + 2\xi\Phi'(\xi) + \xi^2\Phi''(\xi)]^{1/2}e^{-\xi\Phi'(\xi)-\Phi(\xi)}. \tag{5.35}$$

We have thus expressed $A(\cdot)$ in terms of $\Phi(\cdot)$, though the latter remains undetermined. By refining the approximation (5.33) to the "kernel" in (5.30) and obtaining higher order terms in the Laplace expansion of the integral, we can obtain relations between the terms $A^{(j)}$ in the series in (5.31). Using these we can express $A^{(j+1)}$ in terms of $\Phi, A, A^{(1)}, \ldots, A^{(j)}$, but we can never determine Φ. For tries and b-tries the corresponding Φ can be determined using a standard saddle-point expansion. For PATRICIA trees we could only study Φ numerically and asymptotically, which we proceed to do for the DST model.

Next we use asymptotic matching to determine the behaviors of $\Phi(\xi)$ as $\xi \to 2^-$ and $\xi \to 0^+$. We first require that the expansion on the M-scale matches that on the ξ-scale. This amounts to assuming that both are valid on some intermediate scale where $M = 2^{k+1} - n \to \infty$ but $\xi = n2^{-k} = 2n/(n+M) \to 2$. We write this condition symbolically as

$$G(M,k)|_{M\to\infty} \sim F(\xi;n)|_{\xi\to 2}. \tag{5.36}$$

To compare the two sides of (5.36) we expand G as $M \to \infty$, which simply amounts to approximating $(M-1)!$ by Stirling's formula in (5.27). Using (5.28) then yields

$$G(M,k) \sim \sqrt{2M}\left(\frac{2C_0}{e^2}\right)^{n/\xi} e^M \left(\frac{2^k}{M}\right)^M 2^{-k/2}. \tag{5.37}$$

Noting that $n/\xi = 2^k$ and $M = n(2/\xi - 1)$ we rewrite (5.37) in terms of n and ξ. According to (5.36) this should be the expansion of $Ae^{-n\Phi}$ as $\xi \to 2$. We then find that the matching condition is satisfied provided that

$$\Phi(\xi) = \frac{1}{2}\log\left(\frac{e^2}{2C_0}\right) + \frac{1}{2}(2-\xi)\log(2-\xi) + (\xi-2)\left[\frac{1}{4}\log\left(\frac{2C_0}{e^2}\right) + \frac{1}{2}\right] + o(2-\xi) \tag{5.38}$$

and for $\xi \to 2^-$

$$A(\xi) \sim \sqrt{2(2-\xi)}. \tag{5.39}$$

Thus the matching condition yields the behavior of both Φ and A. We show that (5.38) and (5.39) are consistent with (5.35). From (5.38) we get $\Phi(\xi) \sim \Phi(2) = -1 - \log(\sqrt{2C_0})$, $\Phi'(\xi) \sim -\frac{1}{2}\log(2-\xi)$, and $\Phi''(\xi) \sim 1/[2(2-\xi)]$. Using these results in (5.35) yields $A(\xi) \sim \sqrt{4\Phi''(\xi)}e^{-2\Phi'(\xi)}e^{-\Phi(2)} \sim \sqrt{\frac{2}{2-\xi}}(2-\xi)$, which recovers (5.39). To obtain the above we also used the second term in the expansion of $\Phi'(\xi)$ as $\xi \to 2$.

Next we match the WKB expansion to the "left-most" right tail, which we derived in section 4. We let $\xi \to 0$ with $k/\log_2 n = \nu \to 1^+$. Furthermore we choose an intermediate limit where $n \to \infty$, $\xi \to 0$ so that $n\Phi(\xi) \to 0$ and we can approximate

$$1 - h_n^k \sim 1 - Ae^{-n\Phi} \sim 1 - e^{-n\Phi} \sim n\Phi.$$

The expansion that applies for fixed $k/\log_2 n = \nu > 1$ is given by $1 - h_n^k \sim 2^{-k^2/2}2^{-k/2}\tilde{F}_j(n)$, where $\tilde{F}_j$ is given by (4.37). Expanding (4.37) for $k/\log_2 n = \nu \to 1^+$ amounts to doing nothing, since Q_* is periodic and the rest of (4.37) is in the simplest possible form. We have already observed that $2^{-k^2/2}2^{-k/2}\times$ (4.37) can be written as $n\times$ [function of $(k - \log_2 n)$] = $n\times$ [function of ξ]. Thus the matching condition is satisfied if

$$n\Phi(\xi)|_{\xi\to 0^+} \sim \frac{2^{-9/8}}{\sqrt{\log 2}}\frac{n}{(-\log_2\xi)^2}Q_*\left(\log_2\xi - \log_2(-\log_2\xi) + \frac{1}{2}\right) \times \exp\left(-\frac{\log^2\xi}{2\log 2} + (\log_2\xi)\log(-\log_2\xi) + \left(\frac{1}{2} - \frac{1}{\log 2}\right)\log\xi - \frac{[\log(-\log_2\xi)]^2}{2\log 2}\right). \tag{5.40}$$

The above is equivalent to (2.19) and we have used the periodicity of Q_*.

Expression (5.40) represents the leading term for Φ and we may also view it as representing the first six terms in the expansion of $\log\Phi$. These have respective orders of magnitude $O(\log^2\xi)$, $O(|\log\xi|\log|\log\xi|)$, $O(|\log\xi|)$, $O(\log^2|\log\xi|)$, $O(\log|\log\xi|)$, and $O(1)$. The $O(1)$ term involves the periodic function Q_*. The analysis in section 4 suggests that there is an error term in (5.40) of the form $[1 + O(1/|\log\xi|)]$. It may thus be desirable to compute higher order terms for Φ, which would involve higher order matchings (cf. section 3). Finally we note that Φ and all its derivatives vanish as $\xi \to 0^+$. This completes the analysis of the left tail. To summarize, we have treated the M and ξ scales, determined the leading term completely for the former, and obtained partial results for the latter.

Appendix A. We derive the series representation (2.30) for the periodic function $Q_*(z)$. By using the series representation (2.21) for $\vartheta_1(\cdot)$, comparing it to the infinite product form of $\vartheta_1(\cdot)$, and also using $Q(z) = e^{-\pi iz}\csc(\pi z)e^{p(z)}$ we obtain

$$Q(z) = \frac{2^{-z^2/2}2^{-z/2}}{\sin(\pi z)}\left[\prod_{\ell=1}^{\infty}(1-2^{-\ell})^{-2}\right]\sum_{m=-\infty}^{\infty}(-1)^{m+1}2^{-m^2/2}2^{m/2}2^{mz}. \tag{A.1}$$

This yields a third representation for $Q(z)$, which supplements the two in (4.46). We evaluate

$$\begin{aligned} Q_*(z) &= \frac{1}{\sqrt{2\pi}}\int_{-\infty}^{\infty} e^{-s^2/2}Q\left(z+\frac{is}{\sqrt{\log 2}}\right)ds \\ &= \frac{1}{\sqrt{2\pi}}\int_{-\infty}^{\infty} e^{-y^2/2}e^{-i\sqrt{\log 2}zy}2^{z^2/2}Q\left(\frac{iy}{\sqrt{\log 2}}\right)dy, \end{aligned} \tag{A.2}$$

where we have shifted the contour by setting $s = i\sqrt{\log 2}z + y$. Using (A.1) in (A.2) and exchanging the orders of integration and summation, we obtain

$$\begin{aligned} Q_*(z) =& \frac{1}{\sqrt{2\pi}}\left[\prod_{\ell=1}^{\infty}(1-2^{-\ell})^{-2}\right]2^{z^2/2}\sum_{m=-\infty}^{\infty}(-1)^{m+1}2^{-m^2/2}2^{m/2} \\ &\times \int_{-\infty}^{\infty}\Re\left[\frac{e^{-iy\sqrt{\log 2}/2}e^{-i\sqrt{\log 2}zy}2^{miy/\sqrt{\log 2}}}{i\sinh(\pi y/\sqrt{\log 2})}\right]dy, \end{aligned} \tag{A.3}$$

where $\Re$ denotes the real part. From tables of integrals we have

$$\int_{-\infty}^{\infty}\frac{\sin(Ax)}{\sinh(Bx)}dx = \frac{\pi}{B}\tanh\left(\frac{\pi A}{2B}\right). \tag{A.4}$$

Applying (A.4) to (A.3) with $B = \pi/\sqrt{\log 2}$ and $A = \left(m - z - \frac{1}{2}\right)\sqrt{\log 2}$, we get

$$\begin{aligned} Q_*(z) =& \frac{\sqrt{\log 2}}{\sqrt{2\pi}}\left[\prod_{\ell=1}^{\infty}(1-2^{-\ell})^{-2}\right]2^{z^2/2} \\ &\times \sum_{m=-\infty}^{\infty}(-1)^{m+1}2^{-m^2/2}2^{m/2}\tanh\left(\frac{\log 2}{2}\left(m-z-\frac{1}{2}\right)\right). \end{aligned} \tag{A.5}$$

By changing $m \to 1-m$, we see that $Q_*(z) = Q_*(-z)$. We can thus write $Q_*(z) = \frac{1}{2}[Q_*(z) + Q_*(-z)]$. Then we use

$$\begin{aligned} &\tanh\left[\frac{\log 2}{2}\left(m-z-\frac{1}{2}\right)\right] + \tanh\left[\frac{\log 2}{2}\left(m+z-\frac{1}{2}\right)\right] \\ &\quad = \frac{2(2^{m-1/2}-2^{-m+1/2})}{2^{m-1/2}+2^{-m+1/2}+2^z+2^{-z}} \end{aligned}$$

with which (A.5) becomes the same as (2.30).

Appendix B. We obtain a series representation for $\Phi_0(\xi)$, defined in (3.4). We use the series form of $Q(z)$ found in (A.1) and exchange the order of summation and

integration. This yields

$$\Phi_0(\xi) = \pi\,\xi\left[\prod_{\ell=1}^{\infty}(1-2^{-\ell})^{-2}\right]\sum_{m=-\infty}^{\infty}2^{-m^2/2}2^{m/2}(-1)^{m+1} \times \frac{1}{2\pi i}\int_{\frac{5}{2}-i\infty}^{\frac{5}{2}+i\infty}\frac{2^{-s}2^{ms}2^{\Delta s}}{\Gamma(3-s)\sin(\pi s)}ds, \tag{B.1}$$

where $\Delta = -\log_2\xi$. In (3.4) the contour of integration is any vertical contour, but in (B.1) we restrict to $\Re(s) > 2$. Using $\Gamma(3-s)\sin(\pi s) = \pi/\Gamma(s-2)$ (cf. [1]) we see that the integral in (B.1) has simple poles at $s = 2-N$, $N \geq 0$ and hence

$$\frac{1}{2\pi i}\int_{\frac{5}{2}-i\infty}^{\frac{5}{2}+i\infty}\Gamma(s-2)2^{(m+\Delta-1)s}ds = \sum_{N=0}^{\infty}\frac{(-1)^N}{N!}2^{(2-N)(m+\Delta-1)} = 2^{2m+2\Delta-2}\exp(-2^{-m-\Delta+1}). \tag{B.2}$$

Using (B.2) in (B.1) and noting that $2^{2\Delta} = \xi^{-2}$ yields

$$\Phi_0(\xi) = \frac{1}{4\xi}\left[\prod_{\ell=1}^{\infty}(1-2^{-\ell})^{-2}\right]\sum_{m=-\infty}^{\infty}(-1)^{m+1}2^{-m^2/2}2^{5m/2}\exp(-2\xi 2^{-m}), \tag{B.3}$$

which establishes (3.5). The choice $\Re(s) > 2$ was somewhat arbitrary. However, if we choose *any* vertical contour, then the value of the integral in (B.2) will differ from the right side of (B.2) by the residues at a finite number of poles. Each such residue will be proportional to 2^{-Nm}, but this term will vanish after we evaluate the sum over m, in view of (3.6) and the comments below it. Thus, the final result for Φ_0 is independent of the contour chosen.

SIMPLE CONFLUENTLY PERSISTENT CATENABLE LISTS*

HAIM KAPLAN†, CHRIS OKASAKI‡, AND ROBERT E. TARJAN§

Abstract. We consider the problem of maintaining persistent lists subject to concatenation and to insertions and deletions at both ends. Updates to a persistent data structure are nondestructive—each operation produces a new list incorporating the change, while keeping intact the list or lists to which it applies. Although general techniques exist for making data structures persistent, these techniques fail for structures that are subject to operations, such as catenation, that combine two or more versions. In this paper we develop a simple implementation of persistent double-ended queues (deques) with catenation that supports all deque operations in constant amortized time. Our implementation is functional if we allow memoization.

Key words. functional programming, data structures, persistent data structures, stack, queue, stack-ended queue (steque), double-ended queue (deque), memoization

1. Introduction.

Over the last fifteen years, there has been considerable development of *persistent* data structures, those in which not only the current version but also older ones are available for access (*partial persistence*) or updating (*full persistence*). In particular, Driscoll et al. [5] developed efficient general methods to make pointer-based data structures partially or fully persistent, and Dietz [3] developed an efficient general method to make array-based structures fully persistent.

These general methods support updates that apply to a single version of a structure at a time, but they do not accommodate operations that combine two different versions of a structure, such as set union or list catenation. Driscoll, Sleator, and Tarjan [4] coined the term *confluently persistent* for fully persistent structures that support such combining operations. An alternative way to obtain persistence is to use purely functional programming. We take here an extremely strict view of pure functionality: we disallow lazy evaluation, memoization, and other such techniques. For list-based data structure design, purely functional programming amounts to using only the LISP functions CONS, CAR, CDR. Purely functional data structures are automatically persistent, and indeed confluently persistent.

A simple but important problem in data structure design that makes the issue of confluent persistence concrete is that of implementing persistent double-ended queues (deques) with catenation. A series of papers [2, 4] culminated in the work of Kaplan and Tarjan [11, 10], who developed a confluently persistent implementation of deques with catenation that has a worst-case constant time and space bound for any deque

operation, including catenation. The Kaplan–Tarjan data structure and its precursors obtain confluent persistence by being purely functional.

If all one cares about is persistence, purely functional programming is unnecessarily restrictive. In particular, Okasaki [14, 15, 16] observed that the use of lazy evaluation in combination with memoization can lead to efficient functional (but not purely functional in our sense) data structures that are confluently persistent. In order to analyze such structures, Okasaki developed a novel kind of debit-based amortization. Using these techniques and weakening the time bound from worst-case to amortized, he was able to considerably simplify the Kaplan–Tarjan data structure, in particular to eliminate its complicated skeleton that encodes a tree extension of a redundant digital numbering system.

In this paper we explore the problem of further simplifying the Kaplan–Tarjan result. We obtain a confluently persistent implementation of deques with catenation that has a constant amortized time bound per operation. Our structure is substantially simpler than the original Kaplan–Tarjan structure, and even simpler than Okasaki's catenable deques: whereas Okasaki requires efficient persistent deques without catenation as building blocks, our structure is entirely self-contained. Furthermore our analysis uses a standard credit-based approach. We give two alternative, but closely related implementations of our method. The first uses memoization. The second, which saves a small constant factor in time and space, uses an extension of memoization in which any expression can replace an equivalent expression.

The remainder of the paper consists of five sections. In section 2, we introduce terminology and concepts. In section 3, we illustrate our approach by developing a persistent implementation of deques without catenation. In section 4, we extend our approach to handle stacks with catenation. In section 5, we develop our solution for deques with catenation. We conclude in section 6 with some remarks and open problems. An extended abstract of this work appeared in [9].

2. Preliminaries. The objects of our study are lists. As in [11, 10] we allow the following operations on lists:

MAKELIST(x):	return a new list containing the single element x.
PUSH(x, L):	return a new list formed by adding element x to the front of list L.
POP(L):	return a pair whose first component is the first element on list L and whose second component is a list containing the second through last elements of L.
INJECT(L, x):	return a new list formed by adding element x to the back of list L.
EJECT(L):	return a pair whose first component is a list containing all but the last element of L and whose second component is the last element of L.
CATENATE(L, R):	return a new list formed by catenating L and R, with L first.

We seek implementations of these operations (or specific subsets of them) on persistent lists: any operation is allowed on any previously constructed list or lists at any time. For discussions of various forms of persistence, see [5]. A *stack* is a list on which only PUSH and POP are allowed. A *queue* is a list on which only INJECT and POP are allowed. A *steque (stack-ended queue)* is a list on which only PUSH, POP, and INJECT are allowed. Finally, a *deque (double-ended queue)* is a list on which

all four operations PUSH, POP, INJECT, and EJECT are allowed. For any of these four structures, we may or may not allow catenation. If catenation is allowed, PUSH and INJECT become redundant, since they are special cases of catenation, but it is sometimes convenient to treat them as separate operations because they are easier to implement than general catenation.

We say a data structure is *purely functional* if it can be built and manipulated using the LISP functions CAR, CONS, CDR. That is, the structure consists of a set of immutable nodes, each either an atom or a node containing two pointers to other nodes, with no cycles of pointers. The nodes we use to build our structures actually contain a fixed number of fields; reducing our structures to two fields per node by adding additional nodes is straightforward. Various nodes in our structure represent lists.

To obtain our results, we extend pure functionality by allowing memoization, in which a function is evaluated only once on a node; the second time the same function is evaluated on the same node, the value is simply retrieved from the previous computation. In all our constructions, there are only a constant number of memoized functions (one or two). We can implement memoization by having a node point to the results of applying each memoized function to it. Initially each such pointer is undefined. The first function evaluation fills in the appropriate pointer to indicate the result. Subsequent evaluations merely follow the pointer to the result, which takes $O(1)$ time.

We also consider the use of a more substantial extension of pure functionality, in which we allow the operation of replacing a node in a structure by another node representing the same list. Such a replacement can be performed in an imperative setting by replacing all the fields in the node, for instance, in LISP by using REPLACA and REPLACD. Replacement can be viewed as a generalization of memoization. In our structures, any node is replaced at most twice, which means that all our structures can be implemented in a write-once memory. (It is easy to convert an algorithm that overwrites any field only a fixed constant number of times into a write-once algorithm, with only a constant-factor loss of efficiency.) The use of overwriting instead of memoization saves a small constant factor in running time and storage space and slightly simplifies the amortized analysis.

To perform amortized analysis, we use a standard potential-based framework. We assign to each configuration of the data structure (the totality of nodes currently existing) a *potential*. We define the amortized cost of an operation to be its actual cost plus the net increase in potential caused by performing the operation. In our applications, the potential of an empty structure is zero and the potential is always nonnegative. It follows that, for any sequence of operations starting with an empty structure, the total actual cost of the operations is bounded above by the sum of their amortized costs. See the survey paper [17] for a more complete discussion of amortized analysis.

3. Noncatenable deques. In this section we describe an implementation of persistent noncatenable deques with a constant amortized time bound per operation. The structure is based on the analogous Kaplan–Tarjan structure [11, 10] but is much simpler. The result presented here illustrates our technique for doing amortized analysis of a persistent data structure. At the end of the section we comment on the relation between the structure proposed here and previously existing solutions.

3.1. Representation. Here and in subsequent sections we say a data structure is *over* a set A if it stores elements from A. Our representation is recursive. It

is built from bounded-size deques called *buffers*, each containing at most three elements. Buffers are of two kinds: *prefixes* and *suffixes*. A nonempty deque d over A is represented by an ordered triple consisting of a prefix over A, denoted by $pr(d)$; a (possibly empty) *child deque* of ordered *pairs* over A, denoted by $c(d)$; and a suffix over A, denoted by $sf(d)$. Each pair consists of two elements from A. The child deque $c(d)$, if nonempty, is represented in the same way. We define the set of *descendants* $\{c^i(d)\}$ of a deque d in the standard way—namely, $c^0(d) = d$ and $c^{i+1}(d) = c(c^i(d))$, provided $c^i(d)$ and $c(c^i(d))$ exist.

The order of elements in a deque is defined recursively to be the one consistent with the order of each triple, each buffer, each pair, and each child deque. Thus, the order of elements in a deque d is first the elements of $pr(d)$, then the elements of each pair in $c(d)$, and finally the elements of $sf(d)$.

In general the representation of a deque is not unique—the same sequence of elements may be represented by triples that differ in the sizes of their prefixes and suffixes, as well as in the contents and representations of their descendant deques. Whenever we refer to a deque d we actually mean a particular representation of d, one that will be clear from the context.

The pointer representation for this representation is the obvious one: a node representing a deque d contains pointers to $pr(d)$, $c(d)$, and $sf(d)$. Note that the pointer structure of d is essentially a linked list of its descendants, since $c^i(d)$ contains a pointer to $c^{i+1}(d)$, for each i.

3.2. Operations. Implementing the deque operations is straightforward, except for maintaining the size bounds on buffers. Specifically, a PUSH on a deque is easy unless its prefix is of size three, a POP on a deque is easy unless its prefix is empty, and symmetric statements hold for INJECT and EJECT. We deal with buffer overflow and underflow in a proactive fashion, first fixing the buffer so that the operation to be performed cannot violate its size bounds, and then actually doing the operation. The details are as follows.

We define a buffer to be *green* if it contains one or two elements, and *red* if it contains zero or three. We define two memoized functions on a deque: GP, which constructs a representation of the same list but with a green prefix; and GS, which constructs a representation of the same list with a green suffix. We only apply GP (GS, respectively) to a list whose prefix (suffix) is red and can be made green. Specifically, for GP, if the prefix is empty, the child deque must be nonempty, and symmetrically for GS. Below we give implementations of PUSH, POP, and GP; the implementations for INJECT, EJECT, and GS are symmetric. We denote a deque with prefix p, child deque c, and suffix s by $[p, c, s]$. As mentioned in section 2, we can implement the memoization of GP and GS by having each node point to the nodes resulting from applying GP and GS to it; initially, such pointers are undefined.

PUSH(x, d): If $|pr(d)| = 3$, let $e = \text{GP}(d)$; otherwise, let $e = d$. Push x onto $pr(e)$ to form p' and return $[p', c(e), sf(e)]$.

POP(d): If $pr(d)$ is empty and $c(d)$ is not, let $e = \text{GP}(d)$; otherwise, let $e = d$. If $pr(e)$ is nonempty, let $(x, p) = \text{POP}(pr(e))$ and return the pair $(x, [p, c(e), sf(e)])$. Otherwise ($c(e)$ must be empty), let $(x, s) = \text{POP}(sf(e))$ and return the pair $(x, [\emptyset, \emptyset, s])$.

GP(d): If $|pr(d)| = 3$, let x, y, z be the three elements in $pr(d)$. Let p be a prefix containing only x, and let $c' = \text{PUSH}((y, z), c(d))$. Return $[p, c', sf(d)]$. Otherwise ($pr(d)$ is empty and $c(d)$ is not), let $((x, y), c') = \text{POP}(c(d))$ and let p' be a prefix containing x followed by y. Return $[p', c', sf(d)]$.

3.3. Analysis. The amortized analysis of this method relies on the memoization of GP and GS. We call a node representing a deque *secondary* if it is returned by a call to GP or GS and *primary* otherwise. If a secondary node y is constructed by a call GP(x) (GS(x), respectively), the only way to access y later is via another call GP(x) (GS(x), respectively): no secondary node is returned as the result of a PUSH, POP, INJECT, or EJECT operation. This means that GP and GS are called only on primary nodes.

We divide the nodes representing deques into three states: such a node is rr if both its buffers are red, gr if exactly one of its buffers is red, and gg if both its buffers are green. We subdivide the rr and gr states: an rr node is $rr0$ if neither GP nor GS has been applied to it, $rr1$ if exactly one of GP and GS has been applied to it, and $rr2$ if both GP and GS have been applied to it; a gr node is $gr0$ if neither GP nor GS has been applied to it, and $gr1$ otherwise. By the discussion above, every secondary node is $gr0$ or gg. We define $\#rr0$, $\#rr1$, and $\#gr0$ to be the numbers of *primary* nodes in states $rr0$, $rr1$, and $gr0$, respectively. We define the potential of a collection of nodes representing deques to be $4\#rr0 + 2\#rr1 + \#gr0$.

A call to PUSH is either terminal or results in a call to GP, which in turn calls PUSH. Similarly, a call to POP is either terminal or results in a call to GP, which in turn calls POP. We charge the $O(1)$ time spent in a call to GP (exclusive of the inner call to PUSH or POP) to the PUSH or POP that calls GP. A call to PUSH results in a sequence of recursive calls to PUSH (via calls to GP), of which the bottommost is *terminal* and the rest are *nonterminal*. A nonterminal PUSH has one of the following effects: it converts a primary $rr0$ node to $rr1$ and creates a new primary $gr0$ node (the result of the push) and a new secondary $gr0$ node (the result of the call to GP); it converts a primary $rr1$ node to $rr2$ and creates a new primary $gr0$ node and a new secondary $gr0$ node; or, it converts a primary $gr0$ node to $gr1$ and creates a new primary gg node and a new secondary gg node. In each case the total potential drops by one, paying for the time needed for the PUSH (excluding the recursive call). A terminal PUSH takes $O(1)$ time, creates $O(1)$ new nodes, and increases the potential by $O(1)$. We conclude that PUSH takes $O(1)$ amortized time. Analogous arguments apply to POP, INJECT, and EJECT, giving us the following theorem.

THEOREM 3.1. *Each of the operations* PUSH, POP, INJECT, *and* EJECT *defined above takes* $O(1)$ *amortized time.*

3.4. Implementation using overwriting. With the memoized implementation described above, a primary rr node can give rise to two secondary gr nodes representing the same list; a primary gr node can give rise to a secondary gg node representing the same list. These redundant representations exist simultanously. A gr representation, however, dominates an rr representation for performing deque operations, and a gg representation dominates a gr representation. This allows us to improve the efficiency of the implementation by using overwriting in place of memoization: when GP is called on a node, it overwrites the contents of the node with the results of the GP computation, and similarly for GS. Then only one representation of a list exists at any time, and it evolves from rr to gr to gg (via one of two alternative paths, depending on whether GP or GS is called first). Each node now needs only three fields (for prefix, child deque, and suffix) instead of five (two extra for GP and GS).

Not only does the use of overwriting save a constant factor in running time and storage space, but it also simplifies the amortized analysis, as follows. We define $\#rr$ and $\#gr$ to be the number of nodes in states rr and gr, respectively. (There

are now no secondary nodes.) We define the potential of a collection of nodes to be $3\#rr + \#gr$. A nonterminal PUSH has one of the following effects: it converts an rr node to gr and creates a new gr node, or converts a gr node to gg and creates a new gg node. In either case it reduces the potential by one, paying for the $O(1)$ time required by the PUSH (excluding the recursive call). A terminal PUSH takes $O(1)$ time and can increase the potential by $O(1)$. We conclude that PUSH takes $O(1)$ amortized time. Similar arguments apply to POP, INJECT, and EJECT.

3.5. Related work. The structure just described is based on the Kaplan–Tarjan structure of [10, section 4], but simplifies it in three ways. First, the skeleton of our structure (the sequence of descendants) is a stack; in the Kaplan–Tarjan structure, this skeleton must be partitioned into a stack of stacks in order to support worst-case constant-time operations (via a redundant binary counting mechanism). Second, the recursive changes to the structure to make its nodes green are one-sided, instead of two-sided: in the original structure, the stack-of-stacks mechanism requires coordination to keep both sides of the structure in related states. Third, the maximum buffer size is reduced, from five to three. In the special case of a steque, the maximum size of the suffix can be further reduced to two. In the special case of a queue, both the prefix and the suffix can be reduced to maximum size two.

There is an alternative, much older approach that uses incremental recopying to obtain persistent deques with worst-case constant-time operations. See [7] for a discussion of this approach. The incremental recopying approach yields an arguably simpler structure than the one presented here, but our structure generalizes to allow catenation, which no one knows how to implement efficiently using incremental recopying. Also, our structure can be extended to support access, insertion, and deletion d positions away from the end of a list in $O(\log d)$ amortized time, by applying the ideas in [12].

4. Catenable steques. In this section we show how to extend our ideas to support catenation. Specifically, we describe a data structure for catenable steques that achieves an $O(1)$ amortized time bound for PUSH, POP, INJECT, and CATENATE. The data structure is based on the same recursive decomposition of lists as that in section 5 of [10]. The pointer structure that we need here is much simpler than that in [10], and the analysis is amortized, following the framework outlined in section 2 and used in section 3.

4.1. Representation. Our structure is similar to the structure of section 3, but with slightly different definitions of the component parts. As in section 3, we use buffers of two kinds: prefixes and suffixes. Each prefix contains two to six elements and each suffix contains one to three elements. A nonempty steque d over A is represented either by a suffix $sf(d)$ only, or by an ordered triple consisting of a prefix $pr(d)$ over A, a child steque $c(d)$ of pairs over A, and a suffix $sf(d)$ over A. In contrast to section 3, a *pair over* A is defined to be an ordered pair containing a prefix and a possibly empty steque of pairs over A. Observe that this definition adds an additional kind of recursion (pairs store steques) to the structure of section 3. This extra kind of recursion is what allows efficient catenation.

The order of elements in a steque is the one consistent with the order of each triple, each buffer, each pair, each steque within a pair, and each child steque. As in section 3, there can be many different representations of a steque containing a given list of elements; when speaking of a steque, we mean a particular representation of it.

The pointer structure for this representation is straightforward. Each triple is

represented by a node containing three pointers: to a prefix, a child steque, and a suffix. Each pair is represented by a node containing two pointers: to a prefix and a steque.

4.2. Operations. The implementation of the steque operations is much like the implementation of the noncatenable deque operations presented in section 3.2. We call a prefix *red* if it contains either two or six elements, and *green* otherwise. We call a suffix *red* if it contains three elements, and *green* otherwise. The prefix in a suffix-only steque is considered to have the same color as the suffix. We define two memoized functions, GP and GS, which produce green-prefix and green-suffix representations of a steque, respectively. Each is called only when the corresponding buffer is red and can be made green. We define PUSH, POP, and INJECT to call GP or GS when necessary to obtain a green buffer. In the definitions below, we represent a steque with prefix p, child steque c, and suffix s by $[p, c, s]$.

PUSH(x, d):

Case 1. Steque d is represented by a triple. If $|pr(d)| = 6$, then let $e = \text{GP}(d)$; otherwise, let $e = d$. Let $p = \text{PUSH}(x, pr(e))$ and return $[p, c(e), sf(e)]$.

Case 2. Steque d is represented by a suffix only. If $|sf(d)| = 3$, create a prefix p containing x and the first two elements of $sf(d)$, create a suffix s containing the last element of $sf(d)$, and return $[p, \emptyset, s]$. Otherwise, create a suffix s by pushing x onto $sf(d)$ and return $[\emptyset, \emptyset, s]$.

INJECT(d, x):

Case 1. Steque d is represented by a triple. If $|sf(d)| = 3$, let $e = \text{GS}(d)$; otherwise, let $e = d$. Let $s = \text{INJECT}(sf(e), x)$ and return $[pr(e), c(e), s]$.

Case 2: Steque d is represented by a suffix only. If $|sf(d)| = 3$, create a suffix s containing x, and return $[sf(d), \emptyset, s]$. Otherwise, create a suffix s by injecting x into $sf(d)$ and return $[\emptyset, \emptyset, s]$.

CATENATE(d_1, d_2):

Case 1. d_1 and d_2 are represented by triples. First, catenate the buffers $sf(d_1)$ and $pr(d_2)$ to obtain p. Now, calculate c' as follows: If $|p| \leq 5$, then let $c' = \text{INJECT}(c(d_1), (p, c(d_2)))$. Otherwise, $6 \leq |p| \leq 9$. Create two new prefixes p' and p'', with p' containing the first four elements of p and p'' containing the remaining elements. Let $c' = \text{INJECT}(\text{INJECT}(c(d_1), (p', \emptyset)), (p'', c(d_2)))$. In either case, return $[pr(d_1), c', sf(d_2)]$.

Case 2. d_1 or d_2 is represented by a suffix only. Push or inject the elements of the suffix-only steque one by one into the other steque.

Note that both PUSH and CATENATE produce valid steques even when their second arguments are steques with prefixes of length one. Although such steques are not normally allowed, they may exist transiently during a POP. Every such steque is immediately passed to PUSH or CATENATE, and then discarded, however. In order to define the POP, GP, and GS operations, we define a NAIVE-POP operation that simply pops its steque argument without making sure that the result is a valid steque.

NAIVE-POP(d): If d is represented by a triple, let $(x, p) = \text{POP}(pr(d))$ and return the pair $(x, [p, c(d), sf(d)])$. If d consists of a suffix only, let $(x, s) = \text{POP}(sf(d))$ and return the pair $(x, \emptyset)$ if $|d| = 1$ or $(x, [\emptyset, \emptyset, s])$ if $|d| > 1$.

POP(d):

Case 1. Steque d is represented by a suffix only or $|pr(d)| > 2$. Return NAIVE-POP(d).

Case 2. Steque d is represented by a triple, $|pr(d)| = 2$, and $c(d) = \emptyset$. Let x be the first element on pr(d) and y the second. If $|sf(d)| < 3$, push y onto $sf(d)$ to form s and return $(x, [\emptyset, \emptyset, s])$. Otherwise ($|sf(d)| = 3$), form p from y and the first two elements on $sf(d)$, form s from the last element on $sf(d)$, and return $(x, [p, \emptyset, s])$.

Case 3. Steque d is represented by a triple, $|pr(d)| = 2$, and $c(d) \neq \emptyset$. Return NAIVE-POP(GP(d)).

GP(d): If $|pr(d)| = 6$, then create two new prefixes p and p' by splitting $pr(d)$ equally in two. Let $c' =$ PUSH$((p', \emptyset), c(d))$. Return $[p, c', sf(d)]$. Otherwise ($|pr(d)| = 2$ and $c(d) \neq \emptyset$), proceed as follows. Inspect the first pair (p, d') in $c(d)$. If $|p| \geq 4$ or d' is not empty, let $((p, d'), c') =$ NAIVE-POP$(c(d))$; otherwise, let $((p, d'), c') =$ POP$(c(d))$. Now inspect p.

Case 1. p contains at least four elements. Pop the first two elements from p to form p'' and inject these two elements into $pr(d)$ to obtain p'. Let $c'' =$ PUSH$((p'', d'), c')$. Return $[p', c'', sf(d)]$.

Case 2. p contains at most three elements. Push the two elements in $pr(d)$ onto p to obtain p'. Let $c'' =$ CATENATE(d', c') if d' is nonempty, or $c'' = c'$ if d' is empty. Return $[p', c'', sf(d)]$.

GS(d): (Steque d is represented by a triple with $|sf(d)| = 3$) Let p contain the first two elements of $sf(d)$ and s the last element on $sf(d)$. Let $c' =$ INJECT$(c(d), (p, \emptyset))$. Return $[pr(d), c', s]$.

4.3. Analysis. The analysis of this method is similar to the analysis in section 3.3. We define primary and secondary nodes, node states, and the potential function exactly as in section 3.3: the potential function defined there is $4\#rr0+2\#rr1+\#gr0$, where $\#rr0$, $\#rr1$, and $\#gr0$ are the numbers of primary nodes in states $rr0$, $rr1$, and $gr0$, respectively.

As in section 3.3, we charge the $O(1)$ cost of a call to GP or GS (excluding the cost of any recursive call to PUSH, POP, or INJECT) to the PUSH, POP, or INJECT that calls GP or GS. The amortized costs of PUSH and INJECT are $O(1)$ by an argument identical to that used to analyze PUSH in section 3.3. Operation CATENATE calls PUSH and INJECT a constant number of times and creates a single new node, so its amortized cost is also $O(1)$.

To analyze POP, assume that a call to POP recurs to depth k (via intervening calls to GP). By an argument analogous to that for PUSH, each of the first $k-1$ calls pays for itself by decreasing the potential by one. The terminal call to POP can result in a call to either PUSH or CATENATE, each of which has $O(1)$ amortized cost. It follows that the overall amortized cost of POP is $O(1)$, giving us the following theorem.

THEOREM 4.1. *Each of the operations* PUSH, POP, INJECT, *and* CATENATE *defined above takes* $O(1)$ *amortized time.*

We can improve the time and space efficiency of the steque data structure by constant factors by using overwriting in place of memoization, exactly as described in section 3.4. If we do this, we can also simplify the amortized analysis, again exactly as described in section 3.4.

4.4. Related work. The structure presented in this section is analogous to the Kaplan–Tarjan structure of [10, section 5] and the structure of [8, section 7], but simplifies them as follows. First, the buffers are of constant-bounded size, whereas the structure of [10, section 5] uses noncatenable steques as buffers, and the structure of [8, section 7] uses noncatenable stacks as buffers. These buffers in turn must be represented as in section 3 of this paper or by using one of the other methods

mentioned there. In contrast, the structure of the present section is entirely self-contained. Second, the skeleton of the present structure is just a stack, instead of a stack of stacks as in [10] and [8]. Third, the changes used to make buffers green are applied in a one-sided, need-driven way; in [10] and [8], repairs must be made simultaneously to both sides of the structure in carefully chosen locations.

Okasaki [14] has devised a different and somewhat simpler implementation of confluently persistent catenable steques that also achieves an $O(1)$ amortized bound per operation. His solution obtains its efficiency by (implicitly) using a form of path reversal [18] in addition to lazy evaluation and memoization. Our structure extends to the double-ended case, as we shall see in the next section; whether Okasaki's structure extends to this case is an open problem.

5. Catenable deques. In this section we show how to extend our ideas to support all five list operations. Specifically, we describe a data structure for catenable deques that achieves an $O(1)$ amortized time bound for PUSH, POP, INJECT, EJECT, and CATENATE. Our structure is based upon an analogous structure of Okasaki [16], but simplified to use constant-size buffers.

5.1. Representation. We use three kinds of buffers: *prefixes*, *middles*, and *suffixes*. A nonempty deque d over A is represented either by a suffix $sf(d)$ or by a 5-tuple that consists of a prefix $pr(d)$, a left deque of triples $ld(d)$, a middle $md(d)$, a right deque of triples $rd(d)$, and a suffix $sf(d)$. A *triple* consists of a *first middle buffer*, a deque of triples, and a *last middle buffer*. One of the two middle buffers in a triple must be nonempty, and in a triple that contains a nonempty deque both middles must be nonempty. All buffers and triples are over A. A prefix or suffix in a 5-tuple contains three to six elements, a suffix in a suffix-only representation contains one to eight elements, a middle in a 5-tuple contains exactly two elements, and a nonempty middle buffer in a triple contains two or three elements.

The order of elements in a deque is the one consistent with the order of each 5-tuple, each buffer, each triple, and each recursive deque. The pointer structure is again straightforward, with the nodes representing 5-tuples or triples containing one pointer for each field.

5.2. Operations. We call a prefix or suffix in a 5-tuple *red* if it contains either three or six elements and *green* otherwise. We call a suffix in a suffix-only representation *red* if it contains eight elements and *green* otherwise. The prefix of a suffix-only deque is considered to have the same color as the suffix. We introduce two memoizing functions GP and GS as in sections 3.2 and 4.2, which produce green-prefix and green-suffix representations of a deque, respectively, and which are called only when the corresponding buffer is red but can be made green. Below we give the implementations of PUSH, POP, GP, and CATENATE; the implementations of INJECT, EJECT, and GS are symmetric to those of PUSH, POP, and GP, respectively. We denote a deque with prefix p, left deque l, middle m, right deque r, and suffix s by $[p, l, m, r, s]$.

PUSH(x, d):

Case 1. Deque d is represented by a 5-tuple. If $|pr(d)| = 6$, then let $e = \text{GP}(d)$; otherwise, let $e = d$. Return $[\text{PUSH}(x, pr(e)), ld(e), md(e), rd(e), sf(e)]$.

Case 2. Deque d is represented by a suffix only. If $sf(d) < 8$, return a suffix-only deque with suffix $\text{PUSH}(x, sf(d))$. Otherwise, push x onto $sf(d)$ to form s, with nine elements. Create a new prefix p with the first four, a middle with the next two, and a suffix s with the last three. Return $[p, \emptyset, m, \emptyset, s]$.

As in section 4.2, the implementation of POP uses NAIVE-POP.

POP(d):

Case 1. Deque d is represented by a suffix only or $|pr(d)| > 3$. Return NAIVE-POP(d).

Case 2. $|pr(d)| = 3$ and $ld(d) \cup rd(d) \neq \emptyset$. Return NAIVE-POP(GP($d$)).

Case 3. $|pr(d)| = 3$ and $ld(d) \cup rd(d) = \emptyset$. Let x be the first element on $pr(d)$. If $|sf(d)| = 3$, create a new suffix s containing all the elements in $pr(d)$, $md(d)$, and $sf(d)$ except x, and return the pair consisting of x and the deque represented by s only. Otherwise, form p from $pr(d)$ by popping x and injecting the first element on $md(d)$, form m' from $md(d)$ by popping the first element and injecting the first element on $sf(d)$, form s from $sf(d)$ by popping the first element, and return $(x, [p, \emptyset, m', \emptyset, s])$.

GP(d): If $|pr(d)| = 6$, create two new prefixes p and p', with p containing the first four elements of $|pr(d)|$ and p' the last two; return $[p, \text{PUSH}((p', \emptyset, \emptyset), ld(d)), md(d), rd(d), sf(d)]$. Otherwise ($|pr(d)| = 3$ and $ld(d) \cup rd(d) \neq \emptyset$); proceed as follows.

Case 1. $ld(d) \neq \emptyset$. Inspect the first triple t on $ld(d)$. If either the first nonempty middle buffer in t contains three elements or t contains a nonempty deque, let $(t, l) =$ NAIVE-POP($ld(d)$); otherwise let $(t, l) =$ POP($ld(d)$). Let $t = (x, d', y)$ and assume that x is nonempty if t consists of only one nonempty middle buffer. Apply the appropriate one of the following two subcases.

Case 1.1. $|x| = 3$. Form x' from x and p from $pr(d)$ by popping the first element from x and injecting it into $pr(d)$. Return $[p, \text{PUSH}((x', d', y), l), md(d), rd(d), sf(d)]$.

Case 1.2. $|x| = 2$. Inject both elements in x into pr(d) to form p. If d' and y are empty, return $[p, l, md(d), rd(d), sf(d)]$. Otherwise ($d'$ and y are nonempty) let $l' =$ CATENATE(d', PUSH($(y, \emptyset, \emptyset), l)$) and return $[p, l', md(d), rd(d), sf(d)]$.

Case 2. $ld(d) = \emptyset$ and $rd(d) \neq \emptyset$. Inspect the first triple t in $rd(d)$. If either the first nonempty middle buffer in t contains three elements or t contains a nonempty deque, let $(t, r) =$ NAIVE-POP($rd(d)$); otherwise, let $(t, r) =$ POP($rd(d)$). Let $t = (x, d', y)$ and assume that x is nonempty if t consists of only one nonempty middle buffer. Of the following two subcases, apply the appropriate one.

Case 2.1. $|x| = 3$. Form p, m', and x' from $pr(d)$, m, and x by popping an element from m and injecting it into $pr(d)$ to form p, popping an element from m and injecting the first element from x to form m', and popping the first element from x to form x'. Return $[p, \emptyset, m', \text{PUSH}((x', d', y), r), sf(d)]$.

Case 2.2. $|x| = 2$. Inject the two elements in $md(d)$ into $pr(d)$ to form p. Let $r' = r$ if d' and y are empty or $r' =$ CATENATE(d', PUSH($(y, \emptyset, \emptyset), r)$) otherwise. Return $[p, \emptyset, x, r', sf(d)]$.

CATENATE(d_1, d_2):

Case 1. Both d_1 and d_2 are represented by 5-tuples. Let y be the first element in $pr(d_2)$, and let x be the last element in $sf(d_1)$. Create a new middle m containing x followed by y. Partition the elements in $sf(d_1) - \{x\}$ into at most two buffers s_1' and s_1'', each containing two or three elements in order, with s_1'' possibly empty. Let $ld_1' =$ INJECT($ld(d_1), (md(d_1), rd(d_1), s_1')$). If $s_1'' \neq \emptyset$, then let $ld_1'' =$ INJECT($ld_1', (s_1'', \emptyset, \emptyset)$); otherwise, let $ld_1'' = ld_1'$. Similarly, partition the elements in $pr(d_1) - \{y\}$ into at most two prefixes p_2' and p_2'', each containing two or three elements in order, with p_2' possibly empty. Let $rd_2' =$ PUSH($(p_2'', ld(d_2), md(d_2)), rd(d_2)$). If $p_2' \neq \emptyset$ let $rd_2'' =$ PUSH($(p_2', \emptyset, \emptyset), rd_2'$); otherwise, let $rd_2'' = rd_2'$. Return $[pr(d_1), ld_1'', m, rd_2'', sf(d_2)]$.

Case 2. d_1 or d_2 is represented by a suffix only. Push or inject the elements of the suffix-only deque one by one into the other deque.

5.3. Analysis. To analyze this structure, we use the same definitions and the same potential function as in sections 3.3 and 4.3. The amortized costs of PUSH, INJECT, CATENATE, and POP are $O(1)$ by an argument analogous to that in section 4.3. The amortized cost of EJECT is $O(1)$ by an argument symmetric to that for POP. Thus we obtain the following theorem.

THEOREM 5.1. *Each of the operations* PUSH, POP, INJECT, EJECT, *and* CATENATE *defined above takes* $O(1)$ *amortized time.*

Just as in sections 3.4 and 4.3, we can improve the time and space constant factors and simplify the analysis by using overwriting in place of memoization. Overwriting is the preferred implementation, unless one is using a functional programming language that supports memoization but does not easily allow overwriting.

5.4. Related work. The structure presented in this section is analogous to the structures of [16, Chapter 11] and [8, section 9] but simplifies them as follows. First, the buffers are of constant size, whereas in [16] and [8] they are noncatenable deques. Second, the skeleton of the present structure is a binary tree, instead of a tree extension of a redundant digital numbering system, as in [8]. Also, our amortized analysis uses the standard potential function method of [17] rather than the more complicated debit mechanism used in [16]. Another related structure is that of [10, section 5], which represents purely functional, real-time deques as pairs of triples rather than 5-tuples, but otherwise is similar to (but simpler than) the structure of [8, section 9]. It is straightforward to modify the structure presented here to use pairs of triples rather than 5-tuples.

6. Further results and open questions. If the universe A of elements over which deques are constructed has a total order, we can extend the structures described here to support an additional heap order based on the order on A. Specifically, we can support the additional operation of finding the minimum element in a deque (but not deleting it) while preserving a constant amortized time bound for every operation, including finding the minimum. We merely have to store with each buffer, each deque, and each pair or triple the minimum element in it. For related work, see [1, 2, 6, 13].

We can also support a *flip* operation on deques. A flip operation reverses the linear order of the elements in the deque: the ith from the front becomes the ith from the back, and vice versa. For the noncatenable deques of section 3, we implement flip by maintaining a *reversal bit* that is flipped by a flip operation. If the reversal bit is set, a push becomes an inject, a pop becomes an eject, an inject becomes a push, and an eject becomes a pop. To support catenation as well as flip we use reversal bits at all levels. We must also symmetrize the definition in section 5 to allow a deque to be represented by a prefix only and extend the various operations to handle this possibility. The interpretation of reversal bits is cumulative. That is, if d is a deque and x is a deque inside of d, x is regarded as being reversed if an odd number of reversal bits are set to 1 along the path of actual pointers in the structure from the node for d to the node for x. Before performing catenation, if the reversal bit of either or both of the two deques is 1, we push such bits down by flipping such a bit of a deque x to 0, flipping the bits of all the deques to which x points, and swapping the appropriate buffers and deques. (The prefix and suffix exchange roles, as do the left deque and right deque; the order of elements in the prefix and suffix is reversed as well.) We do such push-downs of reversal bits by assembling new deques, not by overwriting the old ones.

We have devised an alternative implementation of catenable deques in which the sizes of the prefixes and suffixes are between 3 and 5 instead of 3 and 6. We do this by

memoizing the POP and EJECT operations and avoiding creating a new structure with a green prefix (suffix, respectively) representing the original deque when performing POP (EJECT, respectively). Using a more complicated potential function than the ones used in earlier sections, we can show that such an implementation runs in $O(1)$ amortized time per operation.

One direction for future research is to find a way to simplify our structures further. Specifically, consider the following alternative representation of catenable deques, which uses a single recursive subdeque rather than two such subdeques. A nonempty deque d over A is represented by a triple that consists of a prefix $pr(d)$, a (possibly empty) child deque of triples $c(d)$, and a suffix $sf(d)$. A *triple* consists of a nonempty *prefix*, a deque of triples, and a nonempty *suffix*, or just of a nonempty prefix or suffix. All buffers and triples are over A. The operations PUSH, POP, INJECT, and EJECT have implementations similar to their implementations in section 5. The major difference is in the implementation of CATENATE, which for this structure requires a call to POP. Specifically, let d_1 and d_2 be two deques to be catenated. CATENATE pops $c(d_1)$ to obtain a triple (p, d', s) and a new deque c, injects $(s, c, sf(d_1))$ into d' to obtain d'', and then pushes $(p, d'', pr(d_2))$ onto $c(d_2)$ to obtain c'. The final result has prefix $pr(d_1)$, child deque c', and suffix $sf(d_2)$. It is an open question whether this algorithm runs in constant amortized time per operation for any constant upper and lower bounds on the buffer sizes.

Another research direction is to design a confluently persistent representation of sorted lists such that accesses or updates d positions from either end take $O(\log d)$ time, and catenation takes $O(1)$ time. The best structure so far developed for this problem has a doubly logarithmic catenation time [12]; it is purely functional, and the time bounds are worst-case.

Acknowledgments. We thank Michael Goldwasser for a detailed reading of this paper and Jason Hartline for discussions that led to our implementations using memoization.

APPROXIMATING THE STRETCH FACTOR OF EUCLIDEAN GRAPHS*

GIRI NARASIMHAN† AND MICHIEL SMID‡

Abstract. There are several results available in the literature dealing with efficient construction of t-spanners for a given set S of n points in $\mathbb{R}^d$. t-spanners are Euclidean graphs in which distances between vertices in G are at most t times the Euclidean distances between them; in other words, distances in G are "stretched" by a factor of at most t. We consider the interesting dual problem: given a Euclidean graph G whose vertex set corresponds to the set S, compute the stretch factor of G, i.e., the maximum ratio between distances in G and the corresponding Euclidean distances. It can trivially be solved by solving the all-pairs-shortest-path problem. However, if an approximation to the stretch factor is sufficient, then we show it can be efficiently computed by making only $O(n)$ approximate shortest path queries in the graph G. We apply this surprising result to obtain efficient algorithms for approximating the stretch factor of Euclidean graphs such as paths, cycles, trees, planar graphs, and general graphs. The main idea behind the algorithm is to use Callahan and Kosaraju's well-separated pair decomposition.

1. Introduction.

Let S be a set of n points in $\mathbb{R}^d$, where $d \geq 1$ is a small constant, and let G be an undirected connected graph having the points of S as its vertices. The length of any edge (p, q) of G is defined as the Euclidean distance $|pq|$ between the two vertices p and q. Such graphs are called *Euclidean graphs*. The length of a path in G is defined as the sum of the lengths of all edges on this path. For any two vertices p and q of G, we denote by $|pq|_G$ the distance in G between them, i.e., the length of a shortest path connecting p and q.

Let $t > 1$ be a real number. We say that G is a *t-spanner* for S if for each pair of points $p, q \in S$, we have $|pq|_G \leq t \cdot |pq|$, i.e., there exists a path in G between p and q of length at most t times the Euclidean distance between these two points.

The smallest t such that G is a t-spanner for S is called the *stretch factor* of G (also referred to as *dilation* [21] or *distortion* [19] in the literature). We will denote the stretch factor by t^*. Note that

$$t^* = \max \left\{ \frac{|pq|_G}{|pq|} : p, q \in S, p \neq q \right\}.$$

Most of the earlier research considered the problem of constructing or analyzing geometric t-spanners for a given set of points. In this paper, we consider the interesting dual problem, stated as follows.

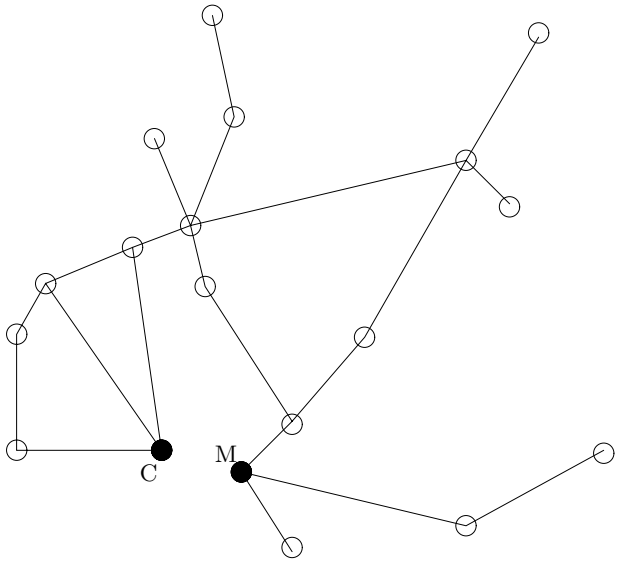

FIG. 1. *A section of the Scandinavian rail network; C denotes Copenhagen and M denotes Malmö.*

PROBLEM. *Given a set S of n points in $\mathbb{R}^d$, and a connected Euclidean graph with vertices from S, design an efficient algorithm to compute (exactly or approximately) its stretch factor.*

Spanners have applications in network design, robotics, distributed algorithms, and many other areas and have been the subject of considerable research [1, 4, 8, 11, 14, 18, 24]. More recently, spanners have received a lot of attention by researchers with the discovery of new applications for them in the design of approximation algorithms for geometric optimization problems such as the Euclidean traveling salesperson problem [3, 23].

If the graph represents, say, a network of highways, then the stretch factor is a measure of the maximum percentage increase in driving distance for using the network of highways over the direct "as-the-crow-flies" distance. Thus the stretch factor of a network is an important parameter to be considered when evaluating and analyzing networks. Furthermore, determining the two vertices in the network for which this increase is maximized helps to identify the "weakest" part of the network in terms of distances.

Figure 1 shows a section of the Scandinavian rail network. It is clear that the stretch factor in this network is determined by Copenhagen (marked C) and Malmö (marked M). A link between these two cities would drastically reduce the stretch factor.[1]

Let $G = (S, E)$ be a Euclidean graph and let $n := |S|$ and $m := |E|$. Clearly, the time complexity of solving the *all-pairs-shortest-path* problem for G is an upper bound on the time complexity of computing the stretch factor of G. Hence, running Dijkstra's algorithm—implemented with Fibonacci heaps—from each vertex of G gives the stretch factor of G in $O(n^2 \log n + nm)$ time (cf. [10]). For some classes of graphs, better running times can be obtained. For example, if G is a planar Euclidean graph, Frederickson [15] has shown that the distances in G between all pairs of vertices can

[1] A 16-kilometer bridge across the Øresund connecting the two cities is currently being built.

be computed in $O(n^2)$ total time. Therefore, the stretch factor of a planar Euclidean graph can be computed in $O(n^2)$ time.

We are not aware of any algorithms that compute the stretch factor in subquadratic time for any class of connected Euclidean graphs. (Exceptions are trivial classes of graphs, such as complete graphs, which have stretch factor one.) For example, we do not even know if the stretch factor of a Euclidean path can be computed in $o(n^2)$ time. This leads to the question whether there are faster algorithms that *approximate* stretch factors.

Let G be a connected Euclidean graph with stretch factor t^*, and let $c_1 \geq 1$, $c_2 \geq 1$, and $t \geq 1$ be real numbers. We say that t is a (c_1, c_2)-*approximate stretch factor* of G if

$$\frac{1}{c_1}\, t \leq t^* \leq c_2 t.$$

1.1. Our results. The results of this paper are as follows.

1. Using the *well-separated pair decomposition* of Callahan and Kosaraju [7], we reduce the problem of approximating the stretch factor of any Euclidean graph G to a sequence of $O(n)$ approximate shortest path queries in G.
2. We prove that, in the algebraic computation tree model, any algorithm that takes as input any connected Euclidean graph G with n vertices and computes an approximation to the stretch factor of G takes $\Omega(n \log n)$ time in the worst case.
3. For any real constant $\epsilon > 0$, we can compute in $O(n \log n)$ time a $(1, 1 + \epsilon)$-approximate stretch factor of any Euclidean path, cycle, or tree with n vertices. By the previous result, this is optimal in the algebraic computation tree model.
4. For any real constant $\epsilon > 0$, we can compute in $O(n\sqrt{n}\,)$ time a $(1, 1 + \epsilon)$-approximate stretch factor of any planar Euclidean graph with n vertices.
5. For any integer constant $\beta \geq 1$ and real constant $\epsilon > 0$, we can compute in $O(mn^{1/\beta} \log^2 n)$ expected time a $(2\beta(1+\epsilon), 1+\epsilon)$-approximate stretch factor of any Euclidean graph with n vertices and m edges.

In our first algorithm (Algorithm $\mathcal{A}$), the stretch factor is approximated by making farthest pair queries on $O(n)$ pairs of *sets of points*. Except for graphs such as paths, cycles, trees, and planar graphs, it is not clear how such queries can be solved efficiently. Our second algorithm (Algorithm $\mathcal{B}$) is much simpler; it makes shortest path queries for $O(n)$ specific pairs of *points*. The time complexity of Algorithm $\mathcal{B}$ is consequently improved over the corresponding one for Algorithm $\mathcal{A}$.

It is interesting that $O(n)$ approximate shortest path queries are sufficient to approximate the stretch factor. It is also interesting to note the pairs of points on which these $O(n)$ shortest path queries are made. In Algorithm $\mathcal{B}$, these linear number of queries depend *only* on the positions of the vertices; they do *not* depend on the edges of the graph G. Finally, our algorithms also determine two vertices for which the stretch factor is approximately maximized.

1.2. Related work. As mentioned already, our reduction uses the well-separated pair decomposition of [7], thus adding to the list of applications of this powerful method. For other applications of this decomposition, see [4, 6, 7].

Some related research in the general direction of approximating stretch factors include papers by Dobkin, Friedman, and Supowit [12] and Keil and Gutwin [17], which showed that the Delaunay triangulation has a stretch factor bounded by a

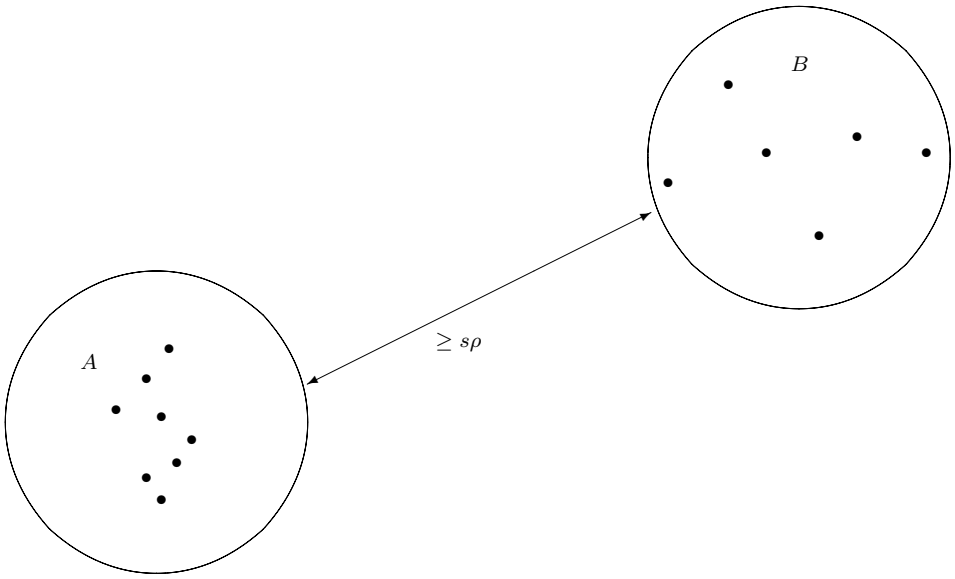

FIG. 2. *Two planar point sets A and B that are well separated with respect to s. Both circles have radius ρ; their distance is at least $s\rho$.*

small constant, and a paper by Eppstein [13], which showed that a certain class of Euclidean graphs (called beta-skeletons) can have arbitrarily large stretch factors. Note that these papers analyze the largest possible stretch factor of *any* Delaunay triangulation or beta-skeleton. For example, Keil and Gutwin showed that for any finite set of points in the plane, the stretch factor of its Delaunay triangulation is bounded from above by $\frac{2\pi}{3\cos\pi/6}$. Clearly, for some sets of points, the stretch factor can be much smaller. The current paper represents the first attempt at devising algorithms to efficiently approximate the stretch factor of a given Euclidean graph.

2. Well-separated pairs. Our algorithms use the *well-separated pair decomposition* devised by Callahan and Kosaraju [7]. We briefly review this decomposition and some of its relevant properties.

DEFINITION 1. *Let $s > 0$ be a real number, and let A and B be two finite sets of points in $\mathbb{R}^d$. We say that A and B are* well separated with respect to s *if there are two disjoint d-dimensional balls C_A and C_B, having the same radius, such that* (i) *C_A contains all points of A,* (ii) *C_B contains all points of B, and* (iii) *the distance between C_A and C_B is at least equal to s times the radius of C_A.*

See Figure 2 for an illustration. In this paper, s will always be a constant, called the *separation constant*. The following lemma follows easily from Definition 1.

LEMMA 2. *Let A and B be two finite sets of points that are well separated with respect to s, let a and p be points of A, and let b and q be points of B. Then*

1. $|ab| \leq (1 + 4/s)|pq|$,
2. $|pa| \leq (2/s)|pq|$.

DEFINITION 3 (see [7]). *Let S be a set of n points in $\mathbb{R}^d$ and $s > 0$ a real number.* A well-separated pair decomposition *(WSPD) for S (with respect to s) is a sequence*

General Algorithm $\mathcal{A}$
The algorithm takes as input a Euclidean graph G on a set S of points in $\mathbb{R}^d$ and a real constant $\epsilon > 0$.
Step 1: Using separation constant $s = 4/\epsilon$, compute a WSPD

$$\{A_1, B_1\}, \{A_2, B_2\}, \ldots, \{A_k, B_k\}$$

for the set S.
Step 2: For each i, $1 \leq i \leq k$, compute two points a_i and b_i, where $a_i \in A_i$ and $b_i \in B_i$, such that

$$|a_i b_i|_G = \max\{|pq|_G : p \in A_i, q \in B_i\},$$

and compute $t_i := |a_i b_i|_G / |a_i b_i|$.
Step 3: Report the value of t, defined as $t := \max(t_1, t_2, \ldots, t_k)$. Also report points a_i and b_i for which $t = t_i$.

FIG. 3. *The first general algorithm for approximating the stretch factor of a Euclidean graph.*

of pairs of nonempty subsets of S,

$$\{A_1, B_1\}, \{A_2, B_2\}, \ldots, \{A_k, B_k\},$$

such that

1. *$A_i \cap B_i = \emptyset$ for all $i = 1, 2, \ldots, k$,*
2. *for any two distinct points p and q of S, there is exactly one pair $\{A_i, B_i\}$ in the sequence, such that*
   (a) *$p \in A_i$ and $q \in B_i$, or*
   (b) *$p \in B_i$ and $q \in A_i$,*
3. *A_i and B_i are well separated with respect to s for all $i = 1, 2, \ldots, k$.*

The integer k is called the size *of the WSPD.*

Callahan and Kosaraju showed how such a WSPD of size $k = O(n)$ can be computed using a binary tree, called the *fair split tree*.

THEOREM 4 (see [7]). *Let S be a set of n points in $\mathbb{R}^d$ and $s > 0$ a separation constant. In $O(n \log n + \alpha_{ds} n)$ time, we can compute a WSPD for S of size at most $\alpha_{ds} n$. The constant in the Big-Oh bound does not depend on s. Moreover, for a large separation constant s, the value of α_{ds} is proportional to $2^d d^{d/2} s^d$.*

3. The first general algorithm. Let S be a set of n points in $\mathbb{R}^d$, and let G be a connected Euclidean graph having the points of S as its vertices. Recall that the stretch factor t^* of G is equal to

$$t^* = \max\left\{ \frac{|pq|_G}{|pq|} : p, q \in S, p \neq q \right\}.$$

Consider a WSPD

$$\{A_1, B_1\}, \{A_2, B_2\}, \ldots, \{A_k, B_k\}$$

for S. It follows from Lemma 2 that all Euclidean distances between a point of A_i and a point of B_i are roughly equal. Hence, if we compute for each i, $1 \leq i \leq k$, a point $a_i \in A_i$ and a point $b_i \in B_i$ whose distance $|a_i b_i|_G$ in G is maximum, then the largest value of $|a_i b_i|_G / |a_i b_i|$ should be a good approximation to the stretch factor t^* of G. This observation leads to our first general algorithm, which we denote by $\mathcal{A}$. See Figure 3. The following lemma proves the correctness of Algorithm $\mathcal{A}$.

LEMMA 5. *The value of t reported by Algorithm $\mathcal{A}$ is a $(1, 1+\epsilon)$-approximate stretch factor of G.*

Proof. Let t^* be the stretch factor of the graph G. We have to show that $t \leq t^* \leq (1+\epsilon)t$. Since t can be written as $|pq|_G/|pq|$ for some points p and q in S, $p \neq q$, it is clear that $t \leq t^*$.

To prove the second inequality, let x and y be two points of S such that $t^* = |xy|_G/|xy|$. Let i be the (unique) index such that (i) $x \in A_i$ and $y \in B_i$ or (ii) $x \in B_i$ and $y \in A_i$. Assume without loss of generality (w.l.o.g.) that (i) holds.

Consider the points $a_i \in A_i$ and $b_i \in B_i$ that were chosen in Step 2 of the algorithm. Clearly, $|xy|_G \leq |a_ib_i|_G$. By Lemma 2, we have $|a_ib_i| \leq (1+4/s)|xy| = (1+\epsilon)|xy|$. This gives

$$t^* = \frac{|xy|_G}{|xy|} \leq \frac{|a_ib_i|_G}{|xy|} \leq (1+\epsilon)\frac{|a_ib_i|_G}{|a_ib_i|} = (1+\epsilon)t_i \leq (1+\epsilon)t.$$

This completes the proof. □

4. An improved algorithm. The main problem with the general Algorithm $\mathcal{A}$ presented in the previous section is that Step 2 is hard to implement efficiently. In a preliminary version of this paper [20], we showed that Algorithm $\mathcal{A}$ can be used to compute a $(1, 1+\epsilon)$-approximation to the stretch factor of Euclidean paths, cycles, and trees in $O(n \log n)$, $O(n \log n)$, and $O(n \log^2 n)$ time, respectively. Using results from Arikati et al. [2], we were able to design an $O(n^{5/3}\mathit{polylog}(n))$-time algorithm for computing a $(2, 1+\epsilon)$-approximation to the stretch factor of planar Euclidean graphs.

In this section, we give a much simpler approximation algorithm. Recall that in Algorithm $\mathcal{A}$ we compute for each pair $\{A_i, B_i\}$ in a WSPD for S, a point $a_i \in A_i$ and a point $b_i \in B_i$ for which $|a_ib_i|_G$ is maximum, and we use $|a_ib_i|_G/|a_ib_i|$ as a candidate for the approximate stretch factor. Below, we prove that we can take *arbitrary* points $a_i \in A_i$ and $b_i \in B_i$ and use $|a_ib_i|_G/|a_ib_i|$, or an approximation to this quantity, as a candidate. Note that this is counterintuitive because the distances in the graph G between points of A_i and points of B_i can vary greatly.

Hence, the problem of approximating the stretch factor of a Euclidean graph can be reduced to the problem of making $O(n)$ (approximate) shortest path query computations. Shortest path query computations can, in general, be implemented more efficiently than the *farthest pair* (between sets of vertices) computations that were required when implementing Algorithm $\mathcal{A}$.

This improved algorithm, which we denote by $\mathcal{B}$, will be given in section 4.1 below. In section 5, we show that Algorithm $\mathcal{B}$ achieves, in subquadratic time, comparable approximation ratios for various classes of Euclidean graphs, as compared to Algorithm $\mathcal{A}$.

4.1. The reduction. Let p and q be two distinct vertices of a connected Euclidean graph G, and let $c \geq 1$ be a real number. We say that the real number $L(p, q)$ is a *c-approximation* to the length of a shortest path in G between p and q if

$$|pq|_G \leq L(p, q) \leq c \cdot |pq|_G.$$

Let $\mathcal{G}$ be a class of connected Euclidean graphs. We assume that we are given an algorithm ASP_c that takes as input (i) any graph G from the class $\mathcal{G}$ and (ii) any sequence of pairs of vertices of G; the algorithm ASP_c computes a c-approximation to $|ab|_G$ for each pair (a, b) in this sequence.

Algorithm $\mathcal{B}$ is given in Figure 4. The following theorem bounds the performance ratio of the output of Algorithm $\mathcal{B}$.

Improved Algorithm $\mathcal{B}$
The algorithm takes as input a Euclidean graph G from the class $\mathcal{G}$, on a set S of points in $\mathbb{R}^d$, and a real constant $\epsilon > 0$.
Step 1: Using separation constant $s = 4(1+\epsilon)/\epsilon$, compute a WSPD

$$\{A_1, B_1\}, \{A_2, B_2\}, \ldots, \{A_k, B_k\}$$

for S. For each i, $1 \le i \le k$, take an arbitrary point $a_i \in A_i$, and an arbitrary point $b_i \in B_i$.
Step 2: Use algorithm ASP_c to compute, for each i, $1 \le i \le k$, a c-approximation $L(a_i, b_i)$ to the length $|a_i b_i|_G$ of a shortest path in G between a_i and b_i. For each i, $1 \le i \le k$, let

$$t_i := \frac{L(a_i, b_i)}{|a_i b_i|}.$$

Step 3: Report the value of t, defined as $t := \max(t_1, t_2, \ldots, t_k)$. Also report points a_i and b_i for which $t = t_i$.

FIG. 4. *The improved algorithm for approximating the stretch factor of a Euclidean graph.*

THEOREM 6. *Let G be a Euclidean graph from the class $\mathcal{G}$ on a set S of points in $\mathbb{R}^d$, let t^* be the stretch factor of G, and let t be the value that is reported by Algorithm $\mathcal{B}$. Then*

$$\frac{1}{c}\, t \le t^* \le (1+\epsilon)^2 t,$$

i.e., t is a $(c, (1+\epsilon)^2)$-approximate stretch factor of G.

Proof. Let i be the index such that $t = t_i = L(a_i, b_i)/|a_i b_i|$. Then

$$t \le c\, \frac{|a_i b_i|_G}{|a_i b_i|} \le c t^*.$$

In the rest of the proof, we will prove the second inequality. To be more precise, we will show that for all points $p, q \in S$, $p \ne q$,

$$\frac{|pq|_G}{|pq|} \le (1+\epsilon)^2 t.$$

This will prove that $t^* \le (1+\epsilon)^2 t$.

The proof is by induction on the rank of the distance $|pq|$ in the sorted sequence of $\binom{n}{2}$ distances in S. To start the induction, assume that p, q is a closest pair in S. Let i be the index such that (i) $p \in A_i$ and $q \in B_i$ or (ii) $p \in B_i$ and $q \in A_i$. Assume w.l.o.g. that (i) holds. Since $s > 2$, it follows from Lemma 2 that $A_i = \{p\}$ and $B_i = \{q\}$. Hence, in Step 2 of the algorithm, we have computed the value $t_i = L(p, q)/|pq|$. It follows that

$$\frac{|pq|_G}{|pq|} \le \frac{L(p, q)}{|pq|} = t_i \le t < (1+\epsilon)^2 t.$$

Now assume that p, q is not a closest pair in S and, moreover, assume that $|xy|_G/|xy| \le (1+\epsilon)^2 t$ for all pairs x, y of points of S such that $x \ne y$ and $|xy| < |pq|$. Let i be the index such that (i) $p \in A_i$ and $q \in B_i$ or (ii) $p \in B_i$ and $q \in A_i$. Again, assume w.l.o.g. that (i) holds. Consider the point $a_i \in A_i$ and the point $b_i \in B_i$ that were chosen in Step 2 of the algorithm. By the triangle inequality, we have

$$|pq|_G \le |pa_i|_G + |a_i b_i|_G + |b_i q|_G. \tag{4.1}$$

We distinguish three cases, depending on whether $|pa_i|_G$ and $|b_iq|_G$ are smaller or larger than $(\epsilon/2)|a_ib_i|_G$, respectively.

Case 1. $|pa_i|_G > (\epsilon/2)|a_ib_i|_G$ and $|b_iq|_G > (\epsilon/2)|a_ib_i|_G$.

First note that $p \neq a_i$, because $|pa_i|_G > 0$. We may assume w.l.o.g. that $|b_iq|_G \leq |pa_i|_G$. It follows from (4.1) that

$$|pq|_G < \frac{2(1+\epsilon)}{\epsilon}\,|pa_i|_G.$$

Since $s = 4(1+\epsilon)/\epsilon$, Lemma 2 implies that $|pa_i| \leq \frac{\epsilon}{2(1+\epsilon)}|pq|$. Therefore,

$$\frac{|pq|_G}{|pq|} < \frac{2(1+\epsilon)}{\epsilon}\,\frac{|pa_i|_G}{|pq|} \leq \frac{|pa_i|_G}{|pa_i|}.$$

Since $|pa_i| < |pq|$, the induction hypothesis implies that

$$\frac{|pq|_G}{|pq|} < \frac{|pa_i|_G}{|pa_i|} \leq (1+\epsilon)^2 t.$$

Case 2. $|pa_i|_G \leq (\epsilon/2)|a_ib_i|_G$.

In this case, (4.1) implies that

$$|pq|_G \leq (1+\epsilon/2)|a_ib_i|_G + |b_iq|_G.$$

Moreover, Lemma 2 implies that $|b_iq| \leq \frac{\epsilon}{2(1+\epsilon)}|pq|$ and $|a_ib_i| < (1+\epsilon)|pq|$.

First assume that $b_i \neq q$. Then

$$\begin{aligned}\frac{|pq|_G}{|pq|} &\leq (1+\epsilon/2)\,\frac{|a_ib_i|_G}{|pq|} + \frac{|b_iq|_G}{|pq|}\\ &< (1+\epsilon/2)(1+\epsilon)\,\frac{|a_ib_i|_G}{|a_ib_i|} + \frac{\epsilon}{2(1+\epsilon)}\,\frac{|b_iq|_G}{|b_iq|}\\ &\leq (1+\epsilon/2)(1+\epsilon)\,\frac{L(a_i,b_i)}{|a_ib_i|} + \frac{\epsilon}{2(1+\epsilon)}\,\frac{|b_iq|_G}{|b_iq|}.\end{aligned}$$

Since $|b_iq| < |pq|$, the induction hypothesis implies that $|b_iq|_G/|b_iq| \leq (1+\epsilon)^2 t$. Hence,

$$\frac{|pq|_G}{|pq|} < (1+\epsilon/2)(1+\epsilon)\,t_i + \frac{\epsilon(1+\epsilon)}{2}\,t \leq (1+\epsilon)^2 t,$$

where the last inequality follows from the fact that $t_i \leq t$.

If $b_i = q$, then basically the same calculation shows that

$$\frac{|pq|_G}{|pq|} < (1+\epsilon/2)(1+\epsilon)\,t_i < (1+\epsilon)^2 t.$$

Case 3. $|b_iq|_G \leq (\epsilon/2)|a_ib_i|_G$.

This case is symmetric to Case 2. □

In the following theorem, we summarize the result of this section. We denote by $T(n,m,k)$ the worst running time of algorithm ASP_c, when given (i) a graph $G \in \mathcal{G}$ having n vertices and m edges and (ii) a sequence of c-approximate shortest path queries, consisting of k pairs of vertices of G.

THEOREM 7. *Let S be a set of n points in $\mathbb{R}^d$, let G be a Euclidean graph from the class $\mathcal{G}$, having the points of S as its vertices, and let ϵ be a real constant such that $0 < \epsilon \leq 3$. We can compute a $(c, 1+\epsilon)$-approximate stretch factor of G in time*

$$O(n \log n) + T(n, m, \beta_{d\epsilon} n).$$

Here, $\beta_{d\epsilon}$ is a constant which is proportional to $24^d d^{d/2} (1/\epsilon)^d$ if $\epsilon \downarrow 0$.

Proof. Run Algorithm $\mathcal{B}$ with ϵ replaced by $\epsilon/3$. Let t be the value that is computed by this algorithm. By Theorem 6, we have $t \leq ct^*$ and

$$t^* \leq (1 + \epsilon/3)^2 t \leq (1+\epsilon)t.$$

The bound on the running time follows immediately from the algorithm and Theorem 4. □

5. Applications of Algorithm $\mathcal{B}$.

5.1. A lower bound. Before we start with the applications, we prove a lower bound for approximating the stretch factor in the algebraic computation tree model. (See Ben-Or [5] or Preparata and Shamos [22] for a description of this model.)

THEOREM 8. *Any algebraic computation tree algorithm that takes as input* (i) *a Euclidean path or cycle on a set of n points in $\mathbb{R}^d$ and* (ii) *real numbers $c_1 \geq 1$ and $c_2 \geq 1$, and that computes a (c_1, c_2)-approximate stretch factor of this graph, has worst-case running time $\Omega(n \log n)$.*

Proof. We give the lower bound proof for the case when the graph is a path. The lower bound proof for the cycle is similar.

Let $\mathcal{C}$ be any algorithm that satisfies the hypothesis. We will show that $\mathcal{C}$ can be used to solve the *element-uniqueness problem*, which is known to have an $\Omega(n \log n)$ lower bound in the algebraic computation tree model. (See [5, 22].)

Let $x_1, x_2, \ldots, x_n$ be a sequence of n real numbers. We consider these numbers as points on the x_1-axis in $\mathbb{R}^d$. Let M be the maximal element in the input sequence. Define the path P by

$$P := (x_1, M+1, x_2, M+2, x_3, M+3, \ldots, x_{n-1}, M+n-1, x_n).$$

Note that each edge of P has a nonzero length. We choose arbitrary real numbers $c_1 \geq 1$ and $c_2 \geq 1$ and run Algorithm $\mathcal{C}$ on the path P. Let t be the (c_1, c_2)-approximate stretch factor of P that is computed. Then it is easy to see that t is finite if and only if the input numbers $x_1, x_2, \ldots, x_n$ are pairwise distinct.

Since the reduction takes $O(n)$ time, it follows that Algorithm $\mathcal{C}$ has a worst-case running time of $\Omega(n \log n)$. □

5.2. Paths, cycles, and trees. Let $\mathcal{G}$ be the class of Euclidean paths, cycles, or trees. For any graph G in this class, we can, after an $O(n)$-time preprocessing, answer exact shortest path queries in $O(1)$ time, if G is a path or cycle, and in $O(\log n)$ time, if G is a tree. (If we allow nonalgebraic operations, then we can even answer shortest path queries in a tree in $O(1)$ time; see [16].) Hence, we can apply Theorem 7, with $c = 1$ and $T(n, m, k) = O(n + k)$, if G is a path or cycle, and $T(n, m, k) = O(n + k \log n)$, if G is a tree, and get the following result.

THEOREM 9. *Let S be a set of n points in $\mathbb{R}^d$; let G be a Euclidean path, cycle, or tree, having the points of S as its vertices; and let ϵ be a real constant such that $0 < \epsilon \leq 3$. In $O(n \log n)$ time, we can compute a $(1, 1+\epsilon)$-approximate stretch factor of G.*

It follows from Theorem 8 that the above result is optimal in the algebraic computation tree model.

5.3. Planar graphs. For the next application, let $\mathcal{G}$ be the class of planar connected Euclidean graphs. Let G be a graph in this class, on a set of n points in $\mathbb{R}^d$. Arikati et al. [2] have shown that we can build a data structure, in $O(n\sqrt{n}\,)$ time, that allows us to solve exact shortest path queries in $O(\sqrt{n}\,)$ time per query. Hence, we can apply Theorem 7 with $c = 1$ and $T(n, m, k) = O(n\sqrt{n} + k\sqrt{n}\,)$. This gives the following theorem.

THEOREM 10. *Let S be a set of n points in $\mathbb{R}^d$, let G be a planar connected Euclidean graph having the points of S as its vertices, and let ϵ be a real constant such that $0 < \epsilon \leq 3$. In $O(n\sqrt{n}\,)$ time, we can compute a $(1, 1+\epsilon)$-approximate stretch factor of G.*

5.4. General graphs. In our final application, we let $\mathcal{G}$ be the general class of connected Euclidean graphs. Let $G \in \mathcal{G}$ be any graph with n vertices and m edges. Note that $m \geq n - 1$. Cohen [9] has shown that for any integer $\beta \geq 1$ and any constant ϵ such that $0 < \epsilon \leq 1/2$, any sequence of $(2\beta(1+\epsilon))$-approximate shortest path queries can be answered in *expected* time

$$O((m+k)n^{1/\beta}\beta \log^2 n),$$

where k is the number of queries. Applying Theorem 7 gives the following result.

THEOREM 11. *Let S be a set of n points in $\mathbb{R}^d$, let G be a connected Euclidean graph having the points of S as its vertices and having m edges, let $\beta \geq 1$ be an integer constant, and let ϵ be a real constant such that $0 < \epsilon \leq 1/2$. In*

$$O(mn^{1/\beta} \log^2 n)$$

expected time, we can compute a $(2\beta(1+\epsilon), 1+\epsilon)$-approximate stretch factor of G.

By choosing different values for the integer constant β, Theorem 11 gives an interesting trade-off between the running time and the approximation factor. For example, by choosing β large enough, the running time in Theorem 11 is almost linear in m, but then the approximation of the stretch factor is very weak (although it is still bounded by a constant).

Theorem 11 implies the following result for *sparse* graphs, i.e., graphs having $O(n)$ edges.

COROLLARY 12. *Let S be a set of n points in $\mathbb{R}^d$, let G be a sparse connected Euclidean graph having the points of S as its vertices, let $\beta \geq 1$ be an integer constant, and let ϵ be a real constant such that $0 < \epsilon \leq 1/2$. In*

$$O(n^{1+1/\beta} \log^2 n)$$

expected time, we can compute a $(2\beta(1+\epsilon), 1+\epsilon)$-approximate stretch factor of G.

6. Conclusions. In this paper we showed how to efficiently compute a close approximation to the stretch factors of Euclidean graphs. We showed that the problem can be reduced either to a sequence of farthest pair queries on $O(n)$ pairs of sets of points or to a sequence of (approximate) shortest path queries for $O(n)$ specific pairs of points. It would be interesting to know whether $o(n)$ shortest path queries are sufficient for determining stretch factors approximately.

Except for trivial classes such as complete graphs, it is not known how to compute the exact stretch factor of *any* class of Euclidean graphs in less time than that required to solve the all-pairs-shortest-path problem. Hence, it is not evenknown if

the exact stretch factor of simple Euclidean graphs, such as paths, can be computed in subquadratic time.

Stretch factors can be thought of as a quantitative measure to compare distances in two different metrics. In this paper, we demonstrated techniques to compute stretch factors in order to compare a "graph metric" with the Euclidean metric. It would be interesting to study stretch factors as a measure to compare two non-Euclidean metrics. Our techniques cannot be used then, since no equivalent of the well-separated pair decomposition is known for non-Euclidean metrics.

Abstract. We investigate the computational complexity of the *formula isomorphism* problem (FI): on input of two boolean formulas F and G decide whether there exists a permutation of the variables of G such that F and G become equivalent. FI is contained in $\Sigma_2\mathbf{P}$, the second level of the polynomial hierarchy.

Our main result is a one-round interactive proof for the complementary *formula nonisomorphism* problem (FNI), where the verifier has access to an **NP**-oracle. To obtain this, we use a result from learning theory by Bshouty et al. that boolean formulas can be learned probabilistically with equivalence queries and access to an **NP**-oracle. As a consequence, FI cannot be $\Sigma_2\mathbf{P}$-complete unless the polynomial hierarchy collapses.

Further properties of FI are shown: FI has and- and or-functions, the counting version, #FI, can be computed in polynomial time relative to FI, and FI is self-reducible.

1. Introduction.

An interesting computational issue is to decide the equivalence of two given programs with respect to some computational model. While the problem is undecidable for computational models such as Turing machines, LOOP-programs, or context-free languages (see [Hu79]), it is **coNP**-complete for LOOP(1)-programs (no nested loops), circuits, branching programs, and boolean formulas. Moreover, it can be efficiently solved for one-time-only branching programs by a randomized algorithm [BCW80]. For deterministic finite automata it can be efficiently solved deterministically (see [Hu79]).

We consider the following generalization of the equivalence problem: determine (for some fixed model) whether there exists a *bijective transformation* of the inputs of one program that makes the two given programs equivalent. Since we consider such a transformation of the input intuitively as an *easy* operation, this captures the idea of a notion of *almost equivalence*.

From a computational perspective, the *graph isomorphism* problem might be the most studied problem of this kind. Here, the bijection is required to be an *isomorphism*, i.e., a permutation of the input vertices (see [Hof82] and [KST93] for a comprehensive discussion of this problem).

From a combinatorial perspective, another such problem has been very well studied too: the *boolean congruence* problem. Mathematicians since the last century have investigated the structure of the sets of boolean functions that are congruent to each other. Here, the *congruence* is a bijective transformation in which a permutation of the variables is composed with a *negation mapping* which maps each variable either

to itself or to its complement. (The paper by Borchert, Ranjan, and Stephan [BRS98] gives extensive background and provides a list of early references on this problem.) To motivate the name, the boolean congruence relation can be seen as a geometrical congruence: there are 2^n assignments for a boolean function f over n variables that form the nodes of an n-dimensional cube in $\mathbf{R}^n$. Those assignments, where f evaluates to one, constitute a subgraph of the cube, *the n-dimensional geometrical cube that represents f*. Two functions f and g are congruent if and only if the n-dimensional geometrical cubes that represent f and g are geometrically congruent, that is, there is a distance-preserving bijection from one subgraph to the other.

In recent years, this and similar problems have been reconsidered from the complexity perspective [BR93, BRS98, CK91]. Of course, one needs to fix a model for representing boolean functions—the most popular of these are formulas and circuits. For formulas, we can define the *formula congruence* problem (FC) as follows: given two boolean formulas over n variables, determine whether they are congruent. One can similarly define the *formula isomorphism* problem (FI) where, instead of a congruence, we ask for an isomorphism. Although congruence is a broader notion than isomorphism, FC is many-one equivalent to FI [BRS98].

It is straightforward to see that FI is **coNP**-hard but it is not known to be in **coNP**. Therefore it is at least as difficult as the boolean formula equivalence problem. As an upper bound on its complexity, it can be easily shown that FI is in the second level of the polynomial hierarchy, $\Sigma_2\mathbf{P}$. It is posed as an open problem by Borchert, Ranjan, and Stephan [BRS98] whether FI is complete for $\Sigma_2\mathbf{P}$. They conjectured that it is not. In this paper we give an affirmative answer to this question in the following sense: we show that FI is *not* complete for $\Sigma_2\mathbf{P}$ unless the polynomial hierarchy collapses.

We also give a lower bound for FI: we show that the problem to decide whether a graph has a unique optimal clique—which is not known to be in the Boolean Hierarchy—many-one reduces to it.

The FI problem shares many similarities with the graph isomorphism problem (GI). Many of the results for GI carry over to FI with similar proofs (including the noncompleteness one), although with some crucial differences.

One can also consider more general bijections than isomorphisms and congruences. We can rewrite any permutation of n variables $\boldsymbol{x} = (x_1, \ldots, x_n)$ as a product of a permutation matrix $\boldsymbol{P}$ with $\boldsymbol{x}$ over $\mathbf{GF}(2)$. That is, an isomorphism can be written as $\boldsymbol{xP}$, and a congruence can be written as $\boldsymbol{xP} + \boldsymbol{c}$ for a vector $\boldsymbol{c} \in \{0,1\}^n$. A natural generalization of the above notions is therefore to consider linear and affine transformations $\boldsymbol{xA}$ and $\boldsymbol{xA} + \boldsymbol{c}$, respectively, where $\boldsymbol{A}$ has to be a bijection on $\{0,1\}^n$. We call two formulas *linear equivalent* or *affine equivalent* if they become equivalent after a linear or an affine transformation of the variables of one of the formulas, respectively. As in the case of isomorphism and congruence, the *formula linear equivalence* problem (FLE) and the *formula affine equivalence* problem (FAE) are many-one equivalent [BRS98]. Also, FI many-one reduces to FAE [BRS98].

Considering circuits as representation of boolean functions instead of boolean formulas, we get the corresponding problems CI, CC, CLE, and CAE. The latter is the most complex problem we considered so far: all the other problems are many-one reducible to it. The above mentioned result for FI holds in fact more generally for CAE. That is, CAE is not complete for $\Sigma_2\mathbf{P}$ unless the polynomial hierarchy collapses.

The paper is organized as follows. In section 3 we show that the formula nonisomorphism (FNI) has a one-round interactive proof, where the verifier has access to

an **NP**-oracle. From this we conclude the above mentioned noncompleteness result. In section 4 we show that FI has and- and or-functions. This will provide us with a lower bound for FI: the unique optimal clique problem (UOClique) can be many-one reduced to it. In section 5 we show that the counting version of FI can be solved in polynomial time relative to FI. This is a result that holds analogously for GI. Finally, in section 6 we show that FI is self-reducible.

2. Preliminaries. For standard notions in complexity theory we refer the reader to textbooks such as [BDG88, BDG91, Hu79]. We fix an alphabet Σ, for example, $\Sigma = \{0, 1\}$. Complexity classes we use are **P**, **NP**, or **RP**. The class of polynomial-time computable *functions* is **FP**. We also use *relativized* classes such as $\mathbf{P}^{\mathbf{NP}}$. The levels of the *polynomial hierarchy* (**PH**) are denoted by $\Sigma_k\mathbf{P}$. The *boolean hierarchy* is the closure of **NP** under boolean operations. Its kth level consists of all sets that can be expressed as the symmetric difference of at most k **NP**-sets. For any class $\boldsymbol{\mathcal{C}}$, we denote the complement class by **co** $\boldsymbol{\mathcal{C}}$.

Set A is *many-one reducible* to set B (we write $A \leq_m^p B$ for short) if there is a function $f \in \mathbf{FP}$ such that for every $x \in \Sigma^*$

$$x \in A \iff f(x) \in B.$$

We write $A \equiv_m^p B$ if both sets are many-one reducible to each other. *Truth-table reductions* generalize many-one reductions by allowing the function $f(x)$ to compute several strings of which we determine membership in B. On the outcome of these membership queries a boolean predicate is applied which decides on the membership of x in A. If the boolean predicate is simply a conjunction or disjunction, we talk of a *conjunctive* or *disjunctive truth-table reduction*, respectively.

Our main results are based on *interactive proof systems* introduced by Goldwasser, Micali, and Rackoff [GMR89] and Babai and Moran [BM88]. For completeness, we give definitions of such classes.

2.1. Complexity classes. An *interactive proof system* [GMR89] for a set L consists of a *prover* P and *verifier* V. The verifier is a randomized polynomial-time algorithm that can communicate with the prover. The prover can make arbitrary computations. After following some communication protocol, the verifier finally has to accept or reject a given input x such that

$$\begin{aligned} x \in L &\implies \exists \text{ prover } P: \ \mathbf{Prob}(V, P)(x) \text{ accepts } = 1, \\ x \notin L &\implies \forall \text{ prover } P: \ \mathbf{Prob}(V, P)(x) \text{ accepts } \leq 1/2, \end{aligned}$$

where the probability is taken over the random choices of the verifier.

IP denotes the class of sets that have an interactive proof system. $\mathbf{IP}[k]$ is the subclass of **IP** where the verifier and the prover exchange at most k messages on every input.

A concept very similar to interactive proof systems was introduced by Babai and Moran [BM88] and called *Arthur–Merlin games*. Here Arthur plays the role of the verifier and Merlin that of the prover. The only difference is in the use of the random bits: the verifier has its own random tape which is secret to the prover. In contrast, Arthur and Merlin have a random tape available to both. The difference between interactive proof systems and Arthur–Merlin games is therefore sometimes pinpointed to *private vs. public coins*.

If there are at most k message exchanges between Arthur and Merlin, the language is in the class $\mathbf{AM}[k]$. In contrast to the notation in interactive proof systems, $\mathbf{AM}$ denotes the class $\mathbf{AM}[2]$.

In a series of surprising results it was shown that, for constant $k \geq 2$, all the above classes coincide [BM88, GS89], that is,

$$\mathbf{IP}[k] = \mathbf{AM}[k] \quad = \quad \mathbf{AM}.$$

We also consider relativizations of these classes. Since the prover and Merlin have unlimited computational power, they don't need an oracle. Hence $\mathbf{IP}^A$ denotes the class of interactive proof systems where the verifier has access to oracle A. Analogously, in $\mathbf{AM}^A$ Arthur has access to oracle A. We note that the above collapse result holds in presence of an oracle as well. In particular, we have $\mathbf{IP}[k]^{\mathbf{NP}} = \mathbf{AM}^{\mathbf{NP}}$.

$\mathbf{AM}$ can be expressed in terms of more standard complexity classes: for a class of sets $\boldsymbol{\mathcal{C}}$, define $\mathbf{BP} \cdot \boldsymbol{\mathcal{C}}$ as the class of sets L such that there exists a set $A \in \boldsymbol{\mathcal{C}}$ and a polynomial p such that for every x

$$\begin{aligned} x \in L &\implies \mathbf{Prob}(x, y) \in A \geq 2/3, \\ x \notin L &\implies \mathbf{Prob}(x, y) \in A \leq 1/3, \end{aligned}$$

where y is chosen uniformly at random from $\Sigma^{p(|x|)}$.

It is well known that $\mathbf{AM} = \mathbf{BP} \cdot \mathbf{NP}$, because in an $\mathbf{AM}$ protocol, *Arthur* can be replaced by a bounded error probabilistic polynomial-time machine that just passes the result of the coin tosses to *Merlin* (see [GS89]). Relative to an $\mathbf{NP}$-oracle, this equation translates to $\mathbf{AM}^{\mathbf{NP}} = \mathbf{BP} \cdot \Sigma_2\mathbf{P}$.

2.2. Isomorphism problems. The graph isomorphism problem (GI) is defined as follows. Given two graphs G_0 and G_1 with n nodes $V = \{1, \ldots, n\}$, decide whether there is a permutation φ on V such that G_1 becomes equal to G_0 when the nodes of G_1 are permuted by φ. In other words, for all nodes $i, j \in V$, we have (i, j) is an edge in G_0 if and only if $(\varphi(i), \varphi(j))$ is an edge in G_1. Clearly, GI is in $\mathbf{NP}$. The complementary *graph nonisomorphism problem* is denoted by GNI and is therefore in $\mathbf{coNP}$.

Two boolean formulas F_0 and F_1 with variables $x_1, \ldots, x_n$ are *equivalent* if they have the same value for every assignment to their variables. The equivalence problem for boolean formulas is known to be $\mathbf{coNP}$-complete.

Two formulas F_0 and F_1 are *isomorphic* if there exists a permutation φ on the set of variables $\{x_1, \ldots, x_n\}$, such that F_1 becomes equivalent to F_0 when the variables of F_1 are permuted by φ, i.e., $F_0(x_1, \ldots, x_n)$ is equivalent to $F_1 \circ \varphi = F_1(\varphi(x_1), \ldots, \varphi(x_n))$. In this case, we call φ an *isomorphism between F_0 and F_1*. The formula isomorphism problem (FI) is to decide whether two given formulas are isomorphic. It follows directly from the definition that $\mathrm{FI} \in \Sigma_2\mathbf{P}$, the second level of the polynomial hierarchy. The complementary *formula nonisomorphism problem* is denoted by FNI.

$\mathsf{Iso}(F_0, F_1)$ denotes the set of isomorphisms between F_0 and F_1. An automorphism of a formula F is an isomorphism between F and F, $\mathsf{Aut}(F) = \mathsf{Iso}(F, F)$. $\mathsf{Aut}(F)$ is a group with composition $\circ$ as group operation. It is a subgroup of the permutation group (on n variables). Every formula has a trivial automorphism: the identity mapping. The *formula automorphism problem* (FA) is to decide whether a formula F has a nontrivial automorphism, i.e., whether $|\mathsf{Aut}(F)| > 1$.

A *negation mapping* on n variables is a function ν such that $\nu(x_i) \in \{x_i, \overline{x}_i\}$ for $1 \le i \le n$. In other words, a negation mapping allows us to replace a variable by its complement. Two formulas F_0 and F_1 are *congruent* if there exists a permutation φ and a negation mapping ν on $\{x_1, \ldots, x_n\}$, such that F_0 and $F_1 \circ \nu \circ \varphi$ are equivalent. The formula congruence problem (FC) is to decide whether two formulas are congruent. Congruence is a more flexible notion than isomorphism, however; FC is clearly in $\Sigma_2\mathbf{P}$. Moreover, FI $\equiv_m^p$ FC [BRS98].

Formulas F_0 and F_1 are *affine equivalent* if there exists a nonsingular $n \times n$ matrix $\boldsymbol{A}$ and a $1 \times n$ vector $\boldsymbol{c}$ over $\mathbf{GF}(2)$ such that for every $\boldsymbol{x} = (x_1, \ldots, x_n)$, $F_0(\boldsymbol{x})$ and $F_1(\boldsymbol{x}\boldsymbol{A} + \boldsymbol{c})$ are equivalent (here addition and multiplication are over $\mathbf{GF}(2)$). The formulas are *linear equivalent* if they are affine equivalent with vector $\boldsymbol{c}$ as the zero vector. We use FAE and FLE to denote the set of pairs of formulas that are respectively affine and linear equivalent.

The above definitions can be applied to circuits instead of formulas. We use CI, CC, CLE, and CAE to denote the set of circuit pairs that are isomorphic, congruent, linear equivalent, and affine equivalent, respectively. We note that the reductions shown in [BRS98] carry over to circuits. That is, we have CI $\equiv_m^p$ CC $\le_m^p$ CLE $\equiv_m^p$ CAE. Since a formula can easily be transformed to a circuit, each boolean formula problem is many-one reducible to its corresponding circuit version. It follows that CLE and CAE are the computationally hardest problems we have defined here.

3. An interactive proof for FNI. We show that there is a one-round interactive proof for FNI where the verifier has access to an **NP**-oracle. Our interactive proof is based on the one for GNI [GMR89]. However, it differs from it in one crucial aspect. In Figure 3.1 we first recall the protocol for GNI on input of two graphs (G_0, G_1), both with nodes $V = \{1, \ldots, n\}$.

V: The verifier randomly picks $i \in \{0, 1\}$, a random permutation φ on V, and permutes G_i with φ. Let H be the graph obtained that way. The verifier sends H to the prover.
P: The prover answers by sending $j \in \{0, 1\}$ to the verifier.
V: Finally, the verifier accepts if $i = j$, and rejects otherwise.

FIG. 3.1. *Interactive protocol for* GNI.

When the input graphs are *not* isomorphic, the prover can find out from which of G_0 or G_1 the graph H was obtained by the verifier, and can therefore make the verifier accept with probability one. On the other hand, when the graphs are isomorphic, then no prover can find out the graph that was chosen by the verifier to construct H. Therefore, the answer of any prover is correct with probability at most 1/2.

Unfortunately, the analogous protocol for FNI does not work. To see this, consider the above protocol on input (F_0, F_1), where

$$F_0 = x_1 \wedge (\overline{x}_1 \vee \overline{x}_2) \quad \text{and}$$
$$F_1 = \overline{x}_1 \wedge x_2.$$

Note that F_0 and F_1 are isomorphic (exchange x_1 and x_2). The verifier randomly picks $i \in \{0, 1\}$, obtains a formula G by randomly permuting F_i, and sends it to the prover. However, even though F_0 and F_1 are isomorphic, the prover can easily detect from which one G has been obtained because of the syntactic structure of G:

any permutation of F_0 will have three literals and any permutation of F_1 will have two literals.

It seems that what we need is a *normal form* for equivalent boolean formulas that can be computed by the verifier. (Recall that the verifier has access to an **NP**-oracle.) Then the verifier could map the formula G in the above protocol to its normal form H, and then the prover could not distinguish whether H is coming from F_0 or F_1, if the formulas are isomorphic.

Clearly, we cannot simply transform G into its disjunctive or conjunctive normal form, because this might lead to formulas that are exponentially longer than G. Another obvious candidate for a normal form is the *smallest* equivalent boolean formula (under some suitable total ordering). However, it requires a $\Sigma_2\mathbf{P}$-oracle to compute this [Uma98], and our verifier only has an **NP**-oracle available.

To overcome this difficulty, we compute what can be called a *randomized normal form* of a formula. It is obtained from an algorithm in learning theory by Bshouty et al. [BCG$^+$96]. We start by providing an informal description of the learning scenario and then give a reformulation in pure complexity theoretic terms.

Let F be a boolean formula given in a *black box*. A probabilistic polynomial-time machine, the *learner*, has to compute a formula that is equivalent to F, but without seeing F. The learner can use an **NP**-oracle, and, furthermore, ask *equivalence queries* of a *teacher* who knows F. That is, the learner can send a formula G to the teacher. If F and G are equivalent, the learner has succeeded in learning F and the teacher will answer "yes." Otherwise, the teacher will send a *counterexample* to the learner, namely an assignment $\boldsymbol{a}$ such that $F(\boldsymbol{a}) \neq G(\boldsymbol{a})$. The learner *succeeds in learning* F if he outputs, with high probability, a formula that is equivalent to F. The learner might sometimes fail to learn F, but only with small probability. In this case, he makes no output. The result of Bshouty et al. [BCG$^+$96] says that boolean formulas can be learned in this setting.

How can we use this for our normal form problem? The crucial observation in the learning process is that the output of the learner does *not* depend on the specific syntactic form of the input formula F: because of the black box approach, the learner has exactly the same behavior on every formula F' given as input that is equivalent to F. *Hence, we take the output of the learner as our normal form.*

Note that this is not a normal form in the classical sense, because the learner produces possibly different equivalent formulas for different random choices. However, on each random path the output remains the same on any F' as input that is equivalent to F. This will suffice for our purposes.

We want to reformulate the result in complexity theoretic terms. Our first step is to throw out the teacher. She has to decide the equivalence of formulas and to compute counterexamples. The latter can easily be done within $\mathbf{P}^{\mathbf{NP}}$ by a standard prefix-search: extend, bit by bit, a partial assignment to the variables where the two given formulas differ. Each bit can be obtained with a query to an **NP**-oracle.

In summary, we get *one* probabilistic algorithm that, with the help of an **NP**-oracle, simulates the learner *and* the teacher. The output is, with high probability, a formula equivalent to the input formula, and, with small probability, there is no output. Moreover, the output does not depend on the syntax of the input formula. More precisely, we have the following.

THEOREM 3.1 (see [BCG$^+$96]). *There is a probabilistic polynomial-time algorithm A that has access to an* **NP***-oracle such that on input of a boolean formula F, algorithm A has the following properties.*

(1) *A outputs a boolean formula that is equivalent to F with probability at least 3/4, and makes no output otherwise.*
(2) *If F' is a formula equivalent to F, then, for any choice of the random bits used by A, it makes the same output on input F and on input F'.*

Now the idea should be clear. The verifier first transforms the randomly produced formula G into the normal form via the above algorithm, and then sends it to the prover. We give the full protocol below.

THEOREM 3.2. FNI $\in \mathbf{IP}[2]^{\mathbf{NP}}$.

Proof. The IP-protocol shown in Figure 3.2 accepts FNI. The inputs are two formulas (F_0, F_1) , both in variables $x_1, \ldots, x_n$, and without loss of generality (w.l.o.g.) of the same length.

V: The verifier randomly picks $i \in \{0,1\}$ and a random permutation φ on the n variables. Let $G = F_i \circ \varphi$. Now, the verifier uses the algorithm of Theorem 3.1 on input G to obtain an equivalent boolean formula H and sends H to the prover. On those paths where the algorithm does not generate an output, the verifier directly accepts.
P: The prover answers by sending $j \in \{0,1\}$ to the verifier.
V: Finally, the verifier accepts if $i = j$, and rejects otherwise.

FIG. 3.2. *Interactive protocol for* FNI.

We show that the above protocol works correctly. If F_0 is *not* isomorphic to F_1, a prover can determine which of F_0 and F_1 formula H is isomorphic to and tell it to the verifier. Also, on the random paths where no equivalent formula is produced, the verifier accepts. Therefore, the verifier accepts with probability one.

Now consider the case when F_0 is isomorphic to F_1. Assume the verifier picks $i = 0$ (the case $i = 1$ is analogous). Then the verifier constructs $G = F_0 \circ \varphi$ for some randomly chosen permutation φ. Since F_0 is isomorphic to F_1, G is isomorphic to F_1 too. Hence there is some permutation φ' such that formula $G' = F_1 \circ \varphi'$ is equivalent to G.

The next step of the verifier is to apply the algorithm of Theorem 3.1 to G and to obtain the equivalent formula H (or no formula). Now observe that the random bits of the verifier that lead to the construction of H on input G would also lead to the construction of H on input G'. In other word, any formula H has the same probability to be sent to the prover, irrespective of whether G was obtained from F_0 or F_1. Therefore the answer of any prover will be correct with probability 1/2.

In summary, the verifier accepts with probability 1/2 on those computations where a formula H is produced and on all computations with no output. The latter occurs with probability at most 1/4. Therefore, the verifier will accept with probability at most $1/2 + 1/4 = 3/4$.

The definition of an interactive proof system requires an error bound of at most 1/2. There is a standard trick to achieve this now: execute the above protocol three times in parallel and accept only if all three executions lead to acceptance. This doesn't change the case when F_0 is not isomorphic to F_1. In the other case, the error decreases to $(3/4)^3 < 1/2$. This proves the theorem. □

COROLLARY 3.3. FNI $\in \mathbf{BP} \cdot \Sigma_2\mathbf{P}$.

For readers familiar with cryptography we remark that the idea used to prove Theorem 3.2 can be used to give a *perfect zero-knowledge* interactive proof for FI, where the verifier has access to an **NP**-oracle.

Schöning [Sch88] gives a direct proof that the graph isomorphism problem is in **AM** by using hash functions. We remark that we can extend Schöning's proof by our technique to directly obtain Corollary 3.3.

Schöning [Sch89] showed that a $\Pi_2\mathbf{P}$-complete set cannot be in $\mathbf{BP}\cdot\Sigma_2\mathbf{P}$ unless the polynomial hierarchy collapses. Combined with Corollary 3.3, we obtain our main result.

COROLLARY 3.4. *If* FI *is* $\Sigma_2\mathbf{P}$*-complete, then* $\mathbf{PH}=\Sigma_3\mathbf{P}$.

The learning result of Bshouty et al. [BCG$^+$96] holds as well for circuits instead of formulas. Therefore we can adapt the interactive proof for FNI for the circuit nonisomorphism problem (CNI). That is, we have CNI $\in \mathbf{IP}[2]^{\mathbf{NP}}$, and consequently, we have the following.

COROLLARY 3.5. *If* CI *is* $\Sigma_2\mathbf{P}$*-complete, then* $\mathbf{PH}=\Sigma_3\mathbf{P}$.

We can extend the interactive proof for FI even further: to the *affine equivalence problem for circuits* (CAE). To do so, we slightly modify the protocol in the proof of Theorem 3.2. The only difference is the kind of transformation that is used: in Theorem 3.2, the verifier randomly generates a permutation. Now, the verifier must randomly generate an *affine transformation*. To achieve this, the verifier randomly generates an n-bit vector and an $n\times n$ 0-1 matrix. To constitute an affine transformation, the matrix should be nonsingular. Our next lemma ensures that there are enough nonsingular matrices for the verifier to find one with high probability.

LEMMA 3.6. *At least* $1/4$ *of the* $n\times n$ *matrices over* $\mathbf{GF}(2)$ *are nonsingular.*

Proof. We successively choose the column vectors of an $n\times n$ matrix such that the next column vector is linearly independent of the previous ones. The first column can be chosen arbitrarily, except that it can't be zero. So there are 2^n-1 choices.

Any k linearly independent vectors in $\mathbf{GF}(2)^n$ span a vector space of size 2^k. Therefore, when we choose the $(k+1)$st column, we have 2^n-2^k choices.

In total, $\prod_{k=0}^{n-1}(2^n-2^k)$ of the 2^{n^2} $n\times n$ matrices over $\mathbf{GF}(2)$ are nonsingular. Thus, their proportion is

$$\begin{aligned}\frac{1}{2^{n^2}}\prod_{k=0}^{n-1}(2^n-2^k) &= \prod_{k=1}^{n}\left(1-\frac{1}{2^k}\right)\\ &= \frac{1}{2}\prod_{k=2}^{n}\left(1-\frac{1}{2^k}\right) \quad (\text{for } n\geq 2)\\ &\geq \frac{1}{2}\prod_{k=2}^{n}\left(1-\frac{1}{k^2}\right) \quad (\text{for } n\geq 6)\\ &= \frac{1}{2}\left(\frac{1}{2}\ \frac{n+1}{n}\right)\\ &\geq \frac{1}{4},\end{aligned}$$

where the second line from bottom follows by induction on n. For values of n smaller than 6, the above bound holds too, as can be checked directly. □

Below we give the full protocol for the affine nonequivalence problem for circuits (CANE).

THEOREM 3.7. CANE $\in \mathbf{IP}[2]^{\mathbf{NP}}$.

Proof. The interactive proof system for CANE is shown in Figure 3.3. The inputs are two circuits (C_0, C_1) , both in variables $x_1,\ldots,x_n$, and w.l.o.g. of the same length.

V: The verifier randomly picks $i \in \{0,1\}$ and an n-bit vector $\boldsymbol{r}$. Furthermore, the verifier makes up to five trials to randomly get a nonsingular $n \times n$ 0-1 matrix.
If all trials fail, the verifier stops and accepts directly. Otherwise, let $\boldsymbol{R}$ be the (nonsingular) random matrix, and let $D = C_i(\boldsymbol{xR} + \boldsymbol{r})$.
Next, the verifier produces the randomized normal form from D according to the algorithm of Theorem 3.1, obtains the equivalent circuit E, and sends E to the prover. If the algorithm fails to produce a normal form, the verifier accepts directly.
P: The prover answers by sending $j \in \{0,1\}$ to the verifier.
V: Finally, the verifier accepts if $i = j$, and rejects otherwise.

FIG. 3.3. *Interactive protocol for* CANE.

We show that the protocol works correctly. If $(C_0, C_1) \in$ CANE, the honest prover can *always* convince the verifier.

Now consider the case where $(C_0, C_1) \notin$ CANE. It suffices to show that the probability that a specific circuit E is presented to the prover is independent of whether it was produced from C_0 or from C_1. In this case, the acceptance probability of the verifier is bounded by $1/2$ for the right answer of the prover, plus $(3/4)^5 < 1/16$ for not finding a nonsingular matrix, plus $1/4$ for not getting a normal form. This sums up to $13/16$. By executing the protocol four times in parallel, we can bring the acceptance probability down to $(13/16)^4 < 1/2$.

It remains to argue that independent of whether i was chosen to be 0 or 1, we have the same chance of getting circuit E. Let $\boldsymbol{xA} + \boldsymbol{c}$ be the affine transformation so that $C_1(\boldsymbol{xA} + \boldsymbol{c})$ is equivalent to C_0. For a random affine transformation, say $\boldsymbol{xR} + \boldsymbol{r}$, applied to C_0, we get $D_0 = C_0(\boldsymbol{xR} + \boldsymbol{r})$. The equivalent circuit via C_1 is $D_1 = C_1(\boldsymbol{xAR} + \boldsymbol{cR} + \boldsymbol{r})$. Now note that $\boldsymbol{x} \mapsto \boldsymbol{xAR} + \boldsymbol{cR} + \boldsymbol{r}$ is still a random affine transformation for fixed $\boldsymbol{A}$ and $\boldsymbol{c}$. Therefore we have the same probability to get D_0 when $i = 0$ and to get D_1 when $i = 1$. Since D_0 and D_1 are equivalent, our randomized normal form algorithm has an identical output distribution on input D_0 and on input D_1. □

COROLLARY 3.8. *If* CAE *is* $\Sigma_2\mathbf{P}$*-complete, then* $\mathbf{PH} = \Sigma_3\mathbf{P}$.

4. FI has and- and or-functions. In this section we show that the disjunctive and conjunctive truth-table degrees of FI collapse to the many-degree of FI. This is a consequence of FI having and- and or-functions. As an application we show that the formula automorphism problem and the unique optimal clique problem are many-one reducible to FI, thereby providing some lower bounds on the complexity of FI.

DEFINITION 4.1. *An* and-function *for a set A is a function* $\mathsf{and} : \Sigma^* \times \Sigma^* \mapsto \Sigma^*$ *such that for any $x, y \in \Sigma^*$, we have $x \in A$* and *$y \in A$ if and only if* $\mathsf{and}(x, y) \in A$. *similarly, an* or-function or *for A fulfills $x \in A$* or *$y \in A$ if and only if* $\mathsf{or}(x, y) \in A$.

4.1. Some technical lemmas on labellings. Before we can define the and- and or-functions for FI, we need some technical lemmas which provide us with some *marking* or *labelling mechanism* for the variables of a boolean formula such that a labelled variable is a *fix point of any automorphism* of the formula. It is not clear whether there exist such labellings that are efficiently computable. However, the following weaker labelling often suffices.

DEFINITION 4.2. *Let $F = F(x_1, \ldots, x_n)$ be a boolean formula. We call variables x_i and x_j* equivalent with respect to *F if, for any assignment $\boldsymbol{a}$ that satisfies F, we have $\boldsymbol{a}(x_i) = \boldsymbol{a}(x_j)$. By $E_F(x_i)$ we denote the set of variables of F that are*

equivalent to x_i.

Consider any automorphism $\varphi \in \mathsf{Aut}(F)$. If φ maps x_i to x_k, then φ must map all variables equivalent to x_i to variables that are equivalent to x_k, i.e., $\varphi(E_F(x_i)) \subseteq E_F(x_k)$. Furthermore, any variable x_j that is mapped by φ to a variable in $E_F(x_k)$ must belong to $E_F(x_i)$. Therefore, $\varphi(E_F(x_i)) = E_F(x_k)$. Since φ is a bijection, we conclude that $E_F(x_i)$ and $E_F(x_k)$ must be of the same size.

By using this property, we can label variable x_i by taking n new variables $z_1, \ldots, z_n$, and make them equivalent to x_i as follows. Define

$$L(x_i, z_1, \ldots, z_n) = \bigwedge_{j=1}^{n} (x_i \leftrightarrow z_j), \text{ and}$$
$$F_{[i]} = F \wedge L(x_i, z_1, \ldots, z_n).$$

The new variables z_i of $F_{[i]}$ are referred to as *labelling variables*.

Any assignment that satisfies $F_{[i]}$ must assign the same value to x_i and $z_1, \ldots, z_n$. Thus, x_i has more equivalent variables (with respect to $F_{[i]}$) than any other variable $x_k \notin E_{F_{[i]}}(x_i)$. Hence any automorphism φ of $F_{[i]}$ maps $E_{F_{[i]}}(x_i)$ onto itself. We say that φ *stabilizes* $E_{F_{[i]}}(x_i)$. Moreover, define φ' to coincide with φ except for the variables in $E_{F_{[i]}}(x_i)$, where φ' is defined to be the identity. Then the resulting permutation is still an automorphism of $F_{[i]}$, with the additional property that it *pointwise stabilizes* $E_{F_{[i]}}(x_i)$.

LEMMA 4.3. *For all* $\varphi \in \mathsf{Aut}(F_{[i]})$*:*

(1) $\varphi(E_{F_{[i]}}(x_i)) = E_{F_{[i]}}(x_i)$*;*
(2) *define* φ' *to coincide with* φ *on all variables not in* $E_{F_{[i]}}(x_i)$ *and to be the identity on* $E_{F_{[i]}}(x_i)$*. Then* $\varphi' \in \mathsf{Aut}(F_{[i]})$*.*

Now let $G = G(x_1, \ldots, x_n)$ be a second formula. We label variable x_j with the same label as x_i, namely, $L(x_j, z_1, \ldots, z_n)$, and we define $G_{[j]} = G \wedge L(x_j, z_1, \ldots, z_n)$. Then any isomorphism for $(F_{[i]}, G_{[j]})$ must map all the variables equivalent to x_j in $G_{[j]}$ to the variables equivalent to x_i in $F_{[i]}$.

COROLLARY 4.4. *For all* $\varphi \in \mathsf{Iso}(F_{[i]}, G_{[j]})$*:*

(1) $\varphi(E_{G_{[j]}}(x_j)) = E_{F_{[i]}}(x_i)$*;*
(2) *define* φ' *to coincide with* φ *on all variables not in* $E_{G_{[j]}}(x_j)$ *and to map* x_j *to* x_i*, to be the identity on the labelling variables* $z_1, \ldots, z_n$*, and an arbitrary bijection on the remaining variables of* $E_{G_{[j]}}(x_j)$*. Then* $\varphi' \in \mathsf{Iso}(F_{[i]}, G_{[j]})$*.*

It follows that when two formulas $F_{[i]}$ and $G_{[j]}$ as above are isomorphic, we know that there is an isomorphism that maps x_j to x_i and keeps the new variables from the labelling process on themselves. We will therefore omit to explicitly mention the new variables in a label and will simply write $L(x_i, n)$ when we label x_i with n variables that do not yet occur in the considered formula.

A more general task is to force automorphisms to stabilize a *set of variables*. Let $\boldsymbol{x} = (x_1, \ldots, x_n)$, $\boldsymbol{y} = (y_1, \ldots, y_m)$, $F = F(\boldsymbol{x}, \boldsymbol{y})$, and suppose we want to consider only automorphisms of F that map x- to x-variables and y- to y-variables. Clearly, we could simply extend the technique from Lemma 4.3 and label variable y_i with $L(y_i, M)$ for $i = 1, \ldots, m$ with $M = \max\{n, m\} + 1$. Note that the formula we get can increase quadratically in size with respect to F. However, later on we need to apply the construction iteratively such that the resulting formula still has polynomial size. In order to guarantee this, the size of the formula we obtain should increase only linearly in size. Thus we need a new technique here. The following works: for a new

variable s and a number M define formula $S(\boldsymbol{x}, \boldsymbol{y}, s, M)$ as follows:

$$S(\boldsymbol{x}, \boldsymbol{y}, s, M) = \left(\bigvee_{i=1}^{n} x_i \to s \right) \quad \wedge \quad \left(\bigvee_{i=1}^{m} y_i \to \overline{s} \right) \quad \wedge \quad L(s, M).$$

Let $S = S(\boldsymbol{x}, \boldsymbol{y}, s, n+m)$. S has the following property: let $\boldsymbol{a}$ be a satisfying assignment of S. If $\boldsymbol{a}$ assigns a 1 to any of the x-variables, then $\boldsymbol{a}(s) = 1$ which implies that $\boldsymbol{a}(\overline{s}) = 0$, and therefore $\boldsymbol{a}$ must assign 0 to all the y-variables. Symmetrically, if $\boldsymbol{a}$ assigns a 1 to any of the y-variables, then $\boldsymbol{a}(\overline{s}) = 1$ which implies that $\boldsymbol{a}(s) = 0$, and therefore $\boldsymbol{a}$ must assign 0 to all the x-variables.

Now consider $F \wedge S$. We claim that any automorphism of $F \wedge S$ must map x- to x-variables and y- to y-variables, unless they are equivalent.

LEMMA 4.5. *Let $F = F(\boldsymbol{x}, \boldsymbol{y})$ be a formula as above such that the all-zero assignment does not satisfy F. Let $\varphi \in \mathsf{Aut}(F \wedge S)$.*

1. *φ maps x- to x-variables and y- to y-variables except, maybe, for variables x_i and y_j which are set to zero by* every *satisfying assignment of $F \wedge S$.*
2. *Define φ' to coincide with φ on all variables that are set to 1 by at least one satisfying assignment of $F \wedge S$, and to be the identity on the remaining variables. Then $\varphi' \in \mathsf{Aut}(F \wedge S)$, and it maps x- to x-variables and y- to y-variables.*

Proof. Any automorphism φ of $F \wedge S$ must stabilize s (more precisely, $E_{F \wedge S}(s)$) because of its label. Let $\boldsymbol{a}$ be an assignment that satisfies $F \wedge S$. By assumption, $\boldsymbol{a}$ is not the all-zero assignment. So let x_i be a variable such that $\boldsymbol{a}(x_i) = 1$ (the case that $\boldsymbol{a}(y_i) = 1$ for some y_i is analogous). Since $x_i \to s$, we have that $\boldsymbol{a}(s) = 1$. Since $y_j \to \overline{s}$, we have that $\boldsymbol{a}(y_j) = 0$ for $j = 1, \ldots, m$. Therefore, φ cannot map x_i to some y_j in order of $\varphi(\boldsymbol{a})$ to satisfy $F \wedge S$. We conclude that φ must map x_i to some x_j.

It follows that whenever φ maps, say, x_j to y_k, then *every* satisfying assignment of $F \wedge S$ assigns zero to both, x_j and y_k, i.e., all such variables are in $E_F(x_j)$. If we modify φ to be the identity on $E_F(x_j)$, we still have an automorphism for $F \wedge S$. The latter shows part 2 of the lemma. □

We extend the lemma to isomorphisms. Let $G = G(\boldsymbol{x}, \boldsymbol{y})$. Then any isomorphism of $(F \wedge S, G \wedge S)$ must map x- to x-variables and y- to y-variables, unless they are equivalent.

COROLLARY 4.6. *Let F and G be formulas as above such that the all-zero assignment does not satisfy F or G. If $(F, G) \in$ FI, then there is a $\varphi \in \mathsf{Iso}(F \wedge S, G \wedge S)$ that maps all the x- to x-variables and all the y- to y-variables.*

For a last generalization step, consider again $F = F(\boldsymbol{x}, \boldsymbol{y})$, where $n = m$. Now we want to allow automorphisms of F to map x- variables to y-variables in the following way: either x-variables are only mapped to x-variables or x-variables are only mapped to y-variables. We can achieve this as follows. For new variables s and t and a number M define formula $ST(\boldsymbol{x}, \boldsymbol{y}, s, t, M)$:

$$ST(\boldsymbol{x}, \boldsymbol{y}, s, t, M) = \left(\bigvee_{i=1}^{n} x_i \to s \right) \quad \wedge \quad \left(\bigvee_{i=1}^{n} y_i \to \overline{s} \right) \quad \wedge \quad (s \leftrightarrow \overline{t})$$
$$\wedge \quad L(s, M) \quad \wedge \quad L(t, M).$$

Let $ST = ST(\boldsymbol{x}, \boldsymbol{y}, s, t, 2n)$. As above for S, a satisfying assignment of ST can assign a 1 to either any of the x-variables or any of the y-variables, but not to both. The difference to S is that now an automorphism of ST can interchange s and t because they have the same label.

Now consider $F \wedge ST$. We claim that any automorphism of $F \wedge ST$

(i) either maps x- to x-variables and y- to y-variables, or

(ii) interchanges x- and y-variables,

unless they are equivalent.

LEMMA 4.7. *Let F be a satisfiable formula as above such that the all-zero assignment does not satisfy F. For all $\varphi \in \mathsf{Aut}(F \wedge ST)$,*

(i) *either $\varphi(s) = s$, and then we have that φ maps x- to x-variables and y- to y-variables except, maybe, for variables x_i and y_j which are set to zero by* every *satisfying assignment of $F \wedge S$, or*

(ii) *$\varphi(s) = t$, and then we have that φ interchanges x- and y-variables except, maybe, for variables x_i, x_j or y_i, y_j which are set to zero by* every *satisfying assignment of $F \wedge S$.*

Furthermore, we can modify φ to an automorphism of $F \wedge ST$ that keeps x- on x-variables in case (i). *Case* (ii) *is more subtle: if we have the same number of x- and y-variables that have value zero in* every *satisfying assignment of F, then we can modify φ to interchange all x- and y-variables in case* (ii).

Proof. We have to distinguish two cases according to whether an automorphism φ maps s to s or t. In the case that $\varphi(s) = s$, we can directly use the proof of Lemma 4.5. Now let $\varphi(s) = t$, and let $\boldsymbol{a}$ be a satisfying assignment of $F \wedge ST$. Let x_i be a variable such that $\boldsymbol{a}(x_i) = 1$. Because $(x_i \to s)$ is a part of formula ST, we get that $\boldsymbol{a}(s) = 1$. Since $s \leftrightarrow \overline{t}$ is part of the formula ST, we must have $\boldsymbol{a}(t) = 0$.

Now consider formula $(F \wedge ST) \circ \varphi$, which is satisfied by the assignment $a \circ \varphi$. Since φ maps s to t, we have $\boldsymbol{a} \circ \varphi(s) = 0$, and, correspondingly, $\boldsymbol{a} \circ \varphi(t) = 1$. Therefore $a \circ \varphi$ must assign zero to all the x-variables. Hence φ must interchange x- and y-variables, except, maybe, variables that have value zero in all satisfying assignments.

Let x_i be a variable that has value zero in all satisfying assignments. Then all such variables are precisely those that are equivalent to x_i, i.e., that are in $E_F(x_i)$. Note that φ maps variables in $E_F(x_i)$ again to $E_F(x_i)$. Moreover, we can change φ arbitrarily on $E_F(x_i)$ and it still remains an automorphism for $F \wedge ST$. Therefore, if there is the same number of x-variables as y-variables in $E_F(x_i)$, we can modify φ to interchange all x- with the y-variables. □

COROLLARY 4.8. *Let F and G be formulas as above such that the all-zero assignment does not satisfy F or G. If $(F, G) \in \mathrm{FI}$, then there is a $\varphi \in \mathsf{Iso}(F \wedge ST, G \wedge ST)$ that*

(i) *either maps x- to x-variables and y- to y-variables, or*

(ii) *interchanges x- and y-variables.*

We therefore omit to explicitly mention the labelling variables in a label and simply write $L(x_i, n)$ when we label x_i with n variables that do not yet occur in the considered formula.

In the above lemmas we assumed that the all-zero assignment does not satisfy a given formula. In the following lemma we show that this *no* restriction when considering instances for FI.

LEMMA 4.9. *Let (F_0, F_1) be an instance for* FI *with n variables. Define $G_i = F_i \wedge z$, for $i = 0, 1$, for a new variable z. Formulas G_0 and G_1 have the following properties:*

(a) 0^n *is* not *a satisfying assignment of G_0 and G_1, and*

(b) $(F_0, F_1) \in \mathrm{FI} \iff (G_0, G_1) \in \mathrm{FI}$.

Proof. Property (a) is obvious. To see (b), let φ be an isomorphism for (G_0, G_1), i.e., φ permutes the variables of G_1 so that it becomes equivalent to G_0. Note that any satisfying assignment for G_0 or G_1 must set z to 1. Therefore φ must map z

to itself or to a variable equivalent to z. In the latter case, we can modify φ to be the identity on $E_{G_1}(z)$ and we still have an isomorphism for (G_0, G_1). Now, φ is an isomorphism for (F_0, F_1) as well (just ignore variable z). □

4.2. The and- and or-functions for FI. In the previous section we have established the technical tools for the construction of the and- and or-functions for FI.

THEOREM 4.10. FI *has and- and or-functions.*

Proof. Let (F_0, F_1) and (G_0, G_1) be two instances for FI. The variables of F_0 and F_1 are $x_1, \ldots, x_n$, and the variables of G_0 and G_1 are $y_1, \ldots, y_m$. By Lemma 4.9 we can assume that the all-zero assignment does not satisfy any of these formulas.

And-function. In order to construct the and-function, we simply combine the formulas by or-ing together F_0 and G_0 on one side, and F_1 and G_1 on the other side. However, we have to make sure that we don't get automorphisms that map x-variables to y-variables. For this we use formula $S = S(\boldsymbol{x}, \boldsymbol{y}, s, M)$ from above with $M = n+m$. Define

$$\mathsf{and}((F_0, F_1), (G_0, G_1)) = (C_0, C_1),$$

where formulas C_0 and C_1 are defined as follows:

$$\begin{aligned} C_0 &= (F_0 \vee G_0) \ \wedge \ S, \\ C_1 &= (F_1 \vee G_1) \ \wedge \ S. \end{aligned}$$

If $(F_0, F_1) \in$ FI and $(G_0, G_1) \in$ FI, then clearly $(C_0, C_1) \in$ FI. For the reverse direction assume that $(C_0, C_1) \in$ FI. By Corollary 4.6 there is an isomorphism φ that maps x- to x-variables and y- to y-variables, i.e., φ can be written as $\varphi = \varphi_x \cup \varphi_y \cup \varphi_S$, where φ_x is a permutation on $\{x_1, \ldots, x_n\}$, φ_y on $\{y_1, \ldots, y_n\}$, and φ_S on the extra variables from formula S.

We argue that φ_x is an isomorphism for (F_0, F_1) (an analogous argument shows that φ_y is an isomorphism for (G_0, G_1)): consider the following partial assignments.

- $\boldsymbol{a}_y$ assigns 0 to all the y-variables and
- $\boldsymbol{a}_S$ assigns 1 to variable s and the labelling variables.

Then we have $G_0(\boldsymbol{a}_y) = 0$, and $G_1(\varphi_y(\boldsymbol{a}_y)) = G_1(\boldsymbol{a}_y) = 0$. Furthermore, the second item implies that, for any assignment $\boldsymbol{a}_x$ of the x-variables, formula S evaluates to one on $\boldsymbol{a} = (\boldsymbol{a}_x, \boldsymbol{a}_y, \boldsymbol{a}_S)$ and on $\varphi(\boldsymbol{a})$. Now, since by assumption $C_0(\boldsymbol{a}) = C_1(\varphi(\boldsymbol{a}))$, we conclude that $F_0(\boldsymbol{a}_x) = F_1(\varphi_x(\boldsymbol{a}_x))$. Therefore, φ_x is an isomorphism for (F_0, F_1).

Or-function. In order to construct the or-function, we need a copy of the variables $\boldsymbol{x} = (x_1, \ldots, x_n)$ and $\boldsymbol{y} = (y_1, \ldots, y_m)$ used in the formulas F_0, F_1 and G_0, G_1, respectively. Let $\boldsymbol{u} = (u_1, \ldots, u_n)$ and $\boldsymbol{v} = (v_1, \ldots, v_m)$ be new variables. Define

$$\mathsf{or}((F_0, F_1), (G_0, G_1)) = (D_0, D_1),$$

where formulas D_0 and D_1 are defined as follows:

$$\begin{aligned} D_0 &= ((F_0(\boldsymbol{x}) \vee G_0(\boldsymbol{y})) \ \vee \ (F_1(\boldsymbol{u}) \vee G_1(\boldsymbol{v}))) \ \wedge \ R, \\ D_1 &= ((F_1(\boldsymbol{x}) \vee G_0(\boldsymbol{y})) \ \vee \ (F_0(\boldsymbol{u}) \vee G_1(\boldsymbol{v}))) \ \wedge \ R, \end{aligned}$$

where

$$R = S((\boldsymbol{x}, \boldsymbol{u}), (\boldsymbol{y}, \boldsymbol{v}), s_0, M_0) \ \wedge \ ST((\boldsymbol{x}, \boldsymbol{y}), (\boldsymbol{u}, \boldsymbol{v}), s, t, M).$$

Here we set $M_0 = n + m$ and $M = 2M_0$. (The additional brackets for the variables in formulas S and ST indicate the two groups of variables that occur in the definition of these formulas.)

The rough idea of this definition is that if there is an isomorphism for either (F_0, F_1) or (G_0, G_1), then we can construct an isomorphism for (D_0, D_1) from it: just map the nonisomorphic formulas to themselves. Formula R will ensure that we don't get more isomorphisms than the ones just described. We give more details below.

Suppose first that $(F_0, F_1) \in \mathrm{FI}$ and let φ_x be an isomorphism. Let φ_u be φ_x^{-1} but on the u-variables. That is, define

$$\varphi_u(u_i) \quad = \quad u_j, \quad \text{if } \varphi_x^{-1}(x_i) = x_j.$$

Define φ as the union of φ_x and φ_u and the identity on all the other variables of D_1. Then it is straightforward to check that φ is an isomorphism of (D_0, D_1), which is therefore in FI.

Now assume that $(G_0, G_1) \in \mathrm{FI}$ via isomorphism φ_y. Then we get an isomorphism φ for (D_0, D_1) as follows. Define

$$\begin{aligned}
\varphi(x_i) &= u_i, \\
\varphi(u_i) &= x_i, \\
\varphi(v_i) &= y_j, \quad \text{if } \varphi_y(y_i) = y_j, \\
\varphi(y_i) &= v_j, \quad \text{if } \varphi_y^{-1}(y_i) = y_j, \\
\varphi(s) &= t, \\
\varphi(t) &= s, \\
\varphi(s_0) &= s_0.
\end{aligned}$$

The remaining variables that come from the labelling process are mapped according to the variables they are equivalent to.

In summary, the isomorphisms we constructed have the following properties:

(i) either they map s and t to itself, respectively, and map x- to x-variables, u- to u-variables, y- to y-variables, and v- to v-variables,

(ii) or they interchange s with t and interchange x- with u-variables and y- with v-variables.

Conversely, if there is an isomorphism for (D_0, D_1) that fulfills property (i) or (ii), then it is easy to see that we get an isomorphism for either (F_0, F_1) or (G_0, G_1) from it, respectively. It remains to show that every isomorphism for (D_0, D_1) must satisfy one of these two properties. The only exception from this might be equivalent variables.

Assume that (D_0, D_1) are isomorphic. We consider formula R. By Corollary 4.6, its first part, $S((\boldsymbol{x}, \boldsymbol{u}), (\boldsymbol{y}, \boldsymbol{v}), s_0, M_0)$, implies that there is an isomorphism φ of (D_0, D_1) that can be written as a union of permutations $\varphi_{x,u}$ on x- and u-variables, $\varphi_{y,v}$ on y- and v-variables, $\varphi_{s,t}$ on s and t, and φ_L for the remaining variables from the labelling. Combined with its second part, $ST((\boldsymbol{x}, \boldsymbol{y}), (\boldsymbol{u}, \boldsymbol{v}), s, t, M)$, we get by Corollary 4.8 that $\varphi_{x,u}$, depending on $\varphi_{s,t}$, either maps all x-variables to x-variables or interchanges x- and u-variables. The same holds analogously for $\varphi_{y,v}$. Thus we get an isomorphism that fulfills property (i) or (ii) above. □

We remark that we can extend the functions and and or to more than two arguments: combine them in a binary-tree-like fashion with the above functions for two arguments. The size of the output of our functions and and or is linear in the size of the input formulas. Therefore we get a polynomial-size output when we combine several instances as described above.

COROLLARY 4.11. *If a set L is disjunctively or conjunctively truth-table reducible to* FI*, then $L \leq_m^p$* FI.

We give two applications of Corollary 4.11. The formula automorphism problem (FA) is disjunctively reducible to FI, because a formula $F = F(x_1, \ldots, x_n)$ is in FA if and only if for some pair $i, j \in \{1, \ldots, n\}$, $i \neq j$, we have that $(F_{[i]}, F_{[j]})$ is in FI. It follows that FA is many-one reducible to FI.

COROLLARY 4.12. FA $\leq_m^p$ FI.

What else can we reduce to FI? Clearly, FI is **coNP**-hard: by true_n we denote a fixed formula over n variables that is a tautology (e.g., $\bigwedge_{i=1}^{n}(x_i \vee \bar{x}_i)$). Then, for a given formula F with n variables, F is a tautology as well if and only if $(F, \mathsf{true}_n) \in$ FI.

Unique satisfiability (USAT) [BG82] is the set of all boolean formulas that have exactly one satisfying assignment. The function

$$F(x_1, \ldots, x_n) \mapsto (F \wedge z) \ \vee \ \left(\bigwedge_{i=1}^{n} x_i \wedge \overline{z} \right)$$

reduces unsatisfiable formulas to uniquely satisfiable ones. Therefore USAT is **coNP**-hard. Since USAT can be written as the difference of two **NP**-sets, USAT is in **DP**, the second level of the boolean hierarchy. On the other hand, USAT is not known to be **NP**-hard. [1]

The function

$$F(x_1, \ldots, x_n) \mapsto \left(F, \bigwedge_{i=1}^{n} x_i \right)$$

reduces USAT to FC. Since FI $\equiv_m^p$ FC [BRS98], USAT can be reduced to FI.

A problem seemingly harder than USAT is the unique optimal clique problem (UOCLIQUE), that is, whether the largest clique of a given graph is unique. The standard reduction from SAT to CLIQUE also reduces USAT to UOCLIQUE. An upper bound for the complexity of UOCLIQUE is $\mathbf{P}^{\mathbf{NP}[\log]}$: with logarithmically many queries to an **NP**-oracle one can compute the size of the largest clique of a given graph. Then, with one more query, one can find out whether there is more than one clique of that size. Papadimitriou and Zachos [PZ83] asked whether UOCLIQUE is complete for $\mathbf{P}^{\mathbf{NP}[\log]}$. This is still an open problem. Buhrman and Thierauf [BT96] provide strong evidence that UOCLIQUE is *not* complete for $\mathbf{P}^{\mathbf{NP}[\log]}$.

UOCLIQUE can be disjunctively reduced to USAT [BT96]. To see this, let UCLIQUE be the unique CLIQUE version. That is, given a graph G and a integer k, decide whether G has a unique clique of size k. Now, observe that $G \in$ UOCLIQUE $\iff \exists k : (G, k) \in$ UCLIQUE. Recall that the generic reduction of an arbitrary **NP**-problem to SAT given by Cook is parsimonious. So in particular, a graph with a unique clique of a certain size reduces to a formula with precisely one satisfying assignment. Therefore we get a disjunctive reduction of UOCLIQUE to USAT. Combined with the reduction from USAT to FI, we have that UOCLIQUE can be disjunctively reduced to FI. By Corollary 4.11, this can be turned into a many-one reduction.

COROLLARY 4.13. UOCLIQUE $\leq_m^p$ FI.

As is the case for UOCLIQUE, it is not known whether FI is **NP**-hard. This is a challenging open question.

[1] However, USAT is **NP**-hard under *randomized* reductions [VV86].

5. The counting version of FI. Mathon [Mat79] showed that the counting version of GI can be (truth-table) reduced to the decision version. Thus GI behaves differently than the known **NP**-complete problems. This was historically the first hint that GI might *not* be **NP**-complete.

We will show an analogous result for FI. The proof follows essentially the same outline as Mathon's proof for GI, however, there is again a technical difficulty to get around. First of all, it is enough to compute the number of *automorphisms* of a graph G: if H is a graph isomorphic to G, the number of isomorphisms between G and H is the same as the number of automorphisms of G (or H). We sketch the algorithm to compute the number of automorphisms of G. See [Mat79] for more details.

> In the beginning, label all nodes of G (with pairwise different labels), so that the identity is the only automorphism of the resulting graph. Then successively take away the labels. If i is the node where the label was cancelled last, compute the orbit of i by asking queries of GI. When all labels are taken away, the number of automorphisms of G is the product of the orbit sizes constructed during this procedure.

In the above algorithm one needs to construct a graph $G_{[I]}$, where $I \subseteq \{1, \ldots, n\}$, such that any automorphism of $G_{[I]}$ *pointwise* stabilizes the nodes in I. Correspondingly, given a formula F in n variables, we need to construct a formula $F_{[I]}$ whose set of automorphisms corresponds to the *pointwise stabilizer of* I in $\mathsf{Aut}(F)$. More precisely, $F_{[I]}$ must retain exactly those automorphisms of F that map variables in $E_F(x_i)$ to themselves for all $i \in I$.

Our formula S from section 4 is of no help for this: though it can stabilize a set of variables, this will not be pointwise. Also, we cannot directly use the labels L defined in section 4 as they take m new variables to label a variable in a formula with m variables. Thus, starting with n variables, we would get $n(2^{|I|} - 1)$ new variables to carry out the marking which is exponential in n when $|I| = \Theta(n)$. This is clearly too much in general.

Here, we give a method to compute $F_{[I]}$ that works in $\mathbf{FP}^{\mathbf{NP}}$. Recall that FI is **coNP**-hard. Therefore we can in particular use this method when we have FI as an oracle.

LEMMA 5.1. *$F_{[I]}$ is computable in $\mathbf{FP}^{\mathbf{NP}}$.*

Proof. Recall from section 4 that for any automorphism φ of F, we have $|E_F(x_i)| = |E_F(\varphi(x_i))|$ for any variable x_i. The trick in Lemma 4.3 was to make $|E_F(x_i)|$ unique by appending several variables that are equivalent to x_i. Now, with an **NP**-oracle, we can actually compute the sets $E_F(x_i)$: just ask the **NP**-oracle whether F is equivalent with $F \wedge (x_i \leftrightarrow x_j)$ for all j. Then, if we want to label x_i, we take the smallest label such that x_i gets a unique number of equivalent variables. This will keep the number of new variables needed small.

We construct formula $F_{[I]}$ by successively labelling the variables in I. Let $F_0 = F$. Suppose that we have already labelled the first k variables of I and obtained the formula F_k for some $k \geq 0$. Say that x_i is the next variable to label for some $i \in I$. That is, x_i is not equivalent to any of the variables already labelled. Now, let t be the smallest number such that, with respect to F_k, we have

$$|E_{F_k}(x_i)| + t \neq |E_{F_k}(x_j)| \quad \text{for any} \quad x_j \notin E_{F_k}(x_i),$$

and define $F_{k+1} = F_k \wedge L(x_i, t)$. This ensures that any automorphism of the new formula F_{k+1} stabilizes the set $E_{F_k}(x_i)$. Thus F_{k+1} has the desired property.

The above process is carried out at most $|I| \leq n$ times. Observe also that the number t is bounded by n in each iteration. Therefore, we introduce in total at most

n^2 new variables. It follows that $F_{[I]}$ has polynomial length and can be constructed in polynomial time with the help of an **NP**-oracle. □

Now we can compute the number of isomorphisms between two boolean formulas in polynomial time relative to FI: simply copy the proof described above, which was used by Mathon [Mat79] to prove the analogous result for graph isomorphism, but with the labelling technique from Lemma 5.1.

THEOREM 5.2. $\#\mathrm{FI} \in \mathbf{FP}^{\mathrm{FI}}$.

We remark that the oracle queries in the algorithm to compute formula $F_{[I]}$ do not depend on each other; they can be made in parallel.

Consequently, #FI can be computed efficiently with parallel queries to FI.

Mathon's algorithm for computing the number of isomorphisms of two graphs is an inductive process, where at each intermediate stage one knows the number of isomorphisms of the labelled graphs that are considered. This observation led to the result that $\mathrm{GI} \in \mathbf{LWPP}$ [KST93] (see [FFK94] for definitions of **PP** and **LWPP**). Since **LWPP** is low for **PP**, that is, $\mathbf{PP}^{\mathbf{LWPP}} = \mathbf{PP}$ [FFK94], it follows that GI is low for **PP**.

Using Lemma 5.1, an analogous argument shows that $\mathrm{FI} \in \mathbf{LWPP}^{\mathbf{NP}}$. Since **LWPP** is low for **PP** *relative to any oracle*, i.e., $\mathbf{PP}^{\mathbf{LWPP}^{\mathbf{NP}}} = \mathbf{PP}^{\mathbf{NP}}$ [FFK94], we get the following result for FI.

THEOREM 5.3. $\mathbf{PP}^{\mathrm{FI}} = \mathbf{PP}^{\mathbf{NP}}$.

6. FI is self-reducible. A set A is self-reducible if, very informally, the decision problem whether a given instance x is in A can be reduced to *smaller* instances for A (under some order). Self-reducibility is a very useful property of a set. For example, if an **NP**-set is self-reducible, then the (seemingly more complex) *construction problem*, i.e., constructing a witness, can be reduced to the decision problem.

In this section we show that FI is self-reducible. We start by giving formal definitions of self-reducibility and the underlying partial order.

DEFINITION 6.1. *A partial order $\prec$ on Σ^* is* polynomially related *if $\prec$ is decidable in polynomial time and there is a polynomial p such that*

(i) *for any $x, y \in \Sigma^*$, we have $x \prec y \implies |x| \le p(|y|)$, and*

(ii) *any chain is polynomially length bounded: if $x_1 \prec x_2 \prec \cdots \prec x_k$, then $k \le p(|x_k|)$.*

DEFINITION 6.2. *A set A is* self-reducible *if there is a polynomially related partial order $\prec$ and a deterministic polynomial-time Turing machine M such that*

(i) *M^A accepts A, and*

(ii) *on input x and any oracle B, M^B queries only strings y such that $y \prec x$.*

The idea to show that FI is self-reducible is pretty simple: for two formulas F and G, we have that

$$(F, G) \in \mathrm{FI} \iff \exists i, j : \ (F_{[i]}, G_{[j]}) \in \mathrm{FI}.$$

Thus the self-reduction constructs the formulas $F_{[i]}$ and $G_{[j]}$ for all values of i and j and queries the oracle. However, we need to define a polynomially related partial order according to these queries. There are some subtle points that one has to take care of.

- For labelling the variables we can use the scheme from Lemma 5.1, which yields polynomially-sized formulas, even after several labellings. To ensure *polynomially-sized chains*, the machine must check if some variables in F and G are already labelled and, in this case, not relabel them. This is possible

since a label is easily detectable: it is of the form $x \leftrightarrow y$. We use the variable with the smallest index as a representative for a label and call it a *basic variable* of F. Note that the variables that don't have a label are also basic variables. By $\#\mathsf{basic}(F)$ we denote the *number of basic variables of* F. The other variables we refer to as *labelling variables*. The *label size* of a basic variable is the number of labelling variables that label it.

- When all the basic variables of F and G have a unique label size, they define a permutation on the variables. Then we have to check whether the permuted formula F is equivalent to G. This we accomplish via the standard self-reduction for the equivalence problem: set the first variable of both formulas to 0 and 1, respectively, and then verify that both pairs of the resulting formulas are equivalent. (Note that all tests can be done with FI as an oracle.)

  Hence our partial order has to respect the order of this latter self-reduction as well.

THEOREM 6.3. FI *is self-reducible.*

Proof. We start by defining the underlying polynomially related partial order $\prec$. By true_n we denote a fixed formula over n variables that is a tautology (e.g., $\bigwedge_{i=1}^{n}(x_i \vee \bar{x}_i)$). In the following, we drop the subscript n and simply write true to denote such a formula when the number of variables is clear from the context.

For formulas F, G, F', G', we define $(F, G) \prec (F', G')$ if the length of F is bounded by a fixed polynomial in the length of F'; the same holds for G and G', and any one of the following three conditions hold.

(i) $\#\mathsf{basic}(F) < \#\mathsf{basic}(F')$, and either $G = \mathsf{true}$ or $\#\mathsf{basic}(G) \leq \#\mathsf{basic}(G')$.
(ii) $\#\mathsf{basic}(G) < \#\mathsf{basic}(G')$, and either $F = \mathsf{true}$ or $\#\mathsf{basic}(F) \leq \#\mathsf{basic}(F')$.
(iii) $\#\mathsf{basic}(F) = \#\mathsf{basic}(F')$, $\#\mathsf{basic}(G) = \#\mathsf{basic}(G')$, and more basic variables in F and G have unique label sizes than in F' and G', respectively.

This finishes the description of the partial order. Note that it is polynomially related in the sense of definition 6.1.

We now describe the self-reducing machine, M, in detail. In particular observe that the queries of M will respect the partial order defined above. At several places, M has to test whether a boolean formula T is a tautology. This is done by checking that $(T[0], \mathsf{true})$ and $(T[1], \mathsf{true})$ belong to FI, where by $T[b]$, $b \in \{0, 1\}$, we denote the formula obtained from T by setting its first basic variable—and the labelled variables associated with it—to the value b.

Let F and G be the input formulas over variables $x_1, \ldots, x_n$. M first checks if either of F and G equals true.

- If both of them do, then they are isomorphic and so M accepts.
- If exactly one of them, say G, is equal to true, then F and G are isomorphic if F is a tautology too. This can be checked using the scheme described above. M accepts if and only if F is a tautology.
- If neither F nor G equals true, then M does the following. It computes the basic variables of F and G, and finds out if any two basic variables of F are equivalent by checking if the formula $T_{F,i,j}$ is a tautology, where

$$T_{F,i,j} = (F \wedge (x_i \leftrightarrow x_j)) \leftrightarrow F$$

  for every pair of basic variables x_i and x_j of F. If $T_{F,i,j}$ is a tautology, then x_i and x_j are equivalent in F; otherwise, they are not.
  - If there are x_i and x_j in F that are equivalent, then M accepts if and only if $(F', G) \in$ FI, where F' is obtained from F by replacing all occurrences

of x_j in F by x_i and and-ing the formula $x_i \leftrightarrow x_j$ to the resulting formula. By this transformation, F and F' are equivalent and F' has one less basic variable than F. If F has no equivalent basic variables, then this is repeated for G instead of F.

– If no two basic variables of F or G are equivalent, M computes for each basic variable its label size. It then checks whether these numbers of F and G match, i.e., when the list of label sizes for F and G are sorted, they must coincide. If not, then M rejects as there cannot be any isomorphism between F and G.
So assume that these numbers match.
  * If all basic variables of F are *uniquely* labelled, then M constructs a permutation φ of variables of F such that $\varphi(x_i) = x_j$, where the label size of x_i in F and x_j in G are the same. φ also maps labelled variables associated with x_i to those associated with x_j. Now, M permutes the variables of F using φ to obtain the formula $F \circ \varphi$, then checks whether $F \circ \varphi \leftrightarrow G$ is a tautology, and accepts in this case.
  * Finally, if there are some basic variables of F with identical label sizes, for every such variable x_i of F, and for every basic variable x_j of G that has the same label size, M queries the oracle whether $(F_{[i]}, G_{[j]}) \in \mathrm{FI}$. It accepts if and only if at least one of these pairs belong to FI.

It is straightforward to see that M respects the partial order defined above, works in polynomial time, and that M^{FI} accepts FI. □

7. Open problems and related work. The hardest **NP**-problem of which we know that reduces to FI is GI. We ask:

- Is FI **NP**-hard?

Let FN be the problem to decide whether two boolean formulas can be made equivalent via negation mappings. That is, each variable is mapped to either itself or its complement. FN is **coNP**-hard and can be many-one reduced to FI [BRS98] but is not known to be many-one equivalent to FI. Because of the restricted nature of the negation transformation (compared to congruence), we expect FN to be an easier problem than FI.

- Can one show a stronger upper bound for FN than we have shown for FI? For example, is FN in $\Sigma_2\mathbf{P} \cap \Pi_2\mathbf{P}$?

Because of the similarity of FI and GI, it might be tempting to think that $\mathrm{FI} \in \mathbf{NP}^{\mathrm{GI}}$. However, recall that FI is **coNP**-hard so that this would imply that $\mathbf{coNP} \subseteq \mathbf{NP}^{\mathrm{GI}}$ which, in turn, would imply that $\Sigma_2\mathbf{P} = \mathbf{NP} \cdot \mathbf{coNP} \subseteq \mathbf{NP} \cdot \mathbf{NP}^{\mathrm{GI}} = \mathbf{NP}^{\mathrm{GI}}$. Hence the polynomial hierarchy would collapse [Sch88]. But we don't have such an argument for the following:

- Is $\mathrm{FI} \in \mathbf{coNP}^{\mathrm{GI}}$?

As we mentioned already in the introduction, the equivalence of *one-time-only branching programs* can be decided efficiently by randomized (Las Vegas type) algorithms: the equivalence problem is in the class **coRP**. Hence, the corresponding isomorphism problem is in $\mathbf{NP} \cdot \mathbf{coRP}$. An obvious question now is whether it is **NP**-hard. Thierauf [Thi98] showed that the isomorphism problem for one-time-only branching programs is *not* **NP**-hard, unless the polynomial hierarchy collapses to the second level.

THE COMPUTATIONAL COMPLEXITY TO EVALUATE REPRESENTATIONS OF GENERAL LINEAR GROUPS*

PETER BÜRGISSER†

Abstract. We describe a fast algorithm to evaluate irreducible matrix representations of complex general linear groups GL_m with respect to a symmetry adapted basis (Gelfand–Tsetlin basis). This is complemented by a lower bound, which shows that our algorithm is optimal up to a factor m^2 with regard to nonscalar complexity. Our algorithm can be used for the fast evaluation of special functions: for instance, we obtain an $O(\ell \log \ell)$ algorithm to evaluate all associated Legendre functions of degree ℓ. As a further application we obtain an algorithm to evaluate immanants, which is faster than previous algorithms due to Hartmann and Barvinok.

1. Introduction.

The theory of representations of Lie groups has countless applications in mathematics and physics. In particular, it is an indispensable tool of quantum mechanics. Let $D\colon G \to \mathrm{GL}_d$ be an irreducible (finite dimensional) continuous representation of the Lie group G. How fast can we compute the representation matrix $D(g)$ for a given $g \in G$? This question contains the problem of the efficient evaluation of special functions and orthogonal polynomials, which can be interpreted as matrix entries of some suitable representation D (see Vilenkin and Klimyk [22]).

In this paper, we investigate the above question for the general linear groups $G = \mathrm{GL}_m$ of complex m by m matrices. This includes the case of the unitary groups $\mathrm{U}(m)$, which are of particular importance for physics, since all the continuous irreducible representations of $\mathrm{U}(m)$ can be obtained from the rational irreducible ones of GL_m by restriction.

It is well known that the irreducible polynomial representations of the general linear group GL_m can be labeled by decreasing sequences $\lambda \in \mathbb{N}^m$ (cf. [3]). With respect to some chosen basis, such a representation is a group morphism

$$D_\lambda : \mathrm{GL}_m \longrightarrow \mathrm{GL}_{d_\lambda},\ A \mapsto D_\lambda(A),$$

and the entries of D_λ are homogeneous polynomials of degree $|\lambda| := \sum_i \lambda_i$ in the entries of A. The matrix $D_\lambda(A)$ is usually called an *invariant matrix* when the entries of A are interpreted as indeterminates. Littlewood [14, 15] found an explicit construction of invariant matrices. He obtained formulas for the polynomial entries of $D_\lambda(A)$ in terms of representations of the symmetric group. Grabmeier and Kerber [10] gave a modern derivation of such formulas, and based on this, they designed an algorithm for computing invariant matrices. This algorithm in fact computes a sparse representation of the polynomial entries of the invariant matrix.

†Department of Mathematics and Computer Science, University of Paderborn, Warburger Str. 100, D-33098 Paderborn, Germany (pbuerg@math.uni-paderborn.de).

However, the example of the m by m determinant already shows that this approach cannot be efficient for evaluating $D_\lambda(A)$ at specific entries $A \in \mathrm{GL}_m$ for larger m: the determinant polynomial has $m!$ terms, but it can be computed with only $O(m^3)$ arithmetic operations using Gaussian elimination.

As unitary representations of $\mathrm{U}(m)$ are important in quantum mechanics, it is not astonishing that various explicit constructions of representations have been developed by physicists. (See for instance the books by Biedenharn and Louck [2], where the entries of invariant matrices are called boson polynomials.)

Gelfand and Tsetlin [9] derived explicit expressions for $D_\lambda(A)$ for generators A of GL_m with respect to bases adapted to the chain of subgroups

$$\mathrm{GL}_m > \mathrm{GL}_{m-1} \times \mathbb{C}^\times > \mathrm{GL}_{m-2} \times (\mathbb{C}^\times)^2 > \cdots > (\mathbb{C}^\times)^m.$$

Such symmetry adapted bases are also called *Gelfand–Tsetlin bases*. A very detailed account of this can be found in the book by Vilenkin and Klimyk [22, Chapter 18]; in section 2 we just present the most basic facts.

The main result of this paper (Theorem 4.1) is an efficient algorithm to evaluate the representation D_λ with respect to a Gelfand–Tsetlin basis. It has a nonscalar cost roughly proportional to $m^2 d_\lambda$. Besides making optimal use of the symmetry (Schur's lemma), our algorithm uses several auxiliary algorithms: an efficient transformation of matrices with the block structure of a Jordan block to a direct sum of Jordan blocks, as well as the fast multiplication of Toeplitz matrices with vectors, based on the fast Fourier transform. These auxiliary algorithms are described in section 3. We remark that our algorithm was inspired by Clausen's fast Fourier transform [7] for the symmetric group, as well as Maslen's extension to compact Lie groups (see the survey [16]). Their techniques also rely heavily on symmetry adapted bases.

In section 5 we complement our algorithmic result by proving that d_λ nonscalar operations are indeed necessary for the computation of $D_\lambda(A)v$. This is easily obtained by combining Burnside's theorem with the dimension bound of algebraic complexity. It shows that our algorithm is optimal up to a factor of m^2 with respect to nonscalar complexity.

Our algorithm provides already in the special case of GL_2 new results. We obtain a fast rational $O(\ell \log \ell)$ algorithm for computing all the associated Legendre functions $P_\ell^\mu(\cos\theta)$, $|\mu| \le \ell$, of degree ℓ from $\cos\theta$ and $\sin\theta$. (See section 6.)

For computing individual entries of the invariant matrix, the cost of our algorithm may appear to be prohibitively high, mainly because the dimension d_λ can be very large. For instance, for $\lambda = (m, 0, \ldots, 0) \in \mathbb{N}^m$ we have $d_\lambda = \binom{2m-1}{m}$, which is exponential in m. Is this inherent to the problem, or are there faster algorithms running with a number of steps polynomially bounded in m?

For approaching this question, we do not focus on individual entries of the invariant matrix, but we study related functions having some invariant meaning. Let λ be a partition of m (or a Young diagram with m boxes). We consider the function sending $A \in \mathrm{GL}_m$ to the sum of the diagonal entries of the invariant matrix $D_\lambda(A)$ corresponding to the weight $(1, \ldots, 1)$. This turns out to be the so-called *immanant*,

$$\mathrm{im}_\lambda(A) = \sum_{\pi \in S_m} \chi_\lambda(\pi) \prod_{i=1}^{m} A_{i,\pi(i)},$$

of the matrix A corresponding to λ, which was introduced by Littlewood (cf. [15]). Here, χ_λ denotes the irreducible character of the symmetric group S_m belonging to λ

(cf. [3] or [12]). Note that this notion contains the permanent and determinant as special cases ($\chi_\lambda = 1$ or $\chi_\lambda = \mathrm{sgn}$).

From our algorithm for evaluating representations of GL_m we derive in section 7 an upper bound on the computational complexity of immanants which improves previous bounds due to Hartmann [11] and Barvinok [1] (see Theorem 7.2).

In a subsequent paper [4], we will complement this upper bound by intractability results. Strictly speaking, we will prove the completeness of certain families of immanants corresponding to hook or rectangular diagrams within the framework of Valiant's algebraic P-NP theory [20, 21, 5]. This means that these families of immanants cannot be evaluated by a polynomial number of arithmetic operations, unless this is possible for the family of permanents.

2. Preliminaries on representations of GL_m. We collect first some facts about the representations of the complex general linear group GL_m (see [3, 8]). Consider GL_{m-1} as the subgroup of GL_m fixing the last canonical basis vector e_m. A polynomial representation $D_\lambda \colon \mathrm{GL}_m \to \mathrm{GL}(V)$ with highest weight $\lambda \in \mathbb{N}^m$ restricted to GL_{m-1} splits according to the branching rule [3, section 5.6] into a direct sum of representations with highest weights $\mu \in \mathbb{N}^{m-1}$, which satisfy the betweenness conditions $\lambda_j \geq \mu_j \geq \lambda_{j+1}$ for $1 \leq j < m$. It is important that each representation corresponding to such μ occurs with *multiplicity* 1. Thus the decomposition of V into corresponding submodules V_μ is unique. We note that this is also the decomposition of V restricted to the subgroup $\mathrm{GL}_{m-1} \times \mathbb{C}^\times$, as the diagonal matrix $\mathrm{diag}(1, \ldots, 1, t)$ operates on V_μ by multiplication with $t^{|\lambda|-|\mu|}$. We recall that a vector $v \in V$ is said to be of weight $w \in \mathbb{N}^m$ iff $D_\lambda(\mathrm{diag}(t_1, \ldots, t_m))v = t_1^{w_1} \cdots t_m^{w_m} v$.

If we restrict the representation D_λ successively according to the chain of subgroups

$$\mathrm{GL}_m > \mathrm{GL}_{m-1} \times \mathbb{C}^\times > \mathrm{GL}_{m-2} \times (\mathbb{C}^\times)^2 > \cdots > (\mathbb{C}^\times)^m, \tag{2.1}$$

we finally end up with a decomposition of V into one-dimensional subspaces of weight vectors. This decomposition is unique, and bases of V adapted to this decomposition are called *Gelfand–Tsetlin bases*. Thus Gelfand–Tsetlin bases are uniquely determined up to a permutation of the basis elements and scaling. We remark that if V is a (finite dimensional) Hilbert space and D_λ restricted to $\mathrm{U}(m)$ is unitary, then a Gelfand–Tsetlin basis can be chosen to orthonormal.

The splitting behavior can be conveniently visualized by a layered graph $G(\lambda)$, whose nodes on level n ($1 \leq n \leq m$) are the occurring irreducible representations of V restricted to $\mathrm{GL}_n \times (\mathbb{C}^\times)^{m-n}$. These nodes can thus be uniquely described by pairs (ν, w), where $\nu \in \mathbb{N}^n$ is a partition and $w \in \mathbb{N}^{m-n}$ satisfies $|\nu| + |w| = |\lambda|$. A node on level n is connected in the graph $G(\lambda)$ with a node on level $n-1$ if the latter appears in the decomposition of the former upon restriction to $\mathrm{GL}_{n-1} \times (\mathbb{C}^\times)^{m-n+1}$ (see Figure 2.1).

The number of paths in $G(\lambda)$ between a node $x = (\nu, w)$ at level n and a node $x' = (\nu', w')$ at level $n' < n$ is just the multiplicity with which x' occurs in x when restricted to $\mathrm{GL}_{n'} \times (\mathbb{C}^\times)^{m-n'}$. We denote this multiplicity by $\mathrm{mult}(x, x')$. We call the maximum of $\mathrm{mult}(x, x')$ taken over all pairs of nodes *two levels apart* the *multiplicity* $\mathrm{mult}(\lambda)$ of the highest weight λ. (In Figure 2.1 we have $\mathrm{mult}(\lambda) = 2$.)

The vectors of a Gelfand–Tsetlin basis can be labeled by paths in $G(\lambda)$ going from the top node λ to a node at level 1. Such paths can be encoded as semistandard tableaus: for instance, in Figure 2.1 we have two vectors of weight $(1, 1, 1)$ corresponding to the tableaus $\begin{array}{|c|c|}\hline 1 & 2 \\ \hline 3 \\ \cline{1-1}\end{array}$ and $\begin{array}{|c|c|}\hline 1 & 3 \\ \hline 2 \\ \cline{1-1}\end{array}$. The quantity $\mathrm{mult}(x, x')$ can thus be alternatively

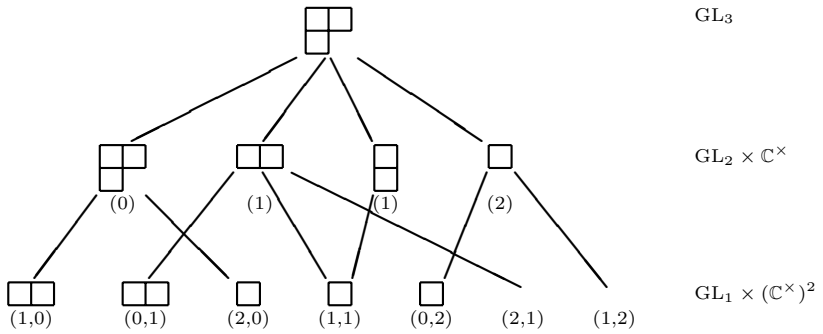

FIG. 2.1. *The graph $G(\lambda)$ for $\lambda = (2,1,0)$, $m = 3$.*

described as the number of semistandard tableaus of the skew diagram $\nu \setminus \nu'$ in which j occurs exactly w'_j times ($n' < j \le n$). These considerations also imply that the dimension d_λ equals the number of semistandard tableaus of the diagram λ. Moreover, the number of vectors of weight $(1,\dots,1)$ in a Gelfand–Tsetlin basis corresponding to λ equals the number s_λ of standard tableaus on the diagram of λ.

Remark 2.1. We have $d_\lambda \ge m$ if $\lambda = (\lambda_1,\dots,\lambda_m) \ne (m,\dots,m)$. For hook partitions $\lambda = (m-i,1,\dots,1)$ we have $\mathrm{mult}(\lambda) \le 2$.

By suitable scaling and ordering of the vectors of a Gelfand–Tsetlin basis, we can obtain a basis of V, which is adapted to the chain (2.1) of subgroups in a strong sense: the corresponding matrix representation D of GL_m satisfies the following conditions for all n.

1. The restriction $D \downarrow \mathrm{GL}_n \times (\mathbb{C}^\times)^{m-n}$ is *equal* to a direct sum of matrix representations of this subgroup.

2. Equivalent irreducible constituents of $D \downarrow \mathrm{GL}_n \times (\mathbb{C}^\times)^{m-n}$ are *equal*.

These properties are crucial for our computational purpose. For convenience, we will call such adapted bases also *Gelfand–Tsetlin bases*.

Consider now the matrix $B_{i,j}(t) \in \mathrm{GL}_m$ with entries 1 in the diagonal, entry t at position (i,j), and entries 0 elsewhere ($i \ne j$). Let $D\colon \mathrm{GL}_m \to \mathrm{GL}(V)$ be a rational representation. Then $F = F_{i,j}\colon \mathbb{C} \to \mathrm{GL}(V)$, $t \mapsto D(B_{i,j}(t))$ is a one-parameter subgroup: we have $F(s+t) = F(s)F(t)$ for $s,t \in \mathbb{C}$. Hence $F'(t) = F'(0)F(t)$, and therefore $F(t) = e^{tF'(0)}$. (Note that $F'(0)$ must be nilpotent.) Let $\epsilon_i \in \mathbb{N}^m$ denote the basis vector having components 0 except at position i, where the component equals 1.

LEMMA 2.2. *$F'_{i,j}(0)$ maps a vector of weight $w \in \mathbb{Z}^m$ into one of weight $w+\epsilon_i-\epsilon_j$.*

Proof. For a fixed vector v of weight w we may write

$$F(t)v = \sum_{s \ge 0} t^s u_s,$$

with vectors $u_s \in V$. We are going to show that u_s must be a vector of weight $w + s(\epsilon_i - \epsilon_j)$. Then we are finished, since $F'(0)v = u_1$.

We have $gB_{i,j}(t)g^{-1} = B_{i,j}(g_i t g_j^{-1})$ for a diagonal matrix $g = \mathrm{diag}(g_1,\dots,g_m)$. This implies

$$D(g)F(t) = D(g)D(B_{i,j}(t)) = D(gB_{i,j}(t)g^{-1})D(g) = F(g_i t g_j^{-1})D(g).$$

Therefore, as $D(g)v = g_1^{w_1} \cdots g_m^{w_m} v$, we obtain

$$\sum_{s\geq 0} t^s D(g)u_s = D(g)F(t)v = g_1^{w_1} \cdots g_m^{w_m} F(g_i t g_j^{-1})v = g_1^{w_1} \cdots g_m^{w_m} \cdot \sum_{s\geq 0} (g_i t g_j^{-1})^s u_s.$$

By comparing the coefficients of t, we see that u_s is indeed a vector of weight $w + s(\epsilon_i - \epsilon_j)$. □

3. Auxiliary fast linear algebra algorithms. We present some auxiliary algorithms, which we will need as subroutines in our algorithm for evaluating representations.

The first one is a variant of Gaussian elimination.

LEMMA 3.1. *Any matrix $A \in \mathrm{GL}_m$ can be factored as $A = A_N A_{N-1} \cdots A_1 \Delta$, where $N \leq 2m^2$, Δ is a diagonal matrix, and all A_i are elementary matrices of the form $B_{n-1,n}(t)$ or $B_{n,n-1}(t)$. Moreover, such a decomposition can be computed with $O(m^3)$ arithmetic operations.*

Proof. Recall that multiplying a matrix from the left by $B_{i,j}(t)$ has the effect of adding the t-fold of the jth row to the ith row. Also note the following: suppose the jth row of A equals zero. Then multiplying A from the left by $B_{i,j}(-1)B_{j,i}(1)$ has the effect of interchanging the jth row with the ith row.

By a sequence of elementary row operations affecting only *neighboring* rows, we can transform a given invertible matrix $A \in \mathrm{GL}_m$ into diagonal form Δ. Hereby, we first take care of the first column of A by working up from the bottom row, then we deal with the second column in a similar way, and so forth. We will illustrate the procedure in the case $m = 4$. Let the symbol $C_{i,j}$ denote either $B_{i,j}(-1)B_{j,i}(1)$ or $B_{i,j}(t)$ for some $t \in \mathbb{C}$. We can obtain a decomposition of the form

$$(C_{3,4}C_{2,3}C_{1,2})(C_{2,3}C_{1,2}C_{4,3})(C_{1,2}C_{3,2}C_{4,3})(C_{2,1}C_{3,2}C_{4,3})\, A = \Delta,$$

where Δ is a diagonal matrix. (The parentheses indicate the treatment of columns.) The number of occurring $C_{i,j}$ matrices equals $m(m-1)$ in the general situation. Moreover, the $C_{i,j}$ and Δ can be computed with $O(m^3)$ arithmetic operations from A. This proves the lemma. □

The next result is well known and relies on the fast Fourier transform (see, for instance, [6, Corollary 13.13]).

PROPOSITION 3.2. *Suppose $J \in \mathbb{C}^{r\times r}$ is a nilpotent Jordan block. Then e^{tJ} is a Toeplitz matrix. Thus $e^{tJ}u$ can be computed from $t \in \mathbb{C}$ and $u \in \mathbb{C}^r$ with $O(r \log r)$ arithmetic operations. For this, $O(r)$ nonscalar operations are sufficient.*

We remark that the computation of $e^{tJ}u$ is equivalent to the task of evaluating the polynomial $f(T) = \sum_{j=0}^{r-1} \frac{u_j}{j!} T^j$ and all its derivatives at $t \in \mathbb{C}$.

The first part of the following lemma shows that a matrix having the block structure of a Jordan block can be efficiently transformed to a direct sum of Jordan blocks. The second part follows then easily with Proposition 3.2.

LEMMA 3.3. *Let $M \in \mathbb{C}^{m\times m}$ be a matrix decomposed into r^2 blocks M_{ij} in $\mathbb{C}^{m_i \times m_j}$, $m = m_1 + \cdots + m_r$. Suppose that all block entries outside the lower diagonal are zero; that is, $M_{ij} = 0$ if $i \neq j+1$. Then the following is true.*

1. *There is an invertible block diagonal matrix $S = [S_{ij}] \in \mathbb{C}^{m\times m}$ (S_{ij} in $\mathbb{C}^{m_i \times m_j}$, $S_{ij} = 0$ for $i \neq j$) and a permutation matrix P such that $PSMS^{-1}P^{-1}$ is a direct sum of nilpotent Jordan blocks of size at most r.*
2. *The product $e^{tM}u$ can be computed with $O(\sum_{\rho=1}^{r} m_\rho^2 + m \log r)$ arithmetic operations from $t \in \mathbb{C}$ and $u \in \mathbb{C}^m$.*

Proof. For showing the first part, it is convenient to take a coordinate-free point of view. Let $V = V_1 \oplus \cdots \oplus V_r$ be a decomposition of vector spaces together with linear maps $\varphi_\rho \colon V_\rho \to V_{\rho+1}$ for $1 \le \rho < r$. Let $\varphi \colon V \to V$ be the linear map satisfying $\varphi(v) = \varphi_\rho(v)$ if $v \in V_\rho$, $\rho < r$, and $\varphi(v) = 0$ if $v \in V_r$. (Note that φ and φ_ρ are coordinate-free versions of M and $M_{\rho+1,\rho}$, respectively.) By a φ-chain of length t we understand an ordered set of vectors $\{v_1, \ldots, v_t\}$ such that $\varphi(v_\tau) = v_{\tau+1}$ for $1 \le \tau < t$, and $\varphi(v_t) = 0$. (φ-chains correspond to nilpotent Jordan blocks.) The first claim of the lemma amounts to showing the existence of a basis E_ρ for each V_ρ such that the basis $E_1 \cup \cdots \cup E_r$ of V is a disjoint union of φ-chains of length at most r.

For $1 \le \rho \le \sigma < r$ let $V_{\rho,\sigma}$ denote the kernel of the composition

$$\varphi_\sigma \circ \cdots \circ \varphi_{\rho+1} \circ \varphi_\rho \colon V_\rho \to V_{\sigma+1}$$

and set $V_{\rho,r} = V_\rho$ for $1 \le \rho \le r$. Note that $V_{\rho,\sigma} \subseteq V_{\rho,\sigma+1}$ and $\varphi_\rho^{-1}(V_{\rho+1,\sigma}) = V_{\rho,\sigma}$. In particular, $\varphi_\rho(V_{\rho,\sigma}) \subseteq V_{\rho+1,\sigma}$.

Choose subsets $E_{1,\sigma} \subseteq V_{1,\sigma}$ such that $E_{1,1} \cup \ldots, E_{1,\sigma}$ is a basis of $V_{1,\sigma}$ for all $1 \le \sigma \le r$. (This means that $E_{1,1} \cup \cdots \cup E_{1,r}$ is a basis of V_1 adapted to the flag $V_{1,1} \subseteq \cdots \subseteq V_{1,r}$ of subspaces.)

By induction on $\rho = 2, \ldots, r$ we are going to construct finite subsets $E_{\rho,\sigma} \subseteq V_{\rho,\sigma}$ satisfying the following conditions for all $\rho \le \sigma \le r$:

(i)$_\rho$ $E_{\rho,\rho} \cup \cdots \cup E_{\rho,\sigma}$ is a basis of $V_{\rho,\sigma}$,

(ii)$_\rho$ $\varphi_{\rho-1}(E_{\rho-1,\sigma}) \subseteq E_{\rho,\sigma}$.

Assume we have already constructed the $E_{\rho-1,\sigma}$ satisfying (i)$_{\rho-1}$ and (ii)$_{\rho-1}$. We claim that the subset $\varphi_{\rho-1}(E_{\rho-1,\sigma}) \subseteq V_{\rho,\sigma}$ is linearly independent modulo $V_{\rho,\sigma-1}$, provided $\rho \le \sigma$. Indeed, if we had a nontrivial linear combination

$$\sum_{v \in E_{\rho-1,\sigma}} \lambda_v \varphi_{\rho-1}(v) \in V_{\rho,\sigma-1},$$

then we would have

$$\sum_{v \in E_{\rho-1,\sigma}} \lambda_v v \in \varphi_{\rho-1}^{-1}(V_{\rho,\sigma-1}) = V_{\rho-1,\sigma-1}.$$

By our inductive assumption (i)$_{\rho-1}$, the set $E_{\rho-1,\rho-1} \cup \cdots \cup E_{\rho-1,\sigma-1}$ is a basis of $V_{\rho-1,\sigma-1}$ and $E_{\rho-1,\rho-1} \cup \cdots \cup E_{\rho-1,\sigma}$ is linearly independent. This is a contradiction! We may now choose subsets $E_{\rho,\sigma}$ containing $\varphi_{\rho-1}(E_{\rho-1,\sigma})$ such that $E_{\rho,\sigma}$ is linearly independent modulo $V_{\rho,\sigma-1}$. Then the conditions (i)$_\rho$ and (ii)$_\rho$ are satisfied.

We have now constructed a basis $E_\rho := E_{\rho,\rho} \cup \cdots \cup E_{\rho,r}$ for each of the spaces V_ρ. We write the basis $E := E_1 \cup \cdots \cup E_r$ as the disjoint union of the subsets

$$F := \bigcup_{\rho<\sigma} E_{\rho,\sigma} \quad \text{and} \quad G := \bigcup_{\rho} E_{\rho,\rho}.$$

By our construction, φ induces an injective map from F to $F \cup G$, and we have $\varphi(G) = \{0\}$. This abstract property easily implies that E is a disjoint union of φ-chains. It is obvious that the length of these chains cannot be bigger than r.

We now provide the proof of the second part of the lemma. Let $PSMS^{-1}P^{-1} = J = J_1 \oplus \cdots \oplus J_s$ be as in the statement of the first part. The J_σ are nilpotent Jordan blocks of size $r_\sigma \le r$. We have

$$e^{tM} = S^{-1}P^{-1}e^{tJ}PS, \; e^{tJ} = \bigoplus_{\sigma=1}^{s} e^{tJ_\sigma}.$$

We can compute $u' = Su$ from a given $u \in \mathbb{C}^m$ with $O(\sum_{\rho=1}^r m_\rho^2)$ arithmetic operations, since S is a block diagonal matrix. The vectors $u'_\sigma \in \mathbb{C}^{r_\sigma}$ satisfying $\oplus_{\sigma=1}^s u'_\sigma = Pu'$ are obtained without further arithmetic operations. By Proposition 3.2, we can compute each of the products $e^{tJ_\sigma}u'_\sigma$ with $O(r_\sigma \log r_\sigma)$ arithmetic operations. Thus we get $u'' := e^{tJ} \oplus_\sigma u'_\sigma$ from the u'_σ with $O(\sum_{\sigma=1}^s r_\sigma \log r_\sigma) \le O(m \log r)$ operations. Summarizing, we have computed $e^{tM}u$ from t and u using $O(\sum_{\rho=1}^r m_\rho^2 + m \log r)$ arithmetic operations. □

4. An algorithm for evaluating representations. The main result of this article is expressed in the following theorem. We call $\lambda \in \mathbb{N}^m$ constant iff its components are all equal.

THEOREM 4.1. *Let D_λ be the matrix representation of GL_m with respect to a Gelfand–Tsetlin basis with highest weight $\lambda \in \mathbb{N}^m$. We suppose that λ is not constant. Then the map*

$$\mathrm{GL}_m \times \mathbb{C}^{d_\lambda} \longrightarrow \mathbb{C}^{d_\lambda},\ (A, v) \mapsto D_\lambda(A)v$$

can be computed with $O(m^2(\mathrm{mult}(\lambda) + \log|\lambda|)\, d_\lambda)$ arithmetic operations. The nonscalar complexity is bounded by $O(m^2 d_\lambda + m\lambda_1)$.

Remark 4.2.

1. We assume exact arithmetic of complex numbers.

2. In the above upper bound the cost for *constructing* the algorithm (preconditioning) is not taken into account. However, the explicit formulas in Vilenkin and Klimyk [22, Chapter 18] for invariant matrices evaluated at special generators of GL_m suggest that this can also be done very efficiently.

3. We need the assumption that λ is not constant. Otherwise, the determinant could be evaluated with $O(m^2 \log m)$ operations (take $\lambda = (1, \ldots, 1)$).

COROLLARY 4.3. *The invariant matrix with respect to a nonconstant $\lambda \in \mathbb{N}^m$ and a Gelfand–Tsetlin basis can be evaluated at a matrix $A \in \mathrm{GL}_m$ with $O(m^2(\mathrm{mult}(\lambda) + \log|\lambda|)\, d_\lambda^2)$ arithmetic operations.*

Proof (of Theorem 4.1). We first factor the given matrix $A \in \mathrm{GL}_m$ according to Lemma 3.1 as $A = A_N A_{N-1} \cdots A_1 \Delta$. Note that the cost for doing this is dominated by $O(m^2 d_\lambda)$, since $d_\lambda \ge m$ for a nonconstant $\lambda \in \mathbb{N}^m$ by Remark 2.1. We therefore have $D_\lambda(A) = D_\lambda(A_N)D_\lambda(A_{N-1}) \cdots D_\lambda(A_1)D_\lambda(\Delta)$. For given $v \in \mathbb{C}^{d_\lambda}$ we first compute $v_0 = D_\lambda(\Delta)v$ and then, successively, $v_i = D_\lambda(A_i)v_{i-1}$ for $1 \le i \le N$. Obviously, $v_t = D_\lambda(A)v$.

As a Gelfand–Tsetlin basis consists of weight vectors, and the matrix $D_\lambda(\Delta)$ is diagonal with entries $t_1^{w_1} \cdots t_m^{w_m}$, where $w_i \le \lambda_1$. Thus $D_\lambda(\Delta)v$ can be certainly computed with $O(m\, d_\lambda \log \lambda_1) \le O(m\, d_\lambda \log|\lambda|)$ arithmetic operations. (Note that $2 \log w_i$ multiplications are sufficient to obtain $t_i^{w_i}$.)

It remains to show that we can compute each of the products $D_\lambda(A_i)v_i$ with $O((\mathrm{mult}(\lambda) + \log|\lambda|)d_\lambda)$ arithmetic operations. We assume that $A_i = B_{n-1,n}(t)$, the case of $A_i = B_{n,n-1}(t)$ being analogous. Let us write $V = \mathbb{C}^{d_\lambda}$ and interpret V as a GL_m-module via D_λ. Recall the graph $G(\lambda)$ introduced in section 2, which describes the splitting behavior of V. We have

$$V \downarrow \mathrm{GL}_n \times (\mathbb{C}^\times)^{m-n} = \bigoplus_x \bigoplus_{j=1}^{f(x)} V_{x,j}, \tag{4.1}$$

where the first sum is over all nodes x of $G(\lambda)$ at level n, $f(x)$ equals $\mathrm{mult}(\lambda, x)$, and $V_{x,j}$ is an irreducible $\mathrm{GL}_n \times (\mathbb{C}^\times)^{m-n}$-module of type x. Because of the symmetry

adaptation, the decomposition (4.1) is compatible with our Gelfand–Tsetlin basis; that is, subsets of this basis form a basis of each $V_{x,j}$. As A_i is contained in GL_n, the matrix $D_\lambda(A_i)$ decomposes according to (4.1) into

$$D_\lambda(A_i) = \oplus_x \oplus_j D_{x,j}(A_i).$$

If we write $v_i = \oplus_x \oplus_j v_{x,j}$ according to (4.1) (this decomposition can be done for free), we have $D_\lambda(A_i)v_i = \oplus_x \oplus_j D_{x,j}(A_i)v_{x,j}$. Now it is sufficient to show that each of the products $D_{x,j}(A_i)v_{x,j}$ can be computed with $O((\mathrm{mult}(\nu_x) + \log|\nu_x|)\, d_{\nu_x})$ arithmetic operations, where $x = (\nu_x, w)$, $\nu_x \in \mathbb{N}^n$, $d_{\nu_x} = \dim V_{x,j}$. Indeed, then $D_\lambda(A_i)v_i$ can be computed with a number of arithmetic operations bounded by

$$\begin{aligned}\sum_x (\mathrm{mult}(\nu_x) + \log|\nu_x|)\, f(x) d_{\nu_x} &\le (\mathrm{mult}(\lambda) + \log|\lambda|) \sum_x f(x) d_{\nu_x} \\ &= (\mathrm{mult}(\lambda) + \log|\lambda|)\, d_\lambda\end{aligned}$$

up to a constant factor. By symmetry adaptation, a subset of the original Gelfand–Tsetlin basis forms a Gelfand–Tsetlin basis of $V_{x,j}$, and $D_{x,j}$ is the corresponding matrix representation. We may therefore continue our argumentation assuming that $n = m$.

We have to prove now that we can compute the product $D_\lambda(B_{m-1,m}(t))v$ with $O((\mathrm{mult}(\lambda) + \log|\lambda|)\, d_\lambda)$ arithmetic operations. Put $F(t) := D_\lambda(B_{m-1,m}(t))$ and $\Gamma := F'(0)$. Similarly as in (4.1), we have the decomposition

$$V \downarrow \mathrm{GL}_{m-2} \times (\mathbb{C}^\times)^2 = \bigoplus_\nu \bigoplus_{a=0}^{|\lambda|-|\nu|\, f(\nu,a)} \bigoplus_{j=1} V_{\nu,a,j}, \tag{4.2}$$

where the first two sums are over all ν, a such that the pair $x := (\nu, w)$ with $w := (a, |\lambda| - |\nu| - a))$ is a node of $G(\lambda)$ at level $m-2$. The irreducible $\mathrm{GL}_{m-2} \times (\mathbb{C}^\times)^2$-module $V_{\nu,a,j}$ is of type x, and $f(\nu, a) = \mathrm{mult}(\lambda, x)$. Note that $f(\nu, a) \le \mathrm{mult}(\lambda)$.

$F(t)$ commutes with GL_{m-2}, and hence so does Γ. Therefore, Γ maps the isotypical components

$$W_\nu := \bigoplus_a \bigoplus_j V_{\nu,a,j}$$

of $V \downarrow \mathrm{GL}_{m-2}$ into itself. Note that $\dim W_\nu = g(\nu) d_\nu$, where $g(\nu) := \sum_a f(\nu, a)$. From Lemma 2.2 we know that Γ maps $\oplus_j V_{\nu,a,j}$ into $\oplus_j V_{\nu,a+1,j}$. Now we decompose Γ according to (4.2) into $d_\nu \times d_\nu$-matrices $\Gamma_{(\nu',a',j'),(\nu,a,j)}$. From the observations made just before, we see that these matrices vanish unless $\nu' = \nu$ and $a' = a + 1$. Such a matrix affords a GL_{m-2}-module morphism $V_{\nu,a,j} \to V_{\nu,a',j'}$. On the other hand, the identity matrix affords as well a GL_{m-2}-module morphism between these spaces, since our basis is adapted to this subgroup. Schur's lemma implies therefore that $\Gamma_{(\nu,a',j'),(\nu,a,j)}$ must be a multiple of the $d_\nu \times d_\nu$ identity matrix.

Let Γ^ν denote the matrix $[\Gamma_{(\nu,a',j'),(\nu,a,j)}]_{(a',j'),(a,j)}$, that is, the matrix of Γ restricted to W_ν. It is not hard to see that Γ^ν equals, after some suitable permutation of our basis of W_ν, a direct sum of d_ν *identical copies* of a matrix $M^\nu \in \mathbb{C}^{g(\nu)\times g(\nu)}$ (see Figure 4.1). This matrix M^ν has a decomposition into $(|\lambda| - |\nu| + 1)^2$ blocks $M^\nu_{a',a} \in \mathbb{C}^{f(\nu,a')\times f(\nu,a)}$, and all blocks outside the lower diagonal vanish: $M^\nu_{a',a} = 0$ unless $a' = a + 1$.

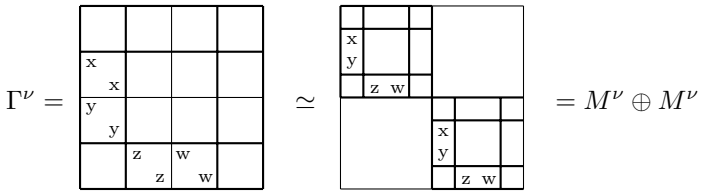

FIG. 4.1. *The matrix* Γ^ν *for* $\lambda = (2,1,0,0)$ *and* $\nu = (1,0)$. *We have* $f(\nu,0) = 1$, $f(\nu,1) = 2$, $f(\nu,2) = 1$, $g(\nu) = 4$, *and* $d_\nu = 2$.

From Lemma 3.3(2) we know that a product $e^{tM^\nu}u$ can be computed from $t \in \mathbb{C}$ and $u \in \mathbb{C}^{g(\nu)}$ with a number of arithmetic operations bounded by

$$\sum_a f(\nu,a)^2 + g(\nu)\log(|\lambda| - |\nu| + 1) \le g(\nu)\mathrm{mult}(\lambda) + g(\nu)\log(|\lambda|+1)$$

up to a constant factor. Therefore, a product $F(t)v$ can be computed with

$$O\Big(\sum_\nu d_\nu g(\nu)\big(\mathrm{mult}(\lambda) + \log(|\lambda|+1)\big)\Big)$$

arithmetic operations, which proves the claim, as $d_\lambda = \sum_\nu d_\nu g(\nu)$.

The estimation of the nonscalar complexity is similar. □

5. A lower bound. The subsequent lower bound result shows that our algorithm is optimal up to a factor of m^2 with respect to the number of nonscalar operations.

THEOREM 5.1. *Let* $\lambda \in \mathbb{N}^m$ *be such that* $|\lambda| > 1$, *and let* $v \in \mathbb{C}^{d_\lambda}$ *be nonzero. Let* D_λ *denote a matrix representation of* GL_m *with highest weight* λ. *Then any arithmetic algorithm (formally, algebraic computation tree) computing the map* $\mathrm{GL}_m \to \mathbb{C}^{d_\lambda}$, $A \mapsto D_\lambda(A)v$ *requires at least* d_λ *nonscalar operations. The evaluation of the invariant matrix* $\mathrm{GL}_m \to \mathrm{GL}_{d_\lambda}$, $A \mapsto D_\lambda(A)$ *requires at least* d_λ^2 *nonscalar operations.*

Proof. The theorem of Burnside (cf. [13]) states that the linear hull of the image of D_λ equals $\mathbb{C}^{d_\lambda \times d_\lambda}$, as D_λ is irreducible. Therefore, the entries of the invariant matrix corresponding to λ are linearly independent polynomials of degree $|\lambda| > 1$. The dimension bound in [6, (4.12)] easily implies the claims. □

6. Fast evaluation of Legendre functions. The algorithm of section 4 can be applied to evaluate many special functions and orthogonal polynomials (Legendre, Jacobi, Gegenbauer polynomials, generalized Beta functions, etc.), since all these are matrix entries of a suitable representation of GL_m (compare [22]). We illustrate this here by the simple example of the associated Legendre functions and obtain a new result.

For the following facts about the representations of GL_2 or the special unitary group $\mathrm{SU}(2)$, see [22, section 6.2]. The natural operation of GL_2 on the space V of homogeneous bivariate polynomials of degree 2ℓ in the indeterminates X, Y affords an irreducible representation of highest weight $\lambda = (2\ell, 0)$ and dimension $d_\lambda = 2\ell + 1$. All irreducible representations of GL_2 are obtained in this way for $\ell \in \frac{1}{2}\mathbb{N}$. Note that $\mathrm{mult}(\lambda) = 1$. In what follows, we will assume that $\ell \in \mathbb{N}$. The basis $(\psi_k)_{-\ell \le k \le \ell}$ given by the elements

$$\psi_k := \frac{X^{\ell-k}\,Y^{\ell+k}}{\sqrt{(\ell-k)!(\ell+k)!}}$$

is a Gelfand–Tsetlin basis having the additional property that the corresponding matrix representation $D^\ell = [D^\ell_{\mu\nu}]_{-\ell\le\mu,\nu\le\ell}$ restricted to SU(2) is unitary. Consider the special unitary matrix

$$A(\theta) := \begin{pmatrix} \cos\theta/2 & i\sin\theta/2 \\ i\sin\theta/2 & \cos\theta/2 \end{pmatrix}.$$

Theorem 4.1 yields an algorithm to compute a column of $D^\ell(A(\theta))$ from $\cos\theta/2$ and $\sin\theta/2$ with $O(\ell\log\ell)$ arithmetic operations. A closer look at this algorithm reveals that the (rational) computation may start with $\cos\theta$ and $\sin\theta$. Indeed, we have the matrix factorization

$$A(\theta) = \begin{pmatrix} 1 & 0 \\ a & 1 \end{pmatrix} \begin{pmatrix} 1 & b \\ 0 & 1 \end{pmatrix} \begin{pmatrix} c & 0 \\ 0 & c^{-1} \end{pmatrix},$$

where $a = i(1-\cos\theta)/\sin\theta$, $2b = i\sin\theta$, and $c = \cos\theta/2$. Moreover, note that $c^{w_1}(c^{-1})^{w_2} = (c^2)^{w_1-\ell} = (\frac{1+\cos\theta}{2})^{w_1-\ell}$ for all weights (w_1, w_2) of V.

In turns out that the middle column of $D^\ell(A(\theta))$ just contains, up to some scaling, the associated Legendre functions P^μ_ℓ (cf. [22, section 6.3.7 (3)]: we have for $|\mu|\le\ell$

$$D^\ell_{-\mu,0}(A(\theta)) = i^{-\mu}\sqrt{\frac{(\ell-\mu)!}{(\ell+\mu)!}}\,P^\mu_\ell(\cos\theta).$$

COROLLARY 6.1. *All the associated Legendre functions $P^\mu_\ell(\cos\theta)$, $|\mu|\le\ell$, can be computed from $\cos\theta$ and $\sin\theta$ by an algorithm using only rational operations with $O(\ell\log\ell)$ arithmetic operations. The nonscalar complexity is bounded by $O(\ell)$.*

Remark 6.2. One can give a direct proof of Corollary 6.1 as follows. The associated Legendre functions P^μ_ℓ satisfy $(0\le\mu\le\ell)$

$$P^\mu_\ell(x) = (-1)^\mu(1-x^2)^{\mu/2}\frac{d^\mu P_\ell(x)}{dx^\mu},$$

where $P_\ell(x)$ denotes the Legendre polynomial of degree ℓ. (This again shows that $P^\mu_\ell(\cos\theta)$ is a polynomial in $\cos\theta$ and $\sin\theta$.) By Proposition 3.2, we can evaluate P_ℓ and all its derivatives at x with $O(\ell\log\ell)$ arithmetic operations (compare the comment following this proposition). Moreover, we have for $0\le\mu\le\ell$ that

$$P^{-\mu}_\ell(x) = (-1)^\mu\frac{\Gamma(\ell-\mu+1)}{\Gamma(\ell+\mu+1)}P^\mu_\ell(x)$$

(cf. [22, section 3.5.8 (10)]; Γ stands for the Gamma function). This finishes the alternative proof of Corollary 6.1.

7. Fast evaluation of immanants. The *immanant* of a matrix $A\in\mathbb{C}^{m\times m}$ corresponding to a partition λ of m is defined as (cf. [15])

$$\mathrm{im}_\lambda(A) = \sum_{\pi\in S_m}\chi_\lambda(\pi)\prod_{i=1}^m A_{i,\pi(i)},$$

where χ_λ denotes the irreducible character of the symmetric group S_m belonging to λ (cf. [3] or [12]). Note that this notion contains the permanent and determinant as special cases ($\chi_\lambda = 1$ or $\chi_\lambda = \mathrm{sgn}$). The reader may find some algebraic properties of immanants in Merris [17, 18].

The following lemma reduces the evaluation of immanants to the evaluation of invariant matrices. It states that immanants are in fact obtained as the sum of the diagonal entries of invariant matrices corresponding to the weight $(1,\dots,1)$. The proof of the lemma follows easily from Theorem 2.4 in [10].

LEMMA 7.1. *Let $\lambda \in \mathbb{N}^m$ be a partition of m. Suppose $D_\lambda = [D_{i,j}]$ is an irreducible matrix representation of GL_m of type λ with respect to a basis of weight vectors. Then we have for all $A \in \mathrm{GL}_m$ that*

$$\mathrm{im}_\lambda(A) = \sum_i D_{i,i}(A),$$

where the sum is over all i corresponding to basis vectors of weight $(1,\dots,1)$.

If we extend the above sum over all indices, we get the character of D_λ evaluated at A. It is interesting that this value can always be computed with a *polynomial number* of arithmetic operations in m. See Proposition 7.4 at the end of this section.

By combining Theorem 4.1 with the above lemma we get the following result.

THEOREM 7.2. *Let $\lambda \in \mathbb{N}^m$ be a nonconstant partition of m, and let s_λ denote the number of standard tableaus on the diagram of λ. One can compute $\mathrm{im}_\lambda(A)$ from $A \in \mathrm{GL}_m$ with a number of arithmetic operations bounded by*

$$O\big(m^2(\mathrm{mult}(\lambda) + \log m)\, s_\lambda d_\lambda\big).$$

The nonscalar complexity is bounded by $O(m^2 s_\lambda d_\lambda)$.

Remark 7.3. Hartmann [11] proved the upper bound $m^{6(m-s)+4}$ for the nonscalar complexity to evaluate permanents corresponding to partitions with at most s parts. Barvinok [1] showed the upper bound $O(m^3 d_\lambda^4)$ for the total complexity. Our bound improves Barvinok's, as $s_\lambda \le d_\lambda$ and $\mathrm{mult}(\lambda) \le d_\lambda$.

To compare our bound with those of Hartmann, consider hook partitions $\lambda = (k,1,\dots,1) \in \mathbb{N}^m$. For such λ one can show that

$$s_\lambda = \tbinom{m-1}{k-1},\ d_\lambda = \tfrac{m+k-1}{m}\binom{m+k-2}{m-k,\,k-1,\,k-1},$$

and hence $m^2 s_\lambda d_\lambda \le m^2 18^m$. This is considerably smaller than Hartmann's bound m^{6k} if $k \ge m/2$.

For permanents, our Theorem 7.2 yields the bound $O(m^{1.5} 4^m \log m)$, which is not too far away from the best-known upper bound $O(m 2^m)$ due to Ryser [19].

In a subsequent paper [4], we will complement this upper bound by completeness results within Valiant's algebraic P-NP theory [20, 21]. (For a comprehensive account of this theory, see [5].) In fact, we will prove the completeness of certain families of immanants corresponding to hook or rectangular diagrams.

We close by showing that the characters of GL_m can be evaluated very rapidly. Let $2 \le \omega < 3$ denote the exponent of matrix multiplication (cf. [6]).

PROPOSITION 7.4. *Let $\epsilon > 0$. Then for all m, the character $\mathrm{Tr}(D_\lambda(A))$ can be evaluated at a given matrix $A \in \mathrm{GL}_m$ with $O(\max\{\lambda_1, m\}^{\omega+\epsilon})$ arithmetic operations.*

Proof. The Schur polynomial of λ is defined as $S_\lambda = \mathrm{Tr}(D_\lambda(\mathrm{diag}(x_1,\dots,x_m)))$. Let σ_i denote the ith elementary symmetric polynomial in m variables, and set $\sigma_i = 0$ if $i < 0$ or $i > m$. Moreover, let $\mu = (\mu_1,\dots,\mu_{\lambda_1})$ be the partition conjugate to λ. Giambelli's formula states that (cf. [8, section A.1 (A.6)])

$$S_\lambda = \det[\sigma_{\mu_i+j-i}]_{1\le i,j\le\lambda_1}.$$

Let $T^m + \sum_{i=1}^{m} (-1)^i c_i(A) T^{m-i}$ be the characteristic polynomial of the matrix A with eigenvalues $x_1, \ldots, x_m$. Then we have $c_i(A) = \sigma_i(x)$ for all i. Therefore, we get from Giambelli's formula that

$$\mathrm{Tr}(D_\lambda(A)) = S_\lambda(x) = \det[c_{\mu_i + j - i}(A)]_{1 \le i,j \le \lambda_1}.$$

The algorithm is now as follows. First, compute the coefficients $c_i(A)$ of the characteristic polynomial for given A with $O(m^{\omega+\epsilon})$ arithmetic operations (cf. [6, section 16.6]). Then compute $\mathrm{Tr}(D_\lambda(A))$ by evaluating the determinant using $O(\lambda_1^{\omega+\epsilon})$ operations (cf. [6, section 16.4]). □

Acknowledgments. I thank M. Clausen and A. Shokrollahi for pointing out to me the papers by Grabmeier and Kerber, and Barvinok, respectively. I am grateful to Steve Smale for inviting me to the City University of Hong Kong, where this work was completed.

THE COMPUTATIONAL COMPLEXITY OF IMMANANTS*

PETER BÜRGISSER†

Abstract. Permanents and determinants are special cases of immanants. The latter are polynomial matrix functions defined in terms of characters of symmetric groups and corresponding to Young diagrams. Valiant has proved that the evaluation of permanents is a complete problem in both the Turing machine model (#P-completeness) as well as in his algebraic model (VNP-completeness). We show that the evaluation of immanants corresponding to hook diagrams or rectangular diagrams of polynomially growing width is both #P-complete and VNP-complete.

Key words. permanents, immanants, computational complexity, algebraic completeness

1. Introduction.

The *permanent* $\operatorname{per}(A)$ of an n by n matrix $A = [a_{i,j}]$ is defined by

$$\operatorname{per}(A) := \sum_{\pi} \prod_{i=1}^{n} a_{i,\pi(i)},$$

where the summation is over all permutations π in S_n. Note that in contrast to the determinant, each term has a positive sign.

From the viewpoint of computational complexity, the determinant and permanent have, in spite of the similarity in their definitions, very little in common. While there are efficient polynomial time algorithms for the evaluation of the determinant, the best-known algorithm for the evaluation of the permanent of an n by n matrix needs $O(n2^n)$ arithmetic operations (Ryser [20]). A hypothesis due to Valiant in fact claims that the permanent cannot be computed with a polynomial number of arithmetic operations. This hypothesis is supported by Valiant's famous result [23] stating that the problem to evaluate the permanent of a matrix with entries in $\{0,1\}$ is #P-complete, as well as his analogous VNP-completeness result [22] in a framework of algebraic computations.

Both permanents and determinants are special cases of immanants introduced by Littlewood [16]. To define these polynomial matrix functions, we have to rely on some basic facts about the characters of the symmetric groups, which can be found for instance in the books by Boerner [2], James and Kerber [13], or Fulton and Harris [9].

It is known that the irreducible characters of the symmetric group S_n can be labeled by *partitions* of n, i.e., by decreasing sequences $\lambda = (\lambda_1, \ldots, \lambda_s)$ of natural numbers adding up to n. A partition will be identified with its (Young) *diagram* $\{(i,j) \mid 1 \le j \le \lambda_i\}$, which can be visualized as a left-justified arrangement of λ_i boxes in the ith row. (Compare Figure 3.1.) We call $|\lambda| := \sum_i \lambda_i$ the *size* and λ_1 the *width* of λ and will use the notation $\lambda \vdash n$ to express that λ is a partition or a diagram of size n. A diagram is called *rectangular* iff $\lambda_1 = \cdots = \lambda_s$.

Let $\chi_\lambda\colon S_n \to \mathbb{Z}$ denote the irreducible character of the symmetric group S_n corresponding to the diagram $\lambda \vdash n$. The *immanant* of an n by n matrix $A = [a_{i,j}]$ corresponding to λ is defined by

$$\mathrm{im}_\lambda(A) := \sum_{\pi \in S_n} \chi_\lambda(\pi) \prod_{i=1}^{n} a_{i,\pi(i)}.$$

For the "horizontal" diagrams given by $\lambda = (n)$ we have $\chi_\lambda = 1$, and the corresponding immanants specialize to the permanents. In the case of the "vertical" diagrams given by $\lambda = (1, \ldots, 1)$ we get $\chi_\lambda = \mathrm{sgn}$, and the immanants specialize to the determinants. These diagrams are special cases of those described by $(k, 1, \ldots, 1)$, which are called *hook diagrams* because of their shape. By *hook immanants* or *rectangular immanants* we will understand the immanant polynomials corresponding to diagrams of the corresponding shape. The reader may find some algebraic properties of immanants in Merris [17, 18].

Our interest for immanants stems from the fact that they constitute a natural parameterized set of polynomials, which allows us to study the change of computational complexity from easy (polynomial time computable) to difficult (complete) as the diagram λ of size n varies between the vertical and the horizontal diagram. To make this more specific, think for instance of the set of hook diagrams $(k, 1, \ldots, 1) \vdash n$ as the parameter k varies between 1 and n.

In the previous paper [3] we have developed a fast algorithm to evaluate representations of general linear groups. As a byproduct, we obtained an algorithm to evaluate the immanant im_λ at a matrix A with nonscalar cost proportional to $n^2 s_\lambda d_\lambda$, where s_λ and d_λ denote the number of standard tableaus and semistandard tableaus on the diagram of λ, respectively. This upper bound improves previous bounds due to Hartmann [11] and Barvinok [1].

In the present article we complement the upper bounds in [3] by completeness results for certain families of immanants. The results will be formulated in Valiant's algebraic P-NP theory, centering around the notion of VNP-completeness. The main features of this theory are recalled in section 2. Note that all VNP-completeness statements in this article refer to a ground field of characteristic zero.

A sequence $(\lambda^{(n)})$ of diagrams such that the size of $\lambda^{(n)}$ is polynomially bounded in n will be called a *p-sequence of diagrams*. If, additionally, the width of $\lambda^{(n)}$ is growing at least polynomially in the size of $\lambda^{(n)}$, then we call such a sequence to be of *polynomially growing width*. The corresponding families of immanant polynomials will also be called so.

We have the following conjecture.

CONJECTURE 1.1. *Any family of immanant polynomials of polynomially growing width is VNP-complete.*

The achievement of this paper is the proof of this conjecture in two special situations: for hook and rectangular immanants. The statement for hook immanants generalizes a result by Hartmann [11], while the claim for rectangular immanants answers an open problem posed by Strassen [21, Problem 14.2].

THEOREM 1.2. *Any family of hook immanants or rectangular immanants of polynomially growing width is VNP-complete.*

For sequences of diagrams of bounded width we have so far no clear idea of the complexity of the corresponding immanants. We raise the following question.

PROBLEM 1.3. *Is the family of rectangular immanants corresponding to rectangles of width* 2 *VNP-complete?*

We remark that families of hook immanants of bounded width are p-computable. This is an immediate consequence of the upper complexity bound in [3] mentioned before.

Our proofs also yield #P-completeness results for the problem to evaluate immanants at matrices A with entries in $\{0,1\}$. However, note that $\mathrm{im}_\chi(A)$ may be negative, with absolute value bounded by $n!\,n^n \le n^{2n}$ for $A \in \{0,1\}^{n\times n}$. We will therefore interpret the evaluation problem below as the modified problem to compute $\mathrm{im}_\chi(A) + n^{2n}$ from $A \in \{0,1\}^{n\times n}$.

COROLLARY 1.4. *Assume in Theorem* 1.2 *that the sequence of diagrams is polynomial time computable. Then the problem to evaluate the corresponding immanant at a given matrix with entries in* $\{0,1\}$ *is* #P*-complete.*

The paper is organized as follows. In section 2 we recall the main features of Valiant's algebraic P-NP theory. The goal of section 3 is the proof of an auxiliary result (Lemma 3.1) which is crucial for our completeness proofs. It expresses values of characters corresponding to rectangular diagrams by characters of hook diagrams. Section 4 is devoted to the proof that families of immanants are indeed p-definable.

In section 5, we provide the proof of Theorem 1.2 in several steps. The general strategy is to identify alternating sums of immanants corresponding to smaller partitions as a projection of a given immanant (Lemma 5.1), by applying the Murnaghan–Nakayama rule for the characters of the symmetric group. In combination with Lemma 3.1 we exhibit alternating sums of hook immanants as projections of rectangular immanants. This is then combined with technical results, which allows to obtain permanents or Hamilton cycle polynomials as projections of linear combinations of hook immanants.

2. Valiant's algebraic model of NP-completeness. We briefly recall the main features of Valiant's algebraic P-NP theory. For detailed expositions we refer to the survey by von zur Gathen [10] and the books by Bürgisser, Clausen, and Shokrollahi [7, Chapter 21] and Bürgisser [6].

We will adopt the following useful convention: we denote matrix functions with small letters, but the corresponding function evaluated at a matrix with distinct indeterminate entries is written in capitals. For instance, $\mathrm{per}(A)$ is the permanent of the n by n matrix A, and

$$\mathrm{PER}_n = \sum_{\pi\in S_n} \prod_{i=1}^{n} X_{i,\pi(i)}$$

denotes the permanent of an n by n matrix with indeterminate entries $X_{i,j}$. Likewise, IM_λ denotes the immanant polynomial corresponding to the diagram $\lambda \vdash n$.

Throughout the paper, the discussion will refer to a fixed field k of characteristic zero. (The reader may assume $k = \mathbb{Q}$.) By a *p-family* we understand a sequence (f_n) of multivariate polynomials $f_n \in k[X_1, \ldots, X_{v(n)}]$ such that the number of variables $v(n)$ as well as the degree $\deg f_n$ are *p-bounded* functions of n, i.e., these functions are majorized by a polynomial in n. Interesting examples are the *permanent family* $\mathrm{PER} = (\mathrm{PER}_n)$, the *determinant family* $\mathrm{DET} = (\mathrm{DET}_n)$, and the family $\mathrm{HC} = (\mathrm{HC}_n)$ of *Hamilton cycle polynomials* defined by

$$\mathrm{HC}_n = \sum_{\pi} \prod_{i=1}^{n} X_{i,\pi(i)},$$

where the sum is over all cycles $\pi \in S_n$ of length n. Note that the value of HC_n at the adjacency matrix of a digraph equals the number of its Hamilton cycles.

Let $L(f_n)$ denote the total *complexity* of $f_n \in k[X_1, \ldots, X_{v(n)}]$, that is, the minimum number of arithmetic operations $+, -, *$ to compute f_n from the variables X_i and constants in k by a straight-line program. We call a p-family *p-computable* iff $L(f_n)$ is p-bounded in n. The p-computable families constitute the complexity class VP.

A p-family (f_n) is called *p-definable* iff there exists a p-computable family (g_n), $g_n \in k[X_1, \ldots, X_{u(n)}]$, such that for all n

$$f_n(X_1, \ldots, X_{v(n)}) = \sum_{e \in \{0,1\}^{u(n)-v(n)}} g_n(X_1, \ldots, X_{v(n)}, e_{v(n)+1}, \ldots, e_{u(n)}).$$

The set of p-definable families form the complexity class VNP.

We will employ a very simple notion of reduction. A polynomial f_n is called a *projection* of a polynomial $g_m \in k[X_1, \ldots, X_u]$, written $f_n \leq g_m$, iff

$$f_n(X_1, \ldots, X_{v(n)}) = g_m(a_1, \ldots, a_u)$$

for some $a_i \in k \cup \{X_1, \ldots, X_{v(n)}\}$. That is, f_n can be derived from g_m through substitution by indeterminates and constants. A p-family (f_n) is called a *p-projection* of a family (g_m) iff there is a p-bounded function $t\colon \mathbb{N} \to \mathbb{N}$ such that f_n is a projection of $g_{t(n)}$ for all n. Finally, a p-definable family (g_m) is called *VNP-complete* iff any $(f_n) \in \mathrm{VNP}$ is a p-projection of (g_m).

In [22] Valiant proved that the p-families PER of permanents and HC of Hamilton cycles polynomials are VNP-complete (over fields k of characteristic different from two, which is a general assumption in this paper). Thus PER is not p-computable iff *Valiant's hypothesis* $\mathrm{VP} \neq \mathrm{VNP}$ is true.

One can prove that the "generating functions" corresponding to several NP-complete graph problems like cliques, graph factors, Hamilton cycles in planar graphs, etc. yield VNP-complete families as well (see [6, Chapter 3]). In fact, Valiant's hypothesis can be considered as a nonuniform algebraic counterpart of the well-known hypothesis $\mathrm{P} \neq \mathrm{NP}$ due to Cook [8]. For results relating these two hypotheses, see [4, 6]. We mention in passing that, by contrast with the classical P-NP theory, one knows specific p-definable families over finite fields, which are neither VNP-complete, nor p-computable, provided the polynomial hierarchy does not collapse (cf. [5, 6]).

For later use, we state some results going back to Valiant [24]; detailed proofs can be found in [6]. The first result shows that the complexity class VNP is closed under various natural operations.

PROPOSITION 2.1. *Let (f_n) and (g_n) be p-definable; say $f_n \in k[X_1, \ldots, X_{v(n)}]$. Then the following hold.*

(i) *Sum and product. $(f_n + g_n)$ and $(f_n \cdot g_n)$ are p-definable.*

(ii) *Substitution. $(f_n(g_1, \ldots, g_{v(n)}))$ is p-definable.*

(iii) *Coefficient. If $h_n \in k[X_{u(n)+1}, \ldots, X_{v(n)}]$ is the coefficient of some power product $X_1^{i_1} \cdots X_{u(n)}^{i_{u(n)}}$ in f_n for some $u(n) \leq v(n)$, then the family (h_n) is p-definable.*

The second result is a useful criterion for p-definability which connects the nonuniform counting complexity class #P/poly to the class VNP. Note that functions φ, which are computable in polynomial time on a Turing machine, are clearly contained in the class #P/poly. (For the definition of #P see [23]; a general definition of nonuniform complexity classes like #P/poly can be found in Karp and Lipton [15].)

PROPOSITION 2.2. *Suppose* $\varphi\colon \{0,1\}^* \to \mathbb{N}$ *is a function in the class* #P/poly. *Then the family* (f_n) *of polynomials defined by*

$$f_n = \sum_{e\in\{0,1\}^n} \varphi(e) X_1^{e_1} \cdots X_n^{e_n}$$

is p-definable.

3. Character formulas for the symmetric group. We first recall some character formulas for the symmetric group for later use. These formulas are then applied to derive Lemma 3.1, which is a crucial ingredient of our completeness proofs. More information on the characters of the symmetric groups can be found in the books by Boerner [2], James and Kerber [13], or Fulton and Harris [9].

We recall that $\lambda \vdash n$ means that $\lambda = (\lambda_1, \ldots, \lambda_s)$ is a partition of n. The irreducible character of S_n corresponding to λ is denoted by χ_λ.

To a partition λ we may assign the strictly decreasing sequence

$$\ell = [\ell_1, \ldots, \ell_s] := (\lambda_1, \ldots, \lambda_s) + (s-1, s-2, \ldots, 1, 0)$$

in $\mathbb{N}^s$ which satisfies $\sum \ell_i = n + \binom{s}{2}$. (We use square brackets to distinguish ℓ notationally from a partition λ.) It is useful to index the irreducible characters of S_n by such sequences, thus we set $\chi_\ell := \chi_\lambda$. We can extend this definition to any $\ell \in \mathbb{N}^s$ satisfying $\sum \ell_i = n + \binom{s}{2}$ by requiring the function $\ell \mapsto \chi_\ell$ to be alternating. In particular, χ_ℓ vanishes if two components of ℓ are equal. We also include the case $n = 0$ by setting $\chi_{[s-1,\ldots,0]}(1) := 1$.

Conjugacy classes of permutations in S_n are described by their *cycle format* $(\rho_1, \ldots, \rho_n)$, where ρ_i denotes the number of i-cycles. Clearly, $\sum_i i\rho_i = n$. It will be convenient to write cycle formats in frequency notation $\rho = 1^{\rho_1} \cdots n^{\rho_n}$, or shorter $\rho \models n$ in order to express that ρ is a cycle format of n. Moreover, we set $\chi_\ell(\rho) := \chi_\ell(\pi)$, where π is any permutation with cycle format ρ.

Let $u_{s,i} := Z_1^i + Z_2^i + \cdots + Z_s^i$ denote the ith elementary power sum in the indeterminates $Z_1, \ldots, Z_s$, and let

$$\Delta_s := \det(Z_i^{s-j})_{1\le i,j\le s} = \prod_{i<j}(Z_i - Z_j)$$

be the discriminant. The characters of S_n are determined by the remarkable *formula of Frobenius* (cf. [9, 4.10, p. 49]):

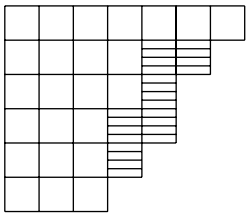
$$\Delta_s \cdot u_{s,1}^{\rho_1} \cdots u_{s,n}^{\rho_n} = \sum_\ell \chi_\ell(\rho) Z_1^{\ell_1} \cdots Z_s^{\ell_s}, \tag{3.1}$$

where the sum is over all $\ell \in \mathbb{N}^s$ satisfying $\sum \ell_i = n + \binom{s}{2}$. From this formula one easily deduces *Frobenius' recursion formula* for the characters of S_n (cf. [2, VI, section 3]): let $1 \le h \le n$ and $\rho \models n-h$. Then we have for all $\ell \in \mathbb{N}^s$ satisfying $\sum \ell_i = n + \binom{s}{2}$

$$\chi_\ell(\rho \cdot h) = \sum_i \chi_{[\ell_1,\ldots,\ell_{i-1},\ell_i-h,\ell_{i+1},\ldots,\ell_s]}(\rho), \tag{3.2}$$

where the sum is over all $1 \le i \le s$ such that $\ell_i \ge h$, and with the property that $\ell_1, \ldots, \ell_{i-1}, \ell_i - h, \ell_{i+1}, \ldots, \ell_s$ are pairwise distinct numbers.

Sometimes it is convenient to use a recursion formula related to (3.2), the so-called Murnaghan–Nakayama rule. We recall that a partition $\lambda \vdash n$ can be represented



$\lambda = (7, 6, 5, 5, 4, 3)$
$\mu = (7, 4, 4, 3, 3, 3)$
$r(\lambda, \mu) = 3$

FIG. 3.1. *A skew hook for the diagram of* λ.

by its *diagram* $\{(i, j) \mid 1 \leq j \leq \lambda_i\}$, which should be visualized as a left-justified arrangement of λ_i boxes in the ith row. A *skew hook* for λ is a connected region of boundary boxes for its diagram such that removing them leaves a diagram for another partition μ. We denote by $r(\lambda, \mu)$ the number of vertical steps in the skew hook, i.e., one less than the number of rows in the hook. For illustration see Figure 3.1.

The *Murnaghan–Nakayama* rule now reads as follows: For $\lambda \vdash n$, $1 \leq h \leq n$, and $\rho \models n - h$, we have

$$\chi_\lambda(\rho \cdot h) = \sum_\mu (-1)^{r(\lambda,\mu)} \chi_\mu(\rho), \tag{3.3}$$

where the sum is over all partitions $\mu \vdash n-h$ that can be obtained from λ by removing a skew hook containing h boxes (cf. [13, 2.4.7, p. 60] or [9, p. 59]).

As an example, let us compute the value of χ_λ on an n-cycle. The Murnaghan–Nakayama rule implies immediately that $\chi_\lambda(n^1) = (-1)^i$ if λ equals a hook partition $(n - i, 1, \ldots, 1)$, and that $\chi_\lambda(n^1) = 0$ otherwise.

For the rest of the paper, we will denote the characters corresponding to the hook partitions $(n - i, 1, \ldots, 1) \vdash n$ by $\chi_{n,i}$ and call them *hook characters*. The corresponding *hook immanant* polynomials will be denoted by $\mathrm{HI}_{n,i}$ for $0 \leq i < n$. Note that $\mathrm{HI}_{n,i}$ corresponds to a diagram of width $n - i$. For instance we have $\mathrm{HI}_{n,0} = \mathrm{PER}_n$ and $\mathrm{HI}_{n,n-1} = \mathrm{DET}_n$.

Now assume $\rho \models n$, $\rho \neq n^1$. The orthogonality relations (cf. [9, I, section 2.2]) and the above observation on the value of χ_λ on an n-cycle imply that

$$\sum_{\lambda \vdash n} \chi_\lambda(n^1)\chi_\lambda(\rho) = \sum_{i=0}^{n-1} (-1)^i \chi_{n,i}(\rho) = 0.$$

From this one easily concludes the following formula due to Merris [19]:

$$\sum_{i=0}^{n-1} (-1)^i \,\mathrm{HI}_{n,i} = n\mathrm{HC}_n. \tag{3.4}$$

We illustrate Frobenius' recursion formula (3.2) by computing the value $\chi_{(2,2,2,2)}$ for permutations in S_8 of cycle format 2^4. To the rectangular partition $(2, 2, 2, 2)$ there corresponds the sequence $\ell = [5, 4, 3, 2]$. The recursive application of (3.2) can be illustrated by the tree $T_{2,2}$ in Figure 3.2. This tree has depth 4 and its nodes carry a label $\ell \in \mathbb{N}^4$ having distinct components. The meaning of the tree $T_{2,2}$ is the following: Consider a node with label ℓ at level $1 \leq t \leq 4$, and let $\ell^{(1)}, \ldots, \ell^{(M)}$ be the labels of the sons of this node. Then we have by (3.2) that

$$\chi_\ell(2^t) = \sum_{i=1}^{M} \chi_{\ell^{(i)}}(2^{t-1}).$$

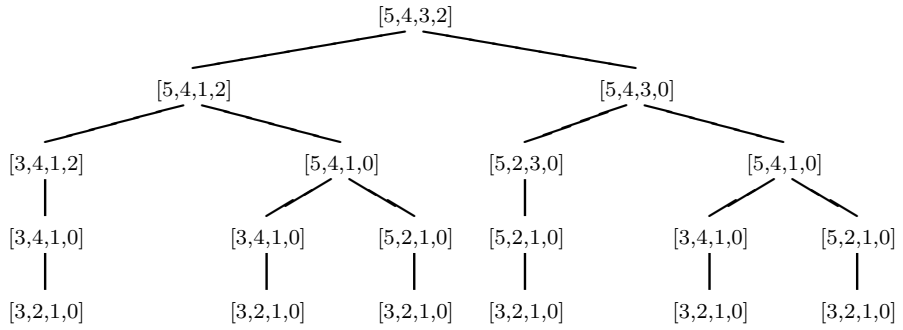


FIG. 3.2. *The tree $T_{2,2}$ illustrating the recursive application of Frobenius' recursion formula.*

From this it follows that $\chi_{[5,4,3,2]}(2^4)$ is the sum of $\chi_{[3,2,1,0]}(1)$ over all leaves of the tree. Hence $\chi_{[5,4,3,2]}(2^4) = 6\chi_{[3,2,1,0]}(1) = 6$.

To simplify notation, we will write χ_{m^s} for the character corresponding to a rectangular partition $(m, \ldots, m) \vdash sm$, and IM_{m^s} for the corresponding *rectangular immanant* polynomial.

The technical lemma below generalizes the above computational example and expresses certain values of χ_{m^s} by hook characters. The lemma will be crucial in our completeness proof in section 5.

LEMMA 3.1. *Let $s = qm + r$, $1 \le r \le m$, $q \ge 0$. Then we have for all cycle formats $\rho \models m$, $\rho \ne m^1$, that*

$$\chi_{m^s}(m^{s-1} \cdot \rho) = \gamma_{m,s} \sum_{i=0}^{r-1} (-1)^i \chi_{m,i}(\rho)$$

and

$$\chi_{m^s}(m^s) = r\gamma_{m,s} + m\beta_{m,s},$$

where

$$\gamma_{m,s} = \frac{(s-1)!}{q!^{m-r}(q+1)!^r}, \quad \beta_{m,s} = q\gamma_{m,s}.$$

Proof. As in the above example (Figure 3.2), we can describe the recursive application of Frobenius' recursion formula (3.2) for computing $\chi_{m^s}(m^s)$ by a labeled tree $T_{m,s}$. This tree is built up as follows. The root carries the label

$$\ell^{(0)} := [m+s-1, m+s-2, \ldots, m] = (m, m, \ldots, m) + (s-1, s-2, \ldots, 0).$$

To an already constructed node with label ℓ, we create a son for every $\ell - me_k$ which has nonnegative and distinct components. Here $e_k \in \{0,1\}^s$ denotes the canonical basis vector having a 1 at position $1 \le k \le s$.

We will soon prove that all leaves of $T_{m,s}$ carry the label $[s-1, \ldots, 1, 0]$. Using this already, we see that the nodes one level above the leaves carry a label of the form $L_k := [s-1, \ldots, 1, 0] + me_k$ for $1 \le k \le m$. Let α_k denote the number of these nodes. By a repeated application of the recursion formula (3.2), we obtain for all $\rho \models m$

$$\chi_{m^s}(m^{s-1} \cdot \rho) = \sum_{k=1}^{m} \alpha_k \chi_{L_k}(\rho).$$

A k-cycle transforms the sequence $(m-k+1,1,\dots,1,0,\dots,0)+(s-1,\dots,1,0)$ into L_k, and thus χ_{L_k} equals up to a sign a hook character: $\chi_{L_k}=(-1)^{k-1}\chi_{m,k-1}$. Now the point is that

$$\alpha_1=\cdots=\alpha_r,\ \alpha_{r+1}=\cdots=\alpha_m. \tag{3.5}$$

Assuming this for the moment, we may conclude for $\rho\models m$, $\rho\neq m^1$, that

$$\begin{aligned}\chi_{m^s}(m^{s-1}\cdot\rho)&=\alpha_1\sum_{i=0}^{r-1}(-1)^i\chi_{m,i}(\rho)+\alpha_{r+1}\sum_{i=r}^{m-1}(-1)^i\chi_{m,i}(\rho)\\&=(\alpha_1-\alpha_{r+1})\sum_{i=0}^{r-1}(-1)^i\chi_{m,i}(\rho),\end{aligned}$$

where we have used formula (3.4) in the last equality. We also get (recall that $\chi_{m,i}(m^1)=(-1)^i$)

$$\chi_{m^s}(m^s)=r\alpha_1+(m-r)\alpha_{r+1}=r(\alpha_1-\alpha_{r+1})+m\alpha_{r+1}.$$

So it remains to show (3.5) and to check that indeed $\alpha_1-\alpha_{r+1}=\gamma_{m,s}$ and $\alpha_{r+1}=q\gamma_{m,s}$.

To a leaf of $T_{m,s}$ there corresponds bijectively the path from the root to this leaf, which can be uniquely described by the sequence of labels $(\ell^{(0)},\dots,\ell^{(s)})$ of the nodes along this path. By assigning to $\ell^{(i)}$ the set $A_i\subseteq B:=\{0,1,\dots,m+s-1\}$ of its components, we get a sequence $(A_0,\dots,A_s)$ of subsets of B all having cardinality s, and which satisfy

$$A_{i+1}=(A_i\setminus\{a_i\})\cup\{a_i-m\} \tag{3.6}$$

with some $a_i\in A_i$ such that $a_i\geq m$ and $a_i-m\notin A_i$. It is easy to see that this correspondence is in fact a bijection between the paths of $T_{m,s}$ from the root to a leaf and the sequences $(A_0,\dots,A_s)$ of subsets of B satisfying (3.6) and such that $A_0=\{m,m+1,\dots,m+s-1\}$.

Now consider the complements $\overline{A_i}:=B\setminus A_i$. They are all of cardinality m. By induction on i one shows that the remainders modulo m of the elements of $\overline{A_i}$ are pairwise distinct. Hence we may write

$$\overline{A_i}=\{p_1^{(i)}m,p_2^{(i)}m+1,\dots,p_m^{(i)}m+m-1\} \tag{3.7}$$

with a uniquely determined vector $p^{(i)}=(p_1^{(i)},\dots,p_m^{(i)})$ contained in

$$W:=\{0,1,\dots,q+1\}^r\times\{0,1,\dots,q\}^{m-r}.$$

Let $a_i\in A_i$ be as in (3.6). As $a_i-m\notin A_i$, we have $a_i-m=p_{\mu_i}^{(i)}m+\mu_i-1$ for some $1\leq\mu_i\leq m$. On the other hand, $a_i=(p_{\mu_i}^{(i)}+1)m+\mu_i-1$ is by construction not contained in A_{i+1}. This implies that

$$p^{(i+1)}=p^{(i)}+e'_{\mu_i}, \tag{3.8}$$

where $e'_{\mu_i}\in\{0,1\}^m$ is the canonical basis vector having a 1 at position μ_i. We can thus regard $(p^{(0)},\dots,p^{(s)})$ as a walk in W which starts in $p^{(0)}=\underline{0}:=(0,\dots,0)$ and

must end in the opposite corner $p^{(s)} = w := (q+1, \ldots, q+1, q, \ldots, q)$. In this walk, a successor of a point is obtained by incrementing exactly one coordinate by 1.

It is now straightforward to check that we have found a bijection between the leaves of $T_{m,s}$ and the above-described walks in W from $\underline{0}$ to the opposite corner w. In particular, all leaves of $T_{m,s}$ carry the same label $[s-1, \ldots, 1, 0]$ corresponding to w, as was claimed at the beginning of the proof.

In what follows we will assume that $q \geq 1$. (The case $q = 0$ can be checked separately.) A node N of $T_{m,s}$ one level above the leaves corresponds to a walk in W ending in one of the points $w - e'_M$, where $1 \leq M \leq m$. To such a walk in turn there corresponds a sequence of sets $(A_0, \ldots, A_{s-1})$. Assume first that $1 \leq M \leq r$. Then it is easily checked that

$$A_{s-1} = (\{0, 1, \ldots, s-1\} \setminus \{qm + M - 1\}) \cup \{(q+1)m + M - 1\}.$$

By comparing this with the set of components of L_k, we obtain $qm + M - 1 = s - k$, and hence $k = r - M + 1$. We conclude that the node N carries the label L_{r-M+1}. The number of nodes of level $s-1$ carrying the label L_{r-M+1} equals the number of walks in W from $\underline{0}$ to $w - e'_M$. Such a walk is uniquely described (cf. (3.8)) by a sequence $(M_0, M_1, \ldots, M_{s-2})$ in $\{1, 2, \ldots, m\}^{s-1}$, in which $\mu \in \{M\} \cup \{r+1, \ldots, m\}$ occurs with frequency q, and $\mu \in \{1, \ldots, r\} \setminus \{M\}$ occurs with frequency $q+1$. The number of these sequences equals the multinomial coefficient

$$\alpha := \frac{(s-1)!}{q!^{m-r+1}(q+1)!^{r-1}}.$$

This proves that $\alpha_1 = \cdots = \alpha_r = \alpha$.

In the case $r < M \leq m$ one can show similarly that N carries the label $L_{r-M+m+1}$ and that the number of nodes carrying this label equals

$$\beta := \frac{(s-1)!}{(q-1)!\, q!^{m-r-1}(q+1)!^{r}},$$

which yields $\alpha_{r+1} = \cdots = \alpha_m = \beta$. A straightforward calculation shows that indeed $\alpha - \beta = \gamma_{m,s}$ and $\beta = q\gamma_{m,s}$, where $\gamma_{m,s} = (s-1)!/(q!^{m-r}(q+1)!^{r})$. □

4. P-definability of immanants. Frobenius' formula (3.1) for the generating function of S_n-characters allows us to express immanants as coefficients of p-computable families of polynomials. We will use this observation to prove the following proposition.

PROPOSITION 4.1. *Any family of immanant polynomials corresponding to a p-sequence of diagrams is p-definable.*

Proof. Let the *cycle format polynomial* of ρ be defined as $\mathrm{CF}_\rho := \sum_\pi \prod_{i=1}^n X_{i,\pi(i)}$, where the sum is over all permutations π having cycle format $\rho \models n$.

We multiply Frobenius' formula (3.1) for $s = n$ with CF_ρ and take the sum over all cycle formats $\rho \models n$. This yields

$$F_n := \Delta_n \sum_{\rho \models n} u_{n,1}^{\rho_1} \cdots u_{n,n}^{\rho_n} \mathrm{CF}_\rho = \sum_\ell \left(\sum_{\rho \models n} \chi_\ell(\rho)\, \mathrm{CF}_\rho \right) Z_1^{\ell_1} \cdots Z_n^{\ell_n}.$$

The immanent $\mathrm{IM}_\lambda = \sum_\rho \chi_\ell(\rho)\mathrm{CF}_\rho$ appears in F_n as the coefficient of the power product $\prod_j Z_j^{\ell_j} = \prod_j Z_j^{\lambda_j + n - j}$. By Proposition 2.1(iii) it is therefore sufficient to

prove that (F_n) is p-definable. Let $T_{i,j}$ be further indeterminates for $1 \le i,j \le n$, and define

$$G_n := \sum_{\rho \models n} \mathrm{CF}_\rho \prod_{(i,j):j \le \rho_i} T_{i,j}.$$

By substituting $T_{i,j}$ by $u_{n,i} = Z_1^i + \cdots + Z_n^i$ in G_n and multiplying the resulting polynomial with $\Delta_n = \prod_{i<j}(Z_i - Z_j)$, we obtain F_n. By Proposition 2.1(i)–(ii) it is therefore enough to show that the family (G_n) is p-definable. If we denote by $\rho_i(\pi)$ the number of i-cycles of π, we may write

$$\begin{aligned} G_n &= \sum_{\pi \in S_n} \left(\prod_{\alpha \le n} X_{\alpha,\pi(\alpha)} \right) \left(\prod_{(i,j):j \le \rho_i(\pi)} T_{i,j} \right) \\ &= \sum_{e,\epsilon \in \{0,1\}^{n \times n}} \varphi_n(e,\epsilon) \prod_{1 \le \alpha,\beta \le n} X_{\alpha,\beta}^{e_{\alpha,\beta}} \prod_{1 \le i,j \le n} T_{i,j}^{\epsilon_{i,j}} \end{aligned}$$

with a uniquely determined function

$$\varphi_n \colon \{0,1\}^{n \times n} \times \{0,1\}^{n \times n} \to \{0,1\}.$$

It is obvious that the extension of all φ_n to a function $\varphi \colon \{0,1\}^* \to \{0,1\}$ is computable by a polynomial time Turing machine. Therefore, Proposition 2.2 implies that (G_n) is p-definable. □

We can alternatively deduce Proposition 4.1 from the following interesting result due to Hepler [12], which shows that computing characters of the symmetric groups is a #P-complete problem. This result should be contrasted with Proposition 7.4 of [3], which shows that the evaluation of characters of GL_n is possible in polynomial time.

THEOREM 4.2. *The function which assigns to $\lambda \vdash n$, $\rho \models n$ the value $\chi_\lambda(\rho) + n^n$ is #P-complete (n given in unary).*

In fact, to deduce Proposition 4.1, we need only the easy part of this theorem stating that the above function is contained in #P. Let a p-sequence of diagrams $(\lambda^{(n)})$ be given. We can interpret $\lambda^{(n)}$ as a "polynomial advice" for n in the sense of Karp and Lipton [15]. By Theorem 4.2, the function which assigns to the description π of the power product $\prod_{i=1}^n X_{i,\pi(i)}$ its coefficient in the polynomial $\mathrm{IM}_{\lambda^{(n)}} + n^n \mathrm{PER}_n$ is in the class #P/poly. Therefore, by Proposition 2.2, the family $(\mathrm{IM}_{\lambda^{(n)}} + n^n \mathrm{PER}_n)_n$ is p-definable. This again implies Proposition 4.1.

5. Completeness proofs. This section is divided into five parts. We first describe the general strategy of our completeness proofs. Using this strategy and applying Lemma 3.1, we then provide a short proof of a special case of Theorem 1.2, namely for rectangular diagrams satisfying a certain divisibility condition.

In order to settle the general case of Theorem 1.2, we develop in subsection 5.3 technical results which allow us to obtain permanents or Hamilton cycle polynomials as projections of linear combinations of hook immanants. These technical results in combination with the general strategy then allow us to prove Theorem 1.2 for hook immanants. Finally, we are able to complete the proof of Theorem 1.2 for rectangular immanants.

5.1. The general proof strategy. We introduce some notation and work out the relationship between matrices and weighted digraphs.

There is a canonical bijective correspondence between square matrices and (edge) weighted digraphs. Namely, we can regard an n by n matrix $A = [a_{i,j}]$ over some field as the adjacency matrix of a weighted digraph G on n nodes, where $a_{i,j} \neq 0$ gives the weight of the edge from node i to node j, and there is no such edge if $a_{i,j} = 0$. We define the weight $\mathrm{wt}(\mathcal{C})$ of a subgraph $\mathcal{C}$ of G as the product of the weights of all its edges. The permutations $\pi \in S_n$ with $\prod_{i=1}^n a_{i,\pi(i)} \neq 0$ correspond bijectively to the *cycle covers* $\mathcal{C}$ of G, i.e., n-node subgraphs of G consisting of node-disjoint cycles. Note that $\mathrm{wt}(\mathcal{C}) = \prod_i a_{i,\pi(i)}$ if $\mathcal{C}$ corresponds to π. A cycle cover $\mathcal{C}$ has a (cycle) format $\rho \models n$, where ρ_i counts the number of i-cycles of $\mathcal{C}$.

We define now the *cycle format value* $\mathrm{cf}_\rho(G)$ of a weighted digraph G as the sum of the weights of all cycle covers of G having the format ρ. A special case of this is the *Hamilton cycle value* $\mathrm{hc}(G) := \mathrm{cf}_n(G)$. (Recall our convention on notations at the beginning of section 2.) The *immanant* $\mathrm{im}_\lambda(G)$ of the weighted digraph G is defined as

$$\mathrm{im}_\lambda(G) := \sum_{\rho \models n} \chi_\lambda(\rho) \mathrm{cf}_\rho(G).$$

If all the weights of G are either rationals, constants, or indeterminates, then $\mathrm{im}_\lambda(G)$ is obviously a projection of IM_λ. Moreover, if DK_n denotes the complete weighted digraph DK_n on n nodes with edge (i,j) carrying the indeterminate weight $X_{i,j}$, then $\mathrm{im}_\lambda(\mathrm{DK}_n) = \mathrm{IM}_\lambda$. Similarly, we define the *cycle format polynomial* by setting $\mathrm{CF}_\rho := \mathrm{cf}_\rho(\mathrm{DK}_n)$. Finally, we will denote the value of the *hook immanant* $\mathrm{HI}_{n,i}$ on G by $\mathrm{hi}_{n,i}(G)$.

We explain now our general strategy for proving completeness for a family of immanants. Let $1 \leq h \leq n$, and let G be the disjoint union of the complete weighted digraph DK_{n-h} on $n-h$ nodes with a directed cycle Z of length h, all of whose edges carry the weight 1. Every cycle cover $\mathcal{C}$ of G consists of a cycle cover $\mathcal{C}'$ of DK_{n-h} and the h-cycle Z, and we have $\mathrm{wt}(\mathcal{C}) = \mathrm{wt}(\mathcal{C}')$. Therefore, we obtain for $\rho \models n-h$

$$\mathrm{cf}_{\rho \cdot h^1}(G) = \mathrm{cf}_\rho(DK_{n-h}) = \mathrm{CF}_\rho,$$

and all other cycle format values of G vanish. From this and the Murnaghan–Nakayama rule (3.3), we obtain

$$\begin{aligned}\mathrm{im}_\lambda(G) &= \sum_{\rho \models n-h} \chi_\lambda(\rho \cdot h^1)\, \mathrm{CF}_\rho = \sum_{\rho \models n-h} \sum_{\mu} (-1)^{r(\lambda,\mu)} \chi_\mu(\rho)\, \mathrm{CF}_\rho \\ &= \sum_{\mu} (-1)^{r(\lambda,\mu)} \sum_{\rho \models n-h} \chi_\mu(\rho)\, \mathrm{CF}_\rho = \sum_{\mu} (-1)^{r(\lambda,\mu)} \mathrm{IM}_\mu.\end{aligned}$$

Let us summarize this important insight in slightly more general form.

LEMMA 5.1. *Let $\lambda^{(1)}, \ldots, \lambda^{(t)} \vdash n$, $\alpha_1, \ldots, \alpha_t \in \mathbb{Q}$, and $1 \leq h \leq n$. Then the linear combination of immanants $\sum_{i=1}^t \alpha_i \mathrm{IM}_{\lambda^{(i)}}$ has as a projection the linear combination of immanants*

$$\sum_{i=1}^{t} \alpha_i \sum_{\mu^{(i)}} (-1)^{r(\lambda^{(i)},\mu^{(i)})} \mathrm{IM}_{\mu^{(i)}},$$

where $\mu^{(i)}$ runs over all partitions $\mu^{(i)} \vdash n-h$ which can be obtained from $\lambda^{(i)}$ by removing a skew hook containing h boxes.

5.2. Completeness of particular rectangular immanants. We present here the proof of a special case of Theorem 1.2, namely for rectangular immanants satisfying a certain divisibility condition.

A rectangular diagram $(m,\dots,m) \vdash sm$ is said to be of *height* s.

PROPOSITION 5.2. *Take a sequence of rectangular diagrams $(\lambda^{(m)})$ of polynomially growing width such that the width of $\lambda^{(m)}$ is a divisor of the height of $\lambda^{(m)}$ for all m. Then the corresponding family of rectangular immanants is VNP-complete.*

Proof. By Proposition 4.1 we know already that the given family is p-definable, so it suffices to show that the family of Hamilton cycle polynomials is a p-projection of the given family.

Let us write $\lambda^{(m)} = (m,\dots,m) \vdash s_m m$ and $s_m = q_m m + r_m$ with $1 \le r_m \le m$, $q_m \ge 0$. The height s_m is p-bounded in m since $(\lambda^{(m)})$ is a p-sequence of diagrams. We will use the divisibility assumption $r_m = m$ only at the end of the proof, in order to make the following reasonings reusable.

Let G_m be the disjoint union of the complete weighted digraph DK_m with $s_m - 1$ directed cycles of length m, all of whose edges having weight 1. By applying our general strategy explained in section 5.1, we obtain that

$$f_m := \mathrm{im}_{m^{s_m}}(G) = \sum_{\rho \models m} \chi_{m^{s_m}}(m^{s_m-1} \cdot \rho)\,\mathrm{CF}_\rho$$

is a projection of $\mathrm{IM}_{m^{s_m}}$. Lemma 3.1 implies that

$$\begin{aligned} f_m &= (r_m\gamma_{m,s_m} + m\beta_{m,s_m})\mathrm{CF}_m + \sum_{\substack{\rho\models m\\ \rho\neq m}} \gamma_{m,s_m} \sum_{i=0}^{r_m-1} (-1)^i \chi_{m,i}(\rho)\,\mathrm{CF}_\rho \\ &= m\beta_{m,s_m}\mathrm{CF}_m + \sum_{\rho\models m} \gamma_{m,s_m} \sum_{i=0}^{r_m-1} (-1)^i \chi_{m,i}(\rho)\,\mathrm{CF}_\rho. \end{aligned}$$

Therefore, we get

$$f_m = m\beta_{m,s_m}\mathrm{HC}_m + \gamma_{m,s_m} \sum_{i=0}^{r_m-1} (-1)^i\,\mathrm{HI}_{m,i}. \tag{5.1}$$

Since we assume that $r_m = m$, we conclude with formula (3.4) that f_m is a nonzero scalar multiple of HC_m. This shows that HC is a p-projection of $\mathrm{IM}_{m^{s_m}}$ and proves our proposition. □

5.3. Projections of linear combinations of hook immanants. In order to settle the general case of Theorem 1.2, we have to develop some technical results which allow us to obtain permanents or Hamilton cycle polynomials as projections of linear combinations of hook immanants.

The following lemma is proved similarly to Theorem 2 in Hartmann [11].

LEMMA 5.3.

(i) *Let $0 \le r < n$ and $\alpha_0,\dots,\alpha_r,\beta \in \mathbb{Q}$. Put $p := \lfloor n/(r+1) \rfloor$ and write $\gamma := \sum_{i=0}^{r}(-1)^i\alpha_i$. Then $\beta\mathrm{HC}_p + \gamma\mathrm{PER}_p$ is a projection of $\beta\mathrm{HC}_n + \sum_{i=0}^{r}\alpha_i\mathrm{HI}_{n,i}$.*

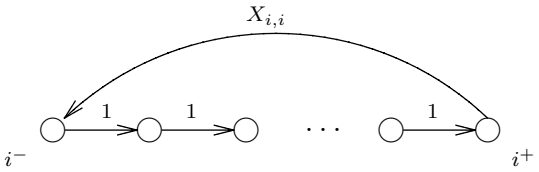
(ii) *Let $1 \le r < n$ and $\alpha_0,\alpha_r,\dots,\alpha_{n-1},\beta \in \mathbb{Q}$. Put*

$$p := \Big\lfloor \frac{n}{n-r+\delta} \Big\rfloor,\ R := n - p(n-r+\delta),\ \gamma := (-1)^{n+R-1} \sum_{i=r}^{n-1} (-1)^i\alpha_i,$$

where $\delta \in \{0,1\}$, $\delta \equiv n-r+1 \bmod 2$. *Then* $\alpha_0\mathrm{PER}_p+\beta\mathrm{HC}_p+\gamma\mathrm{DET}_p$ *is a projection of* $\alpha_0\mathrm{PER}_n + \beta\mathrm{HC}_n + \sum_{i=r}^{n-1} \alpha_i \mathrm{HI}_{n,i}$.

Proof. We note first that by the Murnaghan–Nakayama rule we have for the hook characters $\chi_{n,i}$ that $\chi_{n,i}(\rho) = (-1)^i$ if the cycle format ρ does not contain cycles of length at most i. This observation is crucial for the proof.

(i) For each $i \in \{2,\dots,p\}$ we introduce a cycle of length $r+1$ with edge weights as indicated in the following figure.



Analogously, we introduce a cycle of length $n-(p-1)(r+1)$ for $i=1$. Moreover, we connect the node i^+ with the node j^- by a (directed) edge of weight $X_{i,j}$ for all distinct $i,j \in \{1,2,\dots,p\}$. The resulting weighted digraph G has n nodes and girth $\geq r+1$; that is, all cycles of G have length at least $r+1$. A cycle cover $\tilde{\mathcal{C}}$ of G corresponds bijectively to a cycle cover $\mathcal{C}$ of the complete weighted digraph DK_p. Moreover, $\mathrm{wt}(\tilde{\mathcal{C}}) = \mathrm{wt}(\mathcal{C})$, and $\tilde{\mathcal{C}}$ is a Hamilton cycle iff $\mathcal{C}$ is so.

By the observation at the beginning of the proof we have $\chi_{n,i}(\tilde{\mathcal{C}}) = (-1)^i$ for all $0 \leq i \leq r$ and cycle covers $\tilde{\mathcal{C}}$ of G (which we identify with permutations in S_n). We get therefore for $0 \leq i \leq r$

$$\mathrm{hi}_{n,i}(G) = \sum_{\mathcal{C}} \chi_{n,i}(\tilde{\mathcal{C}})\mathrm{wt}(\tilde{\mathcal{C}}) = (-1)^i \sum_{\mathcal{C}} \mathrm{wt}(\mathcal{C}) = (-1)^i\,\mathrm{PER}_p,$$

and $\mathrm{hc}(G) = \mathrm{HC}_p$; hence

$$\left(\beta\,\mathrm{hc} + \sum_{i=0}^{r} \alpha_i \mathrm{hi}_{n,i}\right)(G) = \beta\,\mathrm{HC}_p + \gamma\mathrm{PER}_p.$$

This proves statement (i).

(ii) We assume that $n-r$ is odd; thus $\delta = 0$. (In the case where $n-r$ is even one can argue analogously.) As in the proof of (i) we construct a weighted digraph G by introducing for each $i \in \{2,\dots,p\}$ a cycle of length $n-r$, and for $i=1$ a cycle of length $n-(p-1)(n-r) = n-r+R$. Again, a cycle cover $\tilde{\mathcal{C}}$ of G corresponds bijectively to a cycle cover $\mathcal{C}$ of DK_p. Note that an ℓ-cycle of DK_p which does not pass through 1 is assigned to a cycle of G having length $\ell(n-r)$, and that $\ell \equiv \ell(n-r) \bmod 2$. To an ℓ-cycle of DK_p passing through 1 there corresponds a cycle of DK_p having length $\ell(n-r)+R$, which is congruent to $\ell + R$ modulo 2. From this we see that for any cycle cover $\mathcal{C}$ of DK_p

$$\mathrm{sgn}(\tilde{\mathcal{C}}) = (-1)^R \mathrm{sgn}(\mathcal{C}).$$

By interchanging rows and columns in the hook diagram $(n-i,1,\dots,1)$ we get the diagram of $(i+1,1,\dots,1)$. Therefore, the corresponding characters are conjugated:

$$\chi_{n,i}(\tilde{\mathcal{C}}) = \mathrm{sgn}(\tilde{\mathcal{C}})\chi_{n,n-i-1}(\tilde{\mathcal{C}})$$

(cf. [9, Ex. 4.4, p. 47]). On the other hand, we have for all $r \leq i < n$ and cycle covers $\tilde{\mathcal{C}}$ that $\chi_{n,n-i-1}(\tilde{\mathcal{C}}) = (-1)^{n-i-1}$, since $\mathrm{girth}(G) \geq n-r$. From these observations we

conclude that for all $r \le i < n$

$$\begin{aligned}\mathrm{hi}_{n,i}(G) &= \sum_{\mathcal{C}} \chi_{n,i}(\tilde{\mathcal{C}})\mathrm{wt}(\tilde{\mathcal{C}}) \\ &= \sum_{\mathcal{C}} (-1)^R \mathrm{sgn}(\mathcal{C})\chi_{n,n-i-1}(\tilde{\mathcal{C}})\mathrm{wt}(\mathcal{C}) \\ &= (-1)^{n+R-1}(-1)^i \sum_{\mathcal{C}} \mathrm{sgn}(\mathcal{C})\mathrm{wt}(\mathcal{C}) \\ &= (-1)^{n+R-1}(-1)^i \,\mathrm{DET}_p.\end{aligned}$$

Taking into account that $\mathrm{hc}(G) = \mathrm{HC}_p$ and $\mathrm{per}(G) = \mathrm{PER}_p$, the claim follows now readily. □

LEMMA 5.4. *Let $\alpha, \beta \in \mathbb{Q}$, $\alpha \neq 0$. Then the following hold.*

(i) PER_{n-1} *is a projection of* $\alpha\mathrm{PER}_n + \beta\mathrm{DET}_n$.

(ii) HC_{n-2} *is a projection of* $\alpha\mathrm{HC}_n + \beta\mathrm{DET}_n$.

Proof. (i) We concatenate the matrix $[X_{i,j}]_{1\le i,j<n}$ of indeterminates with the column $[0,\ldots,0,(2\alpha)^{-1}]^T$ and repeat in the resulting matrix the last row. In this way we get an n by n matrix M having determinant zero. By expanding along the last column we get $\mathrm{per}(M) = 2(2\alpha)^{-1}\mathrm{per}([X_{i,j}]_{i,j<n}) = \alpha^{-1}\mathrm{PER}_{n-1}$. Hence $(\alpha\,\mathrm{per} + \beta\,\det)(M) = \mathrm{PER}_{n-1}$.

(ii) Consider the n by n matrix

$$M := \begin{bmatrix} 0 & 0 & 1 & X_{1,2} & \ldots & X_{1,n} \\ \alpha^{-1} & 0 & 0 & 0 & \ldots & 0 \\ 0 & 0 & 1 & X_{1,2} & \ldots & X_{1,n} \\ 0 & X_{2,1} & 0 & X_{2,2} & \ldots & X_{2,n} \\ \vdots & \vdots & \vdots & \vdots & & \vdots \\ 0 & X_{n,1} & 0 & X_{n,2} & \ldots & X_{n,n} \end{bmatrix}.$$

As the first and third row of M coincide, we have $\det(M) = 0$. We claim that $\mathrm{hc}(M) = \alpha^{-1}\mathrm{HC}_{n-2}$. This is best seen by considering the weighted digraph with adjacency matrix M which is built up as follows from DK_{n-2}. Assume that $\{1,2,\ldots,n-2\}$ is the set of nodes of DK_{n-2}. We delete the loop $(1,1)$ and split the node 1 into nodes 1^- and 1^+. The edges $(i,1)$ of DK_{n-2} are thus replaced by edges $(i,1^-)$, and the edges $(1,i)$ of DK_{n-2} are replaced by edges $(1^+,i)$ for $2 \le i \le n$. Now we introduce a new node O, an edge $(1^-,O)$ of weight α^{-1}, an edge $(O,1^+)$ of weight 1, a loop $(1^+,1^+)$ of weight 1, and edges (O,i) of weight $X_{1,i}$ for $2 \le i \le n$. The reader may easily verify that the resulting weighted digraph G has indeed the adjacency matrix M. On the other hand, it is clear from the construction that every Hamilton cycle of G passes through the edges $(1^-,O)$ and $(O,1^+)$. This shows that indeed $\mathrm{hc}(G) = \alpha^{-1}\mathrm{hc}(\mathrm{DK}_{n-2}) = \alpha^{-1}\mathrm{HC}_{n-2}$. Altogether, we have $(\alpha\,\mathrm{hc} + \beta\,\det)(G) = \mathrm{HC}_{n-2}$, which proves the claim. □

We call a p-family (f_n) *monotone* iff f_n is a projection of f_{n+1} for all n. The above lemma in particular shows that PER is monotone. Also, HC is monotone, which can be demonstrated similarly as part (ii) of the above lemma.

5.4. Completeness of hook immanants. The technical results of the previous section in combination with our general strategy allow us to provide the proof of Theorem 1.2 for hook immanants, stated explicitly below.

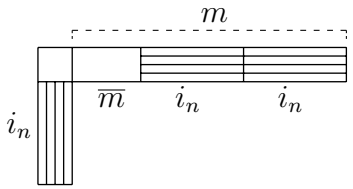


FIG. 5.1. *The hook diagram* $(n - i_n, 1, \ldots, 1)$ *when* $q = 2$.

PROPOSITION 5.5. *Any family of hook immanants of polynomially growing width is VNP-complete.*

Proof. The following notation will be useful: we write $\varphi(n) \gtrsim \psi(n)$ for functions $\varphi, \psi \colon \mathbb{N} \to (0, \infty)$ iff $\liminf_{n\to\infty} \varphi(n)/\psi(n) \geq 1$.

Let $\epsilon > 0$, and let (i_n) be a sequence of natural numbers satisfying $n - i_n \geq n^\epsilon$. We have to prove that (HI_{n,i_n}) is VNP-complete. As we already know from Proposition 4.1 that (HI_{n,i_n}) is p-definable, it is sufficient to prove that PER is a p-projection of this p-family. We distinguish several cases.

Case 1. $i_n \leq \sqrt{n}$.

Let $p_n := \lfloor \frac{n}{i_n+1} \rfloor$. Then $p_n \gtrsim \sqrt{n}$ and Lemma 5.3(i) implies that $(-1)^{i_n}\mathrm{PER}_{p_n}$ is a projection of HI_{n,i_n}.

Case 2. $i_n > \sqrt{n}$.

Put $m := n - i_n - 1$ and let $m = qi_n + \overline{m}$, where $0 \leq \overline{m} < i_n$. By applying Lemma 5.1 with $h = i_n$ we obtain that $f_1 := \mathrm{HI}_{n-i_n,i_n} + (-1)^{i_n-1}\mathrm{HI}_{n-i_n,0}$ is a projection of HI_{n,i_n} (cf. Figure 5.1). Again applying this lemma with $h = i_n$ yields that

$$f_2 := \mathrm{HI}_{n-2i_n,i_n} + (-1)^{i_n-1}\mathrm{HI}_{n-2i_n,0} + (-1)^{i_n-1}\mathrm{HI}_{n-2i_n,0}$$

is a projection of f_1. If we continue in this way, we see that with $\overline{n} := n - qi_n = \overline{m} + i_n + 1$, the polynomial

$$f_q := \mathrm{HI}_{\overline{n},i_n} + q(-1)^{i_n-1}\mathrm{PER}_{\overline{n}}$$

is a projection of HI_{n,i_n}.

Subcase 2.1. $\overline{m} \geq n^{1/4}$.

We apply Lemma 5.1 with $h = i_n$ to f_q and get that $(q+1)(-1)^{i_n-1}\mathrm{PER}_{\overline{m}+1}$ is a projection of HI_{n,i_n}. (Recall that $\overline{m} < i_n$.) Note that the coefficient $(q+1)(-1)^{i_n-1}$ is nonzero!

Subcase 2.2. $\overline{m} < n^{1/4}$ and $q \geq 1$.

We apply Lemma 5.3 (ii) to f_q and obtain

$$g_n := \gamma_n \mathrm{DET}_{p_n} + q(-1)^{i_n-1}\mathrm{PER}_{p_n}$$

as a projection of f_q for some $\gamma_n \in \{-1, 1\}$ and some

$$p_n \geq \left\lfloor \frac{\overline{n}}{\overline{n} - i_n + 1} \right\rfloor \geq \left\lfloor \frac{i_n}{\overline{m} + 2} \right\rfloor \gtrsim n^{1/4}.$$

By invoking Lemma 5.4(i), we see that PER_{p_n-1} is a projection of g_n and thus of HI_{n,i_n}.

Subcase 2.3. $q = 0$.

As in subcase 2.1, we apply Lemma 5.1 with $h = i_n$ to $f_q = \mathrm{HI}_{n,i_n}$ and get that $(-1)^{i_n-1}\mathrm{PER}_{\overline{m}+1}$ is a projection of HI_{n,i_n}. But $\overline{m}+1 = n - i_n \geq n^\epsilon$ by assumption.

To summarize, let $\delta := \min\{\epsilon, 1/4\}$. We have shown the existence of a sequence $N_n \gtrsim n^\delta$ of natural numbers such that PER_{N_n} is a projection of HI_{n,i_n} for all sufficiently large n. Taking into account that PER is monotone, this implies that PER is a p-projection of $(\mathrm{HI}_{n,i_n})_n$ and finishes the proof. ∎

5.5. Completeness of rectangular immanants. The proof of Theorem 1.2 will be achieved by identifying either a hook immanant or a Hamilton cycle polynomial as a projection of a rectangular immanant. This will be sufficient to establish completeness according to the following little observation.

LEMMA 5.6. *Let $f = (f_n)$ and $g = (g_n)$ be VNP-complete families and assume f to be monotone. Moreover, let $I \subseteq \mathbb{N}$ and define the corresponding* mixture $h = (h_n)$ *of f and g as*

$$h_n := \begin{cases} f_n & \text{if } n \in I, \\ g_n & \text{otherwise.} \end{cases}$$

Then h is VNP-complete as well.

Proof. The p-family $(f_1, g_1, f_2, g_2, f_3, g_3, \dots)$ is obviously p-definable and h is a p-projection of it; hence h is also p-definable.

Let $\varphi = (\varphi_n)$ be any p-definable family. Since f is complete, there is a p-bounded function $n \mapsto t_1(n)$ such that φ_n is a projection of $f_{t_1(n)}$: $\varphi_n \leq f_{t_1(n)}$ for all n. We put $D(n) := \max\{\deg g_i \mid 1 \leq i \leq n\}$ and consider the p-definable family

$$\Phi_n := \varphi_n + Z^{1+D(t_1(n))},$$

where Z is a new variable. As g is complete, there is a p-bounded $n \mapsto t_2(n)$ such that $\Phi_n \leq g_{t_2(n)}$ for all n. In particular,

$$D(t_1(n)) < \deg \Phi_n \leq \deg g_{t_2(n)},$$

which implies $t_2(n) > t_1(n)$. By substituting $Z \mapsto 0$ we see that $\varphi_n \leq g_{t_2(n)}$. On the other hand, we also have $\varphi_n \leq f_{t_2(n)}$, as f is monotone. From this it immediately follows that $\varphi_n \leq h_{t_2(n)}$ for all n. This shows that h is a complete family. ∎

We remark that the monotonicity assumption is necessary. Namely, if (f_n) is complete, then the families $(f_1, 0, f_2, 0, \dots)$ and $(0, f_1, 0, f_2, \dots)$ are both complete as well, but their mixture with respect to $I = \{2, 4, 6, 8, \dots\}$ equals the zero sequence.

Finally, we present the proof of Theorem 1.2 in the general situation.

Proof. Suppose that (s_m) is a p-bounded sequence of natural numbers. We wish to show that the sequence of rectangular immanants $\mathrm{IM}_{m^{s_m}}$ is VNP-complete. We write $s_m = q_m m + r_m$ with $1 \leq r_m \leq m$, $q_m \geq 0$.

As in the proof of Proposition 5.2, (5.1), we find that

$$f_m = m\beta_{m,s_m}\mathrm{HC}_m + \gamma_{m,s_m} \sum_{i=0}^{r_m-1} (-1)^i \,\mathrm{HI}_{m,i}$$

is a projection of $\mathrm{IM}_{m^{s_m}}$.

We distinguish now two cases.

Case 1. $1 \leq r_m \leq m - \sqrt{m}$.

We apply Lemma 5.1 with $h = 1$ and obtain that

$$g_m := \gamma_{m,s_m}\left(\mathrm{HI}_{m-1,0} + \sum_{i=1}^{r_m-1}(-1)^i\left[\mathrm{HI}_{m-1,i} + \mathrm{HI}_{m-1,i-1}\right]\right)$$

is a projection of $\gamma_{m,s_m}\sum_{i=0}^{r_m-1}(-1)^i\,\mathrm{HI}_{m,i}$. Recall that this is shown by adding to DK_{m-1} an isolated vertex with a loop (of weight 1). The resulting digraph does not have a Hamilton cycle. From this one easily sees that g_m is also a projection of f_m. The formula for g_m simplifies to (telescoping sum)

$$g_m = \gamma_{m,s_m}(-1)^{r_m-1}\mathrm{HI}_{m-1,r_m-1}.$$

If $r_m > m - \sqrt{m}$, then we define $g_m := \mathrm{HI}_{m-1,0}$. The family (g_m) of hook immanants is complete by Proposition 5.5.

Case 2. $m - \sqrt{m} < r_m \leq m$.

By using relation (3.4) we can rewrite f_m as follows:

$$\begin{aligned} f_m &= m\beta_{m,s_m}\mathrm{HC}_m + \gamma_{m,s_m}\left(m\mathrm{HC}_m - \sum_{i=r_m}^{m-1}(-1)^i\,\mathrm{HI}_{m,i}\right)\\ &= \kappa_m\mathrm{HC}_m + \gamma_{m,s_m}\sum_{i=r_m}^{m-1}(-1)^{i+1}\mathrm{HI}_{m,i}, \end{aligned}$$

where $\kappa_m := m(\beta_{m,s_m} + \gamma_{m,s_m}) > 0$. Lemma 5.3(ii) shows that

$$\varphi_m := \kappa_m\mathrm{HC}_{p_m} + c_m\mathrm{DET}_{p_m}$$

is a projection of f_m for some $c_m \in \mathbb{Q}$ and some

$$p_m \geq \left\lfloor\frac{m}{m - r_m + 1}\right\rfloor \geq \left\lfloor\frac{m}{\sqrt{m}+1}\right\rfloor \geq \lfloor\sqrt{m}\rfloor - 1.$$

Lemma 5.4(ii) together with the fact that HC is monotone implies that the Hamilton cycle polynomial $h_m := \mathrm{HC}_{\lfloor\sqrt{m}\rfloor-3}$ is a projection of φ_m and thus of f_m. The family (h_m) is monotone and complete, as HC has these properties.

To summarize, we have proved that some mixture of the families (g_m) of hook immanants and (h_m) of Hamilton cycle polynomials is a p-projection of (f_m), and thus of $(\mathrm{IM}_{m^{s_m}})$. Hence the family of rectangular immanants $(\mathrm{IM}_{m^{s_m}})$ is complete by Lemma 5.6. □

Finally, we remark that in order to obtain Corollary 1.4 from Theorem 1.2, one can check that the projections $f_n \leq g_m$ occurring in the proof of this theorem actually yield relations $N_n f_n(X) = g_m(a)$, where the components of a are either indeterminates, 0, or 1, and the factor N_n is a nonzero integer. Moreover, m, N_n, and a are computable in polynomial time from n. Thus we get "weakly parsimonious"reductions (cf. [14, p. 107]) between the corresponding problems to evaluate f_n, g_m at $0,1$-values. Moreover, one can obtain from Theorem 4.2 that the problem to compute $\mathrm{im}_{\lambda^{(n)}}(A) + n^{2n}$ from $A \in \{0,1\}^{n\times n}$ is in contained in #P for any polynomial time computable map $n \mapsto \lambda^{(n)}$.

Acknowledgment. Thanks go to M. Clausen for valuable discussions.

AN ALGORITHMIC REGULARITY LEMMA FOR HYPERGRAPHS*

ANDRZEJ CZYGRINOW† AND VOJTECH RÖDL‡

Abstract. In this paper, we will consider the problem of designing an efficient algorithm that finds an ϵ-regular partition of an l-uniform hypergraph.

Key words. hypergraphs, regularity lemma, algorithms

AMS subject classifications. 05C65, 68R05

PII. S0097539799351729

1. Introduction. The regularity lemma of Szemerédi [12] is a powerful tool used in extremal combinatorics and graph theory. The lemma states that the vertex set of any graph can be partitioned into subsets that meet certain regularity conditions. The original proof of the lemma is not constructive, but recently, Alon, et al. [1] found a way to convert it into an efficient algorithm. The algorithm is based on the characterization of regularity which states that a pair of subsets of vertices is irregular if and only if either the degrees of "many" vertices are "far from average" or the cardinality of the intersection of neighborhoods of many pairs of vertices is "far from the average case." The algorithmic version of the lemma has already been applied to design the algorithms for various combinatorial problems. Applications include the max-cut problem [7], the tournament ranking problem [3], or the fast algorithm for computing the frequency of a subgraph [4]. Many of these problems have appealing generalizations to hypergraphs, which leads us to a natural question: Can the regularity lemma be extended to hypergraphs?

In the hypergraph case regularity can be measured in a few different ways. The most straightforward and perhaps natural approach defines the density and regularity in the same way as for graphs. The corresponding hypergraph regularity lemma can be then proved along the lines of Szemerédi's proof for graphs (see [11]). In this paper we consider an algorithmic version of this regularity lemma. Note that other versions of regularity lemma were considered in [2], [5], [6], and recently in [10]. In a proof of the regularity lemma it is necessary to distinguish between bipartite graphs which have uniformly distributed edges (say, which are ϵ-regular) from these which are not. For an algorithmic proof we need to have an efficient algorithm. It was proved, however, in [1] that it is co-NP complete to decide if a bipartite graph is ϵ-regular. Authors of [1] got around this difficulty by finding another polynomial checkable characterization which distinguishes between bipartite graphs which fail to be $\epsilon^{1/5}$-regular and those which are ϵ-regular. Note that in the hypergraph case we were unable to find even such a simple characterization.

We found it convenient to consider a slightly more general weighted version ($l = 2$ and $\omega : [V]^l \to \{0, 1\}$ gives the original Szemerédi version). Let $H = (V, \omega)$ be an l-uniform hypergraph with nonnegative weights $\omega : [V]^l \to Z_+ \cup \{0\}$, and let

$K = \max_{\{v_1,\dots,v_l\}\in[V]^l} \omega(v_1,\dots,v_l) + 1$ (for technical reasons we require that K is strictly larger than $\max_{\{v_1,\dots,v_l\}\in[V]^l} \omega(v_1,\dots,v_l)$). For l subsets $V_1,\dots,V_l$ of V such that $V_i \cap V_j = \emptyset$ if $i \neq j$ define

$$d_\omega(V_1,\dots,V_l) = \frac{\sum\{\omega(v_1,\dots,v_l) : (v_1,\dots,v_l) \in V_1 \times \dots \times V_l\}}{K|V_1|\dots|V_l|}. \tag{1.1}$$

An l-tuple $(V_1,\dots,V_l)$ of subsets of V with $V_i \cap V_j = \emptyset$ is called (ϵ,ω)-regular if for every $W_i \subset V_i$, $i = 1,\dots,l$, with $|W_i| \geq \epsilon|V_i|$ we have

$$|d_\omega(V_1,\dots,V_l) - d_\omega(W_1,\dots,W_l)| < \epsilon. \tag{1.2}$$

An l-tuple $(W_1,\dots,W_l)$ that violates (1.2) is called a witness. A partition $V_0 \cup V_1 \cup \dots \cup V_t$ of V is called (ϵ,ω)-regular if

1. $|V_0| \leq \epsilon|V|$,
2. $|V_i| = |V_j|$ for all $i,j \in [t]$,
3. all but at most ϵt^l l-tuples $(V_{i_1},\dots,V_{i_l})$ with $\{i_1,\dots,i_l\} \subset [t]^l$ are (ϵ,ω)-regular.

The regularity lemma for hypergraphs states that for every $\epsilon > 0$ and every integer m there exist $M = M(\epsilon,m)$ and $N = N(\epsilon,m)$ such that every hypergraph $H = (V,\omega)$ with $|V| \geq N$ admits an (ϵ,ω)-regular partition $V_0 \cup V_1 \cup \dots \cup V_t$ with $m \leq t \leq M$. We show the following theorem.

THEOREM 1.1. *For every l, K, m, and ϵ there exist M, L, and an algorithm which for any l-uniform weighted hypergraph $H = (V,\omega)$ with $K = \max \omega(v_1,\cdots,v_l)+1$ and $|V| = n \geq L$ finds in $O(n^{2l-1}\log^2 n)$ time an (ϵ,ω)-regular partition $V_0 \cup V_1 \cup \dots \cup V_t$ of H with $m \leq t \leq M$.*

Similar results were obtained in Frieze and Kannan [8] (compare also [7]). In particular, [8] contains a randomized algorithm which for every $\epsilon > 0$ and every $\delta > 0$ finds a subset which with probability $1-\delta$ contains all of the information necessary to construct an ϵ-regular partition. Also, [7] and [9] contain many applications of the constructive graph and hypergraph regularity lemma. The approach taken by Frieze and Kannan in [7], [8], and [9] is different from ours. In addition to (1.1), the following density function will be used. Let $(V_1,\dots,V_l)$ be an l-tuple of subsets with $V_i \cap V_j = \emptyset$, and let $1 \leq k \leq l-1$. For $x \in V_{k+1} \times \dots \times V_l$ define

$$d_\omega(x,V_1,\dots,V_k) = \frac{\sum\{\omega(v_1,\dots,v_k,x) : (v_1,\dots,v_k) \in V_1 \times \dots \times V_k\}}{K|V_1|\dots|V_k|}.$$

For an l-tuple $(V_1,\dots,V_l)$ of pairwise disjoint sets and for $1 \leq k \leq l-1$ define

$$ind_k(V_1,\dots,V_l) = \sum_{x\in V_{k+1}\times\dots\times V_l} \frac{(d_\omega(x,V_1,\dots,V_k))^2}{|V_{k+1}|\dots|V_l|} \tag{1.3}$$

and

$$ind_l(V_1,\dots,V_l) = \sum_{x\in V_{l-1}} \frac{(d_\omega(x,V_1,\dots,V_{l-2},V_l))^2}{|V_{l-1}|}. \tag{1.4}$$

Note that

$$ind_{l-1}(V_1,\dots,V_{l-2},V_l,V_{l-1}) = ind_l(V_1,\dots,V_{l-1},V_l). \tag{1.5}$$

Finally, define an index of a partition $P = V_0 \cup V_1 \cup \cdots \cup V_t$ of V as follows:

$$ind(P) = \frac{1}{lt^l} \sum_{(V_{i_1},\ldots,V_{i_l})} \left(\sum_{k=1}^{l} ind_k(V_{i_1},\ldots,V_{i_l}) \right).$$

Clearly, $ind(P)$ is always less than or equal to 1. In the same way as in [1] and [12], if a partition of V is (ϵ,ω)- irregular, then one can construct a subpartition P' such that $ind(P') \geq ind(P) + \frac{\delta^{17}}{16 \cdot l}$, where $\delta = \frac{1}{96} \frac{\epsilon^{2l+1}}{2^{(2l+1)(l-1)}}$. Then, iterating our "improvement" process $\frac{16 \cdot l}{\delta^{17}} + 1$ times, we obtain an (ϵ,ω)-regular partition of the hypergraph. The rest of the paper is organized as follows. In section 2 we prove some facts about hypergraph densities. Sections 3 and 4 contain two procedures that construct "witness sets" for irregular l-tuples. Both procedures are applied in section 5, where we give the description of the algorithm that constructs an (ϵ,ω)-regular partition of a hypergraph. Section 6 contains the analysis of the algorithm. In section 7, we outline two applications of Theorem 1.1. Finally, it should be noted that there was no attempt made to optimize the constants.

2. Preliminary facts. Let us first observe the following property of densities; compare with [12]. Note that l is a fixed constant independent of n and $1 \leq i \leq l$.

FACT 2.1 (continuity of densities).

1. *Let $G = (X, Y, \omega)$ be a weighted bipartite graph. For $\delta \in (0,1)$, let $X' \subset X$, $Y' \subset Y$ be such that $|X'| \geq (1-\delta)|X|$ and $|Y'| \geq (1-\delta)|Y|$. Then*

$$|d_\omega(X', Y') - d_\omega(X, Y)| \leq 2\delta$$

and

$$|(d_\omega(X', Y'))^2 - (d_\omega(X, Y))^2| \leq 4\delta.$$

2. *Let $(V_1 \cup \cdots \cup V_l, \omega)$ be an l-uniform hypergraph with $V_i \cap V_j = \emptyset$. For $\delta \in (0,1)$, let $\bar{V}_1 \subset V_1, \ldots, \bar{V}_i \subset V_i$ be such that $|\bar{V}_j| \geq (1-\delta)|V_j|$, where $j = 1,\ldots,i$. Then for $x \in V_{i+1} \times \cdots \times V_l$,*

$$|d_\omega(x, \bar{V}_1, \ldots, \bar{V}_i) - d_\omega(x, V_1, \ldots, V_i)| \leq i\delta$$

and

$$|(d_\omega(x, \bar{V}_1, \ldots, \bar{V}_i))^2 - (d_\omega(x, V_1, \ldots, V_i))^2| \leq 2i\delta.$$

In many places of the proof, we will use the following defect form of the Schwarz inequality (see [12]).

FACT 2.2. *If for some $m < n$, $\sum_{k=1}^{m} X_k = \frac{m}{n} \sum_{k=1}^{n} X_k + \rho$, then*

$$\sum_{k=1}^{n} X_k^2 \geq \frac{1}{n} \left(\sum_{k=1}^{n} X_k \right)^2 + \frac{\rho^2 n}{m(n-m)}.$$

Let $X = \{x_1, x_2, \ldots, x_N\}$ and $U = \{u_1, u_2, \ldots, u_M\}$ be two disjoint sets. Let $G = (X, U, \omega)$ be a bipartite graph with nonnegative weights on edges $\omega(x,u) < K$. For $i = 1, 2, \ldots, M$, $j = 1, 2, \ldots, N$ set

$$deg(x_j) = \sum_{i=1}^{M} \omega(x_j, u_i),$$

$$d_j = \frac{deg(x_j)}{MK},$$

$$deg(u_i) = \sum_{j=1}^{N} \omega(x_j, u_i),$$

$$\Delta_i = \frac{deg(u_i)}{NK}.$$

We also set

$$d = d_\omega(X,U) = \frac{\sum_{i=1}^{M}\sum_{j=1}^{N}\omega(x_j,u_i)}{MNK} = \frac{\sum_{j=1}^{N} d_j}{N} = \frac{\sum_{i=1}^{M}\Delta_i}{M}$$

and $T = dMNK$ for the total weight of all edges. For $x_i \in X$ consider the vector

$$\overrightarrow{x_i} = (\omega(x_i,u_k))_{k=1}^{M}.$$

DEFINITION 2.3. *A graph $G = (X,U,\omega)$ is called δ-vector regular if $|\langle \overrightarrow{x_i}, \overrightarrow{x_j}\rangle - d_i d_j MK^2| < \delta MK^2$ for all but at most $\delta\binom{N}{2}$ pairs $\{x_i, x_j\}$.*

LEMMA 2.4. *For $\epsilon, \delta \in (0,1)$, suppose $G = (X,U,\omega)$ is δ-vector regular and $|X| \geq 1/\delta$. Then for every $U' \subset U$ with $|U'| \geq \epsilon|U|$*

$$|d_\omega(X,U') - d_\omega(X,U)| < \epsilon,$$

provided $\epsilon^3 \geq 3\delta$.

Proof. Suppose the lemma is false and consider $U' \subset U$ such that $m = |U'| \geq \epsilon|U|$ and

$$|d_\omega(X,U') - d_\omega(X,U)| \geq \epsilon. \tag{2.1}$$

Without loss of generality, assume that $U' = \{u_1, \ldots, u_m\}$, where $m \geq \epsilon M$. Equation (2.1) is equivalent to

$$\left|\sum_{i=1}^{m}\Delta_i - dm\right| \geq \epsilon m. \tag{2.2}$$

From Fact 2.2 (applied with $\rho = \epsilon m$ and $n = M$), we infer that

$$\sum_{i=1}^{M}\Delta_i^2 \geq M\left(d^2 + \frac{\epsilon^3}{1-\epsilon}\right), \tag{2.3}$$

which implies

$$\sum_{i=1}^{M}\binom{deg(u_i)}{2} = \sum_{i=1}^{M}\binom{\Delta_i NK}{2} = \sum_{i=1}^{M}\frac{\Delta_i NK(\Delta_i NK - 1)}{2}$$

$$(2.4) \geq \frac{1}{2}N^2MK^2\left(d^2 + \frac{\epsilon^3}{1-\epsilon}\right) - \frac{NK}{2}\sum_{i=1}^{M}\Delta_i = \frac{1}{2}N^2MK^2\left(d^2 + \frac{\epsilon^3}{1-\epsilon}\right) - \frac{T}{2}.$$

On the other hand, we have

$$\sum_{i=1}^{M}\binom{deg(u_i)}{2}=\sum_{i=1}^{M}\binom{\sum_{j=1}^{N}\omega(x_j,u_i)}{2}=\frac{1}{2}\sum_{i=1}^{M}\left(\sum_{j=1}^{N}\omega(x_j,u_i)\left(\sum_{k=1}^{N}\omega(x_k,u_i)-1\right)\right)$$

$$\leq\frac{1}{2}\left(\sum_{j,k\in[N]}\left(\sum_{i=1}^{M}\omega(x_k,u_i)\omega(x_j,u_i)\right)-T\right)=\frac{1}{2}\left(\sum_{j,k\in[N]}\langle\overrightarrow{x_j},\overrightarrow{x_k}\rangle-T\right). \tag{2.5}$$

By assumption, we know that for all but at most $\delta\binom{N}{2}$ of pairs $\{x_i,x_j\}$, $\langle\overrightarrow{x_i},\overrightarrow{x_j}\rangle\leq(d_id_j+\delta)MK^2$, and we can bound the scalar product for the remaining pairs: $\langle\overrightarrow{x_i},\overrightarrow{x_j}\rangle<MK^2$. Therefore,

$$\sum_{j,k\in[N]}\langle\overrightarrow{x_j},\overrightarrow{x_k}\rangle<\sum_{j,k\in[N]}(d_jd_k+\delta)MK^2+\sum_{j=1}^{N}\langle\overrightarrow{x_j},\overrightarrow{x_j}\rangle+\delta N^2MK^2$$

$$\leq\sum_{j,k\in[N]}(d_jd_k+\delta)MK^2+2\delta N^2MK^2$$

$$\leq\left(\sum_{i=1}^{N}d_i\right)^2MK^2+3\delta N^2MK^2\leq(d^2+3\delta)N^2MK^2. \tag{2.6}$$

By combining (2.5) and (2.6), we see that

$$\sum_{i=1}^{M}\binom{deg(u_i)}{2}<\frac{1}{2}((d^2+3\delta)N^2MK^2-T). \tag{2.7}$$

Comparing (2.4) and (2.7) gives

$$(d^2+3\delta)N^2MK^2>N^2MK^2\left(d^2+\frac{\epsilon^3}{1-\epsilon}\right),$$

which gives $3\delta>\frac{\epsilon^3}{1-\epsilon}$. This contradicts our assumption that $\epsilon^3\geq3\delta$. □

Let $V_1,\ldots,V_k$ be pairwise disjoint sets and let $(V_1\cup\cdots\cup V_k,\omega)$ be a weighted k-uniform hypergraph. We consider a bipartite graph (U,X,ω), where $U=V_1$, $X=\{x_1,\ldots,x_N\}=V_2\times\cdots\times V_k$, and where $\omega(u,x)=\omega(v_1,v_2,\ldots,v_k)$ if $u=v_1$ and $x=(v_2,\ldots,v_k)$. The next lemma shows that irregularity of an l-tuple can be reduced either to vector irregularity or to irregularity of an $(l-1)$-tuple, with weights appropriately defined.

LEMMA 2.5. *If (X,U) is the bipartite graph defined above which moreover satisfies the conditions*

1. $|\langle\overrightarrow{x_i},\overrightarrow{x_j}\rangle-d_id_jMK^2|<\delta MK^2$ *for all but at most* $\delta\binom{N}{2}$ *pairs* $\{x_i,x_j\}$,
2. $|d_\omega(V_1,V_2',\ldots,V_k')-d_\omega(V_1,V_2,\ldots,V_k)|<\frac{\epsilon}{2}$ *for every* $V_i'\subset V_i$ *with* $|V_i'|\geq\frac{\epsilon}{2}|V_i|$,

then for every $V_i' \subset V_i$ *with* $|V_i'| \geq \epsilon |V_i|$

$$|d_\omega(V_1', V_2', \ldots, V_k') - d_\omega(V_1, V_2, \ldots, V_k)| < \epsilon,$$

provided $48\delta \leq \epsilon^{2k+1}$.

Proof. The triangle inequality and the second condition imply that for every $V_i' \subset V_i$ with $|V_i'| \geq \epsilon |V_i|$

$$|d_\omega(V_1', V_2', \ldots, V_k') - d_\omega(V_1, V_2, \ldots, V_k)| \leq \frac{\epsilon}{2} + |d_\omega(V_1', V_2', \ldots, V_k') - d_\omega(V_1, V_2', \ldots, V_k')|.$$

Let $X' = V_2' \times \cdots \times V_k'$. Observe that for at most $\delta\binom{N}{2} \leq \delta\frac{N^2}{2} \leq \frac{\delta}{\epsilon^{2(k-1)}}\frac{|X'|^2}{2} \leq \frac{2\delta}{\epsilon^{2(k-1)}}\binom{|X'|}{2}$ of the pairs $\{x_i, x_j\}$

$$|\langle \overrightarrow{x_i}, \overrightarrow{x_j} \rangle - d_i d_j M K^2| \geq \delta M K^2,$$

and so Lemma 2.4 (applied to X') implies that

$$|d_\omega(V_1', X') - d_\omega(V_1, X')| < \frac{\epsilon}{2}$$

as $6\frac{\delta}{\epsilon^{2(k-1)}} \leq (\frac{\epsilon}{2})^3$. Clearly, $d_\omega(Y, X') = d_\omega(Y, V_2', \ldots, V_k')$, which shows that

$$|d_\omega(V_1', V_2', \ldots, V_k') - d_\omega(V_1, V_2, \ldots, V_k)| < \epsilon. \qquad \square$$

Let $\omega'(v_2, \ldots, v_k) = \sum_{v_1 \in V_1} \omega(v_1, v_2, \ldots, v_k)$ and $K' = K|V_1|$. Then from Lemma 2.5 we see that if a k-tuple $(V_1, V_2, \ldots, V_k)$ is (ϵ, ω)- irregular, then either $|\langle \overrightarrow{x_i}, \overrightarrow{x_j} \rangle - d_i d_j M K^2| > \delta M K^2$ for at least δN^2 pairs $\{x_i, x_j\}$, with $\delta = \epsilon^{2k+1}/48$, or the $(k-1)$-tuple $(V_2, \ldots, V_k)$ is $(\frac{\epsilon}{2}, \omega')$-irregular.

3. Finding witnesses of vector irregularity. Let (X, U, ω) be a weighted "vector irregular" bipartite graph with $X = \{x_1, \ldots, x_N\}$ and $U = \{u_1, \ldots, u_M\}$. In this section we will show how to construct sets $X' \subset X$ and $U' \subset U$ such that $d_\omega(X', U')$ essentially differs from $d_\omega(X', U)$.

THEOREM 3.1. *Let* $\delta \leq \frac{1}{3}$ *and assume that for at least* $\delta\binom{|X|}{2}$ *of the pairs* $\{x_i, x_j\}$ *we have* $|\langle \overrightarrow{x_i}, \overrightarrow{x_j} \rangle - d_i d_j M K^2| \geq \delta M K^2$. *Then there is an* $O(N^2 M \log^2 K)$ *algorithm that finds sets* $X' \subset X$ *with* $|X'| > \frac{\delta^7}{2}|X|$ *and* $U' \subset U$ *with* $|U'| > \delta^6 |U|$ *such that*

$$|d_\omega(X', U') - d_\omega(X', U)| > \delta^2.$$

Proof. Set $\epsilon = \delta^3$ (we will assume that $1/\epsilon$ is an integer), and partition the set X into sets X_r in the following way:

$$X_r = \{x \in X : \epsilon r K M \leq deg(x) < \epsilon(r+1) K M\} \tag{3.1}$$

for $r = 0, \ldots, \frac{1}{\epsilon} - 1$. Since at least $\delta\binom{|X|}{2}$ of the pairs $\{x_i, x_j\}$ satisfy $|\langle \overrightarrow{x_i}, \overrightarrow{x_j} \rangle - d_i d_j M K^2| \geq \delta M K^2$, we can find $x_0 \in X$ such that for at least $\frac{\delta}{2}N$ of the x_j's

$$\langle \overrightarrow{x_0}, \overrightarrow{x_j} \rangle - d_0 d_j M K^2 \geq \delta M K^2, \tag{3.2}$$

or

$$-(\langle \overrightarrow{x_0}, \overrightarrow{x_j} \rangle - d_0 d_j M K^2) \geq \delta M K^2. \tag{3.3}$$

We assume (3.2) and note that in the case of (3.3) the proof can be repeated with minor changes. Then, we can find $r \in \{0, \dots, \frac{1}{\epsilon} - 1\}$ such that for at least $\frac{\epsilon\delta}{2}N$ of x_j's in X_r, $\langle \overrightarrow{x_0}, \overrightarrow{x_j} \rangle - d_0 d_j MK^2 \geq \delta MK^2$. Set $\bar{X} = \{x_j \in X_r : \langle \overrightarrow{x_j}, \overrightarrow{x_0} \rangle \geq (d_0 d_j + \delta)MK^2\}$, and observe that $|\bar{X}| \geq \frac{\epsilon\delta}{2}N$. In addition to the partition $X = \bigcup X_r$, we compute a partition of $U = \bigcup U_s$, where

$$U_s = \{u \in U : \epsilon s K \leq \omega(x_0, u) < \epsilon(s+1)K\} \tag{3.4}$$

with $s = 0, \dots, \frac{1}{\epsilon} - 1$.

CLAIM 3.2. $\sum_{s=0}^{1/\epsilon-1} (s+1)\epsilon K |U_s| \leq (d_0 + \epsilon)MK$.

Proof.

$$\sum_{s=0}^{1/\epsilon-1} (s+1)\epsilon K |U_s| = \sum s\epsilon K |U_s| + \epsilon K \sum |U_s| \leq deg(x_0) + \epsilon MK = (d_0 + \epsilon)MK. \qquad \square$$

CLAIM 3.3. *For every* $x_j \in \bar{X}$

$$\sum_{s;|U_s|>\epsilon^2 M} (s+1)\epsilon K \sum_{u_i \in U_s} \omega(x_j, u_i) \geq (d_0 d_j + \delta - \epsilon)MK^2.$$

Proof. In view of the definition of $\bar{X}$, for every $x_j \in \bar{X}$ the following holds.

$$(d_0 d_j + \delta)MK^2 \leq \langle \overrightarrow{x_0}, \overrightarrow{x_j} \rangle \leq \sum_{s=0}^{1/\epsilon-1} (s+1)\epsilon K \sum_{u_i \in U_s} \omega(x_j, u_i)$$

$$\leq \sum_{s;|U_s|>\epsilon^2 M} (s+1)\epsilon K \sum_{u_i \in U_s} \omega(x_j, u_i) + \epsilon^3 K^2 M \sum_s (s+1)$$

$$\leq \sum_{s;|U_s|>\epsilon^2 M} (s+1)\epsilon K \sum_{u_i \in U_s} \omega(x_j, u_i) + \epsilon K^2 M. \qquad \square$$

Next, we will show the following claim.

CLAIM 3.4. *Fix* $x_{j_0} \in \bar{X}$ *(arbitrarily). Then there exists* $\bar{s} \in \{0, \dots, \frac{1}{\epsilon} - 1\}$ *such that*

(i) $|U_{\bar{s}}| \geq \epsilon^2 M$, *and*

(ii) $\sum_{u_i \in U_{\bar{s}}} \omega(x_j, u_i) \geq |U_{\bar{s}}|(d_{j_0} + \delta^2 + \epsilon)K$ *holds for at least* $\epsilon|\bar{X}|$ *of the* $x_j \in \bar{X}$.

Proof. First, we show that for every $x_j \in \bar{X}$ there is $s \in \{0, \dots, \frac{1}{\epsilon} - 1\}$ such that

$$|U_s| > \epsilon^2 M \tag{3.5}$$

and

$$\sum_{u_i \in U_s} \omega(x_j, u_i) \geq |U_s| \frac{(d_0 d_j + \delta - \epsilon)K}{d_0 + \epsilon}. \tag{3.6}$$

Indeed, assume that there exists j such that for every $|U_s| > \epsilon^2 M$ we have

$$\sum_{u_i \in U_s} \omega(x_j, u_i) < |U_s| \frac{(d_0 d_j + \delta - \epsilon)K}{d_0 + \epsilon}.$$

Then

$$\sum_{s;|U_s|>\epsilon^2 M}(s+1)\epsilon K\sum_{u_i\in U_s}\omega(x_j,u_i)<\sum_s(s+1)\epsilon K|U_s|\frac{(d_0d_j+\delta-\epsilon)K}{d_0+\epsilon},$$

which by Claim 3.2 is less than or equal to $(d_0d_j+\delta-\epsilon)MK^2$. This, however, contradicts Claim 3.3.

Since $\epsilon=\delta^3$ and $\delta\le\frac{1}{3}$, one can further simplify the right-hand side of (3.6) to infer that for every $x_j\in\bar{X}$ there exists s such that

$$|U_s|>\epsilon^2M$$

and

$$\sum_{u_i\in U_s}\omega(x_j,u_i)\ge|U_s|K(d_j+\delta^2+2\epsilon). \tag{3.7}$$

It follows from the definition of X_r that for every $x_{j_1},x_{j_2}\in\bar{X}$, $|d_{j_1}-d_{j_2}|\le\epsilon$, which implies that

$$\sum_{u_i\in U_s}\omega(x_j,u_i)\ge|U_s|(d_{j_0}+\delta^2+\epsilon)K, \tag{3.8}$$

if x_{j_0} is chosen arbitrarily from $\bar{X}$. Therefore, for every $x_{j_0}\in\bar{X}$ and every $x_j\in\bar{X}$ there is an $s\in\{0,\dots,\frac{1}{\epsilon}-1\}$ such that

$$|U_s|>\epsilon^2M$$

and

$$\sum_{u_i\in U_s}\omega(x_j,u_i)\ge|U_s|(d_{j_0}+\delta^2+\epsilon)K.$$

In order to prove (i) and (ii) we need to "reverse" the quantifiers of j and s. We know that for every j there is a "big" set U_s such that (3.8) holds. Since there are at most $\frac{1}{\epsilon}$ choices of s, there exists $\bar{s}\in\{0,\dots,\frac{1}{\epsilon}-1\}$ such that $U_{\bar{s}}$ is "big" and for at least $\epsilon|\bar{X}|$ of the x_j's (3.8) holds. More precisely, there exists $\bar{s}\in\{0,\dots,\frac{1}{\epsilon}-1\}$ such that

(i) $|U_{\bar{s}}|\ge\epsilon^2M$, and

(ii) $\sum_{u_i\in U_{\bar{s}}}\omega(x_j,u_i)\ge|U_{\bar{s}}|(d_{j_0}+\delta^2+\epsilon)K$ holds for at least $\epsilon|\bar{X}|$ of the $x_j\in\bar{X}$,

which proves the claim. □

Let $U'=U_{\bar{s}}$, and let X' be the set of those $\epsilon|\bar{X}|$ vertices from $\bar{X}$ that satisfy (3.8). Observe that $|U'|\ge\delta^6|U|$ and $|X'|\ge\frac{\delta^7}{2}|X|$. We have

$$d_\omega(X',U')=\frac{\sum_{x_j\in X',u_i\in U'}\omega(x_j,u_i)}{K|X'||U'|}\ge\frac{|U'||X'|(d_{j_0}+\delta^2+\epsilon)K}{K|X'||U'|}=(d_{j_0}+\delta^2+\epsilon)$$

and

$$d_\omega(X',U)=\frac{\sum_{x\in X'}deg(x)}{K|X'||U|}\le\frac{|X'|(deg(x_{j_0})+\epsilon KM)}{K|X'||U|}=d_{j_0}+\epsilon.$$

Therefore,

$$d_\omega(X',U')-d_\omega(X',U)\ge(d_{j_0}+\delta^2+\epsilon)-d_{j_0}-\epsilon=\delta^2. \tag{3.9}$$

The above proof gives an efficient algorithm: First compute scalar products to find x_0 and partitions of X and U. Then check all sets U_s to find one that satisfies Claim 3.4. The main computational task is to compute $O(N^2)$ scalar products $\langle \overrightarrow{x_i}, \overrightarrow{x_j} \rangle = \sum_{l=1}^{M} \omega(x_i, u_l)\omega(x_j, u_l)$. Since $\omega(x_j, u_l) < K$, the multiplication $\omega(x_i, u_l)\omega(x_j, u_l)$ can be done in $O(\log^2 K)$ time. Thus the total number of steps is $O(N^2 M \log^2 K)$. ∎

4. Finding a witness of irregularity in a weighted bipartite graph. Let $G = (X, Y, \omega)$ be a bipartite graph with nonnegative weights on edges $\omega(x, y) < K$. In this section, we will show how to find $X' \subset X$ and $Y' \subset Y$ such that

$$|d_\omega(X', Y') - d_\omega(X, Y)| > \delta^2.$$

Unlike in the previous section neither X nor Y will be products of other sets. Note that the algorithm of this section is a generalization of the algorithm of [1] to weighted graphs. Let $M = |X| = |Y|$ and let $d = d_\omega(X, Y)$. We first observe the following fact.

FACT 4.1. *For $\rho \in (0, 1)$, let $X^* = \{x \in X : |deg(x) - dMK| \geq \rho MK\}$. If $|X^*| \geq \rho M$, then there is $X^{**} \subset X^*$ with $|X^{**}| \geq \frac{\rho}{2} M$ such that*

$$|d_\omega(X^{**}, Y) - d_\omega(X, Y)| \geq \rho.$$

Proof. Let $X^{**} = \{x \in X^* : deg(x) - dMK \geq \rho MK\}$. Without loss of generality we can assume that $|X^{**}| \geq \frac{|X^*|}{2}$. Then,

$$d_\omega(X^{**}, Y) - d_\omega(X, Y) = \frac{\sum_{x \in X^{**}} deg(x) - d|X^{**}|MK}{|X^{**}|MK} \geq \rho. \qquad \blacksquare$$

LEMMA 4.2. *For $\epsilon, \delta \in (0, 1)$, $\delta^2 < \epsilon$, $M \geq \frac{1}{\delta}$, let $X^* = \{x \in X : |deg(x) - dMK| > \delta^2 MK\}$. If both of the following conditions are satisfied*

1. *$|X^*| < \delta^2 M$,*
2. *for all but at most $\delta \binom{M}{2}$ of the pairs $\{x_i, x_j\}$ of vertices from X, $|\langle \overrightarrow{x_i}, \overrightarrow{x_j} \rangle - d^2 K^2 M| < \delta K^2 M$,*

then for every $X' \subset X$ with $|X'| \geq \epsilon M$ and every $Y' \subset Y$ with $|Y'| \geq \epsilon M$ we have

$$|d_\omega(X', Y') - d_\omega(X, Y)| \leq 2\frac{\delta^2}{\epsilon} + \frac{\sqrt{5\delta}}{\epsilon^2 - \epsilon\delta^2}.$$

Proof. Fix $X' \subset X$ and $Y' \subset Y$ with $|X'| \geq \epsilon|X|$ and $|Y'| \geq \epsilon|Y|$. Let $X'' = X' \setminus X^*$. Note that $|X''| > (1 - \frac{\delta^2}{\epsilon})|X'|$. Without loss of generality, we can assume that $X'' = \{x_1, \ldots, x_m\}$ and $Y' = \{y_1, \ldots, y_n\}$. For $i = 1, \ldots, m$, we consider vectors $\overrightarrow{a_i} = \overrightarrow{x_i} - (dK, \ldots, dK)$ and hence $\overrightarrow{a_i} = (a_{i1}, \ldots, a_{iM})$, where

$$a_{ij} = \omega(x_i, y_j) - dK. \tag{4.1}$$

Then, due to the fact that

$$||\overrightarrow{a_1} + \cdots + \overrightarrow{a_m}||^2 = \sum_{i=1}^{m} ||\overrightarrow{a_i}||^2 + \sum_{i \neq j} \langle \overrightarrow{a_i}, \overrightarrow{a_j} \rangle$$

and from the form of a_i's, we see that

$$\langle \overrightarrow{a_i}, \overrightarrow{a_j} \rangle = \langle \overrightarrow{x_i}, \overrightarrow{x_j} \rangle - dK \sum_{l=1}^{M} \omega(x_i, y_l) - dK \sum_{l=1}^{M} \omega(x_j, y_l) + d^2K^2M$$

$$\leq \langle \overrightarrow{x_i}, \overrightarrow{x_j} \rangle - 2dK(dKM - \delta^2 KM) + d^2K^2M \leq \langle \overrightarrow{x_i}, \overrightarrow{x_j} \rangle + 2\delta^2 dK^2M - d^2K^2M.$$

Therefore, for all but at most $\delta\binom{M}{2}$ of $\{x_i, x_j\}$

$$\langle \overrightarrow{a_i}, \overrightarrow{a_j} \rangle \leq \delta K^2 M + 2\delta^2 dK^2 M \leq 3\delta K^2 M$$

and always

$$\langle \overrightarrow{a_i}, \overrightarrow{a_j} \rangle \leq K^2 M.$$

We infer that

$$||\overrightarrow{a_1} + \cdots + \overrightarrow{a_m}||^2 \leq \sum_{i=1}^{m} ||\overrightarrow{a_i}||^2 + 3\delta K^2 M^3 + \delta K^2 M^3$$

$$\leq K^2M^2 + 4\delta K^2 M^3 \leq 5\delta K^2 M^3,$$

as $M \geq 1/\delta$. On the other hand, we have $||\overrightarrow{a_1} + \cdots + \overrightarrow{a_m}||^2 = \xi_1^2 + \cdots + \xi_M^2$, where $\xi_i = a_{1i} + \cdots + a_{mi}$. Then $\xi_1^2 + \cdots + {\xi_M}^2 \geq \xi_1^2 + \cdots + \xi_n^2 \geq \frac{1}{n}(\xi_1 + \cdots + \xi_n)^2$, which implies

$$(\xi_1 + \cdots + \xi_n)^2 \leq 5\delta K^2 M^3 n \leq 5\delta K^2 M^4.$$

We infer that

$$|\xi_1 + \cdots + \xi_n| \leq \sqrt{5\delta} K M^2, \tag{4.2}$$

and by (4.1) we can write (4.2) as follows:

$$\left| \sum_{x \in X'', y \in Y'} \omega(x, y) - |X''||Y'|dK \right| \leq \sqrt{5\delta} K M^2.$$

Therefore,

$$|d_\omega(X'', Y') - d| \leq \frac{\sqrt{5\delta} M^2}{|X''||Y'|},$$

and, since $|X''| \geq (1 - \frac{\delta^2}{\epsilon})|X'|$, we infer by continuity of density (Fact 2.1) that

$$|d_\omega(X', Y') - d| \leq |d_\omega(X'', Y') - d| + |d_\omega(X'', Y') - d_\omega(X', Y')|$$

$$\leq 2\frac{\delta^2}{\epsilon} + \frac{\sqrt{5\delta} M^2}{|X''||Y'|}. \tag{4.3}$$

Now, since $|Y'| \geq \epsilon M$ and $|X''| \geq (1-\frac{\delta^2}{\epsilon})\epsilon M$, we can further estimate the right-hand side of (4.3) to obtain

$$|d_\omega(X',Y') - d| \leq 2\frac{\delta^2}{\epsilon} + \frac{\sqrt{5\delta}}{\epsilon^2 - \epsilon\delta^2}. \qquad \square$$

THEOREM 4.3. *Let $G = (X, Y, \omega)$ be a weighted bipartite graph with $M = |X| = |Y|$ and $0 \leq \omega(x,y) < K$. For $\epsilon < 1/10$ and $\delta = \epsilon^7$, if $M > \frac{1}{\delta}$, then there exists an $O(M^3 \log^2 K)$ algorithm such that if (X,Y) is (ϵ,ω)-irregular, then it finds $X' \subset X$, with $|X'| > \delta^4|X|$ and $Y' \subset Y$, with $|Y'| > \delta^4|Y|$ such that*

$$|d_\omega(X',Y') - d_\omega(X,Y)| > \delta^2.$$

Proof. First observe that due to the assumptions about δ and ϵ, $2\frac{\delta^2}{\epsilon} + \frac{\sqrt{5\delta}}{\epsilon^2-\epsilon\delta^2} \leq \epsilon$. Since (X,Y) is (ϵ,ω)-irregular, we can infer from Lemma 4.2 that either

(i) $|X^*| \geq \delta^2 M$, or

(ii) for at least $\delta\binom{M}{2}$ pairs $\{x_i, x_j\}$, $|\langle \overrightarrow{x_i}, \overrightarrow{x_j}\rangle - d^2K^2M| \geq \delta K^2 M$.

In case (i), set $X' = X^{**}$ from Fact 4.1, and $Y' = Y$. Then, by Fact 4.1,

$$|d_\omega(X',Y') - d_\omega(X,Y)| \geq \delta^2.$$

Observe that constructing the set X^{**} requires computing the degrees of $x_j \in X$ which can be done in $O(M^2 \log K)$ time. Hence, in this case we are done. Next, we will show how to construct the witness sets X' and Y' if (ii) holds while (i) is false. Assume that for at least $\delta\binom{M}{2}$ of pairs $\{x_i, x_j\}$, $|\langle \overrightarrow{x_i}, \overrightarrow{x_j}\rangle - d^2K^2M| > \delta K^2 M$ and that $|X^*| < \delta^2 M$. Then for at least $(\delta - 2\delta^2)\binom{M}{2}$ of pairs $\{x_i, x_j\}$, where $x_i, x_j \in X \setminus X^*$, we have $|\langle \overrightarrow{x_i}, \overrightarrow{x_j}\rangle - d^2K^2M| > \delta K^2 M$. Therefore, we can find $x_0 \in X \setminus X^*$ such that for at least $\frac{\delta - 2\delta^2}{2} M$ of $x_j \in X$, either

$$\langle \overrightarrow{x_0}, \overrightarrow{x_j}\rangle - d^2K^2M > \delta K^2 M, \tag{4.4}$$

or

$$-(\langle \overrightarrow{x_0}, \overrightarrow{x_j}\rangle - d^2K^2M) > \delta K^2 M. \tag{4.5}$$

We assume (4.4) and set $\rho = \delta^2$. Let $\bar{X} = \{x_j \in X \setminus X^* : \langle \overrightarrow{x_0}, \overrightarrow{x_j}\rangle - d^2K^2M > \delta K^2 M\}$. We partition the set Y as follows:

$$Y_s = \{y \in Y : s\rho K \leq \omega(x_0, y) \leq (s+1)\rho K\}, \tag{4.6}$$

where $s = 0, \ldots, \frac{1}{\rho} - 1$.

FACT 4.4.

1. $\sum_{s=0}^{1/\rho-1}(s+1)\rho K|Y_s| \leq (d+2\rho)KM$.
2. *For every $x_j \in \bar{X}$*

$$\sum_{s;|Y_s|\geq\rho^2 M} (s+1)\rho K \sum_{y\in Y_s} \omega(x_j, y) \geq (d^2 + \delta - \rho)K^2 M. \tag{4.7}$$

Proof. From (4.6) and the fact that for any $x_0 \in X \setminus X^*$, $deg(x_0) \leq (d+\rho)KM$ we infer that

$$\sum_{s=0}^{1/\rho-1} (s+1)\rho K|Y_s| = \sum s\rho K|Y_s| + \rho K \sum |Y_s| \leq deg(x_0) + \rho KM \leq dKM + 2\rho KM,$$

which shows the first part. To prove the second part, we observe that

$$\langle \overrightarrow{x_0}, \overrightarrow{x_j} \rangle = \sum_{y \in Y} \omega(x_0, y)\omega(x_j, y) \leq \sum_{s=0}^{1/\rho - 1} (s+1)\rho K \sum_{y \in Y_s} \omega(x_j, y)$$

$$\leq \sum_{s; |Y_s| \geq \rho^2 M} (s+1)\rho K \sum_{y \in Y_s} \omega(x_j, y) + \rho^3 M K^2 \sum (s+1)$$

$$\leq \sum_{s; |Y_s| \geq \rho^2 M} (s+1)\rho K \sum_{y \in Y_s} \omega(x_j, y) + \rho M K^2. \tag{4.8}$$

Comparing (4.4) and (4.8), we infer the inequality (4.7). □

We will first show that for every $x_j \in \bar{X}$ there is s such that

$$|Y_s| \geq \rho^2 M \tag{4.9}$$

and

$$\sum_{y \in Y_s} \omega(x_j, y) \geq |Y_s| \frac{(d^2 + \delta - \rho)K}{(d + 2\rho)}. \tag{4.10}$$

Indeed, assume that there exists j such that for every s such that $|Y_s| \geq \rho^2 M$ we have $\sum_{y \in Y_s} \omega(x_j, y) < |Y_s| \frac{(d^2+\delta-\rho)K}{(d+2\rho)}$. Then averaging over all "big" Y_s we see that

$$\sum_{s; |Y_s| \geq \rho^2 M} (s+1)K\rho \sum_{y \in Y_s} \omega(x_j, y) < \sum_{s; |Y_s| \geq \rho^2 M} (s+1)\rho K |Y_s| \frac{(d^2 + \delta - \rho)K}{(d + 2\rho)},$$

which by Fact 4.4 part (1) is less than or equal to $(d^2 + \delta - \rho)K^2 M$. This however contradicts part (2) of Fact 4.4.

Since $\delta = \epsilon^7 < 1/10^7$, the right-hand side of (4.10) can be simplified:

$$\sum_{y \in Y_s} \omega(x_j, y) \geq |Y_s| K \left(d + \frac{\delta}{2} \right). \tag{4.11}$$

Thus for every $x_j \in \bar{X}$ there is $s \in \{0, \ldots, \frac{1}{\rho} - 1\}$ such that $|Y_s| \geq \rho^2 M$ and (4.11) holds. Similarly as in section 3 we use the simple pigeonhole principle to "reverse" the quantifiers of j and s to obtain the existence of $\bar{s} \in \{0, \ldots, \frac{1}{\rho} - 1\}$ that satisfies

(i) $|Y_{\bar{s}}| \geq \rho^2 M$ and

(ii) for at least $\rho|\bar{X}|$ of x_j's from $\bar{X}$, $\sum_{y \in Y_{\bar{s}}} \omega(x_j, y) \geq |Y_{\bar{s}}| K(d + \frac{\delta}{2})$.

Let $Y' = Y_{\bar{s}}$ and let X' be the set of those x_j's that satisfy (ii). Then

$$d_\omega(X', Y') - d = \frac{\sum_{y \in Y', x_j \in X'} \omega(x_j, y)}{K|X'||Y'|} - d \geq \frac{|X'||Y_{\bar{s}}| K(d + \frac{\delta}{2})}{K|X'||Y'|} - d = \frac{\delta}{2} > \delta^2.$$

In order to construct X' and Y' we must compute the scalar products to check (4.4), compute the partition (4.6), and check condition (ii). Since $\omega(x_j, y) < K$ this can be done in $O(M^3 \log^2 K)$ time. □

5. The main algorithm. In this section, we will describe the main algorithm which finds a refinement of an (ϵ,ω)-irregular partition such that the value of the index of the refined partition is closer to one. Let us first outline the idea in the case $l=3$. For each (ϵ,ω)-irregular triple (V_1,V_2,V_3) we either find (using the algorithm from Theorem 3.1) $V_1'\subset V_1$ and $X'\subset V_2\times V_3$ such that

$$|d_{\omega_1}(X',V_1')-d_{\omega_1}(X',V_1)|\geq\delta_1,$$

or using the algorithm from Theorem 4.3, we find $V_2'\subset V_2$ and $V_3'\subset V_3$ such that

$$|d_{\omega_2}(V_2',V_3')-d_{\omega_2}(V_2,V_3)|\geq\delta_2,$$

where ω_1, ω_2, δ_1, δ_2 are defined below. In the first case, only V_1' is used to refine a given partition; in the second case both V_2' and V_3' are used. Let (V,H,ω) be an l-uniform weighted hypergraph with $K=\max|\omega(v_1,v_2,\dots,v_l)|+1$. We introduce some additional notation: For an l-tuple $(V_1,\dots,V_l)$

$$\omega_1(v_1,\dots,v_l)=\omega(v_1,\dots,v_l),\qquad K_1=K,$$

$$\omega_2(v_2,\dots,v_l)=\sum_{v_1\in V_1}\omega_1(v_1,v_2,\dots,v_l),\qquad K_2=|V_1|K_1.$$

In general,

$$\omega_i(v_i,\dots,v_l)=\sum_{v_{i-1}\in V_{i-1}}\omega_{i-1}(v_{i-1},v_i,\dots,v_l),\qquad K_i=|V_{i-1}|K_{i-1}. \tag{5.1}$$

Also, we set

$$\epsilon_k=\frac{\epsilon}{2^{k-1}}$$

and

$$\delta_i=\frac{1}{48}\epsilon_i^{2(l-i+1)+1}.$$

Also, set $X_k=V_{k+1}\times\cdots\times V_l$. Note that for every $i\in[l]$,

$$\delta_i\geq\frac{1}{48}\frac{\epsilon^{2l+1}}{2^{(2l+1)(l-1)}}. \tag{5.2}$$

We can now describe the procedure that "improves" a given partition P. For each (ϵ_1,ω_1)-irregular l-tuple, $(V_1,\dots,V_l)$ consider the weighted bipartite graph (V_1,X_1,ω_1), where $X_1=V_2\times\cdots\times V_l$ and for $x=(v_2,\dots,v_l)$, $\omega_1(v,x)=\omega_1(v,v_2,\cdots,v_l)$. Set $M=|V_1|$ and $N=|X_1|$. The algorithm is illustrated in Figure 5.1: Lemma 2.5 implies that if $(V_1,\dots,V_l)$ is (ϵ_1,ω_1)-irregular, then either (X_1,V_1) is vector irregular and for at least $\delta_1\binom{N}{2}$ of pairs $\{x_i,x_j\}$ of vertices in X_1

$$|\langle\overrightarrow{x_i},\overrightarrow{x_j}\rangle-K_1^2Md_id_j|>\delta_1K_1^2M, \tag{5.3}$$

or the $(l-1)$-tuple $(V_2,\dots,V_l)$ is (ϵ_2,ω_2)-irregular. If (5.3) holds, then we can use the algorithm from Theorem 3.1 to find $X_1'\subset X_1$ with $|X_1'|\geq\frac{\delta_1^7}{2}|X_1|$ and $V_1'\subset V_1$ with $|V_1'|\geq\delta_1^6|V_1|$ such that

$$|d_{\omega_1}(X_1',V_1')-d_{\omega_1}(X_1',V_1)|>\delta_1^2. \tag{5.4}$$

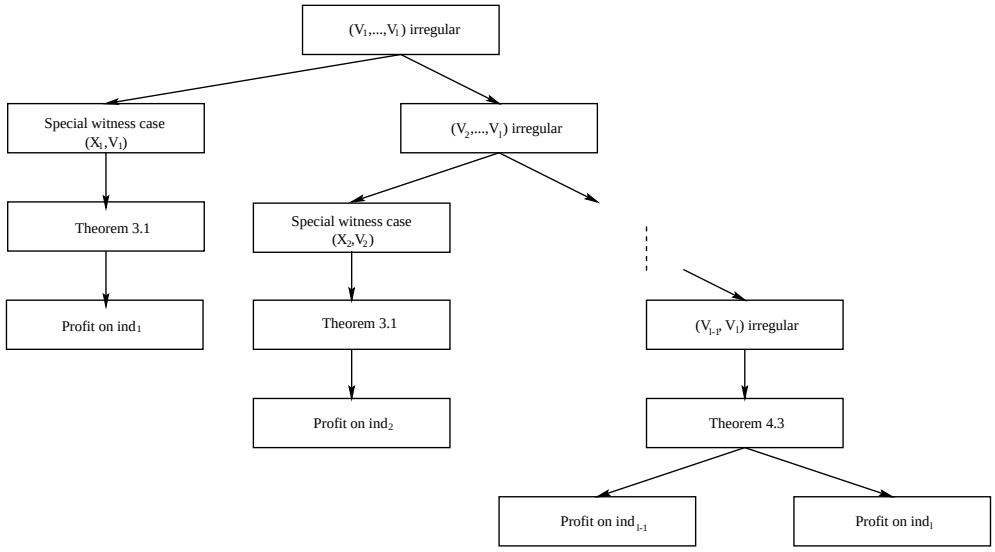

FIG. 5.1. *Proof of Theorem* 1.1.

Note that X_1' will not be used as a witness when improving the partition P; only V_1' will. In case (5.3) does not hold, we continue to apply Lemma 2.5 to the $(l-i)$- tuples $(V_i, \dots, V_l)$ until $i = l-2$. Finally, if we haven't found a witness set so far, we apply Theorem 4.3 to the pair (V_{l-1}, V_l); in this case we find two subsets $V_{l-1}' \subset V_{l-1}$ and $V_l' \subset V_l$ with $|V_{l-1}'| \geq \delta_{l-1}^4 |V_{l-1}|$ and $|V_l'| \geq \delta_{l-1}^4 |V_l|$ such that

$$|d_{\omega_{l-1}}(V_{l-1}', V_l') - d_{\omega_{l-1}}(V_{l-1}, V_l)| > \delta_{l-1}^2.$$

Both V_{l-1}' and V_l' will be used as witness sets to improve P. More precisely, the following algorithm can be used to improve the partition P.

Algorithm Improve

1. For every l-tuple $(V_1, \dots, V_l)$ in the partition P do:

2. For $i = 1$ to $l-2$ successively

3. Apply the procedure from Theorem 3.1 to search for $X_i' \subset X_i = V_{i+1} \times \cdots \times V_l$ and $V_i' \subset V_i$ such that

$$|d_{\omega_i}(X_i', V_i') - d_{\omega_i}(X_i', V_i)| > \delta_i^2. \tag{5.5}$$

4. If (5.5) is satisfied for some $i \leq l-2$, then V_i' is a witness set and we move to the next l-tuple.

5. If there is no $i \leq l-2$ for which (5.5) holds, then we apply the procedure from Theorem 4.3 to search for $V_{l-1}' \subset V_{l-1}$ and $V_l' \subset V_l$ such that

$$|d_{\omega_{l-1}}(V_{l-1}', V_l') - d_{\omega_{l-1}}(V_{l-1}, V_l)| > \delta_{l-1}^2. \tag{5.6}$$

6. In the case of (5.6), both V_{l-1}' and V_l' are witness sets for the l-tuple.

7. If the number of l-tuples for which witness sets were found is at least ϵt^l, then compute a subpartition P' (described below) of P that respects all the witness sets found in steps 3 and 5. Otherwise the partition P is (ϵ, ω)-regular.

Let us conclude this section with the following fact which shows what sets were found by the algorithm **Improve**.

FACT 5.1. *If an l-tuple $(V_1,\dots,V_l)$ is (ϵ,ω)-irregular, then* **Improve** *either finds $X_k'\subset X_k$ and $V_k'\subset V_k$ with $|X_k'|\geq\frac{\delta_k^7}{2}|X_k|$ and $|V_k'|\geq\delta_k^6|V_k|$ such that* (5.5) *holds for some $1\leq k\leq l-2$, or it finds $V_{l-1}'\subset V_{l-1}$ and $V_l'\subset V_l$ with $|V_{l-1}'|\geq\delta_{l-1}^4|V_{l-1}|$ and $|V_l'|\geq\delta_l^4|V_l|$ such that* (5.6) *holds.*

Proof. For every $k=1,\dots,l-2$, Lemma 2.5 implies that if an $(l-k+1)$-tuple $(V_k,\dots,V_l)$ is (ϵ_k,ω_k)-irregular, then either the $(l-k)$-tuple $(V_{k+1},\dots,V_l)$ is $(\epsilon_{k+1},\omega_{k+1})$-irregular or at least $\delta_k|X_k|^2$ of the pairs $\{x_i,x_j\}$ of vertices from X_k satisfy

$$|\langle\overrightarrow{x_i},\overrightarrow{x_j}\rangle-K_k^2Md_id_j|>\delta_kK_k^2M. \tag{5.7}$$

If (5.7) is satisfied, then the algorithm of Theorem 3.1 finds $X_k'\subset X_k$ and $V_k'\subset V_k$ such that (5.5) holds. If (5.7) does not hold for any $1\leq k\leq l-2$, then a pair (V_{l-1},V_l) is $(\epsilon_{l-1},\omega_{l-1})$-irregular and the algorithm of Theorem 4.3 finds $V_{l-1}'\subset V_{l-1}$ and $V_l'\subset V_l$ such that (5.6) holds. □

6. The analysis of the main algorithm. In this section, we will analyze the algorithm **Improve**. Although a little bit technical, the philosophy of the analysis is the same as the Szemerédi's proof of the regularity lemma [12]. We will show that for a subpartition P' computed by the algorithm the value of the index $ind(P')$ is bigger than the value of the index of the original partition $ind(P)$. In addition, we will show that the size of the exceptional class does not increase in any significant way. The proof is divided into five rather technical facts. In Fact 6.1, we will show that the size of the exceptional class does not increase too much. Fact 6.2 shows that the value of the index associated with each (ϵ,ω)-regular l-tuple will remain about the same after the refinement of the original partition. In Fact 6.3, we will show that we get a "profit" on the index if an (ϵ,ω)-irregular l-tuple is reduced to the vector irregularity. Fact 6.4 shows that the index will increase in case an (ϵ,ω)-irregular l-tuple is reduced to the irregularity of the weighted bipartite graph. Lemma 6.5 combines Fact 6.3 and Fact 6.4 to show that the value of the index of the refined partition is greater than the value of the original one.

Similarly as in the original proof of the regularity lemma [12], we consider a subpartition P' of P into atoms of size

$$m=\left\lfloor\frac{|V_i|}{2^{2t^l}}\right\rfloor$$

that respects the Venn diagram of witness sets found for each (ϵ,ω)-irregular l-tuple. For $j=1,\dots,p$, denote by $W_i(j)$ the jth atom in V_i (that is, the jth subset in the partition of V_i), and let

$$\bar{V_i}=\bigcup_{j=1}^{p}W_i(j).$$

Observe that for every i

$$||\bar{V_i}|-|V_i||\leq\frac{|V_i|}{2^{t^l}}. \tag{6.1}$$

We first observe the following fact.

FACT 6.1. *The size of the exceptional class V_0' increases by at most $\frac{n}{2^{t^l}}$ from the size of V_0.*

Proof. Indeed, there are at most 2^{t^l} equivalence classes of atoms and so in the process of refining P we increase $|V_0|$ by at most

$$t2^{t^l}\frac{|V_i|}{2^{2t^l}} \le \frac{n}{2^{t^l}}. \qquad \square$$

FACT 6.2. *For every l-tuple $(V_1,\dots,V_l)$ and every $i \in [l]$*

$$\frac{1}{p^i}\sum_{j_1,\dots,j_i}\sum_{x\in\bar{V}_{i+1}\times\cdots\times\bar{V}_l}\frac{(d_\omega(x,W_1(j_1),\dots,W_i(j_i)))^2}{|\bar{V}_{i+1}|\dots|\bar{V}_l|} \ge ind_i(V_1,\dots,V_l)-\frac{3l}{2^{t^l}}.$$

Proof. For every $x \in V_{i+1}\times\cdots\times V_l$,

$$\frac{1}{p^i}\sum_{j_1,\dots,j_i}(d_\omega(x,W_1(j_1),\dots,W_i(j_i)))^2 \ge \left(\frac{1}{p^i}\sum_{j_1,\dots,j_i} d_\omega(x,W_1(j_1),\dots,W_i(j_i))\right)^2$$

$$= (d_\omega(x,\bar{V}_1,\dots,\bar{V}_i))^2.$$

Since $|\bar{V}_i| \ge (1-\frac{1}{2^{t^l}})|V_i|$, by the continuity of density (Fact 2.1) we have

$$(d_\omega(x,\bar{V}_1,\dots,\bar{V}_i))^2 \ge (d_\omega(x,V_1,\dots,V_i))^2-\frac{2l}{2^{t^l}}, \tag{6.2}$$

and so

$$\frac{1}{p^i}\sum_{j_1,\dots,j_i}\sum_{x\in\bar{V}_{i+1}\times\cdots\times\bar{V}_l}\frac{(d_\omega(x,W_1(j_1),\dots,W_i(j_i)))^2}{|\bar{V}_{i+1}|\dots|\bar{V}_l|}$$

$$\ge \sum_{x\in\bar{V}_{i+1}\times\cdots\times\bar{V}_l}\frac{(d_\omega(x,V_1,\dots,V_i))^2-\frac{2l}{2^{t^l}}}{|\bar{V}_{i+1}|\dots|\bar{V}_l|}$$

$$\ge \sum_{x\in\bar{V}_{i+1}\times\cdots\times\bar{V}_l}\frac{(d_\omega(x,V_1,\dots,V_i))^2}{|V_{i+1}|\dots|V_l|}-\frac{2l}{2^{t^l}}. \tag{6.3}$$

Using (6.1) and the fact that $d_\omega(x,V_1,\dots,V_i)\le 1$,

$$\sum_{x\in V_{i+1}\times\cdots\times V_l}(d_\omega(x,V_1,\dots,V_i))^2-\sum_{x\in\bar{V}_{i+1}\times\cdots\times\bar{V}_l}(d_\omega(x,V_1,\dots,V_i))^2$$

$$\le \sum_{k=i+1}^{l}\sum\{(d_\omega(x,V_1,\dots,V_i))^2, x\in V_{i+1}\times\cdots\times V_{k-1}\times(V_k\setminus\bar{V}_k)\times V_{k+1}\times\cdots\times V_l\}$$

$$\le \frac{l}{2^{t^l}}|V_{i+1}|\dots|V_l|. \tag{6.4}$$

By (6.3) and (6.4),

$$\frac{1}{p^i}\sum_{j_1,\dots,j_i}\sum_{x\in\bar{V}_{i+1}\times\cdots\times\bar{V}_l}\frac{(d_\omega(x,W_1(j_1),\dots,W_i(j_i)))^2}{|\bar{V}_{i+1}|\dots|\bar{V}_l|}$$

$$\geq\sum_{x\in V_{i+1}\times\cdots\times V_l}\frac{(d_\omega(x,V_1,\dots,V_i))^2}{|V_{i+1}|\dots|V_l|}-\frac{3l}{2^{t^l}}$$

$$=ind_i(V_1,\dots,V_l)-\frac{3l}{2^{t^l}}.\qquad\square$$

Suppose that an l-tuple $(V_1,\dots,V_l)$ is (ϵ,ω)-irregular and that for some $1\leq i\leq l-2$, we found two sets $V_i'\subset V_i$ with $|V_i'|>\delta_i^6|V_i|$ and $X_i'\subset X_i$ with $|X_i'|>\frac{\delta_i^7}{2}|X_i|$ such that

$$|d_{\omega_i}(X_i',V_i')-d_{\omega_i}(X_i',V_i)|>\delta_i^2. \tag{6.5}$$

Then we have the following fact.

FACT 6.3. *Assume that an l-tuple $(V_1,\dots,V_l)$ is (ϵ,ω)-irregular and for some $1\leq i\leq l-1$, we found two sets $V_i'\subset V_i$ with $|V_i'|>\delta_i^6|V_i|$ and $X_i'\subset X_i$ with $|X_i'|>\frac{\delta_i^7}{2}|X_i|$ such that $|d_{\omega_i}(X_i',V_i')-d_{\omega_i}(X_i',V_i)|>\delta_i^2$. If $\delta_i^8\geq\frac{l}{2^{t^l-2}}$, then*

$$\frac{1}{p^i}\sum_{j_1,\dots,j_i}\sum_{x\in\bar{V}_{i+1}\times\cdots\times\bar{V}_l}\frac{(d_\omega(x,W_1(j_1),\dots,W_i(j_i)))^2}{|\bar{V}_{i+1}|\dots|\bar{V}_l|}$$

$$\geq ind_i(V_1,\dots,V_l)+\frac{\delta_i^{17}}{8(1-\delta_i^6)}-\frac{4l}{2^{t^l}}.$$

Proof. First observe that for $Z\subset X_i=V_{i+1}\times\cdots\times V_l$, $Y\subset V_i$

$$d_{\omega_i}(Z,Y)=\frac{\sum_{z\in Z,y\in Y}\omega_i(y,z)}{K_i|Z||Y|}=\frac{1}{|Z|}\sum_{z\in Z}\frac{\sum_{y\in Y}\sum_{v_1,\dots,v_{i-1}}\omega(v_1,\dots,v_{i-1},y,z)}{K|V_1|\dots|V_{i-1}||Y|}$$

$$=\frac{1}{|Z|}\sum_{z\in Z}d_\omega(z,V_1,\dots,V_{i-1},Y). \tag{6.6}$$

We may assume that for the witness V_i',

$$\bar{V}_i'=\bigcup_{j_i=1}^{q}W_i(j_i).$$

Then

$$||V_i'|-|\bar{V}_i'||\leq\frac{|V_i'|}{2^{t^l}\delta_i^6}.$$

For every $x \in X_i$, define

$$\alpha_x = \frac{1}{p^i} \sum_{j_1,\ldots,j_i \in [p]} d_\omega(x, W_1(j_1), \ldots, W_i(j_i))$$

$$-\frac{1}{qp^{i-1}} \sum_{j_1\ldots,j_{i-1}\in[p]} \sum_{j_i\in[q]} d_\omega(x, W_1(j_1), \ldots, W_i(j_i)).$$

Observe that

$$\sum_{j_1\ldots,j_{i-1}\in[p]} \sum_{j_i\in[q]} d_\omega(x, W_1(j_1), \ldots, W_i(j_i))$$

$$= \frac{q}{p} \sum_{j_1,\ldots,j_i\in[p]} d_\omega(x, W_1(j_1), \ldots, W_i(j_i)) - qp^{i-1}\alpha_x,$$

and using the defect form of Schwarz inequality (Fact 2.2), we infer that

$$\frac{1}{p^i} \sum_{j_1,\ldots,j_i} (d_\omega(x, W_1(j_1), \ldots, W_i(j_i)))^2$$

$$\geq \left(\frac{1}{p^i} \sum_{j_1\ldots,j_i} d_\omega(x, W_1(j_1), \ldots, W_i(j_i))\right)^2 + \frac{(\alpha_x qp^{i-1})^2 p^i}{p^i qp^{i-1}(p^i - qp^{i-1})}$$

$$= (d_\omega(x, \bar{V}_1, \ldots, \bar{V}_i))^2 + \frac{\alpha_x^2 q}{p-q},$$

due to the fact that $\sum_{j_1,\ldots,j_i} d_\omega(x, W_1(j_1), \ldots, W_i(j_i)) = d_\omega(x, \bar{V}_1, \ldots, \bar{V}_i)$ and since $q \geq \delta_i^6 p$, we have

$$\frac{1}{p^i} \sum_{j_1,\ldots,j_i} (d_\omega(x, W_1(j_1), \ldots, W_i(j_i)))^2 \geq (d_\omega(x, \bar{V}_1, \ldots, \bar{V}_i))^2 + \alpha_x^2 \frac{\delta_i^6}{1-\delta_i^6}. \tag{6.7}$$

Since $|\bar{V}_i| \geq (1 - \frac{1}{2^{t^l}})|V_i|$ and $|\bar{V}_i'| \geq (1 - \frac{1}{2^{t^l}\delta_i^6})|V_i'|$, by the continuity of density (Fact 2.1), we have

$$d_\omega(x, V_1, \ldots, V_i) - d_\omega(x, V_1, \ldots, V_{i-1}, V_i') \leq d_\omega(x, \bar{V}_1, \ldots, \bar{V}_i) - d_\omega(x, \bar{V}_1, \ldots, \bar{V}_{i-1}, \bar{V}_i')$$

$$+|d_\omega(x, V_1, \ldots, V_i) - d_\omega(x, \bar{V}_1, \ldots, \bar{V}_i)| + |d_\omega(x, \bar{V}_1, \ldots, \bar{V}_{i-1}, \bar{V}_i') - d_\omega(x, V_1, \ldots, V_{i-1}, V_i')|$$

$$\leq d_\omega(x, \bar{V}_1, \ldots, \bar{V}_i) - d_\omega(x, \bar{V}_1, \ldots, \bar{V}_{i-1}, \bar{V}_i') + \frac{2l}{2^{t^l}\delta_i^6} = \alpha_x + \frac{2l}{2^{t^l}\delta_i^6}, \tag{6.8}$$

as $\alpha_x = d_\omega(x, \bar{V}_1, \ldots, \bar{V}_i) - d_\omega(x, \bar{V}_1, \ldots, \bar{V}_{i-1}, \bar{V}_i')$.

Applying (6.6) with $Z = X_i'$, $Y = V_i$ (or V_i', respectively) combined with (6.8) yields

$$|d_{\omega_i}(X_i', V_i) - d_{\omega_i}(X_i', V_i')| = \frac{1}{|X_i'|}\left|\sum_{x\in X_i'}(d_\omega(x, V_1, \dots, V_i) - d_\omega(x, V_1, \dots, V_{i-1}, V_i')\right|$$

$$\leq \frac{1}{|X_i'|}\left|\sum_{x\in X_i'}\alpha_x\right| + \frac{2l}{2^{t^l}\delta_i^6}.$$

Since $|d_{\omega_i}(X_i', V_i) - d_{\omega_i}(X_i', V_i')| \geq \delta_i^2$, we have

$$\frac{1}{|X_i'|}\left|\sum_{x\in X_i'}\alpha_x\right| \geq \delta_i^2 - \frac{2l}{2^{t^l}\delta_i^6}. \tag{6.9}$$

Thus,

$$\frac{1}{|X_i|}\sum_{x\in X_i}\alpha_x^2 \geq \frac{1}{|X_i|}\sum_{x\in X_i'}\alpha_x^2 \geq \frac{1}{|X_i||X_i'|}\left(\sum_{x\in X_i'}\alpha_x\right)^2 \geq \frac{|X_i'|}{|X_i|}\left(\delta_i^2 - \frac{2l}{2^{t^l}\delta_i^6}\right)^2. \tag{6.10}$$

Since $|X_i'| \geq \frac{\delta_i^7}{2}|X_i|$ and $\delta_i^2 - \frac{2l}{2^{t^l}\delta_i^6} \geq \frac{\delta_i^2}{2}$,

$$\frac{1}{|X_i|}\sum_{x\in X_i}\alpha_x^2 \geq \frac{\delta_i^{11}}{8}. \tag{6.11}$$

Therefore, by (6.7),

$$\frac{1}{p^i}\sum_{j_1,\dots,j_i}\sum_{x\in \bar{V}_{i+1}\times\cdots\times\bar{V}_l}\frac{(d_\omega(x, W_1(j_1), \dots, W_i(j_i)))^2}{|\bar{V}_{i+1}|\dots|\bar{V}_l|}$$

$$\geq \sum_{x\in \bar{V}_{i+1}\times\cdots\times\bar{V}_l}\frac{(d_\omega(x, \bar{V}_1, \dots, \bar{V}_i))^2 + \alpha_x^2\frac{\delta_i^6}{1-\delta_i^6}}{|\bar{V}_{i+1}|\dots|\bar{V}_l|}.$$

By (6.2),

$$\sum_{x\in \bar{V}_{i+1}\times\cdots\times\bar{V}_l}\frac{(d_\omega(x, \bar{V}_1, \dots, \bar{V}_i))^2 + \alpha_x^2\frac{\delta_i^6}{1-\delta_i^6}}{|\bar{V}_{i+1}|\dots|\bar{V}_l|}$$

$$\geq \sum_{x\in \bar{V}_{i+1}\times\cdots\times\bar{V}_l}\frac{(d_\omega(x, V_1, \dots, V_i))^2 + \alpha_x^2\frac{\delta_i^6}{1-\delta_i^6} - \frac{2l}{2^{t^l}}}{|\bar{V}_{i+1}|\dots|\bar{V}_l|}.$$

Since $|\bar{V}_j| \le |V_j|$, we have

$$\sum_{x\in\bar{V}_{i+1}\times\cdots\times\bar{V}_l} \frac{(d_\omega(x,V_1,\dots,V_i))^2+\alpha_x^2\frac{\delta_i^6}{1-\delta_i^6}-\frac{2l}{2^{t^l}}}{|\bar{V}_{i+1}|\dots|\bar{V}_l|}$$

$$\ge \sum_{x\in\bar{V}_{i+1}\times\cdots\times\bar{V}_l} \frac{(d_\omega(x,V_1,\dots,V_i))^2+\alpha_x^2\frac{\delta_i^6}{1-\delta_i^6}-\frac{2l}{2^{t^l}}}{|V_{i+1}|\dots|V_l|}$$

$$= \sum_{x\in\bar{V}_{i+1}\times\ldots\times\bar{V}_l} \left(\frac{(d_\omega(x,V_1,\dots,V_i))^2}{|V_{i+1}|\dots|V_l|}+\frac{\delta_i^6}{1-\delta_i^6}\frac{\alpha_x^2}{|X_i|}\right)-\frac{2l}{2^{t^l}}.$$

Clearly $d_\omega(x,V_1,\dots,V_i)\le 1$ and $\frac{\delta_i^6}{1-\delta_i^6}\alpha_x \le 1$. Thus, using the same argument as in (6.4) we have

$$\sum_{x\in\bar{V}_{i+1}\times\cdots\times\bar{V}_l} \frac{(d_\omega(x,V_1,\dots,V_i))^2}{|V_{i+1}|\dots|V_l|} \ge \sum_{x\in V_{i+1}\times\cdots\times V_l} \frac{(d_\omega(x,V_1,\dots,V_i))^2}{|V_{i+1}|\dots|V_l|}-\frac{l}{2^{t^l}}$$

and

$$\sum_{x\in\bar{V}_{i+1}\times\cdots\times\bar{V}_l} \frac{\delta_i^6}{1-\delta_i^6}\frac{\alpha_x^2}{|X_i|} \ge \sum_{x\in V_{i+1}\times\cdots\times V_l} \frac{\delta_i^6}{1-\delta_i^6}\frac{\alpha_x^2}{|X_i|}-\frac{l}{2^{t^l}}.$$

Therefore,

$$\sum_{x\in\bar{V}_{i+1}\times\cdots\times\bar{V}_l} \frac{(d_\omega(x,V_1,\dots,V_i))^2+\alpha_x^2\frac{\delta_i^6}{1-\delta_i^6}-\frac{2l}{2^{t^l}}}{|\bar{V}_{i+1}|\dots|\bar{V}_l|}$$

$$\ge \sum_{x\in V_{i+1}\times\cdots\times V_l} \left(\frac{(d_\omega(x,V_1,\dots,V_i))^2}{|V_{i+1}|\dots|V_l|}+\frac{\delta_i^6}{1-\delta_i^6}\frac{\alpha_x^2}{|X_i|}\right)-\frac{4l}{2^{t^l}}. \tag{6.12}$$

Using (6.11) we further estimate the right-hand side of (6.12) from below by

$$\sum_{x\in V_{i+1}\times\cdots\times V_l} \frac{(d_\omega(x,V_1,\dots,V_i))^2}{|V_{i+1}|\dots|V_l|}+\frac{\delta_i^{17}}{8(1-\delta_i^6)}-\frac{4l}{2^{t^l}}$$
$$= ind_i(V_1,\dots,V_l)+\frac{\delta_i^{17}}{8(1-\delta_i^6)}-\frac{4l}{2^{t^l}}. \qquad \square$$

FACT 6.4. *For an $0<\epsilon<1$ let $\delta=\frac{1}{96}\frac{\epsilon^{2l+1}}{2^{(2l+1)(l-1)}}$. Suppose that an l-tuple is (ϵ,ω)-irregular and we found sets $V'_{l-1}\subset V_{l-1}$ with $|V'_{l-1}|\ge\delta_{l-1}^4|V_{l-1}|$ and $V'_l\subset V_l$ with $|V'_l|\ge\delta_{l-1}^4|V_l|$ such that*

$$|d_{\omega_{l-1}}(V'_{l-1},V'_l)-d_{\omega_{l-1}}(V_{l-1},V_l)|>\delta_{l-1}^2.$$

Then either

$$\frac{1}{p^{l-1}}\sum_{j_1,\dots,j_{l-1}}\sum_{x\in\bar{V}_l}\frac{(d_\omega(x,W_1(j_1),\dots,W_{l-1}(j_{l-1})))^2}{|\bar{V}_l|}$$

$$\geq ind_{l-1}(V_1,\dots,V_l)+\frac{\delta^{17}}{8(1-\delta^6)}-\frac{4l}{2^{t^l}},$$

or

$$\frac{1}{p^{l-1}}\sum_{j_1,\dots,j_{l-2},j_l}\sum_{x\in\bar{V}_{l-1}}\frac{(d_\omega(x,W_1(j_1),\dots,W_{l-2}(j_{l-2}),W_l(j_l)))^2}{|\bar{V}_{l-1}|}$$

$$\geq ind_l(V_1,\dots,V_l)+\frac{\delta^{17}}{8(1-\delta^6)}-\frac{4l}{2^{t^l}}.$$

Proof. If

$$|d_{\omega_{l-1}}(V'_{l-1},V'_l)-d_{\omega_{l-1}}(V_{l-1},V_l)|>\delta^2_{l-1}, \tag{6.13}$$

then either

$$|d_{\omega_{l-1}}(V'_{l-1},V_l)-d_{\omega_{l-1}}(V_{l-1},V_l)|>\frac{\delta^2_{l-1}}{2}, \tag{6.14}$$

or

$$|d_{\omega_{l-1}}(V'_{l-1},V'_l)-d_{\omega_{l-1}}(V'_{l-1},V_l)|>\frac{\delta^2_{l-1}}{2}. \tag{6.15}$$

Set $\delta=\frac{1}{96}\frac{\epsilon^{2l+1}}{2^{(2l+1)(l-1)}}$ and note that by (5.2), $\frac{\delta^2_{l-1}}{2}\geq\delta^2$.

In the case of (6.14), we apply Fact 6.3 to $(V_1,\dots,V_{l-2},V_{l-1},V_l)$ with $i=l-1$, $X'_i=V_l$, and $V'_i=V'_{l-1}$ to conclude that

$$\frac{1}{p^{l-1}}\sum_{j_1,\dots,j_{l-1}}\sum_{x\in\bar{V}_l}\frac{(d_\omega(x,W_1(j_1),\dots,W_{l-1}(j_{l-1})))^2}{|\bar{V}_l|}$$

$$\geq ind_{l-1}(V_1,\dots,V_l)+\frac{\delta^{17}}{8(1-\delta^6)}-\frac{4l}{2^{t^l}}.$$

In the case of (6.15), we apply Fact 6.3 to $(V_1,\dots,V_l,V_{l-1})$ with $i=l-1$, $X'_i=V'_{l-1}$, and $V'_i=V'_l$ to conclude that

$$\frac{1}{p^{l-1}}\sum_{j_1,\dots,j_{l-2},j_l}\sum_{x\in\bar{V}_{l-1}}\frac{(d_\omega(x,W_1(j_1),\dots,W_{l-2}(j_{l-2}),W_l(j_l)))^2}{|\bar{V}_{l-1}|}$$

$$\geq ind_{l-1}(V_1,\dots,V_{l-2},V_l,V_{l-1})+\frac{\delta^{17}}{8(1-\delta^6)}-\frac{4l}{2^{t^l}},$$

which by (1.5) is equal to

$$ind_l(V_1,\dots,V_{l-1},V_l)+\frac{\delta^{17}}{8(1-\delta^6)}-\frac{4l}{2^{t^l}}. \qquad \square$$

We have the following lemma.

LEMMA 6.5. *For every $\epsilon \le 1/2$ and $\delta = \frac{1}{96}\frac{\epsilon^{2l+1}}{2^{(2l+1)(l-1)}}$, let $P = V_0 \cup V_1 \cup \cdots \cup V_t$ be an (ϵ,ω)-irregular partition of an l-uniform hypergraph and let $\frac{4l}{2^{t^l}} \le \frac{\delta^{17}}{16\cdot l}$. If we use algorithm* **Improve** *to construct the subpartition P', then*

$$ind(P') \ge ind(P)+\frac{\delta^{17}}{16\cdot l}.$$

Proof. Assume that each V_i has been partitioned into $W_i(j)$ for $j=1,\dots,p$, and let P' be the resulting subpartition. Then

$$P' = W_0 \cup W_1(1)\cup\cdots\cup W_1(p)\cup\cdots\cup W_t(1)\cup\cdots\cup W_t(p).$$

To simplify the notation we will also write

$$P' = W_0 \cup W_1 \cup \cdots \cup W_{t'},$$

where $t' = tp$. Then

$$ind(P') = \frac{1}{l(tp)^l}\sum_{(W_{i_1},\dots,W_{i_l})}\left(\sum_{k=1}^{l} ind_k(W_{i_1},\dots,W_{i_l})\right),$$

and so

$$ind(P') \ge \frac{1}{lt^l}\sum_{(i_1,\dots,i_l)\in[t]^l}\left(\frac{1}{p^l}\sum_{j_1\dots j_l\in[p]}\left(\sum_{k=1}^{l} ind_k(W_{i_1}(j_1),\dots,W_{i_l}(j_l))\right)\right).$$

For every $1\le k\le l$,

$$\frac{1}{p^l}\sum_{j_1,\dots,j_l\in[p]} ind_k(W_{i_1}(j_1),\dots,W_{i_l}(j_l))$$

$$= \frac{1}{p^l}\sum_{j_1,\dots,j_l\in[p]}\ \sum_{x\in W_{i_{k+1}}(j_{k+1})\times\cdots\times W_{i_l}(j_l)} \frac{(d_\omega(x,W_{i_1}(j_1),\dots,W_{i_k}(j_k)))^2}{|W_{i_{k+1}}(j_{k+1})|\dots|W_{i_l}(j_l)|}$$

$$= \frac{1}{p^l}\sum_{j_1,\dots,j_k}\ \sum_{x\in \bar V_{i_{k+1}}\times\cdots\times\bar V_{i_l}} \frac{(d_\omega(x,W_{i_1}(j_1),\dots,W_{i_k}(j_k)))^2}{|W_{i_{k+1}}(j_{k+1})|\dots|W_{i_l}(j_l)|}$$

$$= \frac{1}{p^k}\sum_{j_1,\dots,j_k}\ \sum_{x\in \bar V_{i_{k+1}}\times\dots\times\bar V_{i_l}} \frac{(d_\omega(x,W_{i_1}(j_1),\dots,W_{i_k}(j_k)))^2}{|\bar V_{i_{k+1}}|\dots|\bar V_l|}, \tag{6.16}$$

as $|\bar V_{i_l}| = p|W_{i_l}(j_l)|$. Fact 6.2 implies that for every $1\le k\le l$,

$$\frac{1}{p^l}\sum_{j_1,\dots,j_l\in[p]} ind_k(W_{i_1}(j_1),\dots,W_{i_l}(j_l)) \ge ind_k(V_{i_1},\dots,V_{i_l})-\frac{2l}{2^{t^l}}.$$

If an l-tuple $(V_{i_1},\dots,V_{i_l})$ is (ϵ,ω)-irregular, then by Fact 5.1, we can find either

- $V'_{k_0} \subset V_{k_0}$ and $X'_{k_0} \subset X_{k_0}$ that satisfy the assumptions of Fact 6.3 for some $1 \leq k_0 \leq l-2$, or
- $V'_{l-1} \subset V_{l-1}$ and $V'_l \subset V_l$ that satisfy the assumptions of Fact 6.4.

If the former holds, we combine (6.16) and Fact 3.6 to infer that for some $1 \leq k_0 \leq l-2$,

$$\frac{1}{p^l} \sum_{j_1,\ldots,j_l \in [p]} ind_{k_0}(W_{i_1}(j_1), \ldots, W_{i_l}(j_l)) \geq ind_{k_0}(V_{i_1}, \ldots, V_{i_l}) + \frac{\delta_{k_0}^{17}}{8(1-\delta_{k_0}^6)} - \frac{4l}{2^{t^l}}.$$

If the latter holds, then by Fact 6.4 for $k_0 = l-1$ or for $k_0 = l$,

$$\frac{1}{p^l} \sum_{j_1,\ldots,j_l \in [p]} ind_{k_0}(W_{i_1}(j_1), \ldots, W_{i_l}(j_l)) \geq ind_{k_0}(V_{i_1}, \ldots, V_{i_l}) + \frac{\delta^{17}}{8(1-\delta^6)} - \frac{4l}{2^{t^l}}.$$

Since the partition P is (ϵ, ω)-irregular, at least ϵt^l of l-tuples $(V_{i_1}, \ldots, V_{i_l})$ are (ϵ, ω)-irregular. Thus, (by (5.2) $\delta_{k_0} \geq \frac{1}{48} \frac{\epsilon^{2l+1}}{2^{(2l+1)(l-1)}} > \delta$, $1 - \delta \leq 1$)

$$ind(P') \geq ind(P) + \frac{\delta^{17}}{8 \cdot l} - \frac{4l}{2^{t^l}},$$

and since t satisfies $\frac{4l}{2^{t^l}} \leq \frac{\delta^{17}}{16 \cdot l}$ by assumption, we have

$$ind(P') \geq ind(P) + \frac{\delta^{17}}{16 \cdot l}. \qquad \square$$

Proof of Theorem 1.1. Set $\delta = \frac{1}{96} \frac{\epsilon^{2l+1}}{2^{(2l+1)(l-1)}}$, and partition the vertex set of a hypergraph into t subsets (arbitrarily), but such that

$$\frac{1}{2^{t^l}} \leq \frac{\epsilon \delta^{17}}{16 \cdot l + \delta^{17}}.$$

Invoke the procedure **Improve** $\frac{16 \cdot l}{\delta^{17}} + 1$ times. By Lemma 6.5 (note that $\frac{1}{2^{t^l}} \leq \frac{\delta^{17}}{16 \cdot l}$) after at most $\frac{16 \cdot l}{\delta^{17}} + 1$ iterations we find a partition Q with less than ϵt^l (ϵ, ω)-irregular l-tuples, otherwise $ind(Q) > 1$, which is not possible. Also, by Fact 6.1 the size of the exceptional class

$$|V_0| \leq \left(\frac{16 \cdot l}{\delta^{17}} + 1 \right) \frac{n}{2^{t^l}} \leq \epsilon n.$$

Next we will argue that the complexity of the algorithm is $O(n^{2l-1} \log^2 n)$. First observe that we iterate the algorithm **Improve** a constant number of times. Since l is constant and the number of partition classes is constant, the complexity of **Improve** depends only on the algorithms of Theorem 3.1 and Theorem 4.3. Recall that the complexity of the algorithm of Theorem 3.1 is $O(N^2 M \log^2 K_k)$, where $N = |V_{k+1} \times \cdots \times V_l|$ and $M = |V_k|$. Since $1 \leq k \leq l-1$ and by (5.1), $K_k \leq K n^l$ (K is constant by an assumption), the complexity of the algorithm from Theorem 3.1 is $O(n^{2l-1} \log^2 n)$. The complexity of the algorithm of Theorem 4.3 is $O(M^3 \log^2 K_{l-1})$, where $M = |V_{l-1}| = |V_l|$. Therefore, in this case, the complexity is $O(n^3 \log^2 n)$. The total complexity of **Improve** is $O(n^{2l-1} \log^2 n)$. $\square$

7. Applications. In this section, we outline the applications of Theorem 1.1 to the max-cut problem for hypergraphs and to the problem of estimating the chromatic number of a hypergraph. Let $H = (V, E)$ be an l-uniform hypergraph and let $n = |V|$. We consider the unweighted case $\omega : [V]^l \to \{0, 1\}$, and to simplify the notation we write $d(V_1, \dots, V_l)$ instead of $d_\omega(V_1, \dots, V_l)$. In the max-cut problem one wants to find a partition of V into l subsets which is such that the number of hyperedges that intersect each partition class (have nonempty intersection with each class) is maximized. Case $l = 2$ gives the max-cut problem for graphs and its "dense case" was considered in [7]. Let $OPT(H) = max|\{e \in E : |e \cap V_i| = 1; i = 1, \dots, l\}|$, where the maximum is taken over all partitions $V_1 \cup \dots \cup V_l$ of V.

THEOREM 7.1. *Let $H = (V, E)$ be an l-uniform hypergraph and let $n = |V|$. For every $\epsilon > 0$, there is an $O(n^{2l-1} \log^2 n)$ algorithm that finds a partition $V_1 \cup \dots \cup V_l$ of V which is such that the number of hyperedges that intersect each V_i, $i = 1, \dots, l$ is at least $OPT(H) - \epsilon n^l$.*

Proof. The following algorithm finds the postulated partition. The constant ϵ' depends on ϵ and can be computed explicitly.

1. Find an ϵ'-regular partition of H: $W_0, \dots, W_t$.
2. Check exhaustively all partitions $V_1, \dots, V_l$ in which for every $i \in [l]$ and every $j \in [t]$ we have if $W_j \cap V_i \neq \emptyset$, then $W_j \subset V_i$. Choose a partition $V_1, \dots, V_l$ that maximizes

$$\sum_{W_{j_k} \subset V_k} d(W_{k_1}, W_{k_2}, \dots, W_{k_l})|W_{k_1}| \dots |W_{k_l}|.$$

Note that since there are l^t partitions that are checked in the second step of the algorithm, the complexity of the procedure is $O(n^{2l-1} \log^2 n)$.

For a partition $U_1, \dots, U_l$ of V define

$$f(U_1, \dots, U_l) = \max|\{e \in E : |e \cap U_i| = 1, i = 1, \dots, l\}|$$

and

$$f^*(U_1, \dots, U_l) = \sum_{W_{j_k} \subset U_k} d(W_{j_1}, W_{j_2}, \dots, W_{j_l})|U_1 \cap W_{k_1}| \dots |U_l \cap W_{k_l}|.$$

One can verify that f^* is maximized for a partition $U_1, \dots, U_l$ which is of the form considered in the second step of the algorithm, i.e., if $W_j \cap U_i \neq \emptyset$, then $W_j \subset U_i$. Also, choosing ϵ' appropriately, one can show that for every partition $U_1, \dots, U_l$

$$|f(U_1, \dots, U_l) - f^*(U_1, \dots, U_l)| \leq \frac{\epsilon}{2} n^l.$$

Let $V_1, \dots, V_l$ be a partition found by the algorithm, and let $U_1, \dots, U_l$ be an optimal partition. Then

$$f(V_1, \dots, V_l) \geq f^*(V_1, \dots, V_l) - \frac{\epsilon}{2} n^l \geq f^*(U_1, \dots, U_l) - \frac{\epsilon}{2} n^l$$

$$\geq f(U_1, \dots, U_l) - \epsilon n^l = OPT(H) - \epsilon n^l. \qquad \square$$

Our second application concerns the chromatic number of a hypergraph. The chromatic number $\chi(H)$ is defined as the minimum number of colors needed to color the

vertices of H so that there is no hyperedge of H that contains more than one vertex of the same color. Define

$$\chi_\epsilon(H) = \min\{\chi(H \setminus E') : E' \subset E; |E'| \le \epsilon n^l\}.$$

We define a hyperedge $\{v_1, \dots, v_l\}$ to be crossing in an l-tuple $(V_1, \dots, V_l)$ if for every $i = 1, \dots, l$, $v_i \in V_i$.

THEOREM 7.2. *Let $H = (V, E)$ be an l-uniform hypergraph and let $n = |V|$. For every $\epsilon > 0$ there is an $O(n^{2l-1} \log^2 n)$ time algorithm that finds a number k satisfying*

$$\chi_\epsilon(H) \le k \le \chi(H).$$

Proof. Sketch. Set $\epsilon' = \frac{\epsilon}{4}$ and find an ϵ'-regular partition $W_0, \dots, W_t$. Construct a subhypergraph H' of H by deleting all the hyperedges adjacent to W_0, hyperedges that are crossing in ϵ'-irregular l-tuples, and the hyperedges that are crossing in the ϵ'-regular l-tuples that have densities not greater than ϵ'. In this process we delete at most $3\epsilon' n^l$ hyperedges. Construct a subhypergraph H'' of H' as follows. Group (arbitrarily) classes $W_0, W_1, \dots, W_t$ into $t' = \frac{1}{\epsilon'}$ sets $V_1, \dots, V_{t'}$ (say, $V_i = \bigcup_{j=(i-1)\epsilon' t}^{i\epsilon' t} W_j$), and delete the hyperedges that contain at least two vertices from the same V_i. In this process we delete at most $\epsilon' n^l$ hyperedges. Let $Aux(H'')$ be an l-uniform hypergraph with vertex set $\{W_0, \dots, W_t\}$ and with $\{W_{i_1}, \dots, W_{i_l}\} \in E(Aux(H''))$ if and only if there is at least one hyperedge of H'' contained in $W_{i_1} \cup \dots \cup W_{i_l}$.

CLAIM 7.3. $\chi(Aux(H'')) = \chi(H'')$.

Proof. Clearly, $\chi(Aux(H'')) \ge \chi(H'')$, as a proper coloring of $Aux(H'')$ induces the proper coloring of H''. Assume that $\chi(H'') < \chi(Aux(H''))$. Let $\bar{W}_i \subset W_i$ be a set of vertices colored in the most frequent color of W_i in a $\chi(H'')$-coloring of H'' (ties are resolved arbitrarily). Consider the coloring of $Aux(H'')$ induced by these "most frequent" colors. Then there exists a hyperedge of $Aux(H'')$, $\{W_{i_1}, \dots, W_{i_l}\}$ such that at least two of W_{i_j} have the same color. We next show that there must be a crossing hyperedge in $(\bar{W}_{i_1}, \dots, \bar{W}_{i_l})$. From the construction of H'' it follows that $\chi(Aux(H'')) \le \frac{1}{\epsilon'}$, and so for every $i = 1, \dots, t$

$$|\bar{W}_i| \ge \epsilon' |W_i|. \tag{7.1}$$

Since $\{W_{i_1}, \dots, W_{i_l}\}$ is a hyperedge of $Aux(H'')$, we have $d(W_{i_1}, \dots, W_{i_l}) > \epsilon'$, and by the ϵ'-regularity of $(W_{i_1}, \dots, W_{i_l})$

$$d(\bar{W}_{i_1}, \dots, \bar{W}_{i_l}) > 0. \tag{7.2}$$

Therefore, there is at least one crossing hyperedge in $(\bar{W}_{i_1}, \dots, \bar{W}_{i_l})$ which contradicts the fact that H'' was properly colored. ∎

Since $Aux(H'')$ has t vertices, $\chi(Aux(H''))$ can be found in a constant time by exhaustive search, and so we found $k = \chi(Aux(H'')) = \chi(H'')$ satisfying $k \ge \chi_\epsilon(H)$. ∎

Acknowledgments. We would like to thank referees for helpful comments and suggestions.

A POLYNOMIAL APPROXIMATION ALGORITHM FOR THE MINIMUM FILL-IN PROBLEM*

ASSAF NATANZON†, RON SHAMIR†, AND RODED SHARAN†

Abstract. In the *minimum fill-in* problem, one wishes to find a set of edges of smallest size, whose addition to a given graph will make it chordal. The problem has important applications in numerical algebra and has been studied intensively since the 1970s. We give the first polynomial approximation algorithm for the problem. Our algorithm constructs a triangulation whose size is at most eight times the optimum size squared. The algorithm builds on the recent parameterized algorithm of Kaplan, Shamir, and Tarjan for the same problem.

For bounded degree graphs we give a polynomial approximation algorithm with a polylogarithmic approximation ratio. We also improve the parameterized algorithm.

1. Introduction.

A *chord* in a cycle is an edge between nonconsecutive vertices on the cycle. A *chordless cycle* is a cycle of length greater than 3 that contains no chord. A graph is called *chordal* or *triangulated* if it contains no chordless cycle. If $G = (V, E)$ is not chordal and F is a set of edges such that $(V, E \cup F)$ is chordal, then F is called a *fill-in* or a *triangulation* of G. If $|F| \leq k$, then F is called a *k-triangulation* of G. We denote by $\Phi(G)$ the size of the smallest fill-in of G.

The *minimum fill-in* problem is to find a minimum triangulation (fill-in) of a given graph. The importance of the problem stems from its applications to numerical algebra. In many fields, including VLSI simulation, solution of linear programs, signal processing, and others (cf. [7]), one has to perform a Gaussian elimination on a sparse symmetric positive-definite matrix. During the elimination process zero entries may become nonzeros. Different elimination orders may introduce different sets of new nonzero elements into the matrix. The time of the computation and its storage needs are dependent on the sparseness of the matrix. It is therefore desirable to find an elimination order such that a minimum number of zero entries is filled in with nonzeros (even temporarily). Rose [21] proved that the problem of finding an elimination order for a symmetric positive-definite matrix M, such that fewest new nonzero elements are introduced, is equivalent to the minimum fill-in problem on a graph whose vertices correspond to the rows of M and in which (i, j) is an edge if and only if $M_{i,j} \neq 0$.

In 1979, Garey and Johnson [9] posed the complexity of the minimum fill-in problem as a major open problem. Yannakakis subsequently proved that the minimum fill-in problem is NP-complete [23]. Due to its importance the problem has been studied intensively [2, 11, 13, 22], and many heuristics have been developed for it [5, 12, 20, 21]. None of those gives a performance guarantee with respect to the size

of the fill-in introduced. Note that in contrast, the *minimal* fill-in problem (finding a triangulation of G which is minimal with respect to inclusion) is polynomial [19].

Approximation attempts succeeded only for the related *minimum triangulated supergraph* problem (MTS). In MTS the goal is to add edges to the input graph in order to obtain a chordal graph with minimum *total* number of edges. While as optimization problems MTS and minimum fill-in are equivalent, they may differ drastically as approximation problems. For example, if the input graph has $\Omega(n^2)$ edges and fill-in of size $o(n^2)$, then one can trivially achieve a constant approximation ratio for MTS by making the graph an n-clique (a complete graph), while no such approximation guarantee exists for the minimum fill-in problem. (Throughout we use n and m to denote the number of vertices and edges, respectively, in a graph.) The approximation results regarding MTS use the nested dissection heuristic first proposed by George [10] (see [13] for details). Gilbert [14] showed that for a graph with maximum degree d there exists a balanced separator decomposition such that a nested dissection ordering based on that decomposition yields a chordal supergraph, in which the number of edges is within a factor of $O(d \log n)$ of optimal. The result was not constructive as one has yet to find such a decomposition. Leighton and Rao [17] gave a polynomial approximation algorithm for finding a balanced separator in a graph of size within a factor of $O(\log n)$ of optimal. Agrawal, Klein, and Ravi [1], using Gilbert's ideas and the result of [17], obtained a polynomial approximation algorithm with ratio $O(\sqrt{d} \log^4 n)$ for MTS on graphs with maximum degree d. They also gave a polynomial approximation algorithm for MTS on general graphs, which generates for an input graph G a chordal supergraph with total number of edges $O((m + \Phi(G))^{3/4} \sqrt{m} \log^{3.5} n)$.

In the *parametric* fill-in problem the input is a graph G and a parameter k. The goal is to find a k-triangulation of G, or to determine that none exists. Clearly this can be done in $n^{O(k)}$ time by enumeration. For fixed k and growing n, an algorithm with complexity $2^{O(k)} n^{O(1)}$ is superior. Parameterized complexity theory, initiated by Downey and Fellows (cf. [6]), studies the complexity of such problems. Parameterized problems that have algorithms of complexity $O(f(k)n^{\alpha})$ (with α a constant) are called *fixed parameter tractable*. Kaplan, Shamir, and Tarjan [16] and later independently Cai [3] proved that the minimum fill-in problem is fixed parameter tractable, by giving an algorithm of complexity $2^{O(k)}m$ for the problem. Both used the same algorithm, with the time bound in [3] being slightly tighter. Kaplan, Shamir, and Tarjan also gave a more efficient $2^{O(k)}+O(k^2nm)$-time algorithm (henceforth, the KST algorithm) for the problem.

In this paper we give the first polynomial approximation algorithm for the minimum fill-in problem. Our algorithm builds on ideas from [16]. For an input graph G with minimum fill-in of size k, our algorithm produces a triangulation of size at most $8k^2$, i.e., within a factor of $8k$ of optimal. The approximation is achieved by identifying in G a *kernel* set of vertices A of size at most $4k$, such that one can triangulate G by adding edges only between vertices of A. Our algorithm produces the triangulation without prior knowledge of k. Let $M(n)$ denote the number of operations needed to multiply two integer matrices of order $n \times n$. (The current upper bound on $M(n)$ is $O(n^{2.376})$ [4].) The algorithm works in time $O(knm + \min\{n^2 M(k)/k, nM(n)\})$, which makes it potentially suitable for practical use.

Our algorithm is particularly attractive for small fill-in values. Note that if $k = \Omega(n)$, then our algorithm guarantees only the trivial bound of fill-in size $O(n^2)$, but if, for example, the fill-in size is constant, then the approximation guarantee is a constant.

This type of approximation result is uncommon. It opens the question of obtaining polynomial approximation algorithms with performance guarantees depending on the optimal value for other important problems, even in the presence of hardness-of-approximation results.

We also obtain better approximation results for bounded degree graphs. For graphs with maximum degree d we give a polynomial algorithm which achieves an approximation ratio of $O(d^{2.5}\log^4(kd))$. Since $k = O(n^2)$, this approximation ratio is polylogarithmic in the input size.

In order to compare our results to the approximation results regarding MTS, we translate the latter to approximation ratios in terms of the fill-in obtained. We assume throughout that $m > n$. For general graphs the algorithm in [1] guarantees that the number of edges in the chordal supergraph obtained is $O((m + k)^{3/4}\sqrt{m}\log^{3.5} n)$. In terms of the fill-in obtained, the approximation ratio achieved is $O(m^{1.25}\log^{3.5} n/k + \sqrt{m}\log^{3.5} n/k^{1/4})$. We obtain a better approximation ratio whenever $k = O(m^{5/8}\log^{1.75} n)$. For graphs with maximum degree d, the algorithm in [1] achieves an approximation ratio of $O(((nd + k)\sqrt{d}\log^4 n)/k)$. We provide a better ratio when $k = O(n/d)$. When any of these upper bounds on k is satisfied, our algorithm also achieves a better approximation ratio than [1] for the MTS problem.

Kaplan, Shamir, and Tarjan posed in [16] an open problem of obtaining an algorithm for the parametric fill-in problem with time $2^{O(k)} + O(km)$. The motivation is to match the performance of the $2^{O(k)}m$ algorithm for all k. We make some progress towards solving that problem by providing a faster $2^{O(k)} + O(knm + \min\{n^2M(k)/k, nM(n)\})$-time implementation of their algorithm. We also give a variant of the algorithm which produces a smaller kernel. Finally, we apply our approximation algorithm to the *chain completion* problem and obtain an approximation ratio of $8k$, where k denotes the size of an optimum solution.

The paper is organized as follows. Section 2 contains a description of the KST algorithm and some background. Section 3 improves the complexity of the KST algorithm and reduces the size of the kernel produced. Section 4 describes our approximation algorithm for general graphs. Section 5 gives an approximation algorithm for graphs with bounded degree. Section 6 gives further reduction of the kernel size, and section 7 gives an approximation algorithm for the chain completion problem.

2. Preliminaries. Let $G = (V, E)$ be a graph. We denote its set V of vertices also by $V(G)$ and its set E of edges also by $E(G)$. For $U \subseteq V$ we denote by G_U the subgraph induced by the vertices in U. For a vertex $v \in V$ we denote by $N(v)$ the set containing all neighbors of v in G. We let $N[v] = N(v) \cup \{v\}$. A path with l edges is called an *l-path* and its *length* is l. A single vertex is considered a 0-path. We call a cycle with l edges an *l-cycle*.

Our polynomial approximation algorithm for the minimum fill-in problem builds on the KST algorithm [16]. In the following we describe this algorithm. Our presentation generalizes that in [16] in order to allow succinct description of the approximation algorithm in section 4.

FACT 2.1. *A minimal triangulation of a chordless l-cycle consists of $l-3$ edges.*

LEMMA 2.2 (see [16, Lemma 2.5]). *Let C be a chordless cycle and let p be an l-path on C, $1 \le l \le |C|-2$. If $l = |C|-2$, then in every minimal triangulation of C there are at least $l-1$ chords incident with vertices of p. If $l < |C|-2$, then in every minimal triangulation of C there are at least l chords incident with vertices of p.*

Let $\langle G = (V, E), k\rangle$ be the input to the parametric fill-in problem. The algorithm has two main stages. In the first stage, which is polynomial in n, m, and k, the

algorithm produces a partition A, B of V and a set F of nonedges in G_A, such that $|A| = O(k^3)$ and no chordless cycle in $G' = (V, E \cup F)$ intersects B. We shall call this stage the *partition algorithm*.

In the second stage, which is exponential in k, an exhaustive search is applied to find a minimum triangulation F' of G'_A. $F \cup F'$ is then proved to be a minimum triangulation of G. The search procedure can be viewed as traversing part of a search tree T, which is defined as follows. Each tree node v corresponds to a supergraph $G(v)$ of G. For the root r, $G(r) = G$. Each leaf of T corresponds to a chordal supergraph of G. At an internal node v, a chordless cycle C in $G(v)$ is identified. For each minimal triangulation F_C of C, a node u is added as a child of v, and its corresponding graph $G(u)$ is obtained by adding F_C to $G(v)$. The algorithm visits only nodes v of T for which $|E(G(v))\backslash E| \leq k$. If such a node is a leaf, then the search terminates successfully. Otherwise, no k-triangulation exists for G.

The partition algorithm applies sequentially the following three procedures. All three maintain a partition A, B of V and a lower bound cc on the minimum number of edges needed to triangulate G. Initially $A=\emptyset, B=V$, and $cc=0$.

(i) *Procedure* $P_1(k)$. *Extracting independent chordless cycles.* Search repeatedly for chordless cycles in G_B and move their vertices from B to A. For each chordless l-cycle found, increment cc by $l-3$. If at any time $cc > k$, stop and declare that the graph admits no k-triangulation.

(ii) *Procedure* $P_2(k)$. *Extracting related chordless cycles with independent paths.* Search repeatedly for chordless cycles in G containing at least two consecutive vertices from B. Let C be such a cycle, $|C| = l$. If $l > k+3$, stop with a negative answer. Otherwise, suppose that C contains $j \geq 1$ disjoint maximal subpaths in G_B, each of length at least 1. Move the vertices of those subpaths from B to A. Denote their lengths in nonincreasing order by $l_1, \ldots, l_j$. If $j = 1$, we increase cc either by l_1-1 if $l_1 = l-2$, or by l_1 if $l_1 < l-2$. Otherwise, cc is increased by $\max\{\frac{1}{2}\sum_{i=1}^{j} l_i, l_1\}$. If at any time $cc > k$, stop and declare that the graph admits no k-triangulation.

DEFINITION 2.3. *For every $x, y \in A$ such that $(x, y) \notin E$, denote by $A_{x,y}$ the set of all vertices $b \in B$ such that x, b, y occur consecutively on some chordless cycle in G. If $|A_{x,y}| > 2k$, then (x, y) is called a* k-essential edge.

(iii) *Procedure* $P_3(k)$. *Adding k-essential edges in G_A.* For every $x, y \in A$ such that $(x, y) \notin E$ compute the set $A_{x,y}$. If (x, y) is k-essential, then add it to G. Otherwise, move all vertices in $A_{x,y}$ from B to A.

Denote by A^i, B^i the partition obtained after procedure P_i is completed for $i = 1, 2, 3$. We shall omit the index i when it is clear from the context. Denote by cc_i the value of cc after procedure P_i is completed for $i = 1, 2$. The size of A^2 is at most $4k$ since $k \geq cc_2 = cc_1 + (cc_2 - cc_1) \geq \frac{1}{4}|A^1| + \frac{1}{2}|A^2 \setminus A^1| \geq \frac{1}{4}|A^2|$. The size of A^3 is $O(k^3)$ since there are $O(k^2)$ nonedges in G_{A^2} and the number of vertices moved to A due to any such nonedge is at most $2k$.

The partition algorithm is summarized in Figure 2.1. Let G' denote the graph obtained after the execution of procedure P_3. Kaplan, Shamir, and Tarjan prove

Execute procedure $P_1(k)$.
Execute procedure $P_2(k)$.
Execute procedure $P_3(k)$.

FIG. 2.1. *The KST partition algorithm.*

that every k-essential edge must appear in any k-triangulation of G [16, Lemma 2.7], and that in G' no chordless cycle intersects B [16, Theorem 2.10]. Therefore, by the following theorem it suffices to search for a minimum triangulation of G'_A.

THEOREM 2.4 (see [16, Theorem 2.13]). *Let A, B be a partition of the vertex set of a graph G, such that the vertices of every chordless cycle in G are contained in A. A set of edges F is a minimal triangulation of G if and only if F is a minimal triangulation of G_A.*

The complexity of the partition algorithm is $O(k^2nm)$ [16]. The complexity of finding a minimum triangulation of a given graph is $O(\frac{4^k}{(k+1)^{3/2}}m)$ [3]. Since G'_A contains $O(k^6)$ edges, a minimum triangulation of G'_A can be found in $O(k^{4.5}4^k)$ time. Hence, the complexity of the KST algorithm is $O(k^2nm + k^{4.5}4^k)$.

3. Improvements to the partition algorithm. In this section we show some improvements to the KST partition algorithm. We assume throughout that the input is $\langle G = (V, E), k\rangle$. We first show how to implement procedure P_3 in $O(nm + \min\{n^2M(k)/k, nM(n)\})$-time. We then prove that the size of A^3 is only $O(k^2)$. These results imply that the KST algorithm can be implemented in $O(knm + \min\{n^2M(k)/k, nM(n)\} + k^{2.5}4^k)$-time.

LEMMA 3.1. *There is an $O(nm+\min\{n^2M(k)/k, nM(n)\})$-time implementation of procedure P_3.*

Proof. Let $S = \{(x, y) \notin E : x, y \in A^2\}$. The bottleneck in the complexity of P_3 is computing the sets $A_{x,y}$ for every $(x, y) \in S$. To this end, we find for every $b \in B$ all pairs $(x, y) \in S$ such that $b \in A_{x,y}$. We then construct the sets $A_{x,y}$. This is done as follows.

Fix $b \in B$. Compute the connected components of $G^b = G \setminus N[b]$. This takes $O(m)$ time. Denote the connected components of G^b by $C^b_1, \ldots, C^b_l$. For each $x \in A^2 \cap N(b)$ compute a binary vector $\vec{v}_x = (v^x_1, \ldots, v^x_l)$ such that $v^x_j = 1$ if and only if C^b_j contains a neighbor of x, $1 \le j \le l$. Each vector can be computed in $O(n)$-time. Let $k' = |A^2 \cap N(b)|$, and number the vertices in $A^2 \cap N(b)$ arbitrarily according to some 1-1 mapping $\sigma : \{1, \ldots, k'\} \to A^2 \cap N(b)$. Define a $k' \times l$ boolean matrix M whose ith row is the vector $\vec{v}_{\sigma(i)}$, $1 \le i \le k'$. Note that $k' = O(k)$ and $l \le n$. Let $M^* = MM^T$. It can be seen that for every pair (i, j) such that $1 \le i < j \le k'$ and $(\sigma(i), \sigma(j)) \in S$, $M^*_{i,j} \ge 1$ if and only if $b \in A_{\sigma(i),\sigma(j)}$. Since $k', l \le n$ we can compute M^* in $O(M(n))$-time. If $k = o(n)$, then we can compute M^* in $O(nM(k)/k)$-time by partitioning M and M^T into $\lceil n/k'\rceil$ submatrices of order at most $k' \times k'$, multiplying corresponding pairs of submatrices, and summing the results. Hence, the computation of M^* takes $O(\min\{nM(k)/k, M(n)\})$ time.

After the above calculations are performed for every $b \in B$, it remains to compute the sets $A_{x,y}$. We can do that in $O(\min\{k^2n, n^3\})$-time. The total time is therefore $O(nm + \min\{n^2M(k)/k, nM(n)\})$. ∎

Observation 3.2. Let $x, y \in A^2, (x, y) \notin E$. If $A_{x,y} \ne \emptyset$, then for any triangulation F of G, either $(x, y) \in F$, or for every $b \in A_{x,y}$, F contains an edge incident on b.

LEMMA 3.3. *Assume that G admits a k-triangulation and that in procedure P_3 all sets $A_{x,y}$ moved into A are of size at most d. Then $|A^3 \setminus A^2| \le Mk$, where $M = \max\{d, 2\}$.*

Proof. Let the nonedges in G_{A^2} be $(x_1, y_1), \ldots, (x_l, y_l)$. We process the sets $A_{x_1,y_1}, \ldots, A_{x_l,y_l}$ in this order. Let $A^{(0)} = A^2$. Let $A^{(i)}$ be the set A right after A_{x_i,y_i} was processed, and let $\Delta_i = A_{x_i,y_i} \setminus A^{(i-1)}$ for $1 \le i \le l$.

Let t be a lower bound on the minimum number of edges needed to triangulate G. Initially P_3 starts with $t = 0$. Let t_i be the value of t right after A_{x_i,y_i} was processed ($t_0 = 0$). If $\Delta_i \neq \emptyset$, then by Observation 3.2, t should increase by $\min\{1, |\Delta_i|/2\}$. We must maintain $t \leq k$. If $t_i - t_{i-1} = 0$, then $|\Delta_i| = 0$. If $t_i - t_{i-1} = 1/2$, then $|\Delta_i| = 1$. If $t_i - t_{i-1} \geq 1$, then $|\Delta_i| \leq d$. Therefore for all $1 \leq i \leq l$, $|\Delta_i| \leq M(t_i - t_{i-1})$. Now,

$$|A^3 \setminus A^2| = |A^{(l)} \setminus A^{(0)}| = \sum_{i=1}^{l} |A^{(i)} \setminus A^{(i-1)}|$$
$$= \sum_{i=1}^{l} |\Delta_i| \leq M \sum_{i=1}^{l} (t_i - t_{i-1}) = M(t - t_0) \leq Mk\,. \qquad \square$$

COROLLARY 3.4. *If G has a k-triangulation, then the partition algorithm terminates with $|A| \leq 2k(k+2)$.*

Proof. Let us assume that all k-essential edges were added to G, and denote the new set of edges of G by E'. For all $x, y \in A^2, (x, y) \notin E'$, we know that $|A_{x,y}| \leq 2k$. By Lemma 3.3, $|A^3 \setminus A^2| \leq 2k^2$. Since $|A^2| \leq 4k$, the corollary follows. $\square$

THEOREM 3.5. *There is an $O(knm + \min\{n^2 M(k)/k, nM(n)\} + k^{2.5}4^k)$-time implementation of the KST algorithm.*

Proof. By the analysis in [16], P_1 takes $O(km)$ time, and P_2 takes $O(knm)$ time. By Lemma 3.1, the complexity of P_3 is $O(nm + \min\{n^2 M(k)/k, nM(n)\})$. By Corollary 3.4, if G admits a k-triangulation, then the size of A^3 is $O(k^2)$. Hence, a minimum triangulation of G'_A can be found in $O(k^{2.5}4^k)$-time [3]. The complexity follows. $\square$

4. The approximation algorithm. Let $G = (V, E)$ be the input graph. Let $k_{opt} = \Phi(G)$. The key idea in our approximation algorithm is to find a set of vertices $A \subseteq V$, such that $|A| = O(k_{opt})$ and, moreover, one can triangulate G by adding edges only between vertices of A. Since there are $O(k_{opt}^2)$ nonedges in G_A, we achieve an approximation ratio of $O(k_{opt})$.

In order to find such a set A we use ideas from the partition algorithm. If we knew k_{opt}, we could execute the partition algorithm and obtain a set A, with $|A| = O(k_{opt}^2)$ (by Corollary 3.4), such that G can be triangulated by adding edges only in G_A. This would already give an $O(k_{opt}^3)$ approximation ratio.

Before describing our algorithm we analyze the role of the parameter k given to the partition algorithm. If $k < k_{opt}$, then the algorithm might stop during P_1 or P_2 and declare that no k-triangulation exists. Moreover, k-essential edges are not necessarily k_{opt}-essential. If $k > k_{opt}$, then the size of A may be $\omega(k_{opt}^2)$. The algorithm is shown in Figure 4.1.

Procedures P'_1 and P'_2 execute P_1 and P_2, respectively, without bounding the size of the triangulation implied. Procedure P'_3 takes advantage of the fact that we no

Algorithm APPROX
  Procedure P'_1: Execute $P_1(\infty)$.
  Procedure P'_2: Execute $P_2(\infty)$.
  Procedure P'_3: Execute $P_3(0)$.
  Let G' be the resulting graph.
  Procedure P'_4: Find a minimal triangulation of G'_A.

FIG. 4.1. *The approximation algorithm.*

longer seek a minimum triangulation but rather a minimal one. In order to obtain our approximation result we want to keep A as small as possible. Hence, instead of moving new vertices to A we add new 0-essential edges accommodating for those vertices. By the same arguments as in [16] and section 2, the size of A after the execution of P_2' is at most $4k_{opt}$. Since P_3' does not add new vertices to A, its size remains at most $4k_{opt}$ throughout. The size of the triangulation found by the algorithm is therefore at most $8k_{opt}^2$. The correctness of Algorithm APPROX is established in what follows. We need the following lemma which is implied by the proof of [16, Lemma 2.9]. The subsequent theorem is a generalization of [16, Theorem 2.10].

LEMMA 4.1. *Let $G = (V, E)$ be a graph and let $v \in V$. Let F be a set of nonedges in $G \setminus \{v\}$, such that each $e = (x, y) \in F$ is a chord in a chordless cycle $C_e = (x, z_e, y, \ldots, x)$ in G, where z_e is not an endpoint of any edge in F. Let $G' = (V, E \cup F)$. If there exists a chordless cycle C in G' with v_1, v, v_2 occurring consecutively on C for some $v_1, v_2 \in N(v)$, then either there exists a chordless cycle in G on which v_1, v, v_2 occur consecutively, or there exists a chordless cycle in G, on which v and z_e occur consecutively for some $e \in F$.*

THEOREM 4.2. *Let $G = (V, E)$ be a graph. Let A, B be a partition of V such that no chordless cycle in G contains two consecutive vertices from B. Let $S = \{(x, y) \notin E : x, y \in A, A_{x,y} \neq \emptyset\}$. Then for any choice of $F \subseteq S$ no chordless cycle in $G' = (V, E \cup F)$ intersects $B' = B \setminus (\bigcup_{(x,y)\in S\setminus F} A_{x,y})$.*

Proof. Suppose to the contrary that C is a chordless cycle in G' intersecting B'. Let $v \in C \cap B'$. Let v_1 and v_2 be the neighbors of v on C. Since $v \in B'$, it is not an endpoint of any edge in F. Every edge $e = (x, y) \in F$ is a chord in a chordless cycle $C_e = (x, z_e, y, \ldots, x)$ of G, where $z_e \in B$. Applying Lemma 4.1, we find that two cases are possible.

1. There exists a chordless cycle in G on which v_1, v, v_2 occur consecutively. If $v_1 \in B$ or $v_2 \in B$, we arrive at a contradiction. Hence, $v_1, v_2 \in A$ and $v \in A_{v_1,v_2}$. We conclude that either $(v_1, v_2) \in F$ or $v \notin B'$, a contradiction.

2. There exists a chordless cycle in G on which v and z_e occur consecutively (for some $e \in F$), a contradiction. ∎

THEOREM 4.3. *Let G be a graph and let $k_{opt} = \Phi(G)$. The algorithm finds a triangulation of G of size at most $8k_{opt}^2$ and can be implemented to run in time $O(k_{opt}nm + \min\{n^2M(k_{opt})/k_{opt}, nM(n)\})$.*

Proof. Correctness. By Theorems 4.2 and 2.4 a minimal triangulation of G'_A is a minimal triangulation of G'. Therefore at the end of the algorithm G is triangulated. Throughout the algorithm the only edges added to G are between vertices of A. Since $|A| \leq 4k_{opt}$, the size of the triangulation is at most $8k_{opt}^2$.

Complexity. The complexity analysis of procedures P_1 and P_2 in [16] implies that P_1' and P_2' can be performed in $O(k_{opt}nm)$-time. By Lemma 3.1 the complexity of P_3' is $O(nm + \min\{n^2M(k_{opt})/k_{opt}, nM(n)\})$. Procedure P_4' requires finding a minimal triangulation of G'_A. Since $|A| = O(\min\{k_{opt}, n\})$ and $|E(G'_A)| = O(\min\{k_{opt}^2, n^2\})$, this requires $O(\min\{k_{opt}^3, n^3\})$ time [19]. Hence, the complexity of the approximation algorithm is $O(k_{opt}nm + \min\{n^2M(k_{opt})/k_{opt}, nM(n)\})$. ∎

Note that, although our analysis uses an upper bound of $\binom{t}{2}$ for the triangulation size of a t-vertex graph, replacing G'_A by the complete graph is not guaranteed to produce a triangulation of G.

5. Bounded degree graphs. In order to improve the approximation ratio for bounded degree graphs, we improve P_4'. Instead of simply finding a minimal triangulation of G'_A, we use the triangulation algorithm of Agrawal, Klein, and Ravi [1].

This alone does not suffice to prove a better approximation ratio, since adding 0-essential edges (in P_3') might not be optimal. In other words, if we denote by F the set of 0-essential edges added to G by P_3', then it might be that $|F| + \Phi(G') > \Phi(G)$. To overcome this difficulty we use the KST partition algorithm with $k = \infty$ as its input parameter, which implies that no new edge will be added to G_A by P_3. The approximation algorithm is as follows:

(i) Execute the KST partition algorithm with parameter $k = \infty$.
(ii) Find a minimal triangulation of G_A using the algorithm in [1].

Assume that the input graph G has maximum degree d, and let $k = \Phi(G)$. We will show that the algorithm achieves an approximation ratio of $O(d^{2.5}\log^4(kd))$. Since $k = O(n^2)$, this is in fact a polylogarithmic approximation ratio. It improves over the $O(k)$ approximation ratio obtained in the previous section, when $k/\log^4 k = \Omega(d^{2.5})$.

THEOREM 5.1. *The algorithm finds a triangulation of G of size within a factor of $O(d^{2.5}\log^4(kd))$ of optimal.*

Proof. Correctness. By the correctness of the KST partition algorithm, we obtain a partition A, B of $V(G)$ for which no chordless cycle in G intersects B. By Theorem 2.4 a minimal triangulation of G_A is a minimal triangulation of G. Therefore, the algorithm correctly computes a minimal triangulation of G.

Approximation ratio. When executing P_3, the size of each set $A_{x,y}$ is at most d. By Lemma 3.3, $|A^3 \setminus A^2| = O(kd)$. Since $|A^2| = O(k)$, the size of A when the partition algorithm terminates is $O(kd)$. Setting the parameter value to ∞ in P_3 guarantees that no new edge is added to G_A, and therefore its maximum degree is at most d and $|E(G_A)| = O(kd^2)$. Using the algorithm in [1] we can produce a chordal supergraph of G_A with $O((kd^2+k)\sqrt{d}\log^4(kd))$ edges. The size of the fill-in obtained is therefore within a factor of $O(d^{2.5}\log^4(kd))$ of optimal. ∎

6. Reducing the kernel size. We now return to the parametric fill-in problem. Let $\langle G = (V, E), k\rangle$ be the input instance. By modifying procedure P_3 in the KST partition algorithm we shall obtain a partition A, B of V and a set of nonedges F, such that no chordless cycle in $G' = (V, E \cup F)$ intersects B and $|A| = O(k)$. In fact we shall obtain at most 2^k such pairs (A, F) and prove that if G has a k-triangulation, then at least for one of those pairs G'_A admits a $(k - |F|)$-triangulation. Reducing the size of A results in improving the complexity of finding a minimum triangulation of G'_A to $O(\sqrt{k}4^k)$, although the total time of the algorithm increases, since we have to handle up to 2^k pairs. We include this result, since it gives further insight on the problem and presents ideas that may help resolve the open problem posed in [16].

As in the original algorithm we start by executing procedures $P_1(k)$ and $P_2(k)$. We also compute the sets $A_{x,y}$ for all $x, y \in A^2, (x, y) \notin E$. If (x, y) is k-essential, we add it to G. Otherwise, we do nothing. Let $\hat{E}$ be the set of k-essential edges, and let $e = |\hat{E}|$. Define $P := \{(x, y) \notin E \cup \hat{E} : x, y \in A^2, A_{x,y} \neq \emptyset\}$, and let $p = |P|$.

The algorithm now enumerates subsets $F \subseteq P$. For a given set F, every $(x, y) \in F$ is added as an edge in the triangulation, and for every $(x, y) \in P \setminus F$, the vertices in $A_{x,y}$ are moved from B to A (which was initialized to A^2). Instead of directly enumerating each set F, we branch and bound. We construct these sets incrementally and stop when a lower bound for the size of the triangulation implied by F exceeds k.

Specifically, the algorithm considers pairs in P one at a time in an arbitrary order $(x_0, y_0), \ldots, (x_{p-1}, y_{p-1})$. For the current pair (x_i, y_i) it distinguishes between three cases as follows. Let $t = |A_{x_i,y_i} \setminus A|$ with respect to the current A. Let cc denote a lower bound for the size of the triangulation implied by the set F constructed so

far (cc is initialized to e). If $t = 0$, then the algorithm does nothing. If $t = 1$, it updates A to $A \cup A_{x_i,y_i}$ and increases cc by $1/2$. Finally, if $t \geq 2$, then the algorithm branches into two cases. In the first case, (x_i, y_i) is added to the triangulation and cc is increased by 1. In the second case, the vertices in A_{x_i,y_i} are moved from B to A, and cc is increased by $t/2$. The algorithm is implemented by the recursive procedure shown in Figure 6.1 and is invoked by calling BRANCH$(e, \emptyset, 0, A^2)$.

```
Procedure BRANCH(cc, F, r, A)
  If cc > k then return.
  If r = p then save the pair (A, F ∪ Ê) and return.
  Let t = |A_{x_r,y_r} \ A|.
  If t = 0 then
    Call BRANCH(cc, F, r + 1, A).
  Else if t = 1 then
    Call BRANCH(cc + 1/2, F, r + 1, A ∪ A_{x_r,y_r}).
  Else /* t ≥ 2 */
    Call BRANCH(cc + 1, F ∪ {(x_r, y_r)}, r + 1, A).
    Call BRANCH(cc + t/2, F, r + 1, A ∪ A_{x_r,y_r}).
  Return.
```

FIG. 6.1. *Algorithm BRANCH.*

LEMMA 6.1. *The algorithm terminates after at most* $p2^{k+1} + 1$ *calls to procedure BRANCH.*

Proof. Denote by $T(i, j)$ the number of recursive calls invoked by BRANCH when called with parameters $cc = i, r = j$ (including this first call). Since always $i \geq 0$ and $0 \leq j \leq p$ in the following, we consider these ranges only. Clearly, $T(i, j) \leq 1 + \max\{T(i, j + 1), T(i + 1/2, j + 1), 2T(i + 1, j + 1)\}$ for all $j < p, i$. Also, $T(i, j) = 1$ for all $i > k, j$, and $T(i, p) = 1$ for all i. It follows that $T(0, 0) \geq T(i, j)$ for all i, j. Hence, it suffices to compute an upper bound for $T(0, 0)$.

We prove that $T(i, j) \leq (p - j)2^{k+1-i} + 1$ by induction on i, j. For $i > k$ or $j = p$ the claim is true. Suppose the claim holds for all i, where $i' \leq i \leq k + 1$, and for all j, where $j' < j \leq p$. Then for $i = i'$ and $j = j'$ we have

$$\begin{aligned} T(i, j) &\leq 1 + \max\{T(i, j + 1), T(i + 1/2, j + 1), 2T(i + 1, j + 1)\} \\ &\leq 2 + \max\{(p - j - 1)2^{k+1-i}, (p - j - 1)2^{k+\frac{1}{2}-i}, (p - j - 1)2^{k+1-i} + 1\} \\ &\leq 3 + (p - j - 1)2^{k+1-i} \leq (p - j)2^{k+1-i} + 1 \ . \end{aligned}$$

It follows that $T(0, 0) \leq p2^{k+1} + 1$. ∎

LEMMA 6.2. *The number of pairs saved by the algorithm is at most* 2^k.

Proof. The proof is analogous to that of Lemma 6.1. Denote by $N(i, j)$ the number of pairs saved by procedure BRANCH, when invoked with parameters $cc = i, r = j$. Since always $i \geq 0$ and $0 \leq j \leq p$, in the following we consider these ranges only. Clearly, $N(i, j) \leq \max\{N(i, j + 1), N(i + 1/2, j + 1), 2N(i + 1, j + 1)\}$ for all $j < p, i$. Also, $N(i, j) = 0$ for all $i > k, j$, $N(k, j) \leq 1$ for all j, and $N(i, p) \leq 1$ for all i. It follows that $N(0, 0) \geq N(i, j)$ for all i, j. Thus, it suffices to compute an upper bound for $N(0, 0)$.

We prove that $N(i,j) \leq 2^{k-i}$ by induction on i,j. If $i \geq k$ or $j = p$, then the claim holds. Suppose the claim holds for all i, where $i' \leq i \leq k$, and for all j, where $j' < j \leq p$. Then for $i = i'$ and $j = j'$ we have

$$\begin{aligned} N(i,j) &\leq \max\{N(i,j+1), N(i+1/2,j+1), 2N(i+1,j+1)\} \\ &\leq \max\{2^{k-i}, 2^{k-\frac{1}{2}-i}, 2^{k-i}\} \\ &= 2^{k-i} . \end{aligned}$$

It follows that $N(0,0) \leq 2^k$. □

As usual, for a set $A \subseteq V$ saved by the algorithm, B denotes $V \setminus A$. The following two claims establish the correctness of our partition algorithm.

LEMMA 6.3. *For every pair (A,F) saved by the algorithm, $|A| \leq 6k$, and no chordless cycle in $G' = (V, E \cup F)$ intersects B.*

Proof. Whenever a partition is saved, $cc \leq k$. By definition of BRANCH, $\frac{1}{2}|A \setminus A^2| \leq cc$. Hence, at most $2k$ new vertices were added to A^2 in any partition obtained. Since $|A^2| \leq 4k$, we conclude that $|A| \leq 6k$. By Theorem 4.2 no chordless cycle in G' intersects B. □

DEFINITION 6.4. *A pair (A,F) saved by BRANCH is called* good *if $\Phi(G) = \Phi(G') + |F|$, where $G' = (V, E \cup F)$.*

PROPOSITION 6.5. *If $\Phi(G) \leq k$, then at least one pair saved by the algorithm is good.*

Proof. Let T be the tree of recursive calls of BRANCH. The nodes of T correspond to invocations of BRANCH. The root of T corresponds to the first invocation of BRANCH. The leaves of T correspond to invocations of BRANCH in which either a pair was saved, or cc was found to exceed k. In nodes at level i of T, $0 \leq i < p$, the pair $(x_i, y_i) \in P$ is processed. Let cc_v, F_v, r_v, and A_v denote the parameters of the invocation of BRANCH which correspond to node v of T.

Let F^* denote a minimum triangulation of G. The proof will identify a root-leaf path in T which corresponds to F^*, and trace the changes to cc, A, and F along that path. We use the following notation:

$$\begin{aligned} P_v &:= \{(x_0,y_0), \ldots, (x_{r_v-1}, y_{r_v-1})\} , \\ F_v^* &:= P_v \cap F^* , \\ A_v^* &:= A^2 \cup \bigcup_{(x,y) \in P_v \setminus F_v^*} A_{x,y} , \\ cc_v^* &:= e + |F_v^*| + \frac{1}{2}|A_v^* \setminus A^2| . \end{aligned}$$

LEMMA 6.6. *For every node v of T, $cc_v^* \leq k$.*

Proof. Let v be any node of T. Let $cc^* = e + |P \cap F^*| + \frac{1}{2}|\bigcup_{(x,y) \in P \setminus F^*} A_{x,y}|$. Since $P_v \subseteq P$, it follows that $cc_v^* \leq cc^*$. By Observation 3.2, for every pair $(x,y) \in P$, either $(x,y) \in F^*$, or for every $b \in A_{x,y}$, F^* contains an edge incident on b. Hence, $cc^* \leq |F^*| \leq k$, where the last inequality follows from the fact that F^* is a k-triangulation. □

We now return to the proof of Proposition 6.5. We shall prove that T has a leaf in which a good pair is saved. To this end, we show that for every $0 \leq i \leq p$, T contains some vertex v at level i for which $F_v \subseteq F_v^*$ and $cc_v \leq cc_v^*$. In particular, this claim implies that T has a leaf z at level p for which $F_z \subseteq F_z^*$ and $cc_z \leq cc_z^*$. By Lemma 6.6, $cc_z \leq cc_z^* \leq k$. Hence, the pair $(A_z, F_z \cup \hat{E})$ is saved at z. By [16, Lemma

2.7], $\hat{E} \subseteq F^*$. In addition, $F_z \subseteq F_z^* \subseteq F^*$. Therefore $(A_z, F_z \cup \hat{E})$ is a good pair, since $F_z \cup \hat{E} \subseteq F^*$ and, by definition, $F^* \setminus (F_z \cup \hat{E})$ triangulates $G' = (V, E \cup F_z \cup \hat{E})$.

We prove the claim by induction on i. The base of the induction is obvious, and as for the root r at level 0, $F_r = \emptyset$ and $cc_r = e$. We assume that the claim is true for level $i-1$ $(i > 0)$ and prove its correctness for level i. By the induction hypothesis T contains a node v at level $i-1 < p$ for which $F_v \subseteq F_v^*$ and $cc_v \leq cc_v^*$. By Lemma 6.6 $cc_v \leq cc_v^* \leq k$, and therefore v is not a leaf. Thus, v has either one or two children in T. There are two cases to examine.

1. Suppose that $(x_i, y_i) \in F^*$. Then for any child w of v, $cc_w^* = cc_v^* + 1 \geq cc_v + 1$. If v has a single child w, then $F_w = F_v \subseteq F_v^* \subset F_w^*$ and $cc_w \leq cc_v + 1/2 < cc_w^*$. Otherwise, let w be the child of v for which $(x_i, y_i) \in F_w$. Then clearly $F_w \subseteq F_w^*$ and $cc_w = cc_v + 1 \leq cc_w^*$.

2. Suppose that $(x_i, y_i) \notin F^*$. Since $F_v \subseteq F_v^*$ and $A_v = A^2 \cup \bigcup_{(x,y) \in P_v \setminus F_v} A_{x,y}$, it follows that $A_v^* \subseteq A_v$. Let w be the child of v for which $(x_i, y_i) \notin F_w$. Then $F_w = F_v \subseteq F_v^* = F_w^*$ and

$$cc_w = cc_v + \frac{1}{2}|A_{x_i,y_i} \setminus A_v| \leq cc_v^* + \frac{1}{2}|A_{x_i,y_i} \setminus A_v^*| = cc_w^* . \qquad \square$$

THEOREM 6.7. *If $\Phi(G) \leq k$, then the new partition algorithm produces at least one pair (A, F) for which $|A| \leq 6k$ and $\Phi(G) = \Phi(G'_A) + |F|$, where $G' = (V, E \cup F)$. The complexity of the algorithm is $O(knm + \min\{n^2 M(k)/k, nM(n)\} + k^3 2^k)$.*

Proof. Correctness. By Lemma 6.3 for each pair (A, F) saved by the algorithm, $|A| \leq 6k$ and no chordless cycle in G' intersects B. Therefore, by Theorem 2.4 for each such pair $\Phi(G') = \Phi(G'_A)$. Since $\Phi(G) \leq k$, by Proposition 6.5 the algorithm saves some pair (A, F) for which $\Phi(G) = \Phi(G') + |F|$. Correctness follows.

Complexity. By [16] P_1 and P_2 take $O(knm)$ time. By Lemma 3.1, computing the sets $A_{x,y}$ for all $x, y \in A^2, (x, y) \notin E$ takes $O(nm + \min\{n^2 M(k)/k, nM(n)\})$ time. By Lemma 6.1 and the fact that $|P| = O(k^2)$, the number of calls to BRANCH is $O(k^2 2^k)$. By Lemma 6.3 and since $\Phi(G) \leq k$, the parameters A and F to each invocation of BRANCH satisfy $|A| = O(k)$ and $|F| \leq k$. Also, for all $(x, y) \in P$, $|A_{x,y}| \leq 2k$. Thus, each call can be carried out in $O(k)$ time. The total work done by BRANCH is therefore $O(k^3 2^k)$. $\square$

7. An approximation algorithm for the chain completion problem. A bipartite graph $G = (P, Q, E)$ is called a *chain graph* if there exists an ordering π of P, $\pi : P \to \{1, \ldots, |P|\}$, such that $N(\pi^{-1}(1)) \subseteq N(\pi^{-1}(2)) \subseteq \cdots \subseteq N(\pi^{-1}(|P|))$. This class of graphs was introduced by Yannakakis [23], and independently by Golumbic (cf. [15, page 260]). The *chain completion* problem is defined as follows: Given a bipartite graph $G = (P, Q, E)$, find a minimum set of nonedges F such that $(P, Q, E \cup F)$ is a chain graph. We call $|F|$ the *chain fill-in*. Yannakakis proved that the chain completion problem is NP-complete and used this result to show that the minimum fill-in problem is NP-complete [23]. Chain graphs have been also investigated in [8], where a similar graph modification problem arises.

THEOREM 7.1. *There exists a polynomial approximation algorithm for the chain completion problem, achieving an approximation ratio of $8k$, where k denotes the minimum chain fill-in. The complexity of the algorithm is $O(kn^3)$.*

Proof. Let $G = (U, V, E)$ be an input bipartite graph with chain fill-in k. We apply the following reduction given by Yannakakis [23] from the chain completion problem to the minimum fill-in problem. Build a graph $G' = (U \cup V, E')$, where $E' = E \cup \{(u, v) : u, v \in U\} \cup \{(u, v) : u, v \in V\}$. Observe that G is a chain graph

if and only if G' is chordal. Hence, a set of edges F triangulates G' if and only if $(U, V, E \cup F)$ is a chain graph.

Approximation ratio. By the above argument, k equals $\Phi(G')$. Using our approximation algorithm for the minimum fill-in problem, we can find a triangulation of G' of size at most $8k^2$. Adding these edges to G produces a chain graph. The number of new edges is within a factor of $8k$ of optimal.

Complexity. G' can be computed in $O(n^2)$ time. Due to the reduction, $|E(G')| = \Theta(n^2)$. Therefore the complexity of the approximation algorithm is $O(kn^3)$. □

PARALLEL COMPLEXITY OF COMPUTATIONS WITH GENERAL AND TOEPLITZ-LIKE MATRICES FILLED WITH INTEGERS AND EXTENSIONS*

VICTOR Y. PAN†

Abstract. Computations with Toeplitz and Toeplitz-like matrices are fundamental for many areas of algebraic and numerical computing. The list of computational problems reducible to Toeplitz and Toeplitz-like computations includes, in particular, the evaluation of the greatest common divisor (gcd), the least common multiple (lcm), and the resultant of two polynomials, computing Padé approximation and the Berlekamp–Massey recurrence coefficients, as well as numerous problems reducible to these. Transition to Toeplitz and Toeplitz-like computations is currently the basis for the design of the parallel randomized NC (RNC) algorithms for these computational problems.

Our main result is in constructing nearly optimal randomized parallel algorithms for Toeplitz and Toeplitz-like computations and, consequently, for numerous related computational problems (including the computational problems listed above), where all the input values are integers and all the output values are computed exactly. This includes randomized parallel algorithms for computing the rank, the determinant, and a basis for the null-space of an $n \times n$ Toeplitz or Toeplitz-like matrix A filled with integers, as well as a solution $\mathbf{x}$ to a linear system $A\mathbf{x} = \mathbf{f}$ if the system is consistent. Our algorithms use $O((\log n)\log(n \log \|A\|))$ parallel time and $O(n \log n)$ processors, each capable of performing (in unit time) an arithmetic operation, a comparision, or a rounding of a rational number to a closest integer. The cost bounds cover the cost of the verification of the correctness of the output. The computations by these algorithms can be performed with the precision of $O(n \log \|A\|)$ bits, which matches the precision required in order to represent the output, except for the rank computation, where the precision of the computation decreases. The algorithms involve either a single random parameter or at most $2n - 1$ parameters.

The cited processor bounds are less by roughly factor n than ones supported by the known algorithms that run in polylogarithmic arithmetic time and do not use rounding to the closest integers.

Technically, we first devise new algorithms supporting our old nearly optimal complexity estimates for parallel computations with general matrices filled with integers. Then we decrease dramatically, by roughly factor $n^{1.376}$, the processor bounds required in these algorithms in the case where the input matrix is Toeplitz-like. Our algorithms exploit and combine some new techniques (which may be of independent interest, e.g., in the study of parallel and sequential computation of recursive factorization of integer matrices) as well as our earlier techniques of variable diagonal (relating to each other several known algebraic and numerical methods), stream contraction, and the truncation of displacement generators in Toeplitz-like computations; our development and application of these techniques may be of independent interest.

visor (gcd) of two polynomials of degrees at most n by using $O(n(\log n)^2)$ arithmetic or field operations (that is, additions, subtractions, multiplications, and divisions), but to yield substantial parallel acceleration, one has to reduce the problem to the solution of the associated (possibly singular) Toeplitz-like (resultant or subresultant) or Toeplitz linear system of $O(n)$ equations, $T\mathbf{x} = \mathbf{f}$ [BGH82], [G84], [BP94]. (The concepts of Toeplitz and Toeplitz-like matrices are well known (see [KKM79], [CKL-A87], [BP94], pp. 47–48, 138–141, 148–151), but for the reader's convenience, we recall their definitions below. (Also see Definitions 2.18 and 13.2 in sections 2 and 13.))

The gcd computation is only one (though celebrated) example of various major problems of algebraic and numerical computing whose solution is reduced to solving Toeplitz or Toeplitz-like linear systems of equations. The list of such problems includes the computation of the resultant, the Sturm and subresultant sequences, and the least common multiple (lcm) for a pair of univariate polynomials ([BT71], [BGY80], [BP94], sections 2.8–2.10), as well as the shift register synthesis and linear recurrence computation [Be68], [Ma75], inverse scattering [BK87], adaptive filtering [K74], [H91], modelling of stationary and nonstationary processes [KAGKA89], [KVM78], [K87], [L-AK84], [L-AKC84], numerical computations for Markov chains [Ste94], Padé approximation of an analytic function [BGY80], polynomial interpolation and multipoint evaluation [PSLT93], [PZHY97], solution of partial differential and integral equations [Bun85], [C47/48], [KLM78], [KVM78], parallel computations with general matrices over an arbitrary field of constants [P91], [P92], [KP91], [KP92], approximating polynomial zeros [P95], [P96a], [P97], and the solution of polynomial systems of equations [EP97], [MP98], [BMP98].

Furthermore, the general reduction techniques of [P90] enable us to extend the algorithms available for Toeplitz and Toeplitz-like computations to computations with some other major classes of structured matrices, such as Cauchy-like and Vandermonde-like matrices, also highly important in many areas of computing [PSLT93], [H95], [GKO95], [PZHY97], [OP98], [OP99], [P00], [P00a].

The design of new effective algorithms for parallel solution of Toeplitz and Toeplitz-like linear systems will be our major goal. For the reader's convenience, we will next briefly recall the definitions and some basic properties of Toeplitz and Toeplitz-like matrices. (See section 13 and Definition 2.18 of section 2 for more details.)

$T = (t_{i,j})$ is an $n \times n$ *Toeplitz matrix* if

$$t_{i,j} = t_{i+1,j+1} \quad \text{for} \quad i, j = 0, 1, \dots, n-2, \tag{1.1}$$

that is, if the entries of T are invariant in their shifts into the diagonal direction. Toeplitz matrices are easy to store, since such an $n \times n$ matrix is fully represented by the $2n-1$ entries of its first column (or row, respectively) and its last column (or row). Multiplication of an $n \times n$ Toeplitz matrix by a vector can be reduced to three fast Fourier transforms (FFTs) (e.g., via its reduction to polynomial multiplication modulo x^{2n-1} (see [BP94], p. 133)) and can be performed by using $O(n \log n)$ arithmetic operations. Hereafter, arithmetic operations, as well as comparisons of pairs of rational numbers and the rounding of a rational number to a closest integer, are referred to as *ops*.

Due to the structural properties of Toeplitz matrices, one may solve a nonsingular Toeplitz linear system of n equations by using $O(n(\log n)^2)$ ops [BGY80], [Morf80], [BA80], [Mu81], [dH87], [AGr88], [K95]. (Note that we would need storage space $n^2 + n$ and $2n^2 - n$ ops to multiply a general matrix by a vector and order of n^d ops with $d > 2$ to solve a general nonsingular linear system of n equations.)

The above properties are extended to the class of $n \times n$ *Toeplitz-like matrices*, that is, ones represented in the form

$$T = \sum_{i=1}^{\ell} L_i U_i, \tag{1.2}$$

where L_i and U_i^T are $n \times n$ lower triangular Toeplitz matrices, U_i^T is the transpose of U_i, and ℓ is bounded by a fixed constant, $\ell = O(1)$. (Note that any $n \times n$ matrix can be represented in the form (1.2) for $\ell \le n$.) It suffices to store the $2\ell n$ entries of the first columns of L_i and U_i^T for $i = 1, \dots, \ell$ in order to represent T. These 2ℓ columns form a pair of $n \times \ell$ matrices called a *displacement generator* of T of length ℓ.

Representation (1.2) for a Toeplitz-like matrix enables us to manipulate with $O(n)$ entries of its displacement generator (rather than with its n^2 entries). Furthermore, we may immediately multiply a matrix T of (1.2) by a vector by using $O(\ell n \log n)$ ops, and also we may solve a linear system $T\mathbf{x} = \mathbf{f}$ in $O(\ell^2 n (\log n)^2)$ ops if T is nonsingular [Morf80], [BA80], [Mu81].

We have $\ell \le 2$ in (1.2) for Toeplitz matrices, their inverses, and resultant matrices, and $\ell \le g + h$ for $g \times h$ block matrices with Toeplitz blocks. Furthermore, the transposition of a matrix leaves ℓ invariant, whereas ℓ may grow only slowly in multiplication and addition/subtraction of pairs of matrices and stays unchanged or grows only nominally in the inversion of a nonsingular matrix (see section 13).

1.2. NC and RNC solutions (some background). Due to their reduction to Toeplitz/Toeplitz-like linear systems, several computational problems listed in the previous section, including the gcd, lcm, and resultant computation and Padé approximation, can be solved by using $O(n(\log n)^{d_1})$ ops, where n is the input size, and $d_1 \le 3$. (We may need to allow $d_1 = 3$ in order to handle singular Toeplitz/Toeplitz-like linear systems; we reduce their solution to computing the rank of the coefficient matrix and to the subsequent solution of a nonsingular Toeplitz-like linear system.) Like the Euclidean algorithm, however, such solution algorithms require an order of n parallel steps.

The known alternative algorithms yield NC or randomized NC (RNC) solutions of all the cited computational problems [BGH82], [G84], [BP94], that is, yield their solution by using $t(n) = O((\log n)^c)$ time and $p(n) = O(n^d)$ arithmetic processors, for two fixed constants c and d, under the customary exclusive read exclusive write random access machine (EREW PRAM) arithmetic model of parallel computing [KR90], [J92]. (Alternatively, we may define the NC and RNC solutions as the families of arithmetic, Boolean, or arithmetic-Boolean circuits for the above problems having depths $O((\log n)^c)$ and sizes $O(n^d)$ for two fixed constants c and d [G86].) Indeed, the NC/RNC solution of a linear system of n equations can be computed over any field of constants [Cs76], [Be84], [Ch85], [KP91], [KP92]. These algorithms, however, leave open the important problem of processor efficiency of (R)NC Toeplitz and Toeplitz-like computations, that is, of having the ratios $p(n)/T_+(n)$ or even $p(n)/T_-(n)$ at the level $O((\log n)^{c_1})$ for a constant c_1, where $T_+(n)$ and $T_-(n)$ denote the record upper and lower bounds on the sequential time of the solution, respectively. Indeed, on the one hand, we have already cited the bound $T_+(n) = O(n(\log n)^3)$, and, clearly, $T_-(n) \ge n$. On the other hand, $p(n)$ has order n^d for $d > 3$ in [Cs76], [Be84], [Ch85] and for $d > 2$ in [KP91], [KP92], for solving general linear systems in NC/RNC, whereas $p(n)$ has order n^d for $d \ge 2$ for the known NC/RNC Toeplitz/Toeplitz-like solvers over any field of constants [P92], [KP94], [P96], [P96b]. To yield NC/RNC

and processor efficiency, we must decrease d to the optimal level 1. An approach toward this goal was outlined in [BP94, p. 357], incorporating various nontrivial techniques developed earlier for computations with general and dense structured matrices [Morf80], [BA80], [P85], [P87], [P92], [P92b], [P93], [P93a], and our objective in the present paper is to show in detail how this can be done, under certain assumptions on the model of computing.

1.3. The model of computing. Our main assumption is that the input consists of integers (for the reduction from a real input, one may use binary or decimal chopping followed by scaling) and that rounding a rational number to a closest integer, as well as an arithmetic operation or comparison of two rationals, are allowed as unit cost operations. The bit-precision of these computations will be bounded at the optimal level of the output precision, so that we achieve solution at a low Boolean cost.

Stating our estimates for the computational cost, we will let $O_A(t,p)$ and $O_B(t,p)$ denote the simultaneous bounds $O(t)$ on the parallel time and $O(p)$ on the number of arithmetic or Boolean processors, respectively. We will routinely decrease the processor bounds slightly, by exploiting the B-*principle* of parallel computing, which is a variant of Brent's principle and according to which $O(s)$ time-steps of a single arithmetic or Boolean processor may simulate a single time-step of s arithmetic or, respectively, Boolean processors [KR90], [PP95]. According to the B-principle, the bound $O_A(t,kp)$ implies the bound $O_A(tk,p)$, and similarly $O_B(t,kp)$ implies the bound $O_B(tk,p)$ for a parameter $k \geq 1$. (For $p=1$, we arrive at sequential time bounds $O_A(tk,1)$ and $O_B(tk,1)$.) By applying the well-known technique based on the B-principle, one may slow down the computations at the stages requiring too many processors. In many cases this increases the time bound only by a constant factor but more substantially decreases the processor bound; a celebrated example is the summation of n values, where application of the B-principle decreases the asymptotic cost bound from $O_A(\log n, n)$ to $O_A(\log n, n/\log n)$ (cf. [Q94, pp. 44–46]; [BP94, pp. 297–298]). (The converse trade-off of time and processor bounds is not generally possible, but for almost all matrix computations that we consider and, more generally, for any task of the evaluation of a set of multivariate polynomials, one may always transform an NC/RNC algorithm into one using $O(\log^2 n)$ time and $O(n^d)$ arithmetic processors for some finite but generally quite large constant d [VSBR83], [MRK88]. We will not use the latter result as we are concerned about processor bounds.)

REMARK 1.1. *Our algorithms for Toeplitz/Toeplitz-like computations are essentially reduced to computing the convolutions (which can be performed via FFT, assuming that the* 2^h*th roots of* 1 *are available) and the inner products of pairs of vectors. These basic operations (for vectors of a dimension* n*) can be performed at the cost* $O_A(\log n, n)$ *and* $O_A(\log n, n/\log n)$*, respectively, under both the EREW PRAM model and more realistic models such as hypercube, butterfly and shuffle-exchange processor arrays* [Le92], [Q94]. *Thus, it is possible to implement our algorithms efficiently assuming the latter models.*

1.4. Our main results. The algorithms of this paper extend our previous work on parallel computations with general matrices [P85], [P87], [P93a], [BP94] (cf. also [PR91], [P92a], [P93b], [PR93]) by means of incorporation of some techniques developed in [P90], [P92], [P92b], [P93], [P93a] for computations with Toeplitz and Toeplitz-like matrices. As a result, we arrive at RNC algorithms for the most fundamental computations with the latter classes of matrices filled with integers (such as the computation of their ranks, null-spaces and determinants and solving linear sys-

tems of equations). These algorithms yield optimal (up to polylogarithmic factors) time and processor bounds, which improves by factor n the processor bounds of the known RNC algorithms. By using the known reduction to Toeplitz and Toeplitz-like computations, we also extend our results to yield similar nearly optimal upper bounds on the time and processor complexity (also achieving order of n improvement versus the known RNC algorithms) for many other related computations (e.g., the computation of polynomial gcd and lcm and Padé approximation), where the input values are integers.

We will emulate the historic line, by first treating the case of general matrices and then improving the algorithms in the Toeplitz/Toeplitz-like case. We will start with recalling the record parallel complexity bounds of [P85], [P87] for computations with a general $n \times n$ input matrix; we will give their alternative derivation. Stating these bounds in Theorem 1.1 below, we will use the value ω satisfying $2 \le \omega < 2.376$ and such that a pair of $n \times n$ matrices can be multiplied at the arithmetic cost $O_A(\log n, n^\omega)$. We note that the magnitudes of det A and the integer entries of adj $A = A^{-1}$ det A can be as large as $||A||^n$ or $||A||^{n-1}$, which means the output precision of an order of $n \log ||A||$. We ensure that the precision of the computations by our algorithms does not exceed this level. Furthermore, we compute the rank of A by using even a lower precision, which enables some decrease of the Boolean cost of the computation of the rank.

Technically, we will largely follow the cited outline, given by us in [BP94, chapter 4], and combine a variety of the known techniques, in particular ones developed in [P85], [P87], [P92b], [P93], [P93a], and some new ones (such as the combination of primal and dual recursive decompositions of an integer matrix with the objective to bound the magnitude of the intermediate and output values). The required combination of all these techniques is highly nontrivial and never was presented in either complete or accessible form.

The main purpose of our paper is to give such a presentation or, formally speaking, to give complete and accessible proofs of the two theorems below. The first of them only handles the case of general integer input matrices (in this case our parallel complexity results repeat ones of [P85], [P87], except for the presently improved Boolean cost of the rank computation), but we use distinct alternative proof, which should be technically interesting in its own right and is fully used in our subsequent relatively simpler extension to the Toeplitz/Toeplitz-like case, handled by our second theorem.

THEOREM 1.1. *Let A be a $k \times h$ matrix and let $\mathbf{f}$ be an h-dimensional vector, both matrix and vector filled with integers that range from -2^a to 2^a for some $a > 1$. Let $k + h = O(n)$. Then, with an error probability of at most n^{-c} for a fixed positive constant c, one may compute r, the rank of A, at a randomized computational cost bounded by $O_A((\log n) \log(n \log a), n^\omega)$ and by*

$$O_B((\log n)(\log(n \log a))^2 \log\log(n \log a), n^{\omega+1} \log(na)).$$

Furthermore, one may compute the determinant of A and, if A is nonsingular, then also the inverse of A and the solution to a linear system $A\mathbf{x} = \mathbf{f}$, all of them at a randomized computational cost bounded by $O_A((\log n) \log(na), n^\omega)$ and by

$$O_B((\log n)(\log(na))^2 \log\log(na), (\log n)(a + \log n) n^{\omega+1} / \log(na)).$$

If A is an $n \times n$ singular matrix, the latter bounds also apply to the computation of $n - r$ basis vectors of a null-space of A and a solution $\mathbf{x}$ to a linear system $A\mathbf{x} = \mathbf{f}$ provided

that this system is consistent. The same cost bounds apply to testing correctness of the computed value of r=rank A *as well as of all other output values. In these computations,* $2n-1$ *random parameters are used for computing* rank A, $\det A$, *and the null-space of* A, *and a single random parameter is used for all other tasks including the computation of* $|\det A|$. *The above complexity estimates do not cover the cost of generation of the random parameters.*

In the case of a $k \times h$ Toeplitz or Toeplitz-like input matrix (defined in section 1.1 and also in sections 2 (Definition 2.18) and 13 (Definition 13.2)), an extension of our approach yields much smaller (by factor $n^{\omega-1}/\log n$) upper bounds on the processor complexity of the same computations (with no increase of the asymptotic time-bounds).

THEOREM 1.2. *Under the assumptions of Theorem* 1.1, *let the input matrix* A *be a Toeplitz matrix or a Toeplitz-like matrix. Then all the processor complexity estimates of Theorem* 1.1 *can be decreased by factor* $n^{\omega-1}/\log n$, *preserving the time bounds, to yield the randomized parallel complexity bounds* $O_A((\log n)\log(n\log a), n\log n)$, $O_B\ ((\log n)(\log(n\log a))^2\log\log(n\log a), (n^2\log n)\log(na))$, *and* $O_A((\log n)\log(na), n\log n)$, $O_B((\log n)(\log(na))^2\log\log(na), (a+\log n)(n\log n)^2/\log(na))$, *respectively. Here, the inverse of* A *and the basis matrix for the null-space of* A *are assumed to be output in the form of their displacement generators.*

We refer the reader to Remark 12.2 on possible minor refinement of the estimates of both theorems.

Due to substantial economization of computational resources in our algorithms for Toeplitz/Toeplitz-like computations, they may become practically efficient provided that they are supported by subroutines for multiprecision parallel computations with integers and polynomials and by the development of the interface between algebraic and numerical computing, both required in our algorithms. Such a development is motivated by various potential benefits, our algorithms is but one of many examples. The practical implementation of our algorithms for general $n \times n$ matrices faces a harder problem of the storage of n^2 long integers in the computer memory (versus $2n-1$ in the Toeplitz case), and this task becomes practically infeasible at some point as n increases.

Our algorithms do not improve the known sequential algorithms for Toeplitz and Toeplitz-like computations [BGY80], [Morf80], [BA80], [Mu81], [dH87], which run in nearly optimal arithmetic time of $O(n\log^2 n)$, but some of our techniques may be of practical and theoretical interest for sequential computations too. In particular, our Toeplitz–Newton iteration techniques are effective for rapid practical improvement of approximate solution of Toeplitz and Toeplitz-like linear systems of equations [PBRZ99], and our study of integral version of recursive decomposition as well as our bounds on the growth of the auxiliary integers (particularly, of the auxiliary determinants) is a natural but nontrivial extension of the Bareiss version of Gaussian elimination (cf. [B68]). Even our simple idea of the precision decrease in the randomized computation of the rank (by performing the computation modulo a fixed prime) leads to a substantial decrease of the sequential Boolean time bounds (for both general and Toeplitz/Toeplitz-like matrices). The latter trick also applies to the closely related problem of the computation of the degree of the gcd and lcm of two polynomials with integer coefficients.

1.5. Extensions. We already cited [BGY80], [G84], [P92], [P96b], and [BP94] on the reduction of the computation of the gcd, the lcm, and the resultant of two polynomials as well as Padé approximation of a formal power series or of a polynomial—to

the computation of the rank of a Toeplitz/Toeplitz-like matrix and solving a nonsingular Toeplitz/Toeplitz-like linear system of equations. The integrality of the input can be preserved in this reduction, and the input size may grow by a factor of at most 2. Therefore, *the computational complexity estimates of Theorem* 1.2 *are immediately extended to the listed problems* of the gcd, lcm, resultant and Padé computations (assuming the restrictions on the size and integrality of the input), as well as to various computational problems reducible to the latter ones.

Furthermore, we refer the reader to [P90], on the general techniques that immediately enable extension of our results of Theorem 1.2 to computations with Cauchy-like and Vandermonde-like input matrices, to [BP93], [BP94] on the extension to the case of matrices represented as the sums of Hankel-like and Toeplitz-like matrices, and to [BGY80], [BP94], [P96b], [PSLT93], [PZHY97], and other references cited in the beginning of this paper on various applications of the computations with Toeplitz-like and other structured matrices (see also Remark 14.1).

Among possible extensions of Theorem 1.1, consider the case where the integer matrix A is symmetric positive definite, sparse, and associated with an $s(n)$-separatable graph given with its $s(n)$-separator family (cf. [LRT79], [P93b], [PR93]). If such a matrix A is well conditioned (even if its entries are not integers but any real numbers), then, at the arithmetic cost $O_A((\log n)^3, (s(n))^\omega/\log n)$, the parallel algorithm of [P93b], [PR93] numerically computes both recursive factorization of such a matrix and its determinant, as well as a solution $\mathbf{x} = A^{-1}\mathbf{f}$ to a linear system $A\mathbf{x} = \mathbf{f}$ (if $\det A \neq 0$). Numerical approximation is involved in this algorithm at the auxiliary stages of matrix inversions, where a parallel algorithm of [PR89] is applied. If A is filled with integers, then this stage can be performed exactly, by using the algorithms of [P85], [P87]. Then, the exact recursive factorization of A, $\det A$, and $A^{-1}\mathbf{f}$ can be computed at the arithmetic cost $O_A((\log n)^3, (s(n))^\omega + n)$. By employing the algorithm of this paper for recursive decomposition and inversion of a general integer matrix, one may improve the latter bounds a little, to yield $O_A((\log n)^2, (s(n))^\omega + n)$.

The results of Theorems 1.1 and 1.2 can be further extended to various other matrix computations by using the known reduction techniques of [BP94], [P96], [P96b]. For demonstration, consider the computation of the characteristic polynomial $c_A(x) = \det(xI - A)$ of the above sparse $n \times n$ matrix A. Such a polynomial has degree n. We may first concurrently compute $c_A(x)$ at $n+1$ distinct points $x_0, \dots, x_n$ and then obtain its coefficients by interpolation. If the chosen values of x_i are larger than $n\|A\|$, then the matrices $x_iI - A$ are positive definite, and we may compute $c_A(x_i)$ for $i = 0, 1, \dots, n$, at the overall computational cost $O_A((\log n)^2, ((s(n))^\omega + n)n)$. These bounds dominate the cost of the subsequent interpolation producing the polynomial $\det(xI - A)$.

As another example, the algorithms of [BP94, p. 357], for Padé approximation and polynomial gcd have been used in [P95] and [P96a] in order to obtain the record parallel arithmetic complexity estimates for approximating polynomial zeros. Our present improvement of these results of [BP94] in Theorem 1.2 immediatley implies the respective minor improvement of the results of [P95] and [P96a].

COROLLARY 1.3. *Given a positive b and the coefficients of an nth degree monic polynomial with zeros $z_1, \dots, z_n$ satisfying $\max_i |z_i| \leq 1$, one may compute approximations $z_1^*, \dots, z_n^*$ to $z_1, \dots, z_n$ satisfying $|z_i^* - z_i| < 2^{-b}$, $i = 1, \dots, n$; the computation is randomized; its arithmetic cost is bounded by $O_A((\log n)^3((\log n)^2 + \log(b+2)), \frac{n}{\log n})$.*

1.6. Outline of the method. A major ingredient of our approach is the *variable diagonal method* of [P85], [P87], which combines several algebraic and numerical

techniques to yield effective parallel inversion of a matrix A filled with integers. The method includes *Newton's iteration*, which effectively solves the latter problem provided that a good *initial approximation* to A^{-1} is available. Such an approximation is not available, however, for a general integer matrix A. The recipe of [P85], [P87] is to invert at first the auxiliary matrix $F = V - apI$, where $V = A \bmod p$, I is the identity matrix of an appropriate size, p is a prime, $p \geq n$, and a is a sufficiently large integer. (We follow this recipe and show that it suffices to choose $a = 10pn^2$ in our case.) Then the matrix $-I/(ap)$ is a good initial approximation to F^{-1}, which we rapidly improve by Newton's iteration, until F^{-1} is approximated closely enough. Since F is an integer matrix, $\det F$ and the entries of adj $F = (\det F)F^{-1}$ are integers, which can be recovered by rounding their approximations within absolute errors less than $1/2$. This gives us $(\det A) \bmod p$, $(\text{adj } A) \bmod p$, and $A^{-1} \bmod p$. Then the algebraic technique of *p-adic (Newton–Hensel's) lifting* is applied. In ℓ steps, for a sufficiently large ℓ, the matrix $A^{-1} \bmod p$ is lifted to $A^{-1} \bmod p^L$, $L = 2^l$. Then the lifting of $A^{-1} \bmod p$ is extended to lifting similarly $(\det A) \bmod p$ and $(\text{adj } A) \bmod p$. Finally, $\det A$ and adj A are easily recovered from $(\det A) \bmod p^L$ and $(\text{adj } A) \bmod p^L$.

The remaining ingredient is the approximation of $\det F$. In [P85], [P87], this is achieved as a by-product of solving the more general task of computing $\det(xI - F)$, the characteristic polynomial of F. In the present paper, we employ a more routine approach, based on the computation of *recursive* (block) *decomposition* (RD) of F (cf. [St69], [Morf74], [Morf80], [BA80], [P87]) or, equivalently, on the computation of nested *Schur's complements*, also called *Gauss transforms* (cf. [C74], [F64]). A single recursive step of this approach is the decomposition of the input matrix (represented as a 2×2 block matrix) into the product of a block diagonal matrix and two block triangular matrices (see (2.3)). Such a decomposition can be obtained by block Gauss–Jordan elimination and can be reduced to a few matrix multiplications (their parallel implementation is simple) and inversions (they are made simple by Newton's iteration, since good initial approximations are given by matrices $-I/(ap)$). As in [P85], [P87], random choice of a large prime p in a fixed large interval enables us to avoid degeneration and singularities (with a high probability).

An important point, as in [P85], [P87], is that in spite of computing all the matrix inverses approximately, we finally recover them exactly (as well as all the other matrices involved in the RDs) by exploiting the representation of their entries as the ratios of integers. To emplasize this point, we called the resulting RDs the *integral RDs* (*IRDs*). The only remaining nontrivial problem in the computation of the IRD of F and $\det F$ is *to bound the magnitudes* of the integers involved. In the present paper, this problem is solved based on the computation of the *dual RD*, that is, the RD of F^{-1}. (The celebrated techniques of [B68] do not suffice, and their extension to our case is nontrivial not just because we deal with recursive block decomposition, rather than with the more customary Gaussian elimination, but also because we need to control the magnitudes of the determinants of the matrices involved in the RD, which is a much harder problem, and we use the dual RD in order to solve it.)

As soon as the IRDs of F and F^{-1} are available, we obtain the RDs modulo p of A and A^{-1}. Now, we apply the techniques of p-adic (Newton–Hensel's) lifting not only to $A^{-1} \bmod p$ but to the entire RDs modulo p of A and A^{-1}, in order to obtain the RDs modulo p^L of A and A^{-1} for $L = 2^l$ and a sufficiently large l. $(\det A) \bmod p^L$ is recovered from such an RD of A. As $\det A$ is an integer, we recover easily $\det A$ and then the matrix adj $A = A^{-1} \det A$, whose entries are integers.

This approach only gives us an alternative derivation of the estimates of [P85],

[P87] for parallel complexity of some fundamental computations with general matrices. The new algorithms, however (unlike ones of [P85], [P87]), have an advantage of allowing their effective extension to Toeplitz/Toeplitz-like cases. Indeed, manipulation with displacement generators, rather than with matrices themselves, enables the decrease of the processor complexity of the RNC algorithms outlined above to the optimal level linear in n.

The nontrivial problem in such a Toeplitz/Toeplitz-like extension is the control of the length of the displacement generators in the process of Newton's iteration. (Uncontrolled growth of the length would immediately imply the growth of the processor bounds by factor $n^{\omega-1}/\log n$ for $\omega > 2.375$.) We solve this problem by applying two techniques of *truncation of generators (TG)*, which we borrow from [P92] and [P92b], [P93], [P93a], respectively.

The above outline was essentially given by us in [BP94, chapter 4]. Presently, we also add the technique of *stream contraction* specified in section 10 (and, essentially, being the *pipelining* of the two processes of RD and Newton's iteration) borrowed from [PR91]. Stream contraction enables additional acceleration of our algorithms by factor $\log n$. (Using the technique of stream contraction for the acceleration of Toeplitz-like computations was also proposed in [R95], though the algorithms of [R95] did not give any improvement of the processor bounds in the Toeplitz/Toeplitz-like case versus the much larger bounds known in the case of general input matrices (see our Remarks 6.1, 11.1, and 14.2 and our similar comments in [P96b])).

1.7. Organization of the paper. The order of our presentation will slightly differ from the one outlined above. After some preliminaries in section 2, we will introduce the RD and extended RD (ERD) of a matrix in section 3. In section 4, we define the IRD and show the transition from RD to IRD. We recall an algorithm for approximate matrix inversion via Newton's iteration in section 5 and apply it in order to approximate the RD and the IRD of an integer matrix in section 6. We estimate the errors and parallel complexity of these computations in sections 7–9. We apply pipelining (stream contraction) to achieve acceleration by factor $\log n$ in section 10, extend the results of sections 6 and 10 to computing the ERD modulo a fixed prime in section 11, and use p-adic lifting to recover (from the ERD) the inverse, the determinant, the rank, and the null-space of an integer matrix (thus proving Theorem 1.1) in section 12. In section 13, we recall some known definitions and properties for computations with Toeplitz and Toeplitz-like matrices. In section 14, we apply these properties to improve the results of section 12 in the Toeplitz and Toeplitz-like cases (thus proving Theorem 1.2). Section 15 is left for a brief discussion.

2. Some definitions and auxiliary results for matrix computations. We will next recall some customary definitions and well-known basic properties of general matrices.

DEFINITION 2.1 (matrix notation). *I and 0 denote the* identity *and* null *matrices, of appropriate sizes. W^T is the* transpose *of a matrix or vector W.* diag $(w_i)_{i=0}^{n-1}$ = diag $(w_0, \dots, w_{n-1})$ *is the* diagonal matrix *whose diagonal is filled with $w_0, \dots, w_{n-1}$; $D(W)$ = diag (W) = diag $(w_{i,i})_{i=0}^{n-1}$ for a matrix $W = (w_{i,j})$.* rank W *is the* rank *of W.* det W *is the* determinant *of a square matrix W.* adj W *is the* adjoint (adjugate) matrix *of W, equal to W^{-1}* det W *for a nonsingular matrix W.*

In our error analysis, we will use the customary vector and matrix norms [GL89/96].

DEFINITION 2.2 (vector and matrix norms). $\| \mathbf{v} \| = \| \mathbf{v} \|_1 = \sum_i |v_i|$, $\| \mathbf{v} \|_2 = (\sum_i v_i^2)^{1/2}$ *for a real vector* $\mathbf{v} = (v_i)$. $\| W \|_g = \max_{\|\mathbf{v}\|_g = 1} \| W\mathbf{v} \|_g$, $g = 1, 2$; $\| W \| = \| W \|_1$ *for a matrix W.*

PROPOSITION 2.3 (norm bounds). $\| W \| = \| W \|_1 = \max_j \sum_i |w_{i,j}|$ *for a matrix* $W = (w_{i,j})$. *Furthermore, if* W *is a* $k \times k$ *matrix and* V *is its submatrix, then*

$$||V||_g \le ||W||_g, \ g = 1, 2;$$
$$||W||/k^{1/2} \le ||W||_2 \le ||W||k^{1/2}.$$

Proof. To prove the bound $||V||_g \le ||W||_g$, note that $||W\mathbf{w}||_g \ge ||V\mathbf{v}||_g$ if $\mathbf{v}$ is a subvector of $\mathbf{w}$ and if $\mathbf{w}$ has zero components corresponding to the columns of W that are not in V. Other claimed relations can be found in [GL89/96]. ∎

We will also use the following known fact (cf. [GL89/96] or [BP94]).

PROPOSITION 2.4 (bounds on the determinant and the entries of the adjoint matrix). *Let* W *be a* $k \times k$ *matrix. Then* $|\det W| \le (\| W \|_g)^k$, *and furthermore,* $|v| \le (\| W \|_g)^{k-1}$ *for every entry* v *of adj* W, *where* $g = 1, 2$.

DEFINITION 2.5 (column-diagonally dominant (c.-d.d.) matrices). $d(W) = \| WD^{-1}(W) - I \|$. *A matrix* W *is* column-diagonally dominant *(hereafter, we will use the abbreviation* c.-d.d.*) if* $d(W) < 1$.

DEFINITION 2.6 (leading principal submatrix (l.p.s.) and its Schur complement). *For a* $k \times k$ *matrix* W, *let* $W^{(q)}$ *denote its* $q \times q$ *northwestern or* l.p.s., *formed by the intersection of the first* q *rows and the first* q *columns of* W, $q = 1, 2, \dots, k$. *If* B *is a nonsingular l.p.s. of* W *and if*

$$W = \begin{pmatrix} B & C \\ E & G \end{pmatrix}, \tag{2.1}$$

then the matrix

$$S = S(W, B) = G - EB^{-1}C \tag{2.2}$$

is called the Schur complement *of* B *in* W.

The Schur complement S of (2.2) can be obtained by Gaussian or block Gaussian elimination applied to the matrix W, provided that the elimination process can be carried out (cf. [GL89/96, P3.2.2, p. 103]). In particular, it is easily verified that for $k > q$ the Schur complement of $B = W^{(q)}$ in a $k \times k$ matrix W is the $(k-q) \times (k-q)$ matrix obtained from W in q steps of Gaussian elimination (without pivoting) provided that these steps can be carried out (with no division by 0). The latter assumption holds, in particular, if W is a c.-d.d. matrix.

By applying block Gauss–Jordan elimination to the 2×2 block matrix W of (2.1), with a nonsingular block B, we obtain the following decomposition, which will be fundamental for our study:

$$W = \begin{pmatrix} I & 0 \\ EB^{-1} & I \end{pmatrix} \begin{pmatrix} B & 0 \\ 0 & S \end{pmatrix} \begin{pmatrix} I & B^{-1}C \\ 0 & I \end{pmatrix}. \tag{2.3}$$

If a matrix W is nonsingular, then (2.3) implies that the matrix S is also nonsingular. By inverting the matrices on both sides of (2.3), we obtain that

$$\tilde{W} = W^{-1} = \begin{pmatrix} I & -B^{-1}C \\ 0 & I \end{pmatrix} \begin{pmatrix} B^{-1} & 0 \\ 0 & S^{-1} \end{pmatrix} \begin{pmatrix} I & 0 \\ -EB^{-1} & I \end{pmatrix}. \tag{2.4}$$

Equation (2.4) immediately implies the following proposition.

PROPOSITION 2.7. *Under* (2.1)–(2.4), *the matrix* S^{-1} *is the trailing principal (that is, southeastern) submatrix of* $\tilde{W} = W^{-1}$.

Our algorithms will rely on the decompositions of (2.3), (2.4), recursively applied to the matrices B, B^{-1}, S, and S^{-1}, which we will call RDs. The next definitions and results will cover the nonsingularity properties required for the existence of such recursive extension of (2.3), (2.4) and some other relevant properties of l.p.s.'s and Schur complements (the s.p.d. matrices will be used only at the very end of section 12).

DEFINITION 2.8 (strongly nonsingular matrices). *A matrix W is* strongly nonsingular *if all its leading principal submatrices are nonsingular.*

DEFINITION 2.9 (symmetric positive definite (s.p.d.) matrices). *A real matrix M is s.p.d. if it can be represented as the product AA^T for a nonsingular matrix A.*

The next proposition (cf. [BP94, exercise 4c, p. 212]), extends strong nonsingularity and the s.p.d. property to an l.p.s. and a Schur complement.

PROPOSITION 2.10. *If a matrix W of* (2.1) *is strongly nonsingular (respectively, if W is s.p.d.), then so are its every l.p.s., including the matrix B of* (2.1), *and the Schur complement S of B, defined by* (2.2).

COROLLARY 2.11. *Any s.p.d. matrix is strongly nonsingular.*

By recursively applying block Gaussian elimination at first to the block matrix W of (2.1) with $B = W^{(r)}$ and then to $W^{(r)}$, with the *l.p.* (that is, leading principal or northwestern) block $W^{(q)}$, $q < r$, we obtain the following.

PROPOSITION 2.12 (transitivity of Schur's complementation). *If $r > q$ and if $W^{(r)}$ and $W^{(q)}$ are nonsingular matrices, then $S(W, W^{(q)}) = S(S(W, W^{(r)}), S(W, W^{(r)})^{(r-q)})$.*

We also easily deduce the following.

PROPOSITION 2.13 (transitivity of the c.-d.d. property). *If $d(W) < 1$ for a matrix W of* (2.1), *then B, S, and W are nonsingular matrices, $d(B) \le d(W) < 1$, $d(S) \le d(W) < 1$, and* (2.3)–(2.4) *hold.*

The following result, together with Propositions 2.4 and 2.12, will be basic for our bounds on the values involved in recursive decompositions.

PROPOSITION 2.14. *Assuming* (2.1)–(2.2), *every entry of the matrix S* det B *is a subdeterminant (that is, the determinant of a submatrix) of the matrix W.*

Proof. Let $B = W^{(q)}$. Consider the l.p. (that is, northwestern) entry $s_{0,0}$ of S. By Proposition 2.12, it is the Schur complement of B in the submatrix $W^{(q+1)}$ of W. By Proposition 2.7, $s_{0,0}^{-1} = \det B / \det W^{(q+1)}$. Therefore, $s_{0,0} \det B = \det W^{(q+1)}$, which proves the proposition for $s_{0,0}$. To extend this result to any entry $s_{i,j}$ of S, interchange the ith and 0th rows and the jth and 0th columns of S and the respective pairs of rows and columns of W. □

Clearly, the matrix adj $B = B^{-1}$ det B is filled with integers if W is. Proposition 2.14 (or, alternatively, (2.2)) implies the similar property of the matrix S det B. We summarize these observations for future references.

PROPOSITION 2.15 (integrality of adjoints and scaled Schur complements). *If a matrix W of* (2.1) *is filled with integers, then so are the matrices* adj $B = B^{-1}$det B *and S* det B.

Recursive application of the next result enables us to recover det W from recursive decomposition of W.

PROPOSITION 2.16 (factorization of the determinants and submatrices implied by matrix decomposition). *Matrix equation* (2.3) *implies that* det $W =$ *(*det B*)* det S *and, furthermore, that*

$$W^{(t)} = \begin{pmatrix} I & 0 \\ EB^{-1} & I \end{pmatrix}^{(t)} \begin{pmatrix} B & 0 \\ 0 & S \end{pmatrix}^{(t)} \begin{pmatrix} I & B^{-1}C \\ 0 & I \end{pmatrix}^{(t)} \quad \text{for } t = 1, \dots, k\ ,$$

and $\det W^{(t)} = (\det B) \det S^{(t-q)}$ *for* $t = q+1, \dots, k$, *provided that* W *is a* $k \times k$ *matrix.*

In section 12, we will also use the following definitions and known results.

DEFINITION 2.17 (the null-space of a matrix; cf. [GL89/96] or [BP94]). *The null-space* $\mathbf{N}(A)$ *of a matrix* A *is the linear space formed by all vectors* $\mathbf{x}$ *satisfying the vector equation* $A\mathbf{x} = \mathbf{0}$.

FACT 2.1. *Two vector equations,* $A\mathbf{x} = \mathbf{f}$ *and* $A\mathbf{y} = \mathbf{f}$, *together imply that* $\mathbf{x} - \mathbf{y} \in \mathbf{N}(A)$, *or, equivalently, any solution* $\mathbf{x}$ *to a consistent linear system* $A\mathbf{x} = \mathbf{f}$ *can be represented in the form* $\mathbf{x} = \mathbf{x}_0 + \mathbf{z}$, *where* $\mathbf{x}_0$ *is a fixed specific solution and* $\mathbf{z} \in \mathbf{N}(A)$.

Toeplitz matrix computations will be studied in sections 13 and 14, but also the proposition below involves Toeplitz matrices and is needed in section 12.

DEFINITION 2.18 (Toeplitz matrices). $T = (t_{i,j})$ *is a* $k \times k$ *Toeplitz matrix if* $t_{i+1,j+1} = t_{i,j}$ *for* $i, j = 0, 1, \dots, k-2$ *(cf.* (1.1)*), that is, if the entries of* T *are invariant in their shifts in the diagonal direction. (Such a matrix is defined by its two columns (or rows)—the first one and the last one.) A square lower triangular Toeplitz matrix is defined by its first column* $\mathbf{u}$ *and is denoted* $L(\mathbf{u})$. $Z = Z_k = (z_{i,j})$ *is a* $k \times k$ *lower triangular Toeplitz matrix with the first column* $(0, 1, 0, \dots, 0)^T$, *so that* $z_{i+1,i} = 1$ *for* $i = 0, 1, \dots, k-2$, $z_{i,j} = 0$ *if* $i \neq j+1$.

PROPOSITION 2.19 ([KS91], (cf. [BP94, Lemmas 1.5.1 and 2.13.1])). *Let* S *be a fixed finite set of cardinality* $|S|$. *Let* A, L, *and* U *be* $n \times n$ *matrices, let* $\operatorname{rank} A = r$, *let* L *and* U^T *be unit lower triangular Toeplitz matrices, each defined by the* $n-1$ *entries of its first columns. Let these entries be chosen from* S *at random, independently of each other, under the uniform probability distribution on* S. *Then the matrix* $(UAL)^{(r)}$ *is strongly nonsingular with a probability at least* $1-(r+1)r/|S|$.

3. RD and ERD of a c.-d.d. matrix. With minor deviation from the order of our outine of section 1.6 but in accordance with section 1.7, we will next study the RD, then, in section 4, the integral RD (IRD), and in section 5, matrix inversion.

Hereafter, for convenience, let log stand for $\log_2$, let $n = 2^h$ for an integer $h = \log n$, and let V be a fixed $n \times n$ c.-d.d. matrix.

We will define an RD of such a matrix $W = V$ based on its representation in the form (2.3) for $q = n/2$. We will first apply (2.3) to $W = V$ and then, recursively, to $W = B$ and $W = S$, and so on, though in fact, we will mostly care about the diagonal blocks V, $V_0 = B$, $V_1 = S$, and so on, which we will identify with the nodes of a binary tree, T. Similarly, we define the *dual RD* of $\tilde{W} = W^{-1}$ based on the recursive application of (2.4) to $\tilde{W} = B^{-1}$ and $\tilde{W} = S^{-1}$. (We will study such a dual RD in section 11 and will use it in section 12.)

The node of T associated with a binary strings α of length $|\alpha|$ is a $k \times k$ matrix, denoted by V_α, where $k = n/2^{|\alpha|}$. The root of the tree is the $n \times n$ matrix $V = V_\Lambda$, associated with the empty string Λ. For a string β of length less than h, we let $\beta 0$ and $\beta 1$ denote the two strings obtained by appending 0 and 1 to β, respectively. (We use the two characters α and β to distinguish between the two classes of binary strings—of length at most h and less than h, respectively.) We will assume that the matrix equations (2.1)–(2.4) are satisfied for $W = V_\beta$, $B = V_{\beta 0}$, $S = V_{\beta 1}$, and for any binary string β of length $|\beta| < h$. The resulting RD of the matrix V continues up to the level h, where it reaches its leaves-matrices $V_\alpha = (v_\alpha)$ of size 1×1, where $|\alpha| = h$, and where v_α denotes the single entry of V_α.

PROPOSITION 3.1. *All the nodes* V_α *of the tree* T *are c.-d.d. matrices; moreover,* $d(V_\alpha) \leq d(V) < 1$ *for all binary strings* α.

Proof. Recall that V is a c.-d.d. matrix and recursively apply Proposition 2.13. □

Let us formalize the computation of the RD of V by extending the notation (2.1)–(2.2) to V_α. We will write

$$V_\beta = \begin{pmatrix} B_\beta & C_\beta \\ E_\beta & G_\beta \end{pmatrix}, \tag{3.1}$$

$$V_{\beta 0} = B_\beta\ , \quad V_{\beta 1} = S_\beta = G_\beta - E_\beta B_\beta^{-1} C_\beta\ , \tag{3.2}$$

for all binary strings β of length less than h.

Then, computation of the RD of a c.-d.d. matrix V amounts to recursive computation of $V_{\beta 1}$ of (3.2) for all binary strings β of length increasing from 0 to $h-1$. As a by-product, the computation produces the matrices $V_{\beta 0}^{-1} = B_\beta^{-1}$ for all binary strings β of length less than h. By appending these inverse matrices $V_{\beta 0}^{-1}$ to the nodes $V_{\beta 0}$ of the tree T (and, consequently, to the RD of V), we arrive at the ERD of V. The set of the matrices $V_{\beta 0}^{-1}$ will be called the *extending set of the RD of* V.

The RD and the ERD of any matrix V can be defined as long as all the involved nodes-matrices $V_{\beta 0}$ for all the binary strings β of length less than h are nonsingular. Recursive application of Proposition 2.10 and Corollary 2.11 yields the following.

PROPOSITION 3.2. *There exists the RD and the ERD of any strongly nonsingular (in particular, of any s.p.d.) matrix.*

REMARK 3.1. *As soon as we have the RD of a c.-d.d. matrix* V*, we immediately obtain the RD of* V^{-1} *based on recursive application of* (2.4). *Having such an RD available, we may compute the solution* $\mathbf{x} = V^{-1}\mathbf{f}$ *of a linear system* $V\mathbf{x} = \mathbf{f}$*, at a lower computational cost* $O_A((\log n)^2, n^2/(\log n)^2)$.

4. IRD of a c.-d.d. matrix filled with integers. Suppose that the input matrix V is filled with integers. Then, for all binary strings α, the matrices V_α are filled with rationals, and there exist integer multipliers m_α such that $m_\alpha V_\alpha$ are integer matrices. We will next specify a particular choice of such integer multipliers m_α.

We will use the notation $W^{(q)}$ of Definition 2.6 and the following definition.

DEFINITION 4.1. $(\alpha)_2$ *denotes the binary value represented by a binary string* α *(of length at most* h*).* $\alpha(q)$ *denotes the binary string that represents a nonnegative binary value* q*, so that* $(\alpha(q))_2 = q$. $H(\alpha)$ *denotes* $2^{h-|\alpha|} = n/2^{|\alpha|}$. $Q(\alpha)$ *denotes* $(\alpha)_2 H(\alpha)$.

By applying Proposition 2.12, we obtain the following.

PROPOSITION 4.2. *Let a binary string* α *end with bit* 1 *and have length at most* h*. Then the matrix* V_α *is the Schur complement of* $V^{(Q(\alpha))}$ *in* $V^{(Q(\alpha)+H(\alpha))}$.

By combining this proposition with Proposition 2.14, we obtain the following.

PROPOSITION 4.3. *For any binary string* $\alpha = \beta 1 \gamma$ *of length at most* h *with* γ *being a string of zeros, let*

$$m_\alpha = \det V^{(Q(\beta 1))}. \tag{4.1}$$

Then the entries of the matrix $V_\alpha m_\alpha$ *are the subdeterminants (that is, the determinants of some submatrices) of the matrix* V*. In particular, if* V *is filled with integers, then so are the matrices* $V_\alpha m_\alpha$ *for all* $\alpha, |\alpha| \le h$.

Now we replace the matrix $V_{\alpha\gamma}$ by the pair of the scalar $m_\alpha = m_{\alpha\gamma}$ and the matrix $m_\alpha V_{\alpha\gamma}$, in the binary tree T, for every pair of binary strings α and γ such that

α ends with 1, $|\alpha| + |\gamma| \le h$, and γ consists only of zeros. This gives us the IRD of a c.-d.d. integer matrix V. By definition, we will also include into the IRD of V the two sets, $\{\det V^{(k)},\ k = 1, \dots, n\}$ and $\{\det V_\alpha, |\alpha| \le h\}$, of the determinants associated to the RD of V. Clearly, having the IRD of V available, we may immediately compute the RD of V. Later in this section, we will specify a simple transition from the RD to the IRD. In section 12, we will also compute a dual IRD by similarly extending the dual RD.

By combining Propositions 2.4 and 4.3, we obtain that for all binary strings $\alpha,\ |\alpha| \le h$, we have

$$|m_\alpha| \le \| V \|^n,\ ||m_\alpha V_\alpha|| \le n||V||^n. \tag{4.2}$$

For a c.-d.d. integer matrix V given together with its RD, we will seek its IRD. We recall that v_α for $|\alpha| = h$ denotes the single entry of the 1×1 leaf-matrix V_α of the tree T of the RD. Recursive application of Propositions 2.12 and 2.16 immediately yields the two following results.

PROPOSITION 4.4. *For every binary string α of length at most h, we have*

$$\det V_\alpha = \prod_\beta v_\beta,$$

where $\prod_\beta$ denotes the product in all binary strings β of length h that have α as their prefix; that is, the associated nodes V_β are both leaves of the tree T and descendants of the node V_α in the tree T.

PROPOSITION 4.5. *$\det V^{(q)} = \prod_{(\alpha)_2 < q} v_\alpha$, where $\prod_{(\alpha)_2 < q}$ denotes the product in all binary strings α of length h for which $(\alpha)_2 < q$.*

By applying the well-known parallel prefix algorithm [EG88], [KR90], we deduce the following result from Propositions 4.2–4.5 and 2.15.

COROLLARY 4.6. *Given the RD of a c.-d.d. $n \times n$ matrix V filled with integers, one may compute the IRD of V at the cost $O_A(\log n, n/\log n)$.*

Due to the latter result and to matrix equations (2.1)–(2.3), the computation of the IRD of V can be reduced to a sequence of multiplications, inversions, and subtractions of integer matrices, and we obtain the following parallel arithmetic complexity estimates:

$$t_{\mathrm{IRD}}(n) \le t_I(n/2) + t_{\mathrm{IRD}}(n/2) + 2t_M(n/2) + 1, \tag{4.3}$$

$$p_{\mathrm{IRD}}(n) \le \max\{p_I(n/2), 2p_{\mathrm{IRD}}(n/2), 2p_M(n/2), n^2\}, \tag{4.4}$$

where $O_A(t_{IRD}(k), p_{IRD}(k)), O_A(t_I(k), p_I(k))$, and $O_A(t_M(k), p_M(k))$ denote the time and processor bounds for the computation of the IRD, the inverse and the product of $k \times k$ matrices, respectively, where

$$(O_A(t_M(k), p_M(k)) = O_A(\log k, k^\omega), \quad 2 \le \omega < 2.376 \tag{4.5}$$

[BP94], and where we also use the obvious complexity bounds $O_A(t_S(k), p_S(k)) = O_A(1, k^2)$ for the subtraction of $k \times k$ matrices.

As the computation of the IRD is our major goal, relations (4.3)–(4.5) motivate the next subject of our study, that is, matrix inversion.

5. Approximate matrix inversion via Newton's iteration.

Algorithm 5.1. *Newton's iteration for approximate matrix inversion.*
Input: a nonsingular $k \times k$ matrix B, two positive scalars b and c, $b > c$, and a matrix X_0 (a rough initial approximation to $-B^{-1}$) such that

$$c = -\log \| BX_0 + I \| . \tag{5.1}$$

Output: a matrix X such that

$$\| BX - I \| \leq 2^{-b} \tag{5.2}$$

and, consequently,

$$\| X - B^{-1} \| \leq 2^{-b} \| B^{-1} \| . \tag{5.3}$$

Computations:
1. Compute

$$g = \lceil \log(b/c) \rceil. \tag{5.4}$$

2. Recursively compute the matrices

$$X_i = X_{i-1}(2I + BX_{i-1}) , \quad i = 1, \dots, g. \tag{5.5}$$

3. Output the matrix $X = -X_g$.

To prove *correctness* of Algorithm 5.1, deduce from (5.5) that

$$I + BX_i = (I + BX_{i-1})^2 , \quad i = 1, 2, \dots, g,$$

and, consequently,

$$I + BX_i = (I + BX_0)^{2^i},$$

$$\| I + BX_i \| \leq \| I + BX_0 \|^{2^i}, \tag{5.6}$$

for $i = 1, 2, \dots, g$. In particular, for $i = g$, we have

$$\| I + BX_g \| \leq \| I + BX_0 \|^{2^g} = 2^{-c2^g} \leq 2^{-b}$$

due to (5.1) and (5.4). This gives us (5.2) and (5.3) for $X = -X_g$.

To estimate the overall *computational cost* of performing Algorithm 5.1, observe that the ith step (5.5) amounts to two matrix multiplications and to adding, at the cost $O_A(1, k)$, the matrix $2I$ to the matrix BX_{i-1}. Summarizing, we obtain the following result.

PROPOSITION 5.1. *For g of* (5.4), *g steps* (5.5) *of Newton's iteration, performed at the overall cost $O_A(gt_M(k), p_M(k)) = O_A(g \log k, k^\omega)$ for ω of* (4.5), $2 \leq \omega < 2.376$, *suffice in order to compute a matrix $X = -X_g$ satisfying* (5.2) *and* (5.3).

REMARK 5.1. *Proposition* 5.1 *enables us to estimate the complexity of approximate matrix inversion in terms of a scalar b and a matrix X_0. Their choice depends on the input matrix B and is critical for estimating the approximation errors and the number of iterations. We will elaborate this choice in the next sections. Here are some*

preliminary comments on the choice of X_0. If B is a c.-d.d. matrix so that $d(B) < 1$, then (5.1) *holds for $X_0 = -D^{-1}(B)$ and $c = -\log d(B)$; that is, $||BX_0 + I|| \le d(B)$. This gives us a good policy for the choice of X_0 and c over the class of c.-d.d. matrices B. In this paper, however, we will only need to invert the c.-d.d. matrices B that are close to the scaled identity matrices $-mI$ for a fixed large integer m. The inverse of such a matrix B is well approximated by the scaled identity matrices $X_0 = -I/m$ satisfying*

$$||BX_0 + I|| < 1/(5n^2),\ c > 2\log n. \tag{5.7}$$

In fact our algorithms and complexity estimates will remain valid under some assumptions that are weaker than (5.7). *Say, the bound*

$$c = -\log ||BX_0 + I|| > \theta > 0 \tag{5.8}$$

for a fixed constant θ would suffice. The choice of $X_0 = D^{-1}(B)$ also satisfies the error bound of (5.7), *but $X_0 = -I/m$ is a Toeplitz matrix (see Definition* 2.18), *which will be a crucially important advantage for the proof of Theorem* 1.2 *in sections* 13 *and* 14.

6. Approximate RD of an integer matrix and its extension to the exact evaluation of the IRD. Algorithm 5.1 is intended as matrix inversion block in the algorithms of sections 3–4 for computing the ERD, IRD, and the associated determinants of a c.-d.d. integer matrix V. Then, the matrices V_α and the values of $\det V^{(q)}$ and $\det V_\alpha$ for all q and α are computed approximately, even where we still perform all arithmetic operations over the rationals, with infinite precision and no errors. Our next goal is to yield the exact IRD, assuming that we fixed a sufficiently large b and defined X_0 and c according to Remark 5.1.

Let us write $\tilde{V}_\alpha$, $\tilde{\det}\ V^{(q)}$, and $\tilde{\det}\ V_\alpha$ for the computed approximations to V_α, $\det\ V^{(q)}$, and $\det\ V_\alpha$, respectively. Then we extend the relations (3.1), (3.2), (5.1), (5.4), and (5.5) by writing

$$\tilde{V}_\beta = \begin{pmatrix} \tilde{B}_\beta & \tilde{C}_\beta \\ \tilde{E}_\beta & \tilde{G}_\beta \end{pmatrix}, \tag{6.1}$$

$$\tilde{V}_{\beta 0} = \tilde{B}_\beta\ , \qquad \tilde{V}_{\beta 1} = \tilde{G}_\beta - \tilde{E}_\beta X_\beta \tilde{C}_\beta\ , \tag{6.2}$$

for all binary strings β of length less than h, where the policy of defining $X_{\beta,0}$ (in accordance with Remark 5.1) will be specified later on, and where

$$c(\beta) = -\log \parallel \tilde{B}_\beta X_{\beta,0} + I \parallel, \tag{6.3}$$

$$g(\beta) = \log(b/c(\beta)), \tag{6.4}$$

$$X_{\beta,i} = X_{\beta,i-1}(2I + \tilde{B}_\beta X_{\beta,i-1})\ , \qquad i = 1, \dots, g(\beta), \tag{6.5}$$

$$X_\beta = -X_{\beta,g(\beta)}, \tag{6.6}$$

and I is the identity matrix of an appropriate size.

Algorithm 6.1. *Approximating the RD of a c.-d.d. matrix.*

Input: a positive integer h, $n = 2^h$, a positive b, positive integers $g(\alpha)$ for all binary strings α of length at most h, and an $n \times n$ c.-d.d. matrix $V = \tilde{V}_\Lambda$.

Output: a set of matrices $\tilde{V}_\alpha$ for all binary strings α of length at most h, satisfying (6.1)–(6.6), and the values $\tilde{\det} V_\alpha$ for all α and $\tilde{\det} V^{(q)}$, $q = 1, \dots, n$, defined according to Proposition 4.5 with det and v replaced by $\tilde{\det}$ and $\tilde{v}$, respectively.

Computations: Starting with $V = \tilde{V}_\Lambda$ for the empty string Λ, recursively apply (6.1)–(6.6) and a fixed policy of defining $X_{\beta,0}$, in order to compute $\tilde{V}_{\beta 0}$ and $\tilde{V}_{\beta 1}$ for all binary strings β of length less than h. (For binary strings β of length $h-1$, the matrices $\tilde{V}_{\beta 0}$ and $\tilde{V}_{\beta 1}$ have size 1×1, so $\tilde{V}_{\beta 0}$ is inverted immediately, and then the matrix $\tilde{V}_{\beta 1}$ is computed based on (2.1) and (2.2) for $W = \tilde{V}_\beta$.) Finally, compute $\tilde{\det} V_\alpha$ and $\tilde{\det} V^{(q)}$ for all α and q by applying Propositions 4.4 and 4.5, under the above modification of the notation.

Correctness of the algorithm is immediately verified, provided that the value b is chosen sufficiently large so that all matrices $\tilde{B}_\beta$—which approximate the c.-d.d. matrices B_β—still have the property of being c.-d.d. and that the matrices $X_0 = X_{\beta,0}$ are chosen satisfying (5.8) for $B = \tilde{B}_\beta$ for all binary strings β. We note that (5.6) and (6.4) together imply that $||I + \tilde{B}_\alpha X_\alpha|| \le 2^{-b}$ and, consequently,

$$||X_\alpha - \tilde{B}_\alpha^{-1}|| \le 2^{-b} ||\tilde{B}_\alpha^{-1}||, \tag{6.7}$$

which extends (5.3).

The computational cost is bounded by $O_A((\log n)^2 g, n^\omega)$ for $g = \max_{|\beta|<h} g(\beta)$ and for ω of (4.5). (Recursively apply (4.3)–(4.5) and Proposition 5.1.) A desired upper bound on g (and, consequently, on the parallel time) will be ensured by (5.8), (6.3), (6.4), and appropriate choice of b. Such a choice and its analysis will be shown in the next sections. $g(\beta)$ will in fact be independent of β, that is, we will choose $g(\beta) = g$ for all β.

Next, for a c.-d.d. matrix V filled with integers, we will apply Algorithm 6.1 for a sufficiently large b, and then we will apply the techniques of *integer rounding* (compare [P85], [P87], and [BP94, p. 252]), to extend the resulting approximate RD of V to the evaluation of the IRD of V. To yield this extension, we will choose b in Algorithm 6.1 sufficiently large to ensure the following bounds:

$$|\tilde{\det}\, V^{(q)} - \det V^{(q)}| < 1/2\ , \quad q = 1, \dots, n\ , \tag{6.8}$$

$$\| \tilde{V}_{\beta 1} - V_{\beta 1} \| < \| V \|^{-n}/2 \ \text{ for all binary strings } \beta, \ \ |\beta| < h, \tag{6.9}$$

where $\tilde{\det}\, V^{(q)}$ and $\tilde{V}_{\beta 1}$ denote the approximations to $\det V^{(q)}$ and $V_{\beta 1}$, respectively, computed by Algorithm 6.1 for the fixed value of b.

Under (6.8) and (6.9), we recover the IRD of V as follows.

Algorithm 6.2.

Input: a set $\{\tilde{\det}\, V^{(q)},\ q = 1, \dots, n\}$ of approximations to $\det V^{(q)}$ for all q and an approximate RD of an $n \times n$ matrix V filled with integers, such that (6.8) and (6.9) hold.

Output: the IRD of V.

Computations:

1. Round the values $\det \tilde{V}^{(q)}$ to the closest integers; output the resulting integer values of $\det V^{(q)}$, $q = 1, \dots, n$.

2. Compute the matrices $\tilde{W}_{\beta 1} = \tilde{V}_{\beta 1} \det V^{(Q(\beta 1))}$ and round their entries to the closest integers; output the resulting integer matrices $W_{\beta 1} = V_{\beta 1} \det V^{(Q(\beta 1)}$ for all binary strings β of length less than h.
3. For all binary strings β of length less than h and all binary strings γ filled with zero bits and satisfying $|\beta 1 \gamma| \le h$, output the matrices $W_{\beta 1\gamma} = V_{\beta 1\gamma} \det V^{(Q(\beta 1))}$ (cf. (4.1) and Definition 4.1).

Correctness of Algorithm 6.2 follows since, clearly, the values $\det V^{(q)}$ are integers for all q and since the matrices $W_{\beta 1} = V_{\beta 1} \det V^{(Q(\beta 1))}$ are filled with integers for all β (due to Proposition 4.3). The *computational cost* of performing the algorithm is bounded by $O_A(1, n^2)$.

REMARK 6.1. *Instead of choosing the multipliers $m_{\beta 1}$ based on Proposition* 4.3, *one may follow the more straightforward recipe of* [R95] *and recursively define m_β by using induction on $|\beta|$ and by writing $m_{\beta 1} = m_\beta \det V_{\beta 0}$. Then, however, the order of $\log |m_\beta|$ grows from $|\beta|$ (compare our bounds* (4.2)*) to $|\beta|^2$, and the bit-precision and the bit-complexity of the computations grow by the extra factor n. (The statement of Proposition* 5.1 *of* [R95] *is false. Its proof relies on an erroneous claim that if a matrix mA is filled with integers, then so is the matrix m* adj *A; this claim is false, say, for $m = 3$ and the matrix $A =$* diag $(1/3, \dots, 1/3)$.)

7. Errors of the approximation of the RD and the transition from the RD to the IRD for a c.-d.d. matrix. We are going to implement the next step of the outline of section 1.6 by specifying a c.-d.d. matrix V, whose IRD will give us the IRD of A modulo a prime p. We recall that, according to Definition 2.1, we write I to denote the identity matrices of appropriate sizes. We will next specify (in terms of n and $\|V\|$) a choice of the input parameter b of Algorithm 6.1 that will enable us to satisfy the relations (6.8) and (6.9), where V is an $n \times n$ matrix of the following class.

$$V = F - mI. \tag{7.1}$$

F is an $n \times n$ matrix filled with nonnegative integers that are less than a fixed prime $p \ge n$ (we will work with $F = A \bmod p$ for an input matrix A), and

$$m = 10p^2n^2. \tag{7.2}$$

REMARK 7.1. *The choice of a larger m would have made V more strongly diagonally dominant (which is what we would like to have) but would have involved larger integers, which would have increased the Boolean cost of the resulting computations, so we choose only a moderately large m. In fact, our construction allows us to choose even a little smaller m.*

Next, let us prove that the entries of the matrices V of this class and of all matrices V_α of their RDs satisfy the following rough estimate, which will suffice for our purpose.

PROPOSITION 7.1. *The entries of the matrices $V_\alpha + mI$ lie in the range between $-1/2$ and $p - 1/2$ for all binary strings α of length at most $h = \log n$.*

Proof. By the definition of the matrix V, the entries of the matrix $F = V + mI$ range from 0 to $p-1$. By Proposition 4.2, it suffices to prove that the entries of every Schur complement S of an l.p.s. $B = V^{(q)}$ in V range from $-1/2$ to $p - 1/2$. Since $S = G - EB^{-1}C$ (assuming (2.1) for $W = V$) and since the entries of the submatrix $G + mI$ of F range from 0 to $p - 1$, it suffices to prove that the entries of the matrix

$EB^{-1}C$ range between $-1/2$ and $1/2$. Since the matrices $F^{(q)} = B + mI$, C, and E are submatrices of F, their entries also range from 0 to $p-1$. Therefore,

$$||C|| < (p-1)n, ||E|| < (p-1)n,$$

$$-mB^{-1} = (I - F^{(q)}/m)^{-1} = \sum_{i=0}^{\infty} (F^{(q)}/m)^i,$$

$$||B^{-1}|| \le (1/m)(1/(1-a)),\ a = ||F^{(q)}||/m < (p-1)n/m < 0.03.$$

Consequently, $||B^{-1}|| < 2/m$, $||EB^{-1}C|| \le 2(p-1)^2n^2/m < 1/2$. ∎

Hereafter, we will write

$$w = m + (p-1)n. \tag{7.3}$$

Here are three corollaries of Proposition 7.1; the first and the third of them are immediate.

COROLLARY 7.2. *Let $|\alpha| = h$, so that $V_\alpha = (v_\alpha)$ is a 1×1 matrix. Then we have*

$$|v_\alpha| < m + p.$$

COROLLARY 7.3. $\| V_{\beta 0}^{-1} \| < 1.1/m$ *for all binary strings β of length at most $h-1$.*

Proof. Write $F_{\beta 0} = V_{\beta 0} + mI$. Due to Proposition 7.1, we have $\| F_{\beta 0} \| < (p-1)n < m/(10np)$. On the other hand,

$$V_{\beta 0}^{-1} = \frac{1}{m}(I - F_{\beta 0}/m)^{-1} = \left(\frac{1}{m}\right) \sum_{i=0}^{\infty} \left(\frac{F_{\beta 0}}{m}\right)^i.$$

Therefore,

$$\| V_{\beta 0}^{-1} \| \le \left(\frac{1}{m}\right) \sum_{i=0}^{\infty} \left(\frac{\| F_{\beta 0} \|}{m}\right)^i < \left(\frac{1}{m}\right) \sum_{i=0}^{\infty} \frac{1}{(10np)^i} = \frac{10np}{(10np-1)m} < \frac{1.1}{m}\ .$$ ∎

COROLLARY 7.4. $2^{c_\beta} = ||V_{\beta 0}X_{\beta,0} + I|| < 1/(10pn) \le 1/(10n^2)$ *for $X_{\beta,0} = -I/m$ and for all binary string β of length at most $h-1$.*

Hereafter, we will assume that $n > 1$ and that the matrices $X_{\beta,0}$ for all β are chosen as in Corollary 7.4, so that the relations (5.8) and even (5.7) hold. Our next task is to estimate the desired range for b, which would enable us to recover the IRD. In this section we will prove the following basic proposition.

PROPOSITION 7.5. *Under* (7.1)–(7.3), *both requirements* (6.8) *and* (6.9) *are satisfied if the matrices $V_{\beta 1}$ for all binary strings β of length less than h are approximated by Algorithm* 6.1 *within an error norm bound*

$$\sigma = 0.5/w^n. \tag{7.4}$$

Proof. We deduce from (7.1) and (7.3) that

$$\| V \| \le m + (p-1)(n-1) < w.$$

Therefore, we will satisfy (6.9) if we approximate the matrices $V_{\beta 1}$ within the error norm bound (7.4). To prove that (6.8) is satisfied too, we need the next lemma.

LEMMA 7.6. *The requirement* (6.8) *is satisfied if the values* v_α *for all binary strings* α *of length* h *are approximated within an error bound*

$$\delta \le \overline{w}^{1-n}/(2n+2),\ \overline{w} = m+p < w. \tag{7.5}$$

Proof of the lemma. By the virtue of Proposition 4.5, $\det V^{(q)}$ is the product of exactly q values v_α for α denoting binary strings of length h. Under the assumptions of Lemma 7.6, the maximum error of computing $\det V^{(q)}$ may only increase if we assume that $q = n$, that $v_\alpha = \overline{w}$, and that the approximations to v_α equal $\overline{w} + \delta$ for all α. Then, $\det V = \overline{w}^n$ is approximated by $(\overline{w}+\delta)^n$, with an approximation error

$$E = (\overline{w}+\delta)^n - \overline{w}^n = \overline{w}^n((1+(\delta/\overline{w}))^n - 1) = \overline{w}^{n-1}\delta\sum_{i=1}^{n}(\delta/\overline{w})^{i-1}\begin{pmatrix} n \\ i \end{pmatrix}.$$

We have $\binom{n}{1} = n$, $\binom{n}{i} < 2^n$ for all i, and $\delta/w < 1$. Therefore, $E < (n + (\delta/\overline{w})(n-1)2^n)\delta\overline{w}^{n-1}$.

Equations (7.2) and (7.5) together imply that

$$\overline{w} > (n-1)2^n\delta\ ,$$

and we may rewrite our bound on E as follows:

$$E < (n+1)\delta\overline{w}^{n-1}\ .$$

Substitute (7.5) and obtain that $E < 1/2$. ∎

To complete the proof of Proposition 7.5, we observe that

$$\sigma = 0.5/w^n < w^{1-n}/(2n+2) < \overline{w}^{1-n}/(2n+2)$$

(compare (7.5)), and the values v_α for all binary strings α of length h (except for the string $\alpha(0)$ consisting of h zeros) are among the entries of the matrices $V_{\beta 1}$ for $|\beta| \le h-1$. $v_{\alpha(0)}$ is an entry of V and is known exactly without any computation. Therefore, the assumptions of Lemma 7.6 and, consequently, the requirement (6.8) are satisfied too. ∎

8. Estimating the error accumulation and the precision of the approximation of the matrix inverse. In this section, we will extend Proposition 7.5 by estimating the parameter b of Algorithm 6.1 (which expresses the precision of the matrix inversion) to ensure (7.4) and, consequently, (6.8) and (6.9).

PROPOSITION 8.1. *Under some choice of* $b = O(n \log\ p)$, *the bounds* (6.8) *and* (6.9) *can be satisfied in all applications of Newton's iteration* (6.5) *within Algorithm* 6.1, *which is in turn applied to approximate the RD of a matrix* V *satisfying* (7.1) *and* (7.2).

The remainder of this section is devoted to the proof of Proposition 8.1. Due to the bound (5.6), it is actually quite clear that we would ensure (7.4) if we choose sufficiently large values $b = O(n\log p)$, $g(\alpha)$ of (6.4), and m of (7.1), but we will deduce (7.4) already for m of (7.2) and $g(\alpha) = O(\log(n\log p))$ for all α. As usually in the proofs involving error analysis, some tedious estimates are required. The idea of our proof is to condense estimating the error propagation into a single step, which will allow its recursive extension to cover all the nodes V_α of the tree representing the

RD. This basic step of our analysis will be given in the form of Proposition 8.2. (We will first give some preliminaries, then will state and prove this proposition, and then will show that its conclusion enables us to extend recursively its assumptions (and, consequently, its conclusion too) and thus to extend the error estimates recursively to all the descendants of the current node V_α of the tree.)

Proof of Proposition 8.1. Consider a path in the tree T from the root V to a leaf $V_\alpha = (v_\alpha)$, $|\alpha| = h$. Algorithm 6.1 follows such a path by recursively proceeding from matrices V_β to $V_{\beta 0}$ and $V_{\beta 1}$. For given V_β and $V_{\beta 0}$, the algorithm approximates the matrices $V_{\beta 0}^{-1}$ within the error norm bounds $2^{-b} \parallel V_{\beta 0}^{-1} \parallel$ and then extends such an approximation to approximating $V_{\beta 1}$. The errors of the computed approximations to V_β are accumulated in computation of all descendands of V_β along the paths in T. We need to estimate the resulting overall errors in all the output matrices along all such paths, assuming that b is large though of order $O(n \log\ p)$.

We will next analyze a single recursive step along such a path; that is, we will first bound the matrix $\Delta(V_\beta)$ of the initial errors of the approximation of $W = V_\beta$, and then we will estimate the propagated errors of the approximation of $S = V_{\beta 1}$ caused by the combined errors due to the initial ones, given by $\Delta(V_\beta)$, and ones of Newton's iterates for the inversion of $V_{\beta 0}$.

Hereafter, we will write $\tilde{M}$ to denote the approximations to matrices M computed by Algorithm 6.1, for M denoting V_α (for any binary string α), a submatrix of V_α, or any other auxiliary matrix involved. We will also write

$$\Delta(M) = \tilde{M} - M \ . \tag{8.1}$$

We will first estimate $\parallel \Delta(V_{\alpha 1}) \parallel$ in terms of $\parallel \Delta(V_\alpha) \parallel$. For convenience, we write $W = V_\alpha$, $S = V_{\alpha 1}$, recall (2.1), (2.2), and estimate the error propagation in the transition from W to B and S. From Proposition 7.1 and Corollary 7.3, we obtain that

$$\max\{\parallel B \parallel, \parallel C \parallel, \parallel E \parallel, \parallel G \parallel\} \leq \parallel W \parallel \leq w \ , \tag{8.2}$$

$$\parallel B^{-1} \parallel < 1.1/m \ . \tag{8.3}$$

We also write (cf. (8.1))

$$\tilde{W} = \begin{pmatrix} \tilde{B} & \tilde{C} \\ \tilde{E} & \tilde{G} \end{pmatrix}, \quad \Delta(W) = \begin{pmatrix} \Delta(B) & \Delta(C) \\ \Delta(E) & \Delta(G) \end{pmatrix},$$

$$\tilde{S} = \tilde{G} - \tilde{E}L\tilde{C},$$

where L denotes the computed approximation to $\tilde{B}^{-1}$. Then, clearly,

$$\max\{\parallel \tilde{B} \parallel, \parallel \tilde{C} \parallel, \parallel \tilde{E} \parallel, \parallel \tilde{G} \parallel\} \leq \parallel \tilde{W} \parallel, \tag{8.4}$$

$$\max\{\parallel \Delta(B) \parallel, \parallel \Delta(C) \parallel, \parallel \Delta(E) \parallel, \parallel \Delta(G) \parallel\} \leq \parallel \Delta(W) \parallel \ . \tag{8.5}$$

We will assume that the errors of the approximations obtained via Algorithm 6.1 are sufficiently small so that the following inequalities hold (also cf. the bound $||B^{-1}|| < 1.03/m$ obtained in the proof of Proposition 7.1):

$$\parallel L - \tilde{B}^{-1} \parallel \leq \nu \parallel \tilde{B}^{-1} \parallel, \quad \nu \leq 1/(4000m^2), \tag{8.6}$$

$$\| \tilde{B}^{-1} \| < 1.11/m, \quad \| L \| \le (1+\nu) \| \tilde{B}^{-1} \| < 1.11(1+\nu)/m. \tag{8.7}$$

REMARK 8.1. *The inequalities of* (8.6) *are reconciled with* (5.3) *for* $\nu \le 2^{-b}$, L *replacing* X, *and* $\tilde{B}$ *replacing* B.

In the next proposition we will bound approximation errors for $V_{\beta 0}$ and $V_{\beta 1}$ in terms of a single positive parameter $\Delta = \Delta(\beta)$ defined by the errors of the approximation of V_β and by the parameter ν, which is in turn defined by the error exponent b of Newton's iteration for the approximation of $\tilde{B}^{-1}$.

PROPOSITION 8.2. *Suppose that the inequalities* (8.2)–(8.7) *hold and that a positive* $\Delta = \Delta(\beta)$ *satisfies the following bounds:*

$$||\Delta(W)|| \le \Delta, \ 40\nu m \le \Delta < 0.01 \ w, \tag{8.8}$$

where $W = V_\beta$ *and* β *is a binary string of length less than* h. *Then, we have*

(a) $\| \Delta(B) \| = \| \Delta(V_{\beta 0}) \| \le \Delta$,

(b) $\| \Delta(S) \| = \| \Delta(V_{\beta 1}) \| \le 5\Delta$.

Proof. Part (a) of the proposition follows immediately since $V_{\beta 0}$ is a submatrix of V_β. To deduce part (b), we will use the following bound (implied by (8.2) and (8.8)):

$$\| \tilde{W} \| < 1.01 \ w, \tag{8.9}$$

as well as the next proposition.

PROPOSITION 8.3. *For any* 4*-tuple of* $k \times k$ *matrices,* X, $\tilde{X}$, Y, *and* $\tilde{Y}$, *we have*

(a) $\| \Delta(X \pm Y) \| \le \| \Delta(X) \| + \| \Delta(Y) \|$,

(b) $\| \Delta(XY) \| \le \| \Delta(X) \| \ \| Y \| + \| \Delta(Y) \| \ \| X \| + \| \Delta(X) \| \ \| \Delta(Y) \|$,

and if X *and* $\tilde{X}$ *are nonsingular matrices, then also*

(c) $\| \Delta(X^{-1}) \| \le \| X^{-1} \| \ \| \tilde{X}^{-1} \| \ \| \Delta(X) \|$.

Proof. The parts (a)–(c) follow immediatley from the next simple equations:

(a) $\Delta(X \pm Y) = \Delta(X) \pm \Delta(Y)$,

(b) $\Delta(XY) = \Delta(X)Y + X\Delta(Y) + \Delta(X)\Delta(Y)$,

(c) $\Delta(X^{-1}) = X^{-1}\Delta(X)\tilde{X}^{-1} = -\tilde{X}^{-1}\Delta(X)X^{-1}$. ∎

Since $S = G - EB^{-1}C$ under (2.2), we will next recursively extend the bound $||\Delta W||$ on the error norms of G, E, B, and C to yield some bounds on the error norms of B^{-1}, EB^{-1}, $EB^{-1}C$, and S.

We first apply part (c) of the latter proposition for $X = B$ and $\Delta(X^{-1}) = \tilde{B}^{-1} - B^{-1}$ and obtain that

$$\| \Delta(B^{-1}) \| \le \| B^{-1} \| \ \| \tilde{B}^{-1} \| \ \| \Delta(B) \| .$$

Substitute (8.3) and (8.7) into the latter bound and obtain that

$$\| \Delta(B^{-1}) \| < 1.221 \ \| \Delta(W) \| / m^2.$$

Combine the relations (8.6) and (8.7) to obtain that $||L - \tilde{B}^{-1}|| \le 1.11\nu/m \le (1.11)\Delta/(4000m^3)$. Combine the latter bounds on the norms, recall (8.8), and deduce that

$$\| L - B^{-1} \| \le \| \Delta(B^{-1}) \| + \| L - \tilde{B}^{-1} \| < (1.221 + (1.11)/(4000m))\Delta/m^2$$

$$< 1.3\Delta/m^2 \ . \tag{8.10}$$

Apply part (b) of Proposition 8.3 for $X = E$, $Y = L$, and deduce that

$$\| \Delta(EL) \| \leq \| \Delta(E) \| \| L \| + \| L - B^{-1} \| (\| E \| + \| \Delta(E) \|) .$$

Recall from (7.2) and (7.3) that $w/m \leq 1.02$. By combining the two latter inequalities with our bounds on $\| L \|$, $\| L - B^{-1} \|$, $\| E \|$, and $\| \Delta(E) \|$ (see (8.4)–(8.10)), obtain that

$$\| \Delta(EL) \| \leq \left(\frac{1.11}{m}(1+\nu) + \left(\frac{1.3}{m^2} \right) 1.01w \right) \Delta \leq \frac{2.5}{m} \Delta . \tag{8.11}$$

Then again, we apply part (b) of Proposition 8.3, this time for $X = EL$, $Y = C$, and obtain that

$$\| \Delta(ELC) \| \leq \| \Delta(EL) \| \| \tilde{C} \| + \| \Delta(C) \| \| EL \| .$$

Substitute our previous estimates (8.2), (8.4)–(8.9), and (8.11) into the latter inequality and deduce that

$$\| \Delta(ELC) \| \leq \left(\left(\frac{2.5}{m} \right) 1.01w + \frac{1.11}{m}(1+\nu)w \right) \Delta \leq 3.7 \Delta w/m.$$

Now, since $w/m \leq 1.02$, we have

$$\| \Delta(ELC) \| \leq 4\Delta.$$

We obtain $\| \Delta(G) \| \leq \Delta$ from (8.5) and (8.8). By applying part (a) of Proposition 8.3 for $X = G$, $Y = ELC$, we deduce that

$$\| \Delta(S) \| \leq \| \Delta(ELC) \| + \| \Delta(G) \| \leq 5\Delta,$$

which proves Proposition 8.2. □

Now, we observe that the assumptions of Proposition 8.2 are satisfied for $W = V$, $\tilde{W} = V$, and $\Delta = 40\nu m$, and we extend them to $W = V_\alpha$ for all α. The extension from $W = V_\beta$ to $W = V_{\beta 0}$ for any β is trivial. We will comment on the extension to $W = V_1$, which will be our sample for the extension from $W = V_\beta$ to $W = V_{\beta 1}$ for any β. We write $\tilde{B} = B = V_0$, $L = -X_{1,g}$, $X_{1,0} = -I/m$, $g \geq 4$, and define by (6.5) the matrices $X_{1,i}$ for all i. Now, observe that $||I + X_{1,0}W|| = ||F||/m$, $||I + X_{1,0}\tilde{W}|| \leq ||F||/m + \Delta/m \leq (\Delta + (p-1)n)/m < 1/(10pn) < 1/m^{1/2}$.

Therefore, (5.6) implies that

$$\| X_i + B^{-1} \| \leq \| B^{-1} \| / m^{2^{i-1}}, \quad i = 1, \ldots, g,$$

and, consequently, since $L = -X_g$ for $g \geq 4$, we have

$$\| L - B^{-1} \| \leq \nu \| B^{-1} \| \quad \text{for} \quad \nu \leq 1/m^8 < 1/(4000m^2n^{12}),$$

thus satisfying (8.6). The remaining assumption (8.7) of Proposition 8.2 is also easily verified (by using (8.5) and (8.8) and by following the line of the proof of Corollary 7.3).

Now, we are ready to extend Proposition 8.2 recursively, which will give us the desired upper bound on $||\Delta(V_\alpha)||$ in terms of b. By applying this proposition recursively, we extend its assumptions to $W = V_0$, $W = V_1$, $\Delta = 40\nu m$. (In the subsequent

recursive extension from $W = V_{\beta 1}$ to $W = V_\beta$ for any binary string β of length at most $h-1$, we will choose ν depending on α but satisfying (8.6) for all α.)

Apply the bounds of parts (a) and (b) of Proposition 8.2 recursively and obtain that

$$\| \Delta(W) \| \leq \Delta \sum_{i=0}^{|\alpha|} 5^i < n^3 \Delta$$

for $W = V_\alpha$ and all α (with $|\alpha| \leq h = \log n$). Let us choose a b that enables us to reconcile the initial choice of $\Delta = 40\nu m$ and the latter bound on $||\Delta(W)||$ with (8.6)–(8.8). Recall Remark 8.1, recall that the choice of g according to (6.4) implies the bound (6.7) on the output approximation to the inverse, substitute $\nu = 2^{-b}$, and obtain the desired estimate:

$$\| \Delta(V_\alpha) \| < (40mn^3\Delta)2^{-b} < 2^{2-b}w^2 n \tag{8.12}$$

for all α.

Let us choose b of order $n \log p$ satisfying the bound

$$b \geq 3 + \log n + (n+2)\log w,$$

which is compatible with the choice of $b = \log(1/\nu)$ and with (8.6). Substitute this bound on b into the preceding upper bound on $\| \Delta(V_\alpha) \|$ and obtain that

$$\| \Delta(V_\alpha) \| < 0.5\ w^{-n}$$

for all α. This satisfies the requirement (7.4) of Proposition 7.5 and completes the proof of Proposition 8.1.

REMARK 8.2. *By Corollary* 7.4, $c(\beta) = O(\log n)$ *for all binary strings* β *of length at most* $h-1$. *Furthermore,* (6.4) *and the above choice of* b *are compatible with the choice of* $g = g(\beta)$ *of order* $\log b = \log(n \log p)$ *for all* β.

9. Computations with rounding-off: Estimates for the finite precision and computational cost. So far, we assumed the infinite precision of computing the RD and IRD by means of Algorithms 6.1 and 6.2. Next, we will show that this is not necessary for obtaining the result of Proposition 8.1; that is, we will prove the following.

PROPOSITION 9.1. *The estimates of Proposition* 8.1 *hold even if the computations by Algorithms* 6.1 *and* 6.2 *are performed with a precision of* $\tilde{b}$ *bits, for some* $\tilde{b} = O(n \log\ p)$ *provided that a single extra Newton's step* (6.5) *is performed in each application of Algorithm* 6.1.

Proof. Let us first assume the computations of Newton's step (6.5) with the infinite precision, but in the transition from $W = V_\alpha$ to $S = V_{\alpha 1}$ for all binary strings α, $|\alpha| < h$, let the computations be performed with rounding to the $\tilde{b}$-bit precision. Assuming B^{-1} available, the latter transition involves two multiplications and a subtraction of $k \times k$ matrices for $k = 2^{h-|\alpha|}$ (compare (2.2)). By applying the techniques of backward error analysis [W65], [BL80], we bound the norm of the matrix $\epsilon(S)$ of the errors of the approximation to S caused by rounding:

$$\| \epsilon(S) \| \leq n^{O(1)} 2^{-\tilde{b}} \| W \| (1 + \| L \| \| W \|)$$

for L denoting the computed approximation to B^{-1} (cf. (8.6), (8.7)). By applying the relations (8.2), (8.7), (7.2), (7.3), and Proposition 7.1, we obtain that

$$\| \epsilon(S) \| \leq m^{O(1)} 2^{-\tilde{b}} .$$

By choosing $\tilde{b}$ of order $n \log p$, we make $\| \epsilon(S) \|$ less than $2 \| \Delta(W) \|$ for $W = V_\alpha$ and for all α. This is less than 40% of the upper bound that we have in part (b) of Proposition 8.2. Combining both of these bounds gives us cumulative upper bound $7 \| \Delta(W) \|$, which shows the overall impact of the above rounding errors. This enables us to preserve the validity of the bound (8.12) (since $\sum_{i=0}^{h} 7^i \leq n^3$ for $h = \log n$) and, consequently, of the entire proof of Proposition 8.1.

It remains to estimate the impact of rounding to $\tilde{b}$-bit precision when we perform Newton's steps (6.5). Then again, we deal with two matrix multiplications (we ignore the errors caused by the simple addition step $2I + (WX_{i-1})$). By applying backward error analysis again, we estimate that

$$\| \epsilon(X_i) \| \leq n^{O(1)} 2^{-\tilde{b}} \| X_{i-1} \| (2 + \| W \| \| X_{i-1} \|) , \tag{9.1}$$

where $\epsilon(X_i)$ denotes the matrix of the errors of approximation of X_i due to rounding in performing iteration (6.5).

Our next goal is to prove the bound

$$\| X_{i-1} \| \leq 1.1(1 + 1/\tilde{m})/m < 1.21/m \quad \text{for } i \geq 1, \tag{9.2}$$

ignoring for simplicity the terms of order $2^{-2\tilde{b}}$ or less.

We have from Corollary 7.4 that $\|I + BX_0\| < \frac{1}{\tilde{m}}$ for $\tilde{m} = 10pn \geq 20p$ and for $X_0 = -I/m$. Then we obtain from (5.6) that

$$\| I + BX_{i-1} \| \leq 1/\tilde{m}^{2^{i-1}}.$$

Therefore,

$$\| X_{i-1} + B^{-1} \| \leq \| B^{-1} \| / \tilde{m}^{2^{i-1}} .$$

Consequently,

$$\| X_{i-1} \| \leq \| B^{-1} \| \left(1 + \frac{1}{\tilde{m}^{2^{i-1}}}\right)$$

for $i = 1, 2, \ldots$. Substitute (8.3) and arrive at inequality (9.2).

Substitute bound (9.2) on $\| X_{i-1} \|$ and the bound $\| W \| \leq w$ of (8.2) into (9.1), recall (7.2) and (7.3), and obtain that

$$\| \epsilon(X_i) \| \leq (np)^{O(1)} 2^{-\tilde{b}} \quad \text{for all } i .$$

By choosing a sufficiently large $\tilde{b}$, though of order $n \log\ p$, we easily ensure that

$$\| \epsilon(X_i) \| < 2^{-b} / \| B \| .$$

Therefore,

$$\| I + B(X_i + \epsilon(X_i)) \| \leq \| I + BX_i \| + \| B \| \, \| \epsilon(X_i) \|$$

$$\leq \| I + BX_{i-1} \|^2 + 2^{-b} .$$

Since Newton's iteration (6.5) stops if $\| I + BX_{i-1} \| \leq 2^{-b}$, we may assume that $\| I + BX_{i-1} \| > 2^{-b}$, so that the rounding may at worst change (6.7) into the bound

$$\| I + B(X_i + \epsilon(X_i)) \| \leq 2 \| I + BX_i \| \leq 2^{\sigma} \| I + BX_0 \|^{2^i} < 2(2 \| I + BX_0 \|)^{2^i},$$

where $\sigma = \sum_{s=0}^{i} 2^s < 2^{i+1}$. Since $\| I + BX_0 \| \leq 1/m$, the impact of the rounding on the residual norm of the output approximation computed by Newton's iteration is more than compensated by a single extra step (5.5), (6.5), and this completes the proof of Proposition 9.1. □

Let us next summarize our current complexity extimates for the computation of the IRD before we improve them slightly in the next section. Choose b and $\tilde{b}$ of order $n \log p$ and choose g of order $\log(n \log p)$, which is consistent with (6.4) under (5.7) or (5.8). Now, by combining the results of Corollaries 4.6 and 7.3 and Propositions 8.1 and 9.1 with Remark 8.2 and the estimates for the arithmetic parallel complexity of performing Algorithms 6.1 and 6.2 and by using the B-principle, obtain the following corollary.

COROLLARY 9.2. *Algorithm* 6.2 *computes the IRD of a matrix* V *satisfying* (7.1) *and* (7.2) *at the cost* $O_A((\log n)^2 \log(n \log p), n^{\omega}/\log n)$ *for* ω *of* (4.5). *Furthermore,* $\tilde{b}$*-bit precision suffices in these computations for some* $\tilde{b}$ *of order* $n \log p$.

10. Pipelined computation of the IRD. Our next goal is a modification of Algorithm 7.1, which, as we claimed in section 1.6, will enable us to improve by factor $\log n$ the asymptotic time-complexity bounds of Corollary 9.2, without increasing the processor bound by more than a constant factor. To achieve this goal, we will incorporate into our construction the techniques of *pipelining* along the lines of [PR91] (where such techniques were called *stream contraction* and applied to computing the RD of a matrix over semirings of a certain class). Here are our informal underlying observations.

Algorithm 6.1 is not fully efficient because it spends substantial time and work on refining the approximations to the inverses of the matrices $\tilde{B}_{\beta} = \tilde{V}_{\beta 0}$ (cf. (6.5)); this delays the subsequent use of such approximations in the inversion of the matrices $\tilde{V}_{\beta 10} = \tilde{B}_{\beta 1}$, which anyway starts with a much cruder approximation $-I/m$. Next, we will modify Algorithm 6.1. We will start the Newton process of the inversion of $\tilde{B}_{\beta 1}$ by relying on the available rough approximations to $\tilde{B}_{\beta}^{-1}$, and then we will recursively produce a stream of better approximations when the process progresses.

In other words, we are going to pipeline the recursion on α (decomposition) and the Newton one (inversion). To approximate the matrix $V_{\beta 1}$ of the RD and ERD, we will start using the intermediate approximations to the inverse $V_{\beta 0}^{-1}$, as soon as they are computed by Newton's iteration. We will update the resulting approximation to $V_{\beta 1}$ as soon as the approximation to $V_{\beta 0}^{-1}$ is refined; that is, in the process of the computation of the matrix $\tilde{V}_{\beta 1}$, we will keep refining every step of the computations as soon as we refine its input.

More precisely, we will initialize this process by fixing some natural g, to be specified later on. As before, α and β will denote binary strings, $|\alpha| \leq h$, $|\beta| < h$, and γ will denote the unary strings consisting of zero bits. $u(\alpha)$ will denote the number of bits one in a binary string α. t will denote integers in the range from t_0 to $g + h$.

Here, $t_0 = u(\alpha)$ in (10.1) and (10.3) (where α is fixed), $t_0 = u(\beta) + 1$ in (10.4)–(10.7) (where β is fixed), and $t_0 = 0$ elsewhere, that is, in (10.2).

We will now define the following matrices whose subscripts α, β, γ, and t range as specifed above:

$$V_{\alpha,t} = \begin{pmatrix} B_{\alpha,t} & C_{\alpha,t} \\ E_{\alpha,t} & G_{\alpha,t} \end{pmatrix}, \tag{10.1}$$

$$V_{\gamma,t} = V_\gamma \tag{10.2}$$

(cf. Definition 2.6),

$$V_{\alpha\gamma,t} = (V_{\alpha,t})^{(q)} \text{ for } |\alpha\gamma| \le h,\ q = 2^{h-|\alpha\gamma|}, \tag{10.3}$$

$$X_{\beta,t,0} = \begin{cases} -I/m \text{ for } t = u(\beta) + 1, \\ -X_{\beta,t-1} \text{ for } t > u(\beta) + 1, \end{cases} \tag{10.4}$$

$$X_{\beta,t,i+1} = X_{\beta,t,i}(2I + V_{\beta 0,t} X_{\beta,t,i}),\ i = 0, 1, 2, 3, 4, \tag{10.5}$$

$$X_{\beta,t} = -X_{\beta,t,4}, \tag{10.6}$$

$$V_{\beta 1,t+1} = G_{\beta,t} - E_{\beta,t} X_{\beta,t} C_{\beta,t}. \tag{10.7}$$

Now, we are ready to specify our pipelined algorithm.

Algorithm 10.1. *Stream contraction for approximating the RD.*

Input: natural g, h, and $n = 2^h$; an $n \times n$ matrix V.

Output: for all binary strings α of length at most h, matrices $V_{\alpha,g+u(\alpha)}$ satisfying the equations (10.1)–(10.7) and approximating the matrices V_α, respectively.

Computations:

Stage 0. Apply (10.2) for $t = 0$ to define the matrices $V_{\gamma,0}$, $|\gamma| = 0, \dots, h$.

Stage t, $\mathbf{t = 1, \dots, g + h}$.

Concurrently in all binary strings β of length less than h with $u(\beta) < t$, compute successively:

(a) $X_{\beta,t,0}$, based on (10.4),

(b) $X_{\beta,t,i+1}$ for $i = 0, 1, 2, 3, 4$, based on (10.5),

(c) $X_{\beta,t}$, by (10.6),

(d) $V_{\beta 1,t+1} = G_{\beta,t} - E_{\beta,t} X_{\beta,t} C_{\beta,t}$, based on (10.1) and (10.7),

(e) $V_{\beta 1\gamma,t+1}$, by (10.3) where $\alpha = \beta 1$.

These rules are complemented by the following.

Stopping criterion: Output the matrices $V_{\alpha,g+u(\alpha)}$ for all binary strings α of length at most h and cancel all the subsequent computations involving these matrices.

For the reader's convenience, we will next list the matrices computed at stages 1, 2, and 3, letting $\gamma_0, \gamma_1, \gamma_2, \gamma_3$ denote unary strings filled with zeros.

Stage 1:

$X_{\gamma_0,1,0} = -I/m$,

$X_{\gamma_0,1,i+1} = X_{\gamma_0,1,i}(2I + V_{\gamma_0 0} X_{\gamma_0,1,i})$, $i = 0, 1, 2, 3, 4$,
$X_{\gamma_0,1} = -X_{\gamma_0,1,4}$,
$V_{\gamma_0 1,2} = G_{\gamma_0} - E_{\gamma_0} X_{\gamma_0,1,} C_{\gamma_0}$ for $G_{\gamma_0}, E_{\gamma_0}, C_{\gamma_0}$ of (3.1), $|\gamma_0| < h$,
$V_{\gamma_0 1\gamma_1,2} = V^{(q)}_{\gamma_0 1,2}$ for $q = 2^{h-1-|\gamma_0\gamma_1|}, |\gamma_0\gamma_1| < h$.
Stage 2: $X_{\gamma_0,2,0} = -X_{\gamma_0,1}$,
$X_{\gamma_0,2,i+1} = X_{\gamma_0,2,i}(2I + V_{\gamma_0 0,2} X_{\gamma_0,2,i})$, $i = 0, 1, 2, 3, 4$,
$X_{\gamma_0,2} = -X_{\gamma_0,2,5}$,
$V_{\gamma_0 1,3} = G_{\gamma_0} - E_{\gamma_0} X_{\gamma_0,2} C_{\gamma_0}$ for $|\gamma_0| < h$,
$V_{\gamma_0 1\gamma_1,3} = V^{(q)}_{\gamma_0 1,3}$ for $q = 2^{h-1-|\gamma_0\gamma_1|}$, $|\gamma_0\gamma_1| < h$,
$X_{\gamma_0 1\gamma_1,2,0} = -I/m$,
$X_{\gamma_0 1\gamma_1,2,i+1} = X_{\gamma_0 1\gamma_1,2,i}(2I + V_{\gamma_0 1\gamma_1 0,2} X_{\gamma_0 1\gamma_1,2,i})$, $i = 0, 1, 2, 3, 4$,
$X_{\gamma_0 1\gamma_1,2} = -X_{\gamma_0 1\gamma_1,2,5}$,
$V_{\gamma_0 1\gamma_1 1,3} = G_{\gamma_0 1\gamma_1,2} - E_{\gamma_0 1\gamma_1,2} X_{\gamma_0 1\gamma_1,2} C_{\gamma_0 1\gamma_1,2}$ for $G_{\gamma_0 1\gamma_1,2}, E_{\gamma_0 1\gamma_1,2}, C_{\gamma_0 1\gamma_1,2}$ of (10.1), with $\alpha = \gamma_0 1\gamma_1, t = 2, |\gamma_0\gamma_1| < h - 1$,
$V_{\gamma_0 1\gamma_1 1\gamma_2,3} = V^{(q)}_{\gamma_0 1\gamma_1 1,3}$ for $q = 2^{h-2-|\gamma_0\gamma_1\gamma_2|}, |\gamma_0\gamma_1\gamma_2| < h - 1$.
Stage 3: $X_{\gamma_0,3,0} = -X_{\gamma_0,2}$,
$X_{\gamma_0,3,i+1} = X_{\gamma_0,3,i}(2I + V_{\gamma_0 0} X_{\gamma_0,3,i})$, $i = 0, 1, 2, 3, 4$,
$X_{\gamma_0,3} = -X_{\gamma_0,3,5}$,
$V_{\gamma_0 1,4} = G_{\gamma_0} - E_{\gamma_0} X_{\gamma_0,3} C_{\gamma_0}$ for $|\gamma_0| < h$,
$V_{\gamma_0 1\gamma_1,4} = V^{(q)}_{\gamma_0 1,4}$ for $q = 2^{h-1-|\gamma_0\gamma_1|}, |\gamma_0\gamma_1| < h$,
$X_{\gamma_0 1\gamma_1,3,0} = -X_{\gamma_0 1\gamma_1,2}$,
$X_{\gamma_0 1\gamma_1,3,i+1} = X_{\gamma_0 1\gamma_1,3,i}(2I + V_{\gamma_0 1\gamma_1 0,3} X_{\gamma_0 1\gamma_1,3,i})$, $i = 0, 1, 2, 3, 4$,
$X_{\gamma_0 1\gamma_1,3} = -X_{\gamma_0 1\gamma_1,3,5}$,
$V_{\gamma_0 1\gamma_1 1,4} = G_{\gamma_0 1\gamma_1,3} - E_{\gamma_0 1\gamma_1,3} X_{\gamma_0 1\gamma_1,3} C_{\gamma_0 1\gamma_1,3}$ for $G_{\gamma_0 1\gamma_1,3}, E_{\gamma_0 1\gamma_1,3}, C_{\gamma_0 1\gamma_1,3}$ of (10.1) with $\alpha = \gamma_0 1\gamma_1, t = 3, |\gamma_0\gamma_1| < h - 1$,
$V_{\gamma_0 1\gamma_1 1\gamma_2,4} = V^{(q)}_{\gamma_0 1\gamma_1 1,4}$ for $q = 2^{h-2-|\gamma_0\gamma_1\gamma_2|}, |\gamma_0\gamma_1\gamma_2| < h - 1$,
$X_{\gamma_0 1\gamma_1 1\gamma_2,3,0} = -I/m$,
$X_{\gamma_0 1\gamma_1 1\gamma_2,3,i+1} = X_{\gamma_0 1\gamma_1 1\gamma_2,3,i}(2I + V_{\gamma_0 1\gamma_1 1\gamma_2 0,3} X_{\gamma_0 1\gamma_1 1\gamma_2,3,i})$, $i = 0, 1, 2, 3, 4$,
$X_{\gamma_0 1\gamma_1 1\gamma_2,3} = -X_{\gamma_0 1\gamma_1 1\gamma_2,3,5}$,
$V_{\gamma_0 1\gamma_1 1\gamma_2 1,4} = G_{\gamma_0 1\gamma_1 1\gamma_2,3} - E_{\gamma_0 1\gamma_1 1\gamma_2,3} X_{\gamma_0 1\gamma_1 1\gamma_2,3} C_{\gamma_0 1\gamma_1 1\gamma_2,3}$ for $G_{\gamma_0 1\gamma_1 1\gamma_2,3}, E_{\gamma_0 1\gamma_1 1\gamma_2,3}, C_{\gamma_0 1\gamma_1 1\gamma_2,3}$ of (10.1), with $\alpha = \gamma_0 1\gamma_1 1\gamma_2$, $t = 3$, $|\gamma_0\gamma_1\gamma_2| < h - 2$,
$V_{\gamma_0 1\gamma_1 1\gamma_2 1\gamma_3,4} = V^{(q)}_{\gamma_0 1\gamma_1 1\gamma_2 1,3}, q = 2^{h-3-|\gamma_0\gamma_1\gamma_2\gamma_3|}, |\gamma_0\gamma_1\gamma_2\gamma_3| < h - 2$.

Correctness of Algorithm 10.1 is immediatley verified. It remains to specify the choice of natural g, which would satisfy the requirements of Proposition 7.5, and then to estimate the resulting *compuational cost*.

As in section 8, we assume infinite precision computations in Algorithm 10.1, but the same techniques of backward error analysis as in section 9 enable relatively simple transition to the case of computations with rounding to finite precision of order $n \log\ p$ bits.

The analysis of the approximation errors and of the computation precision given in section 8 is easily extended. In particular, the extension of Proposition 8.2 and its proof is immediate provided that in its statement $V_\beta, V_{\beta 0}$, and $V_{\beta 1}$ are replaced by $V_{\beta,t}$, $V_{\beta 0,t+1}$, and $V_{\beta 1,t+1}$, $t > u(\beta)$. Furthermore, the assumptions of this proposition are extended recursively with each increase of t and the length $|\beta|$ by 1. Such an extension is analyzed as in section 9. (The transition from $V_{\beta,t}$ to $V_{\beta 1,t+1}$ involves five Newton steps (10.5), versus four steps used in section 8; an extra step compensates us for the impact of the rounding errors; this suffices according to the analysis

in section 9.) The small factor 5 of the error propagation bound of part (b) of Propostion 8.2 (even when it increases to 7 due to the rounding errors) is immediately suppressed by Newton's steps (10.5). To accomodate the factors 5 or 7, we also should increase the upper bound on $||V_{\beta 0,t}^{-1}X_{\beta,t,0}+I||$ obtained in Corollary 7.4; the increase is from $1/(10n^2)$ to $1/(2n^2)$ or to $7/(10n^2)$, respectively. This, however, implies only a nominal increase of g, which we may set equal to

$$g = 1 + \lceil \log(b/(2\log n))\rceil, \tag{10.8}$$

say. ($2\log n$ in the denominator replaces $\log(10n^2)$, which more than compensates us for the error propagation factors 5 or 7.) The computation of every $V_{\alpha,g+u(\alpha)}$ involves at least $5g$ Newton steps (10.5), so that the output error norm bound 2^{-b} is guaranteed under (10.8). Therefore, to satisfy the requirement (7.4) of Proposition 7.5, it is sufficient to choose b of order $n\log p$. Then, by (10.8), we have

$$g = O(\log(n\log p)). \tag{10.9}$$

Now, let us estimate the *computational cost* of performing Algorithm 10.1.

For any t, Stage t amounts essentially to ten steps of multiplication of at most n/k pairs of $k\times k$ matrices for $k=2^\ell$, $\ell=1,2,\dots,h$. All these multiplications for $k=2^\ell$ and for all ℓ are performed concurrently. Their overall cost is bounded by $O_A(\log n, n^\omega)$, $2\le\omega<2.376$ (compare (4.5) and observe that $\sum_{\ell=1}^h 2^\ell(n/2^\ell)^\omega = O(n^\omega)$ for $\omega>1$). Summarizing these bounds for all stages t, $t=1,\dots,g+h$, we obtain the following proposition.

PROPOSITION 10.1. *Algorithm* 10.1 *supports approximating the RD of a c.-d.d.* $n\times n$ *matrix* V *of* (7.1) *within the error norm bound* 2^{-b}*, at the overall cost* $O_A((\log n)(\log n+g), n^\omega)$ *for* g *of* (10.8) *and* ω *of* (4.5).

By combining Algorithms 10.1 and 6.2, summarizing the estimates for the computational cost of their performance, given in particular in (10.9) and Proposition 10.1, and extending the rounding error analysis applied in the proof of Proposition 9.1, we obtain the following corollary.

COROLLARY 10.2. *The IRD of a c.-d.d.* $n\times n$ *matrix* V *of* (7.1) *can be exactly computed at the computational cost* $O_A((\log n)\log(n\log p), n^\omega)$ *for* ω *of* (4.5), $2\le\omega<2.376$*; moreover, this computation can be performed by only involving operations with* $\tilde b$*-bit precision numbers for* $\tilde b = O(n\log\ p)$.

11. Computing modulo a fixed prime of the ERD of an integer matrix. Our next goal is probabilistic extension of Corollary 10.2 from the class of matrices V of (7.1) to the class of all strongly nonsingular integer matrices A. In this section, we will compute the IRD and even the ERD of A modulo a fixed prime p; in the next section we will shift to the IRD of A.

Let $A=(a_{i,j})$ be a strongly nonsingular $n\times n$ matrix filled with integers $a_{i,j}$. Then by virtue of Proposition 3.2, there exists the RD of A. Let p be a fixed prime, let $0\le f_{i,j}=a_{i,j} \bmod p<p$ for all i,j, and let

$$F=(f_{i,j})=A \bmod p\ . \tag{11.1}$$

(Here and hereafter, we assume that $0\le a \bmod p<p$ for any integer a.)

We will compute modulo p the ERD of the matrix F as an auxiliary stage of computing the ERD of A. At first, we should examine if there exists the ERD modulo p of F.

LEMMA 11.1 (see [IR82]). *Let $f(n)$ be a function defined on the set of positive integers such that $f(n) > 0$ and $\lim_{n\to\infty} f(n) = \infty$. Then there exist two positive constants C and n_0 such that, for any $n > n_0$, the interval*

$$J = \{p : f(n)/n < p < f(n)\} \tag{11.2}$$

contains at least $f(n)/(C \log f(n))$ distinct primes.

LEMMA 11.2. *Let $f(n)$, $h_q(n)$, and $k_q(n), q = 1, \dots, Q$ be some functions in n such that $h_q(n)$ are integer valued, $h_q(n) \neq 0$,*

$$0 < (h_q(n))^{1/k_q(n)} \le f(n)/n,\ k_q(n) > 0,\ \lim_{n\to\infty} f(n) = \infty \tag{11.3}$$

for $q = 1, \dots, Q$. Let p be a random prime in the interval J of (11.2). *Then for the positive constants C and n_0 of Lemma* 11.1 *and for any fixed $n > n_0$, we have $h_q(n) \neq 0 \bmod p$ for $q = 1, \dots, Q$ with a probability at least $1-(CK(n)\log f(n))/f(n)$, where $K(n) = \sum_{q=1}^{Q} k_q(n)$.*

Proof. Let $l_q(n)$ primes lying in the interval J divide $h_q(n)$. Then their product also divides $h_q(n)$ and, therefore, cannot exceed $h_q(n)$. As these primes lie in the interval J, each of them exceeds $f(n)/n$, and their product exceeds $(f(n)/n)^{l_q(n)}$. Hence, $(f(n)/n)^{l_q(n)} < h_q(n)$. Compare this inequality with the assumed bound $h_q(n) \le (f(n)/n)^{k_q(n)}$ and obtain that $l_q(n) < k_q(n)$. This holds for all q. Therefore, the number of primes lying in J and dividing at least one of the integers $h_q(n)$ (for any q) is at most $\sum_{q=1}^{Q} l_q(n) < \sum_{q=1}^{Q} k(n) = K(n)$. Compare this number with the overall number of primes in J estimated in Lemma 11.1 and obtain the desired probability estimate. ∎

PROPOSITION 11.3. *Let $\rho > 2$ be a fixed scalar, let A be a strongly nonsingular $n \times n$ integer matrix, where $n > 1$, $\|A\| > 1$, and let p be a prime chosen randomly (under the uniform probability distribution) in the interval $J = \{p :\ n^{\rho-1} \log \| A \| < p < n^{\rho} \log \| A \|\}$. Then $p \ge n$, and the matrix F of* (11.1) *is strongly nonsingular modulo p with a probability at least $1-P_{\rho,n}$ for $P_{\rho,n} < (n+1)Cn^{1-\rho}$ and for a positive constant C of Lemmas* 11.1 *and* 11.2.

Proof. Apply Lemma 11.2 for $f(n) = n^{\rho}\log||A||$, $h_q(n) = |\det A^{(q)}|$, $Q = n$, and

$$k_q(n) = (q \log\ ||A||)/\log\ (n^{\rho-1} \log\ ||A||),$$

$q = 1, \dots, n$. Recall from Proposition 2.4 that $|\det A^{(q)}| \le ||A^{(q)}|| \le ||A||^q$ for all q, $q \le n$, and deduce that (11.3) holds for all $q \le n$. We immediately deduce that $K(n) = \sum_{q=1}^{n} k_q(n) = ((n+1)n \log||A||)/(2\log(n^{\rho-1}\log||A||))$ and $(\log f(n))/f(n) = (\log(n^{\rho}\log||A||))/(n^{\rho}\log||A||)$. Substitute these expressions for $K(n)$ and $(\log f(n))/f(n)$ into Lemma 11.2 and obtain that $(\det A^{(q)}) \bmod p \neq 0$ for $q = 1, \dots, n$ with a probability at least $1 - P_{\rho,n}$, where

$$P_{\rho,n} < \frac{(n+1)nC\log\ (n^{\rho}\log\ ||A||)}{2n^{\rho}\log\ (n^{\rho-1}\log\ ||A||)} = \frac{(n+1)C}{2n^{\rho-1}}\left(1 + \frac{\log\ n}{\log\ (n^{\rho-1}\log\ ||A||)}\right)$$

for all k. By assumption, we have $||A|| \ge 2$, $\rho > 2$, $n \ge 2$, and it follows that $\log(n^{\rho-1}\log||A||) > \log\ n$. Combine this bound with the above bound on $P_{\rho,n}$ and obtain the claimed estimate of Proposition 11.3. ∎

Now, we will assume that a prime p has been chosen in the interval J of Proposition 11.3 and the matrix F of (11.1) is strongly nonsingular modulo p and, therefore, possesses its ERD modulo p.

The next algorithm computes modulo p such an ERD, representing each auxiliary or output rational value as a pair of its numerator and denominator given as two integers reduced modulo p. (This enables us to avoid the costly stage of computing integer reciprocals modulo p.) The RD modulo p of A is computed already at Stage 1 of the algorithm. Subsequent stages yield the extending set of the RD modulo p via the computation of the dual RD modulo p (see the definitions of the extending set and the dual RD in section 3).

Algorithm 11.1. *Computing the ERD modulo a fixed prime.*

Input: a prime p and a pair of strongly nonsingular $n \times n$ matrices A and $F = A \mod p$ filled with integers.

Output: the (common) ERD modulo p of A and F.

Computations:

Stage 0. Compute $m = 10(np)^2$ and the c.-d.d. matrix $V = F - mI$ (cf. (7.1), (7.2)).

Stage 1. Compute modulo p the IRD of V by applying Algorithms 10.1 and 6.2. Then, compute modulo p the RD of V, by dividing modulo p all the computed matrices $m_\alpha V_\alpha$ of the IRD by the computed multipliers m_α for all α; represent the result of each division by a pair of an entry of $m_\alpha V_\alpha$ reduced modulo p and $m_\alpha \mod p$. Output the computed RD modulo p of V, which is also the RD modulo p of $F = V \mod p$.

Stage 2. Recall Proposition 4.5 and compute $\det V$.

Stage 3. Recall from Proposition 2.4 that $|\det V| \le \| V \|^n$ and apply Newton's iteration (5.5) for $B = V$ in order to compute an approximation X to V^{-1} satisfying (5.3) for $B = V$ and for b satisfying

$$2^{-b}/m < \| V \|^{-n} /2.2 \ . \tag{11.4}$$

Then, compute the entries of the matrix $X \det V$ and round them to the closest integers, which gives us $\text{adj } V$.

Stage 4. Compute the matrix $\hat{W} = (\text{adj } V) \mod p - mI$. Apply Algorithms 10.1 and 6.2 to compute modulo p the IRD of $\hat{W}$ (we will prove that this is the dual IRD modulo p of A, V, and F). Then compute modulo p the matrices $\hat{W}_{\beta 0}$ of the RD of $\hat{W}$ for all binary strings β of length less than h. Output this set of matrices, to be denoted $\{(\hat{W}_{\beta 0}/\det V) \mod p\}$. Their entries are the pairs of integers, each reduced modulo p; one integer of each pair is an entry of $\hat{W}_{\beta 0} \mod p$ and another is $(\det V) \mod p$. (This set of matrices defines the extending set $\{V_{\beta 0}^{-1} \mod p\}$ of the RD modulo p of the input matrix F.)

To verify *correctness* of Algorithm 11.1, first extend Corollary 7.3 to obtain that $\| V^{-1} \| \le 1.1/m$. Together with (11.4), this implies the bound

$$\| X \det V - \text{adj } V \| < 1/2$$

for the matrix X computed at Stage 3 of Algorithm 11.1. Therefore, the rounding at this stage correctly defines $\text{adj } V$.

Furthermore, the matrices $\hat{W}_\alpha \mod p$ (see Stage 4) represent the RD modulo p of $\text{adj } V$. Therefore, the set $\{(\hat{W}_\alpha/\det V) \mod p\}$ represents the RD modulo p of V^{-1}. To complete the correctness proof, it remains to observe that the set of matrices $\{(\hat{W}_{\beta 0}/\det V) \mod p, |\beta| < h\}$ is nothing else but the extending set $\{B_{\beta 0}^{-1} \mod p, |\beta| < h\}$ of the (common) RD modulo p of the three matrices A, V, and $F = V \mod p = A \mod p$. This follows from the next simple result.

PROPOSITION 11.4. *Let* $\{V_\alpha\}$ *and* $\{W_\alpha\}$ *denote the RD and the dual RD of a pair of* $n \times n$ *matrices* V *and* $W = V^{-1}$*, respectively. Then,* $V_\alpha^{-1} = W_\alpha$ *for all binary strings* α *of length at most* h*.*

Proof. Compare (2.3) and (2.4) to obtain that $V_0^{-1} = W_0$, $V_1^{-1} = S^{-1} = W_1$. Recursively extend this observation to all binary strings α, to complete the proofs of both of Proposition 11.4 and, consequently, of the correctness of Algorithm 11.1. ∎

Similarly to deducing Corollary 10.2, we estimate the complexity of performing Algorithm 11.1. We arrive at the following proposition.

PROPOSITION 11.5. *The ERD modulo a fixed prime* p *of an* $n \times n$ *matrix* A *filled with integers and strongly nonsingular modulo* p *(that is, such that* $(\det A^{(q)}) \bmod p \neq 0$ *for all* q*), as well as* $\det A^{(q)} \bmod p$ *for all* q *can be computed at the cost* $O_A((\log n)\log(n\log p),\ n^\omega)$ *for* ω *of* (4.5)*,* $2 \le \omega < 2.376$*; moreover, this computation can be performed by computing with the* $\tilde{b}$*-bit precision operands for* $\tilde{b} = O(n \log\ p)$*.*

REMARK 11.1. *One can be tempted to simplify Algorithm* 11.1 *and to compute modulo* p *the extending set* $\{V_{\alpha 0}^{-1}\}$ *of the RD of the matrix* V *via a more straightforward application of the techniques of sections* 3–10*. In particular, one may proceed by following the recipe of* [R95]*: first approximate the matrices* $V_{\alpha 0}^{-1}$ *closely enough, then multiply the approximations by appropriate integer multipliers* M_α *to arrive at approximations (within an error norm bounded by less than* $1/2$*) to integer matrices* $M_\alpha V_{\alpha 0}^{-1}$*, and then recover the matrices* $M_\alpha V_{\alpha 0}^{-1}$ *via rounding and* $V_{\alpha 0}^{-1}$ *via divisions by* M_α*. The problem with this approach is in bounding the size of the multipliers* M_α*. We need to have* $\log |M_\alpha| = \tilde{O}(n)$ *in order to support the bit-precision bounds of Proposition* 11.5*, but if we follow the cited recipe, we would only reach the bounds of order* $\tilde{O}(n^2)$ *on* $\log |M_\alpha|$*, which would imply involving extra factor* n *in the bit-precision and the bit-complexity bounds. Here, the notation* $\tilde{O}(s)$ *should be read as* $O(s \log^c s)$ *for a constant* c *independent of* s*.*

12. *p*-adic lifting of the ERDs and the recovery of the inverses, determinants, and ranks of integer matrices. In the previous section, we computed the ERD modulo p of an integer matrix A, which is strongly nonsingular modulo p. We will now compute its p-adic (Newton–Hensel's) lifting, that is, the ERD modulo p^{2^g} of A for a fixed natural $g \ge h = \log n$. We will achieve this by incorporating the known techniques [MC79] for p-adic lifting of matrix inverses into our Algorithm 10.1. In this application we will slightly simplify the algorithm by replacing the four steps of Newton's iteration of (10.4)–(10.6) by a single step of the computation of the matrix

$$X_{\beta,t} = X_{\beta,t,0}(2I - V_{\beta 0,t} X_{\beta,t,0}), \tag{12.1}$$

where

$$X_{\beta,t,0} = \begin{cases} V_{\beta 0,t}^{-1} \bmod p \text{ for } t = u(\beta) + 1, \\ X_{\beta,t-1} \text{ for } t > u(\beta) + 1, \end{cases} \tag{12.2}$$

and all matrices $V_{\beta 0,t}^{-1} \bmod p$ are supplied as an input to the p-adic lifting algorithm. (The latter expression for $X_{\beta,t,0}$ replaces (10.4).) The only other change versus Algorithm 10.1 is that all the arithmetic operations in (10.7) and (12.1) are performed modulo p^{2^s} for $s = t - 1 - u(\beta)$ and for $u(\beta)$ denoting (as in section 10) the number of bits one in a binary string β. Hereafter we refer to the resulting algorithm as Algorithm 12.1.

Correctness of the resulting algorithm follows because (12.1) and the inductive assumption that $X_{\beta,t-1} = V^{-1}_{\beta 0,t-1} \bmod p^{2^s}$, $s = t-2-u(\beta)$, together imply that

$$(I - V_{\beta 0,t}X_{\beta,t} - (I - V_{\beta 0,t}X_{\beta,t,0})^2) \bmod p^{2^{s+1}} = 0\ ,$$

and, therefore,

$$X_{\beta,t} = V^{-1}_{\beta 0,t} \bmod p^{2^{s+1}} \tag{12.3}$$

(compare [MC79] or [BP94, Fact 3.3.1, p. 244]).

The *arithmetic complexity* estimates $O_A((g+\log n)\log n, n^\omega)$ of Proposition 10.1 are extended to the case of Algorithm 12.1, where g denotes a fixed natural input value, $g \geq h = \log n$.

We will keep assuming that p is a prime fixed in the interval J of Proposition 11.3, $\|A\| > 1$, $n > 1$, and the matrix F of (11.1) is strongly nonsingular. Furthermore, hereafter we will assume that

$$g = 1 + \left\lfloor \log \frac{1 + n\log \|A\|}{\log p} \right\rfloor . \tag{12.4}$$

Then, we have

$$4\|A\|^{2n} \geq p^{2^g} > 2\|A\|^n. \tag{12.5}$$

Therefore, by the virtue of Proposition 2.4, the value $0.5p^{2^g}$ exceeds $|\det A|$ as well as the maximum absolute value of any entry of adj A. We observe that

$$q = \begin{cases} q \bmod p & \text{if } q \bmod p < 0.5q, \\ (q \bmod p) - p & \text{otherwise,} \end{cases}$$

provided that q is an integer and $2|q| < p$. These observations, Corollary 4.6, and relations (12.5) together enable us to recover $\det A$ from $(\det A) \bmod p^{2^g}$ and adj A from $(\text{adj } A) \bmod p^{2^g}$, as the p-adic lifting of the ERD is completed. Then, we may immediately compute $A^{-1} = (\text{adj } A)/\det A$, since A is a nonsingular matrix.

REMARK 12.1. *We may control the computational precision at the last lifting stage (where the precision is the largest) simply by performing this stage modulo p^q, where $q = \lfloor \log(2\|A\|^n) \rfloor + 1$, so that $2\|A\|^n \leq p^q \leq 2p\|A\|^n$.*

Summarizing the algorithms and the complexity estimates of this and the previous sections, we arrive at the following proposition.

PROPOSITION 12.1. *Let A be a strongly nonsingular $n \times n$ matrix filled with integers. Let $n > 1$, let $\|A\| > 1$, and let p be a prime from the interval J of Proposition* 11.3 *for a fixed $\rho > 2$. Furthermore, let the matrix A be strongly nonsingular modulo p too. Then, one may compute A^{-1} and $\det A^{(k)}$, $k = 1, 2, \ldots, n$, in two stages that amount essentially to application of Algorithms* 11.1 *and* 12.1, *respectively, and are performed at the arithmetic cost bounded by $O_A((\log n)\log(n\log p), n^\omega)$, at the first stage (compare Proposition* 11.5*) and $O_A((\log n)\log(n\log ||A||), n^\omega)$, at the second stage, for ω of* (4.5), $2 \leq \omega < 2.376$.

Assuming p chosen from the interval J of Proposition 11.3, we obtain that $\log p = O(\log(n\log ||A||))$, so that the overall arithmetic cost is dominated by the cost of the second stage.

COROLLARY 12.2. *Under the assumptions of Proposition* 12.1, *one may compute A^{-1} and $\det A^{(k)}$ for $k = 1, 2, \ldots, n$, at arithmetic cost $O_A((\log n)\log(n\log \|A\|), n^\omega)$ for ω of* (4.5).

Let us extend Proposition 12.1 and Corollary 12.2 to estimate at first the bit-precision and then the Boolean complexity of the same computations.

We immediately recall the bound $O(n \log\ p)$ on the bit-precision required in Algorithm 11.1, that is, at the first stage of the computations of Proposition 12.1. At the second stage (that is, essentially for Algorithm 12.1), we revisit the derivation of Proposition 10.1, where we estimated the complexity of the stage of numerical approximation of the RD and ERD of V, and recall or estimate again that this stage is essentially reduced to at most $g+h$ substages for g of (12.4) and for $h = \log n$, such that the cost of performing each substage is dominated by the cost of ten steps of multiplication of at most n/k pairs of $k \times k$ matrices for $k = 2^\ell$ and $\ell = 0, 1, \dots, h-1$. At the stage of the application of Algorithm 12.1, only four (instead of ten) steps are needed. At each of such four steps, all the matrix multiplications are performed concurrently, as in the case of the derivation of Proposition 10.1. Furthermore, at every step of Substage t of the second stage, $t = 1, \dots, g+h$, at most $n/2^l$ pairs of matrices of the sizes $2^l \times 2^l$ are encountered for $l = n - |\beta| - 1, u(\beta) < t$. Such matrices are pairwise multiplied together modulo $p^{2^{t-u(\beta)}}$,

$$t - u(\beta) \le \lambda(t) = \min\{t, g\}. \tag{12.6}$$

The above bounds on the modulo imply some bit-precision bounds since computation modulo ℓ can be performed with $2\lceil \log \ell \rceil$-bit-precision. Furthermore, we recall the known estimates $O_B((\log k) \log\log k, k)$ for the Boolean complexity of performing an arithmetic operation modulo $2^k - 1$ (see [AHU74], [BP94], [CK91], [RT90]), which can be extended to our computations whenever we perform them with k-bit-precision.

By combining the latter estimates with estimates for the arithmetic cost and for the bit-precision of our computations, we bound the Boolean cost of performing Algorithm 11.1, that is, the first stage of the computations supporting Proposition 12.1 (cf. Corollary 10.1) by

$$O_B((\log n)(\log(n \log p))^2 \log\log(n \log p), n^{\omega+1} \log\ p),$$

and we bound the Boolean cost of performing the tth stage of Algorithm 12.1 by

$$O_B((\log n)(\log(2^{\lambda(t)} \log p)) \log\log(2^{\lambda(t)} \log p), n^\omega 2^{\lambda(t)} \log p),\ t = 1, \dots, g+h.$$

(Compare (12.6) and recall that the tth stage of Algorithm 12.1 is the tth substage of the second stage of the computations of Proposition 12.1.)

By summarizing all these estimates, for p lying in the interval J of Proposition 11.3 and for g satisfying (12.4), (12.5), we estimate the Boolean complexity of our computations. To simplify the expressions for the resulting estimates, we write

$$A = (a_{i,j}), \quad a = \log \max_{i,j} |a_{i,j}| \tag{12.7}$$

and obtain that $g = O(\log(na))$, $g + h = O(\log(na))$, $2^g \log p = O(na)$ for g of (12.4), $\log p = O(\log(na))$, $\log(n \log p) = O(\log(n \log a))$. Then, we rewrite our Boolean cost bounds as follows:

$$O_B((\log n)(\log(n \log a))^2 \log\log(n \log a), n^{\omega+1} \log(na))$$

for performing Algorithm 11.1,

$$O_B((\log n)(\log(na)) \log\log(na), n^{\omega+1} a)$$

for performing the tth stage of Algorithm 12.1 for $t = g+1, \dots, g+h$, where $\lambda(t, g) = g + 1$, and

$$O_B((\log n)(t + \log\log(na)) \log(t + \log\log(na)), n^\omega 2^t \log p)$$

for performing the tth stage of Algorithm 12.1 for $t = 1, \dots, g$, where $\lambda(t, g) = t$. By applying the B-principle, we bound the overall cost of performing the first $g = O(\log(na))$ stages of Algorithm 12.1 by

$$O_B((\log n)(\log(na))^2 \log\log(na), n^{\omega+1} a/\log(na)),$$

and we bound the overall cost of performing its last $h = \log n$ stages by

$$O_B((\log n)^2(\log(na)) \log\log(na), n^{\omega+1} a).$$

Then again, we apply the B-principle to yield the same parallel Boolean time bound, $O((\log n)(\log(na))^2 \log\log(na))$, in all the three estimates (for Algorithm 11.1, for the first g stages of Algorithm 12.1, and for its last h stages), which gives us the Boolean processor bounds

$$O((n^{\omega+1}(\log(n \log a))^2 \log\log(n \log a))/(\log(na) \log\log(na)))$$

$$= O(n^{\omega+1}(\log(n \log a))^2/\log(na)),$$

$$O(n^{\omega+1} a/\log(na)),$$

and

$$O((n^{\omega+1} a \log n)/\log(na))$$

for these three groups of computations, respectively. We note that the sum of the three latter bounds gives us $O((\log n)(a + \log n)n^{\omega+1}/\log(na))$.

By using the Boolean cost bounds of Proposition 11.5 for computing $\det A^{(k)} \bmod p$ for all k, and by combining the cited Boolean time bound and the latter processor bound, we obtain the following proposition.

PROPOSITION 12.3. *Under the assumptions of Proposition* 12.1, *one may compute the inverse matrix* $A^{-1} \bmod p$ *and* $\det A^{(k)} \bmod p$, $k = 1, \dots, n$, *at the Boolean cost*

$$O_B((\log n)(\log(n \log a))^2 \log\log(n \log a), n^{\omega+1} \log(na)),$$

and one may compute the matrix A^{-1} *and* $\det A^{(k)}$, $k = 1, \dots, n$, *at the Boolean cost* $O_B((\log n)(\log(na))^2 \log\log(na), (\log n)(a + \log n)n^{\omega+1}/\log(na))$ *for* ω *of* (4.5) *and* a *of* (12.7).

REMARK 12.2. *Our choice of a prime* p *and our complexity estimates rely on the bounds of Proposition* 2.4 *on* $|\det W|$. *For a large class of matrices* W, *such bounds can be refined a little (e.g., by using Hadamard's upper bound on* $|\det A|$*) and so can our complexity estimates. Likewise, by expressing the estimates of Proposition* 12.3 *in terms of* $||A||$ *rather than* a, *one may obtain some slightly refined (though more complicated) estimates. Finally, our estimates for parallel Boolean cost can be slightly improved if, instead of the bounds* $O_B((\log k) \log\log k, k)$ *on the cost of an arithmetic operation, we will rely on the bounds* $O_B(\log k, k \log\log k)$, *which hold for the cost of*

an addition, a subtraction and a multiplication (see, e.g., [BP94, p. 297]*). We may rely on the latter bound because the ops of the latter three classes are most numerous among all the ops in our algorithms. Similar observations apply to the estimates of Theorems* 1.1 *and* 1.2.

It remains to work out the strong nonsingularity issue in order to extend the complexity estimates of Corollary 12.2 and Proposition 12.3 to estimates of Theorem 1.1. (Note that, in terms of a, the bounds of Corollary 12.2 turn into $O_A((\log n)\log(na), n^\omega)$, as required in Theorem 1.1.)

We will first assume that A is a nonsingular matrix. In this case, AA^T is an s.p.d. matrix and, consequently, a strongly nonsingular matrix, by Corollary 2.11. Consequently, AA^T is strongly nonsingular modulo p, with a probability $1 - P_{\rho,n}$ for $P_{\rho,n}$ bounded according to Proposition 11.3. Therefore, we may apply the results of this section to compute at first $(AA^T)^{-1}$ and then $A^{-1} = A^T(AA^T)^{-1}$ and $\mathbf{x} = A^{-1}\mathbf{f}$ satisfying $A\mathbf{x} = \mathbf{f}$. (Strong nonsingularity (modulo p) of AA^T is tested as a by-product of computing $(AA^T)^{-1}$.) We may also immediately compute $\det(AA^T) = (\det A)^2$, though this does not give us the sign of $\det A$. The matrix A is singular (that is, $\det A = 0$) if and only if application of the same approach to a matrix A requires us to invert a singular matrix at some step.

Next, we will apply randomization to relax the assumptions about (strong) nonsingularity of A when we compute rank A and the sign of $\det A$. Towards this goal, we fix $\rho > 2$, a sufficiently large finite set of integers, S, and two matrices U and L, as specified in Proposition 2.19; we compute the matrix $\tilde{A} = UAL$ (cf. Remark 12.3 at the end of this section), fix a random prime p in the interval J of Proposition 11.3, and extend Algorithm 11.1 to compute $(\det \tilde{A}^{(k)}) \bmod p$ for $k = 1, \dots, n$, and $r(p) = \max\{k,\ (\det\ \tilde{A}^{(k)}) \bmod p \neq 0\}$. Let us write $\tilde{r} = \max\{k,\ \det\ \tilde{A}^{(k)} \neq 0\}$, so that rank $A \geq \tilde{r} \geq r(p)$. Furthermore, $\tilde{r} = $ rank A with a probability at least $P_r = 1 - (\tilde{r}+1)\tilde{r}/|S|$ (due to Proposition 2.19), and $\tilde{r} = r(p)$, with a probability $1 - P_{\rho,n}$, estimated in Proposition 11.3. Thus, we output $r(p)$ as rank A and arrive at the estimate of Theorem 1.1 for the randomized cost of computing rank A. (Note that in this case, the computations modulo p suffice; thus, in our computation of rank A, we omit the p-adic lifting stage and rely on the first Boolean cost estimate of Proposition 12.3.)

Let us extend this technique to the computation of the sine of $\det A$. If $r(p) < n$, then $(\det A) \bmod p = 0$, and we output $\det A = 0$, which is correct with a probability at least $1 - P_{\rho,n}$. Otherwise, that is, if $r(p) = n$, then we have $n \geq$ rank $A \geq r(p) = n$; that is, A is nonsingular. Furthermore, by using the randomization based on Proposition 2.19, we may compute $\det A = \det(UAL)$, because UAL is strongly nonsingular, with a probability at least $1-(n+1)n/|S|$ if A is nonsingular. By letting $|S| = n^4$, say, and by applying Propositions 11.5 and 12.3 to the matrix UAL, we arrive at the desired algorithm for $\det A$, supporting Theorem 1.1.

Now, assume that $r(p) < n$ and that the $r(p) \times r(p)$ leading principal submatrix $B = \tilde{A}^{(r(p))}$ of $\tilde{A}$ is nonsingular. Let us write $\tilde{A} = \left(\begin{smallmatrix} B & C \\ D & E \end{smallmatrix}\right)$, $G = \left(\begin{smallmatrix} I & -B^{-1}C \\ 0 & I \end{smallmatrix}\right)$, and observe that $\tilde{A}G = \left(\begin{smallmatrix} B & 0 \\ D & Q \end{smallmatrix}\right)$, where $Q = 0$ if and only if $r(p) =$ rank A. (Compare [KP91] and [BP94, pp. 110 and 333].) This gives us an algorithm for verification whether $r(p)$=rank A (at the cost within the asymptotic cost bounds of Theorem 1.1). If so, then the $n-r$ columns of the matrix $LG\left(\begin{smallmatrix} 0 \\ I \end{smallmatrix}\right)$, where I denotes the $(n-r)\times(n-r)$ identity matrix, give us a basis for the null-space, $\mathbf{N}(A)$, of A (compare Definition 2.17). We recall from Fact 2.1 that if there exists a solution $\mathbf{x}$ to a linear system $A\mathbf{x} = \mathbf{f}$, then it can be represented as $\mathbf{x} = \mathbf{x}_0 + \mathbf{z}$, $\mathbf{x}_0$ being a fixed specific solution

and $\mathbf{z}$ being a vector from $\mathbf{N}(A)$.

Let $\mathbf{g}$ be the r-dimensional prefix-subvector of $\mathbf{f}$, made by the first r components of $\mathbf{f}$. Let $\mathbf{y} = B^{-1}\mathbf{g}$ be the solution to the nonsingular system $B\mathbf{y} = \mathbf{g}$. Then, a specific solution $\mathbf{x}_0$ to the system $UA\mathbf{x} = U\mathbf{f}$ is given by $\mathbf{x}_0 = LG\begin{pmatrix}\mathbf{y}\\ \mathbf{0}\end{pmatrix}$ if the latter linear system is consistent, and we have $UA\mathbf{x_0} \neq U\mathbf{f}$ otherwise. This completes our proof of Theorem 1.1. □

REMARK 12.3. *Our computations supporting Theorem* 1.1 *include some* $n \times n$ *matrix multiplications (of* A *by* A^T, L, *and* U*). Their cost bound is dominated by the complexity bounds of Theorem* 1.1, *and a similar argument applies to yield the extension of this theorem to Theorem* 1.2, *to be shown in section* 14 *(cf. Proposition* 14.1*). The increase of the matrix norm in the transition from* A *to* AA^T *and* $\tilde{A} = UAL$ *may cause the increase only by a constant factor in the estimate for the precision of the computations and their Boolean complexity (if we choose, say,* $S = \{1, 2, \dots, |S|\}$ *and* $|S| = n^{O(1)}$*).*

13. Some definitions and auxiliary results on computations with structured matrices. Our next goal is to show that the computational cost of our algorithms supporting Theorem 1.1 decreases dramatically, to the level of the estimates of Theorem 1.2, provided that the input matrix has Toeplitz-like structure. In this section we will recall some definitions and some simple and/or well-known facts on Toeplitz-like matrices, which we will use in the next section towards the stated goal (cf. (1.1) and (1.2) of section 1.1, Definition 2.18, and [BP94], [CKL-A87], [KKM79], [P92]).

PROPOSITION 13.1. *The product of a* $k \times k$ *Toeplitz matrix (cf. Definition* 2.18*) and a vector of dimension* k *can be computed at the cost* $O_A(\log k, k)$ *(via reduction to three FFTs, each on* $O(k)$ *points, or to convolution of two vectors of dimension* $O(k)$*).*

DEFINITION 13.2. *For a* $k \times k$ *matrix* A *and for the matrix* Z *of Definition* 2.18, *write* $F_+(A) = A - ZAZ^T$, $F_-(A) = A - Z^TAZ$. *If* $F(A) = GH^T$ *for a pair of* $k \times \ell$ *matrices* G *and* H *and for* $F = F_+$ *or* $F = F_-$, *then the pair of* G, H *is called an* F-generator *of* A *of length* ℓ. *(Note that, in this case, the pair* H, G *is an* F*-generator of* A^T *of the same length.) The minimum length* ℓ *of an* F-generator *of* A, *for fixed* A *and* F, *is called the* F-rank *of* A, *is denoted by* $r_F(A)$, *and is equal to* rank $F(A)$. *A* $k \times k$ *matrix* A *is called a* Toeplitz-like matrix *if it is given with its* F*-generator (for* $F = F_+$ *or* $F = F_-$*) having a length bounded by a constant independent of* k. F*-generators and* F*-ranks, for both* $F = F_+$ *and* $F = F_-$, *are also called* displacement generators *and* displacement ranks *(following the original definitions of* [KKM79]*).*

PROPOSITION 13.3. $r_F(T) \leq 2$ *if* T *is a Toeplitz matrix, and* $r_F(T) \leq 1$ *if* T *is a triangular Toeplitz matrix for* $F = F_+$ *and* $F = F_-$. *In particular,* $r_F(I) = 1$.

The correlation to (1.2) is given by the following result.

PROPOSITION 13.4. G, H *is an* F_+*-generator (respectively,* F_-*-generator) of* A *having a length* ℓ, $G = (\mathbf{g_1}, \dots, \mathbf{g}_\ell)$, $H = (\mathbf{h_1}, \dots, \mathbf{h}_\ell)$, *if and only if* $A = \sum_{s=1}^{\ell} L(\mathbf{g_s})\, L^T(\mathbf{h_s})$ *(respectively, if and only if* $A = \sum_{s=1}^{\ell} L^T(\mathbf{g_s})\, L(\mathbf{h_s})$*).*

Based on the latter results, we will operate with the F-generators of Toeplitz-like matrices, rather than with the matrices themselves. Such a representation is memory space efficient and also enables us to use less sequential time and fewer processors in Toeplitz-like computations, due to the following corollary (cf. Propositions 13.1 and 13.4).

COROLLARY 13.5. *The product of a* $k \times k$ *Toeplitz-like matrix by a vector of dimension* k *can be computed at the cost* $O_A(\log k, k)$.

The next result gives us more specific estimates—the cost bound of Toeplitz-like matrix multiplication is proportional to the square of the sum of the lengths of the F-generators of the input matrices, and such a length is roughly doubled in a matrix addition or multiplication.

PROPOSITION 13.6. *Given F-generators, G_A, H_A of length ℓ_A and G_B, H_B of length ℓ_B, of $k \times k$ matrices A and B, respectively (for $F = F_+$ or $F = F_-$), one may compute an F-generator G_{AB}, H_{AB} of AB of length at most $\ell_A + \ell_B + 1$ at the cost $O_A(\log k, (\ell_A + \ell_B)^2 k)$, whereas an F-generator of $A + B$ of length at most $\ell_A + \ell_B$ is immediately available cost-free.*

In view of the latter results, we will study various bounds on the F-ranks and the length of F-generators, in particular regarding the matrices involved in the RD and Newton's iteration with Toeplitz-like input.

PROPOSITION 13.7.

(a) *$r_{F+}(A) \le r_{F-}(A) + 2$, $r_{F-}(A) \le r_{F+}(A) + 2$ for any matrix A. Furthermore, an F_+-generator (respectively, F_--generator) of a length ℓ for any matrix A can be immediately transformed (at the cost $O_A(\log n, n)$ of performing $O(1)$ convolutions or FFTs) into an F_--generator (respectively, F_+-generator) of length at most $\ell + 2$ for A.*

(b) *If A is nonsingular, then $r_{F+}(A^{-1}) = r_{F-}(A)$.*

The next result is immediately verified (compare Definition 2.6).

PROPOSITION 13.8. *Let $GH^T = F_+(W)$ for a $k \times k$ matrix W. Then $(GH^T)^{(i)} = F_+(W^{(i)})$ for $i = 1, 2, \dots, k$; furthermore, $r_{F_+}(C) \le r_{F_+}(W) + 1$, $r_{F_+}(E) \le r_{F_+}(W) + 1$, under (2.1), and $r_{F_+}(T) \le r_{F_+}(W) + 2$ for any submatrix T of W formed by contiguous sets of row and columns of W.*

It follows that $r_{F_+}(B) \le r_{F_+}(W)$, under (2.1).

We observe similar relations for trailing principal submatrices and the operator F_-. By Proposition 2.7, S^{-1} is a trailing principal submatrix of W^{-1}. Therefore, $r_{F_-}(S^{-1}) \le r_{F_-}(W^{-1})$. By applying Proposition 13.7 (b) for $A = S$ and $A = W$, we obtain that $r_{F_+}(S) \le r_{F_+}(W)$.

PROPOSITION 13.9. *Let (2.1) and (2.2) hold, where B, S, and W are nonsingular matrices. Then $\max\{r_{F_+}(B), r_{F_+}(S)\} \le r_{F_+}(W)$.*

By applying the latter proposition recursively, we bound the F_+-rank throughout the RD.

COROLLARY 13.10. *Let V_α be a matrix of the RD of a matrix A. Then, $r_{F_+}(V_\alpha) \le r_{F_+}(A)$.*

So far, we have no tools yet to counter the growth of the length of the F-generators in the process of Newton's iteration. Developing such tools (which we call the techniques for *the truncation of a generator (TG)*) is our next task. Namely, we will next (in Proposition 13.11) show how to compute a shorter F-generator of a matrix having small F-rank but given with its longer F-generator. This is our first technique of TG. It will be used to refine p-adic (Newton–Hensel's) lifting to bound the length of the F-generators of the matrices involved there. We will prove easily, based on Propositions 13.7 and 13.9, that such matrices have small F-rank if so has the input matrix. For Newton's iteration of Algorithm 5.1, such a property does not hold, and the F-rank of the computed approximations to the Toeplitz-like inverses may grow quite rapidly. These approximations, however, always have matrices with small F-rank nearby, and we will periodically shift to the latter matrices and then restart Newton's process. Our tool for such a shift will be Algorithm 13.1 (see [PBRZ99] on some alternative tools).

PROPOSITION 13.11. *Let an F-generator of a $k \times k$ matrix A of length ℓ (for $F = F_+$ or $F = F_-$) and an upper bound $r^* < l$ on the F-rank $r_F(A)$ be given. Then an F-generator of A of length at most r^* can be computed at the cost $O_A(l,\ kl)$.*

Proof. Apply the proof of Proposition A.6 of [P92] or the solution of Problem 2.11 of [BP94, pp. 111–112]. Verify that all the computations (including the computation of the LSP factorization or, alternatively, the PLU factorization) can be performed at the claimed overall cost. □

Let us next show the promised alternative algorithm for controlling the length of F-generators of matrices involved in Newton's process. The algorithm relies on the *SVD truncation of F-generator*, which is our second TG technique.

Algorithm 13.1 ([P92b], [P93], [P93a]).

Input: $F = F_+$ or $F = F_-$, an F-generator G, H of a $k \times k$ matrix A of length l, and a natural $r' < l$.

Output: an F-generator G', H' of a $k \times k$ matrix A' of length at most r' such that

$$\|A' - A\|_2 \le 2(1 + 2(r_F(A) - r')k) \min_Y \|Y - A\|_2 \ , \tag{13.1}$$

where the minimum is over all $k \times k$ matrices Y of F-rank at most r'.

Computations:

Stage 1. Compute the singular value decomposition (SVD) of the matrix $GH^T = F(A)$; that is, compute a pair U and V of unitary $k \times l$ matrices and an $l \times l$ diagonal matrix $\Sigma = \mathrm{diag}(\sigma_1, \dots, \sigma_l)$ for positive $\sigma_1, \dots, \sigma_l$ satisfying

$$GH^T = F(A) = U\Sigma V^T.$$

Stage 2. Compute and output an F-generator G', H' of A' of length at most r' as follows:

$$G' = U\Sigma_{r'}, \quad H' = VI_{r',l},$$

where $\Sigma_{r'} = \mathrm{diag}(\sigma_1, \dots, \sigma_{r'}, 0, \dots, 0)$ and $I_{r',l} = \mathrm{diag}(1, \dots, 1, 0, \dots, 0)$ are $l \times l$ matrices of rank r'.

On the correctness proof of this algorithm, on the bound $O_A(\log k, k/\log k)$ for $l = O(1)$, and on the *computational cost* of its performance, see [P92b], [P93], [P93a].

REMARK 13.1. *Bound* (13.1) *is proved in* [P92b], [P93], [P93a], *based on approximate computation of the SVD at Stage* 1 *of the algorithm. Any improvement of the approximation of the SVD would decrease the factor* 2 *of* (13.1), *which turns into* 1 *if the SVD is computed exactly.*

REMARK 13.2. *If $r' \ge r_F(A)$, then* (13.1) *implies that $\|A' - A\|_2 = \min_Y \|Y - A\|_2 = 0$, and then Algorithm* 13.1 *is an alternative to the algorithm supporting Proposition* 13.11, *except that the latter algorithm is rational (it can be performed with no errors over the rational), whereas Algorithm* 13.1 *has a nonrational, though numerically stable stage of computing the SVD. This suggests that the algorithm supporting Proposition* 13.11 *should be applied in Algorithm* 12.1, *at the p-adic lifting stage, whereas Algorithm* 13.1 *is a better candidate to use in numerical applications of Algorithm* 11.1, *performed with rounding.*

14. Improvement of the algorithms for the ERD, IRD, inverse, determinant, and rank in the Toeplitz and Toeplitz-like cases. Let us apply the techniques and the results of the previous section to reexamine the computation of

the ERD and IRD of a strongly nonsingular $n \times n$ matrix A filled with integers in the case where A is a Toeplitz or Toeplitz-like matrix given with its F_+-generator G, H of length $r = r_{F_+}(A) = O(1)$.

We recall that $r_{F_+}(V_\alpha) \le r$ for all matrices V_α of the RD of A (compare Corollary 13.10), and we will apply either the algorithm supporting Proposition 13.11 or Algorithm 13.1 in order to decrease (to a level at most r) the length of the computed F-generators of these matrices, in all cases where this length exceeds r. Likewise, we will obtain from Propositions 13.6–13.8 that the computation of $V_{\beta 1,t+1}$, according to (10.1)–(10.7), only involves matrices whose F-ranks are bounded from above by $3r + r_{F_+}(X_{\beta,t}) + 6$.

According to our analysis, the matrix $X_{\beta,t}$ approximates $B_{\beta 0}^{-1}$ for all binary strings β of length at most $h-1$, and since $r_{F_+}(B_{\beta 0}) \le r$, we have $r_{F_-}(B_{\beta 0}^{-1}) \le r$, $r_{F_+}(B_{\beta 0}^{-1}) \le r+2$ (compare Proposition 13.7). We will apply Algorithm 13.1 in order to compute an F_+-generator of length at most $r+2$ for a matrix $X'_{\beta,t}$ approximating $X_{\beta,t}$ and, therefore, also $V_{\beta 0}^{-1}$. (The approximation of $V_{\beta 0}^{-1}$ by $X'_{\beta,t}$ deteriorates slightly, versus the approximation by $X_{\beta,t}$, but since $X'_{\beta,t}$ still closely approxiamtes the matrix $V_{\beta 0}$, we more than compensate ourselves for such a deterioration by performing an extra Newton step in (10.5).) Then, all matrices involved in the computation of the ERD and the IRD of A will be represented by their F_+-generators of length $O(r)$.

A similar argument is applied to the computation of the p-adic lifting of the ERD of A, except that this argument is simplified since (12.3) and Proposition 13.7 together imply that

$$\begin{aligned} r_{F_+}(X_{\beta,t+1} \bmod p^{2^{t-u(\beta)}}) &\le r_{F_-}(X_{\beta,t+1} \bmod p^{2^{t-u(\beta)}}) + 2 \\ &= r_{F_+}(B_{\beta 0}^{-1} \bmod p^{2^{t-u(\beta)}}) + 2 \le r+2. \end{aligned}$$

Thus, to keep the length of the associated F_+-generators bounded, we just apply the rational algorithm that supports Proposition 13.11, instead of applying Algorithm 13.1. In fact, we may also apply other alternative techniques for bounding the length of an F-generator of $X_{\alpha,i+1}$; such techniques may rely on using distinct operators F, such as $F^+(A) = AZ - ZA$ (see [BP94, p. 189]) or operators using some f-circulant matrices instead of Z (see [PBRZ99], [P00]).

Finally, it is easily verified (cf. [P96b]) that the computation (of section 12) of a basis for the null-space of A also involves only matrices represented by their F_+-generators of length $O(r)$ for a matrix A given with its F_+-generator of length r.

Let us now turn to estimating the computational cost, in the case of Toeplitz or Toeplitz-like input. There are two new features versus the case of a general integer input matrix A.

(1) Performing every matrix multipication, we operate with F_+-generators of Toeplitz-like matrices involved in these multiplications and apply Propositions 13.4, 13.6, and Corollary 13.5.

(2) Some of these matrix multiplications are followed by the application of the algorithms supporting Proposition 13.11 or Algorithm 13.1.

The manipulation with the F_+-generators enables us to decrease the arithmetic processor bound of Corollary 12.2 from n^ω to $n \log n$, because concurrent multiplications of $O(2^t)$ pairs of $(n/2^t) \times (n/2^t)$ Toeplitz-like matrices for $t = 1, \dots, h$, $h = \log n$ are performed at the overall cost bounded by $O_A(\log n, n \log n)$ (versus $O_A(\log n, n^\omega)$ in the case of general integer input matrices). The estimated overall cost of the required computations (of A^{-1}, det A, and so on) is dominated by the estimated cost of

all Toeplitz-like matrix multiplications involved, because, according to section 13, the estimated cost of such a multiplication dominates the estimated cost of the application of both Algorithm 13.1 and the algorithm supporting Proposition 13.11.

Summarizing, we obtain the following result.

PROPOSITION 14.1. *If the $n \times n$ input Toeplitz-like matrix A is strongly nonsingular and is filled with integers, then one may modify the randomized computation of its ERD and IRD according to the algorithms of sections* 6–12 *in order to perform all these computations at the overall cost* $O_A((\log n)\log(n\log\|A\|), n\log n)$.

The cost bounds of Proposition 14.1 are immediatley extended to the solution of all the computational problems listed in Theorem 1.1, where now we assume a Toeplitz-like input matrix A and represent its inverse or the basis matrix for its nullspace by their short F-generators. (Verifying the correctness of the computation of the rank and the inverse, we should also deal with short F-generators and use Proposition 13.11 to avoid processing n^2 entries of $n\times n$ matrices, which would have required order of n^2 ops.)

To obtain a similar extension of the Boolean complexity bounds of Proposition 12.3 and Theorem 1.1, let us examine the precision of the computations by our algorithms simplified in the Toeplitz-like case. We recall that our Toeplitz-like computations can be ultimately reduced to vector convolutions (Propositions 13.1, 13.4, and 13.6). Thus, we will bound the cost of our computations at the p-adic lifting stage based on the following estimate.

PROPOSITION 14.2. *Given two vectors of dimension n filled with integers lying in the range from* 0 *to* 2^k-1, *the convolution of these vectors can be computed at the Boolean cost* $O_B((\log(kn), kn\log\log(kn))$.

Proof. The well-known *binary segmentation* techniques (see, e.g., [BP94, section 3.9]) reduces our convolution problem to the multiplication of two integers lying in the range from 0 to $2^{kn}-1$, and the known algorithms solve this task at the required cost. □

The resulting Boolean cost bounds for performing the p-adic lifting stage will repeat the bounds of section 12, except that the Boolean (like arithmetic) processor bounds will decrease by factor $n^{\omega-1}/\log n$.

Let us show that this holds also for the Boolean cost of the rest of our computation.

When we approximate the ERD of an input Toeplitz-like matrix, we will effectively reduce the computations to performing FFTs (see Propositions 13.1 and 13.4) and will recall Corollary 3.4.1 on pp. 255–256 of [BP94], which shows a numerically stable implementation of FFT. We also recall that the known algorithms for the computation of the SVD of a matrix are numerically stable (see [GL89/96], [P93]). From these observations, we deduce that we may perform the computations with the same bit-precision (up to a constant factor independent of n), no matter whether we apply our original Algorithm 11.1 for an arbitrary $n \times n$ input matrix or its Toeplitz-like modification. Since in the latter case we use by factor $n^{\omega-1}/\log n$ fewer arithmetic processors, we will also use by factor $n^{\omega-1}/\log n$ fewer Boolean processors, thus replacing n^ω for ω of (4.5) by $n\log n$ in the Boolean cost estimates of section 12.

This enables us to extend Theorem 1.1 to arrive at Theorem 1.2. □

REMARK 14.1. *Inspection of our algorithms shows immediately that Proposition* 14.1 *and Theorem* 1.2 *can be extended to the case where the input matrix A is given with its F-generator of length r, provided that both time and processor bound increase by factor r. It is possible to confine the cost increase to processor bound (increasing it*

by factor r^2*). The only nontrivial stage is the decrease of the length of* F*-generators (cf. Proposition* 13.11 *and Algorithm* 13.1*). The algorithm supporting Proposition* 13.11*, however, can be modified by extending the probabilistic techniques of the proof of Theorem* 1.1 *(this would include, in particular, application of Proposition* 2.19 *using* $n + r$ *extra random parameters), whereas Algorithm* 13.1 *should be replaced by an alternative approach of* [PBRZ99].

REMARK 14.2. *It may seem that Theorems* 1.1 *and* 1.2 *can be supported by a substantially simpler construction, and simplified construction has indeed been proposed in* [R95]. *Unfortunately, however, the construction of* [R95] *has no power for supporting the claimed results. In particular, the construction relies on the two "simplifying" recipes cited in our Remarks* 6.1 *and* 11.1*, and each of the recipes invalidates the resulting algorithm. (See* [P96c] *for more details on these and some other of the many mishaps of* [R95], and note also that the main result of the paper [R93], cited in [R95], is a rediscovery of some results of [BT90] and [BP91].) *It is instructive, for getting better insight, to discuss two other major gaps of the construction of* [R95] *and of its analysis presented in* [R95]. *Both gaps are in area of Toeplitz-like computations, where* [R95] *becomes particularly prone to serious errors. In* [R95]*, an algorithm of* [BA80] *is used in order to decrease the length of an* F*-generator of a matrix* A *to the level* $r = \text{rank } F(A)$. *Unlike our Algorithm* 13.1 *for the SVD truncation and our algorithm supporting Proposition* 13.11*, the algorithm of* [BA80] *only works if* $(F(A))^{(r)}$*, the* $r \times r$ *l.p.s of* $F(A)$*, is nonsingular. Furthermore, to support the algorithm of* [R95]*, one must have matrix* $(F(A))^{(r)}$ *well-conditioned. Actually, to salvage the algorithm of* [R95] *at this point, one would have had to use some techniques that are absent from* [R95] *and are substantially more advanced than ones used in* [R95]. *Likewise, some techniques are required to prevent the* F*-ranks of the computed approximations to* A^{-1} *from their disturbing growth (from the desired constant level to the level* n*) in less than* $\log n$ *Newton's steps, and then again, such techniques are absent from* [R95] *and are substantially more advanced than ones used in* [R95]. *The growth of the* F*-ranks immediately implies the growth by the extra factor* $n^{\omega-1} \log n$ *(for* ω *of* (4.5)*) of both arithmetic and Boolean processor complexity bounds, versus the ones claimed in* [R95].

15. Discussion. Our paper leaves as a major open question of theoretical importance whether the level of our parallel complexity estimates of Theorem 1.2 for Toeplitz and Toeplitz-like computations can be reached by means of purely algebraic approach, using no rounding to the closest integers. This question is also of practical interest because the algorithms of this paper involve the exact computation of $\det A$ and, therefore, at some stage require us to use the precision of computation of order $\log |\det A|$, which generally means the order of $n \log ||A||$, even if we only need the output with a much lower precision. Historically, a similar open problem had arisen for computations with general integer matrices, after the appearance of [P85], [P87]. In that case (for general integer matrices), the subsequent works of [KP91], [KP92], [P91], and [P92] gave us an alternative randomized algebraic solution that involved no rounding. Will this be eventually done also in the Toeplitz-like case or at least in the Toeplitz case?

Acknowledgments. Detailed and thoughtful comments by a referee and by a reviewer helped me a great deal to improve my original draft and to make it more accessible for the reader. The request by the area editor Joachim von zur Gathen to incorporate the appendix into the body of the paper also served the same goal.

FROM STATIC TO DYNAMIC ROUTING: EFFICIENT TRANSFORMATIONS OF STORE-AND-FORWARD PROTOCOLS*

CHRISTIAN SCHEIDELER† AND BERTHOLD VÖCKING‡

Abstract. We investigate how static store-and-forward routing algorithms can be transformed into efficient dynamic algorithms, that is, how algorithms that have been designed for the case that all packets are injected at the same time can be adapted to more realistic scenarios in which packets are continuously injected into the network. Besides describing specific transformations for well-known static routing algorithms, we present a black box transformation scheme applicable to every static, oblivious routing algorithm. We analyze the performance of our protocols under a stochastic and an adversarial model of packet injections.

One result of our specific transformations is the first dynamic routing algorithm for leveled networks that is stable for arbitrary admissible injection rates and that works with packet buffers of size depending solely on the injection rate and the node degree, but not on the size of the network. Furthermore, we prove strong delay bounds for the packets. Our results imply, for example, that a throughput of 99% can be achieved on an n-input butterfly network with buffers of constant size while each packet is delivered in time $O(\log n)$, with high probability.

Our black box transformation ensures that if the static algorithm is pure (i.e., no extra packets apart from the original packets are routed), its dynamic variant is stable up to a maximum possible injection rate. Furthermore, in the stochastic model, the routing time of a packet depends on local parameters such as the length of its routing path, rather than on the maximum possible path length, even if the static algorithm chosen for the transformation does not provide this locality feature and is not pure. In the adversarial model, the delay bound of the packets is closely related to the time bound given for the static algorithm.

Key words. communication networks, store-and-forward routing, packet scheduling

1. Introduction.

Many static routing protocols have been developed in recent years (see, e.g., [6, 8, 9, 10, 12, 13]). These protocols aim to route as quickly as possible some initially given set of packets along predetermined paths in a network. In practice, however, networks are rarely used in this static fashion, but packets are injected dynamically into the network. Since much less is known in the area of dynamic routing (see, e.g., [5, 15, 17]) than in the area of static routing, it would be highly desirable to transfer the results gathered for static routing to dynamic routing.

In this paper we present transformations for *oblivious* algorithms; i.e., the path of a packet is already fixed when the packet is injected into the system. We investigate how static, oblivious routing algorithms can be transformed into dynamic routing algorithms that are stable and efficient under a stochastic or adversarial model of packet injections. In particular, we will show that the ghost packet protocol [8, 14] and the growing rank protocol [10, 11] can be transformed into dynamic routing protocols

that are stable up to a maximum possible injection rate. Furthermore, we will present a simple and elegant scheme that transforms almost any static protocol into an efficient dynamic protocol that is also stable up to a maximum possible injection rate. Besides showing the stability of these protocols, we will prove bounds on the routing time of the packets. For the protocols derived by the black box transformation we further prove that they recover quickly from any worst-case scenario; that is, packets generated a certain amount of time after a bad event are not influenced by this event anymore.

1.1. Models and problems. We consider arbitrary network topologies modeled as undirected graphs of n nodes. The nodes represent switches, and the edges represent bidirectional communication links, unless otherwise stated, with buffers for incoming packets on either side. These buffers are called *edge buffers*, and bounds on the buffer size always refer to the maximum number of packets that these buffers can hold. Additionally, every node contains an *injection buffer* in which the initial packets, in the case of static routing, or the newly injected packets, in the case of dynamic routing, are stored. Routing is performed in a synchronous "store-and-forward" manner; that is, in every step, each edge can be crossed by at most one packet in each direction. (For simplicity, we assume that time proceeds in discrete time steps.) Once a packet reaches its destination, it is discarded.

We present routing protocols in which the nodes *locally* decide which packets to move forward in each step; i.e., a decision only depends on the routing information carried by the packets and on the local history of the execution. These algorithms are called *local control* or *on-line* algorithms. In general, a packet routing scheme consists of two (not necessarily independent) parts: the first part is responsible for selecting a path for each packet, and the second part is responsible for scheduling the packets along their chosen paths. We assume that some suitable strategy for the path selection is given. Hence, in the following we concentrate only on the question of how to schedule the packets along their fixed paths. We use the following models.

1.1.1. Static packet routing. Here we assume that a fixed collection of paths is given with *congestion* C and *dilation* D; that is, C denotes the maximum number of paths crossing an edge, and D denotes the maximum length of a path. Along each of these paths a packet has to be sent. Further, let M denote the *complexity* of the routing problem; i.e., M is defined to be the maximum of the number of edges, the number of paths, and the dilation. Let us give some examples of known results on the *routing time* for static packet routing, i.e., the time needed to deliver all packets.

- $C \cdot D$: trivial upper bound for any greedy protocol in case of unlimited buffers, i.e., protocols in which a packet is only delayed because other packets move along the next edge on the packet's routing path;
- $(1+\kappa) \cdot C + O(D \cdot \log M)$, w.h.p.[1], for any constant $\kappa > 0$: upper bound for arbitrary paths in arbitrary networks with unbounded buffers [9];
- $O(C + D + \log M)$, w.h.p.: upper bound in leveled networks with bounded buffers of constant size, where D is the depth of the network [14, 8], and upper bound for routing along shortest paths in arbitrary networks with unbounded buffers [10, 11];
- $(1+\kappa) \cdot C + (\log^* M)^{O(\log^* M)} D + O((\log M)^6)$, w.h.p., for any constant $\kappa > 0$: upper bound for routing along *simple paths*, i.e., paths without cycles, in

[1] Throughout this paper, the term "w.h.p." means "with high probability," i.e., with probability at least $1 - M^{-\alpha}$, where $\alpha > 0$ is an arbitrary constant term and M denotes the complexity of the routing problem.

arbitrary networks with unbounded buffers [13];
- $O(C+D+\log^{1+\kappa} M)$, w.h.p., for any constant $\kappa > 0$: upper bound for routing along simple paths in arbitrary networks with unbounded buffers [12].

We will come back to some of these results when using our black box transformations.

1.1.2. Dynamic packet routing. The most commonly used injection models in the dynamic setting are the *stochastic* and the *adversarial* injection model.

The stochastic model. Here the packets are injected by a set of *generators*, each of them mapped to one of the nodes in the network. We allow any relationship between the number of generators and the number of nodes in the network. Furthermore, we place no restrictions on the distribution of the generators among the nodes. That is, one node could have several generators, whereas another node may have none. So a generator may represent a user thread or process, whereas a node may represent a processor. In each time step, each generator g placed on a node v injects a packet with some probability p_g. This probability is called the *injection rate* of g. For each packet, the generator randomly selects a destination and a routing path from v to this destination according to an arbitrary, fixed probability distribution. We assume that each generator is operating independently of other generators, and the injection of a packet and its routing path is independent of injections in previous time steps. Note that we do not demand that the destinations are chosen uniformly from the set of all nodes, or that packets with the same source and destination node follow the same routing path. Finally, we define the *(overall) injection rate*, which is denoted by λ. Define λ_e to be the expected number of messages generated in a time step that contain the edge e in their routing paths. Then λ is defined to be the maximum λ_e over all edges.

The adversarial model. An adversary is allowed to demand network bandwidth up to a prescribed injection rate. For any $w, \lambda > 0$, an adversary is called a *bounded adversary of rate* (w, λ) if for all edges e and all time intervals I of length w, it injects no more than $\lambda \cdot w$ packets during I that contain edge e in their routing paths. As in the stochastic model, λ is defined to be the *injection rate*. (We use the adversarial model as defined by Andrews et al. [1] rather than the original model introduced by Borodin et al. [3] because this model avoids calculating with floors and ceilings. Apart from minor changes in constants, however, all our results hold in the original model of Borodin et al. too.)

For both injection models, a protocol is called *stable* for a given injection rate λ if the number of packets stored in injection or edge buffers does not grow unboundedly with time. We are interested in protocols that are stable for high injection rates. Of course, since an edge can transport at most one packet per step, λ can be at most 1. Our aim is to construct algorithms that are stable under injection rates that are close to 1. Additionally, we are interested in short delays for the packets; i.e., we aim to minimize the time from injection to service for each packet.

Apart from the stability and the routing time, we will consider another property of dynamic routing protocols, the recovery from worst-case scenarios. Although our bounds on the routing time guarantee that bad configurations are very unlikely, they eventually occur from time to time when the routing protocol runs for an infinite number of time steps. Let a *worst-case scenario* denote an arbitrarily bad configuration of the network. Then the *recovery time* with regard to some property $\mathcal{P}$ of the routing protocol is defined as the time that has to pass by after the occurrence of a worst-case scenario until $\mathcal{P}$ holds again. (In our case, we are interested in properties such as the expected routing time of a packet and time bounds that hold w.h.p.)

As in the static model we define the complexity of a dynamic routing problem to be a value capturing all relevant parameters. In particular, the *complexity* is defined to be the maximum of the number of edges, the number of generators, the maximal possible length of a routing path, and $1/(1-\lambda)$. (The number of generators in the adversarial model is defined to be w times the number of edges, which corresponds to the maximum number of packets that can be injected in a single step.)

In the following sections, we will prove results for both the stochastic and the adversarial injection model.

1.2. Previous results. In the last two years a new model called *adversarial queuing theory* emerged. This approach was introduced by Borodin et al. in [3]. Most research in this model focuses on the stability of routing protocols and networks. For example, Borodin et al. [3] show several stability results for greedy protocols on directed acyclic graphs (DAGs) and directed cycles. Andrews et al. [1] extend their results by showing that there exist simple greedy protocols (such as longest-in-system, shortest-in-system, and farthest-to-go protocols) that are stable against any adversary for all networks. However, the delay of the packets and the number of packets stored in a queue might get exponential in the length of the longest path.

Furthermore, Andrews et al. [1] present a transformation of the static protocol presented in [9] into a dynamic protocol that is stable for any injection rate < 1 and fulfills the following constraint on the buffer size: For any fixed time step t, at most $(D \cdot \log m)^k$ packets are stored in any queue at time t, w.h.p., where D denotes the longest routing path, m the number of edges, and k is a suitable constant. Note that this result implies that the delay of the packets is also bounded by $(D \cdot \log m)^k$, w.h.p. However, as the bound on the buffer size does not hold deterministically, any buffer of fixed size will overflow eventually.

Rabani and Tardos [13] present a transformation scheme which yields much better routing times. Assuming there is a static algorithm that delivers all packets in $(1+\kappa)C + g(M)D + f(M)$ steps for some constant $\kappa > 0$, their tansformation yields a dynamic algorithm that delivers each packet to its destination, w.h.p., in $O(w + g(N)D + f(N) + \log N)$ against an adversary of rate $(w, \Theta(\kappa))$, where M and N denote the complexity of the static and dynamic routing problems, respectively. The stability of the dynamic algorithms, however, is not shown. In fact, although most packets will be delivered fast, some packets will never reach their destination and queues will grow to infinity assuming either the stochastic model or the adversarial model in combination with a randomized, static algorithm.

Broder, Frieze, and Upfal [4] introduce a general approach to dynamic packet routing with bounded buffers in the stochastic and adversarial models. They show sufficient conditions for the stability of dynamic packet routing algorithms and investigate how some well-known static routing protocols for the butterfly network can be transformed into dynamic algorithms that fulfill these conditions. In particular, they present a dynamic routing algorithm for the butterfly that is stable for a small constant injection rate, and they show that the expected routing time for each packet is $O(\log n)$, with n denoting the number of nodes on a level.

Andrews et al. [2] investigate another, more restrictive dynamic routing model. In contrast to the stochastic and adversarial models, the packets are injected regularly in "sessions." For each session i, packets are injected at a rate r_i to follow a fixed path of length d_i. They describe a schedule that delivers each packet in a time depending only on local parameters; that is, each packet reaches its destination in time $O(d_i + 1/r_i)$, which is worst-case optimal. We will see that similar local properties, i.e., the routing

time depends on d_i, can be achieved also in the stochastic model.

1.3. New results. In this paper, we present specific transformations of well-known routing protocols and introduce a powerful black box transformation scheme applicable to every static, oblivious routing protocol.

In the following, N denotes the complexity of the routing problem (as defined in section 1.1), D denotes the maximum length of a routing path, and $\epsilon = 1 - \lambda$, where λ denotes the injection rate. Further, we define $\epsilon^* = a \cdot \epsilon^b$, for suitable constants $a, b > 0$. For simplicity, we state our results only for networks of constant degree. For more detailed results the reader is referred to the following sections.

In this paper, we give three specific transformations of well-known routing protocols.

- In section 2, we present a dynamic variant of the ghost packet protocol [8, 14] for leveled networks that is stable for any $\lambda < 1$ in the stochastic model and $\lambda \leq 1$ in the adversarial model, given a sufficiently large but fixed buffer size of $1/\epsilon^*$ in the stochastic model and $2\lambda \cdot w + 2$ in the adversarial model. In the stochastic model, each individual packet is delivered in expected time L/ϵ^*, and in time $(L + \log N)/\epsilon^*$, w.h.p., where L denotes the depth of the network. In the adversarial model, each packet reaches its destination in at most $L + \lambda \cdot w \cdot L - 1$ time steps.
  For example, the tuned ghost packet protocol achieves a throughput of $1 - \epsilon$, for any $\epsilon > 0$, on an n-input butterfly network with buffers of size $1/\epsilon^*$ if we place two generators on each node of level 0, each of which injects packets that are sent to randomly selected nodes of level $\log n$, using a rate of $\lambda = 1 - \epsilon$. Furthermore, the algorithm delivers each individual packet in time $\log n/\epsilon^*$, w.h.p.
  Previous results on routing with bounded buffers in leveled networks obtain stability only for constant injection rates $\lambda \ll 1$ [4, 16] (stochastic model) or require buffers whose size is exponential in the depth of the network [1] (adversarial model).
- In section 3, we present a dynamic routing protocol for arbitrary networks that is stable for any injection rate $\lambda < 1$, assuming buffers of fixed size D/ϵ^*. We prove an expected routing time of $(D^2+w)/\epsilon^*$, and $(D^2+D\cdot\log N+w)/\epsilon^*$, w.h.p., for every individual packet. These bounds hold both for the adversarial model and for the stochastic model (with $w = 0$).
  To the best of our knowledge, this is the first protocol that is stable for buffers of small fixed size under any injection rate $\lambda < 1$. Previous results in the stochastic model with bounded buffers require $\lambda \ll 1$ and besides assume that packets can be dropped and reinjected in later time steps [16]. Previous results in the adversarial model require buffers whose size is exponential (or polynomial, w.h.p.) in D [1]. Note that a bound on the buffer size that does not hold with certainty leaves open the question of what to do in the rare case of a buffer overflow (e.g., dropping or blocking incoming packets), and hence does not guarantee stability for networks with a fixed buffer size.
- In section 4, we describe a dynamic variant of the growing rank protocol [10] for shortest paths in arbitrary networks. The dynamic protocol is stable for any $\lambda < 1$ if unbounded buffers are given. In the stochastic model, each individual packet p with a routing path of length d_p is delivered in time d_p/ϵ^*, expected, and $(d_p + \log N)/\epsilon^*$, w.h.p. In the adversarial model, the d_p in the time bound has to be replaced by $D + w$.

Previously, similar results have been shown only for $\lambda < 1/\mathrm{e}$ in the stochastic model [16].

Furthermore, in section 5, we present a powerful black box transformation scheme that is applicable to every static, oblivious routing algorithm in networks with unlimited buffers. Basically, we combine the ideas of Rabani and Tardos [13] for the fast delivery of packets with the universal stability of the shortest-in-system protocol originally shown by Andrews et al. [1] for the adversarial model. The major problem that we solve is merging these two approaches so that we obtain dynamic protocols that are stable up to some injection rate depending on the static protocol without any significant slowdown due to the inefficiency of the shortest-in-system protocol.

Let $\mathcal{S}$ denote any set of paths, e.g., the set of all simple or all shortest paths in the network. Suppose we are given a static routing algorithm that routes all packets in $\gamma \cdot C + \delta \cdot D + O(\log^\alpha M)$ steps, w.h.p. (or even with certainty), for any collection of paths or subpaths in $\mathcal{S}$ with congestion C, dilation D, and complexity M. Assume that in the dynamic setting only paths in $\mathcal{S}$ are allowed to be generated. Then our black box transformation yields a dynamic variant of this protocol with the following properties. (In the following overview, we describe only the results for the case that γ and δ do not depend on C or D and $\alpha \geq 1$ is a constant. Similar results will be shown for other choices of α, γ, and δ.)

- If the given static protocol is *pure* (i.e., no control messages or copies of packets are allowed), the dynamic algorithm is stable for any injection rate $\lambda < 1$. Otherwise, it is stable for any injection rate $\lambda < 1/\gamma$.
- If $\lambda < 1/\gamma$, then the algorithm guarantees that any packet p that has to travel a distance of d is delivered in time $O(\delta \cdot d + \log^\alpha N)$, w.h.p., in the stochastic injection model, and in time $O(\delta \cdot D + w + \log^\alpha N)$, w.h.p., in the adversarial injection model.
- The algorithm recovers from any worst-case scenario in $O(\delta \cdot D + w + \log^\alpha N)$ time steps (with $w = 0$ in the stochastic model).

The bound on the routing time implies that it might be important for static routing protocols to know the exact factor γ in front of the C since this can be decisive for the performance of their dynamic counterparts. Interestingly, in the stochastic injection model, the dynamic variant is able to exploit locality, whereas the static algorithm does not need to provide this feature. For example, the transformation of a well-known static routing algorithm (see, e.g., [9]) that delivers all packets in time $(1+\kappa) \cdot C + O(D \cdot \log M)$, w.h.p., for any constant $\kappa > 0$ yields a dynamic algorithm that delivers each packet p in time $O(d \cdot \log N)$, w.h.p., for any constant injection rate $\lambda < 1/(1+\kappa)$, where d is the length of p's path.

1.4. Tools. We will frequently apply the following Chernoff bounds.

LEMMA 1.1 (Chernoff). *Let $X_1, \ldots, X_n$ be n independent random variables with $X_i \in \{0,1\}$ for all $i \in \{1,\ldots,n\}$. Furthermore, let $X = \sum_{i=1}^n X_i$ and $\mu \geq \mathrm{E}[X]$. Then it holds for all $\epsilon \geq 0$ that*

$$\Pr[X \geq (1+\epsilon)\mu] \leq \left(\frac{\mathrm{e}^\epsilon}{(1+\epsilon)^{1+\epsilon}}\right)^\mu.$$

This can be simplified to

$$\Pr[X \geq (1+\epsilon)\mu] \leq \begin{cases} \mathrm{e}^{-\epsilon^2\mu/3} & \text{if } \epsilon \in [0,1], \\ \mathrm{e}^{-\epsilon\mu/3} & \text{otherwise.} \end{cases}$$

2. Routing in leveled networks with bounded buffers. In this section, we consider the problem of routing packets in a leveled network with bounded buffers. In a *leveled network*, the nodes can be partitioned into levels $0, \ldots, L$ such that each link in the network leads from some node at level i to some node at level $i + 1$ for $0 \leq i \leq L - 1$. L is called the *depth of the network*.

The routing proceeds in discrete time steps, starting with step 0. In each step, each link can forward at most one packet. The links are assumed to be directed; that is, packets can cross them only in the direction leading to the higher level. Packet injections and arrivals are assumed to happen at the beginning of a time step, so that a packet may leave a node at the end of the time step in which it is injected or arrives at the node. The packets' routing paths may start on any level $k \geq 0$ and end on any level k' with $k < k' \leq L$. Each node has a buffer for each of its incoming edges and a buffer for newly injected packets. Each of the edge buffers has space for storing at most q packets.

Static batches of packets can be routed efficiently on leveled networks by a protocol known as Ranade's, or the ghost packet, protocol [7, 8, 14]. The disadvantage of the static ghost packet protocol is that each node is allowed to forward only one data packet at each time step, rather than forwarding data packets along all outgoing edges in parallel. All edges that are not passed by a data packet in a step are used to exchange control packets that are called *ghost packets*. As a consequence, most of the transmitted packets are ghost packets, which shows that a simple transformation of the static ghost packet protocol into a dynamic protocol cannot yield stability for injection rates close to 1. In order to achieve stability for any injection rate $\lambda < 1$, we introduce a tuned variant of the ghost packet protocol that uses only a very limited number of ghost packets.

The tuned ghost packet protocol. The packets are assigned ranks in order to decide which packet is preferred in case of contention. For each packet p, let $\text{birth}(p)$ denote the time step at which p was injected. The rank of p is set to $\text{birth}(p)$ plus some small value x from the interval $[0, \kappa)$ for some $\kappa < 1$, where x is chosen such that each packet has its own unique rank (e.g., based on the identification number of the generator that injected the packet). Packets with smaller ranks, i.e., older packets, are always preferred against packets with higher rank, i.e., younger packets. As in the static ghost packet protocol, special ghost packets help the algorithm to maintain the following invariant: A packet is routed along an edge only after all the other packets with lower ranks that must pass through the edge have done so. The nodes on level k start working in step k for $0 \leq k \leq L$. In order to give time for initializing the network, we assume that packet injections on level k do not start before time step k. Figure 1 describes the rules for contention resolution in detail.

Ghost packets are discarded as soon as they are delayed in a step. Thus, they never block the buffer for following packets. The role of the ghost packets is to slow down packets that are too fast in order to avoid that a relatively old packet is blocked because younger packets occupy the slots in the next buffer. Note that each outgoing link on level k transmits one packet in each time step $t \geq k$: either a ghost or a real packet. This mechanism ensures that each link transmits packets and ghost packets in the order of increasing rank. (Obviously, this property holds for the links on level 0. For higher levels the property follows by induction.) We will see that this property is crucial for the analysis. Analyzing the performance of a variant of the protocol described above that does not use ghost packets is an interesting open problem, even in the static case.

The following algorithm is executed for each outgoing link e of a node v on level k in each time step $t \geq k$. Each edge buffer can hold up to q packets.

- Let r denote the minimum rank of a packet that is stored in one of v's buffers and aims to pass edge e. If there is no such packet, then $r = \infty$.
- Let g denote the minimum over all ranks of packets or ghost packets that arrived on v at the beginning of step t. If there is no such packet (as v is a node without incoming edges, e.g., on level 0), then g is set to $t + \kappa$.
- If $r < g$, then

  if the buffer of e contains less than q packets at the beginning of step t, then

    forward the (unique) packet with rank r along e;

  else

    send a ghost packet with rank r along e;

  else

    send a ghost packet with rank g along e.

FIG. 1. *Contention resolution in the tuned ghost packet protocol.*

The following analysis shows that the tuned ghost packet protocol is stable for any injection rate $\lambda \leq 1$ in the adversarial model, and $\lambda < 1$ in the stochastic model, provided that the edge buffer size is sufficiently large.

THEOREM 2.1. *Let L denote the depth of the network, Δ the maximum node degree, and q the size of the edge buffers.*

- *Suppose the packets are injected according to the adversarial model with injection rate (w, λ) for any $w \leq (q-2)/(2\lambda)$ and $0 \leq \lambda \leq 1$. Then the tuned ghost packet protocol is stable, and each packet reaches its destination in at most $L + \lambda \cdot w \cdot L$ time steps.*
- *Suppose the packets are injected according to the stochastic model with injection rate $\lambda \leq 1 - \epsilon$ for a suitably chosen $\epsilon = \Theta(\log(q\Delta)/q)$. Then the tuned ghost packet protocol is stable, and the routing time for each individual packet is $O(L \cdot \log(\Delta/\epsilon)/\epsilon + \log(1/\epsilon)/\epsilon^2)$, expected, and $O(L \cdot \log(\Delta/\epsilon)/\epsilon + (\log N)/\epsilon^2)$, w.h.p., where the probability is with respect to the stochastic packet injections.*

Proof. We use a "delay sequence argument" to analyze the tuned ghost packet protocol. Our analysis is similar to the one for the static ghost packet protocol given in [8]. A delay sequence witnesses that a packet needs many time steps to reach its destination. For the adversarial model, we will show that a delay sequence witnessing a long routing time does not exist, so that every packet reaches its destination within

the time bound given in the theorem. For the stochastic model, we will show that "large" delay sequences are very unlikely so that each packet needs only limited time, w.h.p., to reach its destination.

The ghost packet protocol uses fractional ranks. The only reason for the fractional additive is to define a total order among all packets such that a packet p or a ghost packet corresponding to p (i.e., a ghost packet that has the same rank as p) that delays a packet p' in a step cannot be delayed by packet p' or a ghost packet corresponding to p' in another time step. In the following, however, we mainly use *integral ranks*, i.e., the integral values of the fractional ranks, which, in the case of the ghost packet protocol, are equal to the birth date of the corresponding packet.

DEFINITION 2.2 ((p, s, ℓ, r)-delay sequence). *Let p denote a packet, and let $s, \ell, r \geq 1$ denote integers. Then a (p, s, ℓ, r)-delay sequence consists of the following:*

- *A path of length ℓ starting at the destination node of packet p. This path is called the* delay path. *Let $v_0, \ldots, v_\ell$ denote the nodes on the delay path. The delay path may include edges in both directions and, hence, follows a course going up and down the levels of the network.*
- *ℓ* delay edges *$e_1, \ldots, e_\ell$ such that e_i is incident to v_i for $1 \leq i \leq \ell$. These edges are not necessarily included in the delay path.*
- *ℓ nonempty* intervals of integral ranks *$r_1, \ldots, r_\ell$ such that $\sum_{i=1}^{\ell} |r_i| = r$, where $|r_i|$ denotes the length of interval r_i. The maximum integral rank in r_1 is equal to the birth date of packet p, and, for $2 \leq i \leq \ell$, the maximum integral rank in r_i is equal to the minimum in r_{i-1}.*

A (p, s, ℓ, r)-delay sequence is called active *if the adversary or the stochastic generators inject s packets $p_1, \ldots, p_s$ (different from p) such that, for every $1 \leq i \leq s$, packet p_i has an integral rank in r_j and its routing path includes edge e_j for some $1 \leq j \leq \ell$. These packets are called* delay packets.

The following lemma shows that a long routing time of a packet p_0 is always accompanied by an active (p_0, s, ℓ, r)-delay sequence with relatively large s and small ℓ and r.

LEMMA 2.3. *Suppose a packet p_0 takes $L+T$ or more steps to reach its destination for any $T > 0$. Then there is an active (p_0, s, ℓ, r)-delay sequence with $s \geq T + r + (\frac{q}{2} - 2) \cdot \ell - (\frac{q}{2} - 1) \cdot L'$, where L' denotes the difference between the level of the first node, v_0, and the level of the last node, v_s, of the delay path.*

Proof. We will construct a sequence of packets or ghost packets $p_0, \ldots, p_{s'}$ and nodes $v'_0, v'_1, \ldots, v'_{s'}$ such that v'_0 denotes the destination of p_0, and packet p_i or a ghost packet corresponding to this packet delays packet p_{i-1} at node v'_i for $1 \leq i \leq s'$. (Ultimately, s will be set either to s' or to $s' - 1$.) There are two reasons why a packet may be delayed: It is delayed either by a packet or ghost packet with lower rank that wants to traverse the same link, or it is delayed by q other packets with lower ranks occupying the next edge buffer on its path. The first kind of delay is called *m-delay*; the second kind of delay is called *f-delay*.

The active delay sequence is constructed incrementally. Suppose we have already fixed the packets $p_0, \ldots, p_{j-1}$ and nodes $v'_1, \ldots, v'_{j-1}$. Starting from the time step in which p_{j-1} delayed p_{j-2} on node v'_{j-1} or, if $j = 1$, the time step in which $p_{j-1} = p_0$ reached its destination node v'_0, we follow the course of the packet p_{j-1} backwards in time. If p_{j-1} is a ghost packet whose generation was caused by the arrival of another packet, then we identify p_{j-1} with that packet and continue the trace. We stop following when we reach a node on which p_{j-1} either was delayed, was injected

as a nonghost packet, or was injected as a ghost packet on a node without incoming edges. The node on which this event happened is called v'_j. If we stop because of an m-delay, then the packet that caused the delay is called p_j. If we stop because of an f-delay, then the q packets that occupy the corresponding buffer are called $p_j, \dots, p_{j+q-1}$, in decreasing order of ranks. Moreover we set $v'_{j+1}, \dots, v'_{j+q-1} = v'_j$. In both of these cases we can continue our construction. In the other cases, however, our construction ends with a packet p_j that was injected at node v'_j, and we define $s' = j$.

The path from the destination of p_0 to the source of $p_{s'}$ recorded by this process is called the *delay path*. The nodes on this path are defined to be $v_0, \dots, v_\ell$. Note that these nodes are not necessarily identical to $v'_0, \dots, v'_{s'}$, but $\{v'_0, \dots, v'_{s'}\} \subseteq \{v_0, \dots, v_\ell\}$. The edges on which the recorded delays of the packets $p_0, \dots, p_{s'-1}$ take place are defined to be the delay edges. We have to show that the number of these edges is at most ℓ. (Note that the delay edges are not necessarily included in the delay path. Consider, for example, the following scenario. Suppose packet p_j is delayed in step t on level k by an f-delay caused by the packets $p_{j+1}, \dots, p_{j+q}$ stored in a buffer on level $k+1$. Suppose the next event recorded by the delay sequence is an m-delay of packet p_{j+q} caused by packet p_{j+q+1} moving along an edge e to level $k+2$ in step $t-1$, and suppose this packet arrived on level $k+1$ coming from level k in step $t-2$. Then the delay path goes from level k to level $k+1$ and then back to level k, and hence skips the delay edge e.)

Although not every delay edge is included in the delay path, each of these edges is incident to a node of the delay path, and the number of different delay edges is at most ℓ, which can be shown as follows. All delay events in a sequence of consecutive m-delays recorded by the construction above in consecutive time steps, i.e., not separated by packet movements or f-delays, take place at the same edge. Further, an f-delay following immediately after a sequence of m-delays takes place at the same edge, too. (Note that these properties are not given for the original ghost packet protocol.) Hence, considering the incremental construction of the delay sequence, the delay edge changes only in those incremental steps in which the delay path is increased by at least one node. Consequently, every node v_i of the delay path can be assigned one delay edge, which is called e_i for $1 \le i \le \ell$.

The ghost packet protocol ensures that the ranks in the delay sequence are decreasing. In particular, the ranks of the packets traversing edge e_i are larger than the ranks of the packets traversing edge e_{i+1} for $1 \le i \le \ell - 1$. Hence, we can define consecutive intervals of integral ranks $r_1, \dots, r_\ell$ in such a way that every neighboring pair of intervals has one integral rank in common (i.e., overlap by one) and the packets that are delayed at edge e_i have an integral rank in r_i for $1 \le i \le \ell$. We define $r' = \sum |r_i| = \text{birth}(p_0) - \text{birth}(p_{s'}) + \ell$. (Ultimately, r will be set either to r' or to $r' - 1$.)

Next we investigate the relationship between the parameters of the delay sequence. Define t to be the number of time steps covered by the construction, i.e., the time from the birth of the packet $p_{s'}$ to the arrival of the packet p_0 at its destination. Then

$$\begin{aligned} t &\ge \text{birth}(p_0) + L + T - \text{birth}(p_{s'}) \\ &= L + T + r' - \ell. \end{aligned} \tag{1}$$

The delay path is enlarged by one node in each of those time steps that do not represent an m-delay. Let m denote the number of m-delays. Then we can conclude

that $t = m + \ell$ or $m = t - \ell$. Applying the bound in (1) to this equation yields

$$m \geq L + T + r' - 2\ell. \tag{2}$$

Let f be the number of f-delays. Since each f-delay enlarges the delay path by two edges, we have $\ell = L' + 2 \cdot f$, where L' denotes the difference between the level of v_0 and the level of v_s. Hence,

$$f = \frac{\ell - L'}{2}. \tag{3}$$

Further, each m-delay adds one packet to the active delay sequence, and each f-delay adds q packets. As a consequence,

$$\begin{aligned} s' &= m + q \cdot f \\ &\overset{(2,3)}{\geq} L + T + r' - 2\ell + \tfrac{q}{2} \cdot \ell - \tfrac{q}{2} \cdot L' \\ &\geq T + r' + \left(\tfrac{q}{2} - 2\right) \cdot \ell - \left(\tfrac{q}{2} - 1\right) \cdot L', \end{aligned}$$

where the last estimation holds because $L' \leq L$.

Finally, we fix the parameters s and r. For $0 \leq i \leq s' - 1$, every packet p_i is delayed by packet p_{i+1}. As ghost packets are never delayed, $p_1, \ldots, p_{s'-1}$ must be nonghost packets. The definition of s and r depends on whether or not $p_{s'}$ is a ghost packet. If it is not, then we set $s = s'$ and $r = r'$ so that $p_1, \ldots, p_{s'}$ are the packets of the active (p_0, s, ℓ, r)-delay sequence. Otherwise, if $p_{s'}$ is a ghost packet, then we set $s = s' - 1$. In this case, the packets $p_1, \ldots, p_{s'-1}$ are the delay packets. Since $p_{s'}$ is a ghost packet with rank $\text{birth}(p_{s'}) + \kappa$ and $p_{s'}$ is preferred against $p_s = p_{s'-1}$, we have $\text{birth}(p_s) \geq \text{birth}(p_{s'}) + 1$. (Recall that the increment in the rank for ghost packets, i.e., κ, is larger than the increment in the rank for other packets, i.e., some $x \in [0, \kappa)$.) As a consequence, we can set $r = r' - 1$, and the constructed delay sequence fulfills all desired requirements. Hence, Lemma 2.3 is proven. □

Analysis for the adversarial model. We assume an adversary that injects packets at rate (w, λ) for any $w \leq (q-2)/(2\lambda)$ and $0 \leq \lambda \leq 1$; that is, the adversary injects no more than $\lambda \cdot w$ packets for the same edge during every time interval of length w.

Suppose the routing time of a packet p_0 is $L + T$ or more. Then we can construct a (p_0, s, ℓ, r)-delay sequence with parameters as described in Lemma 2.3. The delay sequence specifies edges $e_1, \ldots, e_\ell$ such that e_i is traversed by packets with integral ranks from the interval r_i. On the one hand, the adversary is allowed to inject at most $\lambda \cdot (|r_i| + w - 1)$ packets with an integral rank in r_i that traverse e_i for $1 \leq i \leq \ell$. (Recall that the integral rank of a packet corresponds to its birth date.) Hence, the number of packets that traverse one of the delay edges and have the corresponding integral rank is at most

$$\sum_{i=1}^{\ell} \lambda \cdot (|r_i| + w - 1) = \lambda \cdot (r + \ell \cdot (w - 1)).$$

On the other hand, we conclude from Lemma 2.3 that the total number of packets needed for an active delay sequence corresponding to a routing time of $L + T$ steps is at least $s \geq T + r + \left(\frac{q}{2} - 2\right) \cdot \ell - \left(\frac{q}{2} - 1\right) \cdot L'$. This yields the constraint

$$\lambda \cdot (r + \ell \cdot (w - 1)) \geq T + r + \left(\tfrac{q}{2} - 2\right) \cdot \ell - \left(\tfrac{q}{2} - 1\right) \cdot L'$$

and, therefore,

$$\begin{aligned} T &\le \lambda \cdot (r + \ell \cdot (w-1)) - \left(r + \left(\tfrac{q}{2} - 2\right) \cdot \ell - \left(\tfrac{q}{2} - 1\right) \cdot L'\right) \\ &= (\lambda - 1) \cdot (r - \ell) + \left(\lambda \cdot w - (\tfrac{q}{2} - 1)\right) \cdot \ell + \left(\tfrac{q}{2} - 1\right) \cdot L'. \end{aligned}$$

This upper bound on T can be simplified as follows. First, $(\lambda - 1) \cdot (r - \ell) \le 0$ because $\lambda \le 1$ and $r \ge \ell$. Second, $\left(\lambda \cdot w - (\frac{q}{2} - 1)\right) \cdot \ell \le \left(\lambda \cdot w - (\frac{q}{2} - 1)\right) \cdot L'$ because $\ell \ge L'$ and $w \le (q-2)/(2\lambda)$, so that the factor in front of the ℓ is negative or 0. Applying these two equations to the above bound on T yields

$$\begin{aligned} T &\le \left(\lambda \cdot w - (\tfrac{q}{2} - 1)\right) \cdot L' + \left(\tfrac{q}{2} - 1\right) \cdot L' \\ &\le \lambda \cdot w \cdot L' \ \le \ \lambda \cdot w \cdot L. \end{aligned}$$

Consequently, each packet takes at most $L + \lambda \cdot w \cdot L$ time steps to reach its destination and the tuned ghost packet protocol is stable for any injection rate $\lambda \le 1$.

Analysis for the stochastic model. Now we assume that the packets are injected at random by independent generators at a rate of $\lambda = 1 - \epsilon$ with $\epsilon > 0$. Again we use a delay sequence argument. The major difference between our analysis and the analysis for the static ghost packet protocol given in [8] is that we have to deal with an arbitrarily long history of packet delays. Further, we have to use Chernoff bounds (see Lemma 1.1) instead of simple counting methods in order to prove stability results for injection rates arbitrarily close to 1.

Let L denote the depth of the network, Δ the maximum node degree, and q the size of the edge buffers. We will show that each individual packet reaches its destination within $L + T$ time steps with probability $1 - 2^{-\Omega(\epsilon^2 \cdot T)}/\epsilon^2$, provided that q and T are chosen sufficiently large, i.e., $q \ge 2(k+1)$ and $T \ge k \cdot L$ for some $k = \Theta(\log(\Delta/\epsilon)/\epsilon)$ which will be specified during the proof.

Fix an arbitrary packet p_0. Suppose that p_0 needs more than $L + T$ time steps to reach its destination. Then Lemma 2.3 yields that a (p_0, s, ℓ, r)-delay sequence is active, with

$$\begin{aligned} s &\ge T + r + \left(\tfrac{q}{2} - 2\right) \cdot \ell - \left(\tfrac{q}{2} - 1\right) \cdot L' \\ &\ge k \cdot L + r + (k-1) \cdot \ell - k \cdot L' \\ &\ge r + (k-1) \cdot \ell. \end{aligned} \tag{4}$$

We assume $k \ge 1$. Then at least r packets are needed for an active (p_0, s, ℓ, r)-delay sequence. However, we will show that the expected number of packets that pass the delay edges and have the corresponding integral rank is at most $(1 - \epsilon) \cdot r$. Hence, this event is very unlikely.

Suppose that the delay edges and the range of integral ranks for each delay edge are fixed. Define $R = r_1 \cup \cdots \cup r_\ell$. For each integral rank $j \in R$, let the binary random variable X_j^g be one if and only if generator g generates a packet that has integral rank $j \in r_i$ and traverses delay edge e_i. (The integral rank j may fall in two or more rank intervals corresponding to different delay edges.) Let $X = \sum_{j,g} X_j^g$. Every active (p_0, s, ℓ, r)-delay sequence of length s with fixed delay edges and a fixed rank assignment has at least one choice for the X_j^g's such that $X \ge s$, because each of the packets $p_1, \ldots, p_s$ traverses one of the delay edges e_i and has an integral rank in r_i. (Note that s distinct packets are needed to have an active sequence, regardless of whether a packet traverses more than one delay edge responsible for its integral rank.) Hence, if a delay sequence of length s can be constructed, then $X \ge s$.

Consequently, the probability that a fixed delay sequence becomes active is bounded above by $\Pr[X \geq s]$.

Because the integral rank of a packet corresponds to its birth date and the expected number of packets injected in a time step that include delay edge e_i in their path is at most $\lambda = 1 - \epsilon$,

$$\begin{aligned} \mathrm{E}[X] &\leq \sum_{i=1}^{\ell} (1-\epsilon) \cdot |r_i| \\ &\leq (1-\epsilon) \cdot r \qquad (5) \\ &\overset{(4)}{\leq} (1-\epsilon) \cdot s \qquad (6) \end{aligned}$$

for $k \geq 1$. The binary random variables in the sum of X are stochastically independent, because each generator is operating independently of other generators and previous time steps. Therefore, the probability for a deviation from the expectation can be estimated by using a Chernoff bound (see Lemma 1.1). We define $\delta = s/((1-\epsilon)\cdot r) - 1$. Then

$$\begin{aligned} \Pr[X \geq s] &= \Pr\left[X \geq (1+\delta) \cdot (1-\epsilon) \cdot r\right] \\ &\overset{(5)}{\leq} \mathrm{e}^{-\min\{\delta, \delta^2\} \cdot (1-\epsilon) \cdot r/3}. \end{aligned}$$

A further bound, solely depending on s and ϵ, can be derived as follows:

$$\begin{aligned} \Pr[X \geq s] &= \Pr\left[X \geq \left(1 + \frac{\epsilon}{1-\epsilon}\right) \cdot (1-\epsilon) \cdot s\right] \\ &\overset{(6)}{\leq} \mathrm{e}^{-\min\left\{\frac{\epsilon}{1-\epsilon}, \left(\frac{\epsilon}{1-\epsilon}\right)^2\right\} \cdot (1-\epsilon) \cdot s/3} \\ &\leq \mathrm{e}^{-\epsilon^2 \cdot s/3}. \end{aligned}$$

Up to now we have calculated only the probability that a fixed delay sequence becomes active. It remains to sum over all delay sequences that possibly caused the delay of packet p_0. The number of different (p_0, s, ℓ, r)-delay sequences can be bounded as follows. The maximum node degree in the network is Δ. Hence, the number of possibilities to determine the delay path starting at the destination of p_0 is at most Δ^ℓ. Once the path is fixed, the number of possibilities to choose the delay edges is at most Δ^ℓ, too, because edge e_i is incident to node v_i for $1 \leq i \leq \ell$. Further, the number of different ways of specifying the rank intervals is equivalent to the number of binary strings of length r with exactly $\ell - 1$ ones. This number is $\binom{r}{\ell-1}$. As a consequence, the probability that there exists an active (p_0, s, r, ℓ)-delay sequence for a fixed set of parameters s, ℓ, and r fulfilling the equation in Lemma 2.3 is at most

$$\begin{aligned} \binom{r}{\ell-1} \cdot \Delta^{2\ell} \cdot \Pr[X \geq s] &\leq \underbrace{\left(\frac{\mathrm{e}\Delta^2 \cdot r}{\ell-1}\right)^{\ell} \cdot \sqrt{\mathrm{e}^{-\min\{\delta,\delta^2\}\cdot(1-\epsilon)\cdot r/3}}}_{=:\,Y} \cdot \sqrt{\mathrm{e}^{-\epsilon^2 \cdot s/3}} \\ &\leq \sqrt{\mathrm{e}^{-\epsilon^2 \cdot s/3}}. \qquad (7) \end{aligned}$$

The last inequality assumes $Y \leq 1$, which holds if k is chosen sufficiently large in $\Theta(\log(\Delta/\epsilon)/\epsilon)$. We defer the corresponding calculations to the end of this proof.

Let $t(p_0)$ denote the routing time of packet p_0. If $t(p_0) > L+T$ for any $T > 0$, then we can construct an active delay sequence as described in Lemma 2.3. Consequently, the probability that $t(p_0) > L + T$ is bounded above by the probability for the existence of an active (p_0, s, ℓ, r)-delay sequence whose parameters fulfill the following constraints. Equation (4) yields $r \le s$ and $\ell \le s/(k-1) \le s$, assuming $k \ge 2$. Lemma 2.3 yields $s \ge T$. Now applying the bound in (7), which holds for $T \ge k \cdot L$, we obtain

$$\begin{aligned} \Pr[t(p_0) > L + T] &\le \sum_{s=T}^{\infty} \sum_{\ell=1}^{s} \sum_{r=1}^{s} \sqrt{\mathrm{e}^{-\epsilon^2 \cdot s/3}} \\ &\le \frac{2^{-\beta \cdot \epsilon^2 \cdot T}}{\epsilon^2} \end{aligned} \tag{8}$$

for some suitable constant β. This term is at most $N^{-\alpha}$ for any constant $\alpha > 0$ if $T \ge \alpha' \log N/\epsilon^2$ for a suitably large constant α'. (Recall that $N \ge 1/\epsilon$.) Therefore,

$$t(p_0) \;\le\; \max\left\{L \cdot (k+1), \frac{\alpha' \log N}{\epsilon^2}\right\} \;=\; O\left(\frac{L \cdot \log(\Delta/\epsilon)}{\epsilon} + \frac{\log N}{\epsilon^2}\right),$$

w.h.p. It remains to prove the bound on the expected routing time of p_0. In general, for any integer $Z \ge 0$,

$$\mathrm{E}[t(p_0)] \;=\; \sum_{i=1}^{\infty} \Pr[t(p_0) \ge i] \;\le\; Z + \sum_{i=Z+1}^{\infty} \Pr[t(p_0) \ge i].$$

Applying (8), we obtain that $\sum_{i=Z+1}^{\infty} \Pr[t(p_0) \ge i] \le 2 \cdot Z$ for $Z \ge \max\{L \cdot (k+1), L + 4 \cdot \log(1/\epsilon)/\epsilon^2\}$. In this case,

$$\mathrm{E}[t(p_0)] \;\le\; 3 \cdot Z \;=\; O\left(\frac{L \cdot \log(\Delta/\epsilon)}{\epsilon} + \frac{\log(1/\epsilon)}{\epsilon^2}\right),$$

which corresponds to the bound on the expected routing time given in Theorem 2.1.

Deferred calculations. Finally, we show that $Y \le 1$ if k is chosen sufficiently large in $\Theta(\log(\Delta/\epsilon)/\epsilon)$. First, we estimate δ.

$$\delta = \frac{s}{(1-\epsilon) \cdot r} - 1 \;\overset{(4)}{\ge}\; \frac{r + (k-1) \cdot \ell}{(1-\epsilon) \cdot r} - 1 \;\ge\; \epsilon + \frac{(k-1) \cdot \ell}{r}.$$

Depending on the value of δ, we distinguish two cases. Consider the case $\delta \le 1$. Assume $Y > 1$. Then

$$\left(\frac{\mathrm{e}\Delta^2 \cdot r}{\ell - 1}\right)^{\ell} \cdot \mathrm{e}^{-\delta^2 (1-\epsilon) \cdot r/6} > 1.$$

Applying $\delta \ge \epsilon$, that is, substituting ϵ for δ, and solving the resulting equation for r/ℓ yields $r/\ell = O\left(\log(\Delta/\epsilon)/\epsilon^2\right)$. We assume that k is chosen in such a way that

$$k \ge \sqrt{\frac{r}{\ell} \cdot \frac{6}{(1-\epsilon)} \cdot \log\left(\frac{\mathrm{e}\Delta^2 \cdot r}{\ell - 1}\right)} + 1 \;=\; O\left(\frac{\log(\Delta/\epsilon)}{\epsilon}\right)$$

for all possible choices of r and ℓ. Now applying $\delta \ge (k-1) \cdot \ell/r$ yields

$$Y \le \left(\frac{\mathrm{e}\Delta^2 \cdot r}{\ell - 1}\right)^{\ell} \cdot \mathrm{e}^{-\left(\frac{(k-1) \cdot \ell}{r}\right)^2 \cdot (1-\epsilon) \cdot r/6} \;\le\; 1.$$

Similarly, we get $Y \le 1$ for the case $\delta > 1$, too, already for $k = O(\log(\Delta/\epsilon))$. This completes the proof of Theorem 2.1. □

3. Dynamic routing in arbitrary networks with bounded buffers. The tuned ghost protocol can be used to construct an efficient routing algorithm for arbitrary paths in an arbitrary (nonleveled) network G with bounded buffers. In this section, we consider only the stochastic model. In section 6, we will show how the results obtained in this model can be adapted to the adversarial model. In the stochastic model, our approach yields a dynamic routing protocol that is stable for any injection rate $\lambda < 1$ and requires only small edge buffers. The dynamic protocol uses the following simulation technique.

Suppose the maximum length of a routing path is D. Define $L = \lceil D \cdot (1 + 1/\epsilon) \rceil$ with $\epsilon = 1 - \lambda$. G simulates the tuned ghost protocol on a leveled network G' of depth L under a maximum injection rate of $\lambda' \leq 1 - \epsilon^2$. G' is defined as follows. On each level, it contains a node for every node in G. A node u from level i and a node v from level $i+1$ for $0 \leq i \leq L-1$ are connected by an edge if and only if the corresponding nodes in G are connected by an edge.

Each edge of the leveled network is simulated by its respective counterpart in G. Hence, every edge in G has to simulate L edges of G' and, therefore, the buffer size in G has to be L times the buffer size of the simulated network G'. The simulation works in a round-robin fashion; that is, in each time step t, the edges of G simulate the edges of G' between the nodes of level i and level $i+1$ with $i = t \bmod L$. For each injected packet p, the generator chooses an *offset* κ_p uniformly at random from the range 0 to $\lceil D/\epsilon \rceil - 1$. The routing path in the leveled network starts from level κ_p and simply follows the course prescribed by the original path until it reaches the packet's destination on level $\kappa_p + d_p \leq L$, where d_p denotes the length of the routing path.

Next we calculate the virtual injection rate λ' in the simulated network G'. On the one hand, the virtual rate at which each generator injects packets into G' is L times larger than the actual rate in G, because each edge in G is activated only every Lth step. On the other hand, the probability that an injected packet that traverses an edge e in G also traverses a fixed edge e' in G' that corresponds to e is at most $1/\lceil D/\epsilon \rceil$ because of the randomly selected offset. Therefore,

$$\lambda' \leq \frac{\lambda \cdot L}{\lceil D/\epsilon \rceil} = \frac{(1-\epsilon) \cdot \lceil D \cdot (1+1/\epsilon) \rceil}{\lceil D/\epsilon \rceil} \leq (1-\epsilon) \cdot (1+\epsilon) = 1 - \epsilon^2.$$

Substituting this injection rate into Theorem 2.1 and applying $L = \Theta(D/\epsilon)$ yields the following result.

COROLLARY 3.1. *The simulation of the tuned ghost packet protocol yields a dynamic routing algorithm that is stable for any injection rate $\lambda \leq 1 - \epsilon$ for any $\epsilon > 0$, provided that buffers of sufficiently large size $O(D \cdot \log(\Delta/\epsilon)/\epsilon^3)$ are used. Furthermore, each packet is delivered in time $O(D^2 \cdot \log(\Delta/\epsilon)/\epsilon^4 + D \cdot \log(1/\epsilon)/\epsilon^5)$, expected, and $O(D^2 \cdot \log(\Delta/\epsilon)/\epsilon^4 + D \cdot (\log N)/\epsilon^5)$, w.h.p.*

4. Routing along shortest paths in arbitrary networks. In this section, we assume that each buffer has space for an unlimited number of packets. The goal is to achieve a better routing time than in the previous section, in which we assumed buffers of limited size. We assume that packets do not make detours, that is, all routing paths are shortest paths. Initially, we investigate the stochastic model. In section 6, we will show how the results obtained in this model can be adapted to the adversarial model.

We investigate a dynamic variant of the growing rank protocol that was introduced for static routing in [10, 11]. We have introduced this dynamic variant before in [16],

but the analysis we give there holds only for injection rates $\lambda < 1/e$. In the following, we show that the results can be extended to hold for any constant injection rate $\lambda < 1$.

The dynamic growing rank protocol works as follows. Define the initial rank of a packet to be the time step in which the packet is injected. Whenever the packet traverses a link, its rank is increased by some fixed integer $m \geq 1$, which will be specified later on. If several packets want to traverse the same link at the same time, then the packet with minimal rank is chosen. (In order to break ties, if there are several packets with the same rank, the packet with minimum generator id is taken.)

The following theorem summarizes the results of our analysis of the dynamic growing rank protocol. Note that neither the maximum injection rate for which the protocol is stable nor the routing time depends on the degree of the network.

THEOREM 4.1. *Suppose all routing paths are shortest paths. Then the growing rank protocol is stable for any injection rate λ up to some $1-\epsilon$ with $\epsilon = \Theta((\log m)/\sqrt{m})$. Furthermore, the routing time for each individual packet p that has to travel along a routing path of length d_p is $O(m \cdot d_p)$, expected, and $O(m \cdot (d_p + \log N))$, w.h.p.*

We point out that similar results can be obtained by applying the black box transformation scheme presented later in section 5. The direct transformation of the growing rank protocol, however, is more natural and more elegant, as it does not require to partition the time into fixed size blocks in which the static protocol is executed. Further, the expected routing time guaranteed by the specific transformation is slightly better, i.e., $O(d_p)$ rather than $O(d_p + \log N)$.

Proof. We use a delay sequence argument that is similar to the one for the ghost packet protocol. A (p, s, ℓ, r)-delay sequence is defined as in Definition 2.2 except for the following changes. The delay edges are the edges on the delay path rather than edges that are only incident on that path. The intervals of ranks do not overlap. Instead, the smallest rank in r_i is equal to the maximum rank in r_{i+1} plus m; that is, neighboring intervals are separated by a gap of $m-1$ (integral) ranks. As an additional component, the delay sequence includes ℓ integers $s_1, \ldots, s_\ell$ such that $s = (\sum_{i=1}^{\ell} s_i) - \ell + 1$. In an active delay sequence, each delay edge e_i must be traversed by s_i packets with a rank from r_i.

LEMMA 4.2. *Suppose a packet p_0 that has a routing path of length d_{p_0} takes $m \cdot d_{p_0} + T$ or more steps to reach its destination. Then there is an active (p_0, s, ℓ, r)-delay sequence with $s \geq T + r + (m-2) \cdot \ell$.*

Proof. The construction of the active delay sequence is analogous to the one used in section 2 for the ghost packet protocol. In fact, the construction becomes slightly simpler as we have to consider neither delays because of blocked edges nor delays due to ghost packets. The shortest path restriction ensures that all recorded delay packets are distinct. (For a proof, see [11, Lemma 2.3.]) Neighboring intervals of ranks are separated by a gap of $m-1$ ranks because the rank of a packet increases by m whenever the packet moves along an edge.

It remains to prove the bound on the parameters of the delay sequence. Recall that $r = \sum_{i=1}^{\ell} |r_i|$ with $|r_i|$ denoting the length of the interval of ranks assigned to delay edge e_i. The highest rank in the recorded sequence is $\text{birth}(p_0) + (d_{p_0} - 1) \cdot m$, which is the rank of p_0 on the last edge of its routing path, and the lowest rank is $\text{birth}(p_s)$, which is the rank of p_s on the first edge of its routing path. As neighboring intervals of ranks are separated by a gap of $m-1$ ranks, we get

$$\begin{aligned} r &= \text{birth}(p_0) - \text{birth}(p_s) + (d_{p_0} - 1) \cdot m - (\ell - 1) \cdot (m-1) + 1 \\ &= \text{birth}(p_0) - \text{birth}(p_s) + d_{p_0} \cdot m - \ell \cdot (m-1). \end{aligned} \tag{9}$$

Define t to be the number of time steps covered by the construction, i.e., the time from the birth of the packet p_s to the arrival of the packet p_0 at its destination. Then

$$\begin{aligned} t &\geq \text{birth}(p_0) - \text{birth}(p_s) + d_{p_0} \cdot m + T \\ &\overset{(9)}{=} r + (m-1) \cdot \ell + T. \end{aligned} \tag{10}$$

Each of the t time steps recorded in the delay sequence is either one of s delays or one of ℓ packet movements. Therefore, $t = s + \ell$, and we can conclude

$$\begin{aligned} s &= t - \ell \\ &\overset{(10)}{\geq} r + (m-2) \cdot \ell + T, \end{aligned}$$

which completes the proof of Lemma 4.2. □

Now fix an arbitrary packet p_0, and suppose that p_0 needs more than $d_{p_0} \cdot m + T$ time steps to reach its destination. Then Lemma 4.2 yields that a (p_0, s, ℓ, r)-delay sequence is active with

$$s \geq r + (m-2) \cdot \ell \;\geq\; r + \ell \tag{11}$$

for $m \geq 3$. Hence, at least $r + \ell$ packets are needed for an active (p_0, s, ℓ, r)-delay sequence. However, we will show that the expected number of packets that pass the delay edges and have the corresponding rank is at most $(1-\epsilon) \cdot r$. Hence, this event is very unlikely.

Suppose that the delay edges and the range of ranks for each delay edge are fixed. For $j \in r_1 \cup \cdots \cup r_\ell$ and $1 \leq i \leq \ell$, let the binary random variable $X_{j,i}^g$ be one if and only if generator g generates a packet that has rank $j \in r_i$ at delay edge e_i. Let $X = \sum_{j,i,g} X_{j,i}^g$. Then the probability that a fixed delay sequence becomes active is bounded by $\Pr[X \geq s]$.

The expected number of packets traversing a fixed edge e with some fixed rank r is at most $\lambda = 1 - \epsilon$ because the rank of a packet p at edge e corresponds to its injection time plus an offset that depends on the distance between e and the source node of p. Therefore,

$$\begin{aligned} \mathrm{E}[X] &\leq \sum_{i=1}^{\ell} (1-\epsilon) \cdot |r_i| \\ &\leq (1-\epsilon) \cdot r \\ &\overset{(11)}{\leq} (1-\epsilon) \cdot s. \end{aligned} \tag{12}$$

Thus, applying a Chernoff bound (see Lemma 1.1) yields

$$\begin{aligned} \Pr[X \geq s] &= \Pr\left[X \geq \left(1 + \frac{\epsilon}{1-\epsilon}\right) \cdot (1-\epsilon) \cdot s\right] \\ &\overset{(12)}{\leq} \mathrm{e}^{-\min\left\{\frac{\epsilon}{1-\epsilon}, \left(\frac{\epsilon}{1-\epsilon}\right)^2\right\} \cdot (1-\epsilon) \cdot s/3} \\ &\leq \mathrm{e}^{-\epsilon^2 \cdot s/3}. \end{aligned} \tag{13}$$

So far, we have only calculated the probability that a fixed delay sequence becomes active. It remains to multiply this probability with the number of possible delay sequences. The number of possibilities to choose the r_i's is $\binom{r}{\ell-1}$. The number of

possibilities to choose the s_i's is $\binom{s+\ell-1}{\ell-1}$. Enumerating explicitly all possible delay paths, as we have done for the ghost packet protocol, would give us another factor of Δ^ℓ. However, we can avoid this factor in the case of the growing rank protocol because the delay path is fixed when the delay packets and the s_i's are specified.

The technical problem with the last assumption is that we supposed before, when estimating the probability for $X \geq s$, that the delay path is fixed whereas we assume here that the delay packets and, hence, the random variables $X^g_{j,i}$ are fixed. This dilemma can be solved by constructing the delay path iteratively. Suppose we have specified the delay path up to the dth edge for some $d \geq 0$ starting from the destination of packet p_0. At this point only some of the $X^g_{j,i}$ random variables above are well defined, namely, those variables with $i \leq d$. The specification of the outcome of these variables, however, gives us the delay packets $p_0, \ldots, p_k$ for $k = \sum_{i=1}^{d} s_i$, and following the path of packet p_k backwards for one edge gives us the next edge on the delay path. In this way, the delay path and the outcome of the $X^g_{j,i}$ variables can be determined alternately. Note that the fact that the definition of some random variables depends on the outcome of other variables does not affect the applicability of the Chernoff bounds because their outcome remains independent.

Combining all these results, the probability that a (p_0, s, ℓ, r)-delay sequence for a fixed set of parameters p_0, s, ℓ, and r is active is bounded above by

$$\binom{r}{\ell-1} \cdot \binom{s+\ell-1}{\ell-1} \cdot \Pr[X \geq s] \overset{(11)(13)}{\leq} \left(\frac{\mathrm{e}s}{\ell}\right)^{2\ell} \cdot \mathrm{e}^{-\epsilon^2 \cdot s/3}.$$

Now we can bound the probability that packet p_0 has a long routing time. If this packet takes $d_{p_0} \cdot m + T$ steps, then a (p_0, s, ℓ, r)-delay sequence is active with $s \geq T + r + (m-2) \cdot \ell$. This constraint yields $s \geq T$, $\ell \leq s/(m-2)$, and $r \leq s$. Hence, the probability for this event is bounded above by

$$\sum_{s=T}^{\infty} \sum_{\ell=1}^{s/(m-2)} \sum_{r=1}^{s} \left(\frac{\mathrm{e}s}{\ell}\right)^{2\ell} \cdot \mathrm{e}^{-\epsilon^2 \cdot s/3} \overset{(11)}{\leq} \sum_{s=T}^{\infty} s^2 \cdot (\mathrm{e}(m-2))^{2s/(m-2)} \cdot \mathrm{e}^{-\epsilon^2 \cdot s/3}$$
$$= \frac{2^{-\Omega(\epsilon^2 \cdot T)}}{\epsilon^2}$$

if m is chosen appropriately, that is, if we set $m \geq k \cdot \log(1/\epsilon)/\epsilon^2 + 2$ for a sufficiently large constant k. From this result the bounds on the routing time given in Theorem 4.1 can be derived analogously to the calculations for the ghost packet protocol in section 2. □

5. The black box transformation. In this section, we present a black box transformation scheme for arbitrary static, oblivious routing protocols using the stochastic injection model. In section 6, we will show that the results for the stochastic model can be adapted to the adversarial model, too.

In the adversarial model, the bounds on the routing time obtained by our transformation are almost equivalent to the results achieved by Rabani and Tardos [13]. However, in addition we prove the stability of the dynamic protocols. Furthermore, in the stochastic model, we show an interesting extra feature: the dynamic protocol delivers each packet in a time corresponding to its individual path length even if the transformed static protocol does not provide that property. Moreover, we show that our black box transformation ensures a fast recovery from any worst-case scenario.

Our transformation scheme is especially simple and efficient if the given static protocol is pure. A protocol is called *pure* if it does not use any control packets and

does not duplicate any of its packets; that is, every packet crosses one edge after the other on its routing path, and no other messages are sent. The main results of this section are listed in the following theorem.

Recall that the congestion C of a static routing problem is the maximum number of paths in a path collection crossing the same edge, the dilation D is the maximum length of a path in a path collection, and the complexity M of a static routing problem is the maximum of the number of edges in the network and paths in the path collection. Further, the complexity N of a dynamic routing problem is defined to be the maximum of the number of generators, the number of edges, and $1/(1-\lambda)$.

THEOREM 5.1. *Let $\mathcal{S}$ denote any set of paths in an arbitrary network. Consider any static routing protocol $\mathcal{P}$ that sends packets along every collection of paths or subpaths from $\mathcal{S}$ in at most $\gamma C + \delta D + O(\log^\alpha M)$ time steps, w.h.p. Then $\mathcal{P}$ can be transformed into a dynamic routing protocol $\mathcal{P}'$ possessing the following properties in the stochastic model. Suppose packets are injected at rate λ and are to be routed solely along paths or subpaths from $\mathcal{S}$. Then the expected routing time of a packet following a path of length d is at most*

(1) $O(\epsilon^{-2}(\delta d + \log^\alpha N))$ *if $\alpha \geq 1, \gamma \geq 1$ are constants, $\delta = \Theta(\log^\beta N)$ for some constant $0 \leq \beta \leq 1$ and $\lambda = (1-\epsilon)/\gamma$ for some $\epsilon > 0$;*

(2) $O((\epsilon/2)^{-\frac{2}{1-\beta}}(d \log^{\alpha\beta} N + \log^\alpha N))$ *if $\alpha \geq 1, \gamma \geq 1$ are constants, $\delta = C^\beta$ for some constant $0 < \beta < 1$ and $\lambda = (1-\epsilon)/\gamma$ for some $\epsilon > 0$;*

(3) $O(\epsilon^{-2}(d \log N + \log^2 N))$ *if the bound on the runtime of $\mathcal{P}$ is $C \cdot D$ and $\lambda = (1-\epsilon)/\log N$ for some $\epsilon > 0$.*

All time bounds also hold w.h.p. Furthermore, the recovery time in all three cases is equal to the respective time bound with d replaced by $D(\mathcal{S})$, the length of the longest path in $\mathcal{S}$. If $\mathcal{P}$ is pure, then $\mathcal{P}'$ is stable for any $\lambda < 1$.

Notice that the bounds on the expected routing time of a packet imply stability up to the specified injection rate, depending on the parameters of the static protocol. The stability of pure protocols, however, is independent of these parameters, although the delay of a packet might become exponential in its path length if the injection rate is too high.

Certainly, more than the three cases stated in the theorem can be solved with the techniques below, but we believe that these cases are the most natural ones. Case 1 covers the case in which γ, δ, and α are constants, which we believe is the most important case. Let us apply Theorem 5.1 to some of the static protocols mentioned in section 1.1.1.

- *Routing along simple paths in arbitrary networks.* The static protocol of Ostrovsky and Rabani [12] with runtime $O(C + D + \log^{1+\kappa} M)$, w.h.p., for any constant $\kappa > 0$ can be transformed into a dynamic protocol that guarantees a routing time of $O(d + \log^{1+\kappa} N)$, w.h.p., for any λ up to some constant < 1.
- *Routing along arbitrary paths in arbitrary networks.* The simple static protocol with runtime $(1+\kappa) \cdot C + O(D \log M)$, w.h.p., for any constant $\kappa > 0$, presented by Leighton, Maggs, and Rao in [9], can be used to obtain a dynamic protocol that guarantees a routing time of $O(d \log N)$, w.h.p., for any constant $\lambda < 1$.
- *Greedy routing along simple paths in arbitrary networks.* Any greedy routing protocol can be transformed into a dynamic protocol that delivers each packet in time $O\left(d \log N + \log^2 N\right)$, w.h.p., for any constant $\lambda < 1/\log N$. We point out that the dynamic protocol is greedy, too.

The first and second examples follow from case 1 of the theorem, whereas the last

example follows from case 3. Since all of these protocols are pure, their dynamic counterparts are stable for any $\lambda < 1$.

In the following we show how to transform $\mathcal{P}$ into a dynamic protocol $\mathcal{P}'$ so that Theorem 5.1 holds.

5.1. Description of $\mathcal{P}'$. Let $\mathcal{P}$ be any static, oblivious routing protocol, and let the injection rate λ be $1 - \epsilon$ for some $\epsilon > 0$. Consider the time to be partitioned into consecutive intervals of length T. Let c_T and d_T denote suitable integers. (These parameters will be specified later.) Every newly injected packet waits until the beginning of the next T-interval. Afterwards it tries to traverse d_T edges of its path in each T-interval until it reaches its destination. Whenever it manages to traverse d_T edges within a T-interval, it waits for the next T-interval. If it fails to traverse d_T edges in some T-interval, it is declared a *failed* packet for the rest of the routing.

$\mathcal{P}'$ now works as follows: At the beginning of each T-interval, $\mathcal{P}$ is started with parameters c_T, used as a bound for the congestion, and d_T, used as a bound for the dilation. All packets that have not failed yet are allowed to participate in $\mathcal{P}$. After $(1-\epsilon^2/2)T$ time steps of the T-interval, $\mathcal{P}$ is halted. (All packets that did not manage to traverse d_T edges up to this point fail.) The remaining $T \cdot \epsilon^2/2$ time steps are reserved for the failed packets. To the failed packets, a contention resolution rule called shortest-in-system (SIS) is applied. SIS always gives precedence to the packet most recently injected (i.e., of youngest age) in case several packets contend for the same edge.

If $\mathcal{P}$ is pure, then we can improve $\mathcal{P}'$ so that it becomes greedy; i.e., a packet only has to wait because the next edge on its path is used by another packet. In the pure case, we use SIS as a primary contention resolution rule but we manipulate the age of the nonfailed packets as follows. (As before, a packet that has not traversed $i \cdot d_T$ edges by the end of its ith T-interval is declared a *failed* packet for the rest of its life.) Every newly injected packet gets an initial age of ∞ until the beginning of the next T-interval. Afterwards, as long as it has not failed or reached its destination yet, its age is set to 0 at the beginning of each T-interval. Whenever it traverses $i \cdot d_T$ edges before the end of the ith T-interval in which it participates, its age is set back to ∞ for the rest of that interval. The age of a failed packet is defined by its injection time. In each time interval, the packets with age 0 are scheduled according to protocol $\mathcal{P}$. Notice that packets that participate in $\mathcal{P}$ always have a lower age than the other packets. Hence, if we use SIS as primary contention resolution rule, we can allow the failed packets to be routed together with the other packets without disturbing the schedule of $\mathcal{P}$.

In order to analyze the performance of $\mathcal{P}'$, we need to study the behavior of SIS.

Bounding the routing time for shortest-in-system. In this section we bound the routing time for SIS, given the following model.

Suppose that packets are injected with rate λ, using our standard stochastic model. A packet is said to be *old* if the difference between the actual time step and its injection time is more than K. Otherwise it is called *young*. As long as a packet is young, it is allowed to set its age to an arbitrary value in each step. The age of an old packet is determined by its injection time. The probability that a packet becomes old before it reaches its destination is assumed to be at most p_f (which denotes its *failure probability*). The event that a packet is old may influence the probability that another packet may also be old. We model these dependencies via a *dependency graph* $G = (V, E)$. Each node V represents a (generator, time step)-pair. Edges are chosen in G such that for any independent set $\{(g_1, t_1), \ldots, (g_k, t_k)\} \in V$ with $k \in \mathbb{N}$, under

the assumption that g_i injects a packet P_i at step t_i, the probability that P_i becomes old for all $i \in \{1, \ldots, k\}$ is at most p_f^k. That is, for a proof of an upper bound on the number of old packets, any independent set of (g,t)-pairs can be viewed as having independent failure probabilities.

For this model we show the following lemma.

LEMMA 5.2. *For any $0 < \epsilon < 1$ and $K \geq 0$, the SIS protocol ensures that, under the above model with injection rate $\lambda = 1 - \epsilon$, failure probability p_f and a dependency graph G of maximum degree b, the expected routing time of a packet following a path of length d is at most*

(1) $O((d/\epsilon) \cdot (d(\epsilon^{-1} + b^2) + K))$ *if* $p_f \leq \epsilon/(2(4d+1))$, *and*
(2) $O((K+d) \cdot d/\epsilon^{2d})$ *otherwise.*

Proof. We start by proving item 2. Suppose that there is a packet P that has a routing time of more than $\sum_{i=1}^{d} \tau/\epsilon^{2i}$ steps for some $\tau \geq 2K$. In this case there must exist an $i \in \{1, \ldots, d\}$ for which P was delayed for at least τ/ϵ^{2i} steps at the ith edge of its path. Consider the minimum i for which this holds. Let e be the ith edge on P's path. Then the time interval I from the injection of P till the time when P waited at e for the τ/ϵ^{2i}th time consists of at most

$$\begin{aligned} t &= \sum_{j=1}^{i} \tau/\epsilon^{2j} \leq \tau \cdot \frac{1}{\epsilon^2} \cdot \frac{(1/\epsilon)^{2i} - 1}{(1/\epsilon)^2 - 1} \\ &= \tau \cdot \frac{(1/\epsilon)^{2i} - 1}{1 - \epsilon^2} \end{aligned}$$

time steps. Let the random variable X denote the number of (young and old) packets generated during I with paths containing e. Since P is allowed to choose its age in an arbitrary way only during the first K steps of its life, it holds that if P had to wait for at least τ/ϵ^{2i} steps at e, then $X \geq \tau/\epsilon^{2i} - K$. Clearly,

$$\begin{aligned} \mathrm{E}[X] &\leq (1-\epsilon) \cdot t = \frac{1}{1+\epsilon} \cdot \tau((1/\epsilon)^{2i} - 1) \\ &\leq \left(1 - \frac{\epsilon}{1+\epsilon}\right)(\tau/\epsilon^{2i} - K). \end{aligned}$$

This is less than the number of packets generated in I that have to delay P at e. Because of the independence assumptions in our stochastic injection model we can apply Chernoff bounds (see Lemma 1.1) to show that for any $0 < \epsilon \leq 1$ the probability that p is delayed by at least τ/ϵ^{2i} packets at e is at most

$$\begin{aligned} \Pr\left[X \geq (1+\epsilon)\left(1 - \tfrac{\epsilon}{1+\epsilon}\right)(\tau/\epsilon^{2i} - K)\right] &\leq \mathrm{e}^{-\epsilon^2 \cdot \left(1 - \frac{\epsilon}{1+\epsilon}\right) \cdot (\tau/\epsilon^{2i} - K)/3} \\ &\leq \mathrm{e}^{-\epsilon^2 \cdot (1/2) \cdot (\tau - K)(1/\epsilon^{2i})/3} \leq \mathrm{e}^{-\tau \cdot (1/\epsilon)^{2(i-1)}/12}. \end{aligned}$$

Hence the probability that the routing time of P exceeds $\sum_{i=1}^{d} \tau/\epsilon^{2i}$ is at most

$$\sum_{i=1}^{d} \mathrm{e}^{-\tau \cdot (1/\epsilon)^{2(i-1)}/12} \leq d \cdot \mathrm{e}^{-\tau/12}.$$

Thus the expected routing time of P is at most

$$\begin{aligned}&\sum_{i=1}^{d} 2K/\epsilon^{2i} + \sum_{\tau \geq 2K} \left(\sum_{i=1}^{d} (\tau+1)/\epsilon^{2i} \right) \cdot d \cdot \mathrm{e}^{-\tau/12} \\ &\leq d \cdot 2K/\epsilon^{2d} + \sum_{\tau \geq 2K} (d(\tau+1)/\epsilon^{2d}) \cdot d \cdot \mathrm{e}^{-\tau/12} \\ &= O\left((K+d) \cdot d/\epsilon^{2d}\right).\end{aligned}$$

Next we prove item 1. Suppose that there is a packet P that has a routing time of more than $K + d \cdot 4\tau/\epsilon$ steps for some $\tau \geq K$. In this case there must exist an $i \in \{1, \ldots, d\}$ for which P was delayed for at least $4\tau/\epsilon$ time steps at the ith edge of its path while it was already old. Let I be a time interval covering $4\tau/\epsilon$ of these steps. Furthermore, let the random variable X denote the number of young packets that delayed P in I, and let the random variable Y denote the number of old packets that delayed P in I. It clearly holds that

$$\Pr[X + Y = 4\tau/\epsilon] \leq \Pr[X \geq \tau(4/\epsilon - 1)] + \Pr[Y \geq \tau].$$

We first bound the probability that $X \geq \tau(4/\epsilon - 1)$. It holds that

$$\mathrm{E}[X] \leq \lambda(|I| + K) = (1-\epsilon)(4\tau/\epsilon + K).$$

Because of the independence assumptions in our stochastic injection model, it follows that

$$\begin{aligned}\Pr[X \geq (1 + \tfrac{\epsilon}{2(1-\epsilon)})(1-\epsilon)(4\tau/\epsilon + K)] &\leq \mathrm{e}^{-\min\{(\frac{\epsilon}{2(1-\epsilon)})^2, \frac{\epsilon}{2(1-\epsilon)}\}(1-\epsilon)(4\tau/\epsilon+K)/3} \\ &\leq \mathrm{e}^{-c_1 \cdot \epsilon \cdot \tau}\end{aligned}$$

for some constant $c_1 > 0$. Since $(1 + \frac{\epsilon}{2(1-\epsilon)})(1-\epsilon) = 1 - \epsilon/2$ and

$$\frac{4\tau}{\epsilon} - (1 - \tfrac{\epsilon}{2}) \left(\frac{4\tau}{\epsilon} + K \right) \geq 2\tau - K \geq \tau\ ,$$

we also have

$$\Pr[X \geq \tau(4/\epsilon - 1)] \leq \mathrm{e}^{-c_1 \cdot \epsilon\tau}\ .$$

Next we bound the probability that $Y \geq \tau$. Since P can be delayed in I only by old packets that are younger than P, we get with $p_f \leq \epsilon/(2(4d+1))$ that

$$\mathrm{E}[Y] \leq \left(K + \frac{d \cdot 4\tau}{\epsilon} \right) \cdot p_f \leq \frac{\tau}{2}.$$

In order to prove a tail estimate for Y, we need the following claim which is due to Rabani and Tardos [13]. (We present their result in a slightly improved form.)

Claim 1. *If $X_1, \ldots, X_n$ are binary random variables with a dependency graph of degree at most d and $\mathrm{E}[X_i] \leq p$ for all i, then for any $\delta > 0$,*

$$\Pr[S \geq (1+2\delta)pn] \leq 4d \left(\frac{\mathrm{e}^{\delta}}{(1+\delta)^{1+\delta}} \right)^{p \cdot n/(2d)}.$$

Proof. Any graph of degree $d \geq 1$ can be partitioned into at most $d+1$ independent sets, and therefore into $m \leq c \cdot d + (d+1)$ independent sets, each of size at most $n/(c \cdot d)$ for any $c \in \mathbb{N}$. Let us choose $c = 2$, and let the corresponding set sizes be $n_1, \ldots, n_m$. Let S_i denote the sum of the variables in set i. Since set i is independent and $\mathrm{E}[X_i] \leq p$ for all i,

$$\Pr[S_i \geq p \cdot n_i + \delta pn/(2d)] \leq \Pr[S_i \geq (1+\delta)pn/(2d)] \leq \left(\frac{\mathrm{e}^{\delta}}{(1+\delta)^{1+\delta}}\right)^{p \cdot n/(2d)}$$

according to the Chernoff bounds. Thus we obtain

$$\begin{aligned}\Pr[S \geq (1+2\delta)pn] &\leq \Pr\left[\bigvee_{i \in [m]} S_i \geq p \cdot n_i + \delta pn/(2d)\right] \\ &\leq 4d \left(\frac{\mathrm{e}^{\delta}}{(1+\delta)^{1+\delta}}\right)^{p \cdot n/(2d)}. \qquad \square\end{aligned}$$

Using this claim, we obtain that

$$\Pr[Y \geq \tau] \leq 4b \cdot \mathrm{e}^{-c_2 \cdot \tau/b}$$

for some constant $c_2 > 0$.

The probability bounds for X and Y and the fact that there are d possibilities to select an edge where P experiences a high delay imply that the probability that the routing time of P exceeds $K + d \cdot 4\tau/\epsilon$ is at most

$$d\left(\mathrm{e}^{-c_1 \cdot \epsilon\tau} + 4b \cdot \mathrm{e}^{-c_2 \cdot \tau/b}\right).$$

Thus the expected routing time of P is at most

$$\begin{aligned}&\left(K + \sum_{i=1}^{d} 4K/\epsilon\right) + \sum_{\tau \geq K} (K + d \cdot 4(\tau+1)/\epsilon) \cdot d\left(\mathrm{e}^{-c_1 \cdot \epsilon\tau} + 4b \cdot \mathrm{e}^{-c_2 \cdot \tau/b}\right) \\ &\leq d \cdot 5K/\epsilon + \sum_{\tau \geq K} d \cdot 5(\tau+1)/\epsilon \cdot d \cdot \mathrm{e}^{-c_1 \cdot \epsilon\tau} + \sum_{\tau \geq K} d \cdot 5(\tau+1)/\epsilon \cdot d \cdot 4b \cdot \mathrm{e}^{-c_2 \cdot \tau/b} \\ &= O\left(\frac{K \cdot d}{\epsilon} + \frac{d^2}{\epsilon^2} + \frac{d^2 \cdot b^2}{\epsilon}\right) = O\left(\tfrac{d}{\epsilon}(d(\tfrac{1}{\epsilon} + b^2) + K)\right). \qquad \square\end{aligned}$$

5.2. Analysis of $\mathcal{P}'$ for nonpure $\mathcal{P}$. First let us introduce some notation. Given a time interval I, $|I|$ denotes its *size*, i.e., the time range it includes. A packet p is called a *$\mathcal{P}$-packet* in a T-interval I if $\mathcal{P}$ is applied to p in I, i.e., p was generated before I and has not failed nor reached its destination yet.

Bounding the routing time of successful packets. To prove bounds on the routing time of successful packets, we show the following lemma.

LEMMA 5.3. *Let $\mathcal{S}$ denote any set of paths, and let ϕ be any constant greater than 0. Consider any static routing protocol $\mathcal{P}$ that sends packets along any path collection (consisting of paths from some specified set) with congestion C and dilation D in at most $\gamma C + \delta D + O(\log^{\alpha} N)$ time steps, with probability at least $1 - N^{-\phi}/2$, where $\alpha, \gamma, \delta \geq 1$. Then the following hold for each T-interval I.*

(1) *If* $\gamma = \Theta(1)$, $\delta = \Theta(\log^\beta N)$ *for some constant* $0 \le \beta \le 1$, $\lambda = (1-\epsilon)/\gamma$ *for some* $\epsilon > 0$, $d_T = (\log N)^{\alpha-\beta}$, *and* $T = \Theta(\epsilon^{-2}(\phi \log N + \log^\alpha N))$ *is sufficiently large, then with probability at least* $1 - N^{-\phi}$, $\mathcal{P}'$ *requires at most* $(1-\epsilon^2/2)T$ *time steps in* I *to send any fixed* $\mathcal{P}$*-packet along* d_T *edges.*

(2) *If* $\gamma = \Theta(1)$, $\delta = C^\beta$ *for some constant* $0 < \beta < 1$, $\lambda = (1-\epsilon)/\gamma$ *for some* $\epsilon > 0$, $d_T = (\log N)^{\alpha(1-\beta)}$, *and* $T = \Theta((\epsilon/2)^{-\frac{2}{1-\beta}}(\phi \log N + \log^\alpha N))$ *is sufficiently large, then with probability at least* $1 - N^{-\phi}$, $\mathcal{P}'$ *requires at most* $(1-\epsilon^2/2)T$ *time steps in* I *to send any fixed* $\mathcal{P}$*-packet along* d_T *edges.*

(3) *If the runtime of* $\mathcal{P}$ *is at most* $C \cdot D$, $\lambda = (1-\epsilon)/\log N$ *for some* $\epsilon > 0$, $d_T = \log N$, *and* $T = \Theta(\epsilon^{-2}\phi \log^2 N)$ *is sufficiently large, then with probability at least* $1 - N^{-\phi}$, $\mathcal{P}'$ *requires at most* $(1-\epsilon^2/2)T$ *time steps in* I *to send any fixed* $\mathcal{P}$*-packet along* d_T *edges.*

Proof. First, we bound the expected number of $\mathcal{P}$-packets that participate in a T-interval. Consider any fixed edge e. Let the random variable X_t^e denote the number of packets generated at time step t that intend to cross e. Clearly, $\mathrm{E}[X_t^e] \le \lambda$. Furthermore, let the binary random variable $X_{t,k}^g$ be 1 if and only if generator g generates at time step t a packet that has to cross e as kth edge. Then it holds that $X_t^e = \sum_{g,k} X_{t,k}^g$. Now, let us consider some fixed T-interval I that starts at time t_0. Since we require each packet to traverse $i \cdot d_T$ edges till the end of the ith T-interval in which it participates, the expected number of $\mathcal{P}$-packets that intend to cross e in I is given by

$$\begin{aligned}\sum_g \sum_{i\ge 0} \sum_{j=0}^{T-1} \sum_{k=0}^{d_T-1} \mathrm{E}[X^g_{t_0-(i+1)T+j,i\cdot d_T+k}] &= \sum_g \sum_{i\ge 0} \sum_{k=0}^{d_T-1} T \cdot \mathrm{E}[X^g_{t_0,i\cdot d_T+k}] \\ &= \sum_g \sum_d T \cdot \mathrm{E}[X^g_{t_0,d}] \\ &\le T \cdot \lambda,\end{aligned}$$

because $\Pr[X^g_{t_1,d} = 1] = \Pr[X^g_{t_2,d} = 1]$ for any t_1, t_2, since the injection of packets is independent of the time step.

Now we bound T so that with probability at least $1 - N^{-\phi}$ the $\mathcal{P}$-packets participating in some T-interval I are successful in I. Let us assume that $\lambda = (1-\epsilon)/\gamma$ for some $\epsilon > 0$ (resp., $\lambda = (1-\epsilon)/\log N$ in case 3). We now consider the three cases for the choice of γ and δ given in Lemma 5.3.

Case 1. $\gamma = \Theta(1)$ and $\delta = \Theta(\log^\beta N)$ for some constant $0 \le \beta \le 1$.

From above we know that the expected number of $\mathcal{P}$-packets participating in a T-interval that cross some fixed edge is at most λT.

Suppose that $\epsilon \le 7/8$. Since the injection of a packet is independent of the injection of other packets, we can use a Chernoff bound to show that the probability that the congestion caused by $\mathcal{P}$-packets exceeds $(1+\epsilon)\lambda T$ at some fixed edge is at most $\mathrm{e}^{-\epsilon^2 \lambda T/3}$. Hence, for every $\phi > 0$ there is a $t(\epsilon, \phi) = \Theta(\frac{\phi}{\epsilon^2} \log N)$ such that for all $T \ge t(\epsilon, \phi)$, the probability is at least $1 - N^{-\phi}/2$ that the congestion caused by $\mathcal{P}$-packets in I is at most $(1+\epsilon)\lambda T$. Assume in the following that $T \ge t(\epsilon, \phi)$. Set $c_T = (1+\epsilon)\lambda T$ and $d_T = \log^\psi N$. According to the assumptions of Lemma 5.3, the runtime of $\mathcal{P}$, given a path collection with congestion c_T and dilation d_T, is at most $\gamma c_T + \delta d_T + O(\log^\alpha N)$ with probability at least $1 - N^{-\phi}/2$. Hence, the time required by any fixed $\mathcal{P}$-packet participating in I to be successful is at most

$$\gamma \cdot (1+\epsilon)\lambda T + \delta \log^\psi N + O(\log^\alpha N) = (1-\epsilon^2)T + \delta \log^\psi N + O(\log^\alpha N)$$

with probability at least $1 - N^{-\phi}$. This time bound is at most $T(1 - \epsilon^2/2)$ if $T \geq \frac{2}{\epsilon^2}(\delta \log^\psi N + O(\log^\alpha N))$. (The remaining $T \cdot \epsilon^2/2$ time steps will be important when considering the failed packets.)

Now suppose that $\epsilon > 7/8$. In this case, $\lambda < 1/(8\gamma)$. Thus, according to the Chernoff bounds the probability that the congestion caused by $\mathcal{P}$-packets exceeds $T/(4\gamma)$ can be made as small as $N^{-\phi}$ for any constant $\phi > 0$ if $T = \Theta(\phi \log N)$ is chosen large enough. Set $c_T = T/(4\gamma)$ and $d_T = \log^\psi N$. Analogous to above, the routing time required by the $\mathcal{P}$-packets participating in I to be successful can be made as small as $T(1-\epsilon^2/2)$ with probability of at least $1-N^{-\phi}$ if $T = \Theta(\delta \log^\psi N + \log^\alpha N)$ is chosen large enough.

In both cases for ϵ, the bound for T is (asymptotically) minimal for $\beta + \psi = \alpha$. So altogether $T = \Theta(\frac{1}{\epsilon^2}(\phi \log N + \log^\alpha N))$ suffices to guarantee that any fixed $\mathcal{P}$-packet successfully manages a T-interval with probability at least $1 - N^{-\phi}$.

Case 2. $\gamma = \Theta(1)$ and $\delta = C^\beta$ for some constant $0 < \beta < 1$.

If $\epsilon \leq 15/16$, we set $c_T = (1+\epsilon)\lambda T$ and $d_T = \log^\psi N$. As in Case 1, the probability is at most $N^{-\phi}/2$ that the congestion in I exceeds c_T if $T = \Theta(\frac{\phi}{\epsilon^2} \log N)$ is sufficiently large. In this case, the time required by any fixed $\mathcal{P}$-packet participating in I to be successful is at most

$$\gamma \cdot (1+\epsilon)\lambda T + \delta \log^\psi N + \log^\alpha N \leq (1-\epsilon^2)T + T^\beta \log^\psi N + \log^\alpha N$$

with probability at least $1 - N^{-\phi}$. It holds that

$$\log^\alpha N \leq \frac{\epsilon^2}{4} \cdot T \quad \text{if} \quad T \geq \frac{4}{\epsilon^2} \cdot \log^\alpha N$$

and

$$T^\beta \log^\psi N \leq \frac{\epsilon^2}{4} \cdot T \quad \text{if} \quad \psi = \alpha(1-\beta) \text{ and } T \geq (\epsilon/2)^{-2/(1-\beta)} \log^\alpha N.$$

Thus, if $T = \Theta((\epsilon/2)^{-2/(1-\beta)} \log^\alpha N)$ is sufficiently large, then

$$(1-\epsilon^2)T + T^\beta \log^\psi N + \log^\alpha N \leq (1 - \epsilon^2/2)T.$$

Hence $T = \Theta((\epsilon/2)^{-2/(1-\beta)}(\phi \log N + \log^\alpha N))$ suffices to ensure that any fixed $\mathcal{P}$-packet successfully manages a T-interval with probability at least $1 - N^{-\phi}$.

If $\epsilon > 15/16$, we set $c_T = T/(8\gamma)$ and $d_T = \log^\psi N$. Similar to Case 1, the probability is at most $N^{-\phi}/2$ that the congestion in I exceeds c_T if $T = \Theta(\phi \log N)$ is sufficiently large. In this case, the time required by any fixed $\mathcal{P}$-packet participating in I to be successful is at most

$$\gamma \cdot T/(8\gamma) + \delta \log^\psi N + \log^\alpha N \leq T/8 + T^\beta \log^\psi N + \log^\alpha N,$$

with probability at least $1 - N^{-\phi}$. This is at most $(1 - \epsilon^2/2)T$ if

$$T^\beta \log^\psi N \leq T/4 \quad \text{and} \quad \log^\alpha N \leq T/8,$$

which is true if $\psi = \alpha(1-\beta)$ and $T = \Theta((\epsilon/2)^{-2/(1-\beta)} \log^\alpha N)$ is sufficiently large. Hence, if $T = \Theta((\epsilon/2)^{-2/(1-\beta)}(\phi \log N + \log^\alpha N))$, then also in this case any fixed $\mathcal{P}$-packet successfully manages a T-interval with probability at least $1 - N^{-\phi}$.

Case 3. The runtime of $\mathcal{P}$ is at most $C \cdot D$.

Assume that $\lambda = \frac{1-\epsilon}{\log N}$. If $\epsilon \leq 7/8$, we set $c_T = (1+\epsilon)\lambda T$ and $d_T = \log N$. As above, it can be shown that the probability is at most $N^{-\phi}$ that the congestion in I exceeds c_T if $T = \Theta(\frac{\phi}{\epsilon^2} \log^2 N)$ is sufficiently large. In this case, the time required by any fixed $\mathcal{P}$-packet participating in I to be successful is at most

$$(1+\epsilon)\lambda T \cdot \log N = (1-\epsilon^2)T$$

with probability at least $1 - N^{-\phi}$.

If $\epsilon > 7/8$, then we set $c_T = T/(2 \log N)$ and $d_T = \log N$. If $T = \Theta(\phi \log^2 N)$ is sufficiently large, the probability is at most $N^{-\phi}$ that the congestion in I exceeds c_T. In this case, the time required by any fixed $\mathcal{P}$-packet participating in I to be successful is at most

$$\frac{T}{2 \log N} \cdot \log N \leq (1 - \epsilon^2/2)T$$

with probability at least $1 - N^{-\phi}$. □

It follows for Lemma 5.3(1) that if a packet following a path of length d successfully manages all T-intervals, its runtime is bounded by

$$O\left(\left(\frac{d}{\log^\psi N} + 1\right) \frac{1}{\epsilon^2} \log^\alpha N\right) = O\left(\frac{1}{\epsilon^2} \left(\delta d + \log^\alpha N\right)\right).$$

Similarly, for Case 2, the runtime of a packet following a path of length d that successfully manages all T-intervals is bounded by

$$O\left(\left(\frac{d}{\log^\psi N} + 1\right) (\epsilon/2)^{-\frac{2}{1-\beta}} \log^\alpha N\right) = O\left((\epsilon/2)^{-\frac{2}{1-\beta}} \left(d \log^{\alpha\beta} N + \log^\alpha N\right)\right),$$

and for Case 3 the runtime of the packet is bounded by

$$O\left(\left(\frac{d}{\log N} + 1\right) \frac{1}{\epsilon^2} \log^2 N\right) = O\left(\frac{1}{\epsilon^2} \left(d \log N + \log^2 N\right)\right).$$

These time bounds match the time bounds given in Theorem 5.1 if a packet never fails. According to Lemma 5.3, the probability that a packet fails in some T-interval can be made polynomially small in N if λ is sufficiently small. Hence, in this case all time bounds hold w.h.p. It remains to bound the runtimes of failed packets to be able to compute the expected time a packet needs to reach its destination.

Bounding the routing time of failed packets. Next we bound the runtime of failed packets under the assumption that the injection rate is sufficiently small, that is, each individual packet is successful in every T-interval, w.h.p. For this, we will show how to apply Lemma 5.2 to bound the expected routing time of a failed packet by N^c for some constant c. Combined with the upper bound of $N^{-\phi}$ on the probability that a packet fails, this will result in an expected routing time not much larger than the time that the packet requires if it does not fail in any of its T-intervals, provided that $\phi \geq c$. This yields the bounds for the expected routing time in Theorem 5.1 and implies that $\mathcal{P}'$ is stable.

Now we show how to apply Lemma 5.2. First, we change the situation that only every $\frac{2}{\epsilon^2}$th step can be used by a failed packet to a situation in which every time step can be used by a failed packet. For this, we replace each generator g by $2/\epsilon^2$ generators $g_1, \ldots, g_{2/\epsilon^2}$, where g_i is responsible for the simulation of the behavior of

g at time steps t with $(t \bmod 2/\epsilon^2) + 1 = i$. Furthermore, we assume each time step to represent now $2/\epsilon^2$ time steps in the original situation. Let us consider some fixed edge e. For any generator g and time step t in the new situation, let the binary random variable Y_t^g be 1 if and only if g generates a packet at step t that intends to cross e and that fails in some T-interval of the original situation. From Lemma 5.3 we know that $\Pr[Y_t^g = 1]$ can be made as small as $N^{-\phi}$ for any constant $\phi > 0$.

If the probabilities $\Pr[Y_t^g = 1]$ were independent for different Y_t^g, we could model the injection of failed packets as a simple stochastic injection model with injection rate $\lambda = \Pr[Y_t^g = 1] \cdot 2/\epsilon^2$. For $\Pr[Y_t^g = 1] \cdot 2/\epsilon^2 \leq 1/D(\mathcal{S})$, it would follow directly from Lemma 5.2 (choose $K = 0$ and $\lambda = 1/D(\mathcal{S})$) that the routing time of a failed packet is less than N^ϕ if ϕ is sufficiently large.

Coping with the dependencies. Unfortunately, there can be high dependencies among failures of packets. In order to incorporate these dependencies in the model of Lemma 5.2, we construct a dependency graph $G = (V, E)$ that has a node (g, t) for each random variable Y_t^g, and in which two nodes (g, t) and (g', t') are connected in G if and only if $t - 2T \cdot (D(\mathcal{S})+1) \cdot (\epsilon^2/2) \leq t' \leq t + 2T \cdot (D(\mathcal{S})+1) \cdot (\epsilon^2/2)$. Since there are $2N/\epsilon^2$ generators, the maximum degree of G is at most $(4T \cdot (D(\mathcal{S})+1) + 2/\epsilon^2) \cdot N$, which is polynomial in N. In order to apply Lemma 5.2, we need to show that for any independent set $S \subseteq V$, the probability that $Y_t^g = 1$ for all $(g, t) \in S$ is at most $N^{-\phi|S|}$ for any constant $\phi > 0$ (depending on T).

Recall that the proof of Lemma 5.3 bounds the failure probability of a packet within a T-interval I solely by considering the injection events of packets that could have still been successful at the beginning of I and the behavior of $\mathcal{P}$ within I. Further recall that the proof of Lemma 5.3 only uses the congestion (which is upper bounded by the injection events) in I to obtain a probability bound for the success of $\mathcal{P}$. Hence the space $\Omega_{g,t}$ of relevant outcomes that need to be considered to obtain a probability of at most $N^{-\phi}$ for the random variable Y_t^g to be 1 can be limited to contain solely injection events of packets that can participate in $\mathcal{P}$ in some T-interval together with the packet generated by g at step t. Since a packet can be alive without a failure for at most $T \cdot (D(\mathcal{S})+1) \cdot (\epsilon^2/2)$ time steps, the outcome spaces of any two random variables Y_t^g and $Y_{t'}^{g'}$ with either $t' < t - 2T \cdot (D(\mathcal{S})+1) \cdot (\epsilon^2/2)$ or $t' > t + 2T \cdot (D(\mathcal{S})+1) \cdot (\epsilon^2/2)$ must be disjoint (that is, they do not contain a common injection event (g'', t'')). Thus, using the proof of Lemma 5.3, the probability that both of these random variables are 1 can be shown to be at most $N^{-2\phi}$. The same argument extends to any set of random variables that form an independent set in G.

In order to set the remaining parameters in the model of Lemma 5.2, we set λ equal to the given injection rate and $K = 0$. (Successful packets cannot interfere with failed packets.) According to Lemma 5.2, for these parameters the expected routing time of any failed packet is at most N^ϕ if ϕ is large enough. This completes the proof that for a small enough λ, even when considering failures, the expected routing time of any fixed packet is within the time bounds given in Theorem 5.1.

Recovery. We show that $\mathcal{P}'$ recovers very quickly from any worst-case scenario. Clearly, the SIS rule instantly recovers from any worst-case scenario because younger packets are always preferred. Similar, we show for $\mathcal{P}'$ that after a certain amount of time any configuration of the network has *no* influence on the runtime of the newly generated packets anymore, concerning our probability bounds.

Consider any worst-case scenario for the injection of packets that ends at time step t_0. Since each packet has to traverse d_T edges in each T-interval in order to remain successful, $R = (\lceil \frac{D(\mathcal{S})}{d_T} \rceil + 1) \cdot T$ time steps after t_0 there can be no successful packet

anymore that was generated at time step t_0 or earlier. This implies that afterwards the congestion in a T-interval is based only on packets injected after the worst-case scenario, which according to our stochastic injection model is independent of whatever happened during or before a worst-case scenario. Since in the proof of Lemma 5.3 we used the worst-case assumption that all packets have been successful so far to upper bound the congestion in a T-interval, all probability bounds in Lemma 5.3 are again valid R steps after the worst-case scenario. That is, the probability of a packet to fail in a T-interval is again polynomially small in N. This ensures that sufficiently few packets fail. Once a packet fails, its age is determined by its injection time. Since SIS is used for the failed packets, a failed packet generated at a time step $t > t_0$ cannot be blocked by the packets generated during the worst-case scenario. Hence $\mathcal{P}'$ recovers after $(\lceil \frac{D(\mathcal{S})}{d_T} \rceil) + 1) \cdot T$ time steps. Substituting the right T for each of the three cases (see Lemma 5.3) yields the recovery time given in Theorem 5.1.

5.3. Analysis of $\mathcal{P}'$ for pure $\mathcal{P}$. The analysis for the successful packets is the same as above. However, since we do not have reserved time slots for the failed packets, we need a different analysis for them if $\mathcal{P}$ is pure.

Bounding the routing time of failed packets. Suppose that the injection rate is sufficiently small, that is, each individual packet is successful in every T-interval, w.h.p. For this, we will show how to apply Lemma 5.2 to bound the routing time of a failed packet by N^c for some constant c. Combined with the bound of $N^{-\phi}$ on the probability that a packet fails, this will result in an expected routing time not much larger than the time that the packet requires if it does not fail in any of its T-intervals, provided that $\phi \geq c$. This would yield the bounds for the expected routing time in Theorem 5.1 and would imply that $\mathcal{P}'$ is stable.

Now we show how to apply Lemma 5.2. Let us consider some fixed edge e. For any generator g and time step t, let the binary random variable Y_t^g be 1 if and only if g generates a packet at step t that intends to cross e and that fails in some T-interval. From Lemma 5.3 we know that $\Pr[Y_t^g = 1]$ can be made as small as $N^{-\phi}$ for any constant ϕ. Furthermore, similar to the case that $\mathcal{P}$ is nonpure, the event $Y_t^g = 1$ causes at most $(4T \cdot (D(\mathcal{S})+1)+1) \cdot N$ other random variables $Y_{t'}^{g'}$ to have a probability of $\Pr[Y_{t'}^{g'} = 1] > N^{-\phi}$, namely, those with $t - 2T \cdot (D(\mathcal{S})+1) \leq t' \leq t + 2T \cdot (D(\mathcal{S})+1)$. In order to incorporate these dependencies in the model of Lemma 5.2, we again construct a dependency graph $G = (V, E)$ that has a node (g, t) for each random variable Y_t^g, and in which two nodes (g, t) and (g', t') are connected in G if and only if $t - 2T \cdot (D(\mathcal{S}) + 1) \leq t' \leq t + 2T \cdot (D(\mathcal{S}) + 1)$. Thus the maximum degree of G is $(4T \cdot (D(\mathcal{S}) + 1) + 1) \cdot N$. Furthermore, in the model of Lemma 5.2 we set λ equal to the given injection rate and $K = D(\mathcal{S}) \cdot T$. (Successful packets live for at most $D(\mathcal{S}) \cdot T$ time steps.) According to Lemma 5.2, in this case the expected routing time of any failed packet is at most N^{ϕ} if ϕ is large enough. This completes the proof that, also for a pure $\mathcal{P}$, for a small enough λ the expected routing time of any fixed packet is within the time bounds given in Theorem 5.1.

Stability for any $\lambda < 1$. Next we consider the case that λ is arbitrarily close to 1. In this situation $\mathcal{P}$ might not be good enough to ensure that a packet manages its T-interval with high probability. However, from Lemma 5.2 (set $K = D(\mathcal{S}) \cdot T$) it directly follows that nevertheless $\mathcal{P}'$ remains stable for any $\lambda < 1$, although the runtime of a packet might get exponential in the length of its path.

6. Adapting our results to the adversarial model. Consider any bounded adversary of rate (w, λ). Set $\epsilon = 1 - \lambda$. For each injected packet p we choose uniformly

and independently at random an initial delay of δ_p from the set $\{0, \ldots, K-1\}$, where $K = (k \cdot D + w)/\epsilon^2$ and D is the length of a longest possible path. k will be specified later, as it depends on the routing protocol for which we want to adapt the results. After waiting δ_p time steps in its injection buffer, p chooses the actual time step as its *new injection time* and participates in whatever routing protocol chosen. We say that every packet with new injection time t *touches* an edge e at step t' if e is the ith edge on the routing path of p and $t' = t + k \cdot i$. Let λ' denote the maximum, over all edges and time steps, of the expected number of packets that touch an edge in a time step. Then the following lemma holds.

LEMMA 6.1. $\lambda' \leq 1 - \epsilon/2$.

Proof. Consider some fixed edge e and time step t. The maximum number of packets that touch edge e at step t is at most

$$(1-\epsilon)w \cdot \left\lceil \frac{k \cdot D + K}{w} \right\rceil \leq (1-\epsilon) \cdot (k \cdot D + w) \cdot (1 + 1/\epsilon^2).$$

Since each of these packets chooses a random initial delay out of a range of $[(k \cdot D + w)/\epsilon^2]$, it holds that

$$\begin{aligned} \lambda' &\leq \frac{(1-\epsilon) \cdot (k \cdot D + w) \cdot (1 + 1/\epsilon^2)}{(k \cdot D + w)/\epsilon^2} \\ &\leq (1-\epsilon) \cdot (1 + \epsilon^2) \leq 1 - \epsilon/2 \end{aligned}$$

for any $\epsilon \in [0, 1]$. ∎

As is not difficult to verify, this lemma can be used to transfer all results presented in this paper to the adversarial model. For the ghost packet protocol on general networks, we choose $k = 0$. Then it follows from Lemma 6.1 that the expected number of packets with a fixed rank r that traverse an edge e is at most $1 - \epsilon/2$. Hence, the analysis for the ghost packet protocol on general networks holds without any further change also for the adversarial model. We have to add only w/ϵ^2 to the delay bound of the packets to include the random initial delay.

For the growing rank protocol we choose $k = m$. Then it follows from Lemma 6.1 that, for any edge e and rank r, the expected number of packets with rank r that traverse e is at most $1 - \epsilon/2$. This allows us to use the same analysis as that for the proof of Theorem 4.1 to show that the delay of any packet is bounded by $O(\frac{1}{\epsilon^2}(m \cdot D + w) + m \cdot \log N) = O(m^2 \cdot D + m \cdot (w + \log N))$, w.h.p.

For the black box transformation it suffices to choose $k = T(1/d_T + 1/D)$. Then we get that, for any edge e and T-interval I, the expected number of packets that intend to cross e in I is at most $T(1 - \epsilon/2)$. In this case, the same analysis as in section 5 can be used to show that, for instance, for $\gamma = \Theta(1)$ and $\delta = \Theta(\log^\beta N)$, the delay of any packet is bounded by $O(\frac{1}{\epsilon^2}(\frac{1}{\epsilon^2}\delta D + w + \log^\alpha N))$, w.h.p., if $\lambda \leq (1-\epsilon)/\gamma$.

7. Open problems. In this paper, we presented transformations of well-known static routing algorithms (such as the ghost packet protocol and the growing rank protocol) into efficient dynamic routing algorithms. We obtained, for instance, a dynamic routing algorithm for arbitrary leveled networks that requires only buffers of size depending on the injection rate and the maximum degree of the network to be stable up to a maximum possible injection rate. This algorithm, however, uses ghost or control packets. Although our analysis implicitly shows that these packets are sent very rarely, the question arises whether or not control packets can be avoided completely.

Furthermore, we presented a black box transformation scheme applicable to every static, oblivious routing algorithm. Our results show that it might be important for static routing protocols to know the exact constant in front of the C in the runtime bound, since this determines up to which injection rate the resulting dynamic protocol ensures a small delay for the packets. It is an interesting question how large this constant is for the known static routing protocols, and whether there exist static routing protocols with runtime $C + O(D + \log N)$.

DETERMINING CONSENSUS NUMBERS*

ERIC RUPPERT†

Abstract. Conditions on a shared object type T are given that are both necessary and sufficient for wait-free n-process consensus to be solvable using objects of type T and registers. The conditions apply to two large classes of deterministic shared objects: read-modify-write objects [C. P. Kruskal, L. Rudolph, and M. Snir, *ACM Trans. Prog. Lang. Syst.*, 10 (1988), pp. 579–601] and readable objects, which have operations that allow processes to read the state of the object. These classes include most objects that are used as the primitives of distributed systems. When the sequential specification of T is finite, the conditions may be checked in a finite amount of time to decide the question "Is the consensus number of T at least n?" The conditions are also used to provide a clear proof of the robustness of the consensus hierarchy for read-modify-write and readable objects.

1. Introduction.

A shared-memory distributed system consists of a number of processes that communicate with one another by performing operations on shared data objects. This paper studies asynchronous systems where processes take steps at arbitrarily varying speeds. The wait-free model of fault tolerance is used: each nonfaulty process must complete its task correctly even if any number of processes experiences halting failures. The power of a system to solve problems depends on the types of shared data objects that are available. Determining whether a given collection of object types can be used to solve a given problem is therefore of great importance in the design of distributed systems. A problem may, itself, be modelled as a shared object type: processes pass their input to the object, and the object returns the desired output. Thus, a question about computability may be formulated as a question about implementations: Can one object type be implemented using a given set of primitive object types? Herlihy [10] showed that the consensus problem, in which each process begins with an input and all nonfaulty processes must agree on one of the input values, plays a central role in the study of the power of object types. He proved that objects that solve the consensus problem for n processes can be used, along with read/write registers, to obtain a wait-free implementation of any object for n or fewer processes. This leads to the idea of classifying object types according to their consensus number [10, 14]. An object type T *has consensus number* n if n-process consensus can be solved by using objects of type T and read/write registers, but $(n+1)$-process consensus cannot. If there is no such n, the consensus number of T is ∞. Similarly, the consensus number of a set $\mathcal{S}$ of types is the largest n for which n processes can solve consensus using objects whose types are in $\mathcal{S} \cup \{\text{register}\}$, or ∞ if no such n exists.

This paper addresses the problem of determining whether a given deterministic object type has consensus number n. Two important classes of objects that include most of the objects considered as primitives for distributed systems are studied: read-modify-write (RMW) objects [16] and readable objects. It is reasonable to assume that processes will be able to access the information stored in the data object in some simple way. If processes may read the information directly, without altering the object's state, then the object is called readable. If the operation that reads the information in the data object is combined with an update operation, so that the read and update occur as a single atomic action, the object may be modelled as an RMW object.

A *readable* object O is modelled by an I/O automaton whose state set is the Cartesian product $Q = \bigtimes_{k\in\Gamma} Q_k$, where Γ is an index set and Q_k is a set for each $k \in \Gamma$. Neither Γ nor Q_k must be finite. For each $k \in \Gamma$, processes may execute the operation $read_k$, which returns component k of the current state of O. In addition to the *read* operations, the object may have an arbitrary set of other (deterministic) operations defined on it. Each operation can update any set of components of the state, and the set of components that are updated by an operation may depend on the current state of the object. Any object type with a *read* operation that returns the entire state of the object is readable; in this case, $|\Gamma| = 1$. An array of m 1-bit registers is a readable object, with $\Gamma = \{1, \ldots, m\}$ and $Q_k = \{0, 1\}$ for all $k \in \Gamma$. Readable objects include arrays of registers whose elements can be read, copied, or swapped atomically. An array of unbounded registers that can be read or used for indirect addressing is another example of a readable object; in this case the state set would be $Q = \bigtimes_{k\in\mathbb{N}} \mathbb{N}$ and an indirect write to component i updates the component indexed by the number stored in component i.

An RMW object type allows various kinds of *RMW* operations to be performed on it. Let V be the state set of the RMW object. Any function $f : V \to V$ defines an *RMW* operation, denoted RMW_f, that reads the current value, x, of the RMW object, updates the value to $f(x)$, and returns x. For example, a *fetch&increment* operation applies the function $f(x) = x + 1$, and a *read* operation applies the identity function. An RMW object type is defined by the set F of functions mapping V to itself that may be applied by the *RMW* operations. This class of objects includes compare&swap, test&set, and fetch&add variables.

Previously, ad hoc arguments have been used to determine whether particular object types can be used along with registers to solve n-process consensus. An exception was Herlihy's proof [10] that 2-process consensus can be solved using registers and RMW objects, where the *RMW* operations apply functions from the set F if and only if F contains a function different from the identity. Herlihy also gave a necessary condition on the set F to describe when RMW objects can be used with registers to solve 3-process consensus. In this paper, a decision procedure is developed to determine whether given readable and RMW types with finite specifications can be used to solve n-process consensus for any n. Jayanti and Toueg [15] showed that this question is undecidable for arbitrary object types that are allowed to have infinite state sets. It will be shown here that an RMW or readable type T can be used together with registers to solve the consensus problem among n processes if and only if T satisfies certain conditions which are decidable for types that have finite specifications. An object type that satisfies the conditions is called *n-discerning*. This characterization has been useful for studying the consensus numbers of multi-objects and transactional objects, where processes can access more than one object in an atomic action [21, 22].

Some work has been done on deciding whether a given task can be solved using some particular types of shared objects. Biran, Moran, and Zaks [4] showed that one can decide whether a given task can be solved in a message-passing system if at most one process may fail. Chor and Moscovici [7] gave a decidable characterization of tasks that can be solved by randomized algorithms that use registers only. Gafni and Koutsoupias [9] showed that there is no algorithm which determines whether a given task for three processes can be solved by read/write registers in a wait-free manner. Herlihy and Rajsbaum [11] gave decidability results for the question of whether a given task can be solved using various types of objects (registers, consensus objects, and set consensus objects) in the presence of t process failures.

The proof that the property of being n-discerning is sufficient for the solvability of n-process consensus will also provide upper bounds on the resources required to solve the consensus problem. If an RMW or readable object type T can be used together with registers to solve consensus among n processes, then there is a consensus protocol that uses at most $n-1$ objects of type T and $2(n-1)$ registers. Furthermore, if T is an RMW object type, each process takes $O(n)$ steps in this protocol. It also follows from the construction of the protocol that n-process consensus can be solved using $2(n-1)$ registers and $n-1$ objects, $X_2, \ldots, X_n$, where X_i's type is i-discerning, for each i.

The characterization of n-discerning types will be used in section 5 to obtain a clear proof that the consensus hierarchy is robust [14] for RMW and readable objects. This means that if n-process consensus can be solved using RMW and readable objects of types $T_1, \ldots, T_r$ and registers, then n-process consensus can also be solved using only registers and objects of type T_i for some i. This robustness property allows the consensus number of a set of RMW and readable types to be determined by finding the consensus number of each type separately. Borowsky, Gafni, and Afek [5] claimed that the consensus hierarchy is robust for all deterministic objects. A full version of their paper is not yet available.

The n-discerning conditions for readable objects will also be used to generalize a result about atomic snapshot objects. A snapshot object can be thought of as a finite array of registers with an additional *scan* operation that reads the entire array at once. It is known that the addition of the *scan* operation does not increase the power of an array of registers to solve consensus, since the snapshot object can be implemented from ordinary registers [1, 2, 3]. Here, it will be shown that the addition of an atomic *scan* operation does not increase the power of *any* readable object type to solve consensus.

2. Preliminaries. An object type is defined using a sequential specification, which describes the operations that may be performed on the object and the responses the object should return if the operations are performed sequentially. Formally, an object can be specified as an I/O automaton (see [18]). Each operation causes a state transition and returns a response. If the state transition and response are uniquely determined by the current state of the object and the operation applied, then the object is *deterministic*. When an object is accessed by more than one process concurrently, its behavior can be specified by insisting that operations appear to occur instantaneously at some time between their invocations and their responses. Such an object is called *linearizable* [12]. This paper deals only with deterministic, linearizable objects. For simplicity, it is assumed that all objects are *oblivious*: every process can invoke every operation, and, for any operation, the state transition and response do not depend on the process that invokes the operation.

It is assumed that the designer of a consensus protocol may choose the initial states of the shared objects. There is no real loss of generality in this assumption; Borowsky, Gafni, and Afek [5] showed that if consensus can be solved when the initial states are chosen by the programmer, then consensus can be solved using objects initialized to a particular state, assuming there is some sequence of operations that will move the object from the given initial state into any other state.

The systems studied here are completely asynchronous, so that algorithms must exhibit correct behavior regardless of the way in which the steps of different processes are interleaved by a scheduler. Algorithms are required to be wait-free [10]. This means that the algorithm executed by each nonfaulty process must work correctly even if other processes experience halting failures.

An implementation of an object of type T from objects $O_1, \ldots, O_m$ is a protocol that uses only the shared objects $O_1, \ldots, O_m$. This protocol consists of an algorithm *apply*(*op*) for each process that can simulate every operation *op* on an object of type T. The protocol should also specify the initial states for $O_1, \ldots, O_m$ to be used for any possible initial state of the simulated object. If each process performs the *apply* routine repeatedly, the responses returned should appear as if the operations were carried out atomically on an object of type T. All implementations are assumed to be wait-free.

The consensus number of a set of object types is defined in terms of its ability to solve the consensus problem. For the n-consensus problem, n processes each begin with a private input value, and each nonfaulty process outputs a value in a wait-free manner. The output values must all be the same, and every output must be the input value of some process. These two conditions are called *consistency* and *validity*, respectively.

The proofs that the property of being n-discerning is necessary for the solvability of n-consensus are bivalency arguments. This type of proof was introduced by Fischer, Lynch, and Paterson [8]. The following terminology will be used in the bivalency arguments. The *configuration* of a protocol at any moment in its execution consists of the state of every shared object, together with the internal state of every process. Two configurations are *indistinguishable to process* P if the state of each shared object and the internal state of P is the same in the two configurations. A configuration of a consensus protocol is x-*valent* if all nonfaulty processes decide on the value x in all executions continuing from that configuration. A configuration is called *univalent* if it is x-valent for some x, and *multivalent* otherwise. A configuration is *critical* if it is multivalent and the next step by any process will move the system into a univalent configuration. The value that would be decided if a particular process takes the next step after a critical configuration is called the *critical value* of that process.

3. Solving consensus with RMW objects. Consider an RMW type T with state set V whose *RMW* operations can apply functions from the set F. This section describes the power of a distributed system with $n \geq 2$ processes, $P_1, \ldots, P_n$, to solve consensus using objects of type T and registers. The sets V and F need not be finite.

Let v_0 be a value in V. Partition the set of processes $\{P_1, \ldots, P_n\}$ into two nonempty teams, A and B. Associate a function $f_i \in F$ with each process P_i. The functions f_i need not be distinct. The type T is called n-*discerning* if there exist choices for $v_0, A, B, f_1, \ldots, f_n$ so that, in any schedule in which each process P_i applies the single operation RMW_{f_i} to an object X which initially has value v_0, every process can determine (from the value returned by its operation) whether a process from team A or a process from team B was the first process to take a step in the schedule. Such a type T is called n-discerning since processes can easily use an object of type T to

discern the difference between schedules that start with a process on team A from those that begin with a process on team B. This description is formalized in the following definition. The notation $f \circ g$ is used to denote functional composition: $(f \circ g)(x) = f(g(x))$.

DEFINITION 1. *Let $n \geq 2$. The RMW type defined by the state set V and the set F of functions is n-discerning if there exist*

- *$v_0 \in V$,*
- *a partition of the set of processes $\{P_1, \ldots, P_n\}$ into two nonempty teams A and B, and*
- *a function $f_i \in F$ for each process P_i*

such that

I. *for all $j \in \{1, \ldots, n\}, V_{A,j} \cap V_{B,j} = \emptyset$,*

II. *for all $P_j \in B, v_0 \notin V_{A,j}$, and*

III. *for all $P_j \in A, v_0 \notin V_{B,j}$, where*

$V_{A,j} = \{(f_{i_\alpha} \circ \cdots \circ f_{i_1})(v_0) \mid P_{i_1} \in A,\ \alpha \geq 1$, and $i_1, \ldots, i_\alpha$ are distinct process indices, not including $j\}$, and $V_{B,j} = \{(f_{i_\alpha} \circ \cdots \circ f_{i_1})(v_0) \mid P_{i_1} \in B,\ \alpha \geq 1$, and $i_1, \ldots, i_\alpha$ are distinct process indices, not including $j\}$.

Suppose each process performs its assigned operation to the object X, which is initialized with the value v_0. Consider a process P_j on team A. The set $V_{A,j}$ contains the values that P_j can see when it accesses object X if some other process on team A performs the first step. (The set $V_{A,j}$ will be empty if P_j is the only process on team A. It may be the case that v_0 is in $V_{A,j}$.) The set $V_{B,j}$ is the set of responses that P_j can receive if a process from team B takes the first step. Thus, condition I ensures that P_j can distinguish, using the response it receives, executions starting with another process on team A from those in which a process on team B takes the first step. Condition III ensures that P_j can distinguish executions in which P_j itself takes the first step from those executions in which a process from team B takes the first step. (Similarly, if the process P_j is on team B, conditions I and II guarantee that it can tell which team took the first step.)

It will be shown in Theorems 3 and 9 that RMW objects of type T can be used with registers to solve n-consensus if and only if T is n-discerning.

LEMMA 2. *If S_0 is a critical configuration of an n-process consensus protocol where the next step of every process accesses the same RMW object X of type T, then T is n-discerning.*

Proof. Suppose each process P_i applies the operation RMW_{f_i} to X during its first step after S_0. Let v_0 be the value of X in the configuration S_0. Let a be the critical value of one of the processes. Let A be the set of processes with critical value a, and let B contain the rest of the processes. Team A is nonempty by construction. Since S_0 is multivalent, team B must also be nonempty.

Condition I of Definition 1 must hold for these values of $v_0, A, B, f_1, \ldots, f_n$. Otherwise, let j be a process index such that $V_{A,j} \cap V_{B,j}$ is nonempty. Then, X has the same value in two configurations that can be reached from S_0 by sequences of steps in which each process takes at most one step, process P_j takes no steps, and the first steps in the two sequences are taken by processes on opposite teams. These two configurations are indistinguishable to P_j. A solo execution by P_j from either of these configurations would therefore lead to the same decision value, contradicting the definitions of teams A and B.

Condition II must also hold. Otherwise, let j be the index of a process on team B such that $v_0 \in V_{A,j}$. Then, some sequence of processes, not including process $P_j \in$

B and starting with a process on team A, could each take a step to arrive at a configuration that P_j cannot distinguish from S_0. A solo execution of P_j from these two configurations would then lead to the same decision, contradicting the fact that $P_j \in B$.

The argument that condition III holds is symmetric. □

This lemma can be combined with a bivalency argument to prove that the conditions for being n-discerning are necessary for solving n-process consensus using RMW objects.

THEOREM 3. *If the n-process consensus problem can be solved using registers and RMW objects of type T, then T must be n-discerning.*

Proof. Suppose there is some protocol for n-process consensus using registers and RMW objects of type T. If only one process is scheduled to take steps in an execution, the process must output its own input value. Thus, any initial configuration where processes begin with different input values is multivalent. It follows that there is a critical configuration S_0 of the protocol. Otherwise, one could produce an execution of infinite length by always scheduling a process whose next step produces a multivalent configuration. No process would ever output a decision in this execution, since any configuration in which some process has produced an output is univalent. This is impossible in a wait-free protocol.

A bivalency argument (see [10]) may be used to show that the next operation performed by any process when the system is in the configuration S_0 must be an operation on the same object, say X, and that X cannot be a register. It follows from Lemma 2 that T is n-discerning. □

The following lemma and Propositions 5 and 6 will be used first in the proof of Theorem 9, which provides a converse to Theorem 3, and again in section 4.

A set $\mathcal{O}$ of objects is said to be capable of solving *team-restricted n-consensus* if there is a partition of the n processes $P_1, \ldots, P_n$ into two nonempty teams A and B such that the consensus problem can be solved using only the objects in the set $\mathcal{O}$, provided all processes on the same team have the same input value.

LEMMA 4. *If a set $\mathcal{O}$ of objects can be used to solve team-restricted $(n+1)$-consensus, then $\mathcal{O}$ can be used to solve team-restricted n-consensus.*

Proof. Any consensus protocol for team-restricted $(n+1)$-consensus may be viewed as a protocol for team-restricted n-consensus by thinking of one of the processes on a team with at least two processes as having failed before executing any of its steps. □

PROPOSITION 5. *Let $n \geq 2$. Suppose O_i is a shared object that can be used along with k registers to solve team-restricted i-consensus for all i, $2 \leq i \leq n$. Then n-consensus can be solved using objects $O_2, \ldots, O_n$ and $k(n-1)$ registers.*

Proof. The proposition will be proved by induction on n. For $n = 2$, the team-restricted form of the consensus problem is identical to the general problem of consensus for two processes.

Let $n > 2$. Suppose the claim holds when the number of processes is less than n. This means that, for all $m < n$, $O_2, \ldots, O_m$ can be used, along with $k(m-1)$ registers, to solve m-consensus. Divide the n processes into two nonempty teams A and B as described in the definition of team-restricted n-consensus. The processes of team A first execute a consensus protocol to agree on one of their input values. If $|A| = 1$, no shared objects are used. Otherwise, team A can agree on an input value using $k(|A|-1)$ registers and the shared objects $O_2, \ldots, O_{|A|}$, by the induction hypothesis. Similarly, the processes of team B agree on one of their input values. If $|B| = 1$, no

shared objects are used. Otherwise, it can be done using $k(|B|-1)$ registers and the shared objects $O_{|A|+1}, \ldots, O_{n-1}$. This is possible, since $O_{i+|A|-1}$ can be used with k registers to solve team-restricted i-consensus for $2 \leq i \leq |B|$, by Lemma 4.

Next, the processes agree on which team's value should be used as the common decision value. The processes execute the team-restricted n-consensus protocol, with each process using the decision value of its team as its input. This can be done using O_n and an additional k registers for a total of $k(n-1)$ registers.

By the inductive hypothesis, the agreement within each team is wait-free. The team-restricted n-consensus protocol used to decide between the two teams' values is also wait-free. So, the entire consensus protocol is wait-free. The protocol satisfies the validity condition, since the value agreed upon by the winning team must be one of the input values of a process on that team, by the inductive hypothesis. The protocol satisfies the consistency condition, since the team-restricted n-consensus protocol must satisfy the consistency condition. □

PROPOSITION 6. *Suppose that one object of type T and k registers can be used to solve team-restricted n-consensus. Then, n-consensus can be solved using $n-1$ objects of type T and $k(n-1)$ registers.*

Proof. This follows immediately from Lemma 4 and Proposition 5. □

LEMMA 7. *An RMW object of type T and two registers can be used to solve team-restricted n-consensus if T is n-discerning.*

Proof. Divide the processes into two nonempty teams A and B, assign a function f_i to each process P_i, and choose v_0 to satisfy the conditions of Definition 1. An algorithm will be constructed for the team-restricted n-consensus problem. The algorithm uses an object X of type T that initially has state v_0 and two registers called R_A and R_B.

Each process P_j first writes its team's common input value into the register R_A, if it belongs to team A, or into the register R_B, if it belongs to team B. The process P_j then performs its assigned operation RMW_{f_j} on X and uses the result of this operation to determine whether a process from team A or from team B was the first to access X.

Without loss of generality, suppose that process P_j belongs to team A. If P_j's *RMW* operation returns the value v_0, then a process from team A was the first to access X. To see why this is true, suppose some processes, starting with a process from team B, did access X before P_j. Let $i_1, \ldots, i_\alpha$ be the indices of these processes. Then $(f_\alpha \circ \cdots \circ f_1)(v_0) = v_0$ and $P_{i_1} \in B$, violating condition III. If P_j's *RMW* operation returns a value different from v_0, the process must be able to deduce which team accessed X first by checking whether the value belongs to $V_{A,j}$ or $V_{B,j}$. These two finite sets are disjoint (by condition I), and contain all possible values of the object X that can be observed by process P_j in this protocol. Once P_j decides whether team A or team B accessed X first, it returns the value in R_A or R_B, respectively.
