ON THE DYNAMIC FINGER CONJECTURE FOR SPLAY TREES. PART I: SPLAY SORTING log n-BLOCK SEQUENCES*

RICHARD COLE†, BUD MISHRA†, JEANETTE SCHMIDT‡, AND ALAN SIEGEL†

Abstract. A special case of the dynamic finger conjecture is proved; this special case introduces a number of useful techniques.

Key words. binary search tree, splay tree, amortized analysis, finger search tree

1. Introduction. The splay tree is a self-adjusting binary search tree devised by Sleator and Tarjan [ST85]. It supports the operations search, insert, and delete, collectively called *accesses*. The splay tree is simply a binary search tree; each access will cause some rotations to be performed on the tree. Sleator and Tarjan show that a sequence of m accesses performed on a splay tree takes time $O(m \log n)$, where n is the maximum size attained by the tree ($n \leq m$). They also show that in an amortized sense, up to a constant factor, on sufficiently long sequences of searches, the splay tree has as good a running time as the optimal weighted binary search tree. In addition, they conjecture that its performance is, in fact, essentially as good as that of any search tree. Before discussing these conjectures it will be helpful to review the operation of the splay tree and the analysis of its performance. The basic operation performed by the splay tree is the operation *splay*(x) applied to an item x in the splay tree. *splay*(x) repeats the following step until x becomes the root of the tree.

> SPLAY STEP.
> Let p and g be, respectively, the parent and grandparent (if any) of x.
> CASE 1. p is the root: make x the new root by rotating edge (x, p).
> CASE 2—THE ZIG-ZAG CASE. p is the left child of g and x is the right child of p, or vice-versa: rotate edge (x, p), making g the new parent of x; rotate edge (x, g).
> CASE 3—THE ZIG-ZIG CASE. Both x and p are left children, or both are right children: Rotate edge (p, g); rotate edge (x, p).

Henceforth, we refer to the rotation, single or double, performed by the splay step as a *rotation* of the access or splay operation. A rotation is the basic step for our analysis; the cost of one rotation is termed a *unit*; clearly, this is a constant.

Sleator and Tarjan use the following *centroid potential* to analyze the amortized performance of a splay operation. Node x is given weight, $wt(x)$, equal to the number of nodes in its subtree; they define the *centroid rank* of x, or simply the *rank* of x to be $\text{rank}(x) = \lfloor \log wt(x) \rfloor$ (our terminology). Each node is given a centroid potential equal, in units, to its centroid rank. Let δ denote the increase in centroid rank from x to g, if g is present; otherwise it denotes the increase in centroid rank from x to p. Sleator and Tarjan show that the amortized cost of the splay step if g is present is at most 3δ units, while if g is not present the cost is at most $\delta + 1$ units. Since the total increase in rank for the complete access is bounded by $\log n$, the amortized cost of an access is at most $3 \log n + 1$ units. More generally, this analysis can be applied to weighted trees, in exactly the same way. We call this the *centroid potential analysis*.

The operation $insert(x)$ is performed as follows: first, item x is inserted as in a binary search tree and then the operation $splay(x)$ is carried out. Clearly, the cost of an insertion is dominated by the cost of the corresponding access. So, subsequently, when analyzing the cost of insertions, we count only the cost of the splays themselves.

Now, we list the conjectures formulated by Sleator and Tarjan.

Dynamic Optimality Conjecture. Consider any sequence of successful accesses on an n-node binary search tree. Let A be any algorithm that carries out each access by traversing the path from the root to the node containing the accessed item, at a cost of one plus the depth of the node containing the item, and that between accesses performs an arbitrary number of rotations anywhere in the tree, at a cost of one per rotation. Then the total time to perform all the accesses by splaying is no more than $O(n)$ plus a constant times the time required by algorithm A.

Dynamic Finger Conjecture. The total time to perform m accesses on an arbitrary n-node splay tree is $O(m+n+\sum_{j=1}^{m} \log(d_j+1))$, where, for $1 \le i \le m$, the jth and $(j-1)$th accesses are performed on items whose ranks differ by d_j (ranks among the items stored in the splay tree). For $j = 0$, the jth item is interpreted to be the item originally at the root of the splay tree.

Traversal Conjecture. Let T_1 and T_2 be any two n-node binary search trees containing exactly the same items. Suppose the items in T_1 are accessed one after another using splaying, accessing them in the order they appear in T_2 in preorder (the item in the root of T_2 first, followed by the items in the left subtree of T_2 in preorder, followed by items in the right subtree of T_2 in preorder). Then the total access time is $O(n)$.

Sleator and Tarjan state that the dynamic optimality conjecture implies the other two conjectures. (The proof is nontrivial.)

There have been several works on, or related to, the optimality of splay trees [STT86, W86, T85, Su89, Luc88a, Luc88b]. [STT86] shows that the rotation distance between any two binary search trees is at most $2n-6$ and that this bound is tight; they also relate this to distinct triangulations of polygons; although connected to the splay tree conjectures, this result has no immediate application to them. [W86] provides two methods for obtaining lower bounds on the time for sequences of accesses to a binary search tree; while some specific tight bounds are obtained (such as accessing the bit reversal permutation takes time $\Theta(n \log n)$), no general results related to the above conjectures follow. [T85] proved the scanning theorem, a special case of the traversal conjecture (also a special case of the dynamic finger conjecture): accessing the items of an arbitrary splay tree, one by one, in symmetric order, takes time $O(n)$. Sundar [Su89] considered various classes of rotations on binary trees. Among other things,

this led to results concerning the deque conjecture; formulated by Tarjan [T85], it states that if a splay tree is used to implement a deque, in the natural way, then a sequence of m operations on a deque, initially of n items, take time $O(m+n)$; Sundar proved a bound of $O((m+n)\alpha(m+n))$.

In this paper we investigate a special instance of the splay sorting problem, which is related to the dynamic finger conjecture. Splay sorting is defined as follows. Consider sorting a sequence of n items by inserting them, one by one, into an initially empty splay tree; following the insertions, an inorder traversal of the splay tree yields the sorted order. We call this *splay sort*. A corollary of the dynamic finger conjecture is the following.

SPLAY SORT CONJECTURE. Let U be sequence of n items. Suppose the ith item in U is distance I_i in sorted order from the $(i-1)$th item in U, for $i > 1$. Then splay sort takes time $\mathrm{O}(n + \sum_{i=2}^{n} \log(I_i + 1))$.

Incidentally, an interesting corollary of the splay sort conjecture is the following.

SPLAY SORT INVERSION CONJECTURE. Let U be sequence of n items. Suppose the ith item in U has I_i inversions in U (counting inversions to both the left and right). Then splay sort takes time $\mathrm{O}(n + \sum_{i=1}^{n} \log(I_i + 1))$.

In the remainder of this paper we prove the splay sort conjecture for the following type of sequence. Suppose the sorted set of n items is partitioned into subsets of $\log n$ contiguous items, called *blocks*. Consider an arbitrary sequence in which the items in each block are contiguous and in sorted order. We call such a sequence a *$\log n$-block sequence*. We show an $\mathrm{O}(n)$ bound for splay sorting a $\log n$-block sequence. It is convenient to assume that the set being sorted comprises the integers $1 \ldots n$.

In brief, our analysis has the following form. The first insertion in each block is provided $\Theta(\log n)$ potential; it is called a *global* insertion. Every other insertion in the block is provided $\mathrm{O}(1)$ potential; these insertions are called *local* insertions. In section 2, we analyze the global insertions; then, in section 3, we modify the analysis to take account of local insertions.

Our work has a number of interesting features and introduces several new techniques for proving amortized results.

1. We introduce the notion of *lazy potential*; this notion can be viewed as a tool for designing potential functions. The lazy potential is a refinement of an initial potential function that avoids waste when potentials decrease. (For an example of waste, consider the following splay tree analyzed using the centroid potential. The tree is a path of n nodes, each of unit weight. The last node on the path is accessed. The resulting splay will have a real cost of $\Theta(n)$ but will reduce the potential by $\Theta(n \log n)$. The desired amortized cost of this operation is $\mathrm{O}(\log n)$, so essentially all the reduction in potential is wasted.) The idea of the lazy potential is to keep an old potential, ϕ_{old}, in situations in which the creation of a new (larger) potential, ϕ_{new}, may be followed by a return to the ϕ_{old} potential, with essentially $\phi_{new} - \phi_{old}$ potential being wasted. Not surprisingly, some care is needed in choosing which operations to treat as "lazy."

2. The potential depends on the access sequence; that is, identical trees, if created by distinct access sequences, may have different potentials. (Actually, this is a difference "in principle"; we have not constructed any examples to demonstrate it.) Nonetheless, the bounds we obtain do not depend on the input sequence.

These techniques are used later in the proof of the dynamic finger conjecture [C00]. Some of the techniques are slightly generalized so that they can be used as modules in this later paper.

2. Global insertions. We start with some definitions.

The *left path* of a tree comprises the nodes traversed in following left child pointers from the root, but excluding the root itself; the *right path* is defined analogously. Collectively, they are called *extreme paths*. Extreme paths of a subtree rooted at v are defined analogously; they are also called v's extreme paths. Node u is a *right ancestor* of node v if u is an ancestor of v that is to the right of v in symmetric order; note that v must be in u's left subtree. A *left ancestor* is defined analogously. A *right edge* is an edge to a right child; a *left edge* is defined analogously.

A *block* B is an interval $[i, j] \subseteq [1, n]$ of items; here a block always comprises $\log n$ items with $i = c \log n + 1$ and $j = (c + 1) \log n$ for some integer c. Any block $[i, j]$ induces a binary tree T_B, called the *block tree* of B, which comprises exactly those nodes of the splay tree, S, containing items i to j; they are called the *nodes* of B. Loosely speaking, the block tree is constructed by shrinking paths in S between nodes of B to single edges. More formally, the root, r, of T_B is the lowest common ancestor of nodes i and j in S. The left (resp., right) subtree of r is the tree induced by the set of items in S to the left (resp., right) of r, if nonempty; otherwise the subtree is empty.

The *root* of block B is the root of the corresponding block tree. The *global nodes* are exactly the block roots. The remaining nodes are called *local nodes*.

Every node on an extreme path of a block tree carries a potential of c units, c a constant to be specified later. Also, each node on an extreme path may carry a debit, either *small* or *large*, comprising sd and ld units, respectively; sd and ld are constants that are specified later. A node may not have both a small and a large debit. We note that for any block B the only nodes that may be visited henceforth are those presently on the extreme paths of its block tree, plus its root.

Each global node is given a centroid potential, called its *global potential*; it is defined on the splay tree using the following weights: each global node has weight 1 and each local node has weight 0. It is convenient to define a *global rank* for all nodes: this is the centroid rank in the splay tree under this weighting; $g\_\mathrm{rank}(v)$ denotes the global rank of v. Global nodes have a global potential equal to gp times their global rank, gp a constant to be specified later; the local nodes do not have a global potential.

To avoid difficulties created by the insertion of weighted nodes, for the purposes of the analysis we preinsert all the nodes into an ordinary binary search tree (without splays) in the order of their insertion into the splay tree. Then, in this same order, we access each node, in the binary search tree, by a splay operation. It is easy to see that the rotations performed on the binary search tree are identical to those performed on the splay tree. However, now each insertion can be treated as an access.

In the analysis of global insertions, whenever a rotation is performed (and paid for), another s spare rotations are also paid for, s a constant to be specified later. The spare rotations are needed subsequently to handle the effects of local insertions. We provide $(3 \log n + 1)gp$ units to pay for a global insertion. If a rotation increases the global rank of the item being inserted by Δ, then the rotation is paid for with $3\Delta gp$ of these units. Note that the rank of an inserted item increases by at most $\log n$ (from ≥ 0 to $\log n$). If the last rotation (the one involving the root of the splay tree) involves just two nodes, we call it an *incomplete rotation*; the remaining gp units are used as additional payment for the incomplete rotation, if any.

To avoid special cases it is convenient to redefine the access path for an insertion to exclude the splay tree root r in the event that r is involved in an incomplete

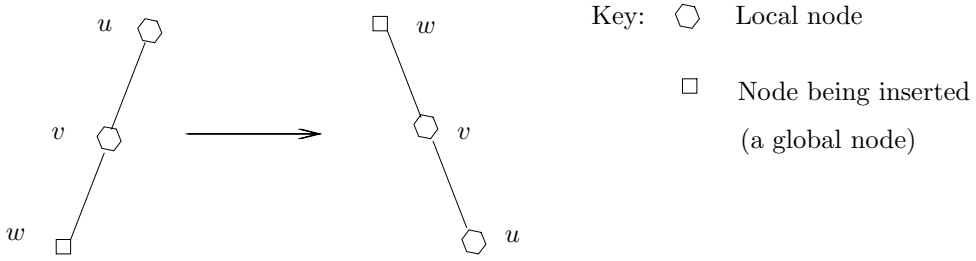

FIG. 1. *A couple comprising two local nodes.*

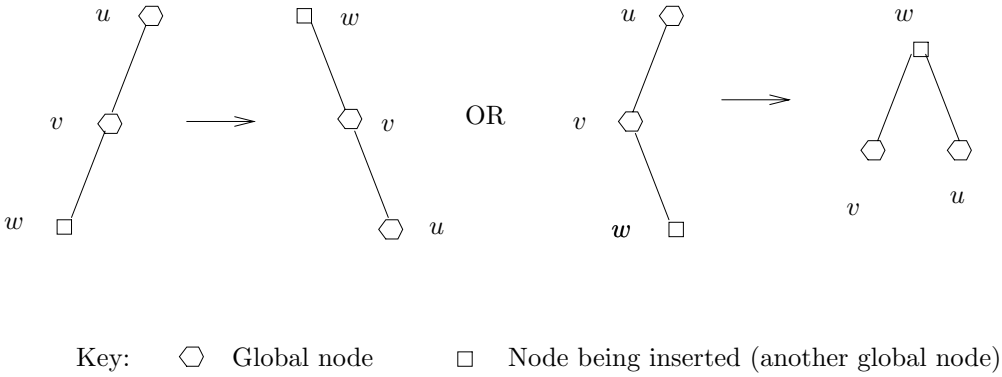

FIG. 2. *A couple comprising two global nodes.*

rotation. Now consider a rotation performed during the splay along the access path. Of the three nodes involved in the rotation, the top two are called the *coupled* nodes of the rotation, or a *couple* for short. The analysis focuses on the coupled nodes in a rotation. In order to provide the reader with some intuition we describe two simple cases.

Case 1. The coupled nodes are both local nodes in the same block (see Figure 1). Nodes u and v are on an extreme path of their block, without loss of generality the left path; v is the left child of u, and w, the node being inserted, is the left child of v. Since node u leaves the extreme path of its block it loses potential c. This pays for the removal of debits (small or large) from nodes u and v and in addition pays for $s+1$ rotations. Later, we see that we want $c \geq s+1+\max\{2sd, ld\}$.

Case 2. The coupled nodes are both global nodes (see Figure 2). Again, let w be the inserted node, let v be w's parent and u be v's parent. This case is analyzed using the centroid potential analysis of Sleator and Tarjan. The cost is at most 3 times the jump in global potential from w to u; to pay for $s+1$ rotations, it suffices to have $gp \geq s+1$; later, we see that in fact we want $gp \geq 6(s+1)+11sd$.

The full analysis is more involved. We begin by stating several invariants about the debits.

INVARIANT 1. *Only local nodes on an extreme path of their block can have debits.*

INVARIANT 2. *See Figure* 3. *Let v be a local node on an extreme path of block B. Suppose that in the splay tree v is the left (resp., right) child of its parent u. v can*

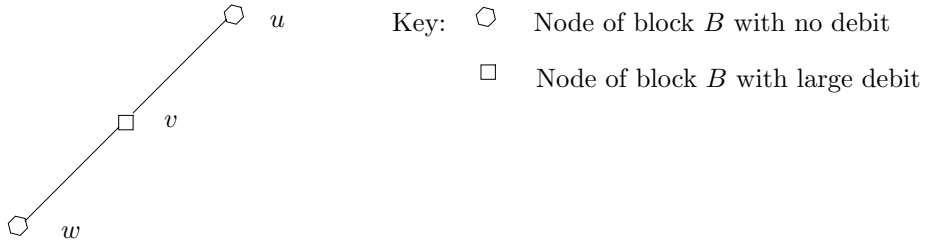

FIG. 3. *Large debits.*

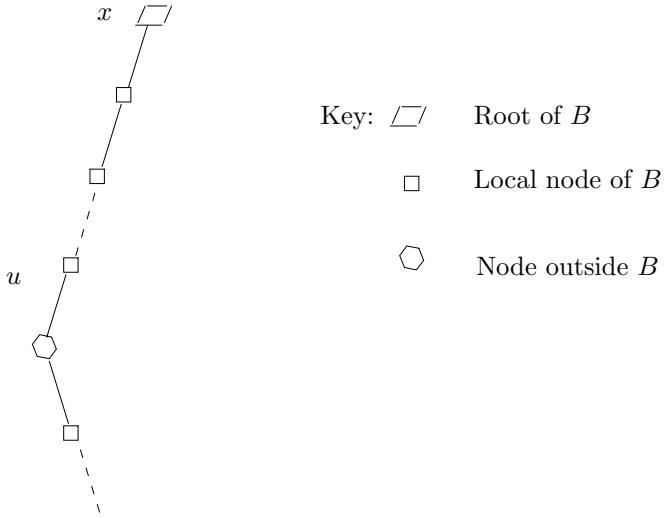

FIG. 4. *A small debit.*

have a large debit only if

(i) *u is a local node of block B,*

(ii) *v has a left (resp., right) child w which is a local node of block B, and*

(iii) *neither u nor w carry any debit,*

(iv) *either w is a local node of block B, or it is the item being accessed.*

INVARIANT 3. *Let u be the root of block B. Let v be a child of u. If v is in B, then v can have a small debit only if* $g\_\mathrm{rank}(v) < g\_\mathrm{rank}(u)$.

INVARIANT 4. *See Figure* 4. *Let x be the root of block B. Let P be an extreme path of the subtree (of the splay tree) rooted at x. Let u be the bottommost node on the path P that is in B. u can have a small debit only if* $g\_\mathrm{rank}(u) < g\_\mathrm{rank}(x)$.

For the purposes of the analysis the access path is partitioned into segments. Recall that each successive two nodes on the path form the coupled nodes of a rotation of the present splay operation. Each segment comprises an even number of nodes, or equivalently a collection of couples. The segments are created by a traversal of the access path from bottom to top; each segment is chosen to have the maximum length such that following the removal of its front (top) two nodes, the (truncated) segment satisfies the following conditions:

(i) The node being inserted has the same global rank throughout the rotations

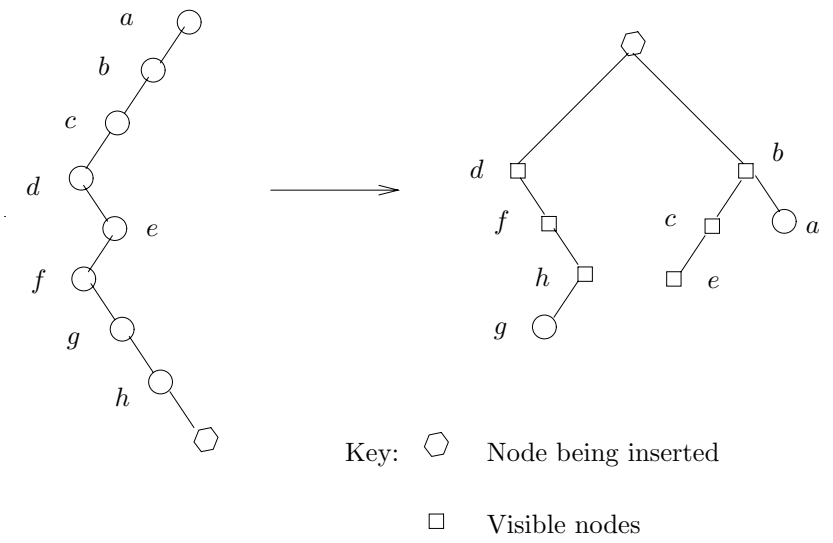

FIG. 5. *Visible nodes.*

involving the truncated segment.

(ii) Each global node on the truncated segment has the same rank following its rotation.

(iii) (This is implied by (i) and (ii).) Each couple in the truncated segment includes at least one local node (i.e., it does not comprise two global nodes).

(iv) See Figure 5. Define a node to be *visible* if it is involved in a zig-zag rotation or it is the lower node in a couple. (Intuitively, the visible nodes are those that remain on one of the traversed paths following the splay. Note that the splay, in general, creates two traversed paths.) For each block there are at most two visible nodes in the truncated segment that are local following the rotation.

The topmost segment is said to be *incomplete* if it satisfies conditions (i)–(iv) prior to truncation. We consider an incomplete segment to comprise a (trivially) truncated segment.

Next, we mark the following types of coupled nodes in each truncated segment. The rotations involving marked couples are self-paying, as is demonstrated later. For each type below, suppose the segment includes a couple, u, v, with u the parent of v.

Type 1. See Figure 6. Suppose u is the root of v's block; then both u and v are marked.

Type 2. See Figure 7. Suppose u is a local node, and let x be the root of u's block. Further suppose u is on the left (resp., right) path descending from x. Let v be the left (resp., right) child of u; if x is in the truncated segment and if v is global, then both u and v are marked.

Note that in a type 2 couple, the node being inserted must be a left (resp., right) child of v if v is a left (resp., right) child of u. Otherwise, the ranks of at least one of v and x would decrease following the rotations of their couples.

Type 3. Suppose u and v are both local nodes of the same block; then both u and v are marked.

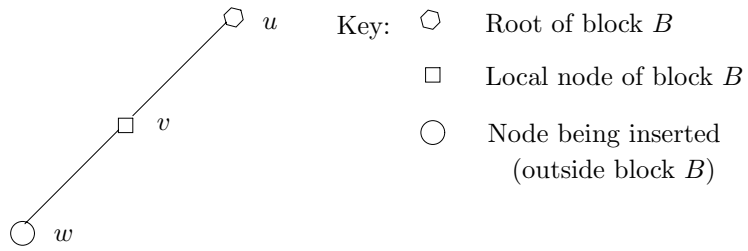

FIG. 6. *Type* 1 *couple.*

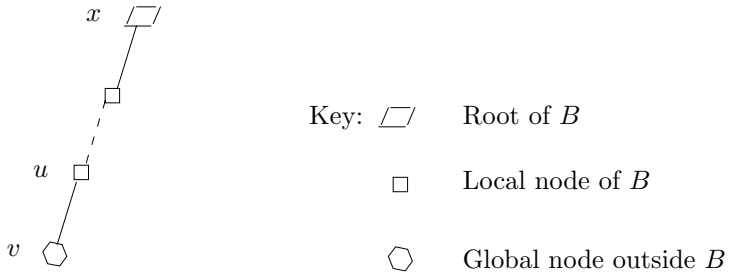

FIG. 7. *Type* 2 *couple.*

We can now prove a bound on the length of a truncated segment.

LEMMA 1. *A truncated segment comprises at most* 10 *unmarked nodes, of which at most* 7 *are local.*

Proof. Define the *left (resp., right) side* of the segment to comprise those nodes that are to the left (resp., right) of the item being inserted. From (ii) we deduce that one side, at least, contains no global nodes; without loss of generality suppose that this is the right side.

Observation 1. The right side contains at most two unmarked nodes. For as the right side contains no global nodes, its nodes must all come from the same block; so, by (iv), the right side comprises at most two sets of contiguous nodes, each one of at most two nodes. Then, because of type 3 markings, there are at most two unmarked nodes remaining on the right side.

The left side of the segment is partitioned in the obvious way into subsegments by the nodes on the right side. By Observation 1, the left side comprises at most three subsegments.

Observation 2. There are at most two couples that include both a node on the left side and a node on the right side. This follows from (iv) applied to the right side of the segment.

Observation 3. There is at most one unmarked couple within each subsegment; if present, this couple comprises the topmost global node and its parent, a local node. For the marking strategy marks all other couples within the subsegment. This is a total of at most three unmarked couples.

Thus there are a total of at most 5 unmarked couples, and at most 2 of these do not include a global node; so there are at most 7 unmarked local nodes. □

It is not hard to see that the marked nodes are all involved in zig-zig rotations.

Next, we show how to pay for the rotations (and associated spares) along a segment. Each marked couple pays for its rotation (and spares), as follows.

Type 1. See Figure 6. By Invariants 2 and 3, node v does not have a debit. The rotation is paid for by giving node u a small debit following the rotation. It is straightforward that Invariants 1–4 are unaffected. So it suffices that

$$sd \geq s + 1. \tag{1}$$

Type 2. See Figure 7. By Invariants 2 and 4, node u does not have a debit (for $g\_\mathrm{rank}(x) = g\_\mathrm{rank}(u)$ as x and u are both in the truncated segment). The rotation is paid for by giving u a small debit following the rotation. Again, it is straightforward that Invariants 1–4 are unaffected. Here too, (1) suffices.

Type 3. This is the Case 1 analyzed earlier. We need to pay for the rotation plus the removal of two small debits or one large debit. Again, it is straightforward to check that Invariants 1–4 are unaffected. So it suffices that

$$c \geq s + 1 + \max\{2sd, ld\}. \tag{2}$$

There remain up to 6 rotations to account for: the up to 5 unmarked couples and the first couple of the segment. These rotations are paid for by the first couple in the segment, which was removed in truncating the segment and which causes a violation of at least one of the conditions (i)–(iv), except in the case of an incomplete topmost segment, which is handled subsequently. The cost of these rotations is called the *segment charge*. Either the rotation involving the first couple causes a change in global potential (Case A) or it creates a sequence of three contiguous local nodes from the same block (Case B), or possibly both. Both cases involve three costs.

1. $Cost1$. The rotation and spares for each couple: $\leq 6(s + 1)$.
2. $Cost2$. Removal of small debits from nodes on the segment; $Cost2$ is analyzed below. (A node with a large debit will always be a marked node of type 3.)
3. $Cost3$. Removal of small debits for local nodes that now violate Invariant 3 or 4; $Cost3$ is analyzed below.

LEMMA 2. *For each segment* $Cost2 + Cost3 \leq 11sd$.

Proof. A definition is helpful here. Let B be a block and let v be the root of B. Consider an extreme path of block B and consider the topmost portion that is contiguous in the splay tree. If this topmost portion is incident on v in the splay tree, then it is called an *abutting extreme path portion* for v, or an *abutting portion* for short. (*Comment.* Node v of Invariant 3 is the top node of an abutting portion for u, while node u of Invariant 4 is the bottom node of an abutting portion for x.)

Next, we make some observations about $Cost3$. Note that none of the nodes from marked couples on the traversed path retain small debits; so these nodes do not contribute to $Cost3$. Contributions to $Cost3$ can arise in one of two ways:

(1) One way contributions to $Cost3$ can arise is through a traversed global node v having a reduction in rank. Then, on an already abutting portion (for v) which continues to be abutting (for v), if the portion was not traversed, we may need to remove up to two single debits in order to maintain Invariants 3 and 4. v can have at most one such abutting portion. This contributes up to $2sd$ to $Cost3$. This contribution can be a consequence of either a zig-zag rotation or a zig-zig rotation. We examine each in turn.
   (a) In a zig-zag rotation, there may be one such abutting portion for each global node in the couple. In this case the contribution to $Cost3$ can be as large as $4sd$.

(b) In a zig-zig rotation only the top node in the couple can retain such an abutting portion; so here the contribution to $Cost3$ is at most $2sd$.

(2) Contributions to $Cost3$ can also arise through the creation of an abutting portion, provided that this abutting portion is not traversed. This can only occur for the top node v of a couple and then only if both nodes in the couple are global and the rotation is a zig-zig rotation. Here, the contribution to $Cost3$ is at most $2sd$.

Next, we determine, in turn, the contribution to $Cost2 + Cost3$ of the truncated segment and of the first couple.

First, we consider the truncated segment. By Lemma 1, the contribution to $Cost2$ is at most $7sd$. For a contribution to $Cost3$, the discussion of the previous paragraph shows we need only consider possibility (2) since global nodes in the truncated segment do not have a change in global rank. Likewise, possibility (2) cannot arise for the couples of the truncated segment each have at most one global node. We conclude that the truncated segment contributes at most $7sd$ to $Cost2 + Cost3$.

We turn to the leading couple. The contribution to $Cost2$ is at most sd for each local node it contains. By the above discussion regarding contributions to $Cost3$, the leading couple may contribute up to $4sd$ to $Cost3$, but only if both nodes of the couple are global; if there is only one global node in the couple, then the contribution to $Cost3$ is at most $2sd$. In any event, the total contribution of the first couple to $Cost2 + Cost3$ is at most $4sd$. □

LEMMA 3. *A global insertion has amortized cost at most* $(3 \log n + 1)gp$ *units, where* $gp, ld = 17(s + 1)$, $c = 18(s + 1)$, *and* $sd = s + 1$.

Proof. In Case A, the segment charge is paid for either by the drop in global potential, which provides at least gp units, or, if there is an increase in global rank, by gp units of the at least $3gp$ units provided for this rotation. In Case B, the middle node in the sequence of three contiguous nodes is given a large debit, which pays for the segment charge. So it suffices to have

$$gp, ld \geq 6(s + 1) + 11sd. \tag{3}$$

Now, we show how to pay for the incomplete segment, if present. Recall that we provided $(3 \log n + 1)gp$ units to pay for the present insertion. The $+gp$ term is used to pay for the incomplete segment; in addition, this term is used to pay for the incomplete rotation, if any; however, the $+gp$ term does not need to account for any increase in rank on the part of the inserted item during the incomplete rotation, for this has already been accounted for. Clearly, the result of Lemma 2 applies here too (in fact, a tighter bound can be shown). Here too, (3) suffices.

The result follows by taking equalities in (1)–(3). □

Actually, we have shown the following.

LEMMA 4. *The path traversed in an access of an item can be partitioned into segments, such that for any segment* σ, *the amortized cost of the rotations for the couples of* σ *is at most* $gp + 2gp \cdot I_\sigma$, *where* I_σ *is the increase in rank undergone by the accessed item in the last rotation of segment* σ. *Furthermore,*

(i) $gp \cdot I_\sigma$ *units of the cost are used to raise the potential of the accessed item;*

(ii) $gp \cdot I_\sigma$ *units of the cost are used to raise the potential of the lower global item, if any, in the final couple of segment* σ*;*

(iii) gp *units are used to pay for all the rotations of* σ, *and all the associated spare rotations and debit removals.*

Remark 1. Later, the form of the blocks will be generalized to allow more complex

situations involving local nodes. Specifically, we will allow local nodes to carry other debits. For the above analysis to continue to apply, it will suffice that

(i) if a local node on its block's right (resp., left) path carries a new debit, then its parent and right child (resp., left child) are both local nodes of the block;

(ii) a zig-zig rotation in which the couple comprises two local nodes pays for the removal of all debits on the couple's nodes, plus $s + 1$ rotations, if the rank of the accessed item does not increase.

Indeed, in a subsequent paper, we will introduce a hierarchy of blocks. A block will comprise a contiguous set of items (with respect to the items' sorted order). A superblock will comprise a contiguous set of blocks. (In this section, the superblock is simply the whole splay tree.) As here, the root of each block is a global item and the other items are local items. Suppose each global item has a positive integer weight and each local item has nonnegative integer weight. Suppose further that there are small and large debits which obey Invariants 1–4; there may be additional types of debits also, but they must obey the following invariant.

INVARIANT 5. *Let v be a local node on an extreme path of block B. Suppose that in the splay tree v is the left (resp., right) child of its parent u. v can have an additional debit only if*

(i) *u is a local node of block B,*

(ii) *v has a left (resp., right) child w which is a local node of block B.*

Then the following lemma has been shown.

LEMMA 5. *Let v be a global node in a superblock B. Suppose that v is the accessed item. Let I be the increase in global rank undergone by v during some (arbitrary) portion P of the access. The amortized cost of the rotations in portion P of the access is bounded by $(3I + 1)gp$ units, where $gp, ld = 17(s + 1)$, $c = 18(s + 1)$, and $sd = s + 1$, provided the conditions of Remark 1 hold. The amortized cost of the traversal comprises a payment of $s+1$ rotations for each couple, the removal of debits on the path traversed and the removal of other debits needed to restore Invariants 3 and 4, minus the debits that are created.*

Proof. The only change compared to Lemma 3 is the introduction of additional debits as constrained by Remark 1. Let x be a node carrying such a debit and let w be its parent. Suppose x is the right child of its parent. Let y be the right child of x. By assumption, w, x, and y are all local nodes of their superblock B. Since the inserted node is global in superblock B, the rotation involving v and x must be a zig-zig rotation; the second node of the couple will be either w or y. The additional cost introduced by the removal of the additional debit from x is paid for by the zig-zig rotation involving node x, as assumed in Remark 1. □

3. Local insertions. We show how to analyze a sequence of local insertions. This leads to the introduction of *lazy trees* which forces a reanalysis of global and local insertions. Following this reanalysis, the overall analysis is readily concluded.

Recall that the insertion of each block comprises one global insertion followed by a sequence of $\log n - 1$ local insertions. Each local insertion traverses a left path up to the right child of the splay tree root (see Figure 8); we call this path the *local access path*. By providing $e(3 \log n + 1)gp$ units to the global insertion, we can treat the first $e - 1$ local insertions as if they were global insertions. Throughout these $e - 1$ local insertions, spare rotations will be accumulating (though, for reasons that will become clear later, it may be that no spares accumulate during the global insertion itself); more precisely, each couple receives s spares in each of these local insertions (see Lemma 7). These spares, plus the spares already accumulated by the nodes of

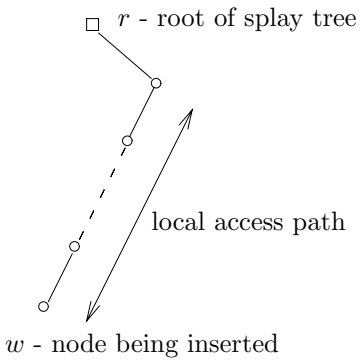

FIG. 8. *The local access path.*

the couple, are given to the node remaining on the local access path. So after $e-1$ local insertions, each node on the local access path, except the topmost, will have at least $(2^{e-1}-1)s$ spare rotations. The rotations in subsequent local insertions will be self-paying, apart from the rotation involving the splay tree root. These subsequent local insertions are called *true local insertions*.

In fact, we provide another $gp \log n$ units to the global insertion. Following the first $e-1$ local insertions, we provide a *reserve* potential to each global node on the local access path. The reserve for global node u is defined as follows: let v be the first proper global descendant of u on the local access path, if any; let $g\_\mathrm{rank}(v)$ be v's global rank if v is present; otherwise, let $g\_\mathrm{rank}(v) = 0$. Then $reserve(u) = gp(g\_\mathrm{rank}(u) - g\_\mathrm{rank}(v))$. The role of the reserve potential will become clear later.

We need one further constant, q, to be specified later. We choose e so that

$$(2^{e-1}-1)s \geq q + (s+1). \tag{4}$$

We note $e \geq 2$. In a true local insertion, each node v removed from the local access path is given potential q; $s+1$ will bound the cost of the rotation involving v. This is paid for by the $(2^{e-1}-1)s$ potential associated with the node removed from the local access path. At the end of the sequence of local insertions, the nodes remaining on the local access path, apart from the topmost node, are also given potential q (these nodes all have $(2^{e-1}-1)s$ potential at hand, which more than suffices).

Consider a true local insertion. The inserted item, e, is not provided a global potential; rather, following the final rotation of the insertion, e becomes the root of the splay tree and acquires the global potential associated with the old root of the splay tree. There are three types of rotation on the local access path. They all involve a couple u, v, with u the parent of v. Either both u and v are local, or one of u or v is local and the other is global, or both are global. Only in the last case is a global node removed from the local access path. The rotations, apart from those involving two global nodes, cost at most $s+1$ units, for there is no increase in global rank in such rotations and there are no debits to remove (for following the global insertion there are only large debits on the nodes of the local access path, which are removed by the first local insertion; as $e \geq 2$, the current insertion is not the first local insertion). In the case of a rotation involving two global nodes we swap their global potentials. The node remaining on the local access path still has the correct global potential, but the node u removed from the path may have too small a potential, which is called its *lazy*

potential. Again, the cost of this rotation is $s+1$ units; however, Invariant 4 may no longer be true for the block B whose root now has a lazy potential. (Invariant 3, which might be in question, remains true, for the local nodes of block B that are now children of B's root had been on the local access path and hence had their debits removed.) All these rotations, as noted in the previous paragraph, are paid for by the potential at hand.

LEMMA 6. *A true local insertion has amortized cost* $c+s+1$ *units.*

Proof. As discussed in the paragraph before the lemma, all couples comprising two nodes on the local access path are paid for by the potential associated with the nodes of the couple. So the only rotation to be paid for is the final rotation of the insertion; it costs $s+1$ units. In addition, the item displaced from the root of the splay tree is given c units of potential, for it has become an additional node on an extreme path of its block. □

Remark 2. We will need to generalize this analysis to take account of the presence of lazy trees on the local access path. The previous analysis will continue to apply if the following conditions hold:

(i) Each node on the local access path has potential $(2^{e-1}-1)s$.

(ii) Each node on the local access path does not carry any debit.

(iii) The rotation of each couple on the local access path costs at most $s+1$ units.

(i) and (ii) will be achieved as here. (iii) will be discussed later.

Every node removed from the access path in a true local insertion and remaining on an extreme path of its block is called a *lazy node*, whether or not it has a lazy potential. Those lazy nodes with a lazy potential are called *heavy* nodes; the other lazy nodes are called *light* nodes. When the insertion of the current block is completed we form *lazy trees*. Each global node v remaining on the local access path becomes the root of a new lazy tree. Its left subtree is empty; its right subtree comprises those lazy nodes created during the insertion of the current block that are in v's right subtree in the splay tree. It is straightforward to see that each new lazy node is contained in a new lazy tree. We call the lazy trees as defined above *initial lazy trees*. (We will be adding and removing a few nodes from the initial lazy tree in order to obtain other lazy trees, which are the lazy trees that are actually analyzed.)

The intuition behind the lazy tree is that if all the lazy nodes were restored to a left path, then the lazy potentials would be the actual global potentials (perhaps with some swapping). Actually, difficulties are caused by the fact that the left subtree of the path may increase in size through rotations between the lazy tree and the remainder of the splay tree. So, strictly speaking, the intuition may be incorrect. More precisely, the constant potentials q provided to the lazy nodes will pay for rotations among lazy tree nodes until these nodes have their global potentials restored (in general, this will not happen by recreating the left path from which these nodes originated).

Let us return to the cost of the insertions. A global insertion, as noted above, costs $e(3\log n+1)gp+gp\log n$ units. We see below that the presence of lazy trees adds a further $4gp\log n$ units to the cost of the global insertions, for a total of

$$e(3\log n+1)gp+5gp\log n \text{ units.} \tag{5}$$

In section 4 we show how to modify the analysis of global and local insertions to account for the presence of lazy trees.

4. The analysis of lazy trees. Most of the analysis focuses on a subtree of the initial lazy tree, called the *truncated lazy tree* or the *lazy tree*, for short. It is

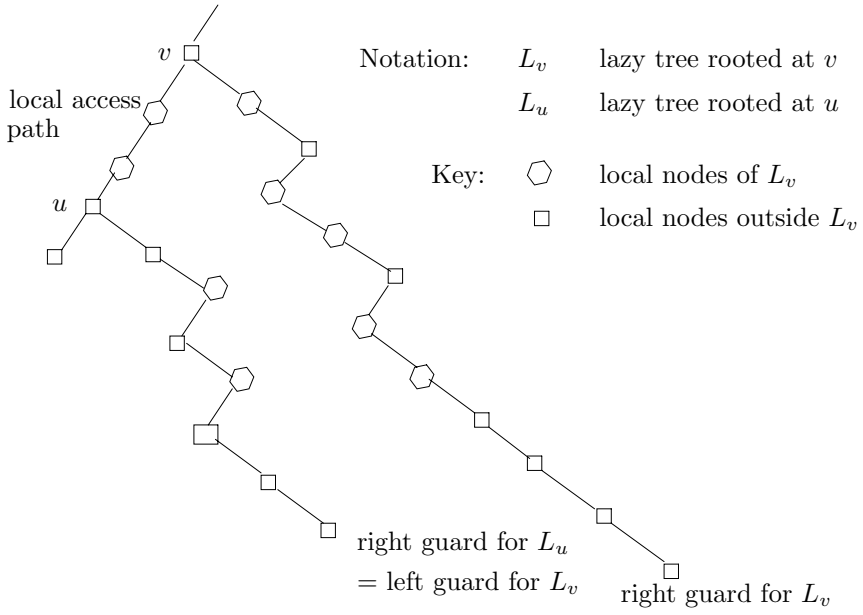

FIG. 9. *Left and right guards.*

defined as follows. Consider a new initial lazy tree, L, created by a sequence of local insertions. Consider the set of heavy nodes in L plus the root of L; the tree they induce is called the *initial lazy block tree*. We remove the rightmost node from the initial block tree; this defines the (truncated) lazy block tree for the (truncated) lazy tree. This rightmost node is called the *right guard* for the lazy tree (see Figure 9). The *left guard* is a global node, defined later, to the left of the nodes of the lazy block tree. The root of the (truncated) lazy block tree is called the root of the (truncated) lazy tree. We define the tree induced by the nodes of the (truncated) lazy block tree plus the left and right guards to form the *large lazy block tree*. Now we define the (truncated) lazy tree as follows.

We define the *left guard*, w, of the lazy tree as follows. Let L be a new lazy tree with root u. Let v be the first proper global descendant of u on the local access path, if any. Suppose v exists; if v is the root of another new lazy tree, let w be the right guard in this lazy tree, while if v is not the root of a new lazy tree, then let $v = w$. Otherwise, let w be the root of the splay tree. In general, a node may be a right guard in one lazy tree and a left guard in a second lazy tree.

The truncated lazy tree comprises the nodes of the (truncated) block tree together with the following light nodes. For each node v in the (truncated) block tree, we add the following nodes from v's block. Let w be any descendant of v in the large lazy block tree. Those nodes in v's block on the path from v to w in the splay tree are added to the (truncated) lazy tree. The light nodes added to the lazy tree form its *skeleton*.

Intuitively, a truncated lazy tree is a megablock comprising several of the blocks at hand. In its interactions with the remainder of the splay tree it will behave in the same way as a block. The root of the lazy tree corresponds to the block root, and the other nodes of the lazy tree, called *local* nodes of the lazy tree, correspond to the

local nodes of the block. The lazy tree local nodes may carry small and large debits according to the invariants specified for blocks; a further *lazy* debit may be carried as specified later.

The right guard of each new lazy tree has its global potential restored (this is paid for by adding its reserve potential to its lazy potential, which suffices, as is stated in Invariant 12, in section 4.3). In addition, Invariant 4 may need to be restored for the right guard; this requires the removal of at most two small debits. These are paid for by the potential $a + b$ (see the following paragraph) associated with the right guard prior to the restoration of its global potential. So it suffices to have

$$2sd \leq a + b. \tag{6}$$

Thus both the left and right guards of each lazy tree have their global potentials.

Next, we provide additional potentials to the nodes in the lazy tree (in addition to the potentials these nodes already carry). All light nodes on the lazy tree carry a potential of $2c'$ units, except for the light nodes from the leftmost block in the lazy tree, which carry a potential of only c' units; c' is a constant to be specified later. In addition, we give the following potential to the heavy nodes. Let v be a heavy node; suppose it has height h in the lazy block tree. Then v receives potential $a\sum_{i=1}^{h} i + b$, where a and b are constants to be specified later. This potential is provided by redistributing the potential q given to each lazy node in the initial lazy trees. Note that each initial lazy tree has the following form: consider the right path descending from its root; the left subtree of each node on this path, excluding the root, is a complete binary tree; in top to bottom order, these trees have strictly decreasing height. The q potentials are redistributed as follows. First, a potential of $a\sum_{i=1}^{k} i + b$ is given to each height k node in the initial lazy tree, other than the lazy tree root. The following argument shows that it suffices to provide each node with a potential of $12a + b$. Each node of height k in a complete binary tree begins by receiving a temporary potential of $\frac{3}{2}ak(k+1)+b$; it provides this by passing a charge of $\frac{3}{2}a[(k-1)k+4(k-1)]$ to each of its children; if it has a parent, in turn, it receives a charge of $\frac{3}{2}a[k(k+1)+4k]$ from the parent; adding its own initial potential of $12a+b$ provides exactly the required temporary potential (note that a leaf will pass a charge of 0 to its nonexistent children). The nodes on a right path acquire their potential from their left child. A node of height $k+1$ receives potential $k(k+1)a$ from its right child, which together with its own initial potential of $12a + b$ suffices to provide the required $[\frac{1}{2}(k + 1)(k + 2)]a + b$ potential; note that the right child still has potential $[\frac{1}{2}k(k + 1)]a + b$, as required. So it suffices to have

$$12a + b \leq q. \tag{7}$$

But the potentials in the initial lazy tree upper bound the potentials desired in the (truncated) lazy block tree. Finally, to provide the light nodes with their potential, it suffices to have

$$2c' \leq a + b. \tag{8}$$

The left (resp., right) extreme path of (truncated) lazy tree, L, is the path from the root of L to the leftmost (resp., rightmost) node in L; it is convenient to exclude the lazy tree root from the extreme paths. We will call these the left and right paths of L, for short.

Nodes on the extreme paths of the lazy tree may have a small or large debit; these debits satisfy Invariants 1–4, where lazy tree L replaces block B in the statement of

the invariants. Also, each light node in the lazy tree may have a *lazy* debit, which is *huge* and has value hd units, $hd \geq ld$, a constant to be defined later. We now state two invariants concerning the lazy debits.

INVARIANT 6. *Let L be a lazy tree. Suppose node v in L has a lazy debit. Then v is a light node of L. Also, v is not on the left path of L. Finally, v does not carry a small or large debit.*

INVARIANT 7. *Let L be a lazy tree. Let u be a local node of L. Suppose u has a lazy debit. Let v be the root of u's block.*

(i) *Suppose that v is not on the left path of L. Then if u is on the right path descending from v in the splay tree, both the parent and child of u on this path are local nodes in u's block.*

(ii) *If u is on the right path of L, then its parent and child in the splay tree are local nodes in u's block; this holds regardless of whether u is on the right path descending from v in the splay tree.*

Next, we show how to incorporate lazy trees into the analysis of global insertions. A global insertion can traverse a lazy tree in one of three ways:

(a) traverse the right extreme path of the lazy tree (or rather a topmost portion of it),

(b) traverse the left extreme path of the lazy tree (or rather a topmost portion of it), or

(c) traverse the interior of the lazy tree and thereby split the lazy tree.

Actually, it is convenient to classify a traversal of type (a) which is to the left of the right guard to be a split (a type (c) traversal); likewise a traversal of type (b) to the right of the left guard is defined to be a split. As we will see later, local insertions only involve traversals of type (a) or (b).

A traversal of type (c) will be paid for in two phases. First, in a preprocessing phase, the current lazy tree is partitioned into several lazy trees and/or ordinary blocks, so as to ensure that the actual splay (the second phase) comprises only traversals of types (a) and (b). (In fact, as we will see, we need a third phase in order to pay for some of the partitioning performed in the first phase.)

We start by considering the interactions between the lazy tree and the remainder of the splay tree (which may include other lazy trees). We treat the lazy tree, as delimited by its extreme paths, as a block. We note that Invariants 6 and 7 ensure that a node on an extreme path, carrying a lazy debit, satisfies condition (i) of Remark 1. In addition, we note that on creation, the nodes of the lazy tree have no debits, so Invariants 1–4 all hold at this point.

Next, we need to show that condition (ii) of Remark 1 is satisfied. That is, we have to show that couples involving two nodes on an extreme path of the lazy tree, which will be marked, can pay for the removal of their debits and $s + 1$ rotations. There are two classes of rotations: those involving at least one light node of the lazy tree and those involving two heavy nodes; they are treated in sections 4.1 and 4.2, respectively.

Segments are defined and paid for essentially as before. The one difference occurs if either node of the leading couple of the segment carries a lazy debit; then the couple pays for its own rotation and the removal of its debits as part of the lazy tree, as we see later; but this can only reduce the total remaining cost of the segment and so the bounds of the previous analysis are still valid.

We need to mention one detail about couples containing the root, u, of a lazy tree and another node, v in the same lazy tree. Following the rotation, v becomes the

root of the lazy tree; v and u interchange roles and potentials (so if v had been light, resp., heavy, u becomes light, resp., heavy).

In section 4.3 we will explain how a lazy tree is split.

4.1. Analysis of couples including one light node. Consider a couple comprising nodes u and v, where u is the parent of v, both u and v are on an extreme path of their lazy tree and one, at least, of u and v is a light node.

Case 1. u and v are both light. u ceases to be on the skeleton. u's c' potential pays for the rotation, s spares, and the removal of all debits on u and v. So it suffices to have

$$c' \geq s + 1 + 2hd. \tag{9}$$

Case 2. u is a light node and v is a heavy node. By Invariants 6 and 7, u and v do not have lazy debits. If u leaves the skeleton, the operation is paid for by u's c' potential, as in Case 1; (9) suffices. Otherwise, u is given a lazy debit; this then pays for the operation. The cost of the operation comprises the rotation, s spares, and the removal of small or large debits, if any, from u and v. So it suffices to have

$$hd \geq s + 1 + \max\{ld, 2sd\} = s + 1 + ld. \tag{10}$$

Case 3. v is a light node, u is the root of v's block (but is not the lazy block tree root). By Invariants 6 and 7, u and v do not have lazy debits. v becomes the block root. As in Case 2, if u leaves the skeleton, the operation is paid for by u's c' potential. Otherwise, u is given a lazy debit, which pays for the operation. The cost of the operation comprises the rotation, s spares, and the removal of small or large debits, if any, from u and v. Here too (9) and (10) suffice.

4.2. Analysis of couples comprising two heavy nodes. The potential associated with the lazy block tree is called the *lazy complete tree potential*.

Consider a couple comprising nodes u and v, where u is the parent of v and both u and v are heavy nodes on an extreme path of the lazy tree. We need to pay for the rotation, for s spares, and for the removal of small or large debits from u and v, if any. In addition, we may need to reestablish Invariant 7 for node u; this may require the removal of up to two lazy debits, which will also be paid for by the rotation. So the cost of this rotation is at most

$$s + 1 + ld + 2hd. \tag{11}$$

For the remainder of section 4.2 we focus on the lazy block tree. Hence when we refer to a node we mean a node in the lazy block tree; likewise a reference to a tree refers to the lazy block tree. The *depth* of a node in the tree is its distance from the root. The height of a node at the time of the creation of the lazy tree is called its *creation_height*; the creation_height does not change subsequently.

Consider how an extreme path traversal appears to the lazy block tree. A top contiguous portion of the nodes on this path are all *touched* (these are the nodes contained in couples of the splay tree). Some (arbitrary) subset of disjoint pairs of touched nodes form couples. Each touched node is provided with $\frac{s'}{2}$ spare units of potential, $s' \leq s$ (this is part of the node's portion of the s spares provided to its couple in the splay tree).[1] The spare potential of the touched nodes, together with

[1] In this paper we can take $s' = s$; the more general form will prove useful in a later paper.

any changes to the potentials of the touched couples will pay for the rotations of the touched couples.

At any time, certain nodes, called *active* nodes, are the nodes that pay for a traversal of the extreme path. Some nodes may pay more than other nodes. This is captured by the notion of *active layers*. A node of creation_height h has an associated *span* of layers $[1, h]$; each active node v of creation_height h has an *active span* of *active layers*, $(i, h]$, $0 \leq i \leq h$; for each l, $i < l \leq h$, we say v is *l-active*. If the active span is nonempty, we say the node is *active*.

Initially, only the nodes on the right path are active. An inactive node becomes active when it first reaches the right path. Once a node becomes active it remains active, whether or not it remains on the right path; also, the active span of a node can only grow.

Recall that a rotation of the splay operation involving a heavy node, v, and the root, r, of the lazy tree causes the two nodes to swap all their potentials. Also, r acquires v's creation_height and active span.

The following invariant states several properties of the active nodes. We prove the invariant later. In order to avoid special cases for the left path we state the invariant with respect to the normal form of the tree, defined as follows. It is obtained by performing the following series of single rotations: one by one, the left path nodes are moved to the right path; each such rotation, between node v and node r, the root of the lazy tree, makes v the root and places r on the right path. r acquires v's active span. The resulting tree is called the *normal tree*.

INVARIANT 8. *Let H be the maximum creation_height for the nodes, other than the root, present in the tree initially. Then, in the corresponding normal tree, the following hold:*

(i) *There is exactly one l-active node, $1 \leq l \leq H$.*
(ii) *Every node on the right path is active (this does not include the root).*
(iii) *Apart from the root, the ancestors of an active node are all active.*
(iv) *Let v be an l-active node. Let w be a j-active node. If $j < l$, then w is to the right of v in symmetric order, while if $j > l$, then w is to the left of v in symmetric order.*
(v) *Let inactive node v have creation_height l. Then its parent has creation_height greater than l.*

When a lazy tree is created the active spans for the nodes in the corresponding lazy block tree are initialized as follows. Let u be a node on the right path, of creation_height h; suppose it has a right child v of creation_height i (if there is no such node v, let $i = 0$). Then u is given active span $[i + 1, h]$. Clearly, the new tree obeys Invariant 8.

The layers of a node are further categorized as *black* or *white*; an active node, with active span $[j, h]$, can be black with respect to each of the layers $[1, j - 1]$. In general, an active node v, with active span $[j, h]$, is black with respect to all the layers in some range $[i, j-1]$, $i \geq 1$, called its *black span*; we say v is *l-black* for $i \leq l \leq j-1$. If the black span is nonempty we say the node is *black*. Nodes are initially white at all layers. A node becomes black as a consequence of a rotation with the root. The following invariant applies to black nodes.

INVARIANT 9.

(i) *All the nodes on the left path of a tree are fully black, i.e., a node with active span $[j, h]$ has black span $[1, j - 1]$.*
(ii) *If a node u is l-black, all u's left ancestors, apart from the root, in the corre-*

sponding normal tree are l-black.

We define the following distances for each node v, active at layer l. Its *right path l-distance*, $d_l(v)$, is the number of proper left ancestors of v on the right path, excluding all l-black nodes. (Recall that a left ancestor of v is an ancestor of v to the left of v in symmetric order.) Its *layer l interior right path distance*, $id_l(v)$, is the number of proper left ancestors of v below the first l-black node and below the right path.

For each l-active node we maintain an l-potential, which satisfies the following invariant.

INVARIANT 10. *The l-potential at node v is at least*

$$a \cdot \min\left\{\frac{d_l(v)}{d}, l\right\} + \frac{a}{d} \cdot id_l(v). \tag{12}$$

We note that initially a node has $a \cdot l$ units of potential for each layer l at which it could become active, so when a node first becomes l-active, Invariant 10 holds.

In addition, for each l-black node we maintain an l-black potential of $\frac{a}{2d}$ units.

In turn, we analyze traversals of the right and left extreme paths.

Immediately prior to a traversal of the right path, each node on that path is given $s'/2$ spare rotations (whether or not the node is part of a couple comprising two heavy nodes of the same lazy tree). Each node's spares are subsequently provided by the rotation which involves that node. Suppose node v remains on the right path following the rotation. Let layer l be the largest layer at which v is presently active. Suppose node u, the other node in v's couple, is not l-black. If $d_l(v) > d \cdot l$, then the spares, called the *l-spares*, for the nodes at depths $(d(l-1), d \cdot l]$ on the right path, are used to pay for v's rotation. Otherwise, a/d units of v's l-potential are used to pay for this rotation. Note that Invariants 8–10 continue to hold following this rotation.

If node w is l-active but is not on the right path, then $id_l(w)$ can increase; thus its l-potential can increase, but only if $d_l(w) > d \cdot l$. In this case, the unit increase in potential is paid for by the l-spares as in the previous paragraph.

A rotation between an l-black node u and its child v, where v is l-active, is paid for by the $\frac{a}{2d}$ units of l-black potential at u; u reduces its black span accordingly, as do all the nodes in u's new right subtree (the subtree following the rotation). Again, it is clear that Invariants 8 and 9 hold following the rotation. To verify Invariant 10 we argue as follows. (See Figure 10.) First, for j-active node w, $j < l$, in v's old right subtree, $d_j(w)$ is unchanged or reduced, since u ceases to be an ancestor of w; in addition, $id_j(w)$ is unchanged. Second, for j-active node w, $j > l$, in v's old left subtree, as in the previous paragraph, if v's j-potential increases, it is paid for by the j-spares. Third, for j-active node w, $j > l$, in u's left subtree, $d_j(w)$ and $id_j(w)$ are unchanged since the locations of w's left ancestors are unchanged, as is their j-black status. Reference to Invariant 8(iv) shows that these are the only possible cases.

A black node is created in a rotation with the root. Node v becomes the new root. Node u, the old root, acquires all of v's potentials; v acquires the root's global potential. If u now has minimum active layer l, it acquires black span $[1, l-1]$. The new portion of its black span, $[1, k-1]$, for some $k \le l$, is paid for as follows. Let w be the j-active node for some $j < k$. If $d_j(w) \le j$ before u's rotation, as $d_j(w)$ is reduced by at least one by u's rotation, $a/2d$ units of w's j-potential provide u's j-black potential. If $d_j(w) > j$, then let w' be the node at depth j. w' transfers a second portion of $\frac{a}{2d}$ units of potential. Note that by Invariant 8(iv) each active layer j' of w' satisfies $j' > j$, and so $d_{j'}(w') < j'$; thus the j'-potential of w' is reduced by

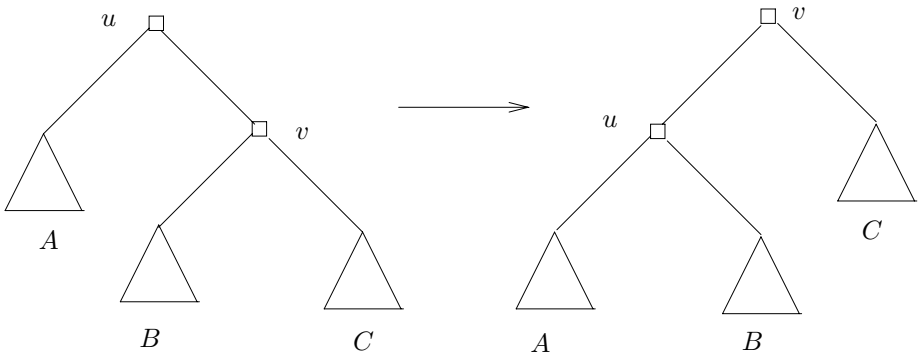

FIG. 10. *Rotations with black nodes.*

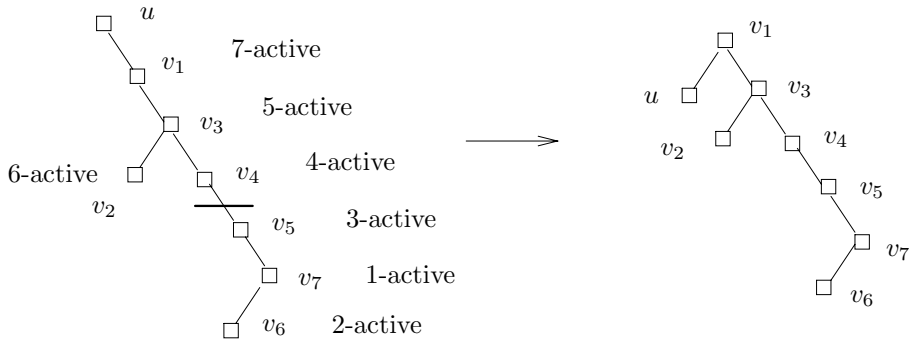


v_3 pays for the 5-black potential and the 2-black potential

FIG. 11. *Creating a black node.*

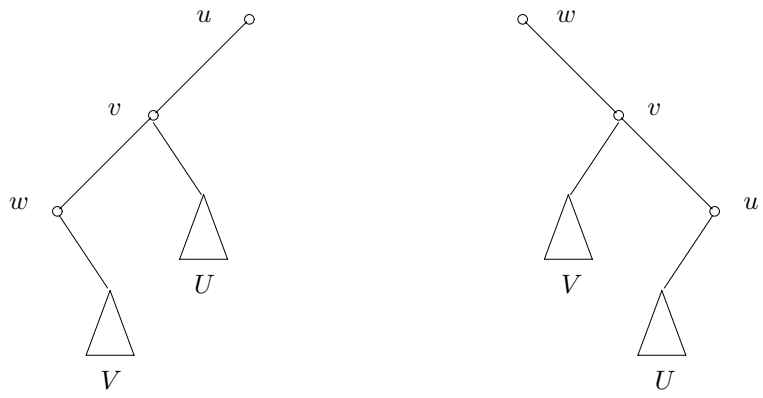
$\frac{a}{d}$, owing to the creation of the black node, and w' can afford to transfer two sets of $\frac{a}{2d}$ units of j'-potential to the new black node (one set for itself and one set for node w). (See Figure 11 for an example.)

We summarize the above discussion. The rotation of a couple costs $coup = s + 1 + ld + 2hd$ units. Suppose the bottom node of the couple is l-active; then these *coup* units are paid for by one of $\frac{a}{d}$ units of l-potential, $\frac{a}{2d}$ units of l-black potential, or the $\frac{d \cdot s'}{2}$ l-spares. While if the l-active node was not involved in a rotation with another global node of the lazy tree, the $\frac{d \cdot s'}{2}$ l-spares may have to provide it with $\frac{a}{d}$ units of potential. So it suffices to have

$$\frac{d \cdot s'}{2} \geq \max\left\{(s + 1 + ld + 2hd), \frac{a}{d}\right\}, \tag{13}$$

$$\frac{a}{2d} \geq s + 1 + ld + 2hd. \tag{14}$$

We turn to the analysis of left path traversals.



Actual situation v, u rotated onto right path

FIG. 12. *Left path traversals.*

Consider a couple, w, v, on the left path, with v the parent of w; let u be the parent of v (see Figure 12). If nodes u and v were on the right path, then subtree U (resp., V) would be the left subtree of u (resp., v). We treat the rotation of couple w, v on the left path as if it were the rotation of couple u, v on the right path. We pay for the rotation between v and w using w's present $\frac{a}{2d}$ units of l-black potential, where w is l-active (note that the present potentials of v and w correspond respectively to those v and u would have if on the right path). Then w and v swap potentials; v and all the nodes in its right subtree reduce their black spans accordingly. Invariants 8–10 continue to hold, as can be seen by arguments similar to those used for the right path traversal.

Remark 3. A left path traversal itself does not cause the spending of any spares, for all the rotations on the left path involving two heavy nodes of the lazy tree (which are the only rotations to spend spares) are paid for by black potentials.

We can conclude (as asserted in the second paragraph of section 3) the following.

LEMMA 7. *For each of the first $e-1$ local insertions in a block's insertion, for each couple, s spares can be provided to the couple.*

In a later paper we will again use lazy trees generalized in various ways. However, the nodes of the lazy trees in the later paper will still have small, large, and lazy debits which obey the present invariants, namely Invariants 1–7. Other additional debits may be present. They will satisfy the following invariant.

INVARIANT 11. *Let light node v carry an additional debit. Then*

(i) *v is not on the left path of the lazy tree;*

(ii) *if v is on the right path of the lazy tree, then so are its parent and right child in the splay tree.*

This invariant meets condition (i) of Remark 1; so long as condition (ii) is also met, the analysis of the traversal of extreme paths of the lazy trees is unaffected. But the presence of new debits, of value ed, say, merely raises the cost of a couple by at most $2ed$. It is convenient to let

$$md = \max\{ed, hd\}. \tag{15}$$

The new debits can be handled in the present analysis by modifying (9), (10), (13), and (14) so as to pay for the removal of up to two debits of value ed from each couple being analyzed, yielding

$$c' \geq s + 1 + 2md, \tag{16}$$

$$hd \geq s + 1 + \max\{ld, 2sd, 2ed\}, \tag{17}$$

$$\frac{d \cdot s'}{2} \geq \max\left\{(s + 1 + \max\{ld, 2ed\} + 2hd), \frac{a}{d}\right\}, \tag{18}$$

$$\frac{a}{2d} \geq s + 1 + \max\{ld, 2ed\} + 2hd. \tag{19}$$

4.3. Splitting the lazy tree. A split of the lazy tree occurs when the inserted item lies in value between the left guard and the right guard in the lazy tree. A split can occur only during a global insertion, as we show next, for a split causes a zig-zag rotation within the lazy tree. However, in a local insertion the only zig-zag rotation involves the splay tree root; but the root is in the same block as the inserted item and hence is not yet part of any lazy tree.

For this section, we assume that each node belongs to at most one lazy tree, apart, possibly, from the sharing of guards. In section 4.5, we analyze the general case.

The split is analyzed in three parts. First, we show that if the lazy tree satisfies Invariant 12, below, then, by promoting appropriate nodes (i.e., restoring their global potentials), the lazy tree is split into several new lazy trees which all also satisfy Invariant 12. In addition, the promotions cost at most $4gp \cdot logn$ units of potential. Second, we show that the cost of removing debits so as to restore all the invariants concerning debits can be charged to the promoted nodes at no further cost. Third, we show how to create the lazy tree potential for each new lazy tree from the corresponding potential for the lazy tree prior to the split.

In order to permit more general accesses in Part II of this paper, we show how to analyze a split when a local item in a block is accessed as well as when a global item is accessed. The goal, when a local item e is accessed, is to remove e's block from the lazy tree so that it becomes a normal block.

4.3.1. The promotions. At this point it is helpful to mention a few properties of the lazy and reserve potentials. Consider the heavy nodes in a new lazy tree. Let SL be the set of global nodes contained strictly between the guards of a lazy tree. For each heavy node, u, in the lazy tree, define its right neighbor $r\_n(u)$ to be the heavy node immediately to its right in the large lazy block tree, and define $SL(u)$ to comprise the subset of SL strictly to the left of u. Finally, define the lazy rank of heavy node v to be $\frac{1}{gp}$ times its lazy potential.

INVARIANT 12. *Let v be a heavy node in the normal form of the lazy block tree for lazy tree L. Then*

(i) $lazy\_\text{rank}(v) \geq \lfloor \log(wt(SL(v)) \rfloor$;

(ii) *if, in the normal form of the large lazy block tree, v has no heavy node or guard in its right subtree, $lazy\_\text{rank}(v) + 1/gp \cdot reserve(v) \geq g\_\text{rank}(v)$, while if v does have a heavy node or guard in its right subtree, then $lazy\_\text{rank}(v) + 1/gp \cdot reserve(v) \geq lazy\_\text{rank}(r\_n(v))$.*

Invariant 12 can be seen to hold when the lazy tree is created by considering node v at the point at which it becomes lazy. Also, it is readily seen that this invariant continues to hold following traversals of the extreme paths (for they leave the lazy rank of nodes in the normal form of the lazy tree unchanged).

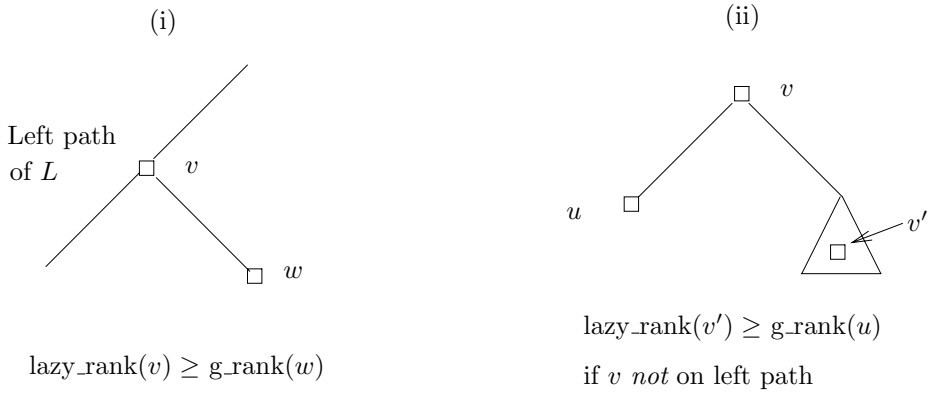


FIG. 13. *Heavy nodes.*

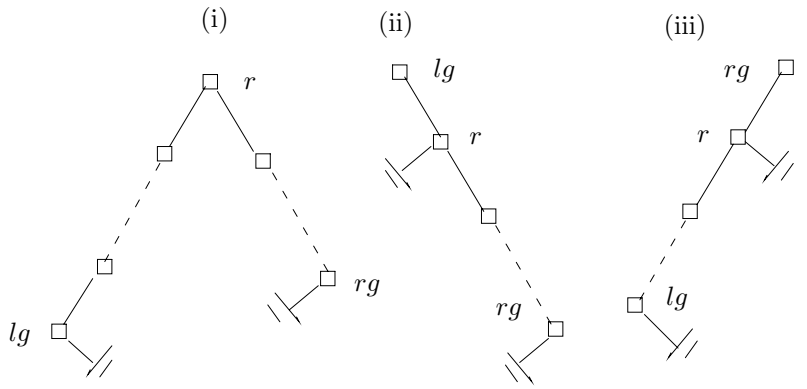

FIG. 14. *The large lazy block tree.*

COROLLARY 8. *See Figure* 13. *Let v be a heavy node other than the root in lazy tree L. Let w be v's right child and u be v's left child.*

(i) *Suppose that v is on the left path of L; then* $lazy\_\mathrm{rank}(v) \geq g\_\mathrm{rank}(w)$.

(ii) *Suppose that v is not on the left path of L. Let v' be a right descendant of v, not necessarily proper. If v' is a heavy node,* $lazy\_\mathrm{rank}(v') \geq g\_\mathrm{rank}(u)$.

It is convenient to define v's *lazy weight* to be $wt(SL(v))$.

The analysis is simplified by, on occasion, modifying the guards of a lazy tree following a traversal of one of its extreme paths. Specifically, we maintain the following invariant.

INVARIANT 13. *See Figure* 14.

Consider a lazy tree L. Let r denote the root of the truncated lazy block tree, and let lg and rg denote, respectively, the left and right guards of L. The large lazy block tree has one of the following three forms.

(i) *r is the root, and the left subtree of rg is empty, as is the right subtree of lg.*

(ii) *lg is the root of the large lazy block tree. Then r is the right child of lg, and r has an empty left subtree, as does rg.*

(iii) *rg is the root of the large lazy block tree. Then r is the left child of rg, and*

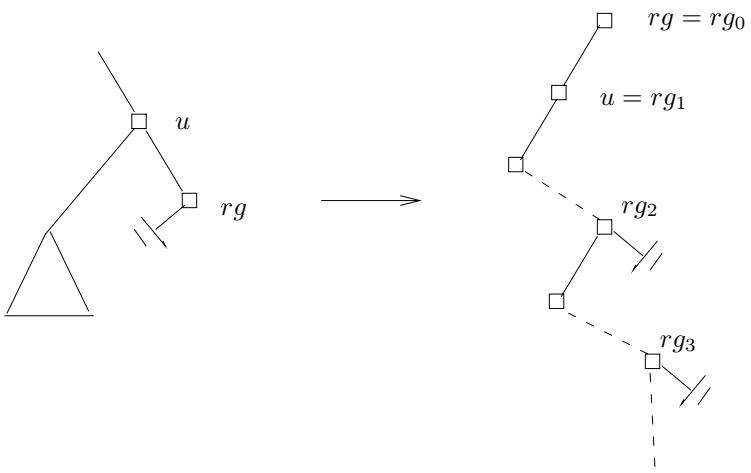

FIG. 15. *The right guard restoration process.*

r has an empty right subtree, as does lg.

Now, we show how to restore Invariant 13 following a traversal of an extreme path. Invariant 13 can cease to hold only if there is a couple containing a guard or the root of the lazy tree and a heavy node. So first consider a couple comprising a heavy node u on the right path and rg (see Figure 15). Following the rotation, let $rg_0 = rg$, and let rg_{i+1} be the rightmost node in the left subtree of rg_i in the large lazy block tree, if this subtree is not empty. This defines a nonempty sequence of nodes $rg_1, \ldots, rg_k$; all these nodes are promoted (i.e., they have their global potential restored) by adding their reserve potential to their lazy potential (this suffices by Invariant 12(ii)). rg_k becomes the new right guard for the remaining lazy tree rooted at r. This is called the *right guard restoration process* applied to rg.

Second, consider a rotation between lg and heavy node u on the left path. Let v be the parent of u in the large lazy block tree. Following the rotation, $lazy\_\text{rank}(u) \geq g\_\text{rank}(u)$ (for by Invariant 12(i), $lazy\_\text{rank}(u) \geq \lfloor \log(wt(SL(v))) \rfloor$—remember the lemma applies to the normal form of the lazy tree). In addition, following the rotation, u has an empty left subtree in the large lazy block tree (since lg had an empty right subtree before the rotation). So u is made the root of a new lazy tree, with left guard lg; temporarily, its right guard, rg_{new}, is the rightmost node in its right subtree in the large lazy block tree; rg_{new} acquires its global potential by adding its reserve potential to its lazy potential (by Invariant 12(ii), this suffices). See Figure 16. rg_{new} also becomes the left guard for the remainder of the lazy tree rooted at r. Then the right guard restoration process is applied to rg_{new} to obtain the actual new right guard for the new lazy tree rooted at u. There is one special case: u has an empty right subtree; then u simply becomes the root of a normal block and r acquires u as its new left guard. This is called the *left guard restoration process* applied to u.

Third, consider case (ii) of Invariant 13; suppose there is a rotation between r and its right child, u, a heavy node (see Figure 17). Then, following the rotation, the left guard restoration process is applied to r, which is now the left child of u, the new root of the lazy tree. Fourth, consider case (iii) of Invariant 13; suppose there is a rotation between r and its left child, u, a heavy node (see Figure 18). Then, following

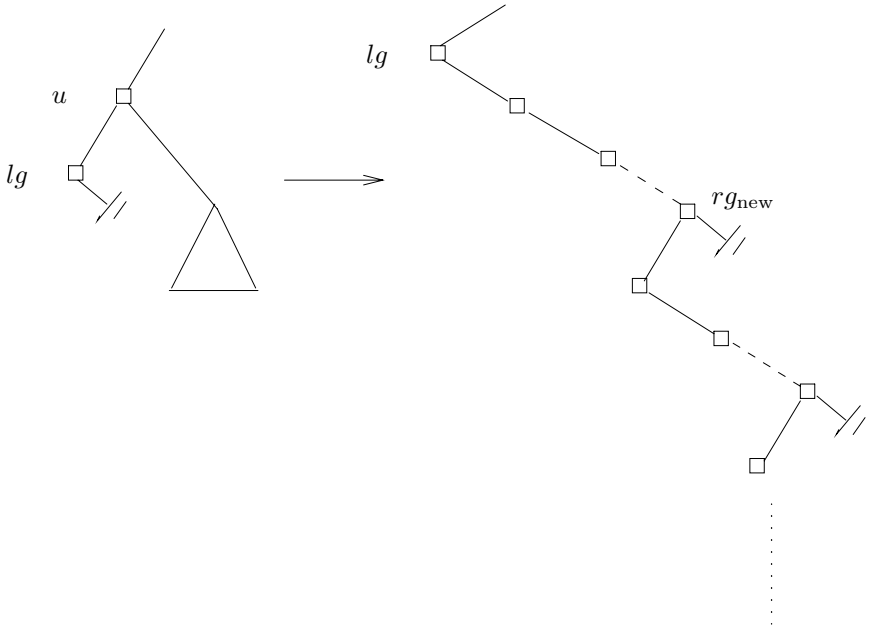

FIG. 16. *The left guard restoration process.*

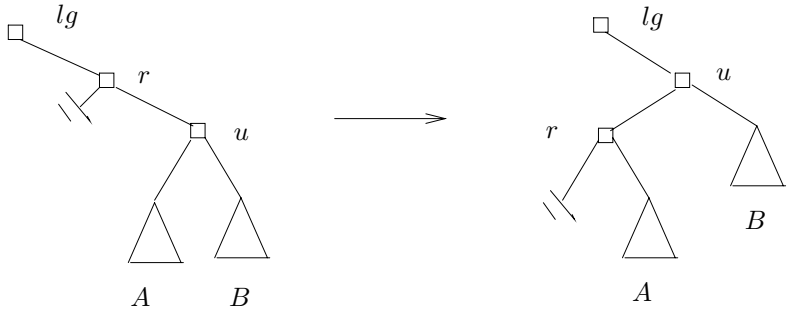

FIG. 17. *Guard restoration for a root and right child couple.*

the rotation, the right guard restoration process is applied to rg.

It remains to discuss how to maintain Invariants 1–10. We explain how to do this later in the section, when we show how to maintain these invariants following a split operation.

We view a split as occurring in three phases. In phase 1 no rotations are performed, but certain heavy nodes are marked as *promoted* (a node is promoted by increasing its lazy potential to its global potential). In fact the nodes are not promoted yet, but the splay will proceed as if they had been promoted. The effect of the promotions is to partition the original lazy tree into several new lazy trees. Phase 3 pays for these promotions. This ensures that in phase 2, the actual splay, only extreme paths of lazy trees are traversed. However, there will be one difference in paying for phase 2 as compared to the previous traversals. Any (apparently) promoted node

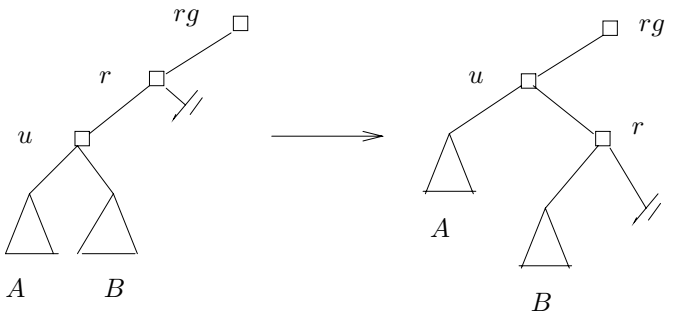

FIG. 18. *Guard restoration for a root and left child couple.*

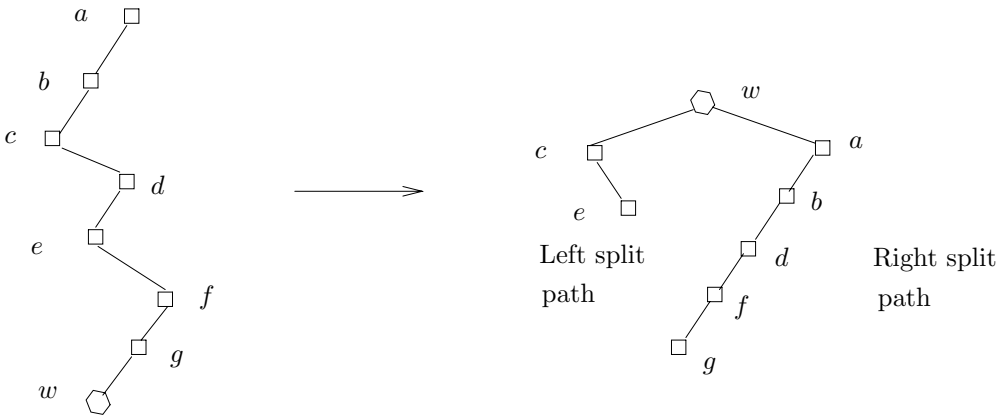

FIG. 19. *The split paths.*

whose global rank drops during the splay does not use gp units of its global potential to pay for the associated segment, for it does not yet have its global potential; instead paying for the segment becomes a charge to be paid for by the promotion (a charge of at most gp units). It is called the *segment charge*; the segment charge is paid for directly by the promoted vertex. Phase 3 pays for the remaining costs of the promotions, at most $4gp \log n$ units.

Phase 3 uses the following *imaginary* tree. Consider performing all the zig-zag operations of the insertion but replacing each of the zig-zig operations by two single rotations performed in bottom to top order. This creates two paths, called *split paths*, descending from the inserted item, the root of the imaginary tree; one path, the *left split path*, to the left of the root, descends to the right, and the other path, the *right split path*, to the right of the root, descends to the left (see Figure 19). The items on the split paths are exactly the items that will be traversed in the splay operation. We provide each global node on the split paths with an *imaginary* global rank, namely the global rank it has in the imaginary tree. The global ranks of the other global nodes are the same in the imaginary tree and the actual tree. Each of the split paths is traversed from bottom to top; for each global node at which there is a jump in imaginary global rank, denoted $jump(v)$, the following potential is provided:

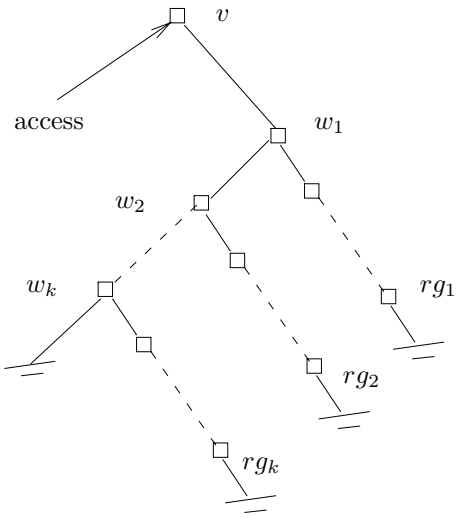

FIG. 20. *Right offset promotions for v.*

$2gp \cdot jump(v)$. The following corollary is helpful.

COROLLARY 9. *Let v be a heavy node in lazy tree L. Suppose that L is split.*

(i) *Also, suppose that v is on the left path of L and is also on the left split path. Then $lazy\_\text{rank}(v) + jump(v) \geq g\_\text{rank}(v)$.*

(ii) *Alternatively, suppose that v is not on the left path of L and is on the right split path. Let v' be a heavy node which is a right descendant of v, not necessarily proper. Then $lazy\_\text{rank}(v') + jump(v) \geq g\_\text{rank}(v)$.*

Proof. We prove (i); the proof of (ii) is very similar. Let w be v's right child in L (if w is not present, define $g\_\text{rank}(w) = 0$). Also, let w' be v's right child in the imaginary tree (again, if w' is not present, define $g\_\text{rank}(w') = 0$). Then, by Corollary 8(i), $lazy\_\text{rank}(v) \geq g\_\text{rank}(w)$. Now w' must be a descendant of w, so $g\_\text{rank}(w) \geq g\_\text{rank}(w')$. Finally, $jump(v) = g\_\text{rank}(v) - g\_\text{rank}(w')$. So $lazy\_\text{rank}(v) + jump(v) \geq g\_\text{rank}(w') + jump(v) = g\_\text{rank}(v)$. □

We now discuss which nodes are promoted in a split and how this is paid for. There are a number of cases.

Case 1. v is a heavy node in the lazy block tree, which is not on the left extreme path. In addition, v is accessed from its left child, u.

Then v is promoted. v's promotion costs at most $gp \cdot jump(v)$ (apply Corollary 9(ii)).

Let w_1 be v's right child, if any, in the lazy block tree, and let $w_2, w_3, \ldots, w_k$ be the maximal left path descending from w_1 in the lazy block tree (see Figure 20). $w_1, w_2, \ldots, w_k$ are also promoted. Between them, these promotions cost at most $gp \cdot jump(v)$. For, by Corollary 8(ii), $lazy\_\text{rank}(w_i) \geq g\_\text{rank}(w_{i+1})$, for $1 \leq i < k$. In addition, $lazy\_\text{rank}(w_k) + jump(v) \geq g\_\text{rank}(v)$ (by Corollary 9(ii)), and $g\_\text{rank}(v) \geq g\_\text{rank}(w_1)$. The nodes w_i become the roots of new lazy trees. Let rg_i be the rightmost node in the subtree of the old lazy block tree rooted at w_i for $1 \leq i < k$. Temporarily, rg_i is made the right guard for w_i. rg_i is promoted; this is paid for by its reserve potential (for note that rg_i has an empty right subtree in the large lazy block tree and apply Invariant 12(ii)). Then the right guard restoration

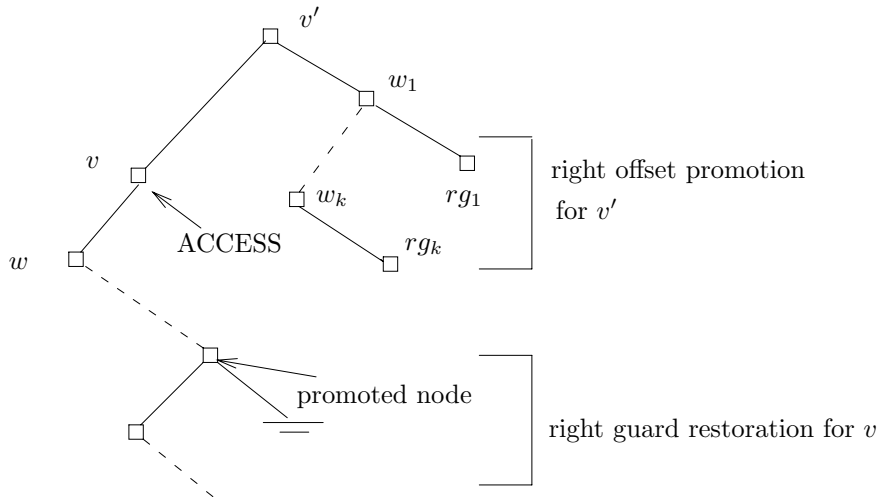

FIG. 21. *Promotions in Case* 2.

process is applied to rg_i for $1 \leq i \leq k$. Also, rg_{i+1} becomes the left guard for the new lazy tree rooted at w_i for $1 \leq i < k$; the tree rooted at w_k uses v as its left guard. If $rg_i = w_i$, for some i, the new lazy tree rooted at w_i comprises only one block; so it is treated as an ordinary block henceforth. We call the promotions described in this paragraph the *right offset promotions* for v.

So Case 1 occasions charges of $2gp \cdot jump(v)$. Recall that v is a node on the right split path.

Case 1.1. v' is a light node which is not on the left extreme path. In addition, v' is accessed from its left child, which is not in the lazy tree.

The right offset promotions for v' are performed (where w_1 is now defined to be the nearest heavy descendant of v'). Let v be the root of the block containing v'. As we will see, v is promoted in Case 2 or Case 3. Thus the cost of Case 1.1 is at most $gp \cdot jump(v)$.

Case 2. v is a heavy node on the left extreme path and it is accessed from its right child, u.

Then v is promoted. v becomes the root of a new lazy tree. v's promotion costs at most $gp \cdot jump(v)$ (apply Corollary 9(i)).

We need to provide a new left guard for the remaining portion of the old lazy tree (see Figure 21.) Let v' be v's parent in the lazy block tree. We perform the right offset promotions for v'. In addition, if v' is not the root of the lazy tree, v' is promoted. v' becomes the root of an ordinary block. If v' is not the root of the lazy tree, rg_1 becomes the left guard for the remainder of the old lazy tree, while if v' was the root, then rg_1 did not need promoting as it was already the right guard of the lazy tree. In the imaginary tree, v''s lazy weight is at least its normal weight; so its promotion comes for free. As in Case 1, $gp \cdot jump(v')$ suffices to pay for the right offset promotions.

The promotion of v' and the associated right offset promotions are also performed if just the left guard, lg, is separated from the remainder of the lazy tree (through being accessed from its right child), and then v' is defined to be the leftmost node in the lazy block tree (note v' will be traversed in the access). This applies even if lg is

the root of the large lazy tree.

We need to provide the new lazy tree rooted at v with a right guard. So let x be the rightmost heavy node in v's lazy tree which is a right descendant of v in the imaginary tree (possibly $x = v$). There are two possibilities to consider.

(i) $x \neq v$. Temporarily, x becomes the right guard for the new lazy tree rooted at v. In the imaginary tree, x's right subtree contains no nodes from its large lazy block tree. So by Invariant 12(ii), the lazy potential for x plus its reserve potential is at least its global potential; thus the promotion can be paid for at no extra charge. Now, the right guard restoration process is applied to x. This has zero amortized cost.

(ii) $x = v$. Let w be v's left child in its new lazy block tree (if v does not have such a child, then the new lazy tree rooted at v comprises only one node and can be treated as an ordinary block henceforth). w is promoted, becoming the root of a new lazy tree while v becomes its right guard. Next, if w's right subtree in the large lazy block tree is nonempty, the right guard restoration process is applied to v. w's promotion is paid for as follows. w adds its reserve potential to its lazy potential; w's modified lazy potential is at least gp times the global rank of v's right child in the imaginary tree (for by Invariant 12(ii), this modified lazy potential is at least $gp \cdot lazy\_\mathrm{rank}(r\_n(v))$ and $r\_n(v)$ must be to the right of the accessed item (as $x = v$); so $lazy\_weight(r\_n(v))$ includes the weight of all of v's right subtree in the imaginary tree; now recall that $lazy\_\mathrm{rank}(r\_n(v)) \geq \log lazy\_weight(r\_n(v))$). Hence $gp \cdot jump(v)$ suffices to pay for this promotion.

Overall, Case 2 occasions a charge of $2gp \cdot jump(v) + gp \cdot jump(v')$. Note that v is on the left split path and v' is on the right split path.

Case 2.1. $\tilde{v}$ is a light node on the left extreme path; it is accessed from its right child, which is not in the lazy tree.

Let v' be the nearest heavy ancestor of v in the lazy tree. v' is treated as in Case 2. Let v be the nearest heavy descendant of $\tilde{v}$ on the left extreme path. v is promoted. v's promotion costs at most $gp \cdot jump(\tilde{v})$ (strictly speaking $jump(\tilde{v})$ was not defined; it is the jump in g_rank on accessing node $\tilde{v}$), which is at least $g\_\mathrm{rank}(v)$. As in Case 2, we need to provide the new lazy tree rooted at v with a right guard. This is handled as in Case 2.

Hence, overall, Case 2.1 occasions a charge of $2gp \cdot jump(\tilde{v}) + gp \cdot jump(v')$. Note that v is on the left split path and v' is on the right split path.

Case 3. The inserted item is to the right of the lazy tree root, r.

Then we need to provide the new lazy tree rooted at r with a new right guard. The method followed is identical to that used in Case 2 for providing the new lazy tree rooted at v with a right guard. So Case 3 occasions a charge of $gp \cdot jump(r)$. Note that r is on the left split path. These promotions are performed even if only the right guard, rg, in the lazy tree is separated from the rest of the lazy tree (through being accessed from its left child). This applies even if rg is the root of the large lazy tree.

LEMMA 10. *The promotions in a global insertion cost at most* $4gp \log n$ *units, where for each split lazy tree there is a charge of* $2gp$ *times the increase in global rank along the right split path and of* $2gp$ *times the increase in global rank along the left split path.*

Proof. Charges of up to $2gp \cdot jump(v)$ arise for nodes on the split paths in Cases 1–3 above. Specifically, in Case 1, there is a charge of $2gp \cdot jump(v)$ for node v on the right split path. In Case 1.1, there is a charge of $gp \cdot jump(v)$ for node v on the left split path. In Case 2 there is a charge of $2gp \cdot jump(v)$ for a node v on the left split

path and a charge of $gp \cdot jump(v')$ for a node v' on the right split path; further v' is not charged in Case 1. v may be the node from Case 1.1, but then Case 2(ii) applies and v is only charged $gp \cdot jump(v)$ for Case 2(ii), giving a total charge of $2gp \cdot jump(v)$ for node v. In Case 2.1 there is a charge of $2gp \cdot jump(\tilde{v})$ for $\tilde{v}$, a light node on the left access path; $\tilde{v}$ is not charged in any other case. Finally, in Case 3, there is a charge of $gp \cdot jump(r)$. These are the only charges that occur. □

The following properties of the new lazy trees are helpful; they are readily confirmed by inspection of the split procedure.

PROPERTY 1. *The left path of each lazy tree created by the split has one of the following two forms:*

(i) *It is a subpath (possibly complete) of the left path of the lazy tree before the split.*

(ii) *It comprises light nodes from just one block.*

PROPERTY 2. *The number of promoted nodes from each old lazy tree L is at least the number of lazy trees into which L is split.*

4.3.2. Debits and their invariants. We need to consider the effect of the split and (from the beginning of section 4.3) of the updates to the guards on Invariants 1–4 and 6–7. We show how to reestablish these invariants by removing debits on the extreme paths of the new lazy trees and on the left and right paths of blocks whose roots cease to be part of the lazy tree.

INVARIANT 1. *The small or large debit, if any, is removed from each promoted node. This is charged to the promoted node. Also, each light node that ceases to be an extreme path node, and hence also ceases to be on a lazy tree, pays for the removal of its small or large debit, if any.*

INVARIANT 2. *For each promoted node, the large debits, if any, are removed from its parent and child (if any) on the extreme path. This is charged to the promoted node. (Note that the reestablishment of Invariant* 1 *has already removed the large debit, if any, from itself.)*

INVARIANT 3. *The small debit, if any, is removed from each extreme path node. This is charged to the promoted node.*

INVARIANT 4. *For each promoted node u, the small debits, if any, are removed from the corresponding nodes w, if present. This is charged to the promoted node.*

Note that reestablishing Invariants 1–4 requires each promoted node to pay for the removal of at most two large debits and three small debits, or one large and four small debits, or six small debits. The maximum charge is achieved with two large and three small debits.

INVARIANT 6. *The lazy debit, if any, is removed from each light node whose block is no longer part of a lazy tree. This includes those light nodes whose block roots become guards for a new lazy tree. We call such blocks* ordinary blocks. *This is charged to the node itself. For each block that becomes the leftmost block in a new lazy tree we reduce the potential of each light node from $2c'$ to c'. This pays for the removal of lazy debits from these nodes. Any other light node on a new left path must have been on the old left path and so already satisfied the invariant.*

INVARIANT 7. *Any node violating Invariant* 7 *must be on a new right path. There are three ways for a light node x on a new right path to still violate Invariant* 7.

Case 1. See Figure 22. x is adjacent to node y in block, B_y, where B_y either has become the leftmost block in a new lazy tree or has become an ordinary block. The removal of x's lazy debit is charged to node y.

Case 2. x's right child is in the same lazy tree but is heavy. Let z be the root

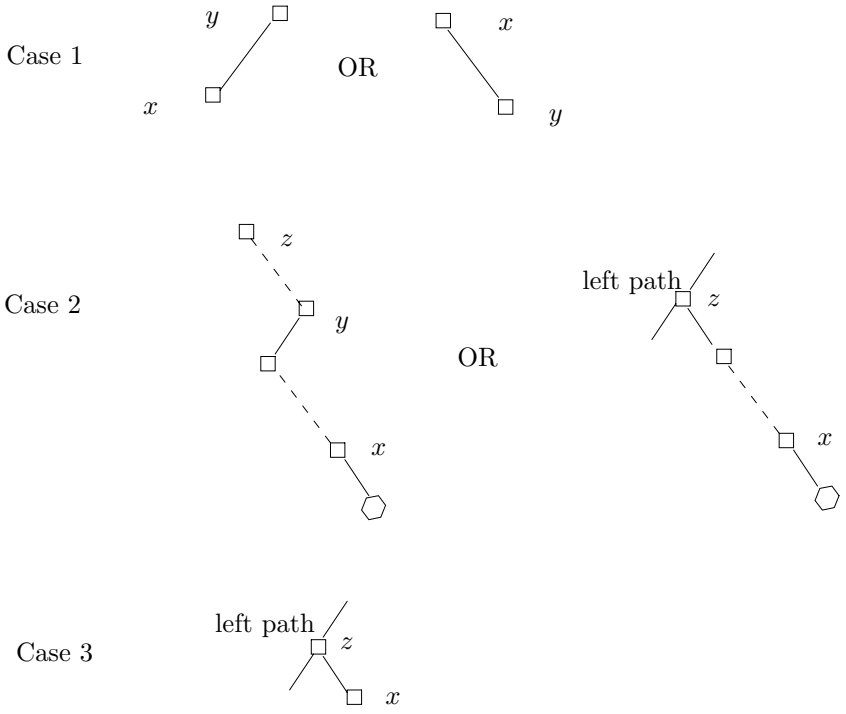

FIG. 22. *Invariant* 7.

of x's block (z is a heavy node also). Let y be the nearest right ancestor of x. If y is between x and z, y must be in a block, B_y, where B_y either has become the leftmost block in a new lazy tree or has become an ordinary block (this follows from Property 1). In addition, for each such node y, there is at most one node x of Case 2, namely the first node, on the right path descending from y's left child, to have a heavy child. The removal of x's lazy debit is charged to node y.

If z had not been on the left extreme path of the lazy tree prior to the split, then there is such a node y, for if not, prior to the split, x would have been on the right path descending from z, and by Invariant 7, would not be carrying a lazy debit.

So if there was no such node y, then z had been on the left path of the lazy tree prior to the split and x was on the right path descending from z in the splay tree. Also, z must be the promoted root of x's new lazy tree. In this case, the removal of x's lazy debit is charged to z.

Note that a promoted node may be charged for the removal of three lazy debits (as node y) or one lazy debit (as node z) but not both.

Case 3. x is the right child of its parent z, which was on the left path of the lazy tree prior to the split. Then z pays for the removal of the lazy debit from x. So z may have to pay for the removal of up to two lazy debits (the first such debit was removed in Case 2).

LEMMA 11. *Following a split, Invariants* 1–4 *and* 6–7 *concerning the debits can be restored provided the following two equations hold:*

$$c' \geq \max\{4hd, ld + 3hd\} = 4hd, \tag{20}$$

$$b \geq 3hd + 2ld + 3sd + gp. \tag{21}$$

Proof. Each light node in a new leftmost or ordinary block is charged for the removal of at most four lazy debits (from itself and the nodes for which it restored Invariant 7) or one small or large debit and three lazy debits (removed from the same nodes). This is charged to the reduction of at least c' in the node's potential. (Recall that each light node in a leftmost block has potential c' and all other light nodes have potential $2c'$.) So it suffices to have (20) hold.

Each promoted heavy node is charged for the removal of at most three lazy debits (from the nodes for which it restored Invariant 7), three small debits and two large debits; it may also have to pay a segment charge. (For the split is the result of a global insertion. Also see (3) and the paragraph preceding (3).) These costs are charged to the promoted node's potential of b units (which it received as a heavy node when its lazy tree was created). So it suffices to have (21) hold. □

4.3.3. Recreating the lazy complete tree potential. We continue by showing how to reestablish Invariants 8–10. To restore Invariant 8, we proceed essentially as in the original creation of active layers. Let h be the maximum creation_height of any node in the normal form of the new lazy tree rooted at u, apart from its root (the creation_heights are those defined with respect to the original tree; they are not redefined with respect to the new lazy tree). Suppose there is no l-active node for some $l \leq h$. Then, in the corresponding normal tree, the lowest node v on the right path whose span includes l becomes l-active (these new active layers are then translated back into the lazy tree at hand). Below, we show that Invariants 8–10 hold once more (incidentally, this implicitly shows that the rule for creating new l-active nodes is well defined).

Clearly Invariant 10 still holds, for if $d_l(v)$ increases, $id_l(v)$ is reduced by an equal amount. Next we consider Invariant 9. In each new lazy tree the black status of the nodes is unchanged; also, by Property 1, the heavy nodes on the new left paths were also previously on left paths. So Invariant 9 still holds.

Next, we show Invariant 8 is reestablished by the creation of new active layers. First, we consider the situation prior to the creation of new active layers. Clearly, Invariant 8 (iii) and (v) still hold; (iv) holds likewise, since the symmetric order of the nodes in the normal form of each new lazy tree is unchanged. We note that each new lazy tree has a span of active layers, possibly empty, of the form $(i, h]$, $0 \leq i \leq h$, where h is the largest creation_height (as provided initially) of any node in the normal form of the new lazy tree, apart from the root. By Invariant 8 (v), (iii), and (iv), the right path in each new normal lazy tree, from top to bottom, contains a sequence, possibly empty, of active nodes with decreasing creation_heights. It is now readily seen that the rule for creating new active layers restores Invariant 8(i)–(ii).

4.3.4. The invariants defined for the split operation. We note that the split operation has been defined so as to maintain Invariant 13. It remains to consider the effect of the split on Invariant 12; but the only effect of a split is to reduce the size and hence weight of a lazy tree; so this Invariant also continues to hold.

4.3.5. Summary and generalization. We have shown (see Lemma 10 and (5)) the following lemma.

LEMMA 12. *The cost of a global access is at most* $e \cdot (3 \log n + 1)gp + 5 \log n \cdot gp$ *units.*

In a later paper we will again use lazy trees which will have heavy and light nodes. The heavy nodes will have the same lazy and reserve potentials as here. It is useful

to summarize and slightly generalize the results of this section.

As already noted, the nodes of the lazy trees in the later paper will still have small, large, and lazy debits which obey the present invariants, namely Invariants 1–4 and 6–7. Other additional debits satisfying Invariant 11 may be present. We need to show how to maintain this invariant following a lazy tree split. It is readily seen that the method for restoring the invariants concerning lazy debits suffice to restore this invariant also, so it suffices to replace hd by md in (20) and (21), yielding

$$c' \geq \max\{4md, ld + 3md\} = 4md, \tag{22}$$

$$b \geq 3md + 2ld + 3sd + gp. \tag{23}$$

The debits may be restricted beyond the invariants of this paper, so long as these new constraints satisfy the following property.

PROPERTY 3. *The restoration of any further invariant concerning the debits requires the removal of at most α additional debits from each lazy tree created by the split, α a constant.*

By Property 2 there are at least as many promoted nodes as there are lazy trees created by the split. Thus the sets of α additional debits can be charged α to each promoted node. Modifying (23) as follows,

$$b \geq 3md + 2ld + 3sd + gp + \alpha \cdot md, \tag{24}$$

suffices to ensure all the invariants can be restored.

We have shown the following lemma.

LEMMA 13. *If a lazy tree comprises light and heavy nodes where the heavy nodes carry lazy potentials as specified in Invariant* 12*, then each lazy tree resulting from a split satisfies the following:*

(i) *Invariant* 12;

(ii) *If the nodes on its left path are new to a left path, then they are all light nodes in the same block; and*

(iii) *Assuming the debits obey Invariants* 1–4 *and* 6–7*, and* 11*, and assuming* (22) *and* (24) *hold, then these invariants can be restored following a split.*

Clearly, we also need the following.

PROPERTY 4. *The potential must be partitionable following a split; i.e., each lazy tree created by the split must be provided with an appropriate potential (e.g., a lazy complete tree potential).*

4.4. Lazy trees and local accesses. We need to reconsider the analysis of local accesses to take the presence of lazy trees into account (see Remark 2). Note that in such an access only the left paths of lazy trees can be traversed. In fact, only two modifications are needed. First, we need to consider couples comprising two heavy nodes. But these are analyzed as in a global insertion: They have $0 \leq s + 1$ amortized cost, for as noted in Remark 3, no spares are spent on paying for changes to the j-potentials and/or j-black potentials. Second, we may need to modify the guards of some lazy trees so as to maintain Invariant 13. This would result in the left guard restoration process being applied, which, as in section 4.3, does not occasion a change to the analysis of the insert operation. So the results of Lemma 6 continue to apply.

4.5. Multiple level lazy trees. It is convenient to refer to the lazy trees encountered so far in the paper as *right lazy trees*. Analogous lazy trees, called *left*

lazy trees, in which the roles of left and right are interchanged are considered in this section. While they are not needed to prove the result of this paper, they lead to a more general result in this section, without adding significantly to the complexity of the current section.

Because a local access path may include nodes of a current lazy tree we may seek to make the root of a lazy tree a heavy node carrying a lazy potential in a new lazy tree. We therefore generalize the form of the lazy trees. Now, a "block," or rather metablock, in a lazy tree may itself be another lazy tree.

In order to distinguish the ages of the different lazy trees, we number the blocks, in insertion order, by $1, 2, \ldots$. A lazy tree is labeled by the number of its corresponding creating block. When a lazy tree is split its parts keep the same age label.

Let L be a lazy tree; its skeleton plus its lazy block tree comprise the nodes on L. The nodes on L are also said to *belong* to L. A node may be on an extreme path of several lazy trees. For each lazy tree to which a node belongs it carries a separate potential. However, a node may carry only one debit, as before. Invariants 1–4 and 6–7 should be interpreted with respect to the newest lazy tree to which the node carrying the debit belongs.

We define a new lazy tree, L_{new}, to *contain* an old lazy tree, L_{old}, if the root, r, of L_{old} is on L_{new}. We write $L_{old} \subset L_{new}$. If there is no tree L_{mid} with $L_{old} \subset L_{mid} \subset L_{new}$, then L_{old} is treated as a metablock of L_{new}. The root of L_{old} is treated as the root of this metablock; the root of L_{old} is a heavy node on L_{new}. All other nodes on L_{old} are light nodes of this metablock, unless they are not even on L_{new}. This matters when defining the potentials for nodes on L_{new}. Suppose that L_{old} is contained in L_{new}; then, apart perhaps for its root, any node on L_{old} that is also on L_{new} must be a light node on L_{new}; in fact, only the root and nodes on an extreme path of L_{old} can be on L_{new}, but it need not be the case that even all these nodes are on L_{new}.

In addition, each guard of a lazy tree may be the root of another lazy tree, rather than being the root of a block. More precisely, suppose that g is the right (resp., left) guard for lazy tree L on creation of L, and L_{old} is the newest lazy tree rooted at g at this time (L_{old} is older than L). Then the root of L_{old} remains the right (resp., left) guard for L until one or both of L and L_{old} are split. Note that the root of L_{old} may at some point become the root of a newer lazy tree, L_{new}; however, the root of L_{new} does not take over the guard role for L.

In order to carry over the previous analysis of an extreme path traversal, we require the following properties concerning lazy trees to apply.

Requirement 1. Suppose u is traversed in the current insertion. Let L be the newest lazy tree to which u belongs.

(i) Let v be an ancestor of u on L. Then L is also the newest lazy tree to which v belongs.

(ii) u is either the root of L, or a heavy or light node of L; if a heavy node it carries a lazy potential defined with respect to L.

(iii) If u is a heavy node of an older lazy tree, then it is a light node of L.

Items (i) and (ii) enable the traversal of node u to be treated as part of the traversal of an extreme path of L; the previous analysis continues to apply. However, a new issue arises because u may also belong to older lazy trees. We maintain u's potentials with respect to each such lazy tree. Maintaining the l-potentials and l-black potentials might appear problematic, for it may involve the spending of k-spares, $k \geq 1$. But we note that each node, u, is heavy in at most one lazy tree,

and this is the only lazy tree with respect to which u carries l-potentials and l-black potentials and to whose heavy nodes it transfers spares (for in all newer lazy trees that contain u, u is light). So there is only one lazy tree with whose l-potentials and l-black potentials u is concerned, and this is the only lazy tree to which u contributes spares or from which u draws spares. Thus the l-potentials and l-black potentials can be maintained as before. Otherwise, the analysis of an extreme path traversal is unchanged, apart possibly for the removal of debits following the maintaining of Invariant 13. We discuss this at the same time as we show how to remove debits following the new split operation.

The following invariant characterizes the overlap of lazy trees.

INVARIANT 14.

(i) *Let L_a and L_b be two lazy trees of the same age. Then the two open intervals defined, respectively, by the guards of L_a and of L_b are disjoint.*

(ii) *Let L_{old} be a lazy tree and let r be its root. Let L_{new} be another, newer, lazy tree. Then the following hold:*

  (a) *If r lies strictly between the guards of L_{new}, then the guards of L_{old} lie between the guards of L_{new}. In addition, let u and v be the items in the large lazy block tree for L_{new} straddling r (r may or may not be an item in this large lazy block tree). Then L_{old} plus its guards lies between u and v. (Recall that the large lazy block tree for lazy tree L comprises the lazy block tree for L plus the guards for L.)*

  (b) *If r is strictly outside the closed interval defined by the guards of L_{new}, then the open intervals defined by the guards of L_{old} and L_{new}, respectively, are disjoint.*

  (c) *Suppose that r is the right (resp., left) guard for L_{new}. Let d_{new} be the rightmost (resp., leftmost) item in the lazy block tree for L_{new}. Then the left (resp., right) guard of L_{old} is either equal to or to the right (resp., left) of d_{new}.*

Thus, in some sense, an older lazy tree is either contained in a newer lazy tree or is disjoint from it. In the next two lemmas we show several consequences of this invariant.

LEMMA 14. *Requirement* 1(i) *holds.*

Proof. Let u and v be as in Requirement 1(i). Suppose that v belongs to lazy tree L_{new}, newer than L. Then L and L_{new} obey Invariant 14(ii)(a). By assumption, only an extreme path of L_{new} is traversed; so the inserted item lies outside the range spanned by the guards of L_{new}; without loss of generality, suppose that the inserted item is to the right of the right guard of L_{new}. By Invariant 14(ii)(a), all of L is to the left of L_{new}'s right guard; so the only items of L that are traversed must also be on L_{new}. □

LEMMA 15. *Let w be on lazy tree L_{old}. Suppose w is also on a newer lazy tree L_{new}. Then w is on an extreme path of L_{old}.*

Proof. Invariant 14(ii)(a) applies to L_{new} and L_{old}. Let u and v be the items of L_{new} straddling the root of L_{old}, as in the statement of the invariant. Since w is on L_{new}, w is on the path from u to v in the range (u, v) (if $u < v$) or (v, u) (if $v < u$). If w does not lie on an extreme path of L_{old}, then some item of L_{old} must lie outside the range (u, v) (or (v, u)), which contradicts Invariant 14(ii)(a). □

INVARIANT 15. *Let L be a lazy tree.*

(i) *The nodes of L, apart from its root, are all heavy or light on L.*

(ii) *Apart possibly from its root, all of L's heavy nodes carry their lazy potential.*

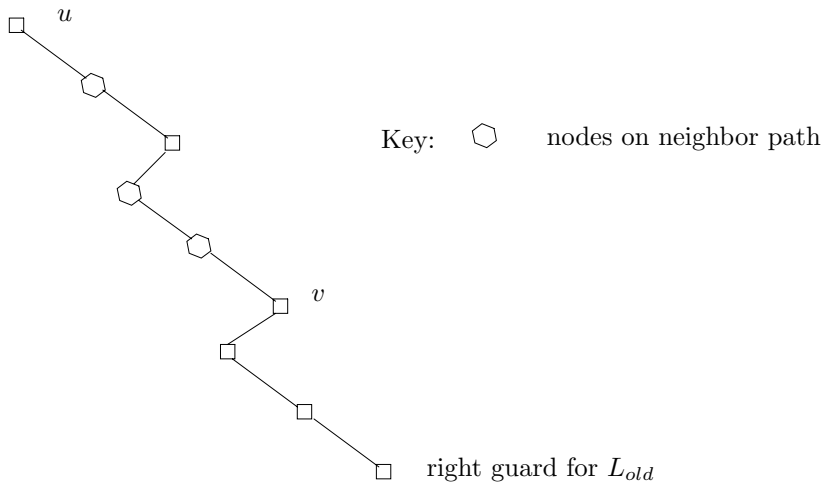

FIG. 23. *A (u, v)-neighbor path.*

(iii) *Each of L's light global nodes is a heavy node in some older lazy tree.*

(iv) *Each node, v, heavy on some lazy tree L, is a light node of all the newer lazy trees to which it belongs.*

Invariant 15 implies Requirement 1(ii) and 1(iii), above.

Before giving the next invariant, a few definitions are helpful. Let L be a lazy tree and let u be a node of its large lazy block tree. v is an *L-neighbor* of u if v is also a node of the large lazy block tree and u and v enclose no other node of the large lazy block tree. Suppose that u is an ancestor of its L-neighbor v; *the (u, v)-neighbor path* comprises those items on the path from u to v in the splay tree which are in the range (u, v), if $u < v$, or (v, u), if $v < u$.

INVARIANT 16. *See Figure* 23. *Let L be a lazy tree. Let u and v be L-neighbors, with u the ancestor of v. Let N denote the (u, v)-neighbor path. If N includes a global node, there is a lazy tree L_{old}, older than L, rooted at u, such that every node in N is on L_{old}. Further suppose that u is a left (resp., right) ancestor of v. Then the right (resp., left) guard for L_{old} is either v or a left (resp., right) descendant of v.*

By inspection plus induction, Invariants 14–16 are true on creation of a lazy tree L_{new}; also, they remain true as the extreme paths of the lazy trees are traversed.

We need to reconsider the analysis of splits. Again, in turn, we consider the promotions, the consequential removal of debits and the recreation of the complete lazy tree potential for the lazy trees created by the split. Actually, the arguments concerning Invariants 8–10 and 12–13 are unchanged from section 4.3 and so we will not discuss further the recreation of the complete lazy tree potential.

4.5.1. The promotions. For each split lazy tree, our goal in a split is to promote the same nodes as in section 4.3 (remember, this needs to be interpreted symmetrically for left lazy trees); however, this may prove too expensive because of the recursive containment of lazy trees. So, sometimes, instead of promoting a node v, heavy on lazy tree L, we will promote a node w which is light on L but heavy on an older lazy tree, and such that w is an ancestor of v.

We consider the promotions to be performed on one lazy tree at a time, oldest

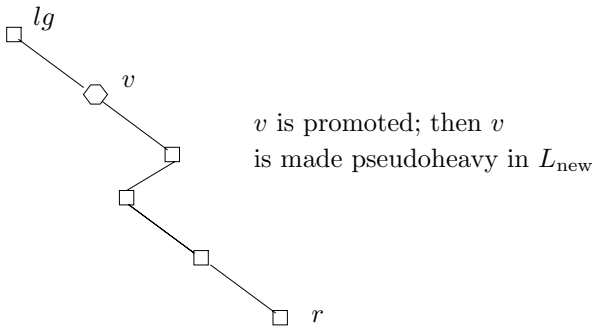

FIG. 24. *Pseudoheavy nodes.*

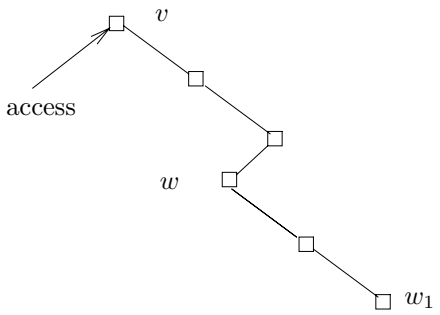

FIG. 25. *Case* 1′.

first. Invariants 14 and 15 are maintained but modified as follows.

Suppose the promotions have been applied to L_{old} but not to L_{new} (see Figure 24). All the promoted nodes which are on L_{new} are made into pseudoheavy nodes of L_{new}. In addition, let lg be the left guard of L_{new} and r its root. Suppose that lg is an ancestor of r. Let v be a node on the path from lg to r in the range (lg, r). If v is promoted, then v also becomes a pseudoheavy node of L_{new}. A similar rule applies with respect to the right guard of L_{new}.

INVARIANT 17. *Invariant* 14(ii)(a) *holds with respect to the heavy and pseudoheavy nodes of* L_{new}*, as do Invariants* 15(i) *and* 16.

Next, we explain how the previous promotion procedure is modified. Consider the promotions on right lazy tree L.

Case 1′. See Figure 25. v is a heavy node in the lazy block tree, which is not on the left extreme path. In addition, v is accessed from its left child, u.

v is promoted as in Case 1 of section 4.3. w_1 is defined as in this Case 1. The right offset promotions for v are performed exactly when no global node on the path from v to w_1, in the range (v, w_1) has been promoted. If such a node has been promoted, there will be one such node; let it be denoted w. Then w becomes a root of a lazy tree formed from L; its left subtree is empty and its right subtree contains exactly the heavy nodes of L in v's right subtree. v provides the left guard for this new lazy tree. The right guard for the lazy tree rooted at w is obtained in the same way as w_1's right guard in Case 1.

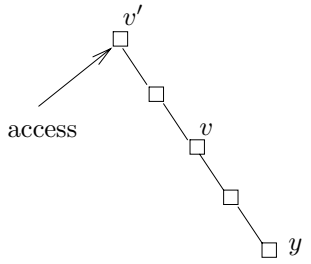

FIG. 26. *Case* 1.1′.

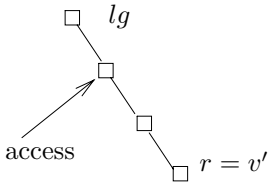

FIG. 27. *Separating the left guard.*

Case 1.1′. See Figure 26. v' is a light node of L, which is not on the left path of L, and v' is accessed from its left child, which is a node not on L.

Suppose v' is a heavy node on some older lazy tree, L_{old}; then v' is on the right path of L_{old} (by Lemma 15) and so v' was already promoted. Suppose that v' is straddled by L's heavy nodes x and y, where y is a descendant of v'. Let v be the promoted node nearest to y on the path from v' to y, in the range $[v', y)$, if any. If $v \neq v'$, v is made the root of a lazy tree formed from L; its left guard is the nearest node on the path from v' to v, in the range $[v', v)$ which has been promoted (in fact, this must be v'). Its right guard is handled as in Case 1. While if $v = v'$ or if v' was not heavy on any older lazy tree, then the right offset promotions for $v = v'$ are performed.

Case 2′. v is a heavy node on the left extreme path and it is accessed from its right child, u.

v' is defined to be the nearest heavy or pseudoheavy ancestor of v; v' must be on the left external path of L. v and v' are promoted as in Case 2 of section 4.3. As in Case 1′, the *right offset promotions* for v' are performed exactly when no global node on the path from v' to w_1, in the range (v', w_1) has been promoted. Again, if the right offset promotions are not performed, a new lazy tree is created exactly as in Case 1′.

If the left guard, lg, is separated from the remainder of L (through being accessed from its right child), and, v', the leftmost heavy node in L, is traversed, then the promotions described in the previous paragraph are performed; but if lg is separated from the remainder of L without v' being traversed (which can arise only if lg is the root of the large lazy block tree) then the new left guard for L is provided by the promoted node, if any, nearest to the root, r, of L, in the range (lg, r), on the path from lg to r. (See Figure 27.) If there is no such promoted node, as in Case 1.1′, the right offset promotions for r are performed.

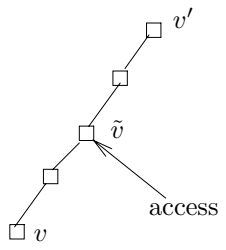

FIG. 28. *Case* 2.1′.

Again, we need to provide the new lazy tree rooted at v with a right guard. As in Case 2 of section 4.3, let x be the rightmost heavy descendant of v in the imaginary tree associated with its lazy block tree. If $x \neq v$, we proceed as in Case 2 of section 4.3. If $x = v$, we proceed as follows. Let w' be v's left child in the lazy block tree for L (if v does not have such a child then the lazy block tree rooted at v will comprise only one node and so can be ignored henceforth). Let w be the first node on the path from v to w', in the range (w', v), which has already been promoted, if any (there will be at most one promoted node on this path). If there is no such node, set $w = w'$ and promote it. w becomes the root of a new lazy tree formed from L with right guard v. Finally, if w has a nonempty right subtree in L, the right guard restoration process is applied to v.

Case 2.1′. $\tilde{v}$ is a light node on the left path of L and $\tilde{v}$ is accessed from its right child (a node which is not on L). See Figure 28.

v' is defined to be the nearest heavy or pseudoheavy ancestor of $\tilde{v}$; v' must be on the left external path of L. v' is handled as in Case 2′, above. Suppose $\tilde{v}$ is a heavy node on some older lazy tree, L_{old}. then $\tilde{v}$ must be on the left path of L_{old} (by Lemma 15), so $\tilde{v}$ was already promoted. $\tilde{v}$ will become the right guard of a new lazy tree formed from L. If a left descendant, w, of $\tilde{v}$, on the left path of L has already been promoted (there can be at most one such node) then w becomes the root of this new lazy tree. If not, w is defined to be the first heavy node on the left path of L which is a proper descendant of $\tilde{v}$; it is promoted. In addition, if w has a nonempty right subtree in L, the right guard restoration process is applied to $\tilde{v}$. Finally, suppose that $\tilde{v}$ was not heavy on any older lazy tree. Let v be the nearest descendant node on the left path of L which is heavy or pseudoheavy. v is promoted if it is not already promoted. It is then handled in the same way as node $\tilde{v}$ earlier in this case.

The charging for the promotions is analyzed shortly. The following lemmas are helpful.

LEMMA 16. *Let v be a node on lazy tree L accessed from its left child and promoted in Case* 1′ *or* 1.1′ *(as node v' in the latter case). Suppose that w' is a promoted node in v's right subtree, in addition, suppose that v and w' are on an older lazy tree L_{old}, where L_{old} is also split by the access. Let $w_1, \ldots, w_k$ be the nodes on L, if any, promoted by the right offset promotions. Then w' is a proper left descendant of w_k.*

Proof. Note that as w' is on L_{old}, an older lazy tree including v, w' must be in the range (v, w_k), by Invariant 14(ii)(a). Suppose, for a contradiction, that w' has an ancestor x on the path from v to w_1 in the range (v, w_1). See Figure 29. (If this is not the case, then w' is a proper left descendant of w_k.) x is global as both w' and

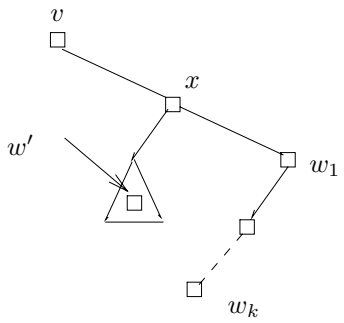

FIG. 29. *Proof of Lemma* 14.

w_1 are global. If x is on L_{old}, x is heavy on L_{old}, for x and its parent are separated, in left to right order, by global w'. Let x' be the first node on the path from v to x, in the range $(v, x]$, on L_{old}, which is heavy on L_{old}, or which is already promoted. Then unless already promoted, x' is promoted when L_{old} is split. (If Case 2(i) were to apply to L_{old}, then x' would not be promoted, as claimed; but, by assumption, w' is promoted; to achieve this promotion, Case 2(ii) needs to be applied, and then x' is indeed promoted.) But if x' is promoted, then w_1 would not be promoted, a contradiction. If x is not on L_{old}, then x is heavy on some tree L' sandwiched in age between L_{old} and L. Again, on replacing L_{old} by L' in the above argument, a contradiction is obtained. □

The next lemma is shown by the same argument as used in Case 1 in section 4.3.

LEMMA 17. *Let $w_1, \ldots, w_k$ be the chain of nodes promoted on lazy tree L by the right offset promotions for node v. In addition, let w' be a promoted node, if any, in v's right subtree on an older lazy tree L_{old}. $lazy\_\text{rank}(w_i) \geq g\_\text{rank}(w_{i+1})$ for $i = 1, \ldots, k-1$; similarly, $lazy\_\text{rank}(w_k) \geq g\_\text{rank}(w')$. Finally, $lazy\_\text{rank}(w_k) + jump(v) \geq g\_\text{rank}(v)$.*

In addition, we note the following.

LEMMA 18. *Let w be a node on lazy tree L promoted in Case 2′ or 2.1′. Let w' be a promoted node in v's left subtree on an older lazy tree L_{old} that is also split by the access. Then*

(i) *w' is a right descendant of w;*

(ii) *$lazy\_\text{rank}(w) \geq g\_\text{rank}(w')$;*

(iii) *$lazy\_\text{rank}(w) + \frac{1}{gp} reserve(w) + jump(v) \geq g\_\text{rank}(v)$.*

Proof. The proof of (i) is very similar to the proof of Lemma 16. (ii) follows from Corollary 8(i). The proof of (iii) uses the argument of Case 2 in section 4.3. □

Case 3′. The inserted item is to the right of the lazy tree root, r.

The new lazy tree rooted at r must be provided with a right guard. The method followed is identical to that used in Case 2′ for providing the new lazy tree rooted at v with a right guard. Lemma 18 applies here too.

It remains to analyze the cost of the split operations. Clearly, for the nodes on the right (resp., left) access path, the cost of the promotions is at most $gp \cdot \log n$, a total of $2gp \cdot \log n$ units for the two access paths. Lemmas 17 and 18 imply that for each promoted node on the right (resp., left) access path the associated promoted nodes form a chain descending to the left (resp., right); let $x_1, x_2, \ldots, x_k$ be a maximal path of such nodes, in descending order. Lemmas 17 and 18 show that $lazy\_\text{rank}(x_i) \geq$

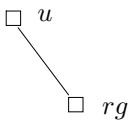

FIG. 30. *Guard restoration.*

$g\_\text{rank}(x_{i+1})$, for $i = 1, \ldots, k-1$ and $lazy\_\text{rank}(x_k) + \frac{1}{gp} reserve(x_k) + jump(v) \geq g\_\text{rank}(v) \geq g\_\text{rank}(x_1)$. (Note that the applications of Lemmas 17 and 18 will be interleaved if there is an interleaved sequence of successively older left and right lazy trees.) We conclude that a further $2gp \cdot \log n$ units of potential pay for the promotion of the nodes x_i.

So, as before, the cost of the split operation is at most $4gp \log n$ and Lemma 10 continues to hold.

LEMMA 10. *The promotions in a global insertion cost at most* $4gp \log n$ *units, where for each split lazy tree there is a charge of* $2gp$ *times the increase in global rank along the right split path and of* $2gp$ *times the increase in global rank along the left split path.*

It should be clear that Invariants 14–17 are maintained over the course of these promotions. When the promotions are complete there are no pseudoglobal nodes remaining, so at this point Invariants 14–16 will have been restored.

Finally, we need to consider the effect of the guard restoration process. We claim that if the guard restoration process is applied to lazy tree L, for each of the promoted nodes the newest lazy tree to which it belonged was L. Then it is easy to see that Invariants 14–16 continue to hold. To show the claim we demonstrate one case; the others are similar. Suppose that rg, the right guard of L, is in a couple with heavy node u of L (see Figure 30). Suppose that u is also on a newer lazy tree L_{new}. Then u is light on L_{new}. If rg is light on L_{new}, then following the rotation, u is no longer on L_{new}. If rg is heavy on L_{new}, then by Invariant 14(ii)(a) applied to L and L_{new}, there are no heavy nodes of L_{new} in rg's left subtree nor in u's left subtree; so, again, following the rotation, u is no longer on L_{new}. A similar argument applies if rg is the right guard of L_{new}.

4.5.2. Removing debits. We show how to restore Invariants 1–4 and 6–7. For each node that was on a newest lazy tree L but is not on a lazy tree derived from L, we charge the removal of its debit, if any, to the node's potential associated with lazy tree L. So we are only concerned with nodes for which the age of their newest lazy tree is unchanged. For such nodes, the invariants are all restored exactly as in section 4.3.

Restoring Invariants 1–4 result in the same maximum charge of three small debits and two large debits to a promoted node; this holds regardless of how many lazy trees the promoted node belonged to. Debit removal charged to the node relinquishing the debit is treated as before; this takes care of Invariant 6 as well. It remains to consider Invariant 7.

For a promoted node to be charged as node z of the argument in section 4.3, it must be a heavy node on the left (resp., right) extreme path of its right (resp., left) lazy tree prior to the split. Likewise, for a node to be charged as node y, it must be a heavy node on its right (resp., left) lazy tree prior to the split and not on the left (resp., right) extreme path. So as a promoted node, a node is charged no more than

before. The same node may receive additional charges, but as light nodes on other newer lazy trees; these charges are paid for by the potentials associated with the node as a light node in these newer lazy trees. So as before, (20) and (21) suffice to enable Invariants 1–4 and 6–7 to be restored.

Again, for the more general case, to restore Invariant 11 (22)–(24) suffice.

To satisfy any further restrictions obeying Property 3, we need to cover a charge of up to $\alpha \cdot md$ for each lazy tree created by the split. For each such lazy tree, the charge is given to its root. However, this cannot be applied solely to the charge made to promoted nodes, as several new lazy trees may share a common root. Instead, the charge is made to each node, either as a light node or for the oldest lazy tree, as a heavy node. This requires modifying (23) to (24) as before, and modifying (22) as follows:

$$c' \geq 4md + \alpha \cdot md. \tag{25}$$

4.5.3. Summary. The presence of multiple levels of lazy trees does not alter the previous analysis of a global insertion, stated in Lemma 12 (except that the constraint of (25) is introduced). The analysis of local insertions is also unaffected, for the discussion of section 4.4 carries over unchanged; so Lemma 6 also continues to hold. In summary, we have shown the following.

LEMMA 19. *The cost of a local access is* $c + s + 1$*, and the cost of a global access is* $e(3 \log n + 1)gp + 5gp \log n$ *units.*

In addition, we note that Lemma 13 continues to hold with (22) replaced by (25) (but now in Lemma 13(ii), "block" is interpreted to mean the newest lazy tree older than the lazy tree in question, to which nodes on the left path belong).

5. Concluding the analysis. We choose $s = 1$. Recall that $s' = s$ (see section 4.2). By Lemma 3 we have $sd = 2$, $gp = ld = 34$, $c = 36$. On taking equality in (7), (10), (13), (14), (20), and (21), we obtain $hd = 36$, $d = 432$, $b = 216$, $c' = 144$, $a = 2 \cdot 216^2 = 93,212$ (incidentally, these values satisfy (6), (8) and (9)) and $q + 4 \leq 2^{21}$; by (4) it suffices to set $e = 22$. For each block we need to pay for one global insertion and $\log n - e$ local insertions (note that the cost of the first $e - 1$ local insertions is covered by the charge for the global insertion). Equations (15)–(19) and (22)–(25) are not used here. From Lemma 19, we conclude the following.

THEOREM 20. *The number of rotations for sorting a* $\log n$*-block sequence is bounded by* $2500n + O(n/\log n)$*. (Recall that the number of rotations dominates the overall cost of the sort.)*

Acknowledgments. We thank Rajamani Sundar for his very careful reading of the paper which uncovered several serious omissions in an earlier draft. We also thank S. Muthukrishnan for his help and advice regarding figure drawing. Finally, we thank an anonymous referee for making a number of detailed suggestions that helped improve the paper's presentation.

ON THE DYNAMIC FINGER CONJECTURE FOR SPLAY TREES. PART II: THE PROOF*

RICHARD COLE†

Abstract. The following result is shown: On an n-node splay tree, the amortized cost of an access at distance d from the preceding access is $O(\log(d+1))$. In addition, there is an $O(n)$ initialization cost. The accesses include searches, insertions, and deletions.

Key words. binary search tree, splay tree, amortized analysis, finger search tree

1. Introduction.

The reader is advised that this paper quotes results from the companion Part I paper [CMSS00]; in addition, the Part I paper introduces a number of the techniques used here but in a somewhat less involved way.

The splay tree is a self-adjusting binary search tree devised by Sleator and Tarjan [ST85]. They showed that it is competitive with many of the balanced search tree schemes for maintaining a dictionary. Specifically, Sleator and Tarjan showed that a sequence of m accesses performed on a splay tree takes time $\mathrm{O}(m \log n)$, where n is the maximum size attained by the tree ($n \leq m$). They also showed that in an amortized sense, up to a constant factor, on sufficiently long sequences of searches, the splay tree has as good a running time as the optimal weighted binary search tree. In addition, they conjectured that its performance is, in fact, essentially as good as that of any search tree. Before discussing these conjectures, it will be helpful to review the operation of the splay tree and the analysis of its performance. The basic operation performed by the splay tree is the operation *splay*(x) applied to an item x in the splay tree. *splay*(x) repeats the following step until x becomes the root of the tree.

> SPLAY STEP.
> Let p and g be, respectively, the parent and grandparent (if any) of x.
> CASE 1. p is the root: Make x the new root by rotating edge (x, p).
> CASE 2—THE ZIG-ZAG CASE. p is the left child of g and x is the right child of p, or p is the right child of g and x is the left child of p: Rotate edge (x, p), making g the new parent of x; rotate edge (x, g).
> CASE 3—THE ZIG-ZIG CASE. Both x and p are left children, or both are right children: Rotate edge (p, g); rotate edge (x, p).

Henceforth, we refer to the rotation, single or double, performed by the splay step as a *rotation* of the access or splay operation. A rotation is the basic step for our analysis; the cost of one rotation is termed a *unit*; clearly, this is a constant.

Sleator and Tarjan use the following *centroid potential* to analyze the amortized performance of a splay operation (our terminology). Node x is given weight, $wt(x)$, equal to the number of nodes in its subtree; they define the *centroid rank* of x, or simply the *rank* of x to be $\text{rank}(x) = \lfloor \log wt(x) \rfloor$ (our terminology). Each node is given a centroid potential equal, in units, to its centroid rank. Let δ denote $\text{rank}(g) - \text{rank}(x)$, if g is present; otherwise it denotes $\text{rank}(p) - \text{rank}(x)$. Sleator and Tarjan showed that the amortized cost of the splay step if g is present is at most 3δ units, while if g is not present the cost is at most $\delta + 1$ units (see [ST85, Lemma 1]). Since the total increase in rank for the complete access is bounded by $\log n$, the amortized cost of an access is at most $3 \log n + 1$ units. More generally, this analysis can be applied to weighted trees in exactly the same way. We call this the *centroid potential analysis*.

We now list the conjectures formulated by Sleator and Tarjan.

Dynamic Optimality Conjecture. Consider any sequence of successful accesses on an n-node binary search tree. Let A be any algorithm that carries out each access by traversing the path from the root to the node containing the accessed item, at a cost of one plus the depth of the node containing the item, and that between accesses performs an arbitrary number of rotations anywhere in the tree, at a cost of one per rotation. Then the total time to perform all the accesses by splaying is no more than $O(n)$ plus a constant times the time required by algorithm A.

Dynamic Finger Conjecture. The total time to perform m accesses on an arbitrary n-node splay tree is $O(m + n + \sum_{j=1}^{m} \log(d_j + 1))$, where, for $1 \le i \le m$, the jth and $(j-1)$th accesses are performed on items whose ranks differ by d_j (ranks among the items stored in the splay tree). For $j = 0$, the jth item is interpreted to be the item originally at the root of the splay tree.

Traversal Conjecture. Let T_1 and T_2 be any two n-node binary search trees containing exactly the same items. Suppose we access the items in T_1 one after another using splaying, accessing them in the order they appear in T_2 in preorder (the item in the root of T_2 first, followed by the items in the left subtree of T_2 in preorder, followed by items in the right subtree of T_2 in preorder). Then the total access time is $O(n)$.

Sleator and Tarjan state that the dynamic optimality conjecture implies the other two conjectures. (The proof is nontrivial.)

There have been several works on, or related to, the optimality of splay trees [STT86, W86, T85, Su89, Luc88a, Luc88b]. [STT86] showed that the rotation distance between any two binary search trees is at most $2n-6$ and that this bound is tight; they also related this to distinct triangulations of polygons; although connected to the splay tree conjectures, this result has no immediate application to them. [W86] provided two methods for obtaining lower bounds on the time for sequences of accesses to a binary search tree; while some specific tight bounds were obtained (such as accessing the bit reversal permutation takes time $\Theta(n \log n)$), no general results related to the above conjectures follow. [T85] proved the scanning theorem, a special case of the traversal conjecture (also a special case of the dynamic finger conjecture): accessing the items of an arbitrary splay tree, one by one, in symmetric order, takes time $O(n)$. Sundar [Su89] considered various classes of rotations on binary trees. Before discussing these we need some terminology. A right rotation is a rotation between a node u and its left child v. A k-right cascade comprises a sequence of k right rotations on the following path: the path is a descending sequence of $2k$ nodes, $v_1, v_2, \ldots, v_{2k}$, where v_{i+1} is the left child of v_i for $1 \le i < 2k$; the rotations are between nodes v_{2i-1} and v_{2i} for

$1 \leq i \leq k$. Sundar [Su89] shows the following bound on the maximum number of k-cascades in a sequence of right rotations on an n-node binary tree: $\Theta(n\alpha_{\lfloor k/2 \rfloor}(n))$, where α_k is the inverse of the kth level of the Ackerman hierarchy; in particular, for $k = 2\alpha(n)$, where α is the inverse Ackerman function, this is a $\Theta(n)$ bound. Our result will make use of this bound. Sundar uses this bound to obtain results concerning the deque conjecture; formulated by Tarjan [T85], it states that if a splay tree is used to implement a deque, in the natural way, then a sequence of m operations on a deque, initially of n items, takes time $O(m+n)$; Sundar proved a bound of $O((m+n)\alpha(m+n))$.

In this paper, we prove a generalized form of the dynamic finger conjecture, which includes insertions and deletions as well as searches among possible accesses (which is implicit in the above formulation of the conjecture). We note that our implementation of the delete operation is not the one described by Sleator and Tarjan [ST85]. The generalized form of the dynamic finger conjecture is as follows.

GENERALIZED DYNAMIC FINGER CONJECTURE. The total time to perform m searches, insertions, and deletions on an arbitrary splay tree, initially of size n, is $O(m+n+\sum_{j=1}^{m} \log(d_j+1))$, where, for $1 \leq i \leq m$, the jth and $(j-1)$th accesses are performed on items whose ranks differ by d_j (ranks among the items stored in the splay tree). For $j = 0$, the jth item is interpreted to be the item originally at the root of the splay tree.

Comment: The $+1$ in the log term is present to avoid problems with $\log 1$ and $\log 0$.

To measure the rank difference for an item deleted or inserted on the previous or the current operation, respectively, simply consider the immediate predecessor or successor of the item at the time of the deletion or insertion.

In the Part I paper a special case of splay sorting was examined. Splay sorting is closely related to the dynamic finger conjecture. It is defined as follows. Consider sorting a sequence of n items by inserting them, one by one, into an initially empty splay tree; following the insertions, an in-order traversal of the splay tree yields the sorted order. This is called *splay sorting*. A corollary of the dynamic finger conjecture is as follows.

SPLAY SORT CONJECTURE. Let S be sequence of n items. Suppose the ith item in S is distance I_i in sorted order from the $i-1$th item in S for $i > 1$. Then splay sort takes time $O(n + \sum_{i=2}^{n} \log(I_i + 1))$.

Incidentally, an interesting corollary of the splay sort conjecture is as follows.

SPLAY SORT INVERSION CONJECTURE. Let S be sequence of n items. Suppose the ith item in S has I_i inversions in S (counting inversions both to left and right). Then splay sort takes time $O(n + \sum_{i=1}^{n} \log(I_i + 1))$.

In the Part I paper we proved the splay sort conjecture for the following type of sequence. Suppose the sorted set of n items is partitioned into subsets of $\log n$ contiguous items, called *blocks*. Consider an arbitrary sequence in which the items in each block are contiguous and in sorted order. We call such a sequence a *$\log n$-block sequence*. We showed an $O(n)$ bound for splay sorting a $\log n$-block sequence.

The key contribution of the Part I paper was the notion of lazy potentials and their analysis. This notion can be viewed as a tool for designing potential functions. The lazy potential is a refinement of an initial potential function that avoids waste when potentials decrease. (For an example of waste, consider the following splay tree analyzed using the centroid potential. The tree is a path of n nodes, each of unit weight. The last node on the path is accessed. The resulting splay will have a real cost of $\Theta(n)$ but will reduce the potential by $\Theta(n \log n)$. The desired amortized cost

of this operation is $O(\log n)$, so essentially all the reduction in potential is wasted.) The idea of the lazy potential is to keep an old potential, ϕ_{old}, in situations in which the creation of a new (larger) potential, ϕ_{new}, may be followed by a return to the ϕ_{old} potential, with essentially $\phi_{new} - \phi_{old}$ potential being wasted. Not surprisingly, some care is needed in choosing which operations to treat as "lazy." In the Part I paper, collections of nodes all having lazy potentials formed *lazy trees*. The nodes in a lazy tree had originally been contiguous nodes on a left (or right) path. The lazy potentials were the "correct" potentials with respect to that original path. The key to the analysis was to provide additional potentials to the nodes of the lazy tree to pay for rotations that restored them towards their original left (or right) path configuration. As it happened, these potentials were linear in the size of the lazy tree and could be provided when the lazy tree was being created.

The lazy potential used here is similar to that used in the Part I paper. But, in contrast to the Part I paper, the additional potentials provided to the lazy trees may be superlinear in the size of the lazy tree. However, whenever we need to provide a superlinear potential, it is superlinear by only an inverse Ackerman function, and again we are able to provide this superlinear potential as the lazy trees are being created (the proof of the superlinear bound relies on the analysis of cascades provided by Sundar [Su89]). At this point it is convenient to define the version of the inverse Ackerman function, α, used in this paper. Define the following:

$$
\begin{aligned}
A_0(j) &= 2j \quad \text{for all } j \geq 1, \\
A_1(j) &= 2^j \quad \text{for all } j \geq 1, \\
A_i(j) &= \begin{cases} A_{i-1}(2) & \text{if } i \geq 2 \text{ and } j = 1, \\ A_{i-1}(A_i(j-1)) & \text{if } i \geq 2 \text{ and } j \geq 2, \end{cases} \\
\alpha(n) &= \min\{k \geq 1 | A_k(1) \geq n\} \quad \text{for all } n \geq 1.
\end{aligned}
$$

The other main feature of our analysis is a hierarchical partitioning of the items into blocks. A block comprises a contiguous set of items in the splay tree. The blocks at level 0 in the partition are called 0-blocks; at successively higher levels of the partition, the blocks are termed 1-blocks, 2-blocks, and so on. The highest level, vis, contains a single block which holds all the items in the tree. A separate potential function is associated with each block. The accesses are divided into sequences with respect to each level of blocks. A sequence, S_i, comprises a maximal series of successive accesses all to the same i-block. We call the first access of each sequence S_{vis-1}, a *global* access. Subsequent accesses of S_{vis-1} are called *local* accesses. We will prove an $O(\log n)$ bound on the amortized cost of global accesses and appropriately smaller bounds on the cost of local accesses.

In section 2, we analyze the global accesses. In section 3, we introduce and analyze the local accesses. We show a bound of $O(\log(d+1) + (\log\log n)\alpha(n))$ on the cost of a local access, where d is the distance, in items, between the current accessed item and the previously accessed item. In section 4, this bound is tightened to obtain the desired $O(\log(d+1))$ bound. The additional $O((\log\log n)\alpha(n))$ term arises because of the interaction between the different levels of blocks, as we will see later. In section 5, we extend the bound to allow insertions and deletions. Unfortunately, the constants in the bound are rather large (10^18). In part, this may be due to the fact that we have not sought to optimize the constants, but, to a larger extent, it is a result of the involved nature of the analysis. In section 6, we briefly discuss whether it might be possible to improve the constants in our bounds.

2. The block structure and global accesses. Before embarking on the analysis of global accesses, we provide some definitions which will be needed throughout the paper. Let S be a nonempty contiguous subset of the items in the splay tree. We define the tree, T_S, induced by S, as follows. Let u and v be, respectively, the leftmost and rightmost items in S. The root, r, of T_S, is the least common ancestor of u and v in the splay tree; note that r is a node of S. The left (resp., right) subtree of r is the tree induced by the set of items in S to the left (resp., right) of r, if nonempty; otherwise the subtree is empty. A node u is a *left descendant* of v if it is in v's left subtree or is v itself; we also say that v is a *right ancestor* of u. Right descendants and left ancestors are defined analogously. The right (resp., left) extreme path of a tree is the path from the root to the rightmost (resp., leftmost) item in the tree, excluding the root itself. The *access path* for an access comprises the traversed nodes other than the accessed node itself.

Next, we define blocks at level i, i-blocks, for $i = 1, 2, \ldots$. A 0-block comprises 1 item; a 1-block comprises c_1 items; an i-block comprises b_i $(i-1)$-blocks for $i > 1$; c_i is the number of items in an i-block for $i \geq 1$. For much of the paper, we choose $b_i = 2^{2^i}$, $c_i = b_{i+1}$ for $i \geq 1$. For each $i \geq 1$, we allow the rightmost i-block to be undersized. At the topmost level, level vis, a single block contains all the items in the tree. Henceforth, to simplify the discussion, we refer to an i-block as the block, an $(i+1)$-block as a superblock, an $(i-1)$-block as a subblock, and a j-block, $j < i-1$, as a miniblock. Sometimes, if confusion may arise, we refer to these blocks as i-superblocks, i-subblocks, and i-miniblocks, respectively.

We make a number of definitions with respect to the superblocks. The *superblock tree* for superblock B is the tree induced by the items in B. The *root* of the superblock tree for a superblock is called the *superblock root*. The block tree and block root for block B are defined analogously. Henceforth, when a node is identified as a block root, it is implicitly assumed not to be a superblock root. The block roots in the superblock and the superblock root itself are called *global nodes*; a global node other than the superblock root is called a *true global node*. All other nodes in the superblock are called *local nodes*. The *skeleton* of a superblock comprises the nodes on the extreme paths of its blocks. The *inner skeleton* of a superblock comprises the nodes on the skeleton other than nodes on an extreme path of the superblock. A node has *visibility* i if it belongs to the inner skeleton of an i-superblock. A node on an external path of the vis-block has visibility vis. On occasion, for precision, the skeleton (resp., inner skeleton) of an i-superblock is called the i-skeleton (resp., i-inner skeleton). Also, the global nodes in an i-superblock are said to be i-global.

Let P be a maximal contiguous path in the splay tree which is a portion of an extreme path for u's block, where u is the root of the block. If P is on the inner skeleton of u's superblock and if the top node on P is a child of u in the splay tree, then P is said to *abut* u. The *right* (resp., *left*) abutting path for u is the path to the right (resp., left) of u that abuts u, if any. Also, u is called the *parent* of P.

The nodes in each i-superblock are given centroid ranks, called the global ranks, or $g_$ranks for short, using the following weighting. Let $K_i = 2^{\lceil \log b_{i+1} \rceil}$ for $i > 0$, and $K_i = 2^{\lceil \log c_1 \rceil}$ for $i = 0$. The root is given weight $-K_i$, each true global node is given weight one, and each local node is given weight zero. The rank of v is given by $\lfloor \log wt(\text{subtree rooted at } v) \rfloor$, where we define $\log 0 = -1$. The two extreme nodes in the superblock are given additional weight K_i. We note that on an extreme path of a superblock tree, each node has the same global rank; also, this global rank is larger than that of any node on the inner skeleton. Each true global node is given a

potential, called its global potential, equal in units to gp times its global rank, gp a constant to be specified later.

Each local node on the skeleton is either *labeled* or *unlabeled*. Each labeled node has potential c, c a constant to be defined later. The labels and potentials are defined with respect to each level of block to which the node belongs. For each maximal path P of unlabeled nodes, the following invariant is maintained.

INVARIANT 1. *Let P be a maximal path of unlabeled local nodes on an extreme path of one block. Suppose that the nodes of P are contiguous in the splay tree. Then P has an associated* path potential *of $2c\lfloor\log(|P|+1)\rfloor$ units.*

Each of the terms just defined, if prefixed by i, will refer to a block at level i; alternatively we may use the prefixes "super," "sub," and "mini" to refer to the terms associated with superblocks, subblocks, and miniblocks. Implicitly, in the discussion that follows, all references are with respect to a fixed i-superblock.

A labeled node on the inner skeleton may carry a *small* or *large* debit. Small and large debits, are worth sd and ld units, respectively, sd and ld constants to be specified later. The following invariants apply to the labels and debits.

INVARIANT 2. *An unlabeled local node is always adjacent, in the splay tree, to two other local nodes which are on the skeleton and in the same block.*

INVARIANT 3. *Only a labeled local node on the inner skeleton can have a debit.*

INVARIANT 4. *Let v be a local node and let v belong to block B. Suppose that in the splay tree, v is the left (resp., right) child of its parent u. v can have a large debit only if*

(i) *u is a local node in block B;*

(ii) *v has a left (resp., right) child w in the splay tree which is a local node and in block B;*

(iii) *neither u nor w carry any debit.*

(Note that both u and w are on an extreme path of block B and hence on the inner skeleton.)

INVARIANT 5. *Let u be a true global node. Let P be a path abutting u, if any. Let v be the top node on P (v is a child of u). v can have a small debit only if $g\_\text{rank}(v) < g\_\text{rank}(u)$.*

INVARIANT 6. *Let u be the root of block B. Let P be a path abutting u, if any. Let w be the bottom node on P. w can have a small debit only if $g\_\text{rank}(w) < g\_\text{rank}(u)$.*

To avoid special cases it is convenient to redefine the access path for an access to exclude the splay tree root r in the event that r is involved in an incomplete rotation (Case 1 of the splay step). Now consider a rotation performed during the splay along the access path. Of the three nodes involved in the rotation, the top two are called the *coupled* nodes of the rotation, or a *couple* for short. The analysis focuses on the coupled nodes in a rotation.

For the purposes of the analysis the access path is partitioned into segments. Each segment comprises an even number of nodes, every two nodes on the path forming the coupled nodes of a rotation of the present splay operation. The segments are created by a traversal of the access path from bottom to top; each segment is chosen to have the maximum length such that, following the removal of its front (top) two nodes, the (truncated) segment satisfies the following conditions:

(i) The nodes on the truncated segment all belong to the inner skeleton of one superblock; in addition, the accessed item is part of the inner skeleton of this superblock immediately prior to the traversal of the current segment.

FIG. 1. *Type* 1 *nodes.*

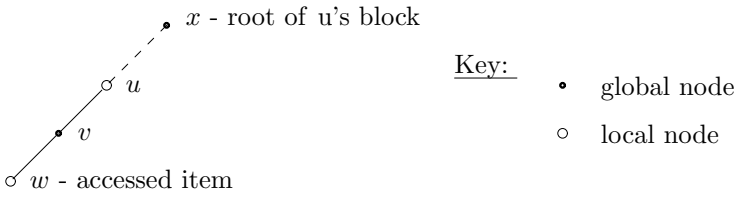

FIG. 2. *Type* 2 *nodes.*

(ii) The node being accessed has the same global rank throughout the rotations involving the truncated segment.

(iii) For each couple, the rotation does not change the total global potentials.

(iv) (This is implied by (ii) and (iii).) Each couple in the truncated segment includes at least one local node (i.e., it does not comprise two global nodes).

(v) Define a node to be *staying* if it is involved in a zig-zag rotation or it is the lower node in a couple. (Intuitively, the staying nodes are those that remain on one of the traversed paths following the splay. Note that the splay, in general, creates two traversed paths.) For each block there are at most two labeled staying local nodes in the truncated segment, following its traversal.

The topmost segment is said to be *incomplete* if it satisfies conditions (i)–(v) prior to truncation. We consider an incomplete segment to comprise a (trivially) truncated segment.

Next, we mark the following types of coupled nodes in each truncated segment. The rotations involving marked couples are self-paying, as is demonstrated later. Each marked couple is involved in a zig-zig rotation. For each type below, suppose the segment includes a couple, u, v, with u the parent of v.

Type 1. See Figure 1. Suppose that u is the root of v's block; then both u and v are marked.

Type 2. See Figure 2. Suppose that u is a local node, and let x be the root of u's block. Further, suppose that u is on the left (resp., right) abutting path for x. Let v be the left (resp., right) child of u; if u does not have a debit and if v is global, then both u and v are marked.

Type 3. Suppose u and v are both local nodes of the same block; then both u and v are marked.

We can now prove a bound on the length of a truncated segment.

LEMMA 1 (see [CMSS00, Lemma 1]). *A truncated segment comprises at most* 10 *unmarked nodes, of which at most* 7 *are local.*

Over the course of the access we maintain the following invariant.

INVARIANT 7. *See Figure* 3. *Let w be the accessed item. Let x be w's right (resp., left) child. Suppose that x is on the inner skeleton of its superblock. Let P*

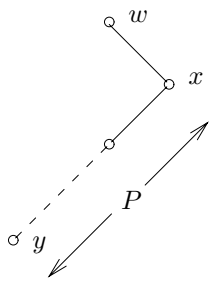

FIG. 3. *Invariant* 7.

be the maximal portion of the extreme left (resp., right) path in x's block descending from x, contiguous in the splay tree. Let y be the bottom node on P (x is the top node). Then neither x nor y carry any debits. w does not carry a debit either.

To initialize Invariant 7 at the start of the access may require the removal of up to five small debits or up to one large debit and three small debits; this costs at most

$$\max\{ld + 3sd, 5sd\}. \tag{1}$$

As we will see, the access will remove the debits from all the traversed nodes (though it may also cause large debits to be placed on some of the traversed nodes).

To understand the cost of individual rotations it is helpful to consider when abutting paths affect Invariants 5 and 6. We define an *untouched* abutting path to be one whose top node is not traversed in the current access and whose top node was not a child of the accessed item at the start of the access; any other abutting path is said to be *touched*. We define an abutting path to be *clean* if it obeys Invariants 5 and 6 with respect to its parent, and to be *dirty* otherwise. Because of Invariant 7, a node that receives a touched abutting path receives a clean abutting path.

LEMMA 2. *Let u be a true global node. Let P be an abutting path. If P is dirty, u must be on the inner skeleton of its superblock.*

Proof. By definition, P is on the inner skeleton. By construction, every node on an extreme path of a superblock has larger global rank than any node on the inner skeleton. So for P to be dirty, u must be on the inner skeleton of its superblock. □

LEMMA 3. *Let u be a node on the access path. Suppose that before the rotation involving u, u was j-global, and that after the rotation it is k-global, $k > j$. Then, after the rotation, u's abutting paths are clean.*

Proof. We note this must be a zig-zig rotation, and u must be the lower node in the couple. So of the at most two abutting paths u acquires, one is touched; the untouched one, if present, had been an abutting path for its parent, t (t and u are in the same couple). The only node added to this abutting path is t, which by assumption carries no debit. u acquires t's k-global rank, and so the untouched abutting path remains clean. □

LEMMA 4. *Let u be a node on the access path. Suppose that before the rotation involving u, u was j-global, and that after the rotation it is k-global, $k < j$. Then, after the rotation, u's abutting paths are clean.*

Proof. u remains on the j-skeleton and hence is not on the inner k-skeleton. The result follows from Lemma 2. □

LEMMA 5. *Let u be a node on the access path. Suppose that both before and after the rotation u is a true j-global node. Further suppose that u is on the inner i-skeleton before the rotation, where $i > j$. Then either*

(i) *u is on the inner j-skeleton after the rotation; then u's j-rank decreases;*

(ii) *u is not on the inner j-skeleton after the rotation; then u has no dirty abutting paths.*

Proof. The conclusion of (i) follows from the definition of the j-ranks. The conclusion of (ii) follows from Lemma 2. □

COROLLARY 1. *Let u be a node on the access path. Following the rotation, u can have a dirty abutting path only if*

(i) *u was a true j-global node both before and after the rotation; also, u is on the inner skeleton of its j-superblock after the rotation, and*

(ii) (a) *either u's j-global rank decreases, or* (b) *u receives a new untouched abutting path.*

Proof. Condition (i) summarizes Lemmas 2–4. There are only two ways in which u can acquire a dirty abutting path. First, an already abutting path becomes dirty; for this to happen, u's j-rank must decrease. Second, u receives a new abutting path; in order for the new abutting path to be dirty, it must be untouched (as already pointed out in the discussion following Invariant 7). □

Next, we investigate possibility (ii(b)) of Corollary 1 further.

LEMMA 6. *Consider the rotation involving couple u and v, where v is a child of u. Following the rotation, v does not have a new dirty untouched abutting path. u can receive a new dirty untouched abutting path only if both*

(i) *the rotation is a zig-zig rotation, and*

(ii) *v is in the same j-superblock as u but in a distinct j-block, where u is a true j-global node.*

Proof. In a zig-zag rotation the new abutting paths are all touched.

If v acquires a new dirty abutting path, v is a true j-global node both before and after the rotation. Also, for u to be in v's new abutting path, u must be in the same j-block as v; but then v was not a true j-global node before the rotation. So v does not have a new dirty untouched abutting path.

If u acquires a new dirty abutting path, u is a true j-global node both before and after the rotation. Again, if v is in the same j-block as u, u is not a true j-global node after the rotation. So v is in a distinct j-block. Suppose that u is on the inner i-skeleton before the rotation, where $i \geq j$. If $i > j$, by Lemma 5, u is on the inner j-skeleton after the rotation, and so v must be in the same j-superblock as u, while if $i = j$, as u was on the inner i-skeleton before the rotation, v must be in the same i-superblock as u. □

LEMMA 7. *Let u be a node on the access path. If u acquires a dirty abutting path, then u is in the leading couple of its segment. In addition, the visibility of w, the accessed item, is unchanged following the rotation involving u.*

Proof. If condition (ii(a)) of Corollary 1 applies, then clearly u is in the leading couple. So suppose that condition (ii(b)) applies. Consider Lemma 6; let v be the other node in u's couple (v is u's child). v is in the same j-superblock as u but in a distinct j-block. Also, the rotation involving u and v is zig-zig. There are two possibilities. First, v is j-global; then the rotation must reduce u's j-global rank or increase w's j-global rank; in either event u is in the leading couple. Second, v is not j-global; in order for v to be in a distinct j-block from u, w cannot be on the inner skeleton of B, u's j-superblock. So this rotation raises w's visibility, violating

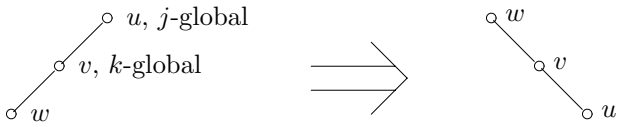

FIG. 4. *Type* 3 *nodes.*

condition (i) of the definition of a truncated segment; again, u must be in the leading couple. Finally, suppose w's visibility increases due to the rotation involving u. Then, u becomes a true k-global node, $k < j$, after the rotation; by Lemma 5, u does not acquire any dirty abutting paths. □

LEMMA 8. *Following the access, the accessed item's abutting paths are clean.*

Proof. This is an immediate consequence of Lemma 2, for the accessed item is not on the inner skeleton of any of its blocks. □

In the analysis of global accesses, whenever a rotation is performed (and paid for) another s spare rotations are also paid for, s a constant to be specified later. The spare rotations are needed subsequently to handle the effects of local accesses.

In order to pay for the rotations we provide the following potential. In each rotation, for each unit increase in rank on the part of the accessed item, w, we provide $3gp$ units of potential. It is used as follows. Consider a rotation involving couple u, v, where u is the parent of v. Suppose that w is currently the root of its block. Suppose that this rotation increases the global rank of w by I. Each of w and v (if global and in the same superblock as w) may increase their global potentials by up to $gp \cdot I$ units; this is a total of at most $2gp \cdot I$ units of potential. If $I > 0$, the remaining at least gp units of potential at hand will pay for the segment that ends at couple u, v (as we will see, gp units always suffice). When w becomes the root of its superblock, it interchanges potentials with the old root of the superblock (it may be that in one double rotation w in turn swaps potentials with v and then with u).

Further potential will also be provided; a total of $gp + vis \cdot vp + (ld + 3sd)$ units, vp being a constant to be specified (the role of the latter potential will become clear towards the end of this section).

Next, we show how to pay for the rotations (and associated spares) along a segment. First, each marked couple pays for its rotation (and spares), as follows. Recall that the marked couples are all involved in zig-zig rotations.

CASE 1. (Type 3.) The coupled nodes are both local nodes in the same i-superblock (see Figure 4). Nodes u and v are on the inner skeleton in the same superblock; without loss of generality, v is the left child of u, and w, the node being accessed, is the left child of v. Node u is j-global, and node v is k-global, $j, k < i$. There are several subcases depending on the relative values of j and k.

Case 1.1. $j > k$. After the rotation, v becomes j-global, and u becomes k-global. u and v exchange potentials. Since v is adjacent to a j-global node, it must be h-labeled, for $k < h \leq j$; it transfers the h-labels and associated potentials to node u. u is given a small j-debit; as it is now a j-local node on an inner j-skeleton, this obeys Invariant 3. By Lemma 2 and Corollary 1, Invariants 5 and 6 continue to hold. The small debit pays for the rotation and s spares. Thus it suffices that

$$sd \geq s + 1. \tag{2}$$

Next, we remove the debits present at u and v, if any. If both nodes are i-labeled,

then u spends its associated potential c; this pays for the removal of debits from both nodes. If only one node is i-labeled, as we show later, the traversal of a portion, or all, of the i-unlabeled path associated with the i-unlabeled node results in the i-labeling of that i-unlabeled node. So we proceed in the same way in this case. If neither node is i-labeled, then they do not carry debits. So it suffices that

$$c \geq \max\{2sd, ld\}. \tag{3}$$

Case 1.2. $j < k$. Then u and v are in the same k-superblock but are in distinct k-blocks. Here, v remains k-global and u j-global. u is given a small k-debit; again, as u is now a k-local node on an inner k-skeleton, Invariant 3 is satisfied. Again, by Lemma 2 and Corollary 1, Invariants 5 and 6 continue to hold. Here too, (2) suffices. The removal of debits is handled as in the previous case.

Case 1.3. $j = k$. The j-rank of u decreases, and this pays for the removal of small or large debits from u and v and of up to two small debits from nodes which now violate Invariants 5 and 6. So it suffices that

$$gp \geq \max\{2sd, ld\} + 2sd. \tag{4}$$

Case 2. (Type 1.) u is i-global and v is j-global, $j < i$ (see Figure 1). This is similar to Case 1.1, above. However, here v cannot have a debit before the rotation, by Invariant 5, since $g\_\text{rank}(u) = g\_\text{rank}(v)$ (this follows from the fact that the global rank of the accessed item does not change). Here u is given a small i-debit, for it remains on the inner i-skeleton. Note that following the rotation, $g\_\text{rank}(u) < g\_\text{rank}(v)$. Invariants 3, 5, and 6 continue to hold.

Case 3. (Type 2.) v is i-global and u is j-global, $j < i$ (see Figure 2). This is similar to Case 1.2, above. But here, u does not have a small debit by assumption (since the couple was marked). It is given a small debit following the rotation. As before, Invariants 3, 5, and 6 continue to hold.

The remaining rotations are paid for by the first couple in the segment, which was removed in truncating the segment and which causes a violation of at least one of the conditions (i)–(v), except in the case of an incomplete topmost segment, which is handled subsequently. The rotation involving the first couple falls into at least one of the following cases.

Case A. The rotation reduces the total global potential of the nodes in the first couple, or it increases the global rank of the accessed node.

Case B. The rotations along the segment create a sequence of three contiguous local nodes from the same block.

Case C. The rotation increases the visibility of the accessed item.

Each case involves three costs.

*Cost*1. The rotation and spares for each unmarked couple, including the leading couple: $\leq 6(s+1)$.

*Cost*2. Removal of small debits from the unmarked couples; *Cost*2 is analyzed below.

*Cost*3. Removal of small debits for local nodes that now violate Invariant 5 or 6; *Cost*3 is analyzed below.

We remind the reader that we remove all debits from the traversed nodes (though we may add new debits).

Lemma 9. (i) *For each segment in which the visibility of the accessed item is unchanged,* $Cost2 + Cost3 \leq 11sd$.

(ii) *For all other segments,* $cost2 + Cost3 \leq 7sd + \max\{2sd, ld\}$.

Proof. Lemma 9(i) is proven in [CMSS00], where it is Lemma 2. To prove (ii), we note that by Lemma 1, the truncated segment contributes at most $7sd$ to $Cost2$. By Lemma 7 it contributes nothing to $Cost3$. The removal of debits from the leading couple costs at most $\max\{2sd, ld\}$. Again, by Lemma 7 there is no contribution to $Cost3$. □

LEMMA 10. *Invariant* 7 *remains true throughout the access.*

Proof. This follows immediately from the fact that the traversed nodes have no debits following their traversal. Thus w's children do not carry debits (the node x of Invariant 7). Consider node y; this node changes only when the new node x has a larger visibility than the old node x; but then the new node y is the new node x. □

LEMMA 11. *A global access costs at most* $(3\sum_{i=1}^{vis} k_i + 1)gp + vp \cdot vis + 2c \cdot vis + (ld+3sd)$ *units, where* $sd = s+1$, $ld, c = 17(s+1)$, $gp = 19(s+1)$, $vp = 30(s+1)$, *vis is the number of levels of blocks, and* k_i *is the* i*-rank of nodes on an* $(i+1)$*-extreme path. (Note* $\sum_{i=1}^{vis}(k_i+1) \le \log n + 3vis + 1$*.)*

Proof. In case A, the cost of the rotation is paid for either by the drop in global potential, which provides at least gp units, or, if there is an increase in global rank for the accessed item, by gp units of the at least $3gp$ units provided for this rotation. In case B, there are at least three labeled staying local nodes; the middle node among these three labeled nodes is given a large debit, which pays for the rotation (note that the three labeled nodes need not be contiguous but they all lie on a contiguous path on the skeleton; the middle node obeys Invariant 4). In Case C, the cost of the rotation is charged to the new visibility level. (vp units are provided per level for a global access to pay for each instance of Case C.)

Thus it suffices to have

$$gp, ld \ge 6(s+1) + 11sd, \tag{5}$$

$$vp \ge 6(s+1) + 7sd + \max\{2sd, ld\}. \tag{6}$$

Recall that an i-superblock comprises b_{i+1} i-blocks; let k_{i+1} denote the i-rank for nodes on an $(i+1)$-extreme path. Clearly, $\sum_{i=1}^{vis} k_i \le \log n + 2vis + 1$; with $b_i = 2^{2^i}$, we get $\sum_{i=1}^{vis} k_i \le \log n + vis + 1 \le 2\log n$. We use $3(k_{i+1}+1)gp + vp$ units of potential to pay for rotations in which the accessed item traverses the inner skeleton of its i-superblock and for which, on completion, the accessed node has reached an extreme path of its i-superblock. The $3(k_{i+1}+1)gp$ units pay for rotations in which the i-global rank of the accessed item increases, as explained earlier. The vp units pay for the rotation in which the accessed item reaches an extreme path of its i-superblock. Overall, we need

$$\sum_{i=1}^{vis}(3(k_i+1)gp + vp) + \max\{ld + 3sd, 5sd\} \tag{7}$$

units to pay for global accesses so far (see (1)).

Now, we show how to pay for the incomplete segment, if present. We provide an additional gp units to pay for this segment; in addition, this term is used to pay for the incomplete rotation, if any; however, the additional gp term does not need to account for any increase in global rank, on the part of the accessed item, during the incomplete rotation, for this has already been accounted for. The result of Lemma 9 applies here too (in fact, a tighter bound can be shown). Here too, (5) suffices.

We have yet to explain how to maintain the potential of an unlabeled path and the invariants concerning labels, Invariants 1 and 2. If a maximal unlabeled path is traversed in its entirety and, in addition, the child on the extreme path of this unlabeled path is also traversed, then the two old endpoints of the path are labeled (or rather, if an old endpoint is in a couple with another unlabeled node, then the new endpoint is given the label) and the remainder of the path is essentially halved in length; the sufficiency of the potential is readily verified (for a path of length at most 4, the potential suffices to label each node on the path; for a path of length $2k+2$, $k>2$, we have $2\lfloor\log(2k+3)\rfloor \geq 2+2\lfloor\log(k+1)\rfloor$, and for a path of length $2k+3$, $k\geq 2$, we have $2\lfloor\log(2k+4)\rfloor \geq 2+2\lfloor\log(k+2)\rfloor$).

If only a portion of an unlabeled path is traversed, then the path was accessed through an increase in the visibility of the accessed item. Consider an unlabeled path that is part of a left extreme path of its block (the case of a right extreme path is analogous). At most two unlabeled nodes need to be labeled to maintain Invariants 1 and 2, namely the new top of the unlabeled path and the old root of the block. This costs at most $2c$ units. This charge is levied once for each unit increase in visibility on the part of the accessed item. Over the whole access this is a cost of $2c\cdot vis$ units.

On taking equalities in (2)–(6), the lemma follows from (7). □

Unfortunately, the potential, as described, may be of size $\Theta(n\log\log n)$ initially. (For example, consider a zig-zag path descending from the root.) To reduce this to linear size, we modify the rules for creating unlabeled paths and modify the analysis accordingly.

For each block, each of its extreme paths is partitioned into chains. A chain for block B, at level i, comprises a maximal sequence of nodes, $v_1, v_2, \ldots, v_k$, from B, such that the path P in the splay tree from v_1 to v_k does not include any j-global node, $j\geq i$. Each chain, C, is given a path potential of size $2c\lfloor\log(|C|+1)\rfloor+c$ units and a reserve path potential of $2\cdot 2c\lfloor\log|C|\rfloor$. The role of the reserve path potential will become clear in section 4. In addition, each node adjacent on P to a node that is not part of the chain is given an additional *zig-zag* potential of c units; this potential is provided once, and not for each block to which the node belongs.

LEMMA 12. *The cost of the path and reserve path potentials is at most*

$$3\sum_{j=1}^{vis}\left\lceil\frac{n}{c_j}\right\rceil 4c[\lfloor\log c_i\rfloor+3\sum_{i=1}^{j}4c\lfloor\log c_i\rfloor]+2c\cdot(j+1).$$

This is bounded by $144c\cdot n$ *if a* j*-block has size* $c_j=2^{2^{j+1}}$ *for* $j\geq 1$ *(with the possibility of one smaller block at each level* j*).*

Proof. The path potential for each chain, apart from the bottommost chain on each extreme path, is charged to the j-global node terminating the chain at the bottom. The remaining at most two chains in each block are charged to the block itself. Each j-global node is charged for at most two chains on the extreme paths of i-blocks, for each $i\leq j$. A chain of an i-block has length at most c_i-1, so the path potential for an i-chain is at most $2c\lfloor\log c_i\rfloor+c$. Hence the charge to a j-global node is bounded by $\sum_{i=1}^{j}12c\lfloor\log c_i\rfloor+2c$. Likewise, the charge to a j-block is bounded by $12c\lfloor\log c_j\rfloor+2c$. Summing over all j-global nodes, j-blocks, and all j gives a total charge of $\sum_{j=1}^{vis}\lceil\frac{n}{c_j}\rceil 12c[\lfloor\log c_j\rfloor+\sum_{i=1}^{j}\lfloor\log c_i\rfloor]+2c\cdot(j+1)$.

For $c_i=2^{2^{i+1}}$ this is bounded by $\sum_{i=1}^{vis}\lceil\frac{n}{c_j}\rceil 72c\cdot 2^j+2c\cdot(j+1)$ which is bounded by $72c\cdot(n+2\log n)+c\cdot(vis+1)(vis+2)\leq 144c\cdot n$, assuming $n\geq 16$ ($vis=\log\log n$).

For $n < 16$, $vis = 1$, so it suffices to give potential c to each node on an extreme path of the splay tree for a total of cn potential. □

LEMMA 13. *A global access costs at most* $(3\sum_{i=1}^{vis}(k_i+1)+1)gp+vp\cdot vis+2c\cdot vis+(ld+3sd)$ *units, where* $sd = s+1$, $ld, c = 17(s+1)$, $gp = 19(s+1)$, $vp = 30(s+1)$, vis *is the number of levels of blocks, and* k_i *is the* i*-rank of nodes on an* $(i+1)$*-extreme path. (Note* $\sum_{i=1}^{vis}(k_i+1) \leq \log n + 3vis + 1$.*) In particular, maintaining the chain potentials requires a charge of at most* $2c$ *for each unit increase in visibility on the part of the accessed item.*

Proof. It suffices to explain how to modify the analysis of Lemma 11 to account for chains. There are two ways a chain can be traversed: in its entirety or in part. We consider each in turn.

If a chain is traversed in its entirety, following the traversal it forms a path for which the associated path potential is sufficient to allow the previous analysis to be performed; indeed this path potential is too large by c units. These c units are used to label the old root of the block if the root of the block is changed by the traversal. All the couples which include just one node of the chain are paid for by the associated zig-zag potential of c units, or to put it in terms of marking, these couples are marked.

Next, consider a chain which is only partially traversed. Suppose, without loss of generality, that this chain is on the right extreme path of its block. Let v_j be the bottommost node on the chain to be traversed. If v_j is accessed from its left child, then the rotation involving v_j results in an increase in the visibility of the accessed item. This increase in visibility pays for the rotation involving node v_j. Again, the old root of the block may need to be labeled, which costs c units; this is also charged to the increase in visibility. The path potential is associated with the remainder of the chain on and below node v_j. The rotations along the traversed portion of the chain are paid for as in the traversal of the full chain. In addition, the nodes on the traversed portion cease to be on an extreme path of their block and so do not need an associated path potential on completion of the traversal. There may be several chains including v_j which are partially traversed, but the number of these chains is bounded by the increase in visibility. More precisely, let v_j be h-global, and suppose it is on an inner i-skeleton. Then every chain including v_j but not ending at v_j must be on an extreme path of an l-block, $h < l \leq i$; thus there are at most $i - h$ such chains. The increase in visibility for the accessed item, in its rotation with v_j is at least $i - h$. Hence each unit increase in visibility is charged c for the labeling of the root of one partially traversed chain of the type described in this paragraph.

Finally, suppose v_j is accessed from its right child. Then there is a node w on the path between v_j and v_{j+1} which is accessed from its right child. The rotation involving w results in an increase in the visibility of the accessed node. This increase in visibility is charged for the additional potential of c units needed to label the old root of v_j's block. Again, the rotations along the traversed portion of the chain are paid for as in the traversal of the full chain. The path potential continues to be associated with the remainder of the chain starting at node v_{j+1}. We note that there may be many chains including nodes v_j and v_{j+1}, each on an extreme path for a different level of block. But the level of node w must be smaller than that of these blocks. To be specific, let w be h-global. Then every chain including v_j and v_{j+1} must lie on an l-block extreme path, with $h < l$. Suppose further that v_j and v_{j+1} are on an inner i-skeleton. Then the increase in visibility of the accessed item in rotation with node w is at least $i - h$, and there are at most $i - h$ chains straddling w, each of which may require a charge of c to label its old root.

Thus an increase in visibility which places the accessed item on the inner skeleton of an i-superblock results in a charge of up to $2c$ to visibility level i. □

Remark 1. Later, the form of the blocks will be generalized to allow more complex situations involving local nodes. Specifically, we will allow local nodes to carry other debits. For the above analysis to continue to apply, it will suffice that

(i) if a local node on its block's right (resp., left) path carries a new debit, then its parent and right child (resp., left child) are both local nodes of the block,

(ii) a couple containing two local nodes must pay for the removal of all debits on the couple's nodes; the $s+1$ rotations will be paid for as before.

3. Local insertions. For each level i of blocks, the access sequence S is partitioned into maximal subsequences S_l; each subsequence comprises accesses in the same i-block. Recall that an $(i+1)$-block contains b_{i+1} i-blocks and c_{i+1} items. We allocate amortized time $O(\log b_{i+1} + |S_l|\alpha(c_{i+1}))$ to pay for the cost of the sequence S_l. Specifically, the first access to an i-block has amortized cost $O(\log b_{i+1})$ and subsequent accesses have amortized cost $O(1+\alpha(c_{i+1}))$. Note that an access occurs in vis sequences; thus the cost of an access comprises the sum of vis terms. So suppose that an access is to a new i-block, but to the same $(i+1)$-block, with respect to the previous access. Then the cost of the access is

$$O\left(\sum_{h=0}^{i} \log b_{h+1} + \sum_{h=i+1}^{vis} [1+\alpha(c_{h+1})]\right) = O(\log b_{i+1} + (\log\log n)\alpha(n)) \tag{8}$$

(assuming $b_i = 2^{2^i}$ which implies $vis = \lceil \log\log n \rceil$). In section 4, we show how to reduce the $O((\log\log n)\alpha(n))$ term to $O(1)$.

It is possible to have an access close to the previous access be in a different high level block (if both accesses are close to the boundary between the blocks). In section 3.7, we will see how to reduce this excess cost and obtain an amortized time for the access proportional to the logarithm of the distance between successive accesses (plus an additional $O(\log\log n\alpha(n))$ term). For now, we focus on the cost of the access at a single level, i. To be specific, we focus on the rotations during which the accessed item is on the inner $(i+1)$-skeleton.

In the present analysis spare rotations will be spent in several ways. We spend the spare rotations in portions of size s', s' a constant to be specified. Recall that s spares are provided per couple. As we will see in section 4, it suffices to have $s \geq 3s'$.

3.1. Forming lazy trees. As in the analysis of splay sorting $\log n$-block sequences, we construct lazy trees. However, their form is more involved here.

For each level of blocks a separate analysis is performed, as in the analysis of global accesses. Here we focus on the traversal of the inner skeleton of superblock B, an $(i+1)$-block. For each item, the analysis of its traversal of the inner skeleton of superblock B is performed as part of the analysis of a maximal sequence S of accesses to the same block B' of superblock B.

We start with a few definitions. Let b be the number of blocks in superblock B and let c' be the number of items in B. Following the first access of S, we define the *right access path* as follows: Let *right_B* denote the set of elements in superblock B to the right of block B'. Consider the tree induced by the nodes of *right_B*; its left extreme path is the *right access path* (see Figure 5). The *left access path* is defined analogously. In the splay tree, an access path may comprise more than one contiguous segment of nodes. Note that as the accesses of sequence S proceed, the access paths become shorter. Lazy trees are formed from the nodes originally on the access paths.

FIG. 5. *The right access path.*

Let $l\_child(v)$ denote the left child of v. For each global node, v, on the right access path, other than the bottom global node, define $jump(v) = g\_\text{rank}(v) - g\_\text{rank}(l\_child(v))$; for the bottom global node, define $jump(v) = g\_\text{rank}(v) + 1$. $jump(v)$ is defined analogously for global nodes on the left access path.

Consider an access in sequence S; there are three possibilities. First, no node on either access path is traversed, in which case no cost is incurred for the traversal of the inner skeleton of superblock B. Second, the right access path (or rather a top portion of it) is traversed. Third, a top portion of the left access path is traversed.

Our goal is to accumulate spares on the nodes of the access paths, so that following e' accesses we can assume that each node on the access paths, apart from the top node, has accumulated at least $2^{e'-1} - 1$ spares, e' a constant to be specified. We need to be careful, however, for higher portions of the access paths may have been traversed more frequently and thus have accumulated more spares. We proceed as follows.

It is convenient to ensure that on each traversal, for each couple, its two nodes have been traversed the same number of times. This need not be true. So we introduce *pseudotraversals*. Initially, each node on an access path has been pseudotraversed zero times. Each time a node is traversed, its pseudotraversal count is incremented, up to a maximum of e' pseudotraversals. In addition, immediately prior to each access of sequence S, apart from the first access, for each couple in the upcoming access, for each lower node in the couple, its pseudotraversal count is increased to the count of the higher node. We note that the pseudotraversal counts are nondecreasing from bottom to top of the access paths (for each time a node is traversed so are all its ancestors on its access path).

Immediately following the first access in S, we provide each global node, v, on an access path with *jump potential* $2gp \cdot e' jump(v)$. Summing over the two access paths, we obtain a cost of $4 \cdot e' gp(\log 2b + 1)$ units charged to the first access of sequence S; the first access itself costs a further $3gp(\log 2b + 1)$ units. As further traversals of the access paths occur, Invariants 8 and 9 below are maintained.

INVARIANT 8. *Each global node, v, on an access path, apart from the first node, carries a jump potential of $2gp \cdot (e' - t)jump(v)$ after having been pseudotraversed $t \le e'$ times.*

INVARIANT 9. *Each node on an access path, global or not, apart from the first node, carries a spare potential of $s' \cdot (2^{(t-1)} - 1)$ units after having been pseudotraversed $t \le e'$ times.*

Clearly the invariants are true following the first access of sequence S.

First, we explain how to maintain the invariants following the increase in pseudotraversal counts (immediately prior to an access). Clearly, Invariant 8 is unaffected

for the jump potentials can only decrease. To maintain Invariant 9, an additional spare potential of $s' \cdot (2^{q-1} - 2^{p-1})$ is provided to a node whose pseudotraversal count increases from p to q. This is a total of at most $s' \cdot 2^{e'-1}$ spare potential per access for the pseudotraversal counts are nondecreasing along the access path (from bottom to top).

Next, we show how to pay for an access and how to restore Invariants 8 and 9 following the access. Consider one couple of this access, where the couple contains nodes u and v, and u is the parent of v. Further suppose that at least one of u and v is on the access path.

The rotation is paid for as in a global access, except that the jump potentials provide the additional potential needed to pay for the segment associated with a rotation which increases the global rank of the accessed item. There is one special case: if the rotation increases the visibility of the accessed item, then the increase in visibility is charged for the segment associated with the rotation, and the increase in the global rank of the accessed item is not charged. In addition, we are no longer seeking to provide a global potential to the accessed item, w. For w eventually acquires the global potential of the old root, x, of w's block, and x then acquires the sub or mini potential of w. More precisely, it will suffice, at each global node, y, on the access path, to provide $2gp \cdot jump(y)$ units of potential, taken from y's jump potential.

It remains to explain how Invariants 8 and 9 are restored following the rotation. We start with Invariant 9. u gives v all its spare potential; in addition, v receives s' of the spares allocated to the couple u, v. This gives v spare potential $s'[2 \cdot (2^{(t-1)} - 1) + 1] = s'(2^t - 1)$, as needed, since t will be incremented.

Invariant 8 needs restoring only if both u and v are global nodes; then u gives v its remaining jump potential. To show this suffices we argue as follows. Without loss of generality, suppose that both u and v are on the right access path. First, we note that $g\_\text{rank}(l\_child(v))$ is unchanged following the rotation involving v (for w, the accessed item, is in block B' and so its left subtree contains no global items, while w's right subtree remains a subtree of v). Likewise, $new\_g\_\text{rank}(v)$, $g\_\text{rank}(v)$ following the rotation involving v, is exactly $g\_\text{rank}(u)$ before this rotation. So $new\_jump(v)$, the value of $jump(v)$ following the rotation, is given by $g\_\text{rank}(u) - g\_\text{rank}(l\_child(v))$, which is $[g\_\text{rank}(u) - g\_\text{rank}(v)] + [g\_\text{rank}(v) - g\_\text{rank}(l\_child(v))]$, or $jump(u) + jump(v)$, as claimed. Hence, following the rotation, v has jump potential $2gp \cdot (e' - (t+1))jump(v)$ (using the new value for $jump(v)$); as t is incremented following the rotation, Invariant 8 continues to hold.

Once a node on an access path, other than the top node, has been pseudotraversed e' times, and hence carries spare potential $s'(2^{e'-1}-1)$, when it is rotated off the access path it becomes a lazy node and is given q_1 units of potential, q_1 a constant to be specified. In addition, if both the nodes u and v in the couple are global, they swap their global potentials; the potential now carried by u, the node leaving the access path, is called its *lazy potential*. Each couple pays for its rotation, spare rotations, and associated segment charge, if any, by a charge of gp units to the spare potential of the node leaving the access path, instead of by the creation of debits. So it suffices to have

$$s'(2^{e'-1} - 1) \geq gp + q_1. \tag{9}$$

When a rotation removes the top node of an access path it too becomes a lazy node; however, it is given $a_3\alpha(c') + b_3$ potential, where a_3 and b_3 are constants to be specified. So following the first access of sequence S, the charge per access for the traversal of nodes on the inner skeleton of block B is bounded by $s' \cdot 2^{e'-1} + a_3\alpha(c') + b_3$.

We note that a lazy node, on creation, carries no debit. For the rotation creating the lazy node is paid for by the gp charge to the node's spare potential (see (9)).

In fact, we provide another $2gp \cdot (\log 2b + 1)$ units to the first access of sequence S. This is used as follows. For each global node u remaining on an access path, as soon as u acquires a proper global descendant v on the access path, which has been pseudotraversed e' times, we provide u a *reserve potential*, defined as follows. Define the *marker_rank* for a global node, v, on the access path to be the global rank of the node following exactly e' pseudotraversals. Define the *reserve_rank* for global node u to be: $reserve\_\text{rank}(u) = marker\_\text{rank}(u) - marker\_\text{rank}(v)$, and the reserve potential for u to be gp times its reserve_rank. The role of the reserve potential will become clear later.

As in the analysis of a global access, the cost of the segment that involves an increase in visibility on the part of the accessed item is at most $vp+2c$, per unit increase in visibility. The presence of lazy trees, as we will see, adds a further $4gp(\log 2b + 1)$ to the cost of the first access of sequence S. So, focusing on superblock B alone, the cost of the first access in S is bounded by

$$(4e' + 9)gp(\log 2b + 1) + vp + 2c, \tag{10}$$

and the cost of a subsequent access of S is bounded by

$$s' \cdot 2^{e'-1} + a_3\alpha(c') + b_3 + vp + 2c. \tag{11}$$

Also, for each access, there are fixed costs of (see (1))

$$ld + 3sd. \tag{12}$$

Each node removed from the access paths is called a *lazy node*, whether or not it has a lazy potential. Those lazy nodes with a lazy potential are called *heavy* nodes; the other lazy nodes are called *light* nodes. When the accesses of sequence S are completed, we form *lazy trees*. Each global node v remaining on the right access path becomes the root of a new *right lazy tree*. Its left subtree is empty; its right subtree comprises the lazy nodes, created during the accesses of sequence S, in v's right subtree in the splay tree. An analogous definition is made with respect to the left access path. It is straightforward that each new lazy node is contained in a new lazy tree. We call the lazy trees as defined above *initial lazy trees*. (We will be adding and removing a few nodes from the initial lazy tree in order to obtain other lazy trees, which are the lazy trees that are actually analyzed.) As we will see, the local nodes on the access paths, which have been pseudotraversed e' times, may be added to the new lazy trees; these nodes too are called light nodes of their lazy trees. We will need to ensure these nodes also carry no debits and have an associated potential of q_1 units. But this is ensured by requiring

$$s'(2^{e'-1} - 1) \geq q_1 + \max\{sd, ld, hd, ed\}, \tag{13}$$

where hd and ed are the values of other debits (huge and enormous debits) introduced later.

Remark 2. We will need to generalize this analysis to take account of the presence of lazy trees on the access paths. The present analysis, with (9) replaced by (14) below, will continue to apply if the following conditions hold.

(i) Each node on the access path, which has been pseudotraversed e' times, has spare potential $(2^{e'-1} - 1)s$.

(ii) A lazy tree node, on creation, carries no debit.

(iii) Following the first e' pseudotraversals of a node v on the access path, if v's couple includes just one node on the extreme path of a lazy tree, the cost of the rotation of this couple is the same as in the present analysis.

(iv) Following the first e' pseudotraversals of a node v on the access path, if v's couple includes two nodes on the extreme path of a lazy tree, the cost of the rotation of this couple is at most $\max\{hd, ed\}$ units. The additional cost of the couple is covered by the spare potential if

$$s'(2^{e'-1} - 1) \geq gp + q_1 + \max\{hd, ed\}. \tag{14}$$

(i) and (ii) will be achieved as here. (iii) will be seen to be true shortly. (iv) will be handled later, in Lemma 14.

Next, we describe the potential provided to the lazy trees and show how to include the lazy trees in the overall analysis.

3.2. The analysis of lazy trees. In the following subsections, unless we specify otherwise, the definitions given apply to right lazy trees. Analogous definitions hold for left lazy trees. We focus on the right lazy trees; we discuss the left lazy trees only where their presence affects the analysis (the only place this arises is in section 3.6).

Much of the analysis focuses on a subtree of the initial lazy tree, called the *truncated lazy tree* or the *lazy tree*, for short. It is defined as follows. Consider a new initial lazy tree, L, created by the sequence S of accesses. Consider the set of heavy nodes in L; the tree they induce is called the *initial lazy block tree*. We remove the rightmost node from the initial lazy block tree; this defines the (truncated) lazy block tree for the (truncated) lazy tree. This rightmost node is called the *right guard* for the lazy tree. The *left guard* is a global node, defined later, to the left of the nodes of the lazy block tree. The root of the (truncated) lazy block tree is called the (truncated) root of the (truncated) lazy tree. We define the tree induced by the nodes of the lazy block tree plus the left and right guards to form the *large lazy block tree*. Now we define the (truncated) lazy tree as follows. It comprises the nodes of the (truncated) lazy block tree together with the following light nodes. For each node v in the (truncated) lazy block tree we add the following nodes from v's block to the (truncated) lazy tree. Let w be any descendant of v in the large lazy block tree. Those nodes in v's block on the path from v to w in the splay tree are added to the (truncated) lazy tree. The light nodes added to the lazy tree form its *skeleton*.

We define the *left guard*, w, of the lazy tree as follows. Let L be a new lazy tree with root u. Let v be the first proper global descendant of u on the portion of the right access path which has been traversed at least e' times, if any. Suppose v exists; if v is the root of another new lazy tree, let w be the right guard in this lazy tree, while if v is not the root of a new lazy tree, then let $v = w$. Otherwise, let w be the root of the splay tree. In general, a node may be a right guard for one lazy tree and a left guard for a second lazy tree.

Intuitively, a truncated lazy tree is a megablock comprising several of the blocks at hand. The megablock is considered to be at level $i - 1$, the level of the blocks it comprises. In its interactions with the remainder of the splay tree the megablock will behave in the same way as a block. The root of the lazy tree corresponds to the block root and behaves like a global node; the other nodes of the lazy tree, called *local* nodes of the lazy tree, correspond to the local nodes from the block. The lazy tree local nodes may carry small and large debits according to the invariants specified for blocks; a further *lazy* debit may be carried as specified later.

The right guard of each new lazy tree has its global potential restored; this is paid for by adding its reserve potential to its lazy potential, which suffices by Invariant 24, in section 3.5. In addition, Invariants 5 and 6 may need to be restored; this requires the removal of at most two small debits. These are paid for by the potential $a_3 + b_3$ associated with each lazy node on paths P_1, P_2, P_3 (see sections 3.3.3 and 3.3.4); these paths always include the right guard. Thus both the left and right guards of each lazy tree carry their global potentials.

We need one more definition: a *rightist tree* is a tree in which the depths of the leaves, from left to right, are nondecreasing. Now, we describe the structure of a typical lazy tree. Consider a newly constructed initial right lazy tree, IL, and the associated lazy tree, L. The main difference between L and IL is that IL may have (many) light nodes which are not in L. The tree induced by the nodes of L comprises its left extreme path (a sequence of light nodes), its root, and a path, P, descending to the right, together with the left subtrees of the nodes on P; each of these left subtrees is a rightist tree (strictly speaking, if v is the root of such a left subtree, then the tree rooted at v in IL is a rightist tree). It is helpful to partition P, the left extreme path and the root into four portions, BL, P_1, P_2, and P_3. BL comprises the light nodes on the skeleton from the leftmost block in L (initially, BL comprises the light nodes on the left extreme path); P_1 is the maximal top contiguous portion of P incident on the root of the lazy tree, minus those nodes in BL, P_2 is the second highest contiguous portion of P below P_1, and P_3 is the remainder of P below $P2$. It is also helpful, for each subtree of P, a rightist tree, R, to partition R into its top right path RP, and the left subtrees of RP, also rightist subtrees (again, strictly speaking, it is the corresponding subtrees in IL which are rightist); let SR denote a typical such rightist subtree (*small rightist subtree*). Now, to analyze a lazy tree, we analyze rotations in each of its six types of components separately; the six types of components are

(i) BL, comprising nodes of type 1,
(ii) the path P_1, comprising nodes of type 2,
(iii) the path P_2, comprising nodes of type 3,
(iv) the path P_3, comprising nodes of type 4,
(v) each path RP, comprising nodes of type 5,
(vi) each rightist subtree SR, comprising nodes of type 6.

The following invariant describes the distribution of the six types of nodes.

INVARIANT 10. *Let L be a right lazy tree. Let v be a node in L. The following nodes all have type equal to or less than type(v):*

(a) *the nodes on the left extreme path of L, other than v's ancestors,*
(b) *the left ancestors of v in L, apart from the root of L.*

In particular, traversing the extreme paths of the lazy tree from the bottom of the right extreme path to the bottom of the left extreme path, including the root of the lazy tree, yields, in order,

(i) a path from a tree SR,
(ii) a portion of a path RP,
(iii) a portion of P_3,
(iv) a portion of P_2,
(v) a portion of P_1,
(vi) a portion of BL.

The portions need not be contiguous portions of the original paths, and some or all of the portions may be empty. There are only two ways in which the type of a node can change: first, a node can leave the lazy tree; second, when the lazy tree is split,

a node may move into a component BL.

The structure of a left lazy tree is entirely analogous.

Our analysis is presented in three parts. First, for each component of the lazy tree, we describe the potentials associated with its nodes. Second, we analyze a traversal of an extreme path of a lazy tree. Third, we analyze a split of a lazy tree. For the moment, this discussion will exclude the possibility of multiple lazy trees contained within one another; in section 3.6 we show how to accommodate this possibility.

Before entering into the details of the potentials it is helpful to introduce the normal form of a (right) lazy tree L. It is obtained by performing the following series of single rotations: one by one, the left path nodes are moved to the right path; each such rotation, between node v and node r, the root of the lazy tree, makes v the root and places r on the right path. r and v interchange potentials and all lazy tree properties. The resulting tree is called the *normal tree* for L.

3.3. The potentials for the components of the lazy tree.

3.3.1. The rightist subtrees SR. We use the potential defined for the lazy trees present in the result on splay sorting $\log n$-block sequences, where it is called the *lazy complete tree potential*. To define this potential we need to introduce the *component lazy block tree*. It is the tree induced by the heavy nodes in the component SR together with the root of the lazy tree. A node of height h in the component lazy block tree, other than the root, is given potential $\frac{1}{2}a_1 \sum_{i=1}^{h} i(i+1) + b_1$, a_1 and b_1 being constants to be specified, while a light node in the subtree SR is given potential c_1, c_1 being another constant to be specified.

Now, we verify that there is enough potential at hand to initialize the trees SR with their correct potential. Let ISR denote the subtree in the initial lazy tree corresponding to SR (the subtree with the same root as SR). We start by giving a node of height k in ISR potential $\frac{1}{2}a_1 \sum_{i=1}^{k} i(i+1) + b_1$, regardless of whether the node is heavy or light. Since, for each heavy node, its height in ISR is at least as large as its height in the component lazy block tree, the heavy nodes will receive sufficient potential. To ensure adequate potential for the light nodes (potential c_1) it suffices to ensure

$$c_1 \leq a_1 + b_1. \tag{15}$$

We explain how to provide the initial potential of $\frac{1}{2}a_1 \sum_{i=1}^{k} i(i+1)+b_1$ to the nodes of ISR. We exploit the fact that the path IRP (the right path in IL corresponding to RP) together with its left subtrees is also a rightist subtree. A nonleaf node, v transfers all but b_1 of the charge for its potential to the following node, w, to its right (see Figure 6). Suppose v's first right ancestor, u, is reached by following e edges to the left and then an edge to the right. Then w is defined to be the descendant of u reached from u's right child by following $e+1$ left edges (edges to left children). The charge, $\frac{1}{2}a_1 h(h+1)$, for a node v at height h, is transfered to a node w at *minimum height* at least $h-1$, where the minimum height of a node is the length, in vertices, of the path to its leftmost descendant. Thus, a node v at minimum height k receives a charge of at most $\frac{1}{2}a_1(k+1)(k+2)$. This charge can be distributed evenly among the nodes by passing a charge of $a_1 \cdot (\frac{1}{2}k^2 + \frac{5}{2}k - \frac{7}{2})$ to each of v's children, if v has minimum height greater than 1 (note that v will receive a similar charge of at most $a_1 \cdot (\frac{1}{2}(k+1)^2 + \frac{5}{2}(k+1) - \frac{7}{2})$ from its parent, for v's parent has minimum height at most $k+1$); also, v keeps a charge of $\frac{15}{2}a_1 + b_1$ locally. A node at minimum height 1 receives, at most, a transfered charge of $3a_1$, a charge of $\frac{7}{2}a_1$ from its parent, and a

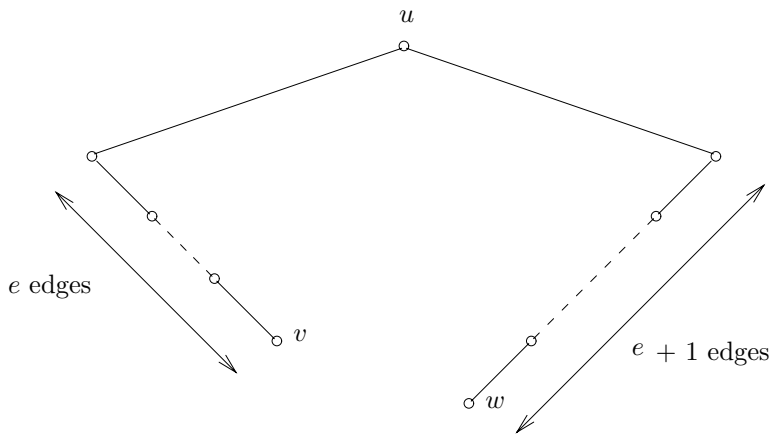

FIG. 6. *The node w receiving potential.*

direct charge of a_1+b_1; this is a total charge of at most $\frac{15}{2}a_1+b_1$. So we see that each node is charged at most $\frac{15}{2}a_1+b_1$. Finally, we note that the charges are transfered only among nodes in the trees ISR.

So, as the lazy tree is being constructed, it suffices to provide each node in a tree ISR with potential $\frac{15}{2}a_1+b_1$; this is guaranteed by having

$$q_1 \geq \frac{15}{2}a_1 + b_1. \tag{16}$$

3.3.2. The paths *RP*. Consider a path, RP. Initially, it comprises a contiguous sequence of nodes, descending to the right. As it is traversed, roughly speaking, it will become a binary tree, at which point the potential for rightist lazy trees becomes adequate. Thus our goal is to provide a potential that progressively converts to a rightist lazy tree potential as the path is repeatedly traversed. As we will see, an initial potential of a_2+b_2 for each node suffices, where a_2 and b_2 are constants to be specified. So it suffices to have

$$q_1 \geq a_2 + b_2. \tag{17}$$

3.3.3. The paths P_1 and P_2. They are treated in exactly the same way as the paths RP. To provide sufficient initial potential here it suffices to have

$$a_3\alpha(c_l) + b_3 \geq a_2 + b_2.$$

In turn, to satisfy this equation, the following suffices:

$$a_3 + b_3 \geq a_2 + b_2. \tag{18}$$

In fact, we modify the statement of section 3.1 that $a_3\alpha(c_l)+b_3$ potential is provided; instead only a_2+b_2 potential is provided, which still suffices. The reason for this modification will become clear in section 4.

3.3.4. The path P_3. This path cannot be treated in the same way as the paths RP for it does not necessarily comprise a contiguous sequence of nodes in the splay tree.

We maintain the following potential; each node on the current right extreme path of the tree induced by the root of the lazy tree plus P_3, with one class of exceptions, carries a potential of c_2, c_2 a constant to be specified. The exceptional nodes are formed by sequences of $4\alpha(c_l)$ contiguous nodes whose parent and right child in the splay tree are both from P_3; such nodes need not carry the c_2 potential. More precisely, each maximal contiguous sequence of nodes on the right extreme path of the tree induced by P_3, from bottom to top, has an initial segment of length one and a final segment of length at least one and at most $4\alpha(c_l)$ in which each node has a potential of c_2; the remainder of the sequence is partitioned into segments of length exactly $4\alpha(c_l)$, and in each such segment either all or none of the nodes carry a potential of c_2. Each node on the current extreme left path of the tree induced by the root of the lazy tree plus P_3 carries a potential of c_2, with no exceptions.

In addition, P_3 has an associated potential, $Pot(P_3)$; before specifying this potential we need to introduce some other definitions and results. A k-right cascade is a sequence of k single left rotations (a rotation between a node and its right child) on a set of k contiguous couples on a right path. A *right k-cascade sequence* is an intermixed sequence of k-right cascades and arbitrary left rotations. We recall that Sundar [Su89] showed that there can be at most $8m$ $2\alpha(m)$-right cascades in a right $2\alpha(m)$-cascade sequence on the normal form of an m-node binary tree. We define $Pot(P_3) = 4c_2\lambda\alpha(c_l)$, where λ denotes the maximum number of $2\alpha(c_l)$-right cascades in a right $2\alpha(c_l)$-cascade sequence that can be performed on the normal form of the tree induced by the nodes of P_3 and the root of the lazy tree, with the root of the lazy tree removed from the normal form (i.e., the cascades never include the root node); this tree comprises at most c_l nodes. The initial values of λ is at most $8|P_3|$, and so $Pot(P_3) \leq 32c_2\alpha(c_l)|P_3|$.

Finally, each node in P_3 carries an additional potential of $4c_2\alpha(c_l) + c_2$. Thus it suffices to provide each node in P_3, on creation, with potential $36c_2\alpha(c_l) + 2c_2$; so it suffices to have

$$a_3\alpha(c_l) + b_3 \geq 36c_2\alpha(c_l) + 2c_2.$$

That is, it suffices to have

$$a_3 \geq 36c_2, \tag{19}$$

$$b_3 \geq 2c_2. \tag{20}$$

3.3.5. *BL*, the skeleton nodes in the leftmost block. Each node in the leftmost block of the lazy tree carries an additional potential of c_3 units. Nodes in the other blocks carry an additional potential of $c_3 + c_4$ units. In order to provide this potential initially, we augment each of q_1, $a_3 + b_3$, and b_3 by $c_3 + c_4$ units. So it suffices to have

$$q_1 \geq \max\left\{\frac{15}{2}a_1 + b_1, a_2 + b_2\right\} + (c_3 + c_4), \tag{21}$$

$$a_3 + b_3 \geq a_2 + b_2 + (c_3 + c_4), \tag{22}$$

$$b_3 \geq 2c_2 + (c_3 + c_4). \tag{23}$$

3.3.6. Debits on the local nodes of the lazy tree. Nodes on the extreme paths of the lazy tree may have a small or large debit; these debits satisfy Invariants 3–6, where lazy tree L replaces block B in the statement of the invariants. Also, each node in the lazy tree can be considered to be labeled. A labeling potential is not needed here, however, for the removal of nodes from an external path of the lazy tree is always paid for in some other way, as we shall see. However, so that we can apply Invariants 3–6, we will consider the nodes of a lazy tree to be labeled. In addition, each light node in the lazy tree may have a *lazy* debit, which is *huge* and has value hd units, $hd \geq ld$, a constant to be defined later. Lazy debits satisfy the following invariants.

INVARIANT 11. *Let L be a right (resp., left) lazy tree. Suppose node v in L has a lazy debit. Then v is a light node of L. Also, v is not on the left (resp., right) extreme path of L. Finally, v does not carry a small or large debit.*

INVARIANT 12. *Let L be a right (resp., left) lazy tree. Let u be a light node of L. Suppose u has a lazy debit. Let v be the root of u's block.*

(i) *Suppose that v is not on the left (resp., right) extreme path of L. Then if u is on the right (resp., left) path descending from v in the splay tree, both the parent and child of u on this path are local nodes in u's block and are in the same component as u.*

(ii) *If u is on the right (resp., left) extreme path of L, then its parent and child in the splay tree are local nodes in u's block and are in the same component as u; this holds regardless of whether u is on the right (resp., left) path descending from v in the splay tree.*

INVARIANT 13. *BL and P_3 do not carry lazy debits.*

In addition, each node in the lazy tree may have a *border* debit, which is enormous and has value ed; ed is a constant to be defined later. Border debits satisfy the following invariants.

INVARIANT 14. *Let L be a right (resp., left) lazy tree. Suppose node v in L has a border debit. Then v is not the root of L and is not on the left (resp., right) extreme path of L. Further, if v is on the right (resp., left) extreme path of L, then both v's parent and right (resp., left) child in the splay tree are in the same component of L.*

INVARIANT 15. *A node has at most one debit.*

Next, we show how to incorporate lazy trees into the analysis of accesses. An access can traverse a lazy tree in one of three ways:

(a) traverse the right extreme path of the lazy tree (or rather a topmost portion of it),

(b) traverse the left extreme path of the lazy tree (or rather a topmost portion of it),

(c) traverse the interior of the lazy tree and thereby split the lazy tree.

Actually, it is convenient to classify a traversal of type (a) which is to the left of the block of the right guard to be a split (a type (c) traversal); likewise a traversal of type (b) to the right of the block of the left guard is defined to be a split.

A traversal of type (c) will be paid for in two phases. First, in a preprocessing phase, the current lazy tree is partitioned into several lazy trees and/or ordinary blocks, so as to ensure that the actual splay (the second phase) comprises only traversals of types (a) and (b). (In fact, as we will see, we need a third phase in order to pay for some of the partitioning performed in the first phase.)

We start by considering the interactions between the lazy tree and the remainder of the splay tree (which may include other lazy trees). We treat the lazy tree, as

delimited by its extreme paths, as a block. We note that Invariant 12 ensures that a node on an extreme path, carrying a lazy debit, satisfies condition (i) of Remark 1. In addition, we note that on creation, the nodes of the lazy tree have no debits; so Invariants 3–6 all hold at this point.

Next, we need to show that condition (ii) of Remark 1 is satisfied. That is we have to show that couples involving two nodes on an extreme path of the lazy tree, which will be marked, can pay for the removal of their debits and $s+1$ rotations. This is done in section 3.4.

Segments are defined and paid for essentially as before. The one difference occurs if either node of the leading couple of the segment carries a lazy debit; then the couple pays for its own rotation and the removal of its debits as part of the lazy tree, as we see later; but this can only reduce the total remaining cost of the segment and so the bounds of the previous analysis are still valid.

We need to mention one detail about couples containing the root u of a lazy tree and another node v in the same lazy tree. Following the rotation, v becomes the root of the lazy tree; v and u interchange roles and potentials (so if v had been light, resp., heavy, u becomes light, resp., heavy).

In section 3.5 we explain how a lazy tree is split.

3.4. Extreme path traversal. We consider all rotations involving two nodes on an extreme path. So consider a couple comprising nodes u and v, where u is the parent of v. We distinguish the following types of couples.

Case 1. u and v are both nodes of P_3. If both u and v carry c_2 potentials, then the potential associated with u, which ceases to be on an extreme path of P_3, is used to pay for the rotation, s spares, and the removal of any debits, which do not include lazy debits (see Invariant 13). So it suffices to have

$$c_2 \geq (s+1) + \max\{2ed, ld\}. \tag{24}$$

If one or both of u and v do not carry a c_2 potential then they are part of a contiguous sequence of $4\alpha(c_l)$ nodes lacking this potential. This sequence undergoes a $2\alpha(c_l)$-right cascade (or perhaps this sequence of nodes shifted by one). The cascade provides c_2 potential to each of these $4\alpha(c_l)$ nodes; we can then handle the rotation between u and v as before. The $4c_2\alpha(c_l)$ cost of the cascade is charged to P_3 (recall that P_3 had been given sufficient potential to pay for the maximum possible number of such cascades).

Case 2. u and v are both nodes of BL. The c_3 potential associated with u, which ceases to be on BL, is used to pay for the rotation, s spares and the removal of any debits, which do not include lazy debits (see Invariant 13). So it suffices to have

$$c_3 \geq (s+1) + \max\{2ed, ld\}. \tag{25}$$

Case 3. u and v are in distinct components. Then u is given a border debit. This pays for the rotation, s spares, and the removal of debits from u and v (note that by Invariants 14 and 12 u and v carry neither lazy nor border debits). So it suffices to have

$$ed \geq (s+1) + ld. \tag{26}$$

Case 4. u and v are in the same tree SR, a *rightist lazy tree*. Again, without loss of generality, we are only considering right lazy trees. The analysis is similar to

that in splay sorting $\log n$-block sequences but the possible presence of border debits changes the cost of the various rotations.

Case 4.1. u and v are both light nodes. u ceases to be on the skeleton. u's c_1 potential pays for the rotation, s spares, and the removal of debits on u and v. So it suffices to have

$$c_1 \geq s + 1 + \max\{2hd, 2ed, ld\} = s + 1 + \max\{2hd, 2ed\}. \tag{27}$$

Case 4.2. u is a light node and v is a heavy node. By Invariant 12, u does not have a lazy debit. If u leaves the skeleton, the operation is paid for by u's c_1 potential, as in Case 4.1; (27) suffices. Otherwise, u is given a lazy debit; this then pays for the operation. The cost of the operation comprises the rotation, s spares, and the removal of the small, large or border debits, if any, from u and v. So it suffices to have

$$hd \geq s + 1 + \max\{ld, 2ed\} = s + 1 + 2ed. \tag{28}$$

Case 4.3. v is a light node, u is the root of v's subblock but is not the lazy tree root. By Invariants 11 and 12, u and v do not have lazy debits. v becomes the block root. As in Case 4.2, if u leaves the skeleton, the operation is paid for by u's c_1 potential. Otherwise, u is given a lazy debit, which pays for the operation. The cost of the operation comprises the rotation, s spares, and the removal of the path or border debits, if any, from u and v. Here too (27) and (28) suffice.

Case 4.4. u and v are both heavy nodes. We need to pay for the rotation, for s spares, and for the removal of path or border debits from u and v, if any. In addition, we may need to reestablish Invariant 12 for the nodes on the path newly abutting u; this may require the removal of up to two lazy debits, which will also be paid for by the rotation. So the cost of this rotation is bounded by

$$s + 1 + 2hd + 2ed. \tag{29}$$

The analysis of this case is identical to that of the corresponding case in the splay sorting of $\log n$-block sequences [CMSS00]; it is omitted in part. However, in order to understand the analysis of Case 5, it is helpful to repeat it in part.

For the remainder of this case, until we indicate otherwise, when we refer to a tree we intend the component lazy block tree. So, for instance, when we refer to a node we mean a node in the component lazy block tree.

We start with some definitions. The *depth* of a node is its distance from the root. The height of a node at the time of the creation of the lazy tree is called its *creation-height* (a leaf has creation-height 1); the creation-height does not change subsequently.

Consider how an extreme path traversal appears to the tree. A top contiguous portion of the nodes on this path are all *touched* (these are the nodes contained in couples of the splay tree). Some (arbitrary) subset of disjoint pairs of touched nodes form couples. Each touched node is provided with $\frac{s'}{2}$ spare units of potential (this is the node's share of the portion of s' spares provided to its couple in the splay tree). The spare potential of the touched nodes, together with any changes to the potentials of the touched couples will pay for the rotations of the touched couples.

At any time, certain nodes, called *active* nodes, are the nodes that pay for a traversal of an extreme path. Some nodes may pay more than other nodes. This is captured by the notion of *active layers*. A node of creation-height h has an associated

span of layers $[1, h]$; each active node v of creation-height h has an *active span* of *active layers*, $(g, h]$, $0 \leq g \leq h$; for each k, $g \leq k \leq h$, we say v is *k-active*. If the active span is nonempty, we say the node is *active*.

Initially, only the nodes on the right path are active. An inactive node becomes active when it first reaches the right path. Once a node becomes active it remains active, whether or not it remains on the right path; also, the active span of a node can only grow.

A rotation of the splay operation involving a heavy node, v, and the root, r, of the lazy tree causes the two nodes to swap all their potentials. Also r acquires v's creation-height and active span.

The following invariant states several properties of the active nodes. We prove the invariant later. In order to avoid special cases for the left path we state our invariants with respect to the normal form of the tree, where the tree comprises the root of the lazy tree together with the component lazy block tree.

INVARIANT 16. *Let H be the maximum creation-height for the nodes, other than the root, present in the tree initially. Then, in the corresponding normal tree, the following hold:*

(i) *There is exactly one k-active node, $1 \leq k \leq H$.*

(ii) *Every node on the right path is active (this does not include the root).*

(iii) *Apart from the root, the ancestors of an active node are all active.*

(iv) *Let v be a k-active node. Let w be a j-active node. If $j < k$, then w is to the right of v in symmetric order, while if $j > k$, then w is to the left of v in symmetric order.*

(v) *Let inactive node v have creation-height k. Then its parent has creation-height greater than k.*

When a lazy tree is created the active spans for the nodes in the corresponding component lazy block tree are initialized as follows. Let u be a node on the right path, of creation-height h; suppose it has a right child v of creation-height g (if there is no such node v let $g = 0$). Then u is given active span $[g + 1, h]$. Clearly, the new tree obeys Invariant 16.

The layers of a node are further categorized as *black* or *white*; an active node, with active span $[g, h]$, can be black with respect to each of the layers $[1, g - 1]$. In general, an active node v, with active span $[g, h]$, is black with respect to all the layers in some range $[f, g - 1]$, $f \geq 1$, called its *black span*; we say v is *k-black*, for $f \leq k \leq g - 1$. If the black span is nonempty we say the node is *black*. Nodes are initially white at all layers. A node becomes black as a consequence of a rotation with the root. The following invariant applies to black nodes.

INVARIANT 17.

(i) *All the nodes on the left path of a tree are fully black, i.e., a node with active span $[g, h]$ has black span $[1, g - 1]$.*

(ii) *If a node u is k-black all of u's left ancestors, apart from the root, in the corresponding normal tree are k-black.*

We define the following distances for each node v, active at layer k. Its *right path k-distance*, $d_k(v)$, is the number of proper left ancestors of v on the right path, excluding all k-black nodes. Its *interior right path k-distance*, $id_k(v)$, is the number of proper left ancestors of v below the first k-black node and below the right path.

For each k-active node we maintain a k-potential, which satisfies the following invariant (d_1 is a constant to be specified).

INVARIANT 18. *The k-potential at k-active node v is at least*

$$a_1 \cdot \min\{d_k(v)/d_1, k\} + a_1 i d_k(v)/d_1.$$

We note that initially a node has $a_1 \cdot k$ units of potential for each layer k at which it could become active, so when a node first becomes k-active, Invariant 18 holds.

For each k-black node we maintain a k-black potential of $\frac{a_1}{2d_1}$ units.

We conclude by stating the sufficient conditions that are imposed by the analysis of [CMSS00] (in the previous analysis a and d replace the present a_1 and d_1, respectively).

$$d_1 s'/2 \geq \max\{s + 1 + 2hd + 2ed, a_1/d_1\}. \tag{30}$$

$$\frac{1}{2} a_1/d_1 \geq s + 1 + 2hd + 2ed. \tag{31}$$

There is one matter related to this analysis which needs detailing. Immediately prior to a traversal of the right path, each node on that path is given $s'/2$ spare rotations (whether or not the node is part of a couple comprising two heavy nodes of the same lazy tree component SR). Each node's spares are subsequently provided by the rotation which involves that node. The $s'/2$ spares associated with each node are redistributed in order to pay for those rotations which are not self paying. The details can be found in [CMSS00].

Case 5. u and v are both in a component RP (or are both in P_1 or P_2).

We begin by describing the potential associated with the nodes of component RP.

The nodes originally forming the path RP are partitioned into three sets:

(i) those nodes on a shortened path, RP', called *pure path nodes*,

(ii) *rare black nodes*,

(iii) *rightist nodes*.

The following invariants apply to the path RP.

INVARIANT 19. *The nodes in RP' form a contiguous path in the splay tree.*

INVARIANT 20. *After t traversals, a node on RP' has potential $a_2 \sum_{j=1}^{t+1} j + b_2$, $a_2 \geq a_1$ and $b_2 \geq b_1$ being constants to be specified.*

INVARIANT 21. *Let N be the normal form of the lazy tree L. Let v be a node in RP, a part of L.*

(i) *Suppose that v is a rare black node. Each of v's left ancestors in N which is also in RP is also a rare black node.*

(ii) *Suppose that v is in RP'. Then each of v's left ancestors in N which is also in RP is either in RP' or is a rare black node.*

INVARIANT 22. $|RP'| \neq 1$.

Each rightist node has a creation-height and corresponding potentials satisfying Invariants 16–18. Each rare black node also has a creation-height; these black nodes have the *rareness property*, namely there are no other nodes in this component RP with the same creation-height. The rare black nodes carry k-black potentials and k-potentials; they too satisfy Invariants 16–18. Owing to the rareness property we are able to reduce their initial values somewhat. However, it is easier to defer the precise specification of these potentials till Cases 5.2 and 5.3, where we explain how the potentials change as the rotations analyzed in these cases are performed. The nodes in RP' acquire creation-heights and appropriate rightist lazy tree potentials as and when they leave RP', either to become rare black nodes or rightist nodes.

Initially, $RP = RP'$. So an initial potential of a_2+b_2 for each node in RP suffices, as claimed in (17).

Case 5.1. Neither u nor v is in RP'. This is treated as a rotation in a rightist lazy tree. It is handled exactly as in Case 4.

Case 5.2. u and v are pure path nodes (i.e., both are on RP'). We require that the cost of the rotation be at most $s+1+ld$. This follows by ensuring that the pure path nodes carry no border or lazy debits. So we add the following invariant.

INVARIANT 23. *Let u be a pure path node in a lazy tree. Then u does not carry a border or lazy debit.* We note that Invariant 23 can be maintained by trimming the ends from RP' whenever an end is part of a couple including a node outside RP'. So if, in couple (u, v), with u the parent of v, v is the top node on RP', v is converted to a rare black node (by the method of Case 5.3, below); while if u is the bottom node on RP', u is converted to a rightist node (by the method of Case 5.4, below).

Suppose that this is the $(t+1)$th traversal of u and v. Then their potentials are adjusted as follows. u, which leaves RP', receives potential $a_1 \sum_{j=1}^{t+1} j + b_1$ and becomes a rightist node with creation-height $t+1$ (at this point we further reduce u's potential if it is light—see section 3.3.1). v remains on RP' and so its potential increases to $a_2 \sum_{j=1}^{t+2} j + b_2$ (see Invariant 20); the rotation itself costs at most $s+1+ld$ units. So it suffices to have

$$a_1 \sum_{j=1}^{t+1} j + b_1 + a_2 \sum_{j=1}^{t+2} j + b_2 + (s+1+ld) \leq 2a_2 \sum_{j=1}^{t+1} j + 2b_2. \tag{32}$$

This equation is satisfied by setting

$$a_2 \geq 2a_1, \tag{33}$$

$$b_2 \geq b_1 + (s+1+ld) + \frac{3}{2}a_2. \tag{34}$$

If v is now the only node on RP', it is converted to a rightist node, with creation-height $t+2$, by reducing its potential to $a_1 \sum_{j=1}^{t+2} j + b_1$ (note Invariant 22).

Note that the creation-heights for rightist nodes obey Invariant 16(v).

Case 5.3. v is on RP', but u is not on RP'. We provide v with appropriate j-potential and j-black potential; v becomes a node of the complete rightist lazy tree to be formed from the initial path RP. In particular, v becomes a rare black node (which behaves in the same way as a black node in a rightist lazy tree). The rotation between u and v is paid for as in a rightist lazy tree rotation (see Case 4 above).

It remains to explain how to provide v with sufficient potential. Suppose the path, RP', immediately before the traversal has length $2^l \leq |RP'| < 2^{l+1}$; further suppose that the nodes on RP' have been traversed t times so far. Then v receives creation-height $h(v) = 2l+t+1$. v requires $\frac{a_1}{2d_1}(h(v)-1) = \frac{a_1}{2d_1}(2l+t)$ units of potential for its k-black potentials; it requires a constant potential of b_1 units; finally, it requires $a_1 \sum_{j=1}^{2l+t} \min\{t, j\}$ units of j-potential. (At first sight, one would expect a quantity $\frac{1}{2}a_1 h(v)(h(v)+1)$. But, in fact, we can reduce this total for two reasons.

(i) The $h(v)$-potential can be set to zero for node v, since $ld_{h(v)}(v) = 0$.

(ii) Only $\min\{t, j\}$ units of j-potential are required for the other values of j, since v can have at most t left ancestors in its component in the normal form of the lazy tree when and if it becomes j-active.

Note that t increases by 1 each traversal, while l decreases by at least 1 each traversal. So the creation-heights of the rare black nodes ordered by time of creation are strictly decreasing; also, they are larger than the creation-heights of all the nonrare rightist nodes that are eventually created—the nonrare rightist node with largest creation-height is the node which is eventually alone on the path RP'; it has creation-height at most $l+t+1$.) As the rare black nodes are also ordered left to right by their creation time, as well as being to the left of all nonrare nodes, Invariant 16(v) is satisfied by the rare black nodes too.

Assuming that

$$d_1 \geq 1, \tag{35}$$

the total potential needed for v is at most $a_1(l + t/2) + \frac{1}{2}a_1t(t + 1) + 2a_1l \cdot t + b_1$, which is $a_1[l(2t + 1) + \frac{1}{2}(t^2 + 2t)] + b_1$. This potential is provided by the potential already at hand for node v plus a charge of $a_1(2t + 1)$ to each node that leaves the path RP'. v already has a potential of $\frac{1}{2}a_2(t + 1)(t + 2) + b_2$ at hand; this covers $\frac{1}{2}a_1(t^2+2t)+b_1+a_1(2t+1)$ units of v's future potential (since $a_2 \geq 2a_1$ and $b_2 \geq b_1$); For $l \geq 1$, $2^{l-1} \geq l$; as there are at least $2^{l-1} - 1$ nodes leaving RP', the charge to the leaving nodes covers the remaining $a_1(l - 1)(2t + 1)$ units of v's future potential. To cover this charge to the leaving nodes it suffices to modify (32) as follows:

$$a_1 \sum_{j=1}^{t+1} j + b_1 + a_2 \sum_{j=1}^{t+2} j + a_1(2t + 1) + b_2 + (s + 1 + ld) \leq 2a_2 \sum_{j=1}^{t+1} j + 2b_2.$$

This equation is satisfied by setting

$$a_2 \geq 2a_1, \tag{36}$$

$$b_2 \geq b_1 + (s + 1 + ld) + 7a_1. \tag{37}$$

If v is a light node, its k-potentials and k-black potentials are replaced by a potential of c_1; (15) guarantees that there is sufficient potential at hand.

Case 5.4. u is on the path RP', but v is not. Then u is made into a rightist node with creation-height $t+1$; the potential presently associated with u is larger than the potential it subsequently requires. If u is a light node its potential is reduced to c_1; (15) guarantees that there is sufficient potential at hand. The rotation is then treated as a rotation in a rightist lazy tree; this is handled by Case 4.

It order to justify the claim made in Remark 2 we need to report the amortized cost of the rotations occurring in the traversal of a lazy tree extreme path.

LEMMA 14. *The cost of each rotation of a couple comprising two nodes on the extreme path of a lazy tree is at most* $\max\{hd, ed\}$.

Proof. In section 3.4 we have considered all couples comprising two nodes on an extreme path. Cases 1, 2, 4.1, 4.4, and 5.2–5.4 are all self-paying (that is, they do not require the creation of debits). Case 5.1 is subsumed by Case 4. Case 3 has cost at most ed and Cases 4.2 and 4.3 have cost at most hd. □

3.4.1. Rotations with the lazy tree root. In a rotation with the lazy tree root, the root and the other node in the couple interchange lazy tree potentials. Debits are removed and created as for normal rotations on the inner skeleton of a block.

3.5. Splitting the lazy tree. A split of the lazy tree occurs when the accessed item lies strictly between the subblocks of the left guard and the right guard of the lazy tree. Thus a split must access a new i-block. So a split is the first access of a new sequence S_l. For this section, we assume that the open intervals spanned by the guards of each lazy tree are disjoint. In section 3.6, we analyze the general case. Without loss of generality, we suppose the lazy tree being split is a right lazy tree.

At this point it is helpful to mention a few properties of the lazy and reserve potentials. Consider the global nodes in a new lazy tree. Let SL be the set of nodes contained strictly between the blocks of the guards of a lazy tree. For each heavy node, u, in the lazy tree, define its right neighbor $r\_n(u)$ to be the heavy node immediately to its right in the large lazy block tree, and define $SL(u)$ to comprise the subset of SL strictly to the left of u's block. Finally, define the lazy rank of heavy node v to be $\frac{1}{gp}$ times its lazy potential.

INVARIANT 24. *Let v be a heavy node in the normal form of the lazy block tree for lazy tree L. Then the following hold:*

(i) $lazy\_\text{rank}(v) \geq \lfloor \log(wt(SL(v))) \rfloor$.

(ii) *If, in the normal form of the large lazy block tree, v has no heavy node or guard in its right subtree, $lazy\_\text{rank}(v)+1/gp \cdot reserve(v) \geq g\_\text{rank}(v)$. While if v does have a heavy node or guard in its right subtree, then $lazy\_\text{rank}(v) + 1/gp \cdot reserve(v) \geq lazy\_\text{rank}(r\_n(v))$.*

Invariant 24 can be seen to hold when the lazy tree is created by considering node v at the point at which it becomes lazy. Also, it is readily seen that this invariant continues to hold following traversals of the extreme paths (for they leave the lazy rank of nodes in the normal form of the lazy tree unchanged).

COROLLARY 2. *Let v be a heavy node other than the root in lazy tree L. Let w be v's right child and u be v's left child.*

(i) *Suppose that v is on the left path of L; then $lazy\_\text{rank}(v) \geq g\_\text{rank}(w)$.*

(ii) *Suppose that v is not on the left path of L. Let v' be a right descendant of v, not necessarily proper. If v' is a heavy node, $lazy\_\text{rank}(v') \geq g\_\text{rank}(u)$.*

It is convenient to define v's *lazy weight* to be $wt(SL(v))$.

At this point, we appeal to the construction in [CMSS00] to show that the split can be performed. To do this we review Invariant 11, Properties 3 and 4, and Lemma 13 of that paper.

INVARIANT 25 (Invariant 11 of [CMSS00]). *Consider a right lazy tree containing node v. Suppose v is a light node and carries an additional debit (this is referring implicitly to a border debit). Then*

(i) *v is not on the left path of the (right) lazy tree.*

(ii) *If v is on the right path of the (right) lazy tree, then so are its parent and right child in the splay tree.*

An analogous invariant applies to left lazy trees.

PROPERTY 1 (Property 3 of [CMSS00]). *The restoration of any further invariants concerning debits (this refers implicitly to Invariants* 12 *and* 14*) requires the removal of at most α additional debits from each lazy tree created by the split, α a constant.*

LEMMA 15 (Lemma 13 of [CMSS00]). *If a lazy tree comprises light and heavy nodes where the heavy nodes carry lazy and reserve potentials satisfying Invariant* 24*, then each lazy tree resulting from the split described in* [CMSS00] *satisfies the following:*

(i) *If the nodes on its left path are new to a left path, then they are all light nodes in the same block.*

(ii) *Assume the debits obey Invariants* 3–6 *and* 13*, and the invariants implicit in Property* 1*, namely Invariants* 12 *and* 14*. If the following equations hold, then these invariants can be restored following a split:*

$$c' \geq \max\{4md, ld + 3md\} = 4md, \tag{38}$$

$$b \geq 3md + 2ld + 2sd + gp + \alpha \cdot md, \tag{39}$$

$$\text{where } md = \max\{ed, hd\}. \tag{40}$$

Note that $b = c' = \min\{c_3, c_4\}$*; they are the additional potentials associated with heavy and light nodes, respectively, to be used to cover the costs of removing these nodes from the lazy tree.*

PROPERTY 2 (Property 4 of [CMSS00]). *The potential must be partitionable following a split; i.e., each (component of each) lazy tree created by the split must be provided with an appropriate potential (e.g., a lazy complete tree potential).*

Clearly Invariant 25 is true of the border debits (see Invariant 14). We use the splitting method from [CMSS00]. To justify its use we need to bound α and prove Property 2. Both results rely on Lemma 15(i). Indeed, Property 2 is already known for the lazy complete tree potential. It remains to consider the other types of potential and to determine a bound on α.

The Path RP. The nodes not on path RP' are treated as ordinary rightist lazy tree nodes. The nodes on RP', are separated into two paths, RP'_1, RP'_2, by the split (one of these paths may be empty). If either path RP'_i is of length 1, then it is converted to a rightist node (that is, its potential is reduced from $a_2 \sum_{j=1}^{i+1} j + b_2$ to $a_1 \sum_{j=1}^{i+1} j + b_1$ for some i). We note that this restores Invariant 22. There is no other change to the potentials of the nodes on the paths RP'_i. It is clear that Invariants 19–21 and 23 continue to hold.

The paths P_1 and P_2 are treated in the same way.

The Path P_3. Following the partitioning we need to provide c_2 potential to each node which is newly on a right extreme path (unless it is part of a contiguous sequence of nodes of length at least $4\alpha(c_l)$). We note that there are no nodes newly on a left extreme path and in a P_3 component (for such nodes become part of a BL component). Each node, v, which had been in component P_3, and which has been promoted or is now in an extreme left subblock of a new lazy tree or is now in a normal subblock (a subblock that is no longer part of a lazy tree), may spend up to $c_2 \cdot (4\alpha(c_l) + 1)$ potential in order to provide c_2 potential for each of the up to $4\alpha(c_l) + 1$ following nodes: those nodes in the contiguous portion of the new right extreme path, if any, immediately below and to the left of v in the splay tree, selected so as to restore the proper distribution of c_2 potentials (see section 3.3.4); this is a portion of a right extreme path in component P_3 for a neighboring new lazy tree (the new component P_3 is a portion of the old component P_3). As node v is no longer in a P_3 component, it can afford to spend potential $4c_2\alpha(c_l) + c_2$.

Also, when the tree formed from P_3 is split, the potential associated with P_3 is partitioned in proportion to how many $2\alpha(c_l)$-right cascades can be performed on each tree formed from P_3 (by Sundar's bound [Su89], there is sufficient potential at hand). To see this, consider the tree induced by the original component P_3 plus the root of the splay tree in its normal form. We simulate the actual rotations as follows. Only traversals of extreme paths of current P_3 components are simulated, and then only on couples comprising two nodes of P_3. The effect is to maintain each current P_3 component in its normal form, so all extreme path traversals are

simulated as right cascade sequences. So the effect of a split is merely to reduce the possible sequences of right cascades; hence Sundar's bound applies, or in other words, the potential associated with P_3 suffices to provide each of its partitions with their associated potential.

Bounding α. The additional constraints on the debits are given in Invariants 12 and 14, in the requirement that neighbors of a node with a lazy or border debit be in the same component and not simply in the lazy tree.

For each lazy tree created by the split, for each component, we remove the lazy or border debits, if any, from the leading and tail nodes of the components on the extreme paths. Clearly, there are at most twelve such lazy debits for each new lazy tree. So we can choose $\alpha = 12$.

By Lemma 10 of [CMSS00] the cost of the promotions is bounded as follows.

LEMMA 16 (Lemma 10 of [CMSS00]). *The promotions in a split have the following cost: $2gp$ times the increase in global rank along the right split path plus $2gp$ times the increase in global rank along the left split path.*

COROLLARY 3. *Consider a single access A and the consequential promotions of nodes in lazy trees on the skeleton of superblock B. Let b be the number of blocks in superblock B. The promotions of access A cost at most $4gp(\log 2b + 2)$ units, there being a charge of $2gp(\log 2b + 1)$ to the right split path and of $2gp(\log 2b + 1)$ to the left split path.*

3.6. Multiple level lazy trees. Because the access paths for a sequence, S_i, of accesses to an i-block may include nodes of a current lazy tree, we may seek to make the root of a lazy tree a global node carrying a lazy potential in a new lazy tree. We therefore generalize the form of the lazy trees. Now, a "block" in a lazy tree may itself be another lazy tree. The generalization is exactly as in [CMSS00]; the analysis proceeds exactly as described there. Lemma 16 continues to hold. The only detail is that (38) needs to be replaced by (see (25) of [CMSS00])

$$c' \geq 4md + \alpha \cdot md = 16md. \tag{41}$$

Recall that $c' = \min\{c_3, c_4\}$ and $\alpha = 12$.

3.7. The full result. We pull together the various equations from the previous subsections in order to bound the cost of an access. First, we define an access to be of type i if the previous access is to a distinct i-block but to the same $(i+1)$-block. We show a bound of the form $f_1 \log b_{i+1} + f_2(\log\log n)^2 + f_3 \log\log n\alpha(n) + f_4$ on the amortized cost of a type i access, where f_i, $i = 1, 2, 3, 4$ are constants. (Recall that we are choosing $b_i = 2^{2^i}$.) Then we show how to replace the $\log b_{i+1}$ term by a $4 \log d$ term, where d is the distance between the currently accessed item and the previously accessed item.

To avoid tedious computations, we will assume that $n \geq 16$.

Recall the statement of Lemma 13; we chose $sd = s + 1$, $ld, c = 17(s + 1)$, $gp = 19(s + 1)$, and $vp = 30(s + 1)$. We need to satisfy the constraints present in (15)–(41). By choosing equalities in some of these constraints we satisfy them all, as we demonstrate. Equalities in (26), (28), and (40) yield $ed = 18(s + 1)$, $md = hd = 37(s + 1)$. Equality in (27) yields $c_1 = 75(s + 1)$, and equality in (39) yields $c_3 = c_4 = 610(s + 1)$ (this subsumes (25), (38), and (41)). Equality in (24) yields $c_2 = 37(s + 1)$. Now, we choose $s = 1$ and hence $s' = \frac{1}{3}$. With equalities in (30) and (31) we obtain $d_1 = 1332$ (which subsumes (35)), and $a_1 = 1332 \times 222(s + 1) = 295,704(s + 1)$ (this subsumes (15)). Next, we choose $b_1 = 0$.

With equalities in the following equations we obtain: (36) (which is identical to (33)) $a_2 = 591,408(s+1)$; (37), $b_2 = 2,069,946(s+1)$ (this subsumes (32) and (34)); (22), $a_3 + b_3 = 2,662,574(s+1)$, and on choosing $a_3 = b_3$, this subsumes (18)–(20) and (23); (21), $q_1 = 2,662,574(s+1)$ (this subsumes (16) and (17)). Finally, from (9), (13), and (14), we deduce that $e' = 24$ suffices.

Substituting these values into (10), (11), and (12), we obtain that the amortized cost for the portion of the traversal in which the accessed item has visibility i for the first access to an i-block is bounded by $4,000 \log 2b_{i+1} + 4,200$, and the amortized cost for a subsequent access is bounded by $[6,000,000 + 3,000,000\alpha(c_{i+1})]$. Summing over all levels, we obtain a bound for the first access in S_i of $8,000 \log b_{i+1} + \lceil \log \log n \rceil [6,000,000 + 3,000,000\alpha(n)]$ (for recall that $b_i = 2^{2^i}$).

Now, we show how to avoid the dependence on block boundaries, which so far has meant that a search a short distance from the previous access may be treated as if it were far away (if a boundary between two high level blocks is crossed). The idea is to average over many possible positions for the block boundaries so that if two nodes, u, v, are distance d apart (counting the number of items spanned by $(u, v]$ or $(v, u]$, according as $v > u$ or $v < u$) then, on average, the two items are contained in a block of size less than d^4.

More precisely, imagine an ordered set of $2n-1$ items, with the n items of the tree occupying n contiguous positions in the set. We define block boundaries on the set of $2n-1$ items, and consider the n positions that can be occupied by the items in the tree. For each such position, the block boundaries partition the tree of n items; the corresponding potential is associated with the tree. The overall potential for the tree is simply the average of these associated potentials.

Now it is straightforward to bound the cost of a search. Suppose the current access is distance $d \geq 16$ from the previous access. Suppose $2^{2^{k+1}} \leq d < 2^{2^{k+2}}$. As we have seen, the first access to a j-block, which we call a search of type j, costs $f_1 2^{j+1} + f_5 \lceil \log \log(2n-1) \rceil$, where $f_1 = 8,000$ and $f_5 = [6,000,000 + 3,000,000\alpha(2n-1)]$. For the n choices of block boundary at hand, let n_j denote the number of boundaries for which the current access is a search of type j. Then $n_{k+h} = d \cdot n / 2^{2^{k+h+1}}$. The cost of the search is therefore

$$\leq \frac{1}{n} \sum_{h \geq 1} f_1 2^{k+h+1} n_{k+h} + f_1 2^{k+1} + f_5 \lceil \log \log(2n-1) \rceil$$

$$\leq f_5 \lceil \log \log(2n-1) \rceil + f_1 \sum_{h \geq 1} 2^{k+h+1} \cdot d / 2^{2^{k+h+1}} + f_1 \cdot \log d$$

$$\leq f_5 \lceil \log \log(2n-1) \rceil + f_1 2^{k+1} \sum_{h \geq 1} 2^h \cdot 2^{2^{k+2}} / 2^{2^{k+h+1}} + f_1 \cdot \log d$$

$$\leq f_5 \lceil \log \log(2n-1) \rceil + f_1 \log d \cdot 4 = 4 f_1 \log d + f_5 \lceil \log \log(2n-1) \rceil.$$

For $d < 16$, the $\log d$ term can be absorbed into the $\log \log$ term.

So we have shown the following.

THEOREM 1. *Consider a sequence of searches performed on an n-node splay tree, $n \geq 16$. Let item v be the current item being accessed and u the previous item accessed. Suppose that the distance from u to v is d. Then the amortized cost of the access, in*

rotations, is bounded by $32,000 \log d + \lceil \log\log(2n-1) \rceil [6,000,000 + 3,000,000\alpha(2n-1)]$.

Finally, we need to consider the initialization costs. For each i-block, we need to provide its root with its global potential, unless it is the root of an i-superblock. Per i-block root, this costs at most $gp(2^{i+1}+1)$; there are at most $n/2^{2^{i+1}}+2$ such nodes, allowing for up to two undersize nodes. In addition, we need to provide the path and reserve path potentials, whose cost is bounded by $144c \cdot n$ as shown in Lemma 12 (the proof requires slight modification to account for up to two undersize blocks per level, but the result is unchanged), and the zig-zag potentials, with cost bounded by cn.

Summing over all levels i, we obtain that the initialization costs are bounded by

$$144c \cdot n + gp \sum_{i=1}^{vis} (2 + n/2^{2^{i+1}}) \cdot (2^{i+1}+1) + cn$$

$$\leq 4930 + 3gp \cdot n \sum_{i \geq 1} (2^{i+1}+1)/2^{2^{i+1}} + gp(2^{vis+3} + 2vis)$$

$$\leq 4930 + 3gp \cdot n + 9gp \cdot n$$

$$\leq 6000n.$$

We conclude the following.

THEOREM 2. *Consider a sequence of searches performed on an n-node splay tree, $n \geq 16$. Let item v be the current item being accessed and u the previous item accessed. Suppose that the distance from u to v is d. (For the first search, $d = n$.) Then the amortized cost of the access, in rotations, is bounded by* $32,000 \log d + \lceil \log\log(2n-1) \rceil [6,000,000 + 3,000,000\alpha(2n-1)]$, *where the cost of initializing the potential is at most* $6000n$.

4. Paying for the level jumps. In this section we show how to remove the additive term of $O([\log\log n]\alpha(n))$ for each access. This charge is associated with the increases in visibility on the part of the accessed item. Recall that an item on the inner skeleton of an i-superblock has visibility i and an item on an external path of the vis-block has visibility vis. For each increase in the visibility of the accessed item there are three distinct charges. We detail these charges for the rotation that causes the accessed item to attain visibility $i+1$, for $i \geq 1$:

(i) the charge vp (see section 2);

(ii) the charge, $a_3\alpha(2^{2^{i+2}}) + b_3$, for making the topmost node of the just traversed right access path lazy (see section 3.1). Recall that an i-superblock contains c' items; now we are setting $c' = \min\{n, 2^{2^{i+2}}\}$;

(iii) the charge of c for each h-block, $h \leq i+1$, which receives a new root; this is a charge of at most $2c$ for each unit increase in visibility (see Lemma 13).

These costs arise at most once at each increase in the visibility of the accessed item. They are charged to the new visibility of the accessed item. The total charge to visibility level $i+1$ is bounded by $cost_{i+1} = vp + a_3\alpha(2^{2^{i+2}}) + b_3 + 2c$.

The cost of the rotation in which the accessed item attains visibility 1 is charged to the access itself; this is a charge of at most $vp + 2c$ (for no lazy trees are created within a 1-block as accesses to the same 0-block are accesses to the same item, which therefore is to be found at the root of the splay tree).

The analysis focuses on an access to the right of the splay tree root; an access to the left of the root is treated entirely analogously.

A few definitions will be helpful. Let B be the i-superblock being accessed currently. Suppose the current access is to the same i-block as the preceding access. The right i-header, i_h_r, is defined to be the topmost node on the right access path for B (see section 3.1 for the definition of the right access path). The *right i-leader* is defined to be the lowest ancestor of the right i-header which is on the right extreme path of the splay tree. We say the right i-header is *available* if it is on the left path (the *left i-path*) descending from the right i-leader. The number of proper right ancestors of i_h_r, called its *right depth*, is denoted i_d_r.

i_h_r has potential $c_5(cost_{i+1} \cdot \min\{i\_d_r, d_5 i \cdot cost_{i+1}\})$, where c_5 and d_5 are constants to be specified.

If the right i-header is not traversed there are no charges to visibility level $i+1$.

Consider an access which traverses the right i-header. The intuition is that the right i-header reduces its right depth and this either reduces its potential, or if it is too deep, i-spares (to be defined) will be available; in either case, these pay for the charge $cost_{i+1}$. Specifically, if the right i-header is available, but is neither the topmost nor the second highest node on the left i-path, then on traversal its right depth decreases. If it is at right depth at most $d_5 i \cdot cost_{i+1}$, then the decrease in its potential provides the required $cost_{i+1}$ charge. If it is at greater depth, then $s'/2$ of the spares associated with the nodes on the left i-path at right depths $(d_5(i-1) \cdot cost_{i+1}, d_5 i \cdot cost_{i+1}]$ cover the $cost_{i+1}$ charge (note that these nodes are traversed). While the accesses are to the same i-block, whether or not the right i-header is traversed, its right depth does not increase.

Next, we handle the case that the right i-header is at right depth 0 or 1. But here charge (ii) is reduced: it becomes $a_2 + b_2$ (see section 3.3.3). This is charged to the access operation itself, as is charge (i). This is a total charge of at most $a_2 + b_2 + 2vp$ (there may be two charges vp: one for a segment ending at the deepest node at right depth 1 and one for a segment ending at the deepest node at right depth 0). In this case we do not provide potential c to a node displaced from the root of its h-block, for $h \leq i$. Instead, we eventually provide the unlabeled portions of the extreme paths of such blocks with new path potentials. Recall that the old root of the h-block was unlabeled because only a top portion of the chain adjacent to the root was traversed (see section 2). As we will see, for each such block there are two possibilities.

To understand the possibilities, consider the right access path up to the right i-header. Consider an h-block B, $h \leq i$, whose left extreme path is partially on the right access path. If a chain of block B has a node on the right access path, then the bottommost node of this chain is on the right access path (for its left child, if any, on the right access path is the root of another h-block). Thus at any point, for each $i \leq vis$, for each $h \leq i$, there is at most one chain belonging to an h-block, for which nodes remain on the right access path and for which paths of unlabeled nodes have been created. It remains to explain how to pay for these unlabeled paths. This happens in one of two ways.

(i) The chain becomes a path (i.e., all its nodes are contiguous in the splay tree). The above process may have created up to two paths of unlabeled nodes without associated path potentials (note we intend paths and not just chains); one path was created while the root of the block had right depth 1, and the other was created while the root had right depth 0. These two paths are provided with path potentials by using the reserve path potential associated with the chain.

(ii) An access is made to a new i-block. Besides the h-block which was being accessed previously, there are at most $2(i-h+1)$ h-blocks, $h \leq i$, which have extreme paths with unlabeled nodes without associated path or chain potentials. The additional h-blocks are those whose roots are the j-leaders, $h \leq j \leq i$, if these j-leaders are the highest or second highest nodes on their j-paths. Again, each such block has at most two unlabeled paths. These paths are provided with path potentials and the cost is charged to the new access. This is a charge of at most $\sum_{h=1}^{i} 8c(i-h+1)\lfloor \log c_h \rfloor \leq 8c \sum_{h=1}^{i} (i-h+1)2^{h+1} \leq 64c \cdot 2^i$.

Now, suppose that the right i-header is not available. Then it need not be the case that its right height will be reduced when next traversed. However, the right i-header then becomes available. Note that once available, the right i-header can cease to be available only if it is traversed, at least during accesses to the same i-block. To cover the cost of the traversal of an unavailable right i-header, we provide it with an additional $cost_{i+1}$ potential. Outside of the initialization cost, this is obtained by doubling the charge for the traversals of the right i-header when available; i.e., in this case a charge of $2cost_{i+1}$ needs to be covered. Thus it suffices to have

$$c_5 \geq 2, \tag{42}$$

$$d_5 s'/2 \geq 2. \tag{43}$$

When an access to a new i-block is made, following the access, the potentials for the right and left h-headers are reinitialized, for $h \leq i$, at a cost of

$$2 \sum_{h=1}^{i} [c_5 d_5 h cost_{h+1}^2 + cost_{h+1}] \leq 2i(i+1)c_5 d_5 cost_{i+1}^2,$$

which is bounded by

$$2(i+1)^2 c_5 d_5 (a_3 \alpha(2^{2^{i+2}}) + b_3 + vp + 2c)^2.$$

In addition, in an access to a new i-block, the charge for the portion of the access in which the accessed item has not yet reached the inner $(i+1)$-skeleton totals

$$\sum_{1 \leq h \leq i} [(4e'+9)gp \cdot (2^{h+1}+1) + vp + 2c \cdot h]$$

(see (10)). The costs of the remainder of the access are covered by the analysis of this section; they total

$$a_2 + b_2 + 2vp + 64c \cdot 2^i.$$

Finally, we note that each node on the access path spends at most 3 sets of $s'/2$ spares (one set is used for the pseudotraversals of section 3.1, one set for traversing an extreme path of a lazy tree, and one set is used for the analysis of this section). This is a total of $s/2$ spares per traversed node; these spares are at hand for s spares are provided per couple.

On taking equality in (42), (43), we obtain $c_5 = 2$, $d_5 = 12$. On summing the charges for this section, we obtain a charge of $48[(i+1)\alpha(2^{2^{i+2}})]^2(6 \cdot 10^6)^2 + 10,000 \cdot 2^{i+1} + 4,300i + 34i^2 + 3 \cdot 10^6$ for an access to a new i-block which is an access to

the same i-superblock. In addition to the initialization costs present previously, we also have to initialize the right and left h-headers, for $h \geq 1$; this costs less than $10^{16}(\lceil \log\log n \rceil \alpha(n))^2$. Using the argument of section 3.7, we obtain the following.

THEOREM 3. *Consider a sequence of searches performed on an n-node splay tree, $n \geq 16$. Let item v be the current item being accessed and u the previous item accessed. Suppose that the distance from u to v is d. (For the first search, $d = n$.) Then the amortized cost of the access, in rotations, is bounded by $42,000 \log d + 10^{16}(\lceil \log\log d \rceil \alpha(d^2))^2$, where the cost of initializing the potential is at most $6000n + 10^{16}(\lceil \log\log n \rceil \alpha(n))^2$.*

5. Insertions and deletions. In this section, the result is extended to incorporate insertions and deletions. The main idea is to allow blocks to have varying sizes and to combine or partition them as they become too small or too large. The previous bounds on block sizes will become lower bounds: An i-superblock will contain at least $b'_{i+1} = 2^{2^{i+1}}$ i-blocks and at most $b_{i+1} = 8b'_{i+1}$ i-blocks. Now, a 1-block will contain between 16 and $8 \cdot 16$ items. There will be no undersize blocks, except possibly at the topmost level, where there is just one vis-block, which contains all the $(vis-1)$-blocks. In fact, with one exception dealt with later, an i-superblock will contain at most $4b'_{i+1}$ i-blocks.

We use the following rule: when an i-superblock reaches its usual upper boundary size ($4b'_{i+1}$ i-blocks), it is partitioned into two i-superblocks, one containing the leftmost $2b'_{i+1}$ i-blocks and the other the rightmost $2b'_{i+1}$ i-blocks. When an i-superblock reaches its lower bound size, it is combined with a neighboring i-superblock in the same $(i+1)$-superblock; this new i-superblock is partitioned in turn if it has size at least $4b'_{i+1}$ i-blocks. If the vis-block is partitioned, then we need to create a new higher level block, a $(vis+1)$-block, to contain the two vis-blocks at hand. Likewise, if there are only 2 $(vis-1)$-blocks and they are combined, then the vis-block is removed and the top level block is at level $vis-1$.

Comment. We use the terms combine and partition rather than the more natural join and split to avoid confusion with the split of a lazy tree.

We determine the cost of the combine and partition operations on an i-superblock. When performing a partition we have the following costs. Each global node on the two extreme paths between the new superblocks has its rank raised to $\lceil \log 2K \rceil$, where $K = 2^{\lceil \log b_{i+1} \rceil}$. This costs up to $4 \cdot 2^{2^{i+1}} \cdot (2^{i+1}+3) \cdot gp$. In addition, a path potential has to be provided for up to four new chains: these are the chains starting and ending at the node that has newly become the root of an i-superblock, chains which are also parts of the extreme paths of i-superblocks. An i-superblock contains at most $4^{i+1} \cdot 2^{2^{i+2}}$ items. So a chain can contain at most one fewer items, and hence the cost of the new chains is at most $24c[2(i+1) + 2^{i+2}] + 4c$ (see section 2). In addition, on the new chains, the i-global nodes may need to be provided with an extra zig-zag potential of c units each, if they are not adjacent to two chain nodes. In fact this applies only to the global nodes newly on an extreme path of an i-superblock, which is at most $4b'_{i+1}$ nodes. So this is a further cost of $4c \cdot 2^{2^{i+1}}$. Finally, the new root of an i-superblock receives its $(i+1)$-global potential, which costs at most $(2^{i+1}+3)gp$. This in turn may raise the global potential of some of its ancestors for a further cost of $(2^{i+1}+3)gp$. The total cost of the partition is

$$part = 2^{2^{i+1}}[4gp(2^{i+1}+3) + 4c] + 2^{i+1} \cdot (48c + 2gp) + i \cdot 48c + (52c + 6gp).$$

The combine has zero cost.

In addition, when a combine or partition is performed, we treat it as ending the current sequence of accesses to the superblock being combined or partitioned. This entails additional costs of $48[(i+2)\alpha(2^{2^{i+3}})]^2(6\cdot 10^6)^2 + 10,000\cdot 2^{i+2} + 4,300(i+1) + 34(i+1)^2 + 3\cdot 10^6$ (see section 4).

In order to cover these costs, each time an i-block is combined or partitioned, it provides the following potential to its parent (the i-superblock in which it is contained): $p_{i+1} = 4gp(2^{i+1}+3) + 4c + [2^{i+1}\cdot(48c+2gp) + i\cdot 48c + (52c+6gp) + 48[(i+2)\alpha(2^{2^{i+3}})]^2(6\cdot 10^6)^2 + 10,000\cdot 2^{i+2} + 4,300(i+1) + 34(i+1)^2 + 3\cdot 10^6 + p_{i+2}]/2^{2^{i+1}}$. It can be checked that $p_{i+1} = 152\cdot 2^{i+1} + 10^{16}$ suffices. The accumulation of this potential by an i-superblock will ensure that when and if it is removed by a combine or partition it will have enough potential at hand to pay for its removal and for the potential that has to be provided to its parent block; for between the creation and removal of an i-superblock there will have been at least b'_{i+1} combines and/or partitions of its i-blocks. At level 0, when an item is inserted or deleted, it needs to provide potential p_1 to its 1-block, but this is $O(1)$.

Next, we need to modify the analysis. For the moment, we ignore the question of accesses that straddle a block boundary. A search is treated as before. An insertion is analyzed as follows. The item is inserted as in a binary search tree. After adding the item, we perform any necessary block partitions. The item is splayed now. When the item is added, it is not provided with any potential, nor are the appropriate chain potentials increased. The reason is that the item does not need any associated potential in order to be splayed; the potential is needed at nodes which are traversed. The access is analyzed as before: as the access proceeds, the item will be provided with potential as described in the earlier analysis. So the cost of an insertion at distance d from the previous access is p_1 plus the cost of a search at distance d.

For the deletion, at least for our analysis, we need to modify the operation described by Sleator and Tarjan [ST85]. We offer reasons as to why such a modification may be needed in order to obtain the finger search result we seek. Sleator and Tarjan proceed as follows. First the item e is splayed, placing it at the root. Then the resulting two subtrees of e are joined (for example, by splaying the rightmost item in the left tree, and then making the right tree its child). Our method differs. First we swap the item, e, to be deleted with its predecessor, if e has a left child. Then the current predecessor of e (previously, the second predecessor, if e had a left child at the start of the operation) is splayed. Following the splay, e has no children, and it is removed. The reason for our choice of deletion method is that the change in potential owing to the removal of item e might be nonconstant if it is the root of a block.

There is an unpleasing assymmetry to the operation described above. An alternate implementation is to perform two splays, in turn on the predecessor and successor of the item, e, to be deleted; then e is deleted—it is the right child of the left child of the root of the splay tree and has no children at this point. The accesses are analyzed as before and the deletion can only reduce the potentials associated with the various blocks. The unattractive feature here is that two searches and two splays are needed.

Now, we analyze the first implementation of the delete operation. The access is analyzed as before. The only novel feature is the elimination of an item, which may add nodes to the extreme path of the blocks to which the item belongs and thereby increase the potential of the splay tree; but this effect can arise only if the item in question is an extreme item in its block. In fact, at the time item e is deleted it is childless, so no nodes are added to the extreme paths of any blocks; indeed, the removal of e can only shorten these paths, thereby reducing the potential. So the cost

of a deletion is at most c_1 plus the cost of an access at distance $d+2$.

It remains to deal with nearby accesses that straddle a block boundary. First we explain how to form sequences of accesses. Consider the i-blocks. The accesses are partitioned into maximal subsequences S_i of accesses to pairs of neighboring i-blocks. Whenever an i-block is partitioned or combined a new sequence is started.

It may be that a particular sequence S_i accesses only one i-block. But suppose that S_i accesses two neighboring i-blocks, B_1' and B_2'. If they are contained in distinct i-superblocks, B_1 and B_2, respectively, then at the start of the sequence S_i, B_1 and B_2 are combined into i-superblock B; at the end of the sequence B is split into B_1 and B_2 with the new boundary being between B_1' and B_2', as before. B_1' and B_2' still exist at this point in time for no partition or combine of these blocks has been caused by their becoming too large or small during sequence S_i, although they may have been combined and partitioned because of accesses straddling neighboring $(i-1)$-blocks. As before the cost of the combine is zero. The cost of the split is modest, because the most recent accesses to the combined B_1 and B_2 are to adjacent i-blocks B_1' and B_2'. We need only provide the following potentials: chain potential for up to three new chains, which costs at most $18c[2(i+1)+2^{i+2}]+3c$, and the $(i+1)$-global potential for the new root of an i-superblock, which costs at most $(2^{i+1}+3)\cdot gp$. There are no i-global nodes whose potential needs increasing.

The subsequence S_i is further partitioned, so that all the accesses in each new subsequence are to the same block. Suppose the i-blocks B_1' and B_2' are not combined for some pair of accesses of S_i which straddle the boundary between i-superblocks B_1 and B_2; this implies these two accesses are to nonneighboring i-subblocks. So an access to a nonneighboring $(i-1)$-block, i.e., an access at distance at least 2^{2^i}, may start a new i-sequence of accesses to an i-block. Let d denote the distance spanned by this access; then $d+2 \geq 2^{2^i}$ (the $d+2$ takes account of the possible additional shift by 2 due to a delete operation). Following the analysis of section 4, the cost of this access is bounded by

$$\sum_{1\leq h\leq i}[(4e'+9)gp\cdot(2^{h+1}+4)+vp+2c\cdot h]$$
$$+\sum_{1\leq h\leq i}2(i+1)^2c_5d_5(a_3\alpha(2^{2^{i+2}})+b_3+vp+2c)^2+p_1+a_2+b_2+2vp+64c2^i.$$

The term $(2^{h+1}+4)$ reflects the increased maximum rank on the boundary of an h-block. The cost is bounded by $new\_cost_i = 20,000\cdot 2^i+10^{16}[(i+1)\alpha(2^{2^{i+2}})]^2+10^{16}$. In turn this is bounded by $20,000\log(d+2)+10^{16}[(\log\log(d+2)+1)\alpha(2^{4\log(d+2)})]^2+10^{16}$.

The last step in the analysis is to account for a series of accesses which each shift a small distance, but cummulatively shift a large distance and cause a high index block boundary to be crossed. Clearly a simple amortization can handle this; we specify this precisely next. Suppose the current access is at distance d from the previous access, where $2^{2^i}\leq d+2<2^{2^{i+1}}$. Then potential $2new\text{-}cost_i\cdot 5^{2-h}$ is provided to the $(i+h)$-block to which the previously accessed item belongs, for $h\geq 0$. Consider a maximal sequence S_j of accesses to a j-block, B_j, and the access immediately following it. The distance spanned by these accesses is at least $2^{2^j}-2$, for otherwise the accesses would all be in adjacent $(j-1)$-blocks and hence in the same j-block (because of our combining rule). We determine the contribution made by these accesses to B_j and show that it is at least $new\text{-}cost_j$. The contribution by an access of length d, where $2^{2^{j-h}}\leq d+2<2^{2^{j-h+1}}$ is $2new\text{-}cost_{j-h}\cdot 5^{2-h}\geq 2new\text{-}cost_j\cdot 5^{2-2h}$. The total

contribution is minimized when each d takes on the maximal value consistent with a given contribution; this yields a total contribution of the form $\sum_l 2new\text{-}cost_j \cdot 5^{2-2h_l}$, where $\sum_l [2^{2^{j-h_l+1}} - 3] \geq 2^{2^j} - 2$; by inspection, the contribution is minimized with $h_l = 2$, when it totals at least $new\text{-}cost_j$.

The additional charge for each operation is $\frac{25}{2} new\text{-}cost_i$, where $2^{2^i} \leq d+2 < 2^{2^{i+1}}$.

We have shown the following.

THEOREM 4. *The extension of the dynamic finger conjecture to incorporate the insert and delete operations is true when the delete is modified as described above. The amortized cost of an access at distance d from the previous access is bounded by* $250,000 \log(d+2) + 10^{18}[(\log\log(d+2)+1)\alpha(2^{4\log(d+2)})]^2 + 10^{18}$.

6. Improved constants. Our conjecture is that the true bound has much smaller constants than those shown here. We briefly sketch one approach for obtaining such a bound.

The main difficulty in improving the bounds lies in the potentials needed for the lazy trees. If it were possible to have $\log n$ levels of visibility, where each superblock contained just a constant number of blocks, we would avoid the need for global potentials and hence for lazy trees. There would still be a need for potentials associated with extreme paths (small and large debits and chain potentials), but changes in these would all be paid for by increases in visibility. This would now be of size $\Theta(\log n)$, rather than $\Theta(\log\log n)$, so there would be a continued need to pay for level jumps (see section 4). Unfortunately, following the analysis used there would lead to an $O(\log^2 d)$ cost for an access at distance d from the previous access. It appears possible to improve this by not providing the chain potentials in full and instead taking a *lazy* approach. In particular, we would provide only $O(1)$ potential for each individual jump in visibility on the access path, however large. This eliminates the need for potentials associated with right i-headers; offsetting this, we now have to handle "missing" chain potentials. We have not worked out all the details, however, for it appears that we still need an inverse Ackerman term, arising for similar reasons to the inverse Ackerman term used in analyzing paths P_3 (see section 3.3.4). At present we do not see how to amortize this term, and it leads at the very least to an additive inverse Ackerman term on the amortized cost of each access. In fact, we suspect that this bound can be reduced to $O(1)$. Perhaps this would follow from improving Sundar's bound for the dequeue conjecture [Su89], or some variant of this conjecture.

Acknowledgments. We thank an anonymous referee for making a number of detailed suggestions that helped improve the paper's presentation. Any remaining errors or lack of clarity are solely due to the author.

ON RAM PRIORITY QUEUES*

MIKKEL THORUP†

Abstract. Priority queues are some of the most fundamental data structures. For example, they are used directly for task scheduling in operating systems. Moreover, they are essential to greedy algorithms. We study the complexity of integer priority queue operations on a RAM with arbitrary word size, modeling the possibilities in standard imperative programming languages such as C. We present exponential improvements over previous bounds, and we show tight relations to sorting.

Our first result is a RAM priority queue supporting `find-min` in constant time and `insert` and `delete-min` in time $O(\log\log n)$, where n is the current number of keys in the queue. This is an exponential improvement over the $O(\sqrt{\log n})$ bound of Fredman and Willard [*Proceedings of the 22nd ACM Symposium on the Theory of Computing*, Baltimore, MD, pp. 1–7]. Plugging this priority queue into Dijkstra's algorithm gives an $O(m \log\log m)$ algorithm for the single source shortest path problem on a graph with m edges, as compared with the previous $O(m\sqrt{\log m})$ bound based on Fredman and Willard's priority queue. The above bounds assume $O(n2^{\varepsilon w})$ space, where w is the word length and $\varepsilon > 0$. They can, however, be achieved in linear space using randomized hashing.

Our second result is a general equivalence between sorting and priority queues. A priority queue is *monotone* if the minimum is nondecreasing over time, as in many greedy algorithms. We show that on a RAM, the amortized operation cost of a monotone priority queue is equivalent to the per-key cost of sorting. For example, the equivalence implies that the single source shortest paths problem on a graph with m edges is no harder than that of sorting m keys. With the current RAM sorting, this gives an $O(m \log\log m)$ time bound, as above, but the relation holds regardless of the future developments in RAM sorting.

From the equivalence result, for any fixed $\varepsilon > 0$, we derive a randomized monotone $O(\sqrt{\log n}^{1+\varepsilon})$ priority queue with expected constant time `decrease-key`. Plugging this into Dijkstra's algorithm gives an $O(n\sqrt{\log n}^{1+\varepsilon} + m)$ algorithm for the single source shortest path problem on a graph with n nodes and m edges, complementing the above $O(m \log\log m)$ algorithm if $m \gg n$. This improves the $O(n \log n/\log\log n + m)$ bound by Fredman and Willard [*Proceedings of the 31st IEEE Symposium on the Foundations of Computer Science*, St. Louis, MO, 1990, pp. 719–725], based on their $O(\log n/\log\log n)$ priority queue with constant `decrease-key`.

1. Introduction.

Priority queues are some of the most fundamental data structures. For example, they are used directly for task scheduling in operating systems. Moreover, they are essential to greedy algorithms. A *priority queue* is a dynamic representation of an ordered set, or multiset, X of keys. A *basic priority queue* supports the operations `find-min`(X) returning $\min X$, `insert`(x, X) setting $X := X \cup \{x\}$, and `delete-min`(X) setting $X := X \setminus \{\min X\}$. Often we will talk about *extracting the minimum key*, which is the combination of finding and deleting the minimum key from X. Using the previous operations, extracting the minimum key can be implemented as $x :=$ `find-min`(X); `delete-min`(X); return x. Sometimes we will go beyond basic priority queues and consider the operations `delete`(x, X) setting

$X := X \setminus \{x\}$, and `decrease-key`(x, d, X) setting $X := (X \setminus \{x\}) \cup \{x - d\}$. Finally, we will study *monotone* priority queues, which are priority queues with the restriction that the minimum should be nondecreasing. Here the minimum of an empty priority queue is considered to be 0. The monotonicity restriction on priority queues has been considered previously by Ahuja et al. [1] and is not a problem for applications in greedy algorithms such as Dijkstra's single source shortest paths algorithm [13]. Our priority queues will allow the user to associate extra information with inserted keys. Then `find-min` returns not only the minimal key but also the information associated with it.

We study the complexity of priority queue operations on a RAM modeling the possibilities in imperative programming languages such as C. The memory is divided into addressable words of w bits. Addresses are themselves contained in words. Hence, assuming that we have at least n input words to address, $w \geq \log n$. Moreover, we have a constant number of registers, each with capacity for one word. The basic machine instructions are conditional jumps and direct and indirect addressing for loading and storing words in registers. Moreover, we have some computational instructions for manipulating words in registers. The computational instructions used in this paper are shifts, comparisons, bit-wise Boolean operations, conversion of integers to floating points, addition, subtraction, multiplication, and division. Except for multiplication and division, all the above operations are in AC^0 meaning that they can be implemented by a constant depth circuit of size polynomial in w. We refer to them as *standard AC^0 operations* to emphasize the fact that they are available in most imperative programming languages. The time complexity is the number of instructions performed and the space complexity is the maximal memory address used. All keys are assumed to be nonnegative integers, each stored in one word, and hence we can operate on them in constant time. We shall return to a discussion of the model and the "dirty tricks" it allows in section 1.3.

On the above RAM, we present exponential improvements over previous bounds for priority queues. Moreover, we establish an equivalence between monotone priority queues and sorting.

1.1. A fast basic priority queue. Our first main result is the following theorem.

THEOREM 1.1. *There is a priority queue supporting* `find-min` *in constant time and* `insert` *and* `delete-min` *in $O(\log\log n)$ time, where n is the current number of keys in the queue.*

This matches the best known per-key cost of integer RAM sorting due to Andersson et al. [3]. Here, by the per-key cost of sorting we mean the total sorting time divided by the number of sorted keys.

1.1.1. A historical perspective. In the comparison based model, we can support a general search structure in $\Theta(\log n)$ time per operation, matching the per-key cost of sorting. Here by a *search structure*, we mean a dynamic ordered set with `insert` and `delete`, and an operation `succ`(x, X) returning y, where y is the smallest element in X which is bigger than or equal to x. This generalizes a priority queue since `find-min`$(X) =$ `succ`(0) and `delete-min`$(X) =$ `delete`(`succ`(0)). Then again, priority queues generalize sorting in that we can sort a set X by first inserting all elements from X in an empty priority queue and then extract them in increasing order.

When Fredman and Willard in 1990 broke the $\Omega(n \log n)$ barrier for RAM integer sorting [17], they did it in terms of a general search structure working in $O(\sqrt{\log n})$

time per operation, implying $O(n\sqrt{\log n})$ sorting as a special case.

Then in 1995, Andersson et al. presented an $O(n \log\log n)$ integer RAM sorting algorithm [3]. As they point out in [3], their sorting algorithm does not work for dynamic sets. Nevertheless, as stated in Theorem 1.1, here we will generalize their $O(\log\log n)$ bound to priority queues for dynamic sets.

It turns out that our $O(\log\log n)$ bound provably does not generalize to searching. Miltersen has pointed out that for $n = 2^{\log^{3/2} w}$, his results in [28] imply an $\Omega(\log^{1/3-o(1)} n)$ lower bound for search structures. This lower bound holds even if we allow randomization and amortization, and it has later been improved to $\Omega(\sqrt{\log n/\log\log n})$ by Beame and Fich [8]. In [28], Miltersen asks if the lower bounds for searching can be beaten if we restrict ourselves to a basic priority queue. Our new $O(\log\log n)$ upper bound for all word sizes answers Miltersen's question in the affirmative. In particular, this implies a separation between priority queues and searching on the RAM.

1.1.2. Space bounds. The priority queue of Theorem 1.1 is simple and implementable with standard AC^0 operations, but it needs $O(n2^{w^\varepsilon})$ space for an arbitrarily small constant $\varepsilon > 0$. If we are satisfied with a monotone priority queue, we can get an *amortized* time bound of $O(\log\log n)$ using $O(n + 2^{w^\varepsilon})$ space. We can also get the whole way down to linear space even without amortization if we are willing to use randomization giving $O(\log\log n)$ *expected* time per operation. Thereby we also involve multiplication which is not in AC^0. The above mentioned sorting and searching results from [3, 17] have similar space bounds. However, in [17] they also achieve a deterministic $O(\log n/\log\log n)$ worst-case bound in linear space.

1.1.3. Applications in greedy algorithms. Plugging the priority queue of Theorem 1.1 into Dijkstra's algorithm [13], we get the following.

COROLLARY 1.2. *There is an $O(m \log\log m)$ algorithm for the single source shortest path problem on a graph with m edges.*

Dijkstra's algorithm above should only be taken as a representative for greedy algorithms. We could equally well apply our priority queue to Hu and Tucker's algorithm from [23] and get an $O(n \log\log n)$ algorithm for the alphabetic tree problem on n codes. Based on Fredman and Willard's priority queue from [18], the previous best bounds for the two problems were $O(m\sqrt{\log m})$ and $O(n\sqrt{\log n})$, respectively. The advantage of focusing on Dijkstra's algorithm is that it facilitates later discussions of constant time `decrease-key` operations.

1.1.4. Techniques. In order to prove Theorem 1.1, we first prove a result for short keys.

THEOREM 1.3. *There is a priority queue with capacity for n $(w/(\log n \log\log n))$-bit keys, supporting* `insert`, `find-min`, *and* `delete-min` *on integers in constant time per operation and in space $O(n)$. The priority queue can be implemented with standard AC^0 operations. Moreover, it allows one word of information to be associated with each key inserted. Then* `find-min` *returns the smallest key and the information associated with it.*

The point of the associated word is that it could be an address to some additional information on the key, or it could be an identification of the key in case we had several keys with the same value. Note that associating one word of information is trivial for priority queues dealing with one-word keys, for then, by only doubling the key length, we can just append the information directly to the key as a least significant

part. Doubling the key length is not a problem because our RAM can simulate $2w$-bit instructions with a constant number of w-bit instructions.

Having proved Theorem 1.3, we reduce the general case of one-word keys to the case of $(w/(\log n \log\log n))$-bit keys using the recursion underlying van Emde Boas' data structure [35, 36].

1.2. Monotone priority queues ≡ sorting. Our other main result is a computational equivalence between sorting and monotone priority queues.

THEOREM 1.4. *For a RAM with arbitrary word size w, if we can sort n w-bit keys in time $n \cdot s(n)$, where s is nondecreasing, then (and only then) there is a monotone priority queue with capacity for n w-bit keys, supporting* `find-min` *in constant time and* `insert` *and* `delete-min` *in $s(n) + O(1)$ amortized time. The amortization presumes that the priority queue starts empty.*

The reduction is deterministic and uses linear space. As stated, it needs either multiplication or some nonstandard AC^0 operations. A variant using only standard AC^0 operations supports `find-min` *in constant time and* `insert` *and* `delete-min` *in $O(\sum_{i=0}^{\log^* n} s(\log^{(i)} n))$ amortized time. Here $\log n = \log n \log\log n$, $f^{(0)}n = n$, $f^{(i)}n = f(f^{(i-1)})$, and $f^*n = \min\{i | f^{(i)}n \le 1\}$.*

The "only then" part follows because we can sort a set of keys by first inserting them into a monotone priority queue and then extract them in increasing order.

To prove Theorem 1.4 we will show how to maintain a monotone priority queue spending constant time on `find-min` and constant amortized time on `insert` and `delete` plus some sorting time. Each key passing through the queue participates in at most one sorting, and when we sort a set of keys, they are all currently contained in the queue.

As an immediate consequence of Theorem 1.4, we get the following strengthening of Corollary 1.2.

COROLLARY 1.5. *On a RAM, the single source shortest path problem on a graph with m edges is no harder than that of sorting m keys, no matter the future developments in sorting.*

Note that Theorem 1.4 potentially could be used to obtain lower bounds for sorting. As mentioned above, [28] implies amortized nonconstant lower bounds on search operations. Similar nonconstant lower bounds on monotone priority queue operations would imply a nonlinear lower bound for RAM sorting.

1.2.1. Applications to constant cost `decrease-key`. We will now show how Theorem 1.4 can be used to construct priority queues with a constant cost `decrease-key` operation. First, Andersson et al. [3] have shown that we can sort n keys in linear expected time if $(\log n)^{2+\varepsilon} \le w$ for some fixed $\varepsilon > 0$. Thus by Theorem 1.4, we have the following.

COROLLARY 1.6. *If $(\log n)^{2+\varepsilon} \le w$ for some fixed $\varepsilon > 0$, there is a randomized linear space monotone priority queue for n keys supporting* `find-min` *in constant time and* `insert` *and* `delete-min` *in expected constant amortized time.*

Based on Fredman and Willard's AF-heaps [18], we will get the following lemma.

LEMMA 1.7. *Provided a monotone/unrestricted basic priority queues for up to $f(n) = \Omega(\log^2 n)$, $f(n) = O(n)$, keys supporting* `find-min`, `insert`, *and* `delete-min` *in constant amortized time, there is a monotone/unrestricted priority queue with capacity n, supporting the operations* `find-min`, `insert`, *and* `decrease-key` *in constant amortized time, and* `delete` *in time $O(\log n / \log f(n))$. The reduction is deterministic and uses linear space, and it can be implemented with standard AC^0 operations.*

In [18], Fredman and Willard show that given $O(n)$ space and preprocessing time, they can support unrestricted priority queues with constant amortized operation cost for up to $(\log n)^2$ keys. By Lemma 1.7, this gives them an unrestricted priority queue with capacity n, supporting `find-min`, `insert`, and `decrease-key` in constant amortized time, and supporting `delete` in $O(\log n/\log(\log n)^2) = O(\log n/\log\log n)$ amortized time.

Corollary 1.6 together with Theorem 1.4 implies a monotone priority queue with constant amortized operation cost for up to $\exp(\sqrt{w}^{1-\varepsilon})$ keys for any fixed $\varepsilon > 0$. Thus we get `delete` in time $O(\log n/\log(\exp(\sqrt{w}^{1-\varepsilon}))) = O(\log n/\sqrt{w}^{1-\varepsilon})$. Using $w \geq \log n$, we conclude the following.

COROLLARY 1.8. *There is a randomized monotone priority queue with capacity n supporting* `find-min`, `insert`, *and* `decrease-key` *in expected amortized constant time, and* `delete` *in expected amortized time $O(\log n/\sqrt{w}^{1-\varepsilon}) = O(\sqrt{\log n}^{1+\varepsilon})$ for any fixed $\varepsilon > 0$.*

Plugging Corollary 1.8 into Dijkstra's algorithm [13], we get the following corollary.

COROLLARY 1.9. *For any $\varepsilon > 0$, randomized and in linear space, we can solve the single source shortest path problem on a graph with n nodes and m edges in expected time $O(n\sqrt{\log n}^{1+\varepsilon} + m)$.*

The previous best bound linear in m was $O(n \log n/\log\log n + m)$, based on the priority queues from [18]. For completeness, Corollary 1.9 should also be compared with the word size dependent bound of $O(n\sqrt{w} + m)$ due to Ahuja et al. [1]. In fact, the bound from [1] is based on priority queues restricted beyond monotonicity, tailored particularly for Dijkstra's algorithm. Since $w \geq \log n$, this bound is only better for $w = (\log n)^{1+o(1)}$. Recall that for small m, we have the complementing $O(n + m \log\log m)$ bound from Theorem 1.1.

1.3. Machine model. The RAM model distinguishes itself from the so-called comparison based model in that besides comparing the integer keys, we can also add, subtract, and multiply them. Of course, it is meaningless to work on integers and say that one can compare but not add them. The point in the comparison based model is that it works for any domain supporting comparisons. In this context it should be noted that ordering nonnegative integers actually covers many more domains than just nonnegative integers. For example, in the standard representation of signed integers, we get the right ordering if we flip the sign bit and interpret the result as an unsigned integer. Floating points are even easier, for the IEEE 754 floating-point standard is designed so that the ordering of floating-point numbers can be deduced by perceiving their representations as multiple word integers. Also, if we are working with fractions where both numerator and denominator are w-bit integers, we get the right ordering if for each fraction, we make the division in floating-point numbers with $2w$ bits of precision. Now we get the correct ordering of the original integer fractions by perceiving the corresponding floating-point numbers as integers. Finally, it will be shown later that we can implement an efficient priority queue for ℓ-word keys using the priority queue for one-word keys from Theorem 1.1.

The essential benefit of adding and subtracting integers is in coding multiple comparisons. The idea of multiple comparisons was first introduced by Paul and Simon [29] in 1980. In our paper, the multiple comparisons are hidden in a black box provided by Albers and Hagerup [2]. It should be noted that this use of uniprocessors as vector processors is a standard trick in practice, not in connection with sorting,

but in connection with graphics, where a single word operation is used to manipulate the information on several pixels, each represented by one byte of the word. With modern MMX graphics processors, these kinds of tricks are even supported directly in hardware, for example, with a special byte-wise multiplication that views words as vectors of bytes and then multiplies the bytes coordinate-wise. This byte-wise multiplication is faster than a multiplication over the full word.

The RAM model further distinguishes itself both from the comparison based model and from the pointer machine in that we allow ourselves to use keys and segments of keys as addresses. We will use this for bucketing in the same way as done in van Emde Boas's data structure [35, 36]. The use of buckets has a very long tradition within sorting. In radix sort, for example, the integers are bucketed according to one digit at the time, starting from the least significant digit. According to Knuth [25], radix sort was mentioned as early as in 1929 by Comrie. Another classic use of buckets in sorting is bucket sort proposed in 1956 by Isaac and Singleton [21]. Bucket sort is interesting in this context because it provides an elementary expected linear time sorting algorithm for uniformly distributed w-bit unsigned integer keys, thoroughly surpassing the $\Omega(n \log n)$ comparison based lower bound for average case sorting. Bucket sort may even be implemented efficiently with standard AC^0 operations: let X be a set of n unsigned w-bit integer keys. Compute $\ell = \lceil \log_2 n \rceil$ and $\Delta = w - \ell$. Bucket each key x according to $\lfloor x \times 2^\ell / 2^w \rfloor = x \gg \Delta$, where $\gg$ denotes right shift. More precisely, we allocate an array B of $2^\ell = O(n)$ lists and put x in list $B[x \gg \Delta]$. Second, we use insertion sort to sort each list $B[i]$ independently. Finally, we concatenate the sorted lists $B[i]$ into one sorted list containing all the elements of X. As analyzed in [25, pp. 99–102], the above algorithm takes linear time for uniformly distributed keys.

Fredman and Willard [17] further use the RAM for advanced tabulation of complicated functions over small domains. Their tabulation is too complicated to be of practical relevance, but tabulation of functions is in itself commonly used to tune code. As a simple example, Bentley [10, pp. 83–84] suggests that an efficient method for computing the number of set bits in 32-bit integers is to have a preprocessing where we first tabulate the number of set bits in all the 256 different 8-bit integers. Now, given a 32-bit integer x, we view it as the concatenation of four 8-bit integers, and for each of these, we look up the number of set bits in our table. Finally we just add up these four numbers to get the number of set bits in x.

Summing up, in the above discussion, it has been argued that all the "dirty tricks" facilitated by the RAM are well established in the practice of writing fast code. Hence, if we disallow these tricks, we are not discussing the time complexity of running imperative programs on real world computers. For further discussion of the model, the reader is referred to [20].

1.4. Subsequent work and historical remarks. Since an extended abstract of this paper was presented at SODA'96 [32], the results and constructions have been involved in several other papers. In [32], Theorem 1.3 appeared in two weaker forms. In one form the keys were of size $w/\log n$ instead of $w/(\log n \log\log n)$, but then the time bounds were $O(\log\log n)$ instead of constant. The other form had constant but amortized time bounds. The key size in the amortized version was $w/(\log n \log\log n)$ as in the current paper. The amortized version used multiplication as it was based on Fredman and Willard's atomic heaps [18]. Later, Raman [30] has found a simple multiplication-free alternative to the atomic heaps inside the priority queue of Theorem 1.3 (cf. Lemma 3.4 below). Consequently, he got an amortized

TABLE 1.1

State of the art in priority queues. The capital letters following a bound show the weaknesses of the result: "M" denotes monotone, "A" denotes amortization, "R" denotes randomization, and "×" denotes use of mutiplication. Finally, "D" means that we use a dictionary over a large set of integers. Using hashing, "D" can be replaced by RM, but alternatively, we may use nonlinear space. If there is no letter following a bound, it means that it is unrestricted, deterministic, and worst-case, and it uses linear space and only standard AC^0 operations.

Priority queue	$O(\log\log n)$ D [this paper] • $O(\log\log n)$ MAR [33] • $O((\log\log n)^2)$ [7] • $O(\log w)$ D [35, 36]
Constant `decrease-key`	$O(\log n)$ A [19] • $O(\log n/\log\log n)$ A× [18] • $O(\sqrt{\log n\log\log n})$ MA [30] • $O(\sqrt[3]{w\log w})$ MA [12] • $O(\min\{\sqrt[4]{w}^{1+\varepsilon}, \sqrt[3]{\log n}^{1+\varepsilon}\})$ MAR× [31]

version of Theorem 1.3 using only standard AC^0 operations. Raman applied this within an $O(\sqrt{\log n\log\log n})$ amortized monotone priority queue with constant time `decrease-key` which uses only linear space and only standard AC^0 operations. In this paper, Theorem 1.3 reaches its final form with constant worst-case time per operation using only standard AC^0 operations. This strong form has not been announced previously.

In the original abstract [32] of this paper, Corollary 1.8 quoted the $O(\sqrt{\log n}^{1+\varepsilon})$ bound but not the $O(\log n/\sqrt{w}^{1-\varepsilon})$ bound. In [32], w was replaced by $\log n \le w$ already in the derivation leading to Corollary 1.8 as the author found it more esthetic just to quote a bound based on n exclusively.

Later, Cherkassky, Goldberg, and Silverstein [12] used the $O(\sqrt{\log n}^{1+\varepsilon})$ bound from Corollary 1.8 for a randomized $O(\sqrt[3]{w}^{1+\varepsilon})$ monotone priority queue with expected constant cost decrease key, improving over a previous $O(\sqrt{w})$ bound of Ahuja et al. [1].

However, Raman [31] has observed that for Cherkassky, Goldberg, and Silverstein's construction [12] it is beneficial not to replace w by $\log n \le w$ but to use the $O(\log n/\sqrt{w}^{1-\varepsilon})$ of Corollary 1.8 directly. In an elegant balancing, Raman arrived at an $O(\min\{\sqrt[4]{w}^{1+\varepsilon}, \sqrt[3]{\log n}^{1+\varepsilon}\})$ bound for monotone priority queues with constant cost decrease key, thus improving both over Cherkassky, Goldberg, and Silverstein's bound of $O(\sqrt[3]{w}^{1+\varepsilon})$ and over the $O(\sqrt{\log n}^{1+\varepsilon})$ bound of Corollary 1.8. For a nice survey of these developments, the reader is referred to Raman's paper [31].

The author [33] has used the reduction of Theorem 1.4 to derive a randomized monotone priority queue with an expected amortized operation cost of $O(\log\log n)$ which is implementable in linear space using only standard AC^0 operations. Further, the author [34] has provided an amortized deterministic unrestricted priority queue with operation time $O((\log\log n)^2)$ using linear space and standard AC^0 operations. The construction was later deamortized together with Andersson [7]. An overview of the current theoretically strongest results on priority queues is presented in Table 1.1.

1.5. Contents. After some preliminaries in section 2, the priority queue of Theorem 1.3 is presented in section 3. Next we derive the time bounds of Theorem 1.1 in section 4 and discuss the corresponding space bounds in section 5. Section 6 contains a brief discussion on priority queues for strings of words. The general reduction of Theorem 1.4 is presented in section 7, and finally, we discuss the reduction of Lemma 1.7 in section 8.

2. Preliminaries. Unless otherwise stated, all logarithms are assumed to be base 2. Our integers are viewed as bit-strings, stored with the most significant bit to the left. Hence, we get the right ordering if we view them as lexicographically ordered bit-strings. By bit i of an integer x, denoted $x[i]$, we mean the $(i+1)$th bit from the left. Thus, if x is a b-bit integer, the number represented by x is $\sum_{i=0}^{b-1} 2^i x[b-1-i]$.

We have defined standard AC^0 operations as AC^0 operations available in a standard programming language such as C. These include shifts, bit-wise Boolean operations, addition, subtraction, and conversion from integer to floating-point representation. We use $\ll$ and $\gg$ to denote left and right shifts. Typically, we use shifts to divide and multiply by powers of two, e.g., $\lfloor x/2^i \rfloor = x \gg i$. Also, we will use shifts to extract parts of a word x: for $i \leq j < w$, let $x[i..j]$ denote $x[i] \cdots x[j]$. Using shifts, we move $x[i..j]$ to the right of x, making all other bits 0 by $(x \ll i) \gg (i+w-1-j)$. Finally, we use shifts to flip, set, and unset bits in words. For example, we flip bit i in x by $x \oplus (1 \ll (w-1-i))$.

The reason for mentioning conversion to floating-point is that if we convert an integer x to floating-point and extract the exponent $\texttt{expo}(x)$, then $\texttt{expo}(x) = \lfloor \log x \rfloor$. Here we presume normalized representation of floating-point numbers, as recommended in the IEEE 754 floating-point standard. In particular, the first set bit in x is bit $w-1-\texttt{expo}(x)$. We shall use this computation in section 7. Although this method of computing the first set bit may seem contrived, it is not just a theoretical trick to stay within AC^0. A quick test on an SGI computer indicated it to be faster than a hard-coded binary search combined with tabulation. It should be noted that Fredman and Willard have shown that `expo` can be computed in constant time using multiplication without the trick of conversion to floating-point [17]. This solution is, however, worse in theory as multiplication is not in AC^0, and worse in practice as it is both more complicated and uses slower operations.

The rest of this section is devoted to some simple standard-type observations on priority queues that will prove helpful in later sections.

2.1. Variable versus fixed size. As our end result, we want *variable-sized* priority queues whose space consumption is proportional to the current number of keys in them. In our constructions, however, we will just focus on priority queues with some given *capacity* n, meaning priority queues with room for n keys. We can then use the following standard-type simulation to get from given capacities to variable size.

LEMMA 2.1. *We can simulate a basic variable-sized priority queue Q using two basic priority queues Q' and Q'' with given capacity linear in the current number of keys in Q. Each operation on Q will translate into a constant number of operations on Q' and Q''.*

Proof. All keys of Q will either be in Q' or in Q'', but not in both. The smallest key will always be in Q', so $\texttt{find-min}(Q) = \texttt{find-min}(Q')$. Also `insert` and `delete-min` operations are addressed to Q'. While Q has at most four keys, we are in an initial state with all keys in Q' and with $Q'' = \emptyset$. In the initial state, Q' has capacity of five keys. Whenever Q gets more than four keys, we enter a general state described below. If Q later gets down to four keys again, we return to our initial state.

In the general state, after each `insert` and `delete-min`, if $|Q''| > 3$, we extract the two smallest keys from Q'' and insert them in Q'. If $|Q''| \leq 3$, we move all keys from Q'' to Q', set $Q'' := Q'$, reallocate Q' with capacity $3/2$ times the current number of keys, rounding up to the nearest integer, extract the smallest key μ from Q'', and put μ in Q'. Note that we automatically enter the latter case when we insert a fifth

key, bringing us from the initial to the general state.

We need to argue that both Q' and Q'' always have enough capacity for the keys inserted and that their capacities remain linear in the current number of keys in Q. When $Q^* = Q'$ is first allocated, it gets capacity $\lceil 3n/2 \rceil$, where n is the current number of keys. After $\lfloor n/2 \rfloor$ operations, all keys from Q'' are moved to $Q^* = Q'$. In this period, the total number of keys in Q remain between $n/2$ and Q^*'s capacity of $\lceil 3n/2 \rceil$. Next Q^* is assigned to Q''. Since no more keys can be inserted in $Q^* = Q''$, its capacity can never be exceeded. Let n' be the number of keys in Q^* when Q^* was assigned to Q''. After $\lfloor n'/2 \rfloor$ operations, all keys are moved from $Q'' = Q^*$ to Q' and Q^* is deallocated. Hence during the life time of Q^*, the number of current keys in Q remain between $\lceil n'/2 \rceil \geq n/4$ and $\lfloor 3n'/2 \rfloor \leq 9n/4$, both of which are linear in Q^*'s capacity of $\lceil 3n/2 \rceil$. □

2.2. Associating information with the keys. In applications of priority queues, we will often want to associate a word of information with the keys of the priority queue. That is, the priority queue contains key-information pairs, but the pairs are only required ordered with respect to the keys. For example, the information could be a pointer to some additional information about the key. If the keys are themselves one word, we can just append the information directly to the key, so that it becomes a two-word key, where the most significant word is the original key. However, here we will also deal with very short keys, and then we need different techniques.

PROPOSITION 2.2. *Using linear space and a basic priority queue for distinct $2b$-bit keys, we can maintain a priority queue for b-bit keys allowing multiplicity of key values and associating one word of information with each key.*

Proof. First observe that it suffices to associate an index $\in \{0, \ldots, n-1\}$ with each key, for then we can just allocate a table I of n words mapping indices to the desired words of information. If $n \leq 2^b$, we simply append the indices to the keys as an extra least significant part. The uniqueness of the indices implies uniqueness of the augmented keys. If $n > 2^b$, we use a priority queue for distinct b-bit keys and a table with 2^b entries, mapping each possible key value x to a list $L[x]$ of indices of keys with that value. The minimum key-index pair (x, i) is then the minimum key value x together with the first index in $L[x]$. □

2.3. Amortized deletions. Most of the priority queues in this paper are basic priority queues from which only the minimum keys can be deleted. Occasionally, we will need to augment a basic priority queue with a general delete, which is the concern of this subsection. In our applications, for delete we are satisfied with amortized time. In principle the implementation via basic priority queues is straightforward. We just take notes on which keys are to be deleted but postpone the actual removal till the keys come out as minimum keys. Then the amortized cost of general deletions is that of `find-min` and `delete-min`. One obstacle in supporting general deletions is, however, that we need to settle on a good interface between the priority queue and its user.

The main issue that arises in implementing a general `delete`(x, Q) is if the priority queue Q contains several keys with the same value x. Then the user may need to be able to specify which of them is to be deleted. This issue becomes even more prominent in connection with the `decrease-key` operation in Lemma 1.7, where the priority queue actually needs a pointer to the key in order to decrement it at constant cost.

The standard solution in practice is that when `insert`(x, Q) is called, the priority queue Q returns a unique identifier $\imath_x$. If the user wants to delete x, he calls

`delete`$(\imath_x, Q)$, and then the priority queue knows exactly which key to delete.

For a given capacity n, our identifiers will be indices $\{0, \ldots, 2n-1\}$. The priority queue Q has a table D which keeps track of which keys are to be deleted when they come out at minimum keys. Thus `delete`(i_x, Q) is implemented by setting $D[i_x] := 1$. Then `find-min` and `delete-min` are implemented so that they skip keys that are to be deleted according to D.

If ever we run out of indices, we "clean" the priority queue Q as follows. First we extract all keys from the queue, finding all keys to be deleted including their indices. These indices are freed for reuse, and all the nondeleted keys are returned to Q. Since the capacity of Q is n, we identify $\geq n$ keys to be deleted, and the removal of these keys pays for the cleaning.

Now, if we want a variable-sized priority queue, we actually need some extra collaboration with the user. Increasing sizes could quite easily be supported by the priority queue alone, but for shrinking sizes, we may have problems with large indices. The simplest solution is to leave the change of size to the user. That is, whenever the number of keys in the queue doubles or halves, the user should extract all keys from the queue and reinsert them into a new priority queue with capacity twice the current number of keys. Thereby all keys get reassigned their indices. Asymptotically, this does not affect the amortized operation cost. Assuming the interface described above, we conclude the following lemma.

LEMMA 2.3. *A basic priority queue can be augmented to support a general delete with the same amortized time bound as* `find-min` *and* `delete-min`. *This includes variable-size and associated one-word information.*

In applications of Lemma 2.3, we will typically not be explicit about the exact interface but just implicitly assume that the user is maintaining the identifiers as described above.

3. A priority queue for small integers. The goal of this section is to prove the following theorem.

THEOREM 3.1. *There is a priority queue with capacity for n $(w/(\log n \log\log n))$-bit keys, supporting* `insert`, `find-min`, *and* `delete-min` *on integers in constant time per operation and in space $O(n)$.*

Combined with Proposition 2.2, this gives the statement of Theorem 1.3.

We need the following result due to Albers and Hagerup.

LEMMA 3.2 (see [2]). *We can merge two sorted lists, each of at most k (w/k)-bit keys stored in a single word, into a single sorted list stored in two words in time $O(\log k)$.*

As an immediate consequence, we get the following lemma.

LEMMA 3.3. *For $n \geq k$, given two sorted lists of n (w/k)-bit integers, spread over $\lceil n/k \rceil$ words, we can merge them into $\lceil 2n/k \rceil$ words in time $O(n/k \cdot \log k)$.*

Lemma 3.3 is implicit in [2] but in a parallel setting. We note the following simple sequential derivation.

Proof. Pop the first word of each of the two lists to be merged. Apply Lemma 3.2 to these two words, obtaining w_0 and w_1. Now w_0 is the first word in the merged list, while w_1 is pushed on the list from which its biggest key came from. Thus we repeat until one list is empty. Hence each application of Lemma 3.2 extracts one word for the final merged list, while the other goes back for the next iteration. □

Further, we shall use the following result by Raman.

LEMMA 3.4 (see [30]). *There is a priority queue with up to $O(k)$ (w/k)-bit integers, supporting* `insert`, `find-min`, *and* `delete-min` *in constant time. Further,*

it supports `delete` *in constant amortized time.*

To prove Theorem 3.1, we will use Lemma 3.2, Lemma 3.3, and Lemma 3.4 with $k = \log n \log\log n$. First, in order to present the intuition, we give a simple amortized version of the result. Afterwards, we deamortize.

3.1. Amortized bounds. Our data structure has the following components: a "reception" R which is a priority queue from Lemma 3.4 with capacity for k keys. Further we have "buffers" $B_0, \ldots, B_{\log(n/k)}$ containing 0, 1, or 2 sorted lists of $\leq 2^i k$ keys where the keys are packed in words with k keys in each word. By Lemma 3.3, two full lists in B_i can be merged in $O(2^i \log k)$ time, which is $O(2^i \log k/(2^i k)) = O(1/\log n)$ time per key. The minimum of R and of each B_i is collected in a priority queue M from Lemma 3.4. Thus, the minimum key in the whole priority queue is found in M. Using Proposition 2.2, we associate with each key information about which R or B_i it came from.

It is only temporarily that a buffer may contain more than one list. Whenever we start supporting an operation, `insert`, `find-min`, or `delete-min`, we may assume that no buffer contains more than one list.

Deleting the minimum is done by deleting the minimum key from M and deleting it from the corresponding R or B_i. To support constant time deletions of the minimum key of a packed sorted list, we keep an index of the first nondeleted key in the first word. Deleting the minimum is then done by incrementing this index and removing the first word when all keys in it are deleted.

When an element is inserted, it is inserted into R in constant time. If thereby R gets full, the keys are extracted from R in sorted order and packed in a sorted list in one word. This list is put in B_0. If there was already a list in B_0, these two lists are merged. If the resulting list has $\leq 2^0 k = k$ keys, it stays in B_0. Otherwise, it is moved to B_1, which may now have two lists that have to be merged. If the resulting list has $> 2^1 k = 2k$ keys, it is moved to B_2 and so forth. As the lists are merged and moved, the minima of R and the B_i in M are updated accordingly.

Finding the minimum and possibly deleting it takes constant time. For the insertions, first note that inserting the key in R takes constant time. Also, moving keys from R to B_0 takes constant time per key. We will now consider the per-key cost accumulated over the merges. For the analysis, we will be a bit lazy removing deleted keys from the list. Lists in buffer B_i will have exactly $2^i k$ keys, some of which may have to be deleted. It is only when we merge two lists in B_i and discover that $\geq 2^i k$ are to be deleted that we remove exactly $2^i k$ of the keys to be deleted. Thus, the result of the merge is of length $2^i k$ or $2^{i+1} k$. In the former case, the result stays in B_i and it is the $2^i k$ removed keys that pay for the merge. In the latter case, the result is moved to B_{i+1}. Since the per-key cost of the merge is $1/\log n$ and since there are only $\log n$ buffers, the total cost of merges moving keys to larger buffers is $O(1)$ per key.

Since the buffers have exponentially increasing sizes, the space usage is dominated by that of the maximal buffer B_{max}. Further, when we created the buffer B_{max}, we know we did it with a newly merged list from B_{max-1} with $> 2^{max-1} k$ nondeleted keys. Hence the space bound for the buffers is $O(n/k)$, and for R and M, the space is constant.

3.2. Worst-case insertions. We are now going to translate the above priority queue into one working in worst-case constant time. First we ignore deletions of the minimum and focus on deamortizing the merging.

Instead of one reception R, we will in fact have three of them: R', R'', and R'''. The first two, R' and R'', consist of priority queues from Lemma 3.4 with at most k keys. The third, R''', consists of a sorted list of k keys stored in one word. All keys in R''' will be smaller than those in R'', that is, $\max R''' \leq \min R''$. Each of the buffers B_i contains 0, 1, or 2 sorted lists of $2^i k$ keys. If there are two lists, we may have parts of them merged. As in the amortized version, we have a priority queue M from Lemma 3.4 taking care of the minimum keys of R', R'', R''', and each B_i. Using Proposition 2.2, we associate information with the keys in M telling whether they are from R', R'', R''', or some B_i. Until section 3.4, we will pretend that M supports general deletions in constant time.

We proceed in rounds of k insertions. At the beginning of a round, R' is empty and so is the sorted list R'''. When a key is inserted, it is inserted in R'. Moreover, if the priority queue R'' is nonempty, the smallest key of R'' is moved to the end of the sorted list R'''. After k insertions, we have moved all keys from R'' to R'''. We then set $R'' := R'$ and $R' := \emptyset$. Further, we move the packed sorted list R''' of k keys to B_0 and set $R''' = \emptyset$.

If a buffer B_i has two packed sorted lists, we will start merging them. Each list is stored in at most 2^i words of k keys, so by Lemma 3.3, merging them takes $O(2^i \log k) = O(2^i k/\log n)$ time. The merging is viewed as divided into $2^i k/\log n$ steps, each taking constant time.

We are going to merge all buffers in parallel as follows. A round of k insertions is divided into $\log n$ mini-rounds, one for each buffer. We will have a counter i telling which buffer B_i we are working in. When a round starts $i = (\log n) - 1$, and we are going to count i down by one modulo $\log n$ at the end of every mini-round.

In a given mini-round, if B_i contains two lists, for each of the $k/\log n$ inserts in the mini-round, we perform a merge step on the two lists. If the merging is thereby completed, we move the resulting list to B_{i+1}. Finally, no matter whether we merged or not, we complete the round by setting $i := i - 1 \pmod{\log n}$.

In the last mini-round of a round, $i = 0$. It is not until this mini-round is completed, and we have moved a possible merged list from B_0 to B_1, that we complete the round by moving the packed list from R''' to B_0.

3.3. No overloading. We are now going to show that we never get more than two lists in any buffer. Here we are still ignoring deletions. First observe the following.

OBSERVATION 3.5. *Merging two lists in B_i takes 2^i rounds.*

Proof. Within every round we spend one mini-round of $k/\log n$ merge steps in B_i. However, by definition, it takes $2^i k/\log n$ merge steps to merge the lists. □

Concerning B_0, it receives a packed sorted list of k keys from R''' at the very end of every round. Suppose B_0 receives a second list at the very end of one round. By the above observation, the two lists will be merged completely during the subsequent round. Then B_0 is emptied before we, at the very end of the subsequent round, receive a third list from R'''.

For the other buffers, we have to show that when B_i sends a merged list to B_{i+1}, B_{i+1} does not already have two lists. To see this, we first argue the following.

LEMMA 3.6. *Buffer B_i is emptied at most every 2^{i+1}th round.*

Proof. The proof is by induction on i. For $i = 0$, it takes two rounds for B_0 to receive two lists, so B_0 is emptied every other round.

For the inductive step, we note that when the first list is moved to B_i, then B_{i-1} is emptied. Thus, by induction, it takes at least 2^i rounds before a second list is

moved from B_{i-1} to B_i, and by Observation 3.5, it further takes 2^i rounds before the two lists are merged so that the result can be moved to B_{i+1}. □

For $i \geq 0$, by Observation 3.5, B_{i+1} contains two lists for at most 2^{i+1} rounds, but this is the minimum time it takes before it receives a third list. Hence B_{i+1} can never have more than two lists.

Introducing `delete-min`. We are now going to introduce deletions in a way that does not tamper with the scheduling of our parallel merging. A key to the scheduling is that it takes exactly 2^i rounds to merge two lists in buffer B_i. Simultaneously 2^i is an upper bound on the number of rounds two lists can remain in B_i, and a lower bound on the number of rounds it takes before B_i can receive a third list from B_{i-1}.

When the minimum key μ is to be deleted from M, we extract μ together with information telling us whether it comes from R', R'', R''', or some B_i. If μ comes from R' or R'', we delete μ with `delete-min`. If μ comes from R''', it is the first key in the list, and it is just deleted. Clearly, deleted keys can only make it faster to move keys from R'' to R''', so this move is still completed within one round.

Suppose now that μ is from some B_i. If we have two partially merged lists in B_i, we preserve the original lists till the merging is completed. Keys are deleted from the original lists, that is, for each list, we have a min-pointer to the first nondeleted key, and one of these two keys is the smallest key in B_i. If μ is deleted from B_i, first we delete it by moving the min-pointer of the list of μ to the μ's successor in the list. Second, we find out which of the two lists in B_i now has the smallest nondeleted key. This new smallest key of B_i is inserted in M. In connection with such a deletion, we further make one merge step in B_i. As a consequence, if we have d deletions from B_i during the merging of B_i, the merging will terminate at least d steps early. Hence to terminate the merging within the 2^i rounds, we have d time steps that we can use to remove d keys from the merged list. These removals may be interspersed with new deletions via M. New deletions are still done in the original lists, but we make a simultaneous deletion in the merged list. Thus we arrive at a merged list with all deleted keys removed within 2^i rounds. In case we finish early, however, for the sake of scheduling we will not view the merging as completed before exactly 2^i rounds have passed. Consequently, this gives us the following.

OBSERVATION 3.7. *Merging two lists in B_i interspersed with deletions takes 2^i rounds.*

LEMMA 3.8. *Despite deletions, buffer B_i is emptied at most every 2^{i+1}th round.*

Proof. As the proof of Observation 3.5, the proof is by induction on i. For $i = 0$, we note that B_i still needs to receive at least two lists before it can be emptied, but now, of course, it may need more lists.

For the inductive step, suppose B_i has just been emptied. When the first new list is moved to B_i, B_{i-1} is emptied. Thus, by induction, it takes at least 2^i rounds before a second list is moved from B_{i-1} to B_i, and by Observation 3.7, it further takes 2^i rounds before the two lists are merged so the result can be moved to B_{i+1}. Note that the merged list is not moved to B_{i+1} if it contains $\leq 2^i k$ keys. Then it will take at least another 2^i rounds before B_i is emptied. □

Now, by Observation 3.7, B_{i+1} contains two lists for at most 2^{i+1} rounds, but this is the minimum time it takes before it receives a third list.

3.4. Deletions from *M*. Recall from section 3.2 that when we emptied a buffer, we assumed that we could just delete the minimum of the buffer from M in constant time. However, M does not solve deletions in constant time. We circumvent this problem as follows. While a buffer contains two lists, it may actually have the minima

of both lists in M. The minima are then associated with the lists rather than with the buffers, so when a list is moved, its minimum remains unchanged in M. The point is that when a buffer receives its second list, it will have two lists for at least one round of k inserts, and this will be plenty of time for us to remove the bigger of the minima of the two lists from M. More precisely, during every round, we will copy M to M', extracting the keys one by one from M, and insert them in M' only if they are not the bigger of the minima of two lists in a buffer. We make one such move from M to M' in connection with each insert. Since we have $O(\log n)$ keys in M, M is emptied within $O(\log n)$ insertions, which is less time than a round. When M is emptied, we swap the roles of M and M'. This completes the proof of Theorem 3.1.

3.5. Sequential storage. It should be mentioned that merging previously has been used in connection with priority queues to adapt them for sequential storage [15]. Our algorithm seems simpler than the one in [15], so it could be interesting to see how it performs on sequential storage if we ignore the packing of keys in words.

4. Priority queues for arbitrary integers. In this section we derive the time bounds of Theorem 1.1, postponing the space bounds to the next section. To get from arbitrary integers to short integers we will use a recursive range reduction which can be seen as a simple specialized variant of van Emde Boas' data structure [35, 36], inspired by the developments in [6, 22, 24, 27]. Let $T(n, b)$ be the time for `insert` and `delete-min` in a priority queue with up to n distinct b-bit integers supporting `find-min` in constant time. We assume that b but not n is known in advance. By Theorem 3.1, $T(n, w/(\log n \log\log n)) = O(1)$. We will show that

$$T(n, b) = O(1) + T(n, b/2). \tag{4.1}$$

Here b is assumed to be a power of 2. We will now implement a b-bit key priority queue Q. For any b-bit integer x, let $\texttt{low}(x)$ denote the contents of last $b/2$ bits, and let $\texttt{high}(x)$ denote the contents of the first $b/2$ bits. Thus, $x = \texttt{high}(x)2^{b/2} + \texttt{low}(x)$.

Let H be a $(b/2)$-bit key priority queue. H will be used for the `high`-values of the inserted keys. We will assume that we can freely allocate constant access time tables with entries from the values in H. We shall return to the implementation of these, including space issues, in the next section. Particularly, such tables allow us to answer whether a value is in H in constant time. Moreover, for each $h \in H$, they allow us to store a $(b/2)$-bit key $l[h]$ and a $(b/2)$-bit key priority queue $L[h]$ such that

- $\{l[h]\} \cup L[h] = \{\texttt{low}(x) | x \in Q, \texttt{high}(x) = h\}$.
- $l[h] < \min L[h]$.

Besides, we will have an integer $h_{min} = \min H$. Initially $H = \emptyset$ and $h_{min} = \infty$. If Q is nonempty,

$$\texttt{find-min}(Q) = 2^{b/2} h_{min} + l[h_{min}] = (h_{min} \ll b/2) + l[h_{min}].$$

We are now ready to present concrete implementations of `insert` and `delete-min` settling recurrence (4.1).

ALGORITHM A. $\texttt{insert}(x, Q)$
A.1. $(h, l) := (\texttt{high}(x), \texttt{low}(x))$.
A.2. If $h \notin H$,
A.2.1. $h_{min} := \min(h, h_{min})$.
A.2.2. $\texttt{insert}(h, H)$.
A.2.3. $l[h] := l$.
A.2.4. Allocate an empty priority queue $L[h]$.

A.3. If $h \in H$,
A.3.1. $(l[h], l) := (\min(l[h], l), \max(l[h], l))$.
A.3.2. `insert`$(l, L[h])$.
ALGORITHM B. `delete-min`(Q)
B.1. If $|L[h_{min}]| > 0$, then
B.1.1. $l[h_{min}] :=$ `find-min`$(L(h_{min}))$.
B.1.2. `delete-min`$(L(h_{min}))$.
B.2. Else
B.2.1. Deallocate $L[h_{min}]$.
B.2.2. $h_{min} :=$ `find-min`(H).
B.2.3. `delete-min`(H).

Each of the above algorithms makes exactly one recursive call, so this settles the time bound described in recurrence (4.1).

We are now essentially in the position to settle Theorem 1.1. By Proposition 2.2 we can support a basic w-bit key priority queue with multiplicity of key values and associated information if we have a basic priority queue for distinct $2w$-bit keys. Starting with these $2w$-bit keys, we apply recurrence (4.1) $\log(2 \log n \log\log n) = O(\log\log n)$ times. In time $O(\log\log n)$ per operation, this reduces our problem to dealing with $(w/(\log n \log\log n))$-bit keys. By Theorem 3.1 together with Lemma 2.1, these can be dealt with in constant time, so the total time is $O(\log\log n)$ per operation. We are still missing, however, how we can test membership in H and how we can use the members of H as entries for tables. These issues are the subject of the next section.

5. Space issues. In order to clarify the space usage of our algorithm, we need to discuss dynamic dictionaries. A *dynamic dictionary* maintains a subset X of a typically much bigger universe $\mathcal{U}$. Elements can be inserted and deleted from X, and further, we can ask membership queries, that is, given $x \in \mathcal{U}$, does x belong to X? In addition, we want it to associate with each element $x \in X$ a unique index $\imath_X$ of size $O(|X|)$. These indices allow us to use X, or really $\{\imath_x | x \in X\}$, as entries to arrays/tables. Thus a dynamic dictionary is exactly what we needed in the last section for testing membership of H and for allocating the tables l and L with entries from H. For our $O(\log\log n)$ time bound for priority queues to hold, we can only use dictionaries where all operations are supported in constant time.

LEMMA 5.1 (see [11, 16, 26]). *We can support a dynamic dictionary for a set* $X \subseteq \{0,1\}^w$

(1) *deterministically with constant operation time in space* $O(|X|2^{\varepsilon w})$ *using standard* AC^0 *operations (here* ε *is any positive constant),*
(2) *randomized with expected constant operation time in space* $O(|X|)$.

Proof. The randomized solution is simply Carter and Wegman's multiplicative hashing [11]. For the deterministic solution, based on Fredkin's tries [16], Mehlhorn [26, section III, Theorem 1] has shown that for universe size N and for any k, we can get operation time $O(\log_k N)$ using $O(|X|k)$ space. Here $N = 2^w$, and we set $k = 2^{\varepsilon w}$, getting an operation time of $O(\log_{2^{\varepsilon w}} 2^w) = O(1/\varepsilon) = O(1)$. The algorithm divides by k and division is not an AC^0 operation. However, we can choose k as a power of 2, and then the division is just a right shift. □

The space dependence on w in the deterministic AC^0 solution is unsatisfying, but if we insist on AC^0 operations, Andersson et al. [4] have proved that there cannot be a solution to the dynamic dictionary problem combining constant operation time with space polynomial in $|X|$.

We will now take a closer look at the dynamic dictionaries needed for the priority queue from the last section. The recursive structure only depends on the keys in the queue. Hence the per-key space consumption can be found by analyzing `insert`. In connection with a call to `insert`, we may introduce a new entry h to l and L. Further, we allocate an empty priority queue $L[h]$. Since the depth of the recursion is $O(\log\log n)$, we conclude that both the total number of dictionaries used and the total number of entries used in all dictionaries is $O(n \log\log n)$.

Following ideas of van Emde Boas [35], we can reduce the number of dictionaries and entries to $O(n)$ as follows. The keys are collected as they are inserted into a list of micro sets, each of size $\log\log n$. For each micro set, it is only the minimum key that is inserted in our recursive priority queue Q. Hence the overall minimum key μ is always found in Q. When μ is deleted from Q, it is deleted from the corresponding micro set S. The new minimum x of $S \setminus \{\mu\}$ is found by a simple scan in $O(|S|) = O(\log\log n)$ time, and then x is inserted in Q. If ever two neighboring sets together get less than $\log\log n$ elements, we merge them. This can only happen in connection with a deletion, and only for one pair of neighbors. The merge is done in $O(\log\log n)$ time. Thus, without violating our $O(\log\log n)$ time bound, we can reduce the number of keys in Q to $O(n/\log\log n)$. Hence the total number of dictionaries and dictionary entries in Q become $O((n/\log\log n)\log\log(n/\log\log n)) = O(n)$. The space bounds in Lemma 5.1 are both linear in $|X|$, so we get the following theorem.

THEOREM 5.2. *There is a priority queue supporting* `find-min` *in constant time and* `insert` *and* `delete-min` *in $O(\log\log n)$ time, where n is the current number of keys in the queue. It uses $O(n2^{\varepsilon w})$ space and may be implemented with standard AC^0 operations. Also, there is a randomized implementation using non-AC^0 operations giving $O(\log\log n)$ expected time and $O(n)$ space.*

In the introduction, we also mentioned that we could get $O(n + 2^{\varepsilon w})$ space deterministically for a monotone priority queue with an $O(\log\log n)$ amortized operation time. This matches the space bound of the deterministic sorting $O(n \log\log n)$ algorithm of Andersson et al. [3], so to get the monotone amortized priority queue, we simply plug the sorting algorithm from [3] into Theorem 1.4.

6. A priority queue for strings. In this section, we implement a priority queue for ℓ-word keys using the priority queues for one-word keys from Theorem 1.1. Essentially, we just use Fredkin's trie [16] as presented by Mehlhorn [26, section III]. Each key is viewed as a string of ℓ characters. The keys are stored in a trie, which is a rooted tree of depth ℓ. Each edge is labeled by a one-word character, and each leaf v represents the string of characters labeling the path from the root to v. Thus n strings are represented by a trie with n leaves.

In order to facilitate basic priority queue operations, we associate with each internal node with more than one child, a dictionary and a priority queue over the characters of its outgoing edges. Thereby we get a total of $n - 1$ entries in the dictionaries and the priority queues, so by Lemma 5.1 and Theorem 5.2, the total space bound for all the dictionaries and priority queues becomes $O(n2^{\varepsilon w})$ for a deterministic solution implemented with standard AC^0 operations, and $O(n)$ for a randomized solution using non-AC^0 operations. Additionally, we need $O(n\ell)$ space to store the keys.

Now, in order to find the minimum string in the queue, we descend from the root of the trie, using a `find-min` operation at each internal node to figure out which child to descend to. Thereby we end at the leaf representing the minimum string. Since `find-min` takes constant time, the time bound for finding the minimum string is $O(\ell)$.

Having performed `find-min` and identified the path from the root to the leaf w

representing the minimum string, we can delete the minimum string by deleting the path from the leaf and up to its first ancestor v with > 1 child. Let a be the character that labeled the edge from v towards w. Then a has to be deleted from the dictionary and the priority queue at v. Deleting the path nodes takes time $O(\ell)$, deleting a from the dictionary at v takes constant time, and deleting a from the priority queue at v is done using `delete-min` in time $O(\log\log n)$. Finally, if v has now only one child, the dictionary and priority queue at v are deallocated in constant time. Consequently, the cost of deleting the minimum string is $O(\ell + \log\log n)$.

To insert a new string s, we first use $O(\ell)$ finds in dictionaries to descend to the node v at which the path representing s should branch out from the current trie. Then the remaining part of the path to the leaf representing s is added to the trie. Finally, the character a on the new path below v has to be inserted in the dictionary and priority queue at v in time $O(\log\log n)$. Note that if v does not already have > 1 child, we first allocate a dictionary and priority queue at v in constant time. Thus, the total cost of an insertion is $O(\ell + \log\log n)$.

7. From monotone priority queues to sorting. We are now going to present a general reduction of Theorem 1.4 from monotone priority queues. More precisely, fix $k = \Theta(\log n \log\log n)$ as a power of 2. Each key of the priority queue will participate in one sorting and go through one priority queue for (w/k)-bit integers and one priority queue with capacity for at most $k+1$ integers at the time. The former priority queue has constant operation cost by Theorem 3.1, and the latter priority queue has constant operation cost due to the following result of Fredman and Willard [18].

LEMMA 7.1 (see [18]). *Given $O(n)$ space and preprocessing time, we can maintain an unrestricted priority queue for up to $O(\log^2 n)$ keys at constant amortized cost per operation.*

Thus, the operation cost of our priority queue becomes the per-key cost of sorting plus a constant. The construction of Lemma 7.1 relies heavily on multiplication, which is not an AC^0 operation [9]. However, Andersson, Miltersen, and Thorup [5] have shown that the construction can be implemented using AC^0 operations only if we allow ourselves some simple nonstandard AC^0 operations.

7.1. Preliminaries. In our reduction, keys are viewed as divided into k (w/k)-bit characters. For $i = 0, \ldots, k-1$, $x\langle i\rangle$ denotes character i in x. Further, for $i \le j < k$, $x\langle i..j\rangle$ denotes $x\langle i\rangle \cdots x\langle j\rangle$. For different keys x and y, $\texttt{split}(x,y)$ denotes the first i such that $x\langle i\rangle \neq y\langle i\rangle$. If $x = y$, we define $\texttt{split}(x,y) = k$. Since our integer keys are stored with the most significant bit first, $x < y \iff x\langle\texttt{split}(x,y)\rangle < y\langle\texttt{split}(x,y)\rangle$.

LEMMA 7.2. *For any two words x, y, $\texttt{split}(x,y)$ is computable in constant time with standard AC^0 operations.*

Proof. If $x = y$, $\texttt{split}(x,y) = k$, and we are done, so assume $x \neq y$. Then $\texttt{split}(x,y) = \lfloor (w - 1 - \texttt{expo}(x \oplus y))/(w/k) \rfloor$. Now k and w are powers of 2, and hence so is w/k, that is $w/k = 2^e$ for some e. Now, we compute $\texttt{split}(x,y)$ as $(w - 1 - \texttt{expo}(x \oplus y)) \gg e$. ∎

7.2. The general idea. Fix μ to denote the minimum key in Q. Since μ is the minimum key, for any other keys $x, y \in Q$

$$\texttt{split}(x,\mu) < \texttt{split}(y,\mu) \Rightarrow x > y. \tag{7.1}$$

Thus $\texttt{split}(\cdot,\mu)$ provides us with a preordering of the keys in Q. We will use this for an initial bucketing of the keys into buckets $B_0, \ldots, B_{k-1}$. That is, when a key $x \neq \mu$ is first inserted, it is put in a bucket $B_{\texttt{split}(x,\mu)}$.

Now, when μ is increased, this may violate the placement of some keys x in a bucket B_i. That is, when μ increases, we may get $\texttt{split}(x, \mu) > i$. In this case, all such x will be sorted and put in a list L_i. It will turn out that we never will need more than one list L_i for $i = 0, \ldots, k-1$.

Thus each key of Q is either in a buckets B_i or in some sorted lists L_i but not in both.

The minimum key in all the lists L_i is maintained by a priority queue from Lemma 7.1. Maintaining the minimum key in each bucket B_i will essentially be done using the priority queue from Theorem 3.1.

It should be noted that bucketing according to $\texttt{split}(\cdot, \mu)$ goes back to Denardo and Fox [14]. However, in [14], when a key x is misplaced because of an increase in the minimum key μ and $\texttt{split}(x, \mu)$, x is reinserted in a new bucket $B_{\texttt{split}(x,\mu)}$. This gives up to k reinsertions per key. Here, instead, we sort all misplaced keys, adding them to a set of sorted lists. The key insight is that only k sorted lists are needed at any time.

7.3. Components. We are now ready to formally state the components of the reduction.

DESCRIPTION C.

C.1. The smallest key μ in the queue. Thus `find-min` is trivially implemented in constant time.

C.2. Some sorted lists $L_0, \ldots, L_{k-1}$ of keys where L_i satisfies for all $x \in L_i$: $\texttt{split}(\mu, x) > i$. Note that $i < j$ implies that any key in L_j could also have been in L_i. Also note that all keys in L_{k-1} have the same value as μ.
Using a priority queue from Lemma 7.1, we keep track of which of the lists $L_0, \ldots, L_{k-1}$ has smallest first key. This key is then the smallest of all the keys in the lists, so $\mu_L = \min \bigcup_i L_i = \min_i \{\min L_i\}$ is computable in constant amortized time.

C.3. Some buckets $B_0, \ldots, B_{k-1}$. Every key $x \in B_i$ has $\texttt{split}(x, \mu) = i$. Thus every key x in $\bigcup_i B_i$ fits in a unique bucket B_i; namely $B_{\texttt{split}(x,\mu)}$.
The keys in B_i are stored in a monotone priority queue from Theorem 3.1 with (w/k)-bit key and w-bits of information. Each keys $x \in B_i$ is entered as the pair $(x\langle i\rangle, x)$. That is, in B_i, the original keys are only ordered with respect to character i.

C.4. The maximum index i_{max} of a nonempty B_i. This is done using a single word α. In α, we set bit $w - 1 - i$ if and only if B_i is nonempty. Then $i_{max} = \texttt{expo}(\alpha)$.

Above it is understood that each key in Q is only represented once, either as the minimum key μ, or in one L_i, or in one B_i.

7.4. Implementing `find-min` and `insert`. As mentioned above, `find-min` is trivially implemented in constant time by returning the value of μ. Concerning insertions, since the priority queue is monotone, an insertion cannot change the minimum key μ, and hence an insertion cannot misplace any key currently in the queue. The implementation is therefore straightforward.

ALGORITHM D. $\texttt{insert}(x, Q)$

D.1. If $x = \mu$, add x to L_{k-1}.

D.2. If $x \neq \mu$ then

D.2.1. $i := \texttt{split}(x, \mu)$.

D.2.2. $\texttt{insert}((x\langle i\rangle, x), B_i)$.

D.2.3. Set bit $w - 1 - i$ in α (cf. C.4).

7.5. Implementing `delete-min`. In order to implement `delete-min`, we need to find the current second smallest key μ' in Q. Note that in case of multiplicities, the second smallest key may have the same value as μ.

LEMMA 7.3. *Let μ_B be the smallest key in $\bigcup_i B_i$. Then μ_B is in $B_{i_{max}}$ and if $(a, x) = \texttt{find-min}(B_{i_{max}})$, $\mu_B\langle 0, \ldots, i_{max}\rangle = \mu\langle 0, \ldots, i_{max} - 1\rangle a$.*

Proof. By (7.1), for all $i < i_{max}$, $\max B_{i_{max}} < \min B_i$. Further, since the keys in $B_{i_{max}}$ agree on characters $0, \ldots, i_{max} - 1$, the smallest key in $B_{i_{max}}$ must minimize character i_{max}. □

Let μ_B, and a be as defined in the above lemma. Further, let μ_L be the minimum key over all lists L_i. Then the current second smallest key μ' is the smaller of μ_B and μ_L, or either if $\mu_B = \mu_L$. From C.2 we know that $\mu_L = \min_i\{\min L_i\}$ is available in constant time. On the other hand, μ_B is not automatically available. However, by Lemma 7.3, $\mu_B\langle 0, \ldots, i\rangle = \mu\langle 0, \ldots, i_{max}\rangle a$, where μ, i_{max}, and a are all available in constant time. That is, we know $\mu_B\langle 0, \ldots, i_{max}\rangle$.

We now divide in cases depending on whether or not $\mu_L\langle 0, \ldots, i_{max}\rangle < \mu_B\langle 0, \ldots, i_{max}\rangle$.

Suppose $\mu_L\langle 0, \ldots, i_{max}\rangle < \mu_B\langle 0, \ldots, i_{max}\rangle$. Then $\mu' = \min\{\mu_B, \mu_L\} = \mu_L$. Hence we delete μ_L from the list L_i it came from and set $\mu := \mu_L$.

We need to argue that replacing μ with μ_L maintains for all $x \in L_i : \texttt{split}(\mu, x) > i$ and for all $x \in B_i : \texttt{split}(\mu, x) = i$ for $i = 0, \ldots, k-1$. In the argument, μ_{old} denotes the old value of μ.

To see that for all $x \in L_i : \texttt{split}(\mu, x) > i$ is maintained, note that for any x, y, z, $x \le y \le z$ implies $\texttt{split}(x, z) \le \texttt{split}(y, z)$. Since μ_L was the second smallest key in the queue, it follows that replacing μ with μ_L can only increase $\texttt{split}(\mu, x)$ for the remaining keys x. Hence the replacement maintains for all $x \in L_i : \texttt{split}(\mu, x) > i$.

We will now argue that for all $x \in B_i : \texttt{split}(\mu, x) = i$ is maintained for $i = 0, \ldots, k-1$. Since μ_L is strictly smaller than all keys in the B_i, by (7.1), $\texttt{split}(\mu_L, \mu) \ge i_{max}$. Hence $\mu_L\langle 0..i_{max} - 1\rangle = \mu_{old}\langle 0..i_{max} - 1\rangle$, so $\texttt{split}(\mu, x) = i$ is preserved for $i < i_{max}$. It follows for $i < i_{max}$ that for all $x \in B_i : \texttt{split}(\mu, x) = i$ is maintained. Consider any $x \in B_{i_{max}}$. Then $x\langle 0..i_{max} - 1\rangle = \mu_{old}\langle 0..i_{max} - 1\rangle = \mu_L\langle 0..i_{max} - 1\rangle$. Moreover, $x\langle 0..i_{max}\rangle \ge \mu_B\langle 0..i_{max}\rangle > \mu_L\langle 0..i_{max}\rangle$, so we conclude that $\texttt{split}(\mu_L, x) = i$, as desired. Since $B_i = \emptyset$ for all $i > i_{max}$, we conclude that for all $x \in B_i : \texttt{split}(\mu, x) = i$ is maintained, for $i = 0, \ldots, k-1$, as desired.

Suppose $\mu_B\langle 0, \ldots, i_{max}\rangle \le \mu_L\langle 0, \ldots, i_{max}\rangle$. Then $\mu'\langle 0, \ldots, i_{max}\rangle = \mu_B\langle 0, \ldots, i_{max}\rangle$. Further, we have the following key lemma.

LEMMA 7.4. *If $\mu_B\langle 0, \ldots, i_{max}\rangle \le \mu_L\langle 0, \ldots, i_{max}\rangle$, $L_{i_{max}} = \emptyset$.*

Proof. Suppose for a contradiction that there is a key $x \in L_{i_{max}}$. By definition (cf. C.2), $\texttt{split}(x, \mu) > i_{max}$. However, $\mu \le \mu_L \le x$, so by (7.1), $\texttt{split}(\mu_L, \mu) > i_{max}$. Hence $\mu_L\langle 0, \ldots, i_{max}\rangle = \mu\langle 0, \ldots, i_{max}\rangle$. Since μ is the smallest key in Q and $\texttt{split}(\mu_B, \mu) = i_{max}$, this contradicts $\mu_B\langle 0, \ldots, i_{max}\rangle \le \mu_L\langle 0, \ldots, i_{max}\rangle$. □

Since $L_{i_{max}} = \emptyset$ is empty, we can now extract the set X of all keys x from $B_{i_{max}}$ with $x\langle i_{max}\rangle = a$, sort S, and make S the new sorted list $L_{i_{max}}$. Since $\mu'\langle 0, \ldots, i_{max}\rangle = \mu_B\langle 0, \ldots, i_{max}\rangle = \mu\langle 0, \ldots, i_{max} - 1\rangle a$, all keys x in $L_{i_{max}}$ satisfy $\texttt{split}(x, \mu') > i_{max}$. Now, μ_B is simply the first key in $L_{i_{max}}$, so `delete-min` is implemented, setting μ to the smaller of μ_B and μ_L, deleting μ from the list L_i it is in.

We need to argue that we have maintained for all $x \in L_i : \texttt{split}(\mu, x) > i$ and for all $x \in B_i : \texttt{split}(\mu, x) = i$ for $i = 0, \ldots, k-1$. Let μ_{old} and be the old value of μ. Further, we have μ' denoting the new value of μ. We have already argued that for

all $x \in L_{i_{max}} : \texttt{split}(\mu', x) > i_{max}$, and the rest of the argument follows the same lines as in the previous case of $\mu_L\langle 0, \ldots, i_{max}\rangle < \mu_B\langle 0, \ldots, i_{max}\rangle$. First, since μ' was the second smallest key, $\texttt{split}(\mu, x)$ can only increase for the remaining keys, so for all $x \in L_i : \texttt{split}(\mu, x) > i$ is preserved for $i \neq i_{max}$.

It remains to argue that for all $x \in B_i : \texttt{split}(\mu, x) = i$ is maintained for $i = 0, \ldots, k-1$. Since $\mu'\langle 0..i_{max}\rangle = \mu_B\langle 0..i_{max}\rangle$, and $\texttt{split}(\mu_B, \mu_{old}) = i_{max}$, $\mu'\langle 0..i_{max} - 1\rangle = \mu_{old}\langle 0..i_{max} - 1\rangle$. Hence for all $x \in B_i : \texttt{split}(\mu, x) = i$ is maintained for $i < i_{max}$. However, all remaining keys x in $B_{i_{max}}$ have $x\langle i_{max}\rangle > a$, so $\texttt{split}(\mu', x) = i_{max}$, as desired. Hence, we conclude that for all $x \in B_i : \texttt{split}(\mu, x) = i$ is maintained for $i = 0, \ldots, k-1$. This completes our proof that `delete-min` is implemented correctly.

The above of description `delete-min` is turned into pseudocode as follows.

ALGORITHM E. `delete-min`(Q)

E.1. $\mu_L := \min \bigcup_h L_h$. Here $\min \emptyset = \infty$ and $\texttt{split}(\mu, \infty) = 0$ for $\mu < \infty$.

E.2. $i_{max} := \texttt{expo}(\alpha)$ (cf. C.4).

E.3. $(a, x) := \texttt{find-min}(B_{i_{max}})$.

E.4. If $\mu\langle 0, \ldots, i_{max} - 1\rangle a \leq \mu_L\langle 0, \ldots, i_{max}\rangle$ then

E.4.1. loop

E.4.1.1. $L_{i_{max}} := L_{i_{max}} \cup \{x\}$.

E.4.1.2. $\texttt{delete-min}(B_{i_{max}})$.

E.4.1.3. if $B_{i_{max}} = \emptyset$, unset bit $w - 1 - i_{max}$ in α (cf. C.4) and exit the loop.

E.4.1.4. $(b, x) := \texttt{find-min}(B_{i_{max}})$.

E.4.1.5. if $b > a$, exit the loop.

E.4.2. Sort $L_{i_{max}}$.

E.4.3. $\mu_L := \min\{\mu_L, \min L_{i_{max}}\}$.

E.5. $\mu := \mu_L$.

E.6. Delete μ_L from its list.

Above we maintain the priority queue spending constant amortized time per `insert` or `delete-min` operation plus sorting. Each key participates in exactly one sorting; namely when it is transferred from $B_{i_{max}}$ to $L_{i_{max}}$. Thus sorting is only done for disjoint subsets of the keys, and all keys sorted are current keys in the queue. This completes the proof of Theorem 1.4 except for the remarks on a variant using only standard AC^0 operations. For $s(n)$ the per-key cost of sorting n keys and $\operatorname{logg} n = \log n \log\log n$, it was claimed that we could support `insert` and `delete-min` in $O(\sum_{i=0}^{\operatorname{logg}^* n} s(\operatorname{logg}^{(i)} n))$ amortized time.

The only part of our construction that is not implementable with standard AC^0 operations is a priority queue Q_L from Lemma 7.1, which was used to maintain the smallest of the minima of the lists L_i (cf. C.2). There are only $k = \operatorname{logg} n$ such lists L_i, so in order to get the claimed bound, it suffices to maintain their minima recursively. Unfortunately, the Q_L is not immediately monotone even though the overall priority queue is monotone. The problem is in `delete-min` if we pass the condition of step E.4 and create a new list $L_{i_{max}}$. If $\mu_B < \mu_L$, the new list $L_{i_{max}}$ will have minimum μ_B which is strictly smaller than the previous minimum μ_L of Q_L.

To preserve monotonicity, note that we do not need to know μ_L if $\mu\langle 0, \ldots, i_{max} - 1\rangle a \leq \mu_L\langle 0, \ldots, i_{max}\rangle$ (cf. E.4). Set $\mu_B^- := \mu\langle 0, \ldots, i_{max} - 1\rangle a \ll (w - i_{max} - 1)$. Then $\mu < \mu_B^- \leq \mu_B$. Before deleting μ from Q_L, we insert μ_B^-. Suppose μ_B^- becomes the minimum after μ is deleted. Then we pass the condition of step E.4, and the new minimum μ_B of $L_{i_{max}}$ is not smaller than μ_B^-, so monotonicity is respected. If μ_B^- does not become the new minimum after deleting μ, we do

not pass the condition of step E.4. Then μ_B^- is just skipped whenever it comes out. Here we refer to the methods described in section 2.3. This completes the proof of Theorem 1.4 including the case of standard AC^0 operations. □

8. Getting constant cost `decrease-key`. In this section, we want to prove the statement of Lemma 1.7:

> *Provided a monotone/unrestricted basic priority queues for up to $f(n) = \Omega(\log^2 n)$, $f(n) = O(n)$, keys supporting* `find-min`*,* `insert`*, and* `delete-min` *in constant amortized time, there is a monotone/unrestricted priority queue with capacity n, supporting the operations* `find-min`*,* `insert`*, and* `decrease-key` *in constant amortized time, and* `delete` *in time $O(\log n/\log f(n))$. The reduction is deterministic and uses linear space, and it can be implemented with standard AC^0 operations.*

The result of Lemma 1.7 is essentially achieved by Fredman and Willard's AF-heaps [18, section 2.2], except that the AF-heaps are not concerned with monotonicity. As in [18], we shall refer to the small constant cost priority queues from the assumption of the lemma as *atomic priority queues*. By Lemma 2.3, we can assume that atomic priority queues support general deletions of arbitrary keys, also at amortized constant cost. Below we briefly repeat the construction of AF-heaps, referring the reader to [18, section 2.2] for further explanations. The emphasis in our presentation is to ensure that if the overall priority queue is monotone, then so are all involved atomic heaps.

The keys in the overall priority queue Q are distributed over B-trees with $B = f(n)/\log n$. Here, a B-tree is a rooted tree where all leaves are on the same depth and where the degree of each internal node is between $B/2$ and B. Since the total number of keys is n, the depth of any involved B-tree is $O(\log n/\log B)$. Since $f(n) = \Omega(\log^2 n)$, $f(n) = \Omega(\sqrt{B})$, and hence the maximal depth is $O(\log n/\log B) = O(\log n/\log f(n))$, which is the claimed cost of deletions.

The keys are placed in heap order meaning that the keys get smaller as we get closer to the root. Thus, the minimum key is among the roots of the trees. There will be at most B trees of each possible height. Since the maximal height is $O(\log n/\log B)$, the maximal number of trees is $O(B\log n/\log B) = O(B\log n) = O(f(n))$. An atomic priority queue, called the "root queue," can therefore maintain the minimum key among the roots, which in turn is the minimum key in the priority queue. Further, at each internal node, we have an atomic priority queue, called the "children queue," maintaining the smaller key among its $\le B = O(f(n))$ children.

In order to implement `insert`, `decrease-key`, and `delete`, we will temporarily relax the requirements to how many keys there are in the different priority queues. Also, we will temporarily allow some node in a B-tree to be empty in the sense of having no key associated with it.

`insert`(x, Q). Create a single node tree containing x, adding x to the root queue. Since the root queue always contains the smallest key in Q, we are not violating monotonicity of the root queue if the overall priority queue is monotone.

`delete`(x, Q). If x is a leaf, we just delete x. Otherwise, we replace x by its smallest child y, and then, recursively, we delete y from where it was. Since $y \ge x$, we are sure to avoid violating monotonicity if we insert y into the children queue of the parent of x before we delete x. Above, if x was a root, the children queue of its "parent" is understood to be the root queue.

`decrease-key`(x, d, Q). First, if x is not a root, cut x from its parent, deleting x from the children queue of its parent. Now the subtree of x is an independent tree

with root x, and then x is added to the root queue. If x is not a root, x is already in the root queue. Now we replace x by $x-d$ in the root priority queue. Since the root queue always contains the smallest key in Q, monotonicity of the root queue is not violated if Q is monotone.

The above operations may result in too many trees, or in some internal node having $< B$ children. As long as any of these problems appear, we repeat.

(i) Suppose at some stage we get B or more trees of the same height h. We then collect a set F of B such trees and remove all but the smallest root x in F from the root queue. Next we create a new tree T. Its root is a new node v with the same value as x, and the subtrees under v are the trees in F. Then T is a B-tree of height $h+1$. The root v already has its value in the root queue, and the roots of F are collected in children queue under v. Finally, we perform a `delete`(v, Q), getting rid of the extra copy of x.

(ii) If at some stage, some internal key x gets $< B/2$ children, we first cut all the children from x. The subtrees of the children are now independent, and the children are moved from priority queue at x to the root queue. Next, if x is not a root, we cut x from its parent, making x a single node tree, and move x from the priority queue at its parent to the root queue.

Above, we always apply (i) before applying (ii). Thereby, we will never get more than $3B/2$ trees of any given height. To see the efficiency of AF-heap, consider the potential function $\Pi = \tau + 2\gamma$ where τ is the number of trees in Q and γ is the sum over all internal nodes v of $B - d(v)$, where $d(v)$ is the degree of v.

Now, `insert`(x, Q) creates a single node tree x in constant time. This increments τ by one while γ is unchanged since x is a leaf. Thus the amortized cost of `insert`(x, Q) is $O(1)$, as desired.

Calling `delete`(x, Q) takes time proportional to the height, which is $O(\log n / \log f(n))$. The only structural change is that some leaf is deleted, increasing γ by 1. Hence the amortized cost of `delete`(x, Q) is $O(\log n / \log f(n))$, as desired.

When calling `decrease-key`(x, d, Q), structurally, we cut x from its parent. This turns the subtree rooted in x into a new tree whose root x is decreased by d and added to the root queue. All this takes constant time. Since we decrease the degree of x's original parent, we increase γ by one. Further, the creation of a new tree increases τ by 1. Summing up, the total amortized cost of `decrease-key`(x, d, Q) is $O(1)$, as desired.

Finally, we need to argue that (i) and (ii) have no associated cost. Now (i) takes $O(\log n / \log f(n))$ time as it deletes v. However, structurally, it decreases the number τ of trees by $B - 1 = \Omega(f(n)/\log n)$, thus paying for the time spent. Note that the new internal node v does not change γ since it gets B children. Hence γ is only increasing by one as part of the deletion.

Clearly (ii) takes $O(B)$ time to execute. It may create as many as $B/2$ new trees, thus increasing τ by $B/2$. On the other hand, the change in γ around x is a decrease by $\geq B/2 - 1$, so the change in Π is a decrease of $B/2 - 2 = \Omega(B)$, paying for the time spent on (ii).

Referring the reader to [18, section 2.2] for further details, this completes the proof of Lemma 1.7.

ROBOT NAVIGATION WITH DISTANCE QUERIES*

DANA ANGLUIN†, JEFFERY WESTBROOK‡, AND WENHONG ZHU§

Abstract. We consider the problem of online robot navigation in an unfamiliar two-dimensional environment, using comparatively limited sensing information. In particular, the robot has local sensors to detect the proximity of obstacles and permit boundary-following, and it is able to determine its current distance and relative bearing to its final destination (via distance queries). By contrast, most previous algorithms for online navigation have assumed that the robot knows its exact current position. Because determining exact location is prone to error that accumulates over time, the usefulness of such algorithms may be limited. In contrast, distance queries give less information, but the accuracy of each query is independent of the number of queries, which means distance queries can be more robust. We formally define our model and give new, efficient navigation algorithms and lower bounds for this setting.

Key words. robot navigation, range query, distance query, robot exploration, analysis of algorithms

1. Introduction.

We consider the problem of navigating a robot from its initial position to a target destination in a two-dimensional (2D) environment partially obstructed by initially unknown obstacles of arbitrary shapes. We assume that the robot is equipped with two kinds of abstract sensors: (1) local sensors, which allow it to detect the proximity of an obstacle and travel along the boundary of an obstacle, and (2) range sensors, which allow it to determine the distance of its current position from the target destination and its relative bearing to the target.

Previous theoretical work on navigation has generally assumed that the robot has access to the (x, y) coordinates of both the target destination and the robot's current position. In practice, an estimate of the robot's current position is usually obtained by odometry, i.e., by integrating a speed estimate over time. This means that error in the position estimate steadily accumulates as the robot travels. The difficulty of determining exact position has recently led robotics researchers to look for navigation algorithms that do not need exact global position but use weaker information that can be determined without cumulative error. In this connection, Taylor and Kriegman [8] introduced the idea of distance queries, based on the capabilities of their robot, RJ.

The general question of how much and what kinds of sensory information a robot needs for various tasks constitutes an exciting area of research; the main contribu-

tion of this paper is to explore the implications for online navigation of replacing the assumption of exact position by the weaker assumption of distance queries. Another contribution of this paper is the definition of our model, the distance query model, which we now describe sufficiently to state our results. (More details appear in section 3).

The boundary of an obstacle is represented as a simple closed curve in R^2 of finite length, with two additional restrictions given below. Each obstacle has an *obstructed region*, which for *normal obstacles* is the interior and for a *room wall* is the exterior. This allows us to model navigation inside a closed room. An obstacle is the union of its boundary and its obstructed region.

A *scene* consists of a nonzero finite number of nonintersecting obstacles, a start point S, and a target point T. *Free space*, the set of points that a robot may reach, consists of all points not in the obstructed region of any obstacle. The boundaries of obstacles are in free space. *Open space* consists of all points not contained in obstacles. The boundaries of obstacles are not in open space. S is assumed to be in free space, but T may be in free space (*reachable*) or not (*unreachable.*) We distinguish between two situations: the *indoor setting,* in which the scene may contain a room wall, and the *outdoor setting*, in which there is no room wall and the robot is effectively located on an unbounded plane.

We place two restrictions on obstacles. The first is that any line segment intersects a given obstacle boundary in a finite number of points and segments. The second is that a clockwise (or counterclockwise) traversal of an obstacle boundary consists of a finite number of maximal segments, each of which is of monotonically increasing, monotonically decreasing, or constant distance to the target. These segments intersect only at their endpoints. The points at which distinct segments intersect are *break points*. The number of these segments is the *complexity* of the obstacle. The parameter n is the maximum complexity of any obstacle in the scene; n is not known to the robot but is used in quantifying the performance of our navigation algorithms.

The robot is modeled as a point. The sensing and action capabilities of the robot are precisely defined in section 3. Informally speaking, there are two actions available to the robot: (1) It may travel toward T through open space until it reaches T or hits an obstacle boundary. When the robot hits an obstacle boundary, it learns its distance to T. (2) It may follow an obstacle boundary in clockwise or counterclockwise direction until it reaches T or a break point. At a break point, the robot learns its distance to the target and whether the directions toward and away from T are blocked. If the direction to T is unblocked, the robot may choose action (1) or (2). Otherwise, it may choose action (2) to continue traversing the boundary of the obstacle in either direction.

We consider four general kinds of problems related to navigation; in each, the robot is started at S, executes some sequence of legal actions, and must eventually halt.

- Target reachability. The robot must correctly declare T reachable or not.
- Circumnavigation. S is on the boundary of an obstacle, and the robot is required to visit every point on that boundary.
- General navigation. The robot must halt at T if it is reachable; otherwise it must halt and declare T to be unreachable. Clearly a solution of the general navigation problem also solves the target reachability problem.
- Reachable-target navigation. T is in free space. The robot must halt at T.

We measure the performance of a navigation algorithm by comparing the distance

traveled by the robot to the sum of the perimeters of the obstacles in the scene. In particular, the *excess distance* traveled by a robot in a scene is the length of its path minus the straight-line distance from S to T. The *excess distance ratio* of a navigation algorithm *with respect to a scene* is the ratio of the excess distance traveled by the robot to the sum of the perimeters of the obstacles in the scene. This ratio measures how much the navigation algorithm has to retrace the boundaries of obstacles in the course of getting from S to T.

The *excess distance ratio* of a navigation algorithm is $f(n)$ if, for every n, the supremum over all scenes of complexity n of the excess distance ratios is $f(n)$. Lumelsky and Stepanov give a construction that implies the following result for the distance query model.

THEOREM 1.1 (Lumelsky and Stepanov [4]). *For any deterministic algorithm for reachable-target navigation in the outdoor setting, the excess distance ratio is bounded below by* 1 *for all* $n \geq 4$.

We present the following new results for the distance query model.

1. If T may be unreachable, then no deterministic algorithm can solve either the target reachability, the circumnavigation, or the general navigation problems.

2. There is a deterministic algorithm for reachable-target navigation in the indoor setting with an excess distance ratio of $O(\log n / \log \log n)$.

3. There is a matching lower bound of $\Omega(\log n / \log \log n)$ for a restricted class of deterministic algorithms for reachable-target navigation in the indoor setting.

4. There is a deterministic algorithm for reachable-target navigation in the outdoor setting with an excess distance ratio bounded by 3. (Compare the lower bound of 1 for this problem.) A variant of this algorithm solves the circumnavigation problem in the outdoor setting when the target is reachable.

Our navigation and circumnavigation algorithms for reachable-target navigation can be used in the general case, but they will fail to halt if the target is unreachable. It is interesting to note that our algorithms will still work if the distance queries return not the exact distance to the target, but values that preserve the linear ordering on distances. This is potentially useful in practice, as discussed below.

2. Related results. Previous theoretical research on online robot navigation has progressed in at least two research communities: the online competitive analysis community [1, 2, 6] and the theoretical robotics community [3, 4, 5, 8]. The competitive analysis community has generally considered various restricted types of polygonal obstacles and has measured the performance of a navigation algorithm by the ratio of the distance traveled by a robot using that algorithm to the length of the shortest obstacle-avoiding path from S to T. The theoretical robotics community has considered obstacles of essentially arbitrary shape and measured the performance of a navigation algorithm by the excess distance ratio, defined above. Since our work continues this latter line of research we now briefly sketch the background.

Lumelsky and Stepanov [3, 4] began this line of research, giving navigation algorithms for a robot with local sensors and access to its exact current position. Their algorithm, BUG1, navigates directly toward T in free space until an obstacle boundary is detected. It then follows the obstacle boundary until it circumnavigates the obstacle, keeping track of the minimum distance to T among points on the boundary. When the robot completes the circumnavigation, it follows the boundary back to one of the points at minimum distance to T and resumes navigating directly toward T in free space.

As described, BUG1 achieves an excess distance ratio bounded by 2 for general

navigation in the outdoor setting in Lumelsky and Stepanov's setting. Assuming the additional capability of keeping track of path lengths, a refinement of BUG1 achieves an excess distance ratio bounded by 3/2, by taking the shorter direction on the boundary back to the departure point. Lumelsky and Stepanov also give a lower bound of 1 on the excess distance ratio for deterministic navigation algorithms in their setting, as mentioned above.[1]

Taylor and Kriegman [8], addressing the practical difficulty of determining a robot's exact position, consider a model in which the robot's global sensors can determine only distance and relative bearing to the target.[2] On their experimental mobile robot, RJ, this information is provided by a vision system which tracks the target as the robot moves. The vision system gives quite accurate distance data using known properties of the target, and the error in the answers is not cumulative. The vision system can give a linear ordering of points by distance simply by comparing the size of the target image at each point. The local sensors are implemented primarily with sonar, which gives a localized map of the free space around the robot.

Taylor and Kriegman give an adaptation of Lumelsky and Stepanov's BUG1 algorithm for this setting. Their algorithm, however, requires a subroutine to solve the circumnavigation problem, and they leave open the question of whether such a subroutine can actually be implemented with local sensors and distance queries. Assuming that the subroutine both exists and traverses the boundary of an obstacle exactly once, Taylor and Kriegman show that their algorithm achieves an excess distance ratio of 2 for general navigation in open space. They use the navigation algorithm as a subroutine in an exploration procedure to find all the recognizable targets in the environment.[3]

The existence of a circumnavigation subroutine is crucial to Taylor and Kriegman's version of BUG1. One goal of our paper is to answer some of the open problems implied by their work: Under what conditions do local sensors and distance queries suffice to solve the circumnavigation problem? When they don't suffice, and hence Taylor and Kriegman's algorithm is unusable, is there some other solution to general navigation with distance queries?

We remark that if the robot has an accurate compass in addition to distance data, then exact position can be recovered. Magnetic compasses are subject to distortions inside buildings due to metals in the construction, and inertial compasses are quite expensive. Therefore, the use of compasses is generally considered impractical for indoor navigation. Nevertheless, Lumelsky and Tiwari [5] examined the use of pure directional information, assuming a robot with an on-board compass and relative bearing to the target in addition to local sensors but no distance data. They give a navigation algorithm for this setting with an $\Omega(n)$ excess distance ratio.

3. The distance query model. We propose a model of navigation in the plane in which an obstacle is defined as the interior or exterior of a simple closed path with some mild restrictions. We hope that the model is intuitive, but we also provide a careful theoretical development of its properties because we discovered subtle pitfalls

[1] Their claim that it holds also for randomized algorithms is not proved.

[2] Differential GPS gives (x, y) position without accumulated error. However, Taylor and Kriegman state that indoor differential GPS accuracy is still insufficient for typical robot navigation problems.

[3] Their model also permits some obstacles to obscure the view of the target, so that in certain regions of space no distance data is available. Their navigation algorithm still works in this setting, under additional assumptions about the regions of obscuration. Our algorithms for navigation within a room can also be modified to work in this setting. See section 8 below for further discussion.

and problems in our earlier attempts to formalize the model, particularly in proving Theorems 4.1 and 7.4.

The environment is an infinite 2D plane, R^2. We follow Newman's treatment of the topology of the plane [7]. Recall that S and T denote the start and target positions, respectively. Without loss of generality, we may assume the target T is at the origin. For any two distinct points P and Q in R^2, PQ denotes the line segment connecting P and Q, and $|PQ|$ denotes the distance between P and Q.

DEFINITION 3.1. *A* path *in R^2 is a continuous mapping p of some closed interval $[0, x] \in R^1$ to R^2. A* closed *path is a path such that $p(0) = p(x)$. A* simple closed *path is a closed path that intersects itself only at $p(0) = p(x)$. A simple closed path is also called a Jordan curve.*

It is convenient to use polar coordinates to specify paths, with the origin at the target T and a particular ray from T specified for the measurement of angles. Path p is specified by the pair of functions $(r(t), \theta(t))$, $t \in [0, x]$, where $r(t)$ is the distance of point $p(t)$ from the origin and $\theta(t)$ is its counterclockwise angular displacement in radians from the specified ray. The angular displacement of any point but the origin is unique modulo 2π, but since we wish to assume that $\theta(t)$ is a continuous function of t, we permit $\theta(t)$ to be outside the interval $[0, 2\pi)$. We use the notation $(r_1, \theta_1) \equiv (r_2, \theta_2)$ to indicate that (r_1, θ_1) and (r_2, θ_2) denote the same point in the plane.

3.1. Obstacles and scenes.

DEFINITION 3.2. *An* obstacle boundary *is a simple closed path of finite length $\beta : [0, 1] \to R^2$. (We specify some additional conditions on an obstacle boundary below.) By Jordan's theorem, β divides the plane into two domains, one bounded and the other unbounded (containing a point arbitrarily far from the origin). The bounded region is called the* interior *and the unbounded region is called the* exterior. *Note that Definition* 3.1 *implies a direction on an obstacle boundary, given by increasing t. We will assume that the boundary curve $\beta = (r(t), \theta(t))$ is parameterized so that increasing t corresponds to a counterclockwise traversal of the boundary path.*

DEFINITION 3.3. *An* obstacle *is a region $Ob \subset R^2$ consisting of an obstacle boundary together with an* obstructed region, obs(Ob), *which is either the interior, in the case of a* normal obstacle, *or the exterior, in the case of a* room wall. *P_{Ob} denotes the length of the boundary of Ob.*

Our definition of obstacle precludes holes without loss of generality. In an actual application the boundary may come from a physical object that contains arbitrarily many holes, but since the robot cannot physically reach any part of the region inside the obstacle boundary, it cannot distinguish this from an obstacle without holes.

DEFINITION 3.4. *A* (proper) boundary segment *of an obstacle with boundary $\beta : [0, 1] \to R^2$ is defined to be $\beta([a, b])$ for any nonempty interval $[a, b] \subset [0, 1]$, or $\beta([a, 1]) \cup \beta([0, b])$, where $0 < b < a < 1$.*

DEFINITION 3.5. *Let $\mathcal{O}$ denote a set of nonintersecting obstacles. The* obstructed space *with respect to $\mathcal{O}$ is the union of the obstructed regions of all the obstacles in $\mathcal{O}$. The* free space *with respect to $\mathcal{O}$ is the complement of the obstructed space with respect to $\mathcal{O}$. Free space therefore includes the obstacle boundaries. The* open space *with respect to $\mathcal{O}$ is the complement of $\mathcal{O}$. Open space therefore excludes the obstacle boundaries.*

DEFINITION 3.6. *A* scene *consists of a finite set of nonintersecting obstacles $\mathcal{O}$, a start position S in free space, and a target position T that may be located anywhere, including in the obstructed region of an obstacle. Note that a scene may contain at*

most one room wall.

Restrictions on obstacles. As we have indicated, the boundary of an obstacle is a simple closed curve of finite length with some additional restrictions. Previous papers have generally assumed obstacle boundaries to be piecewise smooth. We instead require the following two conditions, which are primarily intended to keep the boundaries sufficiently well behaved to allow us to speak reasonably of an "algorithm."

1. The intersection between an obstacle boundary and a line segment can be expressed as the union of a finite number of closed intervals. (A point is a closed interval of length zero.)

2. In any scene, each obstacle boundary can be divided into a finite number of maximal segments such that each of them is of monotonically increasing, monotonically decreasing, or constant distance from T. The segments intersect only at their endpoints.

DEFINITION 3.7. *A* local minimum *or* maximum *of distance to T on a boundary segment is a point closest to or furthest from T, respectively, within some small neighborhood of the point.*

DEFINITION 3.8. *Each point where distinct segments of increasing, decreasing, or constant distance intersect is called a* break point. *A break point is a local minimum or maximum, depending on the precise types of intersecting segments.*

DEFINITION 3.9. *The* complexity *of the obstacle is the number of break points on its boundary.*

LEMMA 3.10. *Suppose P and Q are distinct points in an arbitrary scene. The line segment PQ can be partitioned into a finite sequence of maximal intervals, each of which is contained entirely in one of*

1. *the obstructed region of exactly one obstacle,*
2. *the boundary of exactly one obstacle, or*
3. *open space.*

Proof. Let a segment PQ be given. By the conditions on obstacle boundaries the intersection of PQ and each obstacle boundary is the union of a finite number of closed intervals. Since there are finitely many obstacles, and they are pairwise disjoint, the intersection of PQ and all the obstacle boundaries is the union of a finite number of closed intervals. If we consider the endpoints of these intervals in order along the segment from P to Q, the open intervals between two consecutive endpoints must be contained in the boundary of a single obstacle or contained in open space. The lemma follows. □

Note that in the relative topology of the segment PQ, intervals of types (1) and (3) are open, and intervals of type (2) are closed. Hence intervals of types (1) and (3) can be adjacent to only intervals of type (2) and vice versa.

DEFINITION 3.11. *In the sequence of intervals just described, a* boundary crossing *is a triple of intervals of types* (1), (2), *and* (3) *in sequence, or* (3), (2), *and* (1) *in sequence. That is, there is a transition from the obstructed region of an obstacle to open space, or vice versa, crossing the boundary of that obstacle. Note that because of the alternation required, a segment with both ends in obstructed space (or both ends in open space) must have an even number of boundary crossings.*

DEFINITION 3.12. *For points $P \neq Q$, the* PQ-probe *is the subsegment PQ' of PQ, obtained from the partition described above by starting at P and taking the first interval if it is of nonzero length or by taking the union of the first two intervals if the first one is of length zero (that is, just a single point).*

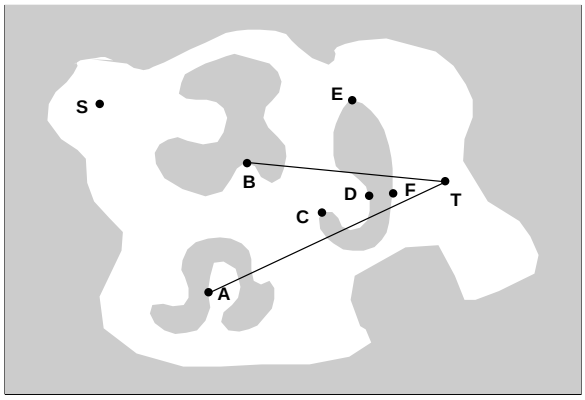

FIG. 3.1. *A scene with a room wall and three normal obstacles. Point A is blocked-away and unblocked-toward. B is both blocked-toward and blocked-away. C, D, E, and F are all break points: C and E are local maxima, D and F are local minima, and F is the closest point of the obstacle to T.*

We note that the PQ-probe is contained either in free space or (except possibly for the point P) in the obstructed region of one obstacle. This is clear if the first interval in sequence from P is of nonzero length; otherwise, the point P must be on the boundary of an obstacle and the following interval is contained either in the obstructed region of that obstacle or in open space. If the PQ-probe is contained in free space, we say it is *free*; otherwise, we say it is *obstructed*. The PQ-probe is thus an idealization of a sensor probe which determines if a robot at point P has an unobstructed path starting in the direction of Q.

DEFINITION 3.13. *A point $P \neq T$ is* unblocked-towards *T if the PT-probe is free. Point P is* blocked-towards *T if the PT-probe is obstructed.*

DEFINITION 3.14. *Let $P \neq T$ and let $Q \neq P$ be any point such that $P \in QT$. P is* unblocked-away *from T if the PQ-probe is free. Point P is* blocked-away *from T if the PQ-probe is obstructed.*

Informally, the robot may move toward the target from a point that is unblocked-towards, and it may move away from the target from a point that is unblocked-away. Although none of our algorithms moves directly away from T, the open space navigation algorithm in section 7 uses the information of whether that direction is blocked or unblocked. Figure 3.1 gives examples of the definitions.

3.2. The robot.

DEFINITION 3.15. *A* robot *is a point-like automaton with the following acting and sensing capabilities:*

1. *move-to-T*(): Move directly along a ray toward T through free space until the robot reaches T or arrives at a point that is blocked-towards. In the latter case, the robot is said to collide with the obstacle. This function returns a ground track entry, defined below.

2. *follow-boundary(DIR)*: Follow the boundary of an obstacle in a clockwise or counterclockwise direction, according to DIR, until the robot reaches T or a break point. DIR is "RIGHT" or "CCW" to indicate a counterclockwise direction and "LEFT" or "CW" to indicate a clockwise traversal. This function returns a ground track entry.

A point at which the robot collides with an obstacle is called a *hitpoint*. By definition, a hitpoint must be blocked-towards. The robot's *ground track* is the sequence of ground track entries generated during its travels. A *ground track entry* contains the following:

1. the distance to the target from the current hitpoint or break point;
2. a field indicating whether the entry was generated by a hitpoint, a local maximum break point; a local minimum break point, or the start point S;
3. a bit indicating whether the point is blocked-towards or unblocked-towards;
4. a bit indicating whether the point is blocked-away or unblocked-away.

Our model is a particular choice of discretization of the control of the robot for navigation tasks. We assume a lower-level reactive control system using the sensors and actuators of the robot that enable it to travel toward the target in free space, to detect the proximity of an obstacle, and to follow the boundary of an obstacle in either direction to a local minimum or maximum of distance to the target. After colliding with an obstacle, the robot can turn right to follow the boundary in a counterclockwise direction or turn left to follow clockwise. Since there may be segments of the boundary of constant distance to the target, we assume that the robot will traverse these to their endpoints (that is, to break points.)

At a hitpoint or break point, the robot receives information about its current situation (summarized as a ground track entry) and decides upon its next action. We assume that the global sensors give distance to the target and also the relative bearing of the target. Combining this with the local sensors, we assume the robot can detect whether the directions straight toward and away from the target are immediately obstructed by obstacles. In the case of Taylor and Kriegman's robot, RJ, the local sensors are implemented by sonar, which in effect gives a localized map of the free space around the robot. Thus, the information we assume to be available in a ground track entry is empirically reasonable.

At the start of an execution, the robot receives an initial ground track entry describing the start point S. Each subsequent ground track entry is associated with a particular point on the boundary of some obstacle in the scene. Multiple (indistinguishable) ground track entries may be associated with the same boundary point. (This happens, for example, if the robot circumnavigates an obstacle twice.)

Specification of the robot's path. Let $rp(k)$ denote the path traveled by the robot up to the kth ground track entry. The path is specified as $rp(k) = (\rho_k(t), \vartheta_k(t))$, $t \in [0,1]$, where $\rho_k(t)$ and $\vartheta_k(t)$ are functions defining the polar coordinates of the points on the robot path. The parameter t is a nondecreasing function of real time, so that as t increases the robot's path is traversed in the forward direction. The actual time taken by the robot and the speed at which the robot travels are irrelevant, since we do not assume that the robot has sensors to measure these quantities.

Path $rp(0)$ consists only of the start point, S. For $k > 0$, path $rp(k-1)$ is a prefix of path $rp(k)$; path $rp(k-1)$ is extended to $rp(k)$ as follows. Let P_{k-1} be the point that generated ground track entry $k-1$. Either $P_{k-1} \equiv S$ or $P_{k-1} \equiv \beta(s)$, where β is the boundary of some obstacle and $s \in [0,1]$. We determine the subpath path, p', followed by the robot from P_{k-1} to the next hitpoint or break point. If there is no such next hitpoint or break point, then the robot does not halt and $rp(k)$ is undefined. Otherwise, path p' is appended to $rp(k-1)$, and the result is reparameterized, giving $rp(k)$. The subpath p depends on the action of the robot after receiving ground track entry $k-1$.

Case 1. The robot executes *follow-boundary(CCW).* Let s' be the minimum value

such that $s \leq s' \leq 1$ and $\beta(s')$ is a break point. Then $p' = \beta([s, s'])$. If there is no such s', then let s' be minimum such that $0 \leq s' \leq s$ and $\beta(s')$ is a break point and let $p' = \beta([s, 1]) \cup \beta([0, s'])$. If there is still no such s', then $rp(k)$ is undefined.

Case 2. The robot executes *follow-boundary(CW)*. Let s' be maximum such that $s \geq s' \geq 0$ and $\beta(s')$ is a break point. Then $p' = \beta([s', s])$. If there is no such s', then let s' be maximum such that $s \leq s' \leq 1$ and $\beta(s')$ is a break point and let $p' = \beta([s', 1]) \cup \beta([0, s])$. If there is still no such s', then $rp(k)$ is undefined. The path p' must be reparameterized so that $p'(0) = \beta(s)$ and $p'(1) = \beta(s')$.

Case 3. The robot executes *move-to-T*(). If the robot is blocked-towards, then $p' = \emptyset$ and $rp(k) = rp(k-1)$. Otherwise, p' is the segment of the inbound ray from P_{k-1} to the next hitpoint reached (or to T if the robot reaches T first).

3.3. Properties of scenes. In this section, some basic properties of scenes are established.

PROPERTY 3.16. *The distance between any two obstacles is positive.*

Proof. This follows because the boundaries of obstacles are nonintersecting closed and bounded sets. □

PROPERTY 3.17. *Other than T, every point is either unblocked-towards or blocked-towards, and every point is either unblocked-away or blocked-away.*

Proof. If $P \neq T$, then the PT-probe is either free or obstructed (see the remark following Definition 3.12). Hence P is either unblocked-towards or blocked-towards but not both. A similar argument applies to the blocked/unblocked-away case. □

PROPERTY 3.18. *Let Ob be an obstacle with boundary β. Either* (a) *all points on β are equidistant from T or* (b) *β contains at least two break points: one at a point at maximum distance from T and one at a point at minimum distance from T.*

Proof. Suppose (a) is false, so that β contains two points P, Q such that $|PT| < |QT|$. Then there are distinct points P' and Q' on β at minimum and maximum distance from T, respectively. Either P' is an endpoint of a maximal segment of monotonically decreasing distance, in which case it is a break point by definition, or it is in the middle of a segment of constant distance, in which case either endpoint of the segment is a break point. A similar argument establishes the existence of a break point at maximum distance from T. □

PROPERTY 3.19. *Let Ob be an obstacle not containing T with boundary β. Any point P on β at minimum distance from T is unblocked-towards.*

Proof. If P is on the boundary of an obstacle Ob, then the PT-probe is contained either in the obstructed region of Ob or in open space. The former is impossible, since otherwise PT must intersect Ob at a point besides P, implying P is not at minimum distance to T. Thus, the PT-probe is free, implying that P is unblocked-towards. □

PROPERTY 3.20. *Let Ob be a normal obstacle with boundary β. Any point P on β at maximum distance from T is unblocked-away.*

Proof. An argument analogous to that for Property 3.19 suffices. □

PROPERTY 3.21. *If the boundary of an obstacle Ob not containing T has a point P that is blocked-towards, then it has a break point.*

Proof. Since P is blocked-towards, the PT-probe, PT', must be contained in the obstructed region of Ob except for P. Hence $T'T$ must intersect the boundary of Ob at a point Q closer to T than P. Hence the boundary of Ob contains two points at different distances from T, and we apply Property 3.18. □

PROPERTY 3.22. *Let Ob be a normal obstacle not containing T. Let P be a break point on the boundary of Ob that is unblocked-towards and a local minimum. Then*

the PT-probe is contained in open space except for the point P.

Proof. Because P is unblocked-towards, the PT-probe is contained in free space and must be either exterior to Ob except for the point P or contained in the boundary of Ob, which means that there are points of the boundary of Ob arbitrarily close to P that are closer to T than P. However, this would contradict the assumption that P is a local minimum of distance to T. □

PROPERTY 3.23. *Let Ob be a normal obstacle not containing T, and let P be a break point on the boundary of Ob that is unblocked-away and a local maximum of distance to T. Let $Q \neq P$ be any point such that P is in the segment QT. Then the PQ-probe is contained in open space except for the point P.*

Proof. The proof is analogous to the proof of Property 3.22. □

4. The limits of distance queries. In this section we show that the circumnavigation, target reachability, and general navigation problems cannot be solved by deterministic algorithms. This shows that distance information is strictly weaker than exact position information, because all these problems can be solved deterministically if exact position information is available [3, 4].

These negative results are derived from a theorem, proved below, which states that there is no deterministic algorithm which will successfully circumnavigate every obstacle that contains the target in its interior. There is one obstacle that defeats every algorithm: a circular obstacle boundary centered on the target. Once a robot hits this obstacle and starts to follow the boundary in any direction, it never encounters a break point, or indeed any point distinguishable from the hitpoint, and so never halts. A similar statement is true for a circular room wall centered on T.

The case of a circle centered at T, however, is uniquely pathological in having no break points; all other obstacle boundaries have at least two break points. One might hypothesize therefore that navigation is possible as long as there are no such pathological obstacles. We will show, however, that even if the obstacles are required to have an arbitrarily large number of break points, any deterministic algorithm will fail on some obstacle.

The intuition behind this result is as follows. Let Ob be some normal obstacle of the desired complexity with T in its interior. Let $\beta = (r(t), \theta(t))$ be the boundary of Ob, $t \in [0, 1]$, where the angle is taken with respect to T, and $\theta(0) = 0$. Let A be a deterministic circumnavigation algorithm, used to control a robot that is started at position $(r(0), \theta(0)) = (x, 0)$. If A fails to circumnavigate Ob, then the desired result is immediate. Suppose A circumnavigates Ob exactly once. Now consider the curve $\beta^* = (r(t), \theta(t)/2)$, which starts at angle 0 and stops at angle π. Since scaling the angle does not affect distance, the curve β^* contains the same sequence of local minima and maxima, at exactly the same distances from T and with exactly the same blocked/unblocked status, as the entire boundary of Ob. Therefore, if the robot is started on β^* at $(r(0), \theta(0)/2) = (x, 0)$, it will see exactly the same sequence of ground track entries and will halt upon reaching point $t = 1$. We can close β^* in any way (in particular, with another copy of β^*) to get an obstacle Ob^* which A will thus fail to circumnavigate.

In general, the robot may go around the obstacle more than once, in one or both directions. This can be dealt with by scaling the obstacle boundary more strenuously and joining several scaled copies of it in a circle around T. Figure 4.1 shows an example spiral-like obstacle and Figure 4.2 shows how six scaled copies of this obstacle are combined. Thus, an algorithm that made five counterclockwise circumnavigations of the obstacle in Figure 4.1 and then halted would not complete a circumnavigation

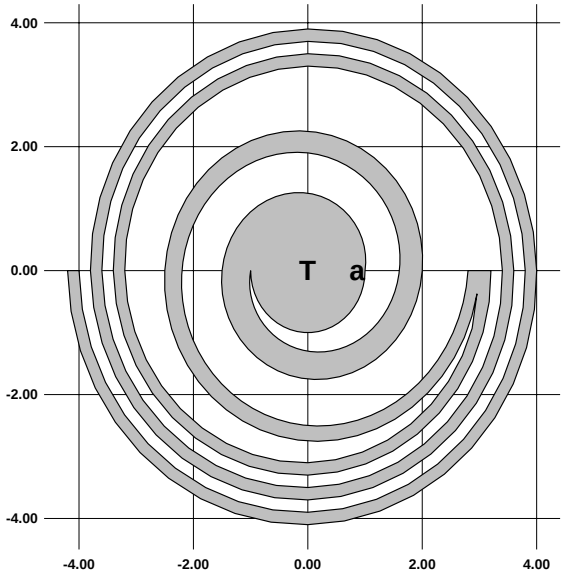

FIG. 4.1. *A spiral-like obstacle Ob. The target T is at* $(0,0)$. *Letting* β *denote the boundary curve,* $a = \beta(0) = \beta(1) = (1,0)$.

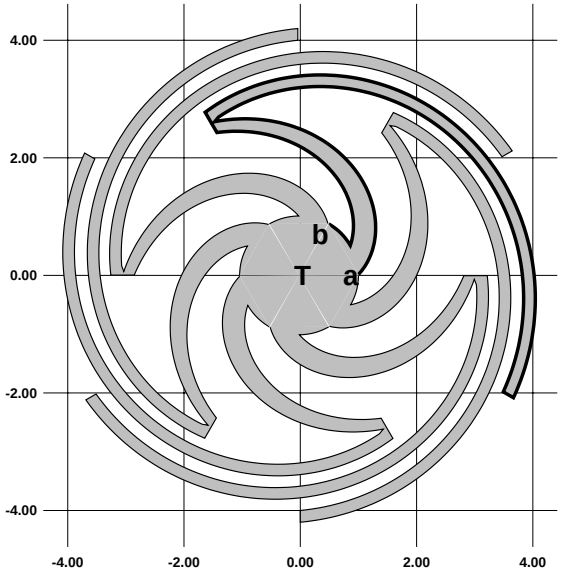

FIG. 4.2. *Obstacle* $Z(Ob, 6)$ *constructed from the obstacle Ob of Figure* 4.1. *(The function Z is defined precisely in the appendix.) The first scaled copy of the original boundary is shown in bold. Letting* β^* *denote this scaled curve, point* $a = \beta^*(0) = (1,0)$ *and* $b = \beta^*(1) = (1, \pi/3)$.

of the obstacle in Figure 4.2. In the appendix to this paper we formalize this transformation and prove the indistinguishability of the robot's ground track on the two obstacles, which leads to a proof of the following result.

THEOREM 4.1. *In the distance query model, if there may exist an obstacle whose interior contains the target (either a normal obstacle with the target in its obstructed region, or a room wall with the target in its complement), then there is no deterministic algorithm for circumnavigation. Furthermore, there are arbitrarily complex obstacles which any given deterministic algorithm fails to circumnavigate.*

COROLLARY 4.2. *In the distance query model, there is no deterministic algorithm for target reachability.*

Proof. We show that any algorithm A that solves target reachability must also solve circumnavigation. Consider an obstacle Ob containing the target T, and suppose we start A at some point on the boundary of T. Suppose A halts and declares T unreachable but does not circumnavigate Ob. Then there is some nonzero segment of the boundary of Ob, no point of which is traversed by A. Consider the obstacle Ob^* in which that segment is replaced by an arbitrarily narrow passage that leads to T. Since A never reaches any point on the segment, its behavior on Ob^* will be the same as on Ob, and in particular it will incorrectly declare the target unreachable. □

5. Target-reachable navigation inside a room. For the remainder of this paper we assume that the target is reachable. If the target is contained in the obstructed region of an obstacle, the algorithms we present will reach that obstacle but will not halt.

In any instance of the navigation problem, the robot alternates between moving toward T in free space and following an obstacle boundary searching for T or a *possible departure point*, that is, an unblocked-towards break point from which it can head back into free space. A point at which the robot heads back into free space is an *actual departure point*. In general, an obstacle may have many possible departure points, and making a good choice of actual departure points is the heart of a navigation algorithm in this setting.

One strategy is to search in a fixed direction for the first possible departure point and leave from there. A simple construction (adapted from Lumelsky and Stepanov) forces this strategy to cycle indefinitely, repeatedly departing from an obstacle and hitting it again. A variant requiring the actual departure point to be a local minimum also cycles.

For example, in Figure 5.1, if the robot starts in the center interior of the U-shaped obstacle, the nearest break points in either direction are the tips of the U. But departing from those points leads the robot right back to the center of the obstacle.

Cycling is prevented if the robot always leaves from a *monotone departure point*, that is, a possible departure point whose distance from T does not exceed the distance from T of the preceding hitpoint. To formalize this, we define the class MONOTONE of navigation algorithms that operate as follows. Initially the robot executes *move-to-T*(). If any action ever returns a ground track entry at distance zero from T, the robot halts, having reached T. Whenever *move-to-T*() returns a hitpoint, the robot uses some sequence of *follow-boundary(DIR)* operations to search the obstacle boundary, either halting at T or choosing some monotone departure point from which to execute *move-to-T*() and leave the obstacle.

LEMMA 5.1. *Regardless of how the actual departure points are chosen, any algorithm from the class MONOTONE reaches T after a finite number of actions.*

Proof. If the robot moves straight to T without colliding with any obstacle, then it reaches T. Suppose the robot collides with some obstacle. If T is not on the boundary, then Properties 3.18 and 3.20 show that there is at least one monotone departure point on the boundary, namely, a break point at the global minimum distance from T. If

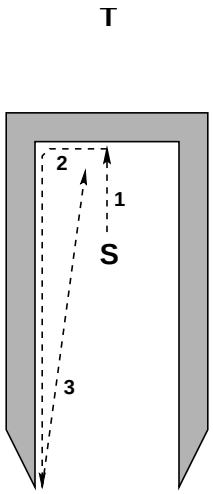

FIG. 5.1. *After hitpoint, turn left or right and leave at the nearest break point. The robot never escapes the cup.*

T is on the boundary, then either there is a monotone departure point or the robot must reach T.

Thus, if the robot never reaches T, it must do so by repeatedly colliding with obstacles that have monotone departure points and departing from them. Let $h_1, d_1, h_2, d_2, \ldots$ be the sequence of distance values of the robot's position at each hitpoint and subsequent actual departure point, ordered by time. By the definition of monotone departure point, $h_i \geq d_i$. On the other hand, by the definition of unblocked-towards, $d_i > h_{i+1}$. Hence the departure point distances form a monotonically decreasing sequence. This implies that the robot can depart from a specific break point at most once. But each obstacle has a finite number of break points, and there are a finite number of obstacles. □

We remark that if the robot starts on the boundary of a room wall consisting of a circle centered at T, then there are no break points, which is why the first action of the algorithm is to move toward T.

Perhaps the simplest algorithm in the class MONOTONE searches the boundary in a fixed direction for the first monotone departure point. The construction in Figure 5.2 shows that this strategy has excess distance ratio $\Omega(n)$.

On the other hand, a very good choice of a departure point is a break point at the global minimum distance to T among all boundary points; this is the choice made by Lumelsky and Stepanov's BUG1 algorithm. If a robot departs from an obstacle at such a point, it will never revisit the obstacle again, since any subsequent departure point is some positive distance closer to the target, and there is no such point on Ob. If the robot could solve the circumnavigation problem, it could guarantee to find and depart from such a point. However, the results of section 4 show that deterministic circumnavigation of a room wall is impossible. Hence the algorithms we develop in this section do not attempt to circumnavigate objects but rather try to limit the number of times an obstacle boundary will be revisited.

5.1. Algorithm 2-REPEATS. We now describe 2-REPEATS, our first navigation algorithm for the indoor setting. Initially the robot executes *move-to-T*().

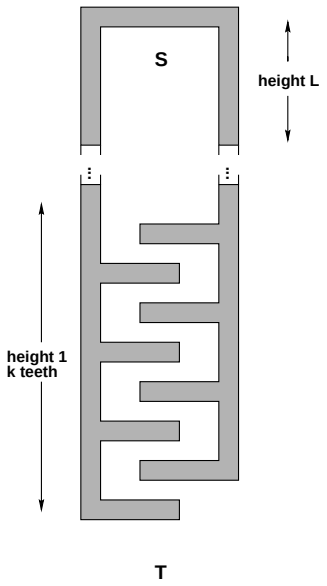

FIG. 5.2. *After each hitpoint, turn left and leave at the nearest monotone break point. (The distance L is $\Omega(k)$.) The robot escapes the comb after traveling completely around the inside of the upper loop $\Omega(k)$ times. The obstacle complexity $n = \Theta(k)$.*

If any action returns a ground track entry indicating that the robot has reached T, it halts. When the robot collides with an obstacle, it turns left and begins traveling clockwise around the boundary, saving its ground track from the hitpoint. If the robot has not already reached T, then as soon as its ground track forms a 2-*repeat departure sequence* the robot leaves the obstacle by executing *move-to-T*().

A 2-repeat departure sequence has the form

$$h\alpha_0 g_0 \alpha_1 g_1 \alpha_2 g_2,$$

where h is the hitpoint, g_i is a ground track entry, α_j is a possibly empty sequence of ground track entries, and $\|\alpha_0\| \leq \|\alpha_1\| = \|\alpha_2\|$, where $\|\alpha\|$ denotes the length of the sequence (number of break points). Each g_i, $0 \leq i \leq 2$, is a ground track entry for an unblocked-towards local minimum which is also the global minimum in the sequence. That is, $|Tg_i| = |Tg_j|$ for all $0 \leq i < j \leq 2$, and $|Tg_i| \leq |TQ|$ for all break points Q in the departure sequence.

LEMMA 5.2. *Let Ob be an obstacle and H any hitpoint at which the robot collides with Ob. As the robot travels clockwise around the boundary, either it will reach T or its ground track will eventually form a 2-departure sequence.*

Proof. By Properties 3.18 and 3.20, the existence of a hitpoint implies the existence of a break point G on the obstacle boundary at minimum distance to T. If the robot travels around the obstacle boundary for sufficiently long, it will either reach T or generate the 2-departure sequence in which $h = H$, $g_i = G$, $h\alpha_0$ is the ground track from H to G, and $\alpha_1 = \alpha_2$ is the ground track given in one complete circumnavigation of *Ob* starting and ending at G. □

Either the robot finds T or it leaves the obstacle from a point no farther from T than the most recent hitpoint. Therefore 2-REPEATS is in the class MONOTONE.

Lemma 5.2 provides some intuition for 2-REPEATS. If the robot sees the same minimum distance twice, then it may well have circumnavigated the obstacle and found the closest point to the target. In this case, the robot will leave and never return to this obstacle. Of course, it may be that a small segment of the boundary, far from the closest point, just happens to contain a departure sequence. The next lemma shows that by looking for the repetition $\alpha_1 g \alpha_2 g$, the robot avoids going over the same ground too many times.

LEMMA 5.3. *Let Ob be an obstacle of complexity n. Any particular break point P on the boundary is traversed $O(\log n)$ times over the total operation of finding a path from S to T.*

Proof. Define an *encounter with obstacle Ob* to be a particular collision with, search around, and departure from Ob by the robot. Since 2-REPEATS is monotone, the robot eventually halts at T (Lemma 5.1), so it encounters Ob a finite number of times. Between each encounter with Ob, the robot may collide with many other obstacles. On the other hand, if Ob is sufficiently complicated, the robot may depart from one point of Ob only to immediately collide with another arm of Ob.

Let $E_1, E_2, \ldots, E_k$ be the subsequence of encounters in which break point P is traversed. If it is traversed more than once in an encounter, then Ob has been circumnavigated, and, as remarked above, the robot will never collide with Ob again. Therefore, in encounter E_i, $i < k$, P is traversed exactly once. In the last encounter, E_k, P is traversed $O(1)$ times: at most three times if E_k circumnavigates Ob, or once otherwise. Hence P is traversed $O(k)$ times. We now bound k.

Let D_i denote the segment of the boundary that is traversed during E_i, and let n_i be the number of break points in D_i. In all encounters but the last there is a one-to-one correspondence between ground track entries in the departure sequence and break points of D_i, so we will not distinguish between them.

CLAIM 5.4. *For any i, j such that $j < i$, D_j contains none of the points h_i or $g_{i\ell}$, $0 \le \ell \le 2$.*

To verify this claim, observe that at each encounter, the hitpoint is strictly closer to T than the preceding departure point, so $|h_i T| < |g_{j2} T|$. Since $|g_{i\ell} T| \le h_i T$, and g_{j2} is the point at minimum distance in D_j, none of the specified points can be in D_j.

Since D_j and D_i both contain P, D_j intersects D_i. Claim 5.4 implies that D_j is entirely contained in one of the three subsegments of D_i lying between h_i, g_{i0}, g_{i2}, and g_{i3}, respectively. Therefore all the break points in D_j must be a subset of the break points in exactly one of α_{i0}, α_{i1}, or α_{i2}. Hence $n_j \le \|\alpha_{i1}\|$. Since $2\|\alpha_{i1}\| \le n_i$, we conclude $2n_j \le n_i$.

Since $n_1 = 2$ and $n_i < n$ for all i, it follows that $k = O(\log n)$. ∎

Each point on the boundary of an obstacle either is a break point or will be traversed at most as many times as the first break point in the clockwise direction. We have the following theorem.

THEOREM 5.5. *Let $\mathcal{O}$ be the set of obstacles with a point at distance at most $|ST|$ from T. Let P_{Ob} be the length of the boundary of $Ob \in \mathcal{O}$ and n_{Ob} be its complexity. The length of the path generated by 2-REPEATS is bounded by*

$$|ST| + \sum_{Ob \in \mathcal{O}} O(P_{Ob} \log n_{Ob}). \tag{5.1}$$

Thus, the excess distance ratio of 2-REPEATS is $O(\log n)$, where n is the maximum complexity of any obstacle in $\mathcal{O}$.

5.2. An improved worst-case bound. We can generalize the above algorithm by making the robot repeat the sequence αg more than twice in the departure sequence. This makes the robot search farther in hopes of finding a better departure point. On the other hand, if the robot finds the closest point right away, then all the remaining repetitions are just a waste of time.

A *q-repeat* departure sequence is a sequence of the form

$$h\alpha_0 g_0 \alpha_1 g_1 \dots \alpha_q g_q$$

such that $\|\alpha_{i-1}\| = \|\alpha_i\|$ for $2 \le i \le q$ and g_i is a global minimum in the sequence. Lemma 5.2 can be easily extended to q-departure sequences, for any q, since the robot can generate such a departure sequence by going entirely around an obstacle q times. The containment property established by Claim 5.4 still holds, and for any constant q, we can extend Lemma 5.3 to show that a boundary point is traversed $O(\log_q n)$ times.

To decrease the asymptotic bound we further require departure sequences to satisfy either the conditions

$$\|\alpha_1\| < 4 \quad \text{and} \quad q = 2$$

or the conditions

$$\|\alpha_1\| \ge 4 \quad \text{and} \quad q = \left\lceil \frac{\log \|\alpha_1\|}{\log\log \|\alpha_1\|} \right\rceil.$$

We call the navigation algorithm using departure sequences of this form MORE-REPEATS.

THEOREM 5.6. *Using the algorithm MORE-REPEATS, the length of the path generated by the robot is bounded by*

$$|ST| + \sum_{Ob \in \mathcal{O}} O(P_{Ob} \log n_{Ob} / \log\log n_{Ob}), \tag{5.2}$$

where $\mathcal{O}$, P_{Ob}, and n_{Ob} are defined as in Theorem 5.5.

Proof. Consider a particular break point P on an obstacle Ob of complexity n. Suppose P is traversed in a sequence of encounters $E_1, \dots, E_k$. Our goal is to bound the length of the sequence, k, since for $j < k$ each boundary point is traversed exactly once and in encounter k the obstacle is circumnavigated $O(\log n / \log\log n)$ times. For convenience we assume $n \ge 4$. Otherwise each break point is visited $O(1)$ times.

We use the definitions of D_i and n_i from the proof of Lemma 5.3. Claim 5.4 from that proof can be extended to any value of q. We can therefore conclude that $n_{i-1} \le \|\alpha_{i1}\| < n_i$ for $i > 1$.

To bound k, we first bound the number of encounters E_i in which $n_i \le n^{1/\log\log n}$. Let k' be maximal such that $n_{k'} \le n^{1/\log\log n}$. Since $n_i \ge 2\|\alpha_{i1}\|$ by either condition, we have $2n_{i-1} \le n_i$ for $1 < i$. Also, $n_1 = 2$. Therefore $n_i \ge 2^i$, and $n_{k'} \le n^{1/\log\log n}$ implies $k' < \log n / \log\log n$.

Now we bound the number of encounters E_i when $i > k' + 1$. For any $i > k' + 1$, the number of repetitions q satisfies

$$q \ge (\log \|\alpha_{i1}\|)/(\log\log \|\alpha_{i1}\|)$$

and

$$\|\alpha_{i1}\| \ge n_{i-1} \ge n_{k'} \ge n^{1/\log\log n},$$

which imply that

$$q \geq (\log n)/(\log\log n)^2.$$

By construction, $n_i \geq q n_{i-1}$, and thus

$$\begin{aligned} n_i &\geq n_{i-1} \frac{\log n}{(\log\log n)^2} \\ &\geq \left(\frac{\log n}{(\log\log n)^2}\right)^{i-k'}. \end{aligned}$$

Since $n_k \leq n$

$$n \geq (\log n/(\log\log n)^2)^{k-k'},$$

which implies

$$k - k' = O(\log n/\log\log n). \qquad \square$$

Thus, the excess distance ratio of MORE-REPEATS is $O(\log n/\log\log n)$, where n is the maximum complexity of any obstacle in $\mathcal{O}$.

6. Lower bounds in the indoor setting. In the previous section we defined the class MONOTONE, containing navigation algorithms that always depart an obstacle from a point no farther from the target than the hitpoint. We now define another class of navigation algorithms, ONE-WAY. A one-way navigation algorithm chooses a fixed direction (clockwise or counterclockwise) for the robot to travel around obstacle boundaries. Upon hitting an obstacle, the robot always travels around the obstacle in that direction and never reverses its direction of traversal. We allow a one-way algorithm to use any possible departure point, and therefore MONOTONE and ONE-WAY are incomparable classes.

The navigation algorithms in this paper all belong to the intersection of MONOTONE and ONE-WAY. We now show that the excess distance used by MORE-REPEATS is optimal among deterministic algorithms in the union of MONOTONE and ONE-WAY.

THEOREM 6.1. *Each deterministic ONE-WAY algorithm for target-reachable navigation in the indoor setting has an excess distance ratio of* $\Omega(\log n/\log\log n)$.

Proof. Let A be a deterministic ONE-WAY navigation algorithm for the indoor setting. We assume that it directs the robot to travel CCW (i.e., turn right) around any obstacle; the CW case is analogous. Let n be a sufficiently large positive integer. We construct a room wall of complexity at most n on which the excess distance traveled by A is $\Omega(\log n/\log\log n)$ times the perimeter of the obstacle. Let $k = \log n/c_1 \log\log n$, where the constant $c_1 > 1$ is chosen to make k an integer and will be determined later.

The overall plan is shown in Figure 6.1. T is placed at the origin, and a room wall is constructed. Most of the wall is a circular arc of radius 1. The shaded region contains a fractal-like boundary segment.

To fill the shaded region, we recursively construct an open path parameterized from $t = 0$ starting at the left side, called the *entry point*, to $t = 1$ at the right side called the *exit point*. The entry and exit points of the path will be at distance 1 from T. To complete the room wall, the open path is closed by an arc of radius

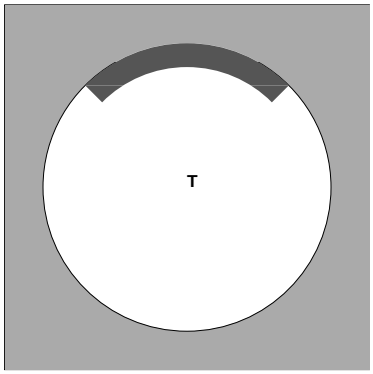

FIG. 6.1. *The structure of the obstacle for the lower bound proofs. The dark shaded region will contain a complex boundary segment spliced into a circular wall centered on T.*

1 centered on T, connecting the exit to the entry. The path is constructed so that vertical segments have very small dimension, and horizontal segments have either very small dimension or dimension slightly greater than 1.

For simplicity, we describe, picture, and analyze our constructions in a Cartesian coordinate system and then consider the effect of transforming them to our actual setting. In Cartesian coordinates, the path will consist of axis-parallel horizontal and vertical segments. Horizontal segments represent arcs of circles centered at T, and vertical segments represent segments of rays from T. We use a rectangle of width w and height h to represent a portion of an annulus between a circle of radius 1 and a circle of radius $1-h$, with outer arc length w and inner arc length $(1-h)w$. Then a boundary of path length L in the rectangle represents a boundary of path length L' in the portion of the annulus, where

$$(1-h)L \leq L' \leq L.$$

The basic structure used is a hook-shaped piece of room wall boundary, as indicated in Figure 6.2. This structure is called a *simple hook*. The L-shaped portion of the boundary is called the *arm* of the hook, and the boundary segment shown in bold is called the *recursive region* of the hook.

If we assume that the boundary corresponding to the recursive region of a hook has been defined, with its entry and exit points, we go on to define the remaining boundary of the hook as follows. Let $\epsilon = 1/k^{2k}$. The entry point of the hook is ϵ to the left of the left edge of the arm, and the exit point of the hook is aligned with the right edge of the arm. The arm itself has width ϵ and extends ϵ to the right of the exit point of the recursive region. It also clears the lowest point of the recursive region by ϵ. This is indicated schematically in Figure 6.2.

We define long and short hooks at level i (H_i^L and H_i^S) and long and short hook sequences at level i (B_i^L and B_i^S) as follows. The recursive region of H_1^L is a horizontal segment of length 1; the recursive region of H_1^S is a horizontal segment of length 0. Once H_i^L and H_i^S are defined, B_i^L consists of one level i long hook (H_i^L) followed by $k-1$ level i short hooks (H_i^S), while B_i^S consists of k consecutive level i short hooks (H_i^S). Finally, once long and short hook sequences at level i are defined, we define level $i+1$ long and short hooks as follows. H_{i+1}^L has B_i^L in its recursive region, and

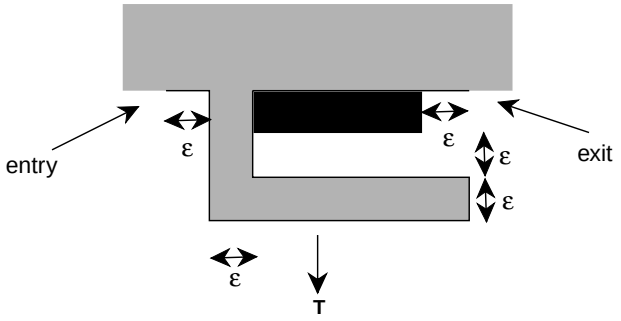

FIG. 6.2. *The basic hook shape. The recursive region is contained in the dark rectangle.*

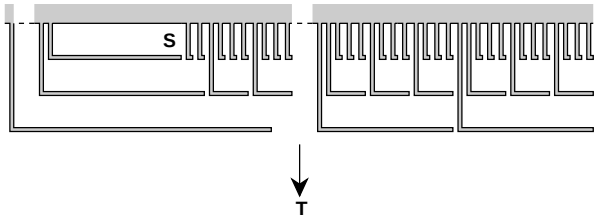

FIG. 6.3. *Constructing B_3^L (with $k = 3$). B_2^L is the recursive region of the long hook H_3^L, and two copies of the short hook H_3^S are added on the right.*

H_{i+1}^S has B_i^S in its recursive region. Figure 6.3 gives an example of the construction of a long hook sequence at level 3 (assuming $k = 3$.)

The intuition behind the construction is as follows. The robot cannot differentiate between traversing a long hook at a given level and traversing a short hook of the same level, since both yield the same ground track. If the robot ever traverses the boundary of a long hook followed by all $k - 1$ short hooks at the same level, then replacing the short hooks by a circular arc makes the robot repeat the boundary of the long hook k times. On the other hand, if the robot always takes off toward T after traversing the long hook on a level (for example, leaving from the bottom of one of the short hooks), then at each level i the long hook will be traversed $k-i+1$ times because of the recursive construction, thus also resulting in a path that is $\Omega(k)$ times as long as the obstacle's perimeter.

Define the *width* of a hook or hook sequence to be the minimum width of an axis-parallel rectangle containing it, and similarly define *height*. Let $W(i, S)$ and $W(i, L)$ denote the width of H_i^S and H_i^L, respectively. Let $ht(i)$ denote the height of both H_i^S and H_i^L. These functions satisfy the following recurrences:

$$
\begin{aligned}
W(1, S) &= 3\epsilon, \\
W(i, S) &= 3\epsilon + k \cdot W(i-1, S), \quad i > 1, \\
W(1, L) &= 1 + 3\epsilon, \\
W(i, L) &= 3\epsilon + W(i-1, L) + (k-1)W(i-1, S), \quad i > 1, \\
ht(1) &= 2\epsilon,
\end{aligned}
$$

$$ht(i) = ht(i-1) + 2\epsilon, \quad i > 1.$$

Using these recurrences, it follows that $W(i,S) = \Theta(\epsilon k^{i-1})$, $W(i,L) = 1 + \Theta(\epsilon k^{i-1})$, and $ht(i) = 2i\epsilon$.

Next we consider the path lengths of the boundary segments. Recall that $W(i,L)$ is the width of hook H_i^L. The path length of the arm H_i^L is $2W(i,L)+2ht(i)-\epsilon$. Since $\epsilon = 1/k^{2k}$ and $ht(i) = \Theta(i\epsilon)$, the contribution of the arm to the path length of H_i^L is $\Theta(W(i,L))$ for $i \le k$. A similar statement holds for H_i^S. Let $P(i,L)$ and $P(i,S)$ denote the total length of H_i^L and H_i^S, respectively. According to our discussion, these path lengths satisfy the following recurrences:

$$\begin{aligned}
&P(0,S) = 0,\\
&P(i,S) = \Theta(W(i,S)) + kP(i-1,S), \quad i > 0,\\
&P(0,L) = 1,\\
&P(i,L) = \Theta(W(i,L)) + (k-1)P(i-1,S) + P(i-1,L), \quad i > 0.
\end{aligned}$$

Together with the formulas for $W(i,S)$ and $W(i,L)$, these recurrences imply $P(i,S) = \Theta(\epsilon i k^{i-1})$ and $P(i,L) = \Theta(i + \epsilon i k^{i-1})$.

Now we consider the transformation from the Cartesian obstacles to the actual obstacles composed of arcs of circles centered at T and segments of rays to T. At the risk of slight confusion, we will use the same names, H_i^S, H_i^L, and so on, for the transformed obstacles. Then $ht(i) = 2i\epsilon$ is equal to 1 minus the minimum distance to T at any point on the boundary of H_i^L or H_i^S. Let $P'(i,L)$ denote the path length of the transformed boundary H_i^L. By our previous remarks,

$$P'(i,L) \ge (1 - 2i\epsilon)P(i,L).$$

Finally, consider the complexity of H_i, denoted $C(i)$. A single H_i consists of $O(1)$ new boundary segments plus the number of segments in the recursive region. Hence $C(i)$ satisfies

$$\begin{aligned}
&C(1) = \Theta(1),\\
&C(i) = \Theta(1) + kC(i-1).
\end{aligned}$$

This implies $C(i) = \Theta(k^{i-1})$.

It can be verified by induction on the level that H_i^L contains exactly one long hook and one long hook sequence at each of the levels $1 \ldots i$ and that H_j^L (respectively, B_j^L) is the leftmost hook (respectively, hook sequence) of level $j \le i$. It can also be verified by induction that if the robot executes *move-to-T*() from some point in the recursive region of H_i it will hit a point that belongs to the boundary of H_i and lies clockwise from the departure point.

The bad obstacle will be constructed from H_i^L, for some $i \le k$, together with the circular arc around T that closes the path. To choose the value of i, consider the actions of a robot using some algorithm A to navigate out of the obstacle H_k^L. The robot is started inside the level 1 long hook, shown as S in Figure 6.4.

The robot's motion can be divided into phases that correspond to the levels of the obstacle. Assume that at the start of phase i, $i < k$, the robot executes *move-to-T*() from a point s that is unblocked-towards and such that the first obstacle the robot will hit is the arm of the single long level i hook, H_i^L. This assumption holds true in phase 1, when the robot is started at point S.

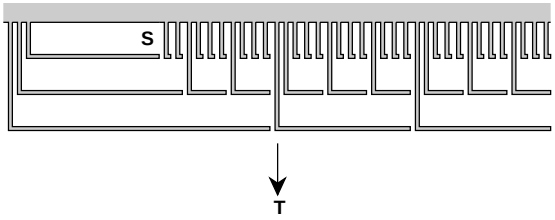

FIG. 6.4. *The result of the construction in Figure* 6.3.

Upon hitting the hook of H_i^L, the robot must turn right (recall the assumption of CCW traversal) and follow the boundary. Eventually, it must make its way through the recursive region and reach the exit point of H_i^L. Otherwise, it can never reach the target, because the arm of H_i^L intersects all rays from the target to points in the recursive region. (We say the hook *blocks* the target from these points.)

After reaching the exit of H_i^L, the robot may continue on through the subsequent copies of H_i^S that make up the hook sequence B_i^L. Either it passes through all k copies and reaches the exit of B_i^L, or it departs from a point that is not blocked from the target by any portion of the boundary making up B_i^L, for example, the bottom of some short hook.

If the robot passes through all k copies, then we choose H_i^L to be the obstacle. Observe that the robot cannot distinguish the ground track given by passing through each successive copy of H_i^S from the ground track formed by going completely around the circular arc from exit to entry and then through the single copy of H_i^L. Hence the robot will circumnavigate the obstacle boundary k times, giving an excess distance ratio $\Theta(k)$.

If the robot departs from a point on B_i^L that is not blocked from the target by any other point on that boundary, then at that time the robot satisfies the assumptions for the start of phase $i+1$. Now suppose that the robot completes k phases, in each phase departing before visiting all k copies. We choose the bad obstacle to be H_k^L. We show that in this case, the total distance traveled by the robot is $\Omega(k^2)$.

CLAIM 6.2. *The distance traveled by the robot in phase i is at least $P'(i, L)$.*

Proof. The robot must at least move from the starting point of phase i to the exit of H_i^L by executing some sequence consisting of *follow-boundary(RIGHT)* operations and *move-to-T*() operations. Since any *move-to-T*() will put the robot at a point clockwise (left) of the departure point, and hence farther from the exit than the departure point, omitting all *move-to-T*() operations only decreases the total distance traveled. But a sequence of *follow-boundary(RIGHT)* operations will still traverse all points on the path between the starting point and the exit.

Using Claim 6.2, the total distance traveled over all phases is at least

$$\sum_{i=1}^{k-1} P'(i, L) \geq (1 - 2k\epsilon) \sum_{i=1}^{k-1} P(i, L) = \Omega((1 - 2k\epsilon)(k^2 + k^{k+1}\epsilon)).$$

Since $\epsilon = 1/k^{2k}$, the ratio of distance traveled to the length of the perimeter of the obstacle, $O(k + \epsilon k^k)$, is $\Omega(k)$.

The maximum value of k is determined by the maximum allowed complexity of the obstacle, n. Since $C(k) = \Theta(k^{k-1})$, any obstacle which satisfies $k^{k-1} \leq n$ is

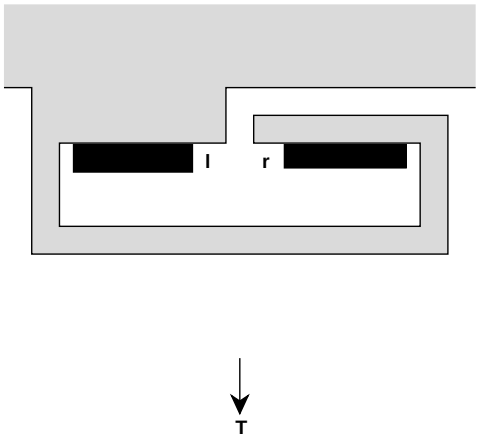

FIG. 6.5. *A simple corral, with left and right exit points and recursive regions shown in bold.*

feasible, and in particular we may choose $c_1 > 1$ and $k = \log n / c_1 \log\log n$. The theorem follows. □

Using a somewhat more complex construction, we prove a similar lower bound on the excess distance used by any deterministic MONOTONE algorithm for reachable-target navigation in a room.

THEOREM 6.3. *Any deterministic MONOTONE algorithm for reachable-target navigation in the indoor setting has an excess distance ratio of* $\Omega(\log n / \log n \log n)$.

Proof. Let A be a deterministic MONOTONE navigation algorithm for the indoor setting. Recall that algorithm A has a property such that upon hitting an obstacle it follows the obstacle boundary, changing direction at any break point. However, it will never leave from a point that is farther from the target than its hitpoint on the obstacle. Let n be a sufficiently large positive integer. We construct a room wall of complexity at most n on which the excess distance traveled by A is $\Omega(\log n / \log\log n)$ times the perimeter of the obstacle. Let $k = \log n / c_1 \log\log n$, where $c_1 > 1$ is a constant chosen to make k an integer, which will be determined later.

As in the proof of Theorem 6.1, we specify our construction using Cartesian coordinates and then transform the boundary so that the top edge lies on the arc of a circle of radius 1 centered at T and is closed using the rest of the circle to form a room wall obstacle. The basic structure we use is a U-shaped piece of room wall boundary, as indicated in Figure 6.5, and referred to henceforth as a *simple corral*. A simple corral has two exits, marked l and r, and two recursive regions, shown in bold.

We first describe the construction of short corrals and short corral sequences. Let $\epsilon = 1/k^{\beta k}$, where $\beta > 0$ is a constant to be determined below. As in the preceding proof, widths and clearances are taken to be size ϵ in the construction of short and long corrals. A level 1 short corral, C_1^S, is a simple corral in which the recursive regions are horizontal segments of length 0. A level i short corral sequence, B_i^S, consists of $2k+1$ copies of C_i^S connected end to end. For $i > 1$, a level i short corral, C_i^S, is constructed from a simple corral by replacing both the left and right recursive regions with B_{i-1}^S. Figure 6.6 gives an example of the construction of a level 3 short corral for $k = 1$. If $W(i, S)$ denotes the width of a level i short corral, then we have

$$W(1, S) = 9\epsilon,$$

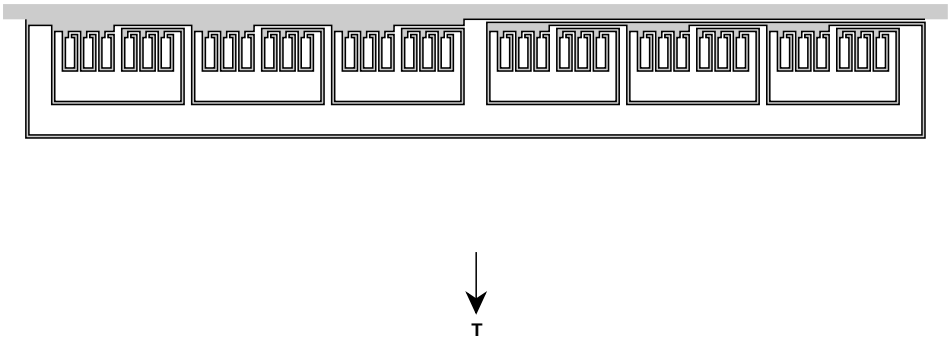

FIG. 6.6. *A level* 3 *short corral.*

and for $i > 1$,

$$W(i, S) = 9\epsilon + 2(2k + 1)W(i - 1, S).$$

The solution to the recurrence is

$$W(i, S) = 9\epsilon((4k + 2)^i - 1)/(4k + 1)) = \Theta(\epsilon(4k + 2)^{i-1}).$$

We also define long corrals and long corral sequences. For level i, there are 2^i possible different long corrals; which one we use at each level in the final construction will depend on the behavior of the algorithm A. A level 1 long corral is a simple corral in which the one of the two recursive regions is a horizontal segment of length 1, and the other is a horizontal segment of length 0. A level i long corral sequence consists of a sequence of k level i short corrals, followed by one level i long corral, followed by k more level i short corrals. For $i > 1$, a level i long corral is constructed from a simple corral by replacing one recursive region by a level i long corral sequence and the other recursive region by a level i short corral sequence. The width of a level i long corral is exactly one more than the width of a level i short corral, that is, $1 + \Theta(\epsilon(4k + 2)^{i-1})$.

To specify the final obstacle, we consider the motion of the robot in a bottom-up fashion with respect to the transformed boundaries in which horizontal segments represent arcs of circles centered at T, and vertical segments represent segments of rays from T. As before, we use the same names for the transformed constructions, C_i^S, C_i^L, and so on. As in the proof of Theorem 6.1 we divide the robot's motion into phases. The robot begins phase 1 inside one of the two possible level 1 long corral sequences, where the level 1 long corral has its long arc in the left recursive region if the robot first leaves the corral at the left exit, and in the right recursive region otherwise. The starting point S is shown in Figure 6.7; in this example, the robot exits the level 1 long corral at the left exit.

Assume that at the start of phase i, $1 < i < k$, we have constructed a path consisting of a particular level $(i - 1)$ long corral sequence, B_{i-1}^L, and the choice of long and short corrals is completely specified within the path. Assume also that the robot has just executed *move-to-T*() from some point s on one of the bottom segments of B_{i-1}^L and that this is the first action the robot has taken so far that would result in it reaching a point not on B_{i-1}^L.

Consider the level i long corral C_l given by embedding B_{i-1}^L into the left recursive region of a simple corral and embedding a copy of B_{i-1}^S into the right region. To

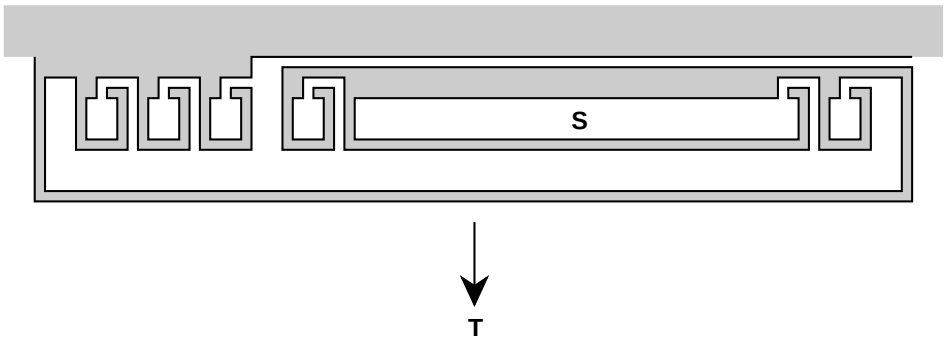

FIG. 6.7. *A level* 2 *long corral with a level* 1 *long corral in its right recursive region. The level* 1 *long corral has a long arc in its left recursive region.*

escape the corral in phase i, the robot must eventually reach one of two exit points, l or r. Since it is MONOTONE, the robot must eventually traverse every point on the boundary between the hitpoint and whichever exit it reaches. (This property is not true of a ONE-WAY algorithm on this boundary.)

If the robot reaches the left exit, then we have guaranteed that the robot retraces all of B_{i-1}^L during phase i. Suppose it only reaches the right exit, r. Then consider the level i long corral C_r given by embedding B_{i-1}^L into the *right* recursive region of a simple corral and embedding a copy of B_{i-1}^S into the left region. Since the robot has not ventured outside of B_{i-1}^L prior to the start of phase i, its behavior up until the start of phase i is the same regardless of whether it starts in C_l or C_r. Furthermore, the robot's behavior between the start of phase i and its reaching r must also be the same whether it is started in C_l or C_r. This follows from two observations: first, the initial hitpoint is on a segment of constant distance, and so the robot cannot tell from which side it departed at the start of phase i; second, the ground track given by traversing the recursive region is the same whether the region is long or short. Hence on obstacle C_r the robot still reaches the right exit and so retraces all of B_{i-1}^L during phase i. We set C_i^L to be whichever of C_r or C_l is chosen. In Figure 6.7 we show an example in which the phase 1 choice is the left exit and the phase 2 choice is the right exit.

Having chosen a particular level i long corral C_i^L, we use it to construct the long corral sequence B_i^L by adding k copies of C_i^S to both sides of C_i^L. Consider the behavior of the robot on B_i^L. The robot executes some sequence σ of *follow-boundary(LEFT)* and *follow-boundary(RIGHT)* instructions. It ends with a *follow-boundary(·)* instruction that will take it beyond one of the ends of the boundary path, or it executes *move-to-T*() from the bottom of one of the level i corrals.

Suppose the robot executes a *follow-boundary(·)* instruction that will take it past the left (respectively, right) end of B_i^L. Then the robot must have traveled at least once through each of the k level i short corrals between C_i^L and the left (right) end of B_i^L. We choose the final obstacle Ob to be just C_i^L, extended to wrap entirely around the target. The robot cannot distinguish the ground track observed while executing instruction sequence σ on this obstacle from the ground track observed on while executing σ on B_i^L. Since σ includes k traversals of level i corrals, the robot

must make k traversals of the boundary of obstacle Ob, giving an excess distance ratio of $\Omega(\log n/\log logn)$.

On the other hand, suppose the robot executes *move-to-T*() before exiting from B_i^L. At this point, phase i ends and phase $i+1$ starts. Note that the assumptions for the start of a phase are satisfied. If the robot completes k phases, let the final obstacle Ob be the long corral C_k^L that is constructed in phase k, with an arc joining the exit point to the entry point. Let $P(i,L)$ denote the path length of the Cartesian boundary C_i^L. For this quantity we can show $P(i,L) = \Theta(i+(4k+2)^{i-1}\epsilon)$. If $P'(i,L)$ is the path length of the transformed boundary C_i^L, then we have

$$(1-3i\epsilon)P(i,L) \le P'(i,L) \le P(i,L).$$

We can choose $\epsilon = 1/k^{\beta k}$ small enough that $P'(i,L) = \Theta(i)$. As shown above, the obstacle is constructed so that in phase i the robot retraces the whole path C_{i-1}^L. Hence the total distance traveled by the robot is $\Omega(k^2)$, and the excess distance ratio is $\Omega(k) = \Omega(\log n/\log\log n)$. The maximum value of k is determined by the maximum allowed complexity of the obstacle, n. The complexity of a level i corral, denoted $C(i)$, is described by a recurrence analogous to that in the proof of Theorem 6.1 and can be seen to be $\Theta(k^{\alpha k})$ for a small constant α. Hence $C(i) \le n$ for an appropriate choice of c_1 in the equation $k = \log n/c_1 \log\log n$. □

7. Navigation and circumnavigation in the outdoor setting. In this section we present an algorithm, FAR-NEAR, for reachable-target navigation in the outdoor setting. FAR-NEAR has an excess distance ratio bounded by 3. A variant of FAR-NEAR performs circumnavigation in the reachable-target outdoor setting, traveling around the obstacle boundary at most two times.

7.1. The FAR-NEAR algorithm. The robot starts by moving toward T. If any action brings it to T, it halts, having reached T. When the robot collides with obstacle Ob, it searches left until it reaches T or until its ground track forms a *circumnavigating departure sequence.*

A circumnavigating departure sequence has the form

$$h\alpha_0 Q_1 \alpha_1 P_1 \alpha_2 Q_2 \alpha_3 P_2,$$

where P_1 and P_2 are unblocked-towards break points of minimum distance and Q_1 and Q_2 are unblocked-away break points of maximum distance, where maximum and minimum are taken over all break points in the sequence.[4] The robot departs from P_2.

LEMMA 7.1. *Suppose the robot collides with normal obstacle Ob at hitpoint h. Traveling clockwise from h, either the robot will reach T or its ground track will eventually form a circumnavigating departure sequence.*

Proof. If T is on the boundary of Ob, then the robot will reach T by the time it has circumnavigated Ob from h. If T is not on the boundary of Ob, then Properties 3.18, 3.19, and 3.20 of section 3 imply the existence of points P, Q such that P is a break point on the boundary at minimum distance to T and Q is a break point at maximum distance to T. Starting at P, two circumnavigations of the boundary of Ob give the desired ground track. (The lemma is not true if the obstacle is a room wall.) □

Thus, the algorithm FAR-NEAR is in the class MONOTONE. The next lemma shows that if the robot encounters a departure sequence of the above form, it has completely circumnavigated the obstacle boundary.

[4] Thus perhaps the algorithm should be called FAR-NEAR-FAR-NEAR.

LEMMA 7.2. *Let Ob be a normal obstacle with boundary β. In any proper subsegment s of β there is no sequence of distinct points P_1, Q_1, P_2, Q_2 (or Q_1, P_1, Q_2, P_2) in order, such that P_1 and P_2 are unblocked-towards and of minimum distance (within s) to T, and Q_1 and Q_2 are unblocked-away and of maximum distance (within s) to T.*

Proof. Without loss of generality we may assume $T \notin Ob$. To see this, suppose there is a counterexample to the lemma consisting of an obstacle Ob containing T and a proper subsegment s of its boundary with the required properties. By rerouting the boundary of Ob, we can construct an obstacle Ob' such that $T \notin Ob'$ and Ob' and s also constitute a counterexample to the lemma. If T is in the interior of Ob, we take a segment of the boundary of Ob disjoint from s and cut a narrow channel from there into the interior of Ob that includes T, so that $T \notin Ob$. If T is on the boundary of Ob, then T is not in s (otherwise, $P_1 = P_2 = T$, contradicting the distinctness of P_1 and P_2) and we slightly reroute the boundary of Ob near T to ensure $T \notin Ob'$. Because the points in s are unaffected by the rerouting in either case, Ob' and s give a counterexample to the lemma in which $T \notin Ob'$. Thus, we assume $T \notin Ob$ for the remainder of the proof.

The proof is by contradiction. Consider a scene containing only the given obstacle and suppose there is a proper subsegment s of the boundary of the obstacle that starts with point P_1, contains point Q_1, then point P_2, and ends with point Q_2, where P_1 and P_2 are unblocked-towards and of minimum distance to T among points of s and Q_1 and Q_2 are unblocked-away and of maximum distance to T among points of s.

Let s_{11} denote the segment of s from P_1 to Q_1, let s_{12} denote the segment of s from Q_1 to P_2, and let s_{22} denote the segment of s from P_2 to Q_2. Also, let s' denote the rest of the boundary, that is, the segment from Q_2 back to P_1.

We define three circles centered at T: C_{ex}, which completely contains the obstacle in its interior; C_{max}, which contains the points Q_1 and Q_2; and C_{min}, which contains the points P_1 and P_2 (see Figure 7.1.) We now argue that Q_2 must be interior to the boundary b consisting of line segments P_1T, P_2T and boundary segments s_{11} and s_{12}. Since every point interior to this boundary has distance to T strictly smaller than $|Q_1T|$, this contradicts our assumption that Q_2 is also at maximum distance to T in the segment s.

To argue that Q_2 must be interior to b, we construct two paths to divide the disc D_{ex} bounded by C_{ex} using the following pieces. Let R_1 be the point on C_{ex} that is beyond Q_1 on the ray TQ_1. Since T is exterior to the obstacle by assumption, there exists a simple path p to T from outside D_{ex} that does not intersect the boundary of the obstacle. There must be a segment u of p that intersects C_{min} in some point R_3, intersects C_{max} in some point R_4, and otherwise is contained strictly between the two circles C_{min} and C_{max}. Let R_2 be the point on C_{ex} beyond R_4 on the ray TR_4. Since R_4 is different from Q_1, R_2 must be different from R_1.

Now we construct a simple path β_1 in D_{ex} from R_2 to R_1 consisting of line segment R_2R_4, path segment u, line segment R_3T, line segment TP_1, boundary segment s_{11}, and line segment Q_1R_1. The path β_1 does not contain the points P_2 or Q_2 and divides the disc D_{ex} into two regions. P_2 and Q_2 must be in the same region of D_{ex} with respect to β_1, because the boundary segment s_{22} joining them does not intersect β_1. To see this, note that s_{22} lies between the circles C_{min} and C_{max} and cannot intersect path segment u (by construction) or boundary segment s_{11}. Since these are the only portions of β_1 between C_{min} and C_{max}, s_{22} does not intersect β_1.

We construct another simple path β_2 from R_2 to R_1 consisting of line segment

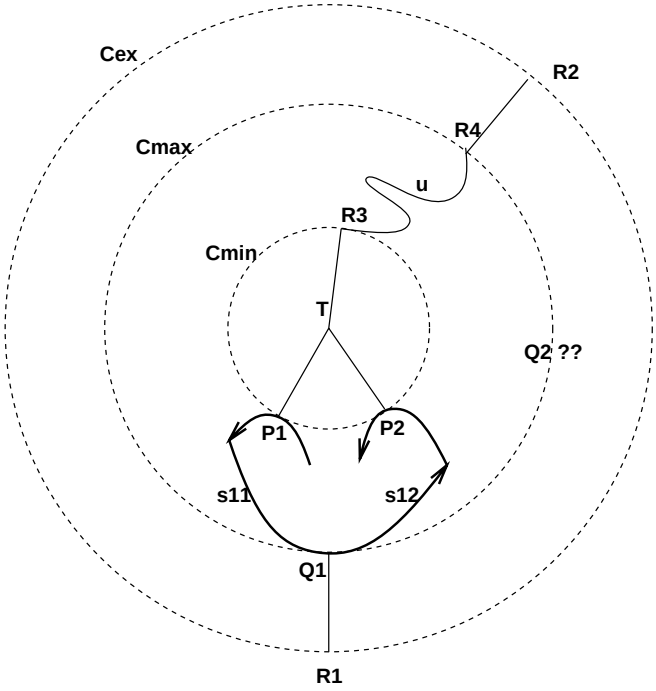

FIG. 7.1. *Figure for proof of Lemma* 7.2.

R_2R_4, path segment u, line segment R_3T, line segment TP_2, boundary segment s_{12}, and line segment Q_1R_1. Then β_2 does not contain points P_1 or Q_2 and it also divides the disc D_{ex} into two regions. We now argue that P_1 and Q_2 must be in the same region of D_{ex} with respect to β_2. To do so, we consider the segment s' of obstacle boundary from Q_2 to P_1. Although s remains between circles C_{min} and C_{max}, we have no such guarantee for s'. However, we argue that s' must cross the path β_2 an even number of times, which means P_1 and Q_2 are in the same region of D_{ex} with respect to β_2.

Considering each piece of the path β_2 in turn, we have the following. The segment R_2R_4 joins two points exterior to the obstacle and must be crossed by the boundary of the obstacle an even number of times. Because s lies between the circles C_{min} and C_{max}, the only crossings of R_2R_4 must be by s'. The path segment u does not intersect the boundary of the obstacle at all, so there are zero crossings of it by s'. The segment R_3T joins two points exterior to the obstacle and must be crossed by the boundary of the obstacle an even number of times. The only portion of the boundary that can intersect this segment is s'. By Property 3.22, the P_2T-probe, which we denote by P_2X, is exterior to the obstacle except for the point P_2, because P_2 is unblocked-towards and a local minimum of distance to T. Since T and X are both exterior to the obstacle, the subsegment TX must be crossed by the boundary of the obstacle an even number of times, and the only part of the boundary that can intersect it is s'. Since the segment P_2X is exterior to the obstacle except for P_2, it does not intersect s' at all. The boundary segment s_{12} does not intersect the boundary segment s' at all. Finally, by Property 3.23, the Q_1R_1-probe, which we denote by Q_1Y, is exterior to the obstacle except for the point Q_1 (because Q_1 is unblocked-away and a local

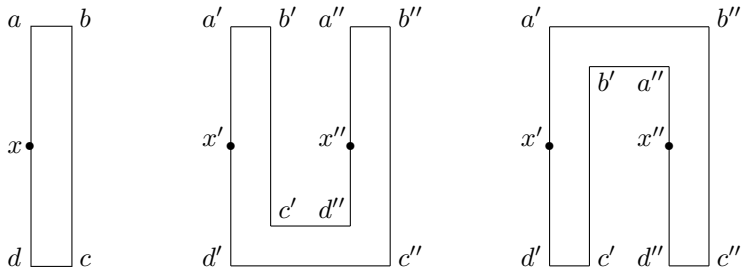

FIG. 7.2. *Obstacles for circumnavigation.*

maximum of the distance to T). Then s' does not intersect Q_1Y at all, and it crosses YR_1 an even number of times, because Y and R_1 are exterior to the obstacle.

Since each portion of the path β_2 either is not intersected by s' or is crossed an even number of times, P_1 and Q_2 are in the same region of D_{ex} with respect to β_2.

Finally, since Q_2 and P_2 are in the same region of D_{ex} with respect to β_1 and also Q_2 and P_1 are in the same region of D_{ex} with respect to β_2, Q_2 is in the region bounded by b consisting of s_{11}, s_{12}, and line segments TP_1 and TP_2. Clearly Q_2 cannot be a point of the boundary b, so it must be interior to b, which is the contradiction we sought. The case in which the points appear in the order Q_1, P_1, Q_2, and P_2 is handled analogously. □

THEOREM 7.3. *Let $\mathcal{O}$ be the set of obstacles with a point at distance at most $|ST|$ from T. Let P_{Ob} be the length of the boundary of $Ob \in \mathcal{O}$. The length of the path generated by the FAR-NEAR navigation algorithm is bounded by $|ST|+\sum_{Ob\in\mathcal{O}} 3P_{Ob}$.*

Proof. The robot collides with any obstacle Ob at most once, since by Lemma 7.2, the departure sequence circumnavigates Ob at least once.

Traveling from the hitpoint to Q_1 is at most one traversal of the obstacle boundary, from Q_1 to Q_2 is at most a second, and from Q_2 to P_2 is at most a third. As remarked in [4, 8], if the robot leaves an obstacle by a circumnavigating departure sequence, it will never hit that obstacle again. □

Thus, the FAR-NEAR algorithm has excess distance ratio ≤ 3. Compare this to the lower bound of 1 from Lumelsky and Stepanov [4]. A variant of the navigation algorithm can be used to detect circumnavigation.

THEOREM 7.4. *There is a deterministic algorithm to circumnavigate any normal obstacle that does not contain the target in its interior, using at most two complete traversals of its boundary.*

Proof. By Lemma 7.2, if the robot detects a sequence of break points P_1, Q_1, P_2, and Q_2 (or Q_1, P_1, Q_2, and P_2) such that P_1 and P_2 are unblocked-towards and of minimum distance to T among the boundary points traversed so far, and Q_1 and Q_2 are unblocked-away and of maximum distance to T among the boundary points traversed so far, then it has circumnavigated the obstacle. Moreover, if T is exterior to the obstacle, then such a sequence of points will be detected in at most two traversals of the boundary, using Properties 3.19 and 3.20. In the case that T is on the boundary of the obstacle, this fact will be detected in one boundary traversal, and, by the time T is reached again, the robot has circumnavigated the obstacle. □

The optimality of two boundary traversals for deterministic circumnavigation of normal obstacles not containing T in the interior is shown in the next subsection.

7.2. A lower bound for detecting complete circumnavigation.

THEOREM 7.5. *For any deterministic boundary-following circumnavigation algorithm and for any $\epsilon > 0$, there exists a normal obstacle not containing the target for which the robot's path length is at least $2 - \epsilon$ times the perimeter of the obstacle.*

Proof. Suppose we are given any deterministic algorithm for boundary-following circumnavigation in our model and any $\epsilon > 0$. We first analyze the behavior of the algorithm on the three obstacles depicted in Figure 7.2 to show that when it is started at point x on the rectangle, every possible computation path must make, in addition to an initial traversal of half the edge ad, at least two complete traversals of one of the vertical edges and one complete traversal of the other. If we take the horizontal dimension of the rectangle to be sufficiently small compared to the vertical dimension, this implies that the robot's path length will be at least $7/4 - \epsilon$ times the perimeter of the rectangle in every computation path. (As before, the vertical segments of the diagram represent segments aligned along rays to T and the horizontal segments represent arcs of a circle centered at T.)

Consider any computation path of the given algorithm when started at point x on the rectangle. The initial segment of the robot's path must traverse half the edge ad to reach either a or d. Suppose the point reached is a; then we focus on the $\sqcup$-shaped object; a corresponding argument will hold for the $\sqcap$-shaped object if the robot reaches d instead.

Note that the only points in the $\sqcup$-shaped object that are distinguishable to the robot from their counterparts in the rectangle are the points c' and d''. Clearly, to complete a circumnavigation of the rectangle, the robot must completely traverse both edge ad and edge bc. (Recall that in our model, the robot has no way of stopping in the middle of traversing a vertical edge.) Suppose for the sake of contradiction that these are the only two full traversals of vertical edges of the rectangle. Then in this computation path, either edge ad is traversed first and then edge bc or vice versa.

In the case that the edge ad is traversed first, consider what can happen when the robot, making the same choices, is started at point x' on the $\sqcup$-shaped obstacle. The initial segment of the path takes it to point a'. Then it traverses the edge $a'd'$ and then the edge $b''c''$ and halts without traversing any other vertical edges and without reaching either of the distinguishing points c' and d''. Thus, in this computation, the robot erroneously halts without circumnavigating the $\sqcup$-shaped object.

A similar argument holds in the case that the computation path of the robot traverses edge bc and then edge ad. In this case, there is a corresponding computation path for the robot when started at point x'' in the $\sqcup$-shaped obstacle that first proceeds to a'', traverses edge $b''c''$ and then edge $a'd'$, and halts without circumnavigating the $\sqcup$-shaped obstacle. Thus in either case our assumption that the path contained only two full traversals of vertical edges leads to a contradiction.

The other case is that in which the computation path we are considering takes the robot first to point d. Analogously, the assumption that the robot performs only two further full traversals of vertical edges in the rectangle leads to a contradiction by considering the behavior of the robot using the same choices in the $\sqcap$-shaped object, starting either at x' or x''.

To improve the lower bound to $2 - \epsilon$, start the robot at point x on the rectangle and observe whether it proceeds to point a or point d. If it proceeds to point a, then we slide the rectangle up until the point x is very close to the point d. If the robot begins by proceeding to point d, then we slide the rectangle down until point x is very close to point a. Then in either case, the initial segment traversed is very nearly the whole vertical edge ad. The argument that we have at least three more

vertical traversals to go still holds, which gives a lower bound of $2 - \epsilon$ times the perimeter. □

8. Remarks. Although our definition of a scene specifies a finite collection of obstacles, our results hold as long as a finite number of obstacles intersect the disk centered at the target with radius equal to the distance from start to target.

If the robot is given an a priori upper bound on the number of break points on any obstacle, then it can detect circumnavigation of an obstacle by simple counting. Our negative result of section 4 will not hold. Our algorithms will still be preferable, however, when the average number of break points on an obstacle is substantially less than the upper bound. Our algorithms do not need to save their entire ground track; they can be implemented using $O(1)$ registers.

An important problem in vision-based tracking is that the robot's view of the target is sometimes occluded by intervening obstacles. Taylor and Kriegman classify obstacles into transparent obstacles, which are invisible to the robot until it actually collides with them, and opaque obstacles, which the robot can detect because they intervene in the line of sight [8]. Although the robot can detect the existence of opaque obstacles, it cannot determine the distance to such an obstacle until, once again, it actually collides with it. In practice, transparent obstacles are things such as tables and boxes that are lower than the robot camera, and opaque obstacles are tall cabinets, bookcases, and partitions. Taylor and Kriegman's procedures work even if the target is obscured at various positions, as long as the target is visible from the start point.

Our algorithm for navigation within a room can be modified to cope with regions of obscured visibility, provided the target is visible from the starting point. The key intuition is that whenever the robot moves in open space it moves directly toward T, so when it encounters an obstacle, T is visible at the hit point. This ensures that the obstacle has some unblocked-towards point that is nearer to T than the hitpoint and from which T is visible. The above bounds still hold, but the definition of break point must be extended to include points at the end of boundary segments from which the target is continuously visible.

There are several interesting problems left open by our work. Is there a deterministic algorithm for navigation in the indoor setting that achieves an excess distance ratio of $o(\log n / \log \log n)$? Our lower bound results (section 6) show that if there is such an algorithm, it must be neither MONOTONE nor ONE-WAY, that is, it must travel in both clockwise and counterclockwise directions, and it must sometimes depart obstacles from break points that are farther from the target than the prior hitpoint. Can the excess distance ratio for navigation in the free space problem be reduced below 3? Do these results extend to other surfaces besides the plane? Is there a significant advantage in using randomized algorithms for these problems? We note that the lower bound of $7/4 - \epsilon$ for circumnavigation given in section 7.2 holds against randomized algorithms (for an appropriate definition of randomization). We believe that the impossibility results of section 4 and the lower bounds of section 6 can also be extended to randomized models.

Appendix. Proof of Theorem 4.1.

We begin by proving some technical lemmas, and then we restate Theorem 4.1 and give its proof.

DEFINITION A.1. *Let $p = (r(t), \theta(t))$, $t \in [0, 1]$, be an arbitrary path. Let j and k be integers $j \geq 0$ and $k > 0$. Then $\Gamma(p, j, k)$ is the path $(r'(t), \theta'(t))$ for $t \in [0, 1]$,*

where

$$r'(t) = r(t),$$
$$\theta'(t) = \frac{1}{k}(\theta(t) + 2\pi j).$$

$\Gamma(p, j, k)$ is an angularly scaled and rotated copy of the path p. It preserves distances from the origin but divides angular displacements by k, and it also rotates the start of the path counterclockwise around the origin by $2\pi j/k$. We use $\Gamma(p, j, k)(t)$ to indicate the point on the curve $\Gamma(p, j, k)$ given by parameter t. The following technical lemmas will be useful.

LEMMA A.2. *Given paths p_1 and p_2 let $p_1' = \Gamma(p_1, j_1, k)$ and $p_2' = \Gamma(p_2, j_2, k)$. If $p_1'(t_1) \equiv p_2'(t_2)$ for some $t_1, t_2 \in [0, 1]$, then $p_1(t_1) \equiv p_2(t_2)$.*

Proof. Let $p_1 = (r_1(t), \theta_1(t))$ and let $p_2 = (r_2(t), \theta_2(t))$. By hypothesis and the definition of Γ,

$$r_1(t_1) = r_1'(t_1) = r_2'(t_2) = r_2(t_2)$$

and

$$(\theta_1(t_1) + 2\pi j_1)/k = (\theta_2(t_2) + 2\pi j_2)/k + 2\pi i$$

for some integer i. Hence $\theta_1(t_1) = \theta_2(t_2) + 2\pi(j_2 - j_1 + ik)$. This implies $p(t_1) \equiv p(t_2)$, since j_1, j_2, i, and k are integers. Note that p_1 and p_2 may be the same path. □

LEMMA A.3. *Given paths p_1 and p_2, suppose $p_1(t_1) \equiv p_2(t_2)$ for some $t_1, t_2 \in [0, 1]$. Then for any nonnegative integer $j_1 < k$ there exists a nonnegative integer $j_2 < k$ such that $p_1'(t_1) = \Gamma(p_1, j_1, k)(t_1) \equiv \Gamma(p_2, j_2, k)(t_2) = p_2'(t_2)$.*

Proof. Let $p_1 = (r_1(t), \theta_1(t))$ and let $p_2 = (r_2(t), \theta_2(t))$. For any choice of j_1, j_2,

$$r_1'(t_1) = r_1(t_1) = r_2(t_2) = r_2'(t_2)$$

by hypothesis and definition of the transform Γ. By hypothesis, for some integer i,

$$\theta_1(t_1) = \theta_2(t_2) + 2\pi i.$$

Given integer j_1 with $0 \le j_1 < k$, let $j_2 = (i + j_1) \pmod k$. Then for some integer m, $j_2 = (i + j_1) + mk$, and

$$\theta_2'(t_2) = \frac{\theta_2(t_2) + 2\pi j_2}{k} = \frac{\theta_2(t_2) + 2\pi i + 2\pi j_1 + 2\pi mk}{k} = \frac{\theta_1(t_1) + 2\pi j_1}{k} + 2\pi m$$
$$\equiv \theta_1'(t_1). \qquad \square$$

LEMMA A.4. *Given path $p = (r(t), \theta(t))$ let $p_1 = \Gamma(p, j_1, k)$ and $p_2 = \Gamma(p, j_2, k)$ for $0 \le j_1, j_2 < k$. If $p_1(t_0) \equiv p_2(t_0)$ for some single value of the parameter $t = t_0$, then $j_1 = j_2$.*

Proof. By hypothesis $\theta_1(t_0) = \theta_2(t_0) + 2\pi i$ for some integer i. Hence

$$(\theta(t_0) + 2\pi j_1)/k = (\theta(t_0) + 2\pi j_2)/k + 2\pi i.$$

This implies $(j_1 - j_2)/k = i$. But since $0 \le j_1, j_2 < k$, equality can only hold if $j_1 = j_2$ and $i = 0$. □

DEFINITION A.5. *Let $p = (r(t), \theta(t))$, $t \in [0, 1]$, be an arbitrary curve, and let $k > 0$ be an integer. Then $Z(p, k)$ is the path given by the union of the family of*

curves $\Gamma(p, j, k)$ *for* $0 \le j < k$. *That is, the angular part of* p *is scaled by* k, *and then* k *copies of the result are placed around the origin, the* i*th copy starting at angle* $2\pi i/k$ *and ending at angle* $2\pi(i+1)/k$. $Z(p,k)$ *can be written as*

$$(r(\{s\}), (\theta(\{s\}) + 2\pi\lfloor s \rfloor)/k),$$

$s \in [0, k]$ *(where* $\{s\} = s - \lfloor s \rfloor$ *denotes the fractional part of* s*).*

Let Ob be an obstacle containing T in its bounded domain (i.e., interior). We assume the target is at the origin $(0,0)$ and that the boundary of Ob, $\beta = (r(s), \theta(s))$, $s \in [0,1]$, is parameterized so that $\theta(0) = 0$, $\theta(1) = 2\pi$, and θ increases in a counterclockwise direction. Let $\beta^* = Z(\beta, k)$. The next sequence of lemmas establishes that β^* is a simple closed curve. Furthermore, β^* can be used to define an obstacle Ob^* such that the sequence of ground track entries produced by one circumnavigation of Ob^* is exactly the same as the sequence of ground track entries produced by k circumnavigations of Ob. Figure 4.1 shows an example obstacle and Figure 4.2 shows the result of applying Z to that obstacle with $k = 6$.

LEMMA A.6. *The curve* $\beta^* = Z(\beta, k)$ *is simple and closed.*

Proof. That $\beta^*(0) \equiv \beta^*(k)$ follows from the definition of $\Gamma(\cdot,\cdot,\cdot)$ and the fact that $r(0) = r(1)$, $\theta(0) = 0$, and $\theta(1) = 2\pi$. Hence β^* is closed.

To show that β^* is simple, we show that for any s_1, s_2 such that $0 \le s_1 < s_2 < k$, $\beta^*(s_1) \not\equiv \beta^*(s_2)$. (Since $\beta^*(0) \equiv \beta^*(k)$ all cases with $s_2 = k$ are covered by cases with $s_1 = 0$.)

Let $j_1 = \lfloor s_1 \rfloor$ and $j_2 = \lfloor s_2 \rfloor$. Then $\beta^*(s_1)$ is the point on curve $\Gamma(\beta, j_1, k)$ given by parameter $\{s_1\}$, and $\beta^*(s_2)$ is the point on curve $\Gamma(\beta, j_2, k)$ given by parameter $\{s_2\}$. If $\beta^*(s_1) \equiv \beta^*(s_2)$, then by Lemma A.2, $\beta(\{s_1\}) \equiv \beta(\{s_2\})$. Since β is a simple closed curve by definition, this is only possible if $\{s_1\} = \{s_2\}$. Applying Lemma A.4 we conclude $j_1 = j_2$, and hence $s_1 = s_2$, a contradiction. □

Since β^* is a simple closed curve, it divides the plane into two regions, one of which contains T.

LEMMA A.7. *The target* T *is in the interior (bounded) domain of* β^*.

Proof. Suppose T is not in the bounded domain. Then there is a path q^* from T to a point Q arbitrarily far from T such that q^* does not intersect β^*. Define $q^* = (r'(t), \theta'(t))$, $t \in [0,1]$, and let q be the path $(r'(t), k \cdot \theta'(t))$.

Since Q can be made arbitrarily far from T, $q(1)$ is in the unbounded region of Ob. Therefore, path q must cross β at some point $\beta(s_0) \equiv q(t_0)$. By definition, therefore,

$$r'(t_0) = r(s_0), \tag{A.1}$$

$$k \cdot \theta'(t_0) = \theta(s_0) + 2\pi i \tag{A.2}$$

for some integer i. Now let $j = i \pmod k$, and consider the curve $\Gamma(\beta, j, k)$ at point s_0. By definition $\Gamma(\beta, j, k)(s_0) = (r(s_0), (\theta(s_0) + 2\pi(i \pmod k))/k)$. On the other hand, A.2 yields

$$\theta'(t_0) = \frac{\theta(s_0) + 2\pi(kx + i \pmod k)}{k} = \frac{\theta(s_0) + 2\pi(i \pmod k)}{k} + 2\pi x$$

for some integer x. Therefore $q^*(t_0) \equiv \Gamma(\beta, j, k)(s_0)$. This contradicts the assumption that q^* does not touch β^*, since $\Gamma(\beta, j, k)(s_0) \subset \beta^*$. □

If Ob is a normal obstacle, then let Ob^* be the obstacle with boundary β^* whose obstructed region is the bounded domain containing T. If Ob is a room wall, then let the obstructed region of Ob^* be the unbounded domain not containing T. Next we study the relationship between the break points of Ob and those of Ob^*.

LEMMA A.8. *Point $P^* = \beta^*(s)$ is a local minimum or local maximum with respect to distance if and only if point $P = \beta(\{s\})$ is a local minimum or local maximum, respectively.*

Proof. Since distances are unchanged, the distances of the points in a small neighborhood of P^* are the same as the distances of the points in the corresponding neighborhood of P. The only special case occurs when $\{s\} = 0$, but in this case the points on β^* in the distance $s - \varepsilon$ are the same as the points on β in the distance $1 - \varepsilon$. □

LEMMA A.9. *Point $P^* = \beta^*(s_0)$ is unblocked-towards if and only if $P = \beta(\{s_0\})$ is unblocked-towards.*

Proof. For convenience, assume for the moment that Ob is a normal obstacle. We show that if P is unblocked-towards, then P^* is also unblocked-towards. By definition, if P is unblocked-towards, the PT-probe is a segment PR of nonzero length that is contained entirely in free space. Let Q be some point in free space at distance greater than any boundary point of Ob. Since Q is in free space (the unbounded region is free with respect to Ob) there is a path connecting R to Q that lies entirely in free space. Let q denote a path consisting of the segment from P to R followed by the path from R to Q.

Let $j_0 = \lfloor s_0 \rfloor$. Let $q' = \Gamma(q, j_0, k)$. Then $P^* \equiv q'(0)$. Note that q' begins with a segment P^*R^* of nonzero length that lies along the ray P^*T. We show that q' lies entirely in free space, which implies that the segment P^*R^* is in free space. This then implies that P^* is unblocked-towards.

To show that q' lies entirely in free space, we observe that by Lemma A.2, the curve q' can only intersect β^* at point $q'(0) \equiv P^*$. Since the point Q^* is at a distance greater than any point on Ob^*, this point must be in free space, and since q' does not cross the boundary of Ob^*, all other points on q' must be in the same region as Q^*.

Suppose on the other hand that point P is blocked-towards. We construct a path q that begins at P, starts with a small segment PR along ray PT, and then continues from R to T along a path entirely contained within the obstacle. We apply the same transformation to q to derive a path from T to P^* lying entirely within one domain of the obstacle boundary β^*. Since T is in the obstructed domain by definition, this path is entirely within the obstructed region and hence shows that P^* is blocked-towards.

If the obstacle is a room wall rather than a normal obstacle, then the exterior domain is the obstructed region. In this instance, we reverse the cases of unblocked-towards and blocked-towards, since if a point is blocked-towards, then there is a path within the obstacle to some point Q very far away, and if it is unblocked-towards, then there is a path in free space to T. □

LEMMA A.10. *Point $P^* = \beta^*(s_0)$ is unblocked-away if and only if $P = \beta(\{s_0\})$ is unblocked-away.*

Proof. The proof is analogous to that of Lemma A.9, the only difference being that the probes point away from T rather than toward T. □

COROLLARY A.11. *Point $P^* = \beta^*(s_0)$ is a break point if and only if $P = \beta(\{s_0\})$ is a break point. Furthermore, if $P^* = \beta^*(s_0)$ is a break point, then the ground track entry generated at P^* is identical to the ground track entry generated at P.*

Proof. The corollary is a consequence of Lemmas A.8, A.9, and A.10. □

THEOREM 4.1. *In the distance query model, if there may exist an obstacle whose interior contains the target (either a normal obstacle with the target in its obstructed region, or a room wall with the target in its complement), then there is no deterministic algorithm for circumnavigation. Furthermore, there are arbitrarily complex obstacles*

which any given deterministic algorithm fails to circumnavigate.

Proof. Let A be any circumnavigation algorithm. Let Ob be any sufficiently complex obstacle containing T in its bounded domain (i.e., interior). We assume the target is at the origin and the boundary of Ob, $\beta = (r(s), \theta(s))$, $s \in [0,1]$, is parameterized so that $\theta(0) = 0$ and $\theta(1) = 2\pi$. The robot is started at point $\beta(0) = (r(0), \theta(0))$ using algorithm A.

If algorithm A fails to circumnavigate Ob, either by halting incorrectly or never halting, then the theorem holds immediately. Otherwise we construct an obstacle Ob^* which A fails to circumnavigate.

Choose a constant k as follows. Suppose the robot halts after receiving m ground track entries. Then $rp(m) = (\rho(t), \vartheta(t))$, $t \in [0,1]$, is the complete path followed by the robot while performing its circumnavigation.

Choose any integer k such that $k > \max_t\{|\vartheta(t)|\}/\pi$. Let $\beta^* = Z(\beta, k)$, and let Ob^* be the obstacle with boundary β^* whose interior region contains T. Lemmas A.8–A.10 and Corollary A.11 hold of the obstacle Ob^* and its boundary β^*. We claim that on Ob^* the robot will follow the path $p^* = (\rho(t), \vartheta(t)/k)$. If this claim is true, then for all s,

$$-\frac{\max_s\{|\vartheta(s)|\}}{k} \le \vartheta^*(s) \le \frac{\max_s\{|\vartheta(s)|\}}{k}.$$

Since $k > \max_s\{|\vartheta(s)|\}/\pi$, this implies $-\pi < \vartheta^*(s) < \pi$. But since every ray from T intersects Ob^* at some point there must be a point at angle π, which is not reached by the robot in traveling over path p^*. Hence the robot fails to circumnavigate Ob^*.

It remains to prove the claim. The proof is by induction on the number of ground track entries generated as the robot travels path p. We show that

(i) if $rp(\ell)$ on Ob is $(\rho(t), \vartheta(t))$, $t \in [0,1]$ then $rp^*(\ell)$ on Ob^* is $(\rho(t), \vartheta(t)/k)$.

To do this, we show that two additional invariants hold:

(ii) For all ℓ, the first ℓ ground track entries generated while running on Ob^* are identical to the first ℓ entries generated while running on Ob.

(iii) If $rp^*(\ell) = \beta^*(j_0 + s_0)$, $s_0 \in [0,1)$, and $0 \le j_0 < k$, then $rp(\ell) = \beta(s_0)$.

For the basis case, observe $rp(0) \equiv rp^*(0) = S$, and all the invariants are trivially true. Now suppose the robot has generated ℓ ground track entries while running on Ob^*. By invariant (ii), on both Ob and Ob^*, the navigation algorithm, having seen the same set of ground track entries, will take the same action.

Case 1. The robot executes *follow-boundary(CCW)*. On both Ob and Ob^*, the robot's path is coincident with the respective obstacle boundary until reaching the first break point in the CCW direction. On Ob, $rp(\ell+1) = rp(\ell) + \beta([s_0, s_1])$. Now set

$$j_1 = \begin{cases} j_0 & \text{if } s_0 < s_1 < 1, \\ j_0 + 1 \bmod k & \text{if } 0 \le s_1 < s_0. \end{cases}$$

By Corollary A.11, $\beta^*(j_1 + s_1)$ is the first break point the robot reaches on Ob^*. Therefore invariants (ii) and (iii) hold. Either path $rp^*(\ell+1) = rp^*(\ell) + \Gamma(\beta, j_0, k)([s_0, s_1])$ or $rp^*(\ell+1) = rp^*(\ell) + \Gamma(\beta, j_0, k)([s_0, 1]) + \Gamma(\beta, j_1, k)([0, s_1])$, depending on whether $s_0 < s_1 < 1$. By the definition of $\Gamma(\beta, j, k)$, invariant (i) holds.

Case 2. The robot executes *follow-boundary(CW)*. This is analogous to Case 1.

Case 3. The robot executes *move-to-T*(). Let $Q = \beta(s_0)$ be the point on Ob from which the robot departs. By invariant (iii), the robot will depart Ob^* at $Q^* = \beta^*(s_0 + j_0)$. Consider the ray $q = TQ$ and the transformed ray $q^* = S(q, j_0, k)$. From

Ob the robot travels inbound on ray q and from Ob^* the robot travels inbound on ray q^*. Let P be the hitpoint reached on Ob and let P^* be the hitpoint reached on Ob^*. We argue that $P = \beta(s_1)$ and $P^* = \beta^*(s_1 + j_1)$ for some j_1. This will immediately establish invariants (ii) and (iii). Invariant (i) also follows, since from both Ob and Ob^* the robot follows an inbound ray, without changing its angular coordinate, until stopping at a point at the same radius in both cases.

Since ray q intersects β at P, it follows from Lemma A.3 that ray q^* intersects β^* at some point $R^* = \beta^*(s_1 + j_1)$. Since P is blocked-towards, R^* is blocked-towards (Lemma A.9). If $R^* \equiv P^*$ we are done. Suppose therefore that $R^* \not\equiv P^*$. Then P^* must have a radius coordinate greater than R^*. Since ray q^* intersects β^* at P^*, it follows from Lemma A.2 that ray q intersects β at some point $R = \beta(s_2)$. Furthermore, R has the same radius coordinate as R^* and is also blocked-towards (Lemma A.9). But this contradicts the assumption that P is the first hitpoint encountered when the robot heads in along ray q. Therefore it must be the case that $R^* = P^*$, as desired. □

Acknowledgments. We thank David Kriegman and C. J. Taylor for bringing this problem to our attention, and Drew McDermott, Greg Hager, Stan Eisenstat, and the two anonymous referees for many helpful comments.

PREEMPTIVE SCHEDULING OF PARALLEL JOBS ON MULTIPROCESSORS*

XIAOTIE DENG†, NIAN GU‡, TIM BRECHT§, AND KAICHENG LU¶

Abstract. We study the problem of processor scheduling for n parallel jobs applying the method of competitive analysis. We prove that for jobs with a single phase of parallelism, a preemptive scheduling algorithm without information about job execution time can achieve a mean completion time within $2 - \frac{2}{n+1}$ times the optimum. In other words, we prove a competitive ratio of $2 - \frac{2}{n+1}$. The result is extended to jobs with multiple phases of parallelism (which can be used to model jobs with sublinear speedup) and to interactive jobs (with phases during which the job has no CPU requirements) to derive solutions guaranteed to be within $4 - \frac{4}{n+1}$ times the optimum. In comparison with previous work, our assumption that job execution times are unknown prior to their completion is more realistic, our multiphased job model is more general, and our approximation ratio (for jobs with a single phase of parallelism) is tighter and cannot be improved. While this work presents theoretical results obtained using competitive analysis, we believe that the results provide insight into the performance of practical multiprocessor scheduling algorithms that operate in the absence of complete information.

Key words. processor scheduling, parallel programs, competitive analysis, unknown information

1. Introduction.

The CPU scheduling problem for computer systems distinguishes itself from general scheduling problems (e.g., job shop scheduling) in its variety of requirements of the system and variety of performance metrics. While minimizing makespan (the time at which the last job completes execution) is usually a natural objective function for many general scheduling problems, a number of different possibilities exist for CPU schedulers in a general purpose multiuser computing environment [31]. Nevertheless, minimizing the mean completion time (the sum of the times at which each job completes, divided by the number of jobs) is a commonly used objective function [22], [18], [34], [35], [27]. We can equivalently just consider the sum of the completion times. In this paper, the phrase *completion times* is used to imply that all jobs are available for execution at time zero, while the phrase *response time* implies that there are new job arrivals.

Several recent analytic results have been obtained for the problem of minimizing mean completion times using nonpreemptive scheduling algorithms which assume that

job information is completely known [35], [34], [27], [18]. These results initiated the first (theoretical) step toward understanding the general problem. Our work takes the next significant step and is distinguished from these results in that *we remove the unrealistic assumption that the job execution time is known.* Knowledge of execution times for some jobs may be obtained, but this is clearly not a valid assumption for all jobs in general purpose computing environments.

Using the terminology of Feitelson et al. [9], the work by Turek et al. [35] and Schwiegelshohn et al. [27] examines nonpreemptive scheduling policies using a rigid job model. That is, the number of processors required by a job is defined by the job and must be assigned to the job for its lifetime. Subsequent work [34], [18] relaxes the job model to consider moldable jobs. A moldable job [9] is one which can be run on any number of processors provided that once the processors have been allocated they remain allocated to that job for the duration of its execution. In this case the scheduler is free to determine the number of processors to allocate to each job. However, once a job is assigned processors it cannot be preempted. Additionally, some of these studies [34], [18] explicitly model jobs with sublinear speedup.

By comparison, in this work we model malleable jobs in order to examine dynamic preemptive scheduling policies. That is, we model jobs that are capable of executing with a changing number of processors and scheduling algorithms that can modify the number of processors allocated to jobs during their execution in order to adjust to changing requirements or system loads. Note that in using this model, threads of a job can migrate (i.e., they can be suspended on one processor and resumed at a later time on another processor). We also explicitly study jobs with multiple phases of parallelism in order to approximate jobs with sublinear speedups. During each phase of execution a job is capable of executing with perfect speedup until a maximum degree of parallelism is reached. The addition of extra processors beyond this limit neither increases nor decreases the execution time of the job. While each phase executes with linear speedup (up to the maximum degree of parallelism), multiple phases of execution with different maximum degrees of parallelism can be combined to produce an overall model of sublinear speedup.

In this paper we show that the dynamic equipartition (DEQ) policy [33], [38] produces mean completion times that are no more than $2 - \frac{2}{n+1}$ times the optimum for any set of n parallel jobs with one phase of parallelism, and that no policy can guarantee a better competitive ratio without a priori knowledge of job execution times. Although the competitive ratio turns out to be the same as in the sequential problem (not necessarily by accident), our result requires a completely different and rather difficult proof. In fact, *the ratio of* $2 - \frac{2}{n+1}$ *cannot be further improved mathematically* for jobs with a single phase of parallelism.

This result provides a theoretical foundation for analyzing and understanding the performance of the DEQ policy, which, along with its various derivatives, has been shown to be superior to nonpreemptive algorithms in recent simulation and experimental studies [33], [17], [38], [16], [20], [21].

The remainder of the paper is organized as follows. We complete section 1 with a further description of the problem and a discussion of related work. In section 2, we give a formal definition of the DEQ allocation policy. Then we establish a lower bound on the optimal total completion time for parallel jobs by extending the squashed area bound and the height bound [34], using a completely different approach from those used previously. In section 3, we give a formal proof that the total completion time of DEQ is no more than twice the optimal total completion time for any job set. The

mathematical induction used in this proof requires a delicate balance of the squashed area and height bounds on the work needed to be executed by each job. Furthermore, in section 4, we show that our results can be extended to jobs which may change the number of processors required during their execution, including interactive jobs which may block and therefore need not be assigned to a CPU while waiting for user input. In section 5, we present theoretical results which demonstrate that DEQ is robust in the presence of faulty jobs. We consider the case where there are faulty jobs which may execute infinitely and show that, in this case, DEQ achieves the optimal competitive ratio for makespan. In section 6, we conclude the paper.

1.1. Preemptive scheduling. Schedulers in most general purpose computer systems are preemptive for several reasons [31]. First, job execution times may not be known prior to their completion. Thus, when nonpreemptive scheduling algorithms are used, short jobs may be penalized by long jobs which utilize the CPUs for long periods of time. Second, interactive jobs require some processing, and preemptive (time-sharing) scheduling policies allow them to execute by providing them with a slice of CPU time. Third, some jobs may execute infinitely, due to programming errors. If a nonpreemptive scheduling policy is used they may execute forever and exclude other jobs from being processed. Obviously, the preemptive execution of jobs incurs some overhead. For multiprocessor systems, this may become more expensive. However, these overheads can be absorbed in a time-sharing scheme by choosing a scheduling quantum that is sufficiently large or by dynamically space-sharing processors instead [33], [38], [20], [26]. This is consistent with the trend toward coarse grained machines for general purpose parallel computations, as suggested in the LogP model [3]. Setup costs can then be absorbed by pipeline routing if the size of a problem is sufficiently large in comparison with the number of processors in the system [36]. Independently, there have been extensive empirical studies on the preemptive cost caused by time/space-sharing scheduling policies [38], [20], [37]. Even for some cases when the preemption cost is relatively high, simulation and experimental studies support preemptive over nonpreemptive scheduling policies [38], [20], [23], [24].

1.2. Competitive analysis. We make the assumption that job execution times are not known prior to their completion. This is quite realistic for modern general purpose multiprocessors. Since execution times are not known at the time jobs are scheduled, it is possible that any given scheduling policy may not perform very well on some specific job set. For this reason, we use competitive analysis to study policies that do not deviate from the optimal solution (which has and uses complete information about the job set) by more than a constant factor. The competitive analysis of algorithms is a measure of algorithms operating with incomplete information, first introduced in the study of system memory management [32], [13], [19]. Policies for this problem are required to handle future unknown requests. The competitive ratio of a policy is defined to be the worst case ratio of the cost of the policy (which is different for different problems) to the optimal cost for the same input sequence. In the CPU scheduling problem the situation is similar in that the execution time of a job is unknown until its execution is completed. The competitive ratio of a scheduling policy S is thus defined as the worst case ratio of the mean completion time (or makespan), $S(\mathcal{J})$, of the policy on a set of jobs, $\mathcal{J}$, over the minimum mean completion time (or makespan) $OPT(\mathcal{J})$ on the same job set $\mathcal{J}$: $\max_{all\ \mathcal{J}} \frac{S(\mathcal{J})}{OPT(\mathcal{J})}$. An algorithm is said to be *f(n)-competitive* in mean completion time (or makespan) if $S(\mathcal{J}) \leq f(n)OPT(\mathcal{J})$. The goal is to find an algorithm which leads to the minimum

competitive ratio. Shmoys, Wein, and Williamson studied the optimal competitive ratio in the makespan of sequential jobs being scheduled on parallel machines [30]. For minimizing the mean completion time of sequential jobs, Motwani, Phillips, and Torng have shown that a preemptive time-sharing policy, round-robin, achieves the optimal competitive ratio. It guarantees a mean completion time which is within $2 - \frac{2}{n+1}$ times optimal, and no policy can guarantee a better competitive ratio [22]. As further evidence that preemptive policies should be preferred to nonpreemptive policies, it is not hard to see that any nonpreemptive policy can result in a mean completion time that is $\Omega(n)$ times the optimum when n jobs are scheduled.

1.3. The job model. The most detailed description of a parallel program's execution on a multiprocessor is a data-dependency directed acyclic graph (DAG), where edges represent data dependencies between the data (nodes). The DAG is revealed as the computation proceeds as a result of data-dependent conditional statements. Using a delay model introduced by Papadimitriou and Yannakakis [25], Deng and Koutsoupias show that given uniform communication delay, τ, for any scheduler, there exists a DAG for which the scheduler will produce a schedule whose execution is at least $\frac{\tau}{\log \tau}$ times the optimal execution time of that DAG [4]. The same claim holds for both the bulk synchronous parallelism (BSP) and the LogP models. That is, for a parallel system with communication latency L between processors, the competitive ratio of any scheduler is at least $\frac{L}{\log L}$. This work shows that it is not possible for a compiler to optimally (or near-optimally) execute all jobs for distributed memory parallel systems, and it calls for the characterization of parallel jobs and the use of these characteristics in scheduling policies.

We characterize a parallel job, J_i, using two parameters: its execution time, h_i, and its parallelism, P_i. P_i is the number of processors a job is capable of using during its execution, and h_i is the time that the job needs to complete execution if it is allocated P_i processors. When less than P_i processors are allocated to job J_i, we assume that the job's execution will be prolonged proportionally. That is, if p_i processors ($p_i < P_i$) are allocated to J_i, its actual execution time is $\frac{P_i}{p_i} h_i$. For a job, (P_i, h_i), its parallelism P_i is known to the scheduler but the execution time h_i is unknown prior to its completion. Therefore, jobs are considered malleable and the scheduling algorithms are dynamic and preemptive, since they can adjust the number of processors allocated to a job during its execution [9].

In general, we can use parallelism profiles to characterize parallel jobs. A parallelism profile is defined as the number of processors an application is capable of using at any point in time during its execution [15]. During execution, if the parallelism of an application varies with time, it is said to have multiple phases of parallelism. Note that although our job model assumes linear speedup within each phase of parallelism, jobs with multiple phases of parallelism will execute with sublinear speedup. We also consider interactive jobs by introducing phases during which a job does not require access to a processor because it is blocked while waiting for user input.

1.4. Related results. Motwani, Phillips, and Torng [22] show that, for uniprocessor systems, the mean completion time of the round-robin scheduling policy is $2 - \frac{2}{n+1}$ times the optimum and that without a priori information about job execution times, no policy can guarantee mean completion times within a better approximation factor of the optimum (called the competitive ratio [32], [13], [19]).

The problem of minimizing the mean completion time of parallel jobs executing on multiprocessors is also of interest, and here a number of positive results exist.

Recently, there have been several analytic results which assume that job information is completely known. The first significant work is that of Turek et al. [35] who introduce an approximation algorithm of 32 times the optimum for a nonpreemptive scheduling model. This result for nonpreemptive algorithms has been subsequently improved and extended [34], [27], [18].

A number of different preemptive policies have been proposed and studied for scheduling parallel jobs in multiprocessors [33], [29], [38], [20], [28], [26], [23], [24], [2]. In particular, experimental and simulation studies have shown that the DEQ algorithm yields low mean completion times under a variety of workloads and is reported to possess desirable properties of a good scheduler [33], [17], [16]. DEQ was first introduced to parallel scheduling by Tucker and Gupta as a *process control* policy [33] and was modified by Zahorjan and McCann [38]. The main idea behind this approach is to distribute processors evenly among jobs, provided they have sufficient parallelism.

One of the main drawbacks of DEQ, when compared with other approaches like gang scheduling, is that it requires each job to be implemented in such a way that the number of processes allocated to the job can change during its execution. It also requires significant coordination between the operating system and the run-time system. While these requirements might seem restrictive, studies have shown that it is relatively simple to write malleable applications, that coordination between the scheduler and run-time system is not prohibitive, and that performance is improved significantly when compared with other techniques [20], [10], [23], [24]. In addition, the DEQ algorithm is simple to implement and requires no information about job execution times. Therefore, this work examines the DEQ scheduling algorithm.

Our proof that DEQ is $2 - \frac{2}{n+1}$-competitive uses the notion of a *squashed area bound*, introduced for the nonpreemptive scheduling of parallel jobs [18], [35], [27], [34]. Turek et al. show that the minimum completion time for a set of jobs, $\mathcal{J} = \{(P_1, h_1), (P_2, h_2), \ldots, (P_n, h_n)\}$, is no more than the minimum completion time of the job set $\mathcal{J}_{squash} = \{(P, \frac{P_1 h_1}{P}), (P, \frac{P_2 h_2}{P}), \ldots, (P, \frac{P_n h_n}{P})\}$ [35]. The squashed area bound is the total completion time (the product of the number of jobs and the mean completion time) for $\mathcal{J}_{squash}$ under the least work first (LWF) policy. Sevcik shows that the LWF policy is optimal if all jobs have the same parallelism P [28].

2. Preliminaries. Consider n jobs in a system of P processors. Job J_i is characterized by the parallelism-time pair (P_i, h_i), and the amount of work is $w_i = P_i h_i$, $1 \leq i \leq n$. Denote the job set by $\mathcal{J} = \{J_1, J_2, \ldots, J_n\}$. Suppose that under a scheduler S the actual completion time of job J_i is t_i, $1 \leq i \leq n$. The total completion time of $\mathcal{J}$, denoted by $TC_S(\mathcal{J})$, is defined as $\sum_{i=1}^{n} t_i$. Then the mean completion time $MC_S(\mathcal{J})$ is defined as $\frac{TC_S(\mathcal{J})}{n}$. The height bound $H(\mathcal{J})$ is defined as $\sum_{i=1}^{n} h_i$ [35]. Since J_i requires at least h_i units of execution time, $1 \leq i \leq n$, $H(\mathcal{J})$ is an obvious lower bound on the optimal total completion time. Let the jobs be ordered according to their total work $w_1 \leq w_2 \leq \cdots \leq w_n$. The squashed area bound $A(\mathcal{J})$ is then defined as $\sum_{i=1}^{n} (n-i+1)\frac{w_i}{P}$ [35]. Notice that any preemptive scheduling of the job set $\mathcal{J}$ can be obtained by a preemptive scheduling of the job set $\{(P, \frac{w_1}{P}), (P, \frac{w_2}{P}), \ldots, (P, \frac{w_n}{P})\}$. It follows that $OPT(\mathcal{J}) \geq OPT\{(P, \frac{w_1}{P}), (P, \frac{w_2}{P}), \ldots, (P, \frac{w_n}{P})\}$. Since each job has the same parallelism, the shortest job first (or LWF) strategy gives the optimal solution for the total completion time, easily provable as in sequential systems (see [35], [28] for details). This gives exactly the squashed area bound.

Our main result utilizes a nontrivial extension to the squashed area bound and the height bound. Suppose each job (P_i, h_i) is divided into two parts: (P_i, h_{i1}) and (P_i, h_{i2}) such that $h_i = h_{i1} + h_{i2}$. Let $\mathcal{J}(1) = \{(P_i, h_{i1}) : 1 \leq i \leq n\}$ and $\mathcal{J}(2) =$

$\{(P_i, h_{i2}) : 1 \le i \le n\}$. We have the following lemma for a lower bound on the optimal total completion time of the job set $\mathcal{J}$.

LEMMA 2.1. $OPT(\mathcal{J}) \ge A(\mathcal{J}(1)) + H(\mathcal{J}(2))$.

Proof of Lemma 2.1. Consider the optimal scheduling algorithm on the input $\mathcal{J}$. Let t_{i1} be the time when the remaining portion of J_i is (P_i, h_{i2}) and t_{i2} be the time when J_i completes execution $1 \le i \le n$. Obviously, $t_{i2} - t_{i1} \ge h_{i2}$. The total completion time for the optimal scheduler is

$$OPT(\mathcal{J}) = \sum_{i=1}^{n} t_{i2} \ge \sum_{i=1}^{n} t_{i1} + \sum_{i=1}^{n} h_{i2} \ge A(\mathcal{J}(1)) + H(\mathcal{J}(2)),$$

where the last inequality is derived from the height bound and the squashed area bound [35]. □

We formally define the DEQ allocation policy recursively as follows:

(1) If $P_i \ge \frac{P}{n}$ for all $i : 1 \le i \le n$, each job is assigned $\frac{P}{n}$ processors.
(2) Otherwise, each job J_i with parallelism $P_i < \frac{P}{n}$ is allocated P_i processors. Update n and P. If $n > 0$, recursively apply DEQ.

Obviously, this schedule is valid only when $\frac{P}{n}$ is an integer. In practice, if $\frac{P}{n}$ is a rational number, and larger than 1, we can take its integer part $\lfloor \frac{P}{n} \rfloor$ and ignore its fraction part $\frac{P}{n} - \lfloor \frac{P}{n} \rfloor$. The result will be affected by a small constant factor. If $\frac{P}{n}$ is a fractional number smaller than 1, we view all the parallel jobs as sequential jobs and apply the round-robin policy so that in unit time, a fraction $\frac{P}{n}$ of one processor's CPU time is assigned to one job. To simplify our proof, we allow a fractional number of processors to be assigned to a job, $\frac{P}{n}$, as long as that number is smaller than the parallelism of the job. Let $\mathcal{J}_{para}$ be the set of jobs that are allocated P_i processors, and the rest of the jobs form the set $\mathcal{J}_{equi}$ (which are each assigned an equal number of processors, denoted by $\bar{p}$).

LEMMA 2.2. *If there are no idle processors, then* $\sum_{J_i \in \mathcal{J}_{para}} P_i + |\mathcal{J}_{equi}|\bar{p} = P$, $(\forall J_i \in \mathcal{J}_{para}) P_i \le \bar{p}$, *and* $\bar{p} \ge \frac{P}{n}$.

Consider the execution of jobs under the DEQ policy. Each job (P_i, h_i) is divided into two modes of execution: It is in *full-parallelism mode* if P_i processors are assigned, and it is in *equipartition mode* if less than P_i processors are assigned. It is not difficult to see that under the DEQ allocation policy, once a job enters full-parallelism mode, it will stay in that mode until completion. Let $h_i(f)$ be the length of execution of job i in full-parallelism mode, and $h_i(e) = h_i - h_i(f)$. Let $\mathcal{J}(f) = \{(P_i, h_i(f)) : 1 \le i \le n\}$ and $\mathcal{J}(e) = \{(P_i, h_i(e)) : 1 \le i \le n\}$. In the next section, we prove

$$TC_{DEQ}(\mathcal{J}) \le \left(2 - \frac{2}{n+1}\right)[A(\mathcal{J}(e)) + H(\mathcal{J}(f))]. \tag{2.1}$$

Combining this with Lemma 2.1, we have the following theorem.

THEOREM 2.3. $TC_{DEQ}(\mathcal{J}) \le (2 - \frac{2}{n+1})OPT(\mathcal{J})$. □

It is not hard to extend the lower bound for the competitive ratio of sequential jobs by Motwani, Phillips, and Torng [22] to this situation. In fact, we can replace each job in their proof with a parallel job of the same execution time with parallelism P, the number of processors in the system. Thus, this competitive ratio is optimal.

3. Minimizing mean completion time. In this section, we prove that (2.1) holds. Suppose jobs are initially divided into $\mathcal{J}_{para}$ and $\mathcal{J}_{equi}$ according to the discussion in section 2. We need the following lemma.

LEMMA 3.1. *If there are no idle processors, then*

$$(n+1)P|\mathcal{J}_{equi}| \le (n-1)P|\mathcal{J}_{para}| + n\bar{p}|\mathcal{J}_{equi}|(|\mathcal{J}_{equi}|+1).$$

Proof of Lemma 3.1.

$$\begin{aligned} RHS &= P(|\mathcal{J}_{equi}| + |\mathcal{J}_{para}| - 1)|\mathcal{J}_{para}| + n\bar{p}|\mathcal{J}_{equi}|(|\mathcal{J}_{equi}|+1) \\ &\ge P|\mathcal{J}_{equi}||\mathcal{J}_{para}| + P(|\mathcal{J}_{para}|-1)|\mathcal{J}_{para}| + P|\mathcal{J}_{equi}|(|\mathcal{J}_{equi}|+1) \\ &\ge P|\mathcal{J}_{equi}|(|\mathcal{J}_{para}| + |\mathcal{J}_{equi}| + 1) = P|\mathcal{J}_{equi}|(n+1). \end{aligned}$$

In the above, the first inequality follows from Lemma 2.2, and the second inequality follows from the fact $(|\mathcal{J}_{para}|-1)|\mathcal{J}_{para}| \ge 0$. □

When one of the jobs, say J_1, finishes its execution under DEQ, we will reallocate processors according to DEQ. Every job in $\mathcal{J}_{para}$ will still be assigned the same number of processors as its parallelism. Let $\mathcal{J}'_{para} \subseteq \mathcal{J}_{equi}$ be the subset of jobs in $\mathcal{J}_{equi}$ which are assigned the same number of processors as their parallelism after the reallocation of processors. Let $\mathcal{J}'_{equi} = \mathcal{J}_{equi} - \mathcal{J}'_{para}$. Thus, jobs in $\mathcal{J}'_{equi}$ are now assigned the same number of processors.

Proof of (2.1). For simplicity of presentation, let $C = 2 - \frac{2}{n+1}$. In order to avoid case-by-case analysis in the proof, we prove the claim by induction on the number of jobs which have nonzero execution time, n.

Since $2 - \frac{2}{n+1}$ is an increasing function of n and jobs of zero length would change neither the squashed area bound nor the height bound, the claim would also hold when we allow n to be the number of total jobs, including jobs of zero length. Therefore, we can simply prove the claim for the case when all jobs have nonzero lengths while allowing the induction hypothesis to include the case when jobs of zero length are present.

For the base case $n = 1$, if the parallelism, P_1, of job J_1 is less than or equal to P ($P_1 \le P$), it is assigned P_1 processors ($h_1(f) = h_1$). Otherwise, P processors are assigned to the job ($h_1(e) = h$) and its execution ends in time $\frac{P_1 h_1}{P}$, which is the same as the squashed area bound.

Assume the claim holds when the number of jobs of nonzero length is less than n. Consider the case of n jobs, all of nonzero length, $\mathcal{J} = \{(P_i, h_i) : 1 \le i \le n\}$. If there are idle processors, the claim follows immediately. So we assume there are no idle processors. Without loss of generality, let $J_1 = (P_1, h_1)$ be the first to finish and let τ denote its completion time. Therefore, the remaining portion of jobs $J_i \in \mathcal{J}_{equi}$ is $(P_i, h_i - \frac{\tau\bar{p}}{P_i})$, and the remaining portion of jobs $J_i \in \mathcal{J}_{para}$ is $(P_i, h_i - \tau)$. Therefore, the total completion time is

$$TC_{DEQ}(\mathcal{J}) = n\tau + TC_{DEQ}\left(\left\{\left(P_i, h_i - \frac{\tau\bar{p}}{P_i}\right) : i \in \mathcal{J}_{equi}\right\} \cup \{(P_i, h_i - \tau) : i \in \mathcal{J}_{para}\}\right), \tag{3.1}$$

where the first term is the completion time of J_1 plus the time that the other $n-1$ jobs have been in the system so far, and the second term is needed in recursion for the remaining portion of the $n-1$ jobs. By the induction hypothesis,the second term

in (3.1) is bounded by C times

$$A\left(\left\{\left(P_i, h_i(e) - \frac{\tau\bar{p}}{P_i}\right) : i \in \mathcal{J}_{equi}\right\}\right) + H(\{(P_i, h_i(f)) : i \in \mathcal{J}_{equi}\}) + \sum_{i\in\mathcal{J}_{para}} (h_i - \tau), \tag{3.2}$$

where $h_i(e) \geq \frac{\tau\bar{p}}{P_i}$ for each $i \in \mathcal{J}_{equi}$. DEQ will redistribute processors among jobs in $\mathcal{J}_{equi}$ after the departure of J_1. Let $\mathcal{J}'_{para} \subseteq \mathcal{J}_{equi}$ be the subset of $\mathcal{J}_{equi}$ such that for each $i \in \mathcal{J}'_{para}$, J_i is assigned P_i processors after the redistribution. Let $\mathcal{J}'_{equi}$ be the rest of the jobs in $\mathcal{J}_{equi}$. Since jobs in $\mathcal{J}'_{para}$ will stay in full parallelism mode, we have

$$\forall i \in \mathcal{J}'_{para} h_i(e) = \frac{\tau\bar{p}}{P_i}. \tag{3.3}$$

Similarly,

$$\forall i \in \mathcal{J}'_{equi} h_i(e) > \frac{\tau\bar{p}}{P_i}. \tag{3.4}$$

From (3.3), we have

$$A\left(\left\{\left(P_i, h_i(e) - \frac{\tau\bar{p}}{P_i}\right) : i \in \mathcal{J}_{equi}\right\}\right) = A\left(\left\{\left(P_i, h_i(e) - \frac{\tau\bar{p}}{P_i}\right) : i \in \mathcal{J}'_{equi}\right\}\right). \tag{3.5}$$

Let the jobs in $\mathcal{J}'_{equi}$ be ordered as $j_1, j_2, \ldots, j_k$, $k = |\mathcal{J}'_{equi}|$, according to the increasing order of the amount of remaining work $P_i(h_i(e) - \frac{\tau\bar{p}}{P_i})$, $i \in \mathcal{J}'_{equi}$, which is the same as the increasing order of $P_i h_i(e)$, $i \in \mathcal{J}'_{equi}$. Then,

$$\begin{aligned} A\left(\left\{\left(P_i, h_i(e) - \frac{\tau\bar{p}}{P_i}\right) : i \in \mathcal{J}'_{equi}\right\}\right) &= \frac{1}{P}\sum_{i=1}^{k}(k-i+1)P_{j_i}\left(h_{j_i}(e) - \frac{\tau\bar{p}}{P_{j_i}}\right) \\ &= \frac{1}{P}\sum_{i=1}^{k}(k-i+1)P_{j_i}h_{j_i}(e) - \frac{1}{P}\sum_{i=1}^{k}(k-i+1)\tau\bar{p}. \end{aligned}$$

Therefore,

$$A\left(\left\{\left(P_i, h_i(e) - \frac{\tau\bar{p}}{P_i}\right) : i \in \mathcal{J}'_{equi}\right\}\right) = A(\{(P_i, h_i(e)) : i \in \mathcal{J}'_{equi}\}) - \frac{k(k+1)}{2P}\tau\bar{p}. \tag{3.6}$$

We also have

$$H(\mathcal{J}_{equi}(f)) + \sum_{i\in\mathcal{J}_{para}} (h_i - \tau) = H(\mathcal{J}(f)) - |\mathcal{J}_{para}|\tau. \tag{3.7}$$

Combining (3.1) and (3.2), we know that $TC_{DEQ}(\mathcal{J})$ is no more than

$$n\tau + C \cdot \left(A\left(\left\{\left(P_i, h_i(e) - \frac{\tau\bar{p}}{P_i}\right) : i \in \mathcal{J}_{equi}\right\}\right) + H(\{(P_i, h_i(f)) : i \in \mathcal{J}_{equi}\}) + \sum_{i\in\mathcal{J}_{para}} (h_i - \tau)\right).$$

By (3.5), this is the same as

$$n\tau + C \cdot \left(A\left(\left\{ \left(P_i, h_i(e) - \frac{\tau\bar{p}}{P_i} \right) : i \in \mathcal{J}'_{equi} \right\} \right) + H(\{(P_i, h_i(f)) : i \in \mathcal{J}_{equi}\}) + \sum_{i \in \mathcal{J}_{para}} (h_i - \tau) \right).$$

Now by substituting (3.6) and (3.7), we have the following upper bound for $TC_{DEQ}(\mathcal{J})$:

$$n\tau - C \cdot \frac{k(k+1)\tau\bar{p}}{2P} - C \cdot |\mathcal{J}_{para}|\tau + C \cdot A(\mathcal{J}'_{equi}) + C \cdot H(\mathcal{J}(f)).$$

Since

$$A(\mathcal{J}_{equi}(e)) = A(\mathcal{J}'_{equi}(e)) + \sum_{i=1}^{|\mathcal{J}'_{para}|} \frac{(k + |\mathcal{J}'_{para}| - i + 1)\tau\bar{p}}{P},$$

the above upper bound is equal to

$$n\tau - C \cdot \frac{k(k+1)\tau\bar{p}}{2P} - C \cdot |\mathcal{J}_{para}|\tau - C \cdot \sum_{i=1}^{|\mathcal{J}'_{para}|} \frac{(k + |\mathcal{J}'_{para}| - i + 1)\tau\bar{p}}{P} + C \cdot (A(\mathcal{J}_{equi}(e)) + H(\mathcal{J}(f))).$$

To show that this is no more than

$$C \cdot A(\mathcal{J}(e)) + C \cdot H(\mathcal{J}(f)) = C \cdot A(\mathcal{J}_{equi}(e)) + C \cdot H(\mathcal{J}(f)),$$

it is sufficient to show that

$$n \le C \cdot \frac{k(k+1)\bar{p}}{2P} + C \cdot |\mathcal{J}_{para}| + C \cdot \sum_{i=1}^{|\mathcal{J}'_{para}|} \frac{(k + |\mathcal{J}'_{para}| - i + 1)\bar{p}}{P}.$$

This inequality is the same as

$$nP \le C \cdot |\mathcal{J}_{para}| P + \frac{C}{2} |\mathcal{J}_{equi}| (|\mathcal{J}_{equi}| + 1)\bar{p}.$$

Equivalently,

$$|\mathcal{J}_{equi}| P \le (C-1) |\mathcal{J}_{para}| P + \frac{C}{2} |\mathcal{J}_{equi}| (|\mathcal{J}_{equi}| + 1)\bar{p}.$$

Since $C = 2 - \frac{2}{n+1}$, the above inequality follows from Lemma 3.1. □

4. Multiphased parallelism and interactive jobs. At any point in time some jobs are assigned a number of processors equal to their parallelism (those in full-parallelism mode) and others are assigned $\bar{p}$ processors (those in equipartition mode). Both the parallelism of the jobs and $\bar{p}$ may change over time. We continue to use the notation $\mathcal{J}(f)$ for the portion of jobs in $\mathcal{J}$ in full-parallelism mode, and $\mathcal{J}(e)$ for the portion of jobs in equipartition mode.

THEOREM 4.1. *For jobs with multiple phases of parallelism, we have*

$$TC_{DEQ}(\mathcal{J}) \leq \left(2 - \frac{2}{n+1}\right) A(\mathcal{J}(e)) + \left(2 - \frac{2}{n+1}\right) H(\mathcal{J}(f)). \tag{4.1}$$

Therefore, DEQ is $4 - \frac{4}{n+1}$ *competitive for mean job completion time.*

Proof. The conclusion of $4 - \frac{4}{n+1}$ competitiveness follows immediately from the fact that both the squashed area bound and the height bound are lower bounds on the optimal total completion time. Our focus is thus on (4.1). We consider an inductive proof using the result for single-phased jobs as the base case. A difficulty in this case is that the order of jobs in the squashed area bound may change as execution of the jobs (according to DEQ) proceed. To deal with this problem, we divide the execution time of the jobs into intervals such that in each interval, the parallelism of all jobs does not change; and the order, according to which the squashed area bound is applied, of the total remaining work to be executed under the equipartition mode of all jobs does not change. Thus between two consecutive intervals, either some job changes its parallelism or two jobs have the same amount of remaining work to be executed under the equipartition mode. We prove our claim by induction on the number of such intervals.

For the base case, the parallelism of all jobs is the same and the claim follows from our result on jobs with a single phase of parallelism in section 3. To apply the inductive proof, consider the execution of all jobs for τ time units in the interval during which no job changes its parallelism. The case with idle processors is trivial. So we assume there are no idle processors. For jobs in full-parallelism mode during this period of time (denoted by $\mathcal{J}_{para}$), their height decreases by τ. For jobs in equipartition mode during this period of time (denoted by $\mathcal{J}_{equi}$), their work decreases by $\bar{p}\tau$. Applying the induction hypothesis to the remaining portions after the first time interval, we have

$$\begin{aligned} TC_{DEQ}(\mathcal{J}) \leq n\tau + C \cdot \left[A(\mathcal{J}(e)) - \sum_{i=1}^{|\mathcal{J}_{equi}|} \frac{(n-i+1)\tau\bar{p}}{P} \right] \\ + C \cdot \left[H(\mathcal{J}(f)) - \sum_{i=1}^{|\mathcal{J}_{para}|} \tau \right], \end{aligned}$$

where $C = 2 - \frac{2}{n+1}$. The condition that the order of total work in $\mathcal{J}(e)$ does not change is crucial in the above formulation. At the end of the interval, it is possible that two jobs may be tied in the remaining portion of $\mathcal{J}(e)$. We can exchange their order without changing the squashed area bound. The new order would then be used for the next interval. To obtain our proof, it is sufficient to show

$$n\tau \leq C \cdot \sum_{i=1}^{|\mathcal{J}_{equi}|} \frac{(n-i+1)\tau\bar{p}}{P} + C \cdot |\mathcal{J}_{para}|\tau.$$

This holds if we have

$$n\tau \leq C \cdot \sum_{i=1}^{|\mathcal{J}_{equi}|} \frac{i\tau\bar{p}}{P} + C \cdot |\mathcal{J}_{para}|\tau,$$

which is equivalent to

$$nP \leq C \cdot \frac{|\mathcal{J}_{equi}|(|\mathcal{J}_{equi}|+1)\bar{p}}{2} + C \cdot |\mathcal{J}_{para}|P.$$

This can be shown in the same way as in the proof of Theorem 2.3 by applying Lemma 3.1. In fact, Lemma 3.1 holds independently of the fact that jobs contain a single phase of parallelism or multiple phases of parallelism. □

Interactive jobs can be formulated as jobs alternating between periods of being blocked while waiting for input from a user (requiring no processor), and periods of processing. Our result above also applies to such interactive jobs. We assume that users respond to each request for input in a finite amount of time. The degenerate case, where a user may not respond to an input request, is considered in detail in section 5. Thus, we have the following corollary.

COROLLARY 4.2. *DEQ is* $4 - \frac{4}{n+1}$ *competitive for the mean completion time of interactive jobs.* □

This result immediately carries over to sequential job scheduling problems and produces the same competitive ratio for the round-robin policy. However, in this case we have a better result.

THEOREM 4.3. *Round-robin is* $3 - \frac{2}{n+1}$ *competitive for the mean completion time of interactive jobs on sequential machines.*

Proof. Let $W(\mathcal{J}) = \sum_{i=1}^{n}(n-i+1)t_i$ for a job set $\mathcal{J} = \{J_1, J_2, \ldots, J_n\}$, where t_i is the cumulative time job J_i requires CPU processing, $1 \leq i \leq n$, and $t_1 \leq t_2 \leq \cdots \leq t_n$. Let $H(\mathcal{J}) = \sum_{i=1}^{n} h_i$, where h_i is the cumulative time job J_i does not require CPU processing (i.e., when it is blocked). We now show

$$TC_{RR}(\mathcal{J}) \leq \left(2 - \frac{2}{n+1}\right) W(\mathcal{J}) + H(\mathcal{J}). \tag{4.2}$$

The theorem follows from (4.2) since both $W(\mathcal{J})$ and $H(\mathcal{J})$ are lower bounds for the optimal total completion time.

In a fashion similar to the above proof of Theorem 4.1, we use the round-robin policy to divide the execution of jobs into a finite number of intervals in which the order of remaining cumulative CPU times of jobs does not change and each job is in the same phase (ready to execute or be blocked). We apply an inductive proof to the number of such intervals. The base case follows from the result of Motwani, Phillips, and Torng [22]. Consider one such interval of length τ; let K be the set of jobs ready to execute, $k = |K|$. The case $k = 0$ is trivial and we thus assume $k \geq 1$. Each such job is executed for $\frac{\tau}{k}$ time units. The cumulative blocked time for each of the other jobs is decreased by τ. Thus we have

$$TC_{RR}(\mathcal{J}) \leq n\tau + \left(2 - \frac{2}{n+1}\right)\left[W(\mathcal{J}) - \sum_{i \in K}(n-i+1)\frac{\tau}{k}\right] + H(\mathcal{J}) - (n-k)\tau,$$

which is less than or equal to $(2 - \frac{2}{n+1})W(\mathcal{J}) + H(\mathcal{J})$ if

$$n \leq \left(2 - \frac{2}{n+1}\right)\sum_{i \in K}(n-i+1)\frac{1}{k} + (n-k).$$

This last inequality holds even for the worst choice of set K. Therefore, the theorem follows. □

5. Robustness of DEQ. Competitive analysis has been successfully applied in multiple processor scheduling problems to minimize the makespan [30]. There are, however, some objections to using makespan as a computer system's performance measure. One of them is that makespan does not distinguish one policy from another. Under our model, any work-conserving policy (i.e., no processors are idle as long as there are jobs available for execution [6]) has a competitive ratio of two, which is asymptotically optimal [1]. On the other hand, when there are new arrivals and the scheduler has no a priori information about the execution time, using mean response time as the performance objective, Motwani, Phillips, and Torng [22] have shown that no scheduling policy can achieve a performance ratio that is better than $n^{1/3}$. In this case, mean response time is a performance metric that is extremely difficult to minimize without any a priori information, since the adversary is able to choose arrival times and job sizes that can defeat any scheduler. Rather than using competitive analysis one might consider using mathematical analysis or simulation to compare various scheduling algorithms. In addition, Kellerer, Tautenhahn, and Woeginger [14] have shown that mean response time is also difficult to minimize even in the presence of complete job information. Unfortunately, these approaches require either knowing or making assumptions about job arrival and execution times. The power of competitive analysis is that a positive result applies without the need to understand or justify the workload model. That is, it applies for all workloads.

Since it is not possible to obtain a positive result for minimizing the competitive ratio for mean response times when there are new arrivals, as a compromise, we examine competitive scheduling policies for minimizing makespan. These policies are robust in the presence of infinite (possibly faulty) jobs. More precisely, we assume that there are up to K infinite jobs in the system but the scheduler does not know which jobs they are. Let $T_A(\mathcal{J})$ be the completion time of the last finished finite job under the scheduling policy A. Let $OPT(\mathcal{J})$ be the optimal completion time with full information about finite jobs (and information about which are infinite jobs). Notice that from now on, $OPT(\mathcal{J})$ refers to the optimal makespan instead of mean completion time. Obviously, infinite jobs are not executed under the optimal scheduler. The competitive ratio is defined as $\max_{\mathcal{J}} \frac{T_A(\mathcal{J})}{OPT(\mathcal{J})}$.

Since the same issue arises in uniprocessor systems, we first consider this case.

THEOREM 5.1. *In a system with K infinite jobs, when there are new arrivals, the competitive ratio of the makespan of the round-robin policy is $K+1$, which is optimal.*

Proof. To show that (K+1) is a lower bound on the competitive ratio, consider a case of $K+1$ jobs including K infinite jobs and one finite job with execution time t. No matter what scheduling algorithm is used, the adversary always assigns the finite job to execute last. Thus, the total time required to complete the finite job is at least $(K+1)t$. An optimal schedule with complete information will take only t time units, running only the finite job in t time units and not even running the infinite jobs. Therefore, the competitive ratio is at least $K+1$ for any scheduling algorithm.

For the upper bound, without loss of generality, we assume that all K faulty jobs are present in the system at time t_0, and there are N other jobs, whose execution time is $x_1, x_2, \ldots, x_N$, arriving at time $t_1, t_2, \ldots, t_N$, respectively. We consider the following two cases.

Under the optimal scheduling algorithm with complete information, if new jobs always arrive before the last finite job in the system has finished, no processor will be left idle, and the optimal makespan will be $\sum_{i=1}^{N} x_i$. A round-robin scheduler will

always execute at least $\frac{1}{K+1}$ of the finite jobs, and all of the finite jobs will complete by time $\frac{1}{K+1}\sum_{i=1}^{N} x_i$. Therefore, the competitive ratio is bounded above by $K+1$ in this case.

The second case to consider under the optimal scheduling algorithm is when new jobs arrive some time after the last finite job in the system has finished execution. Let indices be defined according to job arrival orders. In this case, denote by m the maximum index when a job arrives at time t_m and finds no remaining jobs in the system (all previous jobs have completed their execution). Let $t^* = t_m$. In this case, the optimal completion time will be $OPT = t^* + \sum_{i=m}^{N} x_i$. Consider the last consecutive interval $[\tau_1, \tau_2]$, $0 \le \tau_1 < \tau_2 \le t^*$, during which there is at least one finite job executing under the round-robin policy. The total length of finite jobs arriving during this interval will be no more than $\tau_2 - \tau_1$, since an optimal scheduler (with complete information) will finish all of them. Since the round-robin policy will assign at least $\frac{1}{K+1}$ of the total processing power to one finite job whenever there is one in the system, by time τ_2 the remaining total length of jobs is no more than $\frac{K}{K+1}(\tau_2 - \tau_1) \le \frac{K}{K+1}t^*$. From then on, the processor will always devote a fraction (at least $\frac{1}{K+1}$) of its time to finite jobs. Therefore, round-robin will finish all of the finite jobs within at most $(K+1)(\frac{K}{K+1}t^* + \sum_{i=m}^{N} x_i)$ time units after t^*. Thus the completion time of all finite jobs will be at most $(K+1)(t^* + \sum_{i=m}^{N} x_i)$, which is $(K+1)OPT$. Therefore, the round-robin policy achieves a competitive ratio of $K+1$. □

A similar argument can be applied to parallel job scheduling on multiprocessors.

THEOREM 5.2. *In a multiprocessor system with new job arrivals with multiple phases of parallelism and K infinite jobs, the competitive ratio for the makespan of DEQ is $K+1$, which is the best possible competitive ratio.*

Proof. Without loss of generality, assume that all K faulty jobs are present in the system at time $t_0 = 0$, and there are N other finite jobs, $J_1, J_2, \ldots, J_N$, which arrive at time $t_1, t_2, \ldots, t_N$, respectively. Similarly, we examine the last finished finite job J_i according to the DEQ policy. Again, we divide the execution of this job J_i into two parts: let t_{para} be the total time during which the number of processors allocated to the job is equal to its parallelism, and let t_{equi} be the total time during which it is assigned its fair share of processors according to DEQ. Let W_{equi} be the total amount of work executed by J_i during the period it is assigned its fair share of processors (i.e., during t_{equi}). Since there are at most K infinite jobs, the total amount of work performed on the infinite jobs during the period when J_i is assigned its fair share of processors is no more than KW_{equi}. Let W' be the total work performed on finite jobs during the same period. Then the completion time of DEQ is bounded by $t_i + t_{para} + \frac{KW_{equi}+W'}{P}$. On the other hand, for the optimal completion time, we have $t_i + t_{para} + \frac{W_{equi}}{P} \le OPT$, which is the minimum time to complete J_i, ignoring all other jobs. Furthermore, $\frac{(K-1)W_{equi}}{P} \le (K-1)OPT$, and $\frac{W'}{P} \le OPT$. This concludes our proof that DEQ has a competitive ratio of $K+1$ when the system has new arrivals of jobs with multiple phases of parallelism. □

6. Remarks and discussion. We started our work on competitive analysis for the parallel scheduling problem by facing two obstacles with this approach: the lower bound of Deng and Koutsoupias on scheduling an arbitrary DAG [4] and the lower bound of Motwani, Phillips, and Torng for scheduling with new job arrivals. While the former points out that it is impossible to obtain a general on-line strategy that

schedules arbitrary jobs on parallel machines (with a given communication latency) near-optimally, the latter points out that it is impossible to obtain a general online preemptive strategy that schedules sequential jobs on a uniprocessor to minimize mean response time if job arrivals are unpredictable [22]. (This result can also be extended to parallel jobs.) These two results raise serious doubts about the possibility of obtaining a near-optimal scheduling strategy in realistic computing environments for parallel jobs with new arrivals.

In this paper, we avoid the first difficulty by utilizing a special class of parallel jobs. This class includes jobs with sublinear speedups by modeling them using multiple phases of parallelism. With Edmonds and Chinn we have also recently extended some of our positive results to larger classes of jobs and to models of systems which more explicitly account for communication delays [7]. It seems that the second difficulty may be much harder to overcome since it holds even for single processor scheduling. If the objective of computer system scheduling is indeed to minimize mean response time, more empirical workload studies will help to understand arrival times and job sizes in typical computer systems. (Recent work has begun to examine workload characteristics on multiprocessor systems [8], [11].) Workload information could be used to more accurately reflect typical arrival times and job sizes and to perhaps avoid scenarios that prevent competitive ratios from being obtained for algorithms that perform well in practice. Alternatively, we may study other objective functions. The explicit definition of interactive jobs introduced in this paper and the related constant competitive ratio (for minimizing makespan) is an effort in this direction. Under these conditions (including the presence of infinite jobs), the DEQ policy stands out among other parallel scheduling policies in that it achieves the optimal competitive ratio for makespan. An alternative approach to this second difficulty has been proposed by Kalyanasundaram and Pruhs [12]. They show that a moderate increase in the speed of the processor used by a nonclairvoyant scheduler can effectively give this processor power equal to clairvoyance.

A central question that must be considered when developing and comparing scheduling algorithms for multiprocessors is, What is the objective function being used to determine how well the algorithm is performing? For example, is it more desirable to minimize mean response time than to minimize makespan, or should maximizing throughput be the main goal of the scheduler? As well, real systems must also be careful to provide quick turnaround time to interactive programs. Additional consideration must also be given to the fact that in some cases knowing or deriving a competitive ratio for an algorithm does not mean that the complexity of the algorithm is acceptable or that an algorithm can be easily constructed. These issues are quite similar to solution concepts in the game theoretical framework for the study of sharing economic resources, and it might be interesting to explore possible links between them [5].

NONUNIFORM DISCRETIZATION FOR KINODYNAMIC MOTION PLANNING AND ITS APPLICATIONS*

JOHN H. REIF† AND HONGYAN WANG†

Abstract. The first main result of this paper is *a novel nonuniform discretization approximation method for the kinodynamic motion-planning problem.* The kinodynamic motion-planning problem is to compute a collision-free, time-optimal trajectory for a robot whose accelerations and velocities are bounded. Previous approximation methods are all based on a uniform discretization in the time space. On the contrary, our method employs a nonuniform discretization in the configuration space (thus also a nonuniform one in the time space). Compared to the previously best algorithm of Donald and Xavier, the running time of our algorithm reduces in terms of $1/\varepsilon$, roughly from $O((1/\varepsilon)^{6d-1})$ to $O((1/\varepsilon)^{4d-2})$, in computing a trajectory in a d-dimensional configuration space, such that the time length of the trajectory is within a factor of $(1+\varepsilon)$ of the optimal. More importantly, our algorithm is able to take advantage of the obstacle distribution and is expected to perform much better than the analytical result. This is because our nonuniform discretization has the property that it is coarser in regions that are farther from all obstacles. So for situations where the obstacles are sparse, or the obstacles are unevenly distributed, the size of the discretization is significantly smaller.

Our second main result is the *first known polynomial-time approximation algorithm for the curvature-constrained shortest-path problem in three and higher dimensions.* We achieved this by showing that the approximation techniques for the kinodynamic motion-planning problem are applicable to this problem.

Key words. robotic motion planning, nonholonomic motion planning, kinodynamic motion planning, nonuniform discretization

1. Introduction.

Nonholonomic motion planning involves planning a collision-free path (or trajectory) for a robot subject to *nonholonomic* constraints on its dynamics. A *holonomic* constraint is one that can be expressed as an equation of the robot's configuration parameters (a placement of a robot with k degrees of freedom can be uniquely specified by k such parameters), while a *nonholonomic* one can only be expressed as a *nonintegrable* equation involving also the derivatives of the configuration parameters (see [30] for a more detailed discussion on nonholonomic constraints). Examples of nonholonomic constraints are bounds on velocities, accelerations, and curvatures. Although there has been considerable recent work in the robotics literature (see [2, 3, 4, 5, 6, 7, 19, 24, 27, 28, 29, 31, 33, 34, 39, 42, 45, 47, 48] and references therein) on nonholonomic motion-planning problems, relatively little theoretical work has been done on these problems. Nonholonomic motion planning is considerably harder than holonomic. For one thing, a robot with k degrees of freedom cannot be described completely by k parameters. A complete description has to include the k parameters and their derivatives. The *configuration-space* approach, which is widely used for the holonomic motion-planning problems, does not apply to the problems with nonholonomic constraints because such constraints are not expressed by the

configuration-space representation. On the other hand, these problems bear major significance in robotic engineering. In reality, a robot arm has to move not only in a collision-free fashion, but also in conformation of the dynamic bounds due to limited force or torque from motors.

It is also desirable, in many cases, to minimize the cost of a motion plan under some cost function (e.g., path length, time length, number of turns, clearance, etc.). Finding an optimal solution is significantly harder than just finding any solutions. For example, the seemingly easy problem of finding the shortest path for a point robot in three dimensions among polyhedral obstacles is already NP-hard (see Canny and Reif [10]), even without constrained dynamics.

In this paper, we study two optimal nonholonomic motion-planning problems: the *kinodynamic motion-planning* problem and the *curvature-constrained shortest-path* problem. The kinodynamic motion-planning problem studies the problem of finding collision-free time-optimal trajectories for a robot whose motion is governed by Newtonian dynamics and whose accelerations and velocities are bounded. A *trajectory* of a robot with d degrees of freedom is a map $\Gamma\colon [0,T] \to \mathbb{R}^d \times \mathbb{R}^d$ given by $\Gamma(t) = (p(t), \dot{p}(t))$, where $p(t)$ and $\dot{p}(t)$ give the location and the velocity at time t, respectively, in a d-dimensional configuration space. $\ddot{p}(t)$ is the acceleration function, which determines a trajectory uniquely once an initial state is fixed. The constraints on dynamics are given by bounding the norms of the accelerations and velocities. The most studied norms are the L_∞-norm (called the *decoupled* case) and the L_2-norm (called the *coupled* case). In this paper, we study the coupled kinodynamic problem, which happens to be harder than the decoupled one. The decoupled case is simpler because each dimension is independent of the others, and a d-dimensional problem can be reduced to a one-dimensional (1D) one.

The curvature at one point on a path describes how fast the direction of the path changes at that point. Generally, a curvature constraint requires that a path has a curvature of at most c at every point along the path, where $c > 0$ is a given parameter. The curvature-constrained shortest-path problem is to compute a shortest collision-free path such that the path satisfies the given curvature constraint.

Our major contribution in this paper is a *nonuniform* discretization approximation method for the kinodynamic motion-planning problem. The discretization is nonuniform in the sense that it is coarser in regions which are farther from all obstacles. The intuition behind this is that in regions that are far away from all obstacles, even with a coarse discretization, we are still able to find an approximation trajectory which does not intersect obstacles. The nonuniform discretization on one hand reduces the search space and the running time, and on the other hand still enables us to obtain a collision-free trajectory whose time length is within a given factor of the optimal time length. Nonuniform discretization is widely used in solving PDEs (see Miller et al. [35, 36] and references therein), but research in that area focuses on quite different issues. Applying the idea to kinodynamic motion planning was first suggested by Xavier [49] but without a rigorous proof. As it happens, provably good bounds given by us are quite intriguing to obtain.

Our nonuniform discretization is based on a box decomposition of the configuration space. Other geometric algorithms using similar box decompositions include the work of Mitchell, Mount, and Suri [38] on ray-shooting problems and that of Hershberger and Suri [21] on two-dimensional (2D) shortest-path problems without constraints. Using nonuniform discretization for geometric planning with nonholonomic constraints presents a new challenge.

Instead of using a deterministic discretization, Kavraki et al. [25, 26] developed a *random sampling technique*, where in preprocessing, grid-points (called *milestones*) are chosen *randomly* and are connected by feasible paths to form a network. The method is similar to ours in that both do a preprocessing to obtain a set of valid paths (or trajectories) which are used later in answering planning queries. However, they have to preprocess for each new environment, where in our method, the preprocessing is only done once for some fixed parameters, and can be used repeatedly for different environments.

1.1. Previous work on the kinodynamic motion-planning problem. With the exceptions of 1D and 2D cases (see Ó'Dúnlaing [40] and Canny, Rege, and Reif [9]), there are no exact solutions for the kinodynamic motion-planning problem. In fact, as an implication of the result of [10], the problem is at least NP-hard in three and higher dimensions. In light of this lower bound, most study has been focusing on finding approximation solutions. The earlier approximation algorithms of Sahar and Hollerbach [44] did not guarantee goodness of their solutions. Moreover, the running time was exponential in the resolution. Canny et al. [8, 16] developed the first provably good, polynomial-time approximation algorithm for the decoupled kinodynamic case. Their work was followed up by a series of work in which Donald and Xavier [11, 15] improved the running time for the decoupled case, Heinzinger et al. [20] and Donald and Xavier [13, 14] investigated the problem for open chain manipulators, and independent work of Donald and Xavier [12, 13, 15] and Reif and Tate [43] gave approximation algorithms for the coupled kinodynamic problem. The best-known result for the coupled case, given by [15], is that given an $\varepsilon > 0$, one can compute in time $O(c(d)p(n, \varepsilon, d)L^d(1/\varepsilon)^{6d-1})$ an approximation trajectory whose time length is at most $(1+\varepsilon)$ times the time length of an optimal safe trajectory (roughly speaking, a safe trajectory is one that can be perturbed without intersecting obstacles), where d is the dimension, L is the size of the configuration space to which the robot is confined, n is the number of equations describing the configuration obstacles, $c(d)$ is a function depending solely on d, and $p(n, \varepsilon, d)$ is a lower-order polynomial in n, ε, and d.

1.2. Previous work on the curvature-constrained shortest-path problem. Dubins [17] was perhaps the first to study the curvature-constrained shortest paths who gave a characterization of the shortest paths in 2D in the absence of obstacles. Reeds and Shepp [41] extended the obstacle-free characterization to robots that can make reversals. (Boissonnat, Cerezo, and Leblond [4] gave an alternative proof for both cases, using ideas from control theory.) In the presence of obstacles, Fortune and Wilfong [18] gave a $2^{poly(n,m)}$-time algorithm, where n is the number of vertices and m is the number of bits of precision with which all points are specified; their algorithm only decides whether a path exists, without necessarily finding one. Jacobs and Canny [23] gave an $O((\frac{n+L}{\varepsilon})^2 + (\frac{n+L}{\varepsilon})n^2 \log n)$-time algorithm that computes an approximation path whose length is at most $(1+\varepsilon)$ times the length of an optimal path, where n is the number of obstacle vertices and L is the total edge length of the obstacles. This running time was later improved significantly by Wang and Agarwal [46] to $O((n^2/\varepsilon^2)\log n)$. Agarwal, Raghavan, and Tamak [1] studied a special case when the boundaries of obstacles are also constrained to have a curvature of at most 1. There has also been work on computing curvature-constrained paths when the robot is allowed to make reversals [2, 32, 37]. However, no result has been obtained for the curvature-constrained problem in three or higher dimensions, even in the absence of obstacles.

1.3. Models and results. Let B be a point robot moving in a d-dimensional configuration space. The velocity of B is bounded by $v_{\max}$ in L_2-norm and the acceleration of B is bounded by $a_{\max}$ in L_2-norm, where $v_{\max} > 0$ and $a_{\max} > 0$ are arbitrary. In section 2.7, we show that we can always scale $v_{\max}$ and $a_{\max}$ to 1 by scaling both time and the size of the configuration space. Therefore, without loss of generality, we will set $v_{\max} = 1$ and $a_{\max} = 1$.

A *state* x of B is a pair $(\text{LOC}(x), \text{VEC}(x))$, where $\text{LOC}(x)$ is a point representing the location of B in the d-dimensional configuration space and $\text{VEC}(x)$ is a vector representing the velocity of B. A trajectory is an $(\bar{a}, \bar{v})$-trajectory if at any time during the trajectory, the acceleration is bounded by $\bar{a}$ and the velocity is bounded by $\bar{v}$, both in L_2-norm. Thus only $(1, 1)$-trajectories are valid trajectories for robot B. Let Ω be a set of configuration obstacles. A trajectory is *collision free* if its path does not intersect the interior of Ω. A trajectory from state x to state y is *optimal* if it is a collision-free $(1, 1)$-trajectory with a minimum time length, where the minimum is taken over all collision-free $(1, 1)$-trajectories from x to y. The kinodynamic motion-planning problem is to compute such optimal trajectories.

Since we have seen that computing exact solutions is hard, we focus on developing fast approximation algorithms. To discuss approximation solutions, the notion of a safe trajectory needs to be introduced. A point p has a *clearance* of μ if for any point $q \in \Omega$, $\|p - q\|_\infty \geq \mu$, where $\|\cdot\|_\infty$ denotes the L_∞-norm operation. A path is *μ-safe* if for any point p along the path, p has a clearance of μ. A trajectory is a *μ-safe trajectory* if its path is μ-safe. A trajectory is an *optimal μ-safe* trajectory from state x to state y if its time length is the minimum over all μ-safe $(1, 1)$-trajectories from x to y.

The first main result of this paper is a faster algorithm for computing approximations to optimal safe trajectories. Let W be a d-dimensional configuration space of size L (without loss of generality, we can assume that W is a d-dimensional cube), where the point robot is confined to move. Let Ω be a set of configuration obstacles defined by a total of n algebraic equations, each of $O(1)$ degrees. Given the initial and the final states i and f and two parameters $l > 0$ and $\varepsilon > 0$, we can compute an approximation to the optimal $3l$-safe $(1, 1)$-trajectory from i to f in time $O(nN + N \log N(1/\varepsilon)^{4d-2})$, where $N = O((L/l)^d)$. The time length of the computed trajectory is at most $(1 + \varepsilon)$ times the time length of the optimal trajectory. The computed trajectory connects two states which are close to i and f, respectively. More precisely, if the computed trajectory is from state i' to state f', then $\|\text{LOC}(i') - \text{LOC}(i)\|_\infty \leq \varepsilon l$, $\|\text{VEC}(i') - \text{VEC}(i)\|_\infty \leq \varepsilon$, $\|\text{LOC}(f') - \text{LOC}(f)\|_\infty \leq \varepsilon l$, and $\|\text{VEC}(f') - \text{VEC}(f)\|_\infty \leq \varepsilon$.

Here we introduce two parameters ε and l, which are independent except that in general $\varepsilon < l$. ε describes how close the approximation should be to the optimal safe trajectory in time, while l describes how safe the optimal trajectory is. If we require that l be as small as ε, the running time of our algorithm in terms of ε is roughly $O((1/\varepsilon)^{5d-2})$, which improves over the running time $O((1/\varepsilon)^{6d-1})$ of the previously best algorithm of Donald and Xavier. If we choose a big l, our algorithm may fail to find a trajectory because $3l$-safe trajectories connecting the initial state to the final state may not exist due to, for example, the crowded obstacles. However, we can still choose the parameters such that $l \gg \varepsilon$, with both parameters being small. In this case, the running time of our algorithm in terms of ε is $O((1/\varepsilon)^{4d-2})$. Moreover, because of our nonuniform discretization, there are cases when the number of boxes is much smaller than the worst-case bound of $N = O((L/l)^d)$. In these cases, our

algorithm is expected to perform much better than the given time bound. Such cases include sparse obstacle distributions and uneven obstacle distributions. As will be pointed out in the conclusion section, one future work is to look for more accurate bounds on the number of boxes with respect to different obstacle distributions.

By showing that the approximation techniques for kinodynamic motion planning are applicable to the curvature-constrained shortest-path problem, we are able to obtain the second main result of this paper—the first known polynomial-time approximation algorithm for the curvature-constrained shortest-path problem in three and higher dimensions. The detailed model and result are presented in section 3.

2. The kinodynamic motion-planning problem.

2.1. Preliminaries. In this paper, we generally use $\|\cdot\|_\infty$ to denote the L_∞-norm operation and $\|\cdot\|$ the L_2-norm one.

Given a trajectory Γ, let $T(\Gamma)$ be the time length of Γ. Let $p_\Gamma(t), v_\Gamma(t), a_\Gamma(t)$ for $0 \le t \le T(\Gamma)$ be the location, the velocity, and the acceleration of Γ, respectively, at time t.

Let Π be a path and A a subset of the configuration space. We say that $d(\Pi, A) \le \rho$ for some real number $\rho \ge 0$ if for every point $p \in \Pi$, there is a point $q \in A$ such that $\|p - q\|_\infty \le \rho$. $d(\Pi, A) = 0$ if every point $p \in \Pi$ is also in A. Similarly, for two paths Π and Π', we say that $d(\Pi', \Pi) \le \rho$ if for every point $p \in \Pi'$, there is a point $q \in \Pi$ such that $\|p - q\|_\infty \le \rho$. Let Γ and Γ' be two trajectories and let Π and Π' be the paths of Γ and Γ', respectively. $d(\Gamma', \Gamma) \le \rho$ if $d(\Pi', \Pi) \le \rho$. Also $d(\Gamma', A) \le \rho$ if $d(\Pi', A) \le \rho$, where A is a subset of the configuration space.

For a state x, define

$$ngb(x, \rho, \nu) = \{x' \mid \|\textsc{loc}(x') - \textsc{loc}(x)\|_\infty \le \rho \text{ and } \|\textsc{vec}(x') - \textsc{vec}(x)\|_\infty \le \nu\}$$

for some $\rho, \nu > 0$. Thus $ngb(x, \rho, \nu)$ defines a set of states which are close to x. Notice that if $x' \in ngb(x, \rho, \nu)$, then $x \in ngb(x', \rho, \nu)$.

Lemma 2.1 (time-rescaling lemma, Hollerbach [22]). *Let Π be the path of an $(\bar{a}, \bar{v})$-trajectory Γ. Π can be traversed by an $(\bar{a}/(1+\varepsilon)^2, \bar{v}/(1+\varepsilon))$-trajectory Γ' in time $(1+\varepsilon)\,T(\Gamma)$ for any $\varepsilon > 0$.*

The time-rescaling lemma shows a trade-off between time and the dynamic bounds. Later we will see that in our approximation algorithm, we first compute a trajectory whose acceleration and velocity bounds are slightly bigger than 1. Then applying the time-rescaling lemma, we can reduce the dynamic bounds to 1 by sacrificing the time length by a small factor.

The TC-graph method developed in [13] by Donald and Xavier applies a graph-searching technique to compute approximations to time-optimal trajectories (for a brief description of the method, see the appendix). The following corollary states a result of the TC-graph method.

Corollary 2.2 (see [13]). *Let W be a d-dimensional configuration space of size L. Let Γ be a $(1,1)$-trajectory from state i to state f such that Γ lies inside W. Given any $\varepsilon > 0$ and $\rho = O(1)$, applying the TC-graph method with appropriate parameters, we can compute in time $O(L^d(1/\varepsilon)^{6d-1})$ a $(1,1)$-trajectory Γ' from a state i' to a state f' such that $i' \in ngb(i, \varepsilon\rho/2, \varepsilon/2)$, $f' \in ngb(f, \varepsilon\rho/2, \varepsilon/2)$, $T(\Gamma') \le (1+\varepsilon)\,T(\Gamma)$, and $d(\Gamma', W) \le \varepsilon\rho/2$.*

The above corollary states that by applying the TC-graph method, one can compute in polynomial time (in terms of L and ε) a trajectory which obeys the dynamic constraints and which approximates the given trajectory in the following ways. The

computed trajectory connects two states which are close to the given initial and final states, respectively. The time length of the computed trajectory is within $(1+\varepsilon)$ times that of the given trajectory. Also the path of the computed trajectory stays close to the region W, within which the path of the given trajectory lies.

We will see that in later sections we apply the TC-graph method to precompute a set of trajectories which in turn become the building-block trajectories in our approximation method. Here we present the result for cases where there are no obstacles. This is sufficient for our purpose, though the TC-graph method works also in the presence of obstacles.

In the rest of the paper, we fix $l > 0$ and $\epsilon > 0$ unless otherwise stated, where l gives the size of the smallest box in the box decomposition and ϵ describes the fineness of the discretization.

2.2. Overview of the algorithm. Following the framework of many motion-planning algorithms, our algorithm reduces the problem to that of computing and then searching on a graph. The nodes of the graph correspond to a set of states (see section 2.3) which are induced by a nonuniform discretization over the configuration space. Therefore, we term our method the CS-graph method, where C stands for the configuration space and S the state space.

Section 2.5 describes how to compute the edge set of the graph. Each edge corresponds to a collision-free, near-optimal trajectory between two nodes. It is shown in this section that the graph satisfies the property that if there is an optimal safe trajectory, then there exists a path in the graph that corresponds to a collision-free trajectory whose time length is near optimal. Thus the problem is reduced to a shortest-path search on the computed graph.

In order to compute the edge set efficiently, we perform precomputations. We derive a set of canonical trajectories (section 2.4), which are sufficient for building the graph. These trajectories, once computed, can be used repeatedly for different problem instances with different distributions of obstacles.

A technical lemma, the correcting lemma (Lemma 2.15), is described in section 2.6. This lemma is a precise statement of our intuition that the discretization can be coarser in regions farther away from all obstacles.

2.3. Nonuniform grids. The set of nonuniform grids is generated based on a box decomposition of the configuration space (see section 2.3.1). The decomposition is such that the size of a box is roughly proportional to the smallest distance between the box and the obstacles. Each box contributes the same number of grids, despite its size; the distances among grids induced by larger boxes are larger. Thus the grids are nonuniform (see section 2.3.2).

2.3.1. A box decomposition. Let $\tilde{\Xi}(s)$ be a set $\{p = (p_1, \ldots, p_d) \mid -s/2 \le p_1, \ldots, p_d \le s/2\}$. $\tilde{\Xi}(s)$ is called a d-dimensional *canonical box* of size s. Each set of $\{p \mid p \in \tilde{\Xi}(s) \text{ and } p_j = -s/2\}$ and $\{p \mid p \in \tilde{\Xi}(s) \text{ and } p_j = s/2\}$ for $1 \le j \le d$ is called a *face* (of size s) of $\tilde{\Xi}(s)$. Ξ is a d-dimensional *box* of size s if it is a region which can be obtained from $\tilde{\Xi}(s)$ by translation and rotation (reflection is not necessary because of the symmetry of the box). Similarly we can define the faces of Ξ. Notice that a face of a d-dimensional box Ξ of size s is really a $(d-1)$-dimensional box of size s. A d-dimensional box has $2d$ faces.

Given a d-dimensional box of size s, we can decompose it into 2^d boxes, each of size $s/2$. Each of them can be further decomposed into 2^d boxes of size $s/4$ and so on. We stop further decomposing until certain conditions hold. We refer to this procedure,

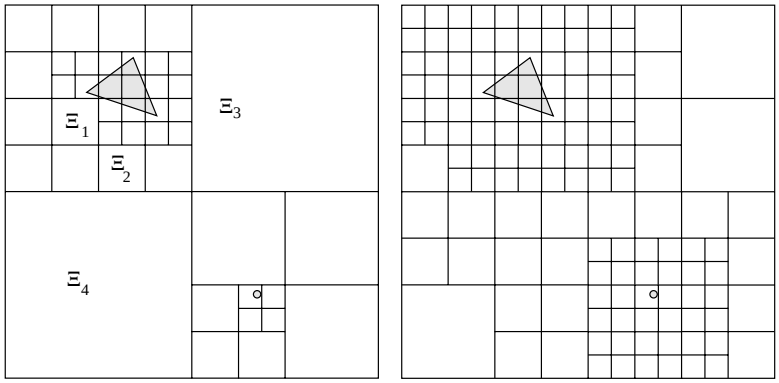

FIG. 2.1. (a) *A box decomposition satisfying* C1; (b) *one also satisfying* C2 *and* C3.

as well as the collection of nondecomposed boxes obtained, as a *box decomposition*. When we refer to a box of a decomposition, we mean a nondecomposed box.

Let W be a d-dimensional configuration space (assuming without loss of generality that W is a d-dimensional box) of size L, with a set Ω of configuration obstacles. (We consider the initial and final locations also as obstacle vertices.) A box is *free* if it does not intersect the interior of Ω. A box is *occupied* if it is a subset of Ω. Otherwise a box is called *partially occupied*. A box B_1 is *adjacent* to a box B_2 (or B_1 and B_2 are *neighbors*) if B_1 and B_2 share common points. We perform a box decomposition on W until the following conditions are satisfied:

C1. The size of every partially occupied box is l.

C2. If a free box is adjacent to a nonfree box, or to a free box with nonfree boxes as neighbors, its size is l.

C3. The decomposition is *balanced*, i.e., a free box has only adjacent free boxes whose sizes are either twice as large or half as small.

Figure 2.1 shows an example of a box decomposition in two dimensions. The shaded triangle is an obstacle, and the shaded disk represents the initial location. Figure 2.1(a) gives a box decomposition only satisfying C1. In Figure 2.1(b), boxes are further decomposed to satisfy C2 (e.g., boxes Ξ_1 and Ξ_2) and C3 (e.g., boxes Ξ_3 and Ξ_4).

We use a tree structure to represent the box decomposition, where an internal node represents a decomposed box and a leaf node a nondecomposed one. Each internal node has 2^d children. We can perform the box decomposition in two stages. In the first stage, decompose until C1 is satisfied. Let M be the number of boxes obtained after this stage. It is easy to see that this stage can be computed in time $O(nM)$, where n is the number of obstacle constraints. In the second stage, we further decompose certain boxes until C2 and C3 are satisfied. Basically, we check all the leaf nodes in a bottom-up manner, working from small boxes to large ones. For each leaf node, find its neighbors and further decompose them if their sizes are too large. Let N be the size of the final box decomposition. We claim that the time spent in this stage is $O(Nlog(L/l))$. Since the size of the smallest box is l, the box-decomposition tree has a depth of $O(\log(L/l))$. Thus finding the neighbors of a box takes at most $O(\log(L/l))$ time. Since we find neighbors for at most N boxes, the total running time is $O(N \log(L/l))$.

Notice that in the worst case, $N = O((L/l)^d)$, but N tends to be much smaller for cases where the obstacles are sparse.

Let $\mathcal{B}$ be the final box decomposition of W. Later, when we refer to a box (resp., a face) of $\mathcal{B}$, we mean a nondecomposed box (resp., face) of $\mathcal{B}$.

2.3.2. Discretization. Let $\mathcal{B}$ be the box decomposition of W (with respect to Ω) satisfying C1–C3. For each face Δ of $\mathcal{B}$ such that Δ is not further decomposed (recall that Δ is a $(d-1)$-dimensional box), we select $(2/\epsilon)^{d-1}$ uniformly spaced points on Δ, with spacing $\epsilon s/2$, where s is the size of Δ. The set of points obtained in this way are called the *CS grid points* of $\mathcal{B}$. Notice that the number of grid points on each face is the same, while the spacing of grid points grows linearly with the size of the faces. Thus we obtain a nonuniform discretization of the configuration space.

Let

$$\mathcal{V} = \{v = (j_1\epsilon, \ldots, j_d\epsilon) \mid j_1, \ldots, j_d \in \mathbb{Z} \text{ and } \|v\| \leq 1\}. \tag{2.1}$$

$\mathcal{V}$ is called the set of *grid velocities*. A state a is called a *CS grid state* of $\mathcal{B}$ if $\textsc{loc}(a)$ is a *CS* grid point of $\mathcal{B}$ and $\textsc{vec}(a) \in \mathcal{V}$. The grid states of $\mathcal{B}$ (including the initial and the final states) are the nodes of the graph to be constructed.

For a state a that lies on a face Δ, let $s(a)$ be the function returning the size of the face Δ. Define $ngb(a) = ngb(a, \epsilon s(a)/4, \epsilon/2)$. By the construction of the grid states, it is easy to show the following result.

LEMMA 2.3. *If a is a state such that $\textsc{loc}(a)$ lies on a face Δ of $\mathcal{B}$, there exists a CS grid state a' such that $a \in ngb(a')$.*

2.4. Precomputing canonical trajectories. In this section, we derive a set of *canonical trajectories*, which once computed can be used repeatedly for different problem instances with different obstacle distributions. These canonical trajectories are from grid states to grid states which lie on the faces of an *extended box*. The extended boxes are to guarantee that each canonical trajectory has a length at least proportional to the size of the box it lies in (see section 2.4.1). Section 2.4.2 describes the canonical trajectories and how to compute them.

2.4.1. Extended boxes. Let $\mathcal{B}$ be the box decomposition of W. Given a state a, define $\xi(a)$ to be the *extended box* of a, which is the smallest region composed of boxes such that (i) the boundary of the union of these boxes forms a closed $(d-1)$-dimensional surface and (ii) for any point q that lies on the closed surface, $\|\textsc{loc}(a) - q\|_\infty \geq s(a)/2$.

Let Δ be a face of $\mathcal{B}$ of size s and let Ξ be the box that contains Δ (pick one arbitrarily if both of the two boxes containing Δ have size s). Decompose Δ into 2^{d-1} $(d-1)$-dimensional boxes, each of size $s/2$, and label them $\Delta_1, \ldots, \Delta_{2^{d-1}}$. Given any two states a and b, if both $\textsc{loc}(a)$ and $\textsc{loc}(b)$ lie in the interior of Δ_j, then $\xi(a)$ and $\xi(b)$ are the same. This implies that we can extend the definition of extended boxes for faces. Define $\xi(\Delta_j)$ to be the extended boxes of Δ_j, which are the same as the extended boxes of $\xi(a)$, for any state a such that $\textsc{loc}(a)$ lies in the interior of Δ_j. $\xi(\Delta_j)$ is called an extended box of *size* $s/2$, since Δ_j is a face of size $s/2$.

An extended box (resp., a box) is said to have a *clearance* of μ if for any point p that lies in the extended box (resp., the box), p has a clearance of μ. Notice that a free box has a clearance of s if all its neighbors are free boxes and have a size of at least s. The following two lemmas describe the clearance properties of extended boxes of different sizes.

LEMMA 2.4. *An extended box of size $s \geq 2l$ has a clearance of at least $s/2$; an extended box of size l has a clearance of at least l.*

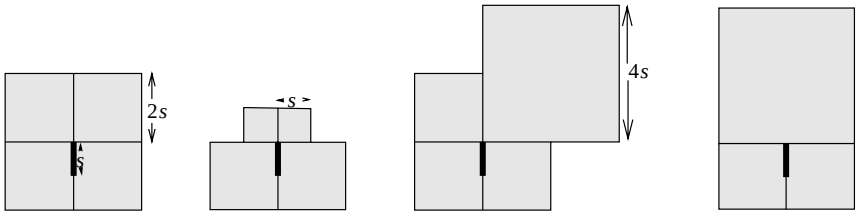

FIG. 2.2. *Some canonical extended boxes of* $\tilde{\Delta}(s)$*, where* $\tilde{\Delta}(s)$ *is a line segment drawn in thick lines.*

Proof. Suppose that the extended box is an extended box of face Δ_j whose size is s. Let Ξ be the box containing Δ_j and the size of Ξ be $2s$. Each other box in the extended box is a neighbor of Ξ. Thus their sizes are at least s, by the balanced property of the box decomposition.

If $s \geq 2l$, for any box Ξ' in the extended box, its neighbors must have sizes $\geq s/2$. By property C2 of the box decomposition, these neighbor boxes must be free. Otherwise, the size of Ξ' cannot be larger than l. Thus Ξ' has a clearance of $\geq s/2$. This implies that the extended box has a clearance of $\geq s/2$.

If $s = l$, then Ξ is a box of size $2l$. Since the box decomposition satisfies C2, we know that all Ξ's neighbors and all their neighbors are free boxes whose sizes are at least l. This implies that the extended box has a clearance of l. This completes the proof. □

LEMMA 2.5. *Let* $\xi(\Delta_j)$ *be an extended box of a face* Δ_j *of size* $l/2$*. If there exists a point* p *on* Δ_j *such that* p *has a clearance of* $3l$*, then the clearance of the extended box is at least* l*.*

Proof. It suffices to prove that for each point q on the boundary of $\xi(\Delta_j)$, q has a clearance of l. If q lies on the face of a box of size l, then $\|q - p\|_\infty \leq 2l$. Since the clearance of p is $3l$, the clearance of q is at least $3l - 2l = l$. If q lies on the face of a box of size $\geq 2l$, its clearance is at least l, since the clearance of this box is at least l. □

Let $\tilde{\Delta}(s/2) = \{p = (p_1, \ldots, p_d) \,|\, p_1 = -s/2 \text{ and } 0 \leq p_2, \ldots, p_d \leq s/2\}$. $\tilde{\Delta}(s/2)$ is called the *canonical face* of size $s/2$. We can transform Δ_j, Ξ, and $\xi(\Delta_j)$ by translation, rotation, and reflection such that Ξ becomes $\tilde{\Xi}(s)$, the canonical box of size s, and Δ_j becomes $\tilde{\Delta}(s/2)$. The transformed extended box $\xi(\Delta_j)$ is called a *canonical extended box* of $\tilde{\Delta}(s/2)$, or a canonical extended box of size $s/2$. Since the box decomposition $\mathcal{B}$ is balanced, the number of canonical extended boxes of a fixed size is a function depending only on the number of dimensions d, but not on the size or the location. Let $\xi(s)$ be the set of canonical extended boxes of $\tilde{\Delta}(s)$. We can give an order to $\xi(s)$ and let $\xi(s, j)$ be the jth canonical extended box of $\tilde{\Delta}(s)$ for some valid j. Figure 2.2 gives some examples of canonical extended boxes in two dimensions.

Let $\mathcal{P}(s)$ be the set of $(1/\epsilon)^{d-1}$ uniformly spaced points on $\tilde{\Delta}(s)$ with spacing ϵs. Define $\mathcal{Q}(s, j)$ as follows. If Δ is a face of size s' belonging to the boundary of $\xi(s, j)$, include the set of $(2/\epsilon)^{d-1}$ uniformly spaced points with spacing $\epsilon s'/2$ on Δ in $\mathcal{Q}(s, j)$. Let $\mathcal{I}(s) = \mathcal{P}(s) \times \mathcal{V}$ and $\mathcal{F}(s, j) = \mathcal{Q}(s, j) \times \mathcal{V}$. A state in the set $\mathcal{I}(s)$ is called a *canonical starting state* and a state in the set $\mathcal{F}(s, j)$ is called a *canonical ending state* of $\xi(s, j)$. It is easy to see that $|\mathcal{I}(s)| = O((1/\epsilon)^{2d-1})$. It also holds that $|\mathcal{F}(s, j)| = O(d(1/\epsilon)^{2d-1})$. This is because of the balanced property of the box decomposition. The boundary of $\xi(s, j)$ can contain at most $O(d)$ faces, each contributing $O((1/\epsilon)^{2d-1})$ states.

2.4.2. Computing connection tables. Let $\xi(s,j)$ be the jth canonical extended box of $\tilde{\Delta}(s)$ for some valid s and j. Let $CT(s,j)$ be the *connection table* of $\xi(s,j)$. The connection table contains precomputed trajectories which connect canonical starting states and canonical ending states. In this section we describe how to compute the connection tables.

First we introduce our correcting lemma (whose proof can be found in section 2.6), which states a result essential to the proofs of other lemmas.

LEMMA 2.6 (correcting lemma). *Fix a constant $c \leq 1$ and let $\rho_c = \bar{v}^2/(c\bar{a})$, where $\bar{a}, \bar{v} > 0$ are arbitrary. Let Γ be an $(\bar{a},\bar{v})$-trajectory from i to f. Given any $\rho > 0$ and $\varepsilon > 0$ and given any two states g and h, if $\rho > \rho_c$, $\|\text{LOC}(f) - \text{LOC}(i)\|_\infty \geq \rho$, $g \in ngb(i, \varepsilon\rho/2, \varepsilon\bar{v}/2)$, and $h \in ngb(f, \varepsilon\rho/2, \varepsilon\bar{v}/2)$, we can construct a trajectory Γ' from g to h by correcting Γ such that Γ' satisfies the following properties:*

P1. $T(\Gamma') = T(\Gamma)$.

P2. *Γ' is a $((1+4c\sqrt{d}\varepsilon)^2\bar{a}, (1+4c\sqrt{d}\varepsilon)\bar{v})$-trajectory.*

P3. $d(\Gamma', \Gamma) \leq (17/16)\varepsilon\rho$.

Here onwards, we fix

$$c = \max(2/l, 1), \tag{2.2}$$

where l is the size of the smallest box. In our later application of this lemma, it always holds that $\bar{v}^2/\bar{a} = 1$, thus $\rho_c = 1/c$. This implies that

$$l/2 \geq \rho_c. \tag{2.3}$$

Also let

$$e = 4c\sqrt{d}. \tag{2.4}$$

Consider a pair of states (i,f) that lie on the boundary of an extended box ζ. A $(1,1)$-trajectory from i to f is called *legal* if its path lies inside ζ. The pair (i,f) is *legal* if there exists at least a legal trajectory from i to f. We will see later that these legal trajectories are the potential trajectories that we need to approximate. We call a pair of grid states (i,f) *good* if there exists at least a legal pair (g,h) such that $g \in ngb(i)$ and $h \in ngb(f)$. Recall that $ngb(i) = ngb(i, \epsilon s(i)/4, \epsilon/2)$, where $s(i)$ gives the size of the face where the location of state i lies. Roughly speaking, the next lemma (existence lemma) states that if (i,f) is a good pair, then there *exists* a trajectory Γ from i to f such that Γ approximates *any* legal trajectories for any legal pair (g,h), where $g \in ngb(i)$ and $h \in ngb(f)$. Thus for our purpose of approximation, it is enough to compute only the trajectories for good pairs. For a pair of legal states (a,b), let $\hat{T}(a,b)$ be the time length of the legal trajectory from a to b whose time length is the smallest among all legal trajectories from a to b.

LEMMA 2.7 (existence lemma). *Let $\xi(s,j)$ be the jth canonical extended box of $\tilde{\Delta}(s)$ for some valid s and j. For any $i \in \mathcal{I}(s)$ and $f \in \mathcal{F}(s,j)$, if (i,f) is good, then there exists a trajectory Γ from i to f such that the trajectory satisfies the following properties:*

P1. *For any $i' \in ngb(i)$ and $f' \in ngb(f)$, if (i',f') is legal, $T(\Gamma) \leq \hat{T}(i',f')$.*

P2. *Γ is a $((1+e\epsilon)^2, (1+e\epsilon))$-trajectory.*

P3. $d(\Gamma, \xi(s,j)) \leq (17/8)\epsilon s$.

Proof. Let $g \in ngb(i)$ and $h \in ngb(f)$ be such that (g,h) is legal and that $\hat{T}(g,h)$ is the smallest among those of all such legal pairs;let Γ' be the $(1,1)$-trajectory from g

to h whose time length is $\hat{T}(g,h)$. We will show the existence of a trajectory satisfying P1–P3 by constructing one from Γ'. There are three cases depending on whether $s(f)$ (the size of the face where f lies) is s, $2s$, or $4s$. We will prove the case when $s(f) = 4s$; this case gives the worst bounds. The other two cases can be handled in a similar way.

Let Γ be the trajectory obtained by correcting Γ'. Let $\bar{a} = 1$, $\bar{v} = 1$, and $\rho = 2s$ in the correcting lemma (Lemma 2.6). Since $s \geq l/2$, $\rho = 2s \geq l > \rho_c$. We can show that $\|\textsc{loc}(h) - \textsc{loc}(g)\|_\infty \geq 2s = \rho$. Since $g \in ngb(i)$, $g \in ngb(i, \epsilon\, s(i)/4, \epsilon/2)$. Since $\rho = 2s = s(i)$, it is also true that $g \in ngb(i, \epsilon\rho/2, \epsilon/2)$. This implies that $i \in ngb(g, \epsilon\rho/2, \epsilon/2)$. Similarly, $f \in ngb(h, \epsilon\rho/2, \epsilon/2)$. Thus the conditions of the correcting lemma are satisfied. This implies that $T(\Gamma) \leq \hat{T}(g,h)$, satisfying P1. Γ is a $((1+e\epsilon)^2, (1+e\epsilon))$-trajectory, and $d(\Gamma, \Gamma') \leq (17/16)\epsilon\rho = (17/8)\epsilon s$. Since $d(\Gamma', \xi(s,j)) = 0$, $d(\Gamma, \xi(s,j)) \leq (17/8)\epsilon s$, proving P3. □

For a good pair (i,f) (with respect to $\xi(s,j)$), our goal is to approximate (since we do not know how to compute exactly) such a trajectory Γ as stated in the existing lemma (Lemma 2.7). The approximation is done in two steps. First, we apply the TC-graph method to compute a trajectory Γ' which is close to Γ timewise and spatially. However, the TC-graph method does not guarantee that Γ' is from i to f. Instead, we only know that Γ' is from some i' close to i to some f' close to f. Second, we correct Γ' to obtain a trajectory Γ'' which is really from i to f. By the correcting lemma, Γ'' approximates Γ', and thus approximates Γ. In the first step, by setting $\rho = l/2$ and $\varepsilon = \epsilon$ in Corollary 2.2, we are able to guarantee that

- Γ' is a $((1+e\epsilon)^2, (1+e\epsilon))$-trajectory. (Notice that even though Corollary 2.2 is about $(1,1)$-trajectories, the results apply to $((1+e\epsilon)^2, (1+e\epsilon))$-trajectories.)
- $T(\Gamma') \leq (1+\epsilon)T(\Gamma)$.
- Γ' is from some $i' \in ngb(i, \epsilon l/4, \epsilon/2)$ to some $f' \in ngb(f, \epsilon l/4, \epsilon/2)$.
- $d(\Gamma', \xi(s,j)) \leq (17/8)\epsilon s + \epsilon l/2$. The existence of a trajectory satisfying this condition in the TC graph is due to the fact that $d(\Gamma, \xi(s,j)) \leq (17/8)\epsilon s$ and to the existence of a trajectory $\tilde{\Gamma}$ in the graph such that $d(\tilde{\Gamma}, \Gamma) \leq \epsilon l/2$.

In the second step, setting $\bar{a} = (1+e\epsilon)^2$, $\bar{v} = 1 + e\epsilon$, and $\rho = l/2 \geq \rho_c$, we can see that the conditions of the correcting lemma are satisfied. Thus Γ'' is a $((1+e\epsilon)^4, (1+e\epsilon)^2)$-trajectory, $T(\Gamma'') = T(\Gamma') \leq (1+\epsilon)T(\Gamma)$, and $d(\Gamma'', \Gamma') \leq (17/32)\epsilon l$. Since $d(\Gamma', \xi(s,j)) \leq (17/8)\epsilon s + \epsilon l/2$, $d(\Gamma'', \xi(s,j)) \leq (17/8)\epsilon s + (33/32)\epsilon l \leq 5\epsilon s$ (using the fact that $s \geq l/2$). In summary, we obtain the following result.

LEMMA 2.8 (loose-tracking lemma). *Let $\xi(s,j)$ be the jth canonical extended box of $\tilde{\Delta}(s)$ for some valid s and j. Let $i \in \mathcal{I}(s)$ and $f \in \mathcal{F}(s,j)$. If (i,f) is good, then Γ'' computed as above satisfies the following properties:*

P1. *For any $g \in ngb(i)$ and $h \in ngb(f)$, if (g,h) is legal, $T(\Gamma'') \leq (1+\epsilon)\,\hat{T}(g,h)$.*

P2. *Γ'' is a $((1+e\epsilon)^4, (1+e\epsilon)^2)$-trajectory.*

P3. *$d(\Gamma'', \xi(s,j)) \leq 5\epsilon s$.*

Fix a canonical extended box $\xi(s,j)$ for some valid s and j. For each $i \in \mathcal{I}(s)$ and $f \in \mathcal{F}(s,j)$, we precompute a trajectory from i to f as described above. We store the trajectory (i.e., the initial state i, the final state f, the acceleration function, and the time length) in the connection table $CT(s,j)$. A connection table computed in this way satisfies the following property.

LEMMA 2.9 (connection-table property). *Let $\xi(s,j)$ be the jth canonical extended box of $\tilde{\Delta}(s)$ for some valid s and j and let $CT(s,j)$ be the connection table for $\xi(s,j)$. For any canonical starting state $i \in \mathcal{I}(s)$ and any canonical ending state $f \in \mathcal{F}(s,j)$, if (i,f) is good, then $CT(s,j)$ contains a trajectory Γ from i to f and Γ satisfies the*

following properties:

P1. *For any* $g \in ngb(i)$ *and* $h \in ngb(f)$*, if* (g,h) *is good,* $T(\Gamma) \leq (1+\epsilon)\,\hat{T}(g,h)$.

P2. Γ *is a* $((1+e\epsilon)^4, (1+e\epsilon)^2)$*-trajectory.*

P3. $d(\Gamma, \xi(s,j)) \leq 5\epsilon s$.

Let $\xi(l/2,0)$ be the canonical extended box that consists of four boxes of size l. Apart from $CT(l/2,0)$, we maintain a special connection table CT_0 for this canonical extended box. For each $i \in \mathcal{I}(l/2)$, we construct a TC graph G rooted at i (for a description of the TC-graph method, see the appendix). We add a trajectory Γ from i to f in CT_0, if (i) f is a node of G, (ii) f either lies inside $\xi(l/2,0)$ or its L_∞ distance to the extended box is no more than $\epsilon l/2$, (iii) there is a path on G from i to f (whose corresponding trajectory is Γ). By the property of the TC-graph method, we can show the following.

LEMMA 2.10. *Let* $i \in \mathcal{I}(l/2)$*. For any pair of states* g *and* h *such that* $g \in ngb(i, \epsilon l/2, \epsilon/2)$*,* h *lies inside* $\xi(l/2,0)$*, and the optimal* $(1,1)$*-trajectory from* g *to* h *lies inside* $\xi(l/2,0)$*, there exists a* $(1,1)$*-trajectory in* CT_0 *from* i *to some* f *such that* $f \in ngb(h, \epsilon l/2, \epsilon/2)$ *and the time length of this trajectory is no more than* $(1+\epsilon)$ *times the time length of the optimal* $(1,1)$*-trajectory from* g *to* h*.*

To correct a trajectory takes only $O(1)$ time, since it basically involves computing and adding $O(1)$ number of corrective acceleration terms (see section 2.6). So the time complexity of computing a connection table $CT(s,j)$ is determined by how fast we can compute a trajectory Γ' for each pair of canonical starting and ending states. We can compute the trajectories using the TC-graph method in the following manner. For each canonical starting state i, compute the TC graph rooted at i. Expand the graph until all the canonical ending states of $\xi(s,j)$ are reached, or no new nodes can be added. A shortest graph path from i to a canonical ending state gives a trajectory between these two states. All these paths can be stored in a concise way by storing at each node its preceding node along the paths. Since the extended box is of size s, the graph has $O(s^d(1/\epsilon)^{6d-1})$ edges. (For a brief analysis on the number of TC-graph edges, see the end of the appendix.) This also bounds the time and space for computing the trajectories for a single canonical starting state. Since there are $O((1/\epsilon)^{2d-1})$ canonical starting states for an extended box, it takes $O(s^d(1/\epsilon)^{8d-2})$ time and space to compute a connection table $CT(s,j)$. A similar analysis shows that CT_0 can also be computed in $O(l^d(1/\epsilon)^{8d-2})$ time and space.

2.5. Approximation in the presence of obstacles.

2.5.1. The algorithm. In this section we present our approximation algorithm for computing collision-free near-optimal trajectories in the presence of obstacles. Let W be a d-dimensional configuration space of size L with a set Ω of obstacles. Let i and f be the initial and the final states, respectively. And let $\mathcal{B}$ be the box decomposition of W satisfying C1–C3 (recall that we presented C1–C3 and how to obtain such a box decomposition in section 2.3.1). Our approximation algorithm constructs a weighted directed graph $G = (V,E)$, where V includes i, f, and a subset of CS grid states induced by $\mathcal{B}$. A CS grid state a is included in V if (i) $s(a) \geq 2l$ or (ii) $s(a) = l$ and the clearance of $\xi(a)$ is at least l.

Let a and b be two states that lie within an extended box ζ. To see if there is a precomputed trajectory from a to b, we transform ζ to its canonical form, and also a and b with it. If $\mathcal{T}$ is the transformation, we say that there is a precomputed trajectory from a to b if there is a trajectory from $\mathcal{T} \circ a$ to $\mathcal{T} \circ b$ in the connection table of $\mathcal{T} \circ \zeta$. If Γ is the trajectory from $\mathcal{T} \circ a$ to $\mathcal{T} \circ b$, then $\mathcal{T}^{-1} \circ \Gamma$ is the trajectory

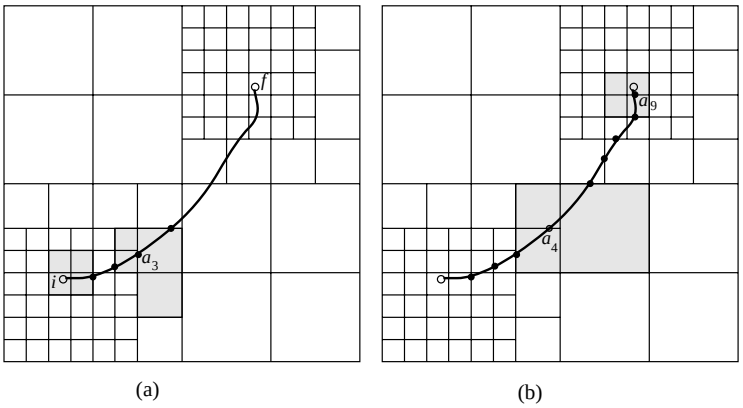

FIG. 2.3. (a) $\xi(a_0)$ *and* $\xi(a_3)$; (b) $\xi(a_4)$ *and* $\xi(a_9)$.

from a to b. It is easy to see that $\mathcal{T}^{-1} \circ \Gamma$ satisfies the connection-table properties P1–P3 (see Lemma 2.9) with respect to ζ.

We construct the edge set in the following way. For node i, add an edge from i to another node a if (i) i lies within $\xi(a)$ and (ii) there is a precomputed trajectory from[1] a^- to i^-. Similarly, for node f, add an edge from a node a to f if (i) f lies within $\xi(a)$ and (ii) there is a precomputed trajectory from a to f. For any other node a, add an edge from a to another node b if (i) b lies on the boundary of $\xi(a)$ and (ii) there is a precomputed trajectory from a to b. The weight of each edge is equal to the time length of its corresponding trajectory.

THEOREM 2.11 (safe loose-tracking theorem). *If there exists an optimal* $3l$*-safe* $(1,1)$*-trajectory* Γ *from state* i *to state* f*, then the graph* G*, constructed as above, contains a path whose corresponding trajectory* Γ' *satisfies the following properties:*

P1. $T(\Gamma') \leq (1+\epsilon)\,T(\Gamma)$.

P2. Γ' *is a* $((1+e\epsilon)^4, (1+e\epsilon)^2)$*-trajectory.*

P3. Γ' *does not intersect the interior of* Ω.

P4. Γ' *is from some* $i' \in ngb(i, \epsilon l/2, \epsilon/2)$ *to some* $f' \in ngb(f, \epsilon l/2, \epsilon/2)$.

Proof. Let Γ be divided into segments of trajectories $\Gamma_{a_0a_1} \| \Gamma_{a_1a_2} \| \dots \| \Gamma_{a_{m-1}a_m}$ such that $a_0 = i$, $a_m = f$, and each a_j is the state where Γ first exits $\xi(a_{j-1})$ for $1 \leq j \leq m-1$. Figure 2.3 gives an example in 2D. The optimal $(1,1)$-trajectory from i to f (drawn in thick curve) is divided into 10 segments (each dark circle represents an a_j for $1 \leq j < 10$). Some of the extended boxes are shown as shaded regions. We consider the following parts $\Gamma_{a_0a_1}$, $\Gamma_{a_1a_2} \| \dots \| \Gamma_{a_{m-2}a_{m-1}}$, and $\Gamma_{a_{m-1}a_m}$ separately.

Since each a_j, for $1 \leq j \leq m-1$, is on some face of $\mathcal{B}$, by Lemma 2.3, we can find a CS grid state b_j such that $a_j \in ngb(b_j)$. If $s(a_j) \geq 2l$, then $s(b_j) \geq 2l$ and b_j is in the node set V. Otherwise, since a_j is $3l$-safe, $\xi(a_j)$ has a clearance of at least l. Since $\xi(b_j) = \xi(a_j)$, $\xi(b_j)$ also has a clearance of at least l and b_j is in the node set V. We will show that the graph path $(b_1, b_2) \| \dots \| (b_{m-2}, b_{m-1})$ corresponds to a trajectory satisfying P1–P3. To this end, we show that there is an edge from b_{j-1} to b_j whose corresponding trajectory $\Gamma_{b_{j-1}b_j}$ satisfies P2, P3, and $T(\Gamma_{b_{j-1}b_j}) \leq (1+\epsilon)\,T(\Gamma_{a_{j-1}a_j})$ for $1 < j < m$.

By the way Γ is divided, $d(\Gamma_{a_{j-1}a_j}, \xi(a_{j-1})) = 0$. Thus each pair (a_{j-1}, a_j) is legal. This implies that each (b_{j-1}, b_j) is good. By the connection table property

[1] For a state a, we use a^- to denote a state of $(\text{LOC}(a), -\text{VEC}(a))$.

(Lemma 2.9), there is a precomputed trajectory $\Gamma_{b_{j-1}b_j}$ from b_{j-1} to b_j. Thus an edge from b_{j-1} to b_j is added in the construction of G. Also by the connection table property, $\Gamma_{b_{j-1}b_j}$ is a $((1+e\epsilon)^4,(1+e\epsilon)^2)$-trajectory, and its time length is no more than $(1+\epsilon)T(\Gamma_{a_{j-1}a_j})$. Next we need to show that $\Gamma_{b_{j-1}b_j}$ is collision free.

Let s be the size of $\xi(b_{j-1})$. We consider the three cases $s \geq 2l$, $s = l$, and $s = l/2$ separately. If $s \geq 2l$ (resp., $s = l$), the extended box $\xi(b_{j-1})$ has a clearance of $s/2$ (resp., l). On the other hand, $d(\Gamma_{b_{j-1}b_j}, \xi(b_{j-1})) \leq 5\epsilon s$. Thus if $\epsilon \leq 1/10$ is chosen small enough, $\Gamma_{b_{j-1}b_j}$ is collision free. When $s = l/2$, $\xi(b_{j-1})$ has a clearance of at least l. This is because a_{j-1} is $3l$-safe. By Lemma 2.4, $\xi(a_{j-1})$ has a clearance of at least l. This implies that $\xi(b_{j-1})$ has a clearance of at least l, since $\xi(b_{j-1}) = \xi(a_{j-1})$. Since $d(\Gamma_{b_{j-1}b_j}, \xi(b_{j-1})) \leq (5/2)\epsilon l$, $\Gamma_{b_{j-1}b_j}$ is collision free if ϵ is chosen small enough.

Now consider the part $\Gamma_{a_{m-1}a_m}$, which lies inside $\xi(a_{m-1})$. When constructing $\mathcal{B}$, $\textsc{loc}(f)$ is considered as an obstacle vertex. Thus the box containing $\textsc{loc}(f)$ and its neighbors all have size l. This means that $\xi(a_{m-1})$ is an extended box consisting of four boxes of size l. By Lemma 2.10, there exists in CT_0 a precomputed trajectory $\Gamma_{b_{m-1}f}$ from b_{m-1} to some $f' \in ngb(f, \epsilon l/2, \epsilon/2)$. Thus an edge from b_{m-1} to f is added in the construction of G. Also $\Gamma_{b_{m-1}f}$ is a $(1,1)$-trajectory whose time length is no more than $(1+\epsilon)\Gamma_{a_{m-1}a_m}$. To show that $\Gamma_{b_{m-1}f}$ is collision free, notice that the clearance of $\xi(a_{m-1})$ is at least l, since a_{m-1} is $3l$-safe. But $d(\Gamma_{b_{m-1}f}, \xi(b_{m-1})) \leq \epsilon l/2$, so this trajectory is also collision free. We can show similar results for $\Gamma_{a_0a_1}$. This completes the proof of this theorem. □

Thus the approximation problem is transformed to one of searching for a shortest path on the graph G. Notice that in order for this algorithm to be correct, each edge introduced in G must correspond to a collision-free trajectory. This is guaranteed by the way we choose the node set V and the connection table properties (a proof similar to the one showing that each $\Gamma_{b_{j-1}b_j}$ is collision free, used in the above theorem). We do not have to explicitly check whether each trajectory segment is collision free. The obtained shortest path corresponds to a $((1+e\epsilon)^4,(1+e\epsilon)^2)$-trajectory. Applying the time-rescaling lemma (Lemma 2.1) with a scaling factor of $(1+e\epsilon)^2$, we can obtain the following.

COROLLARY 2.12. *Let W be a d-dimensional configuration space of size L and Ω a set of obstacles. Let Γ be an optimal $3l$-safe $(1,1)$-trajectory from i to f. We can compute a $(1,1)$-trajectory Γ' from some $i' \in ngb(i, \epsilon l/2, 3e\epsilon)$ to some $f' \in ngb(f, \epsilon l/2, 3e\epsilon)$ such that $T(\Gamma')$ is at most $(1+3e\epsilon)$ times $T(\Gamma)$.*

2.5.2. The time complexity. The running time of the algorithm consists of the following components:

1. Time to generate the graph nodes (i.e., the grid states). If N is the total number of boxes in the final decomposition, the time to perform the decomposition is $O(nN + N\log N)$, where n is the number of constraints defining the configuration obstacles. Since each box contributes at most $O((1/\epsilon)^{2d-1})$ grid states, the time to generate the grid states, after a decomposition, is $O(N(1/\epsilon)^{2d-1})$.
2. Time to compute the graph edges. Since each node is connected to at most $O((1/\epsilon)^{2d-1})$ other nodes, the total number of edges is $O(N(1/\epsilon)^{4d-2})$. This bounds the time to compute the edges, since it takes $O(1)$ time to compute an edge.
3. Time to search for a shortest graph path. Using Dijkstra's algorithm with the priority queue implemented with a binary heap, this time is $O((|V| + |E|)\log|V|)$, where $|V|$ and $|E|$ are the number of nodes and edges, respec-

tively. Plugging in our numbers, the searching time is roughly $O(dN \log N (1/\epsilon)^{4d-2})$.

4. Time to rescale the obtained trajectory to a $(1,1)$-trajectory, which is $O(1)$.

Combining Corollary 2.12 and the time-complexity analysis, and choosing ϵ sufficiently small, we obtain the following result.

THEOREM 2.13. *Fix an $l > 0$ and an $\varepsilon > 0$. After some precomputation, we can achieve the following.*

Let W be a d-dimensional configuration space of size L. Let Ω be a set of configuration obstacles defined by a total of n algebraic equations, each of $O(1)$ degrees. Given any two states i and f, we can compute a collision-free $(1,1)$-trajectory from i' to f' such that the time length of the trajectory is at most $(1+\varepsilon)$ times the time length of an optimal $3l$-safe $(1,1)$-trajectory from i to f. Furthermore, $\|\textsc{loc}(i') - \textsc{loc}(i)\|_\infty \le \varepsilon l$, $\|\textsc{vec}(i') - \textsc{vec}(i)\|_\infty \le \varepsilon$, $\|\textsc{loc}(f') - \textsc{loc}(f)\|_\infty \le \varepsilon l$, and $\|\textsc{vec}(f') - \textsc{vec}(f)\|_\infty \le \varepsilon$.

The running time of our algorithm is $O(nN + N \log N (1/\varepsilon)^{4d-2})$, where $N = O((L/l)^d)$.

2.6. Correcting a trajectory. In this subsection we prove the correcting lemma (Lemma 2.6). The correcting lemma roughly states the following. Let Γ be an $(\bar{a}, \bar{v})$-trajectory from a state i to a state f. Given another pair of states g and h, we can construct a trajectory Γ' from g to h by correcting Γ. Furthermore, we show that if g and h are close to i and f, respectively, the correction is small. Note that in this subsection, the results are presented in the absence of obstacles.

For simplicity of illustration and analysis, we first look at the 1D case. Let $\delta a(t)$ be the corrective acceleration, i.e., $a_{\Gamma'}(t) = a_\Gamma(t) + \delta a(t)$ for $0 \le t \le T(\Gamma)$. Let $\delta v(t) = v_{\Gamma'}(t) - v_\Gamma(t)$ and $\delta p(t) = p_{\Gamma'}(t) - p_\Gamma(t)$. Also let $\Delta v_i = v_{\Gamma'}(0) - v_\Gamma(0) = \textsc{vec}(g) - \textsc{vec}(i)$, $\Delta v_f = v_{\Gamma'}(T) - v_\Gamma(T) = \textsc{vec}(h) - \textsc{vec}(f)$, $\Delta p_i = p_{\Gamma'}(0) - p_\Gamma(0) = \textsc{loc}(g) - \textsc{loc}(i)$, and $\Delta p_f = p_{\Gamma'}(T) - p_\Gamma(T) = \textsc{loc}(h) - \textsc{loc}(f)$. Thus,

$$\begin{aligned}\delta v(t) &= v_{\Gamma'}(0) + \int_0^t (a_\Gamma(\mu) + \delta a(\mu))\, d\mu - \left(v_\Gamma(0) + \int_0^t a_\Gamma(\mu)\, d\mu\right)\\ &= \Delta v_i + \int_0^t \delta a(\mu)\, d\mu\end{aligned}$$

and

$$\begin{aligned}\delta p(t) &= p_{\Gamma'}(0) + \int_0^t (v_\Gamma(\mu) + \delta v(\mu))\, d\mu - \left(p_\Gamma(0) + \int_0^t v_\Gamma(\mu)\, d\mu\right)\\ &= \Delta p_i + \int_0^t \delta v(\mu)\, d\mu\\ &= \Delta p_i + \int_0^t \left(\Delta v_i + \int_0^\mu \delta a(\nu)\, d\nu\right) d\mu\\ &= \Delta p_i + \Delta v_i t + \int_0^t \int_0^\mu \delta a(\nu)\, d\nu\, d\mu.\end{aligned}$$

Our object is to find $\delta a(t)$ such that

$$\Delta v_i + \int_0^T \delta a(\mu)\, d\mu = \Delta v_f \text{ and}$$

$$\Delta p_i + \Delta v_i T + \int_0^T \int_0^\mu \delta a(\nu)\, d\nu\, d\mu = \Delta p_f,$$

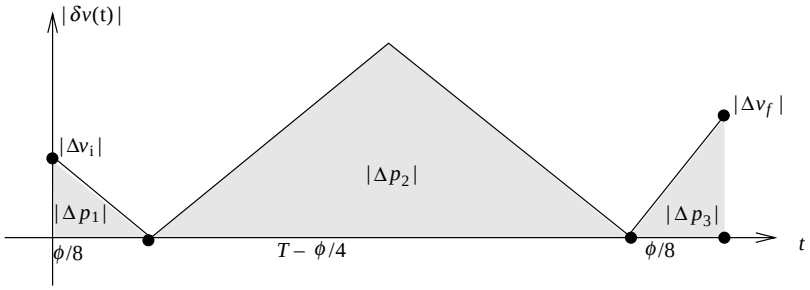

FIG. 2.4. *The correcting scheme.*

where $T = T(\Gamma)$. We also want to keep the absolute values of $\delta v(t)$, $\delta a(t)$, and $\delta p(t)$ small.

Fix a constant $c \geq 1$ and let

$$\rho_c = \bar{v}^2/(c\bar{a}).$$

Assume that

$$|\text{LOC}(f) - \text{LOC}(i)| \geq \rho \geq \rho_c$$

for some ρ, and let

$$\phi = \rho/\bar{v}.$$

Thus $T(\Gamma) \geq \phi$. Our correcting scheme is illustrated in Figure 2.4. Basically, we correct in three phases. In the first phase, we use a constant corrective acceleration to make $\delta v(t)$ become 0, while in the last phase, we use a constant corrective acceleration to make $\delta v(t)$ become Δv_f. The middle phase is used to correct the distance. Notice that at the beginning and the end of the second phase, $\delta v(t) = 0$.

The time length of the first and the last phases is $\phi/8$. Let Δa_1 be the constant corrective acceleration used in the first phase. Then

$$\Delta a_1 = -\frac{\Delta v_i}{\phi/8} = -\frac{8\Delta v_i}{\phi}.$$

If Δp_1 is the distance covered in this phase, then $\Delta p_1 = \Delta v_i \phi/16$. In this phase, $|\delta v(t)|$ is getting smaller and is upper bounded by $|\Delta v_i|$, while $|\delta p(t)|$ is upper bounded by $|\Delta p_i| + |\Delta p_1|$. Let Δa_3 be the constant corrective acceleration used in the last phase. Similarly, we have

$$\Delta a_3 = \frac{8\Delta v_f}{\phi}.$$

$\Delta p_3 = \Delta v_f \phi/16$ is the distance covered in this phase. In this phase, $|\delta v(t)|$ is upper bounded by $|\Delta v_f|$. At the beginning of this phase, $\delta p(t) = \Delta p_f - \Delta p_3$. Thus $|\delta p(t)|$ is upper bounded by $|\Delta p_f| + |\Delta p_3|$ during this phase.

Let $T' = T(\Gamma) - \phi/4$ be the time spent in the second phase. This phase is divided into two subphases of equal length. The corrective accelerations used in these two subphases have the same absolute value but opposite directions. The effect is that at the end of this phase, $\delta v(t)$ becomes 0 again. If Δp_2 is the distance covered in this

phase, $\Delta p_2 = \Delta p_f - \Delta p_i - \Delta p_1 - \Delta p_3$. Notice that $|\Delta p_2|$ and $\delta p(t)$ are both upper bounded by $|\Delta p_i| + |\Delta p_1| + |\Delta p_3| + |\Delta p_f|$. Let Δa_2 be the corrective acceleration used in the first subphase. Then

$$\Delta a_2 = \frac{4\Delta p_2}{(T')^2}.$$

In this phase, $|\delta v(t)|$ is upper bounded by $2|\Delta p_2|/T'$.

LEMMA 2.14. *For any $\varepsilon > 0$ and any two states g and h, if $g \in ngb(i, \varepsilon\rho/2, \varepsilon\bar{v}/2)$ and $h \in ngb(f, \varepsilon\rho/2, \varepsilon\bar{v}/2)$, where ρ is defined as above, then the trajectory Γ', constructed as above, satisfies the following properties:*

P1. $T(\Gamma') = T(\Gamma)$.

P2. Γ' *is a* $((1+4c\varepsilon)^2\bar{a}, (1+4c\varepsilon)\bar{v})$*-trajectory.*

P3. $d(\Gamma', \Gamma) \leq (17/16)\varepsilon\rho$.

Proof. P1 holds obviously. During the whole time period $T(\Gamma)$, the maximum difference in position is upper bounded by

$$\begin{aligned}
|\Delta p_i| + |\Delta p_1| + |\Delta p_3| + |\Delta p_f| &\leq \frac{1}{2}\varepsilon\rho + \frac{|\Delta v_i|\phi}{16} + \frac{|\Delta v_f|\phi}{16} + \frac{1}{2}\varepsilon\rho \\
&\leq \varepsilon\rho + \frac{(\varepsilon\bar{v})(\rho/\bar{v})}{16} \\
&\leq \left(1 + \frac{1}{16}\right)\varepsilon\rho \\
&\leq \frac{17}{16}\varepsilon\rho.
\end{aligned}$$

This implies that $|p_{\Gamma'}(t) - p_\Gamma(t)| \leq (17/16)\varepsilon\rho$ for $0 \leq t \leq T(\Gamma)$. By definition, $d(\Gamma', \Gamma) \leq (17/16)\varepsilon\rho$, proving P3. The maximum difference in velocity is upper bounded by

$$\begin{aligned}
\max\left(|\Delta v_i|, |\Delta v_f|, \frac{2|\Delta p_2|}{T'}\right) &\leq \max\left(\frac{\varepsilon\bar{v}}{2}, \frac{2(17/16)\varepsilon\rho}{(1-1/4)\phi}\right) \\
&\leq \max\left(\frac{\varepsilon\bar{v}}{2}, \frac{3\varepsilon\rho}{\phi}\right) \\
&\leq \max\left(\frac{\varepsilon\bar{v}}{2}, 3\varepsilon\bar{v}\right) \\
&\leq 4c\varepsilon\bar{v}.
\end{aligned}$$

The maximum difference in acceleration is upper bounded by

$$\begin{aligned}
\max\left(|\Delta a_1|, |\Delta a_2|, |\Delta a_3|\right) &\leq \max\left(\frac{8|\Delta v_i|}{\phi}, \frac{4|\Delta p_2|}{(T')^2}, \frac{8|\Delta v_f|}{\phi}\right) \\
&\leq \max\left(\frac{4\varepsilon\bar{v}}{\phi}, \frac{4(17/16)\varepsilon\rho}{((3/4)\phi)^2}\right) \\
&\leq \max\left(\frac{4\varepsilon\bar{v}}{\phi}, \frac{8\varepsilon\bar{v}}{\phi}\right) \\
&= \frac{8\varepsilon\bar{v}}{\phi} \\
&= \frac{8\varepsilon\bar{v}^2}{\rho}
\end{aligned}$$

$$\leq \frac{8\varepsilon\bar{v}^2}{\rho_c}$$
$$= 8c\varepsilon\bar{a}.$$

Thus the velocity of Γ' is upper bounded by $(1+4c\varepsilon)\bar{v}$ and the acceleration is bounded by $(1+4c\varepsilon)^2\bar{a}$, proving P2. □

In higher dimensions, we can add corrective accelerations for each dimension separately. Since the time length of the trajectory is not changed, the corrections can be carried out simultaneously without affecting each other. Let $v_\Gamma^j(t)$ be $v_\Gamma(t)$ projected in the jth dimension for $1 \leq j \leq d$. By Lemma 2.14, we have

$$|v_{\Gamma'}^j(t)| \leq 4c\varepsilon\bar{v} + |v_\Gamma^j(t)|.$$

By the triangle inequality,

$$\begin{aligned}\|v_{\Gamma'}(t)\| &\leq \|v_\Gamma(t)\| + \|v_{\Gamma'}(t) - v_\Gamma(t)\| \\ &\leq \bar{v} + \sqrt{\sum_{j=1}^{d}(v_{\Gamma'}^j(t) - v_\Gamma^j(t))^2} \\ &\leq \bar{v} + \sqrt{\sum_{j=1}^{d}(4c\varepsilon\bar{v})^2} \\ &\leq \bar{v} + 4c\sqrt{d}\varepsilon\bar{v} \\ &= (1 + 4c\sqrt{d}\varepsilon)\bar{v}.\end{aligned}$$

Similarly for the acceleration, we can obtain that

$$\|a_{\Gamma'}(t)\| \leq (1 + 4c\sqrt{d}\varepsilon)^2\bar{a}.$$

In summary, we have Lemma 2.6, reproduced here as Lemma 2.15.

LEMMA 2.15 (correcting lemma). *Fix a constant $c \geq 1$ and let $\rho_c = \bar{v}^2/(c\bar{a})$, where $\bar{a}, \bar{v} > 0$ are arbitrary. Let Γ be an $(\bar{a}, \bar{v})$-trajectory from a state i to a state f. Given any $\rho > 0$ and $\varepsilon > 0$ and given any two states g and h, if $\rho > \rho_c$, $\|\text{LOC}(f) - \text{LOC}(i)\|_\infty \geq \rho$, $g \in ngb(i, \varepsilon\rho/2, \varepsilon\bar{v}/2)$, and $h \in ngb(f, \varepsilon\rho/2, \varepsilon\bar{v}/2)$, then we can construct a trajectory Γ' from g to h by correcting Γ such that Γ' satisfies the following properties:*

P1. $T(\Gamma') = T(\Gamma)$.

P2. *Γ' is a $((1 + 4c\sqrt{d}\varepsilon)^2\bar{a}, (1 + 4c\sqrt{d}\varepsilon)\bar{v})$-trajectory.*

P3. $d(\Gamma', \Gamma) \leq (17/16)\varepsilon\rho$.

2.7. Scaling the dynamic bounds. So far, our presentation considers only the case when both the accelerations and the velocities are upper bounded by 1. This is sufficiently general because, as we mentioned in section 1.3, we can scale arbitrarily given bounds to 1 by scaling time and the configuration space. In this section, we will show how the scaling is done. Basically, for given arbitrary bounds, we scale the configuration space (also the locations and the velocities of the initial and final states) by some appropriate factors decided by the given bounds. We then apply the algorithm described in section 2.5 to compute a trajectory in the scaled configuration space with both dynamic bounds set to 1. Finally we "scale back" the computed trajectory. We will see that the scaled trajectory abides by the given dynamic bounds and is a close approximation to an optimal trajectory.

For a path Π, we use $L(\Pi)$ to denote the path length of Π. Let Π and Π' be two paths. We say that $\Pi' = \alpha\Pi$, or that Π' is Π scaled by a factor of α, if $L(\Pi') = \alpha\, L(\Pi)$ and $\Pi'(\ell) = \alpha\, \Pi(\ell/\alpha)$ for $0 \le \ell \le \alpha\, L(\Pi)$.

In the following, we first present the velocity-scaling lemma, which shows the scaling relation between the velocity and the time and the space. Next, the acceleration-scaling lemma shows how to scale the acceleration by scaling the time and the space. By combining these two lemmas, we obtain the acceleration-velocity scaling lemma. Note that unlike the time-rescaling lemma (Lemma 2.1), the acceleration and the velocity can be scaled by different and unrelated factors in our lemma.

LEMMA 2.16 (velocity-scaling lemma). *Let Γ be an $(\bar{a}, \bar{v})$-trajectory and Π be its path. The path $(1/\alpha^2)\Pi$ can be traversed by an $(\bar{a}, \bar{v}/\alpha)$-trajectory Γ' in time $T(\Gamma)/\alpha$. Moreover Γ is an optimal $(\bar{a}, \bar{v})$-trajectory if and only if Γ' is an optimal $(\bar{a}, \bar{v}/\alpha)$-trajectory.*

Proof. Define Γ' to be the following: $p_{\Gamma'}(0) = p_\Gamma(0)/\alpha^2$, $v_{\Gamma'}(0) = v_\Gamma(0)/\alpha$, and $a_{\Gamma'}(t) = a_\Gamma(\alpha t)$, $0 \le t \le T(\Gamma)/\alpha$. We will show that, for $0 \le t \le T(\Gamma)/\alpha$,

$$v_{\Gamma'}(t) = v_\Gamma(\alpha t)/\alpha \text{ and}$$

$$p_{\Gamma'}(t) = p_\Gamma(\alpha t)/\alpha^2.$$

This is because

$$\begin{aligned} v_{\Gamma'}(t) &= v_{\Gamma'}(0) + \int_0^t a_{\Gamma'}(s)\, ds \\ &= v_\Gamma(0)/\alpha + \int_0^t a_\Gamma(\alpha s)\, ds \\ &= v_\Gamma(0)/\alpha + \int_0^{\alpha t} a_\Gamma(s')(1/\alpha)\, ds' \\ &= v_\Gamma(0)/\alpha + \left(\int_0^{\alpha t} a_\Gamma(s')\, ds' \right) /\alpha \\ &= v_\Gamma(\alpha t)/\alpha \end{aligned}$$

and

$$\begin{aligned} p_{\Gamma'}(t) &= p_{\Gamma'}(0) + \int_0^t v_{\Gamma'}(s)\, ds \\ &= p_\Gamma(0)/\alpha^2 + \int_0^t v_\Gamma(\alpha s)/\alpha\, ds \\ &= p_\Gamma(0)/\alpha^2 + \int_0^{\alpha t} (v_\Gamma(s')/\alpha^2)\, ds' \\ &= p_\Gamma(0)/\alpha^2 + (1/\alpha^2) \int_0^{\alpha t} v_\Gamma(s')\, ds' \\ &= p_\Gamma(\alpha t)/\alpha^2. \end{aligned}$$

Let Π' be the path traversed by Γ', and let ℓ and t be such that$\Pi'(\ell) = p_{\Gamma'}(t)$.

Thus

$$\begin{aligned}\ell &= \int_0^t v_{\Gamma'}(s)ds \\ &= \int_0^t v_\Gamma(\alpha s)/\alpha ds \\ &= (1/\alpha^2)\int_0^{\alpha t} v_\Gamma(s)ds.\end{aligned}$$

This implies that $\Pi(\alpha^2\ell) = p_\Gamma(\alpha t)$. Since

$$\begin{aligned}\Pi'(\ell) &= p_{\Gamma'}(t) \\ &= p_\Gamma(\alpha t)/\alpha^2 \\ &= \Pi(\alpha^2\ell)/\alpha^2,\end{aligned}$$

therefore Π' is $(1/\alpha^2)\Pi$. The scaling preserves the optimality. This completes the proof of the lemma. □

LEMMA 2.17 (acceleration-scaling lemma). *Let Γ be an $(\bar{a}, \bar{v})$-trajectory and Π be its path. The path $(1/\alpha)\Pi$ can be traversed by an $(\bar{a}/\alpha, \bar{v}/\alpha)$-trajectory Γ' in time $T(\Gamma)$. Moreover Γ is an optimal $(\bar{a}, \bar{v})$-trajectory if and only if Γ' is an optimal $(\bar{a}/\alpha, \bar{v}/\alpha)$-trajectory.*

Proof. Define Γ' to be the following: $p_{\Gamma'}(0) = p_\Gamma(0)/\alpha$, $v_\Gamma(0) = v_\Gamma(0)/\alpha$, and $a_{\Gamma'}(t) = a_\Gamma(t)/\alpha$, $0 \le t \le T(\Gamma)$. We can show that, for any $0 \le t \le T(\Gamma)$,

$$v_{\Gamma'}(t) = v_\Gamma(t)/\alpha \text{ and}$$

$$p_{\Gamma'}(t) = p_\Gamma(t)/\alpha.$$

This is because

$$\begin{aligned}v_{\Gamma'}(t) &= v_{\Gamma'}(0) + \int_0^t a_{\Gamma'}(s)\, ds \\ &= v_\Gamma(0)/\alpha + \int_0^t a_\Gamma(s)/\alpha\, ds \\ &= v_\Gamma(0)/\alpha + \left(\int_0^t a_\Gamma(s)\, ds\right)/\alpha \\ &= v_\Gamma(t)/\alpha\end{aligned}$$

and

$$\begin{aligned}p_{\Gamma'}(t) &= p_{\Gamma'}(0) + \int_0^t v_{\Gamma'}(s)\, ds \\ &= p_\Gamma(0)/\alpha + \int_0^t v_\Gamma(s)/\alpha\, ds \\ &= p_\Gamma(0)/\alpha + \left(\int_0^t v_\Gamma(s)\, ds\right)/\alpha \\ &= p_\Gamma(t)/\alpha.\end{aligned}$$

Let Π' be the path traversed by Γ'. Similarly to the proof of Lemma 2.16, we can show that $\Pi' = (1/\alpha)\Pi$. This completes the proof of the lemma. ∎

LEMMA 2.18 (acceleration-velocity scaling lemma). *Let Γ be an $(\bar{a}, \bar{v})$-trajectory and let Π be its path. The path $(\beta/\alpha^2)\Pi$ can be traversed by an $(\bar{a}/\beta, \bar{v}/\alpha)$-trajectory Γ' in time $(\beta/\alpha)\,T(\Gamma)$. Moreover Γ is an optimal $(\bar{a}, \bar{v})$-trajectory if and only if Γ' is an optimal $(\bar{a}/\beta, \bar{v}/\alpha)$-trajectory.*

Proof. Let $\Pi'' = (1/\beta)\Pi$. By Lemma 2.17, Π'' can be traversed by an $(\bar{a}/\beta, \bar{v}/\beta)$-trajectory Γ'' in time $T(\Gamma)$.

Let $\gamma = \alpha/\beta$ and let $\Pi' = (1/\gamma^2)\Pi''$. By Lemma 2.16, Π' can be traversed by an $(\bar{a}/\beta, \bar{v}/(\beta\gamma))$-trajectory in time $T(\Gamma'')/\gamma$. Since

$$\Pi' = (1/\gamma^2)\Pi'' = (1/\gamma^2)(1/\beta)\Pi = (\beta/\alpha^2)\Pi,$$

$$\bar{v}/(\beta\gamma) = \bar{v}/\alpha,$$

and

$$T(\Gamma'')/\gamma = T(\Gamma)/\gamma = (\beta/\alpha)T(\Gamma),$$

therefore this trajectory is the one desired. ∎

By applying the acceleration-velocity scaling lemma, we obtain the following corollary.

COROLLARY 2.19. *Given a kinodynamic motion-planning problem with the following parameters: the size of the configuration space L, the dynamic bounds $\bar{a}$ and $\bar{v}$, the two parameters l and ε, the initial state i, and the final state f, we can scale the problem to one with $\bar{a} = 1$ and $\bar{v} = 1$ by scaling the initial and final velocities by a factor of $(1/\bar{v})$ and scaling the configuration space (including the obstacles, the parameter l, $\text{LOC}(i)$, and $\text{LOC}(f)$) by a factor of $(\bar{a}/\bar{v}^2)$. Let Γ be the trajectory obtained for the scaled problem. Then the trajectory Γ' such that*

$$a_{\Gamma'}(t) = \bar{a} \cdot a_{\Gamma}((\bar{a}/\bar{v})t)$$

for $0 \le t \le (\bar{v}/\bar{a})T(\Gamma)$ is the solution for the original problem.

3. The curvature-constrained shortest-path problem in three and higher dimensions.

3.1. Introduction. Let $P : I \to \mathbb{R}^d$ be a d-dimensional differentiable path parameterized by arclength $s \in I$. The *average curvature* of P in the interval $[s_1, s_2] \subseteq I$ is defined by $\|\dot{P}(s_1) - \dot{P}(s_2)\|/|s_1 - s_2|$. In the curvature-constrained shortest-path problem, we require that the path have an average curvature of at most 1 in every interval. Again, we can always scale an arbitrarily given curvature bound to 1 by scaling the configuration space, thus it is general enough to consider the case when the bound is 1. Notice that we use average curvature instead of curvature because the curvature of a differentiable path may not exist at certain points. Also, the curvature of a path, wherever it is defined, is bounded by 1 if and only if its average curvature is bounded by 1 for all intervals.

A *position* X is a pair $(\text{LOC}(X), \text{ORN}(X))$, where $\text{LOC}(X)$ is a point in the d-dimensional space and $\text{ORN}(X)$ is a vector representing an orientation in the d-dimensional space. Notice that $\|\text{ORN}(X)\| = 1$. Given a set Ω of obstacles in a d-dimensional space, an initial position I, and a final position F, the curvature-constrained shortest-path problem is to find a shortest path from I to F such that the path obeys the curvature constraint and does not intersect Ω.

It has been observed in [18] that the curvature-constrained shortest-path problem is a restricted case of the kinodynamic motion-planning problem, with the L_2-norms of the velocities fixed to be 1. However, if we require that the velocities of the approximation trajectories be fixed in L_2-norm, the techniques developed so far for the general kinodynamic case cannot be applied to this restricted case. As pointed out in [12], a necessary condition for the techniques to apply is that the set of *feasible instantaneous accelerations* (accelerations that can be applied without violating the dynamic constraints) spans d dimensions. On the other hand, if the velocities are fixed in L_2-norm, the set of instantaneous accelerations spans only $d-1$ dimensions, because they have to be perpendicular to the instantaneous velocity.

Our contribution is that we look at the curvature-constrained shortest-path problem from a different viewpoint, which enables us to overcome the difficulty mentioned above. Basically, instead of requiring that the L_2-norms of the velocities be fixed to be 1, we only force them to fall within a small range close to 1. In this way, we are able to obtain a path whose maximum curvature is slightly larger than, but can be arbitrarily close to, 1. It should be noted that under this same variation, the former approximation algorithms of Donald and Xavier [15] and Reif and Tate [43] can also be applied to compute approximating solutions for the curvature-constrained shortest-path problem.

In this section, we use lowercase letters to denote states as defined for the kinodynamic case, but uppercase letters (usually X, Y, U, V) to denote positions (i.e., $\|\textsc{orn}(X)\| = \|\textsc{orn}(Y)\| = \|\textsc{orn}(U)\| = \|\textsc{orn}(V)\| = 1$). A path is called a *c-constrained* path if its average curvature is at most c. We say that Γ is a $(1, \tilde{1})$-trajectory if $\|a_\Gamma(t)\| \leq 1$ and $\|v_\Gamma(t)\| = 1$ for $0 \leq t \leq T(\Gamma)$. Given a path Π, let $L(\Pi)$ be its path length. Notice that the notation of *ngb* extends to positions. Therefore, for a position X, a position $X' \in ngb(X, \rho, \nu)$ if $\|\textsc{loc}(X') - \textsc{loc}(X)\|_\infty \leq \rho$ and $\|\textsc{orn}(X') - \textsc{orn}(X)\|_\infty \leq \nu$.

3.2. Approximating in the absence of obstacles. The following lemma states a result similar to Corollary 2.2 but for the curvature-constrained case. This lemma enables us to apply the method developed in the previous sections to the curvature-constrained shortest-path problem.

LEMMA 3.1. *Let W be a d-dimensional configuration space of size L. Let Π be a 1-constrained path from position X to position Y and lying inside W. Given any $\varepsilon > 0$ and $\rho = O(1)$, we can compute in time $O(L^d(1/\varepsilon)^{6d-1})$ a path Π' such that Π' satisfies the following properties:*

P1. *Π' is $(1+\varepsilon)$-constrained.*
P2. *$L(\Pi') \leq (1+\varepsilon)L(\Pi)$.*
P3. *$d(\Pi', W) \leq \varepsilon\rho/2$.*
P4. *Π' is from some position $X' \in ngb(X, \varepsilon\rho/2, \varepsilon/2)$ to some position $Y' \in ngb(Y, \varepsilon\rho/2, \varepsilon/2)$.*

Proof. Let $\delta = \varepsilon/8$, $\eta_x = \varepsilon\rho/2$, and $\eta_v = \varepsilon/(8\sqrt{d})$.

We consider Π to be the path of a trajectory Γ such that Γ is from state $i = (\textsc{loc}(X), \textsc{orn}(X)/(1+\delta))$ to state $f = (\textsc{loc}(Y), \textsc{orn}(Y)/(1+\delta))$ and $\|v_\Gamma(t)\| = 1/(1+\delta)$. Notice that $T(\Gamma) = (1+\delta)\,L(\Pi)$. Since Π is a 1-constrained path, and at any time t, the curvature of Π is given by $\|a_\Gamma(t)\|/\|v_\Gamma(t)\|^2$, the acceleration of Γ is bounded by

$$\|a_\Gamma(t)\| \leq 1 \cdot \|v_\Gamma(t)\|^2 \leq 1/(1+\delta)^2.$$

This implies that Γ is a $(1/(1+\delta)^2, 1/(1+\delta))$-trajectory. Let $\mathcal{A}_\delta$ be the set of accel-

erations whose L_2-norms are bounded by $1/(1+\delta)^2$. This is the set of accelerations used by Γ.

Let $\mu = \kappa_l = \delta/(4\sqrt{d})$ and $\mathcal{A}_\mu$ be the set of accelerations as defined in the appendix (see (A.5) and (A.6)). Thus $\mathcal{A}_\mu$ has a uniform advantage of κ_l over $\mathcal{A}_\delta$. By the tracking lemma (see the appendix), there exists a $\tau = O(\varepsilon)$ (satisfying (A.4)) and a τ-bang trajectory Γ' using $\mathcal{A}_\mu$ such that $T(\Gamma') = T(\Gamma)$ and Γ' tracks Γ to a tolerance of (η_x, η_v). This implies that

$$\|v_{\Gamma'}(t) - v_\Gamma(t)\|_\infty \le \eta_v,$$

$$\|v_{\Gamma'}(t) - v_\Gamma(t)\| \le \sqrt{d}\eta_v,$$

$$\|v_\Gamma(t)\| - \sqrt{d}\eta_v \le \|v_{\Gamma'}(t)\| \le \|v_\Gamma(t)\| + \sqrt{d}\eta_v,$$

$$\frac{1}{1+\delta} - \sqrt{d}\frac{\varepsilon}{8\sqrt{d}} \le \|v_{\Gamma'}(t)\| \le \frac{1}{1+\delta} + \sqrt{d}\frac{\varepsilon}{8\sqrt{d}},$$

$$\frac{1}{1+\delta} - \frac{\varepsilon}{8} \le \|v_{\Gamma'}(t)\| \le \frac{1}{1+\delta} + \frac{\varepsilon}{8},$$

$$1 - \frac{\varepsilon}{4} \le \|v_{\Gamma'}(t)\| \le 1 + \frac{\varepsilon}{8}.$$

Let Π' be the path of trajectory Γ'. We will show that Π' satisfies P1–P4. Since $\|a_{\Gamma'}(t)\| \le 1$, this bounds the maximum curvature of Π' to be at most

$$\frac{1}{(1-\varepsilon/4)^2} \le 1 + \varepsilon,$$

proving P1. Since $T(\Gamma') \le T(\Gamma) = (1+\delta)L(\Pi)$, then

$$L(\Pi') \le \left(1 + \frac{\varepsilon}{8}\right) T(\Gamma') \le \left(1 + \frac{\varepsilon}{8}\right)(1+\delta)L(\Pi) \le (1+\varepsilon)L(\Pi),$$

proving P2, where $(1 + \frac{\varepsilon}{8})$ is the upper bound on $\|v_{\Gamma'}(t)\|$. P3 follows directly from the fact that Γ' tracks Γ to a tolerance of (η_x, η_v) with $\eta_x = \varepsilon\rho/2$, and that Γ lies inside W.

Let i' and f' be the initial and the final states of Γ', and X' and Y' be the initial and the final positions of Π'. Thus $\textsc{loc}(X') = \textsc{loc}(i')$, $\textsc{loc}(Y') = \textsc{loc}(f')$, $\textsc{orn}(X') = \textsc{vec}(i')/\|\textsc{vec}(i')\|$, and $\textsc{orn}(Y') = \textsc{vec}(f')/\|\textsc{vec}(f')\|$, and

$$\begin{aligned}
&\|\textsc{orn}(X') - \textsc{orn}(X)\|_\infty \\
&\le \|\textsc{orn}(X') - \textsc{orn}(X)\| \\
&= \|\textsc{orn}(X') - \textsc{vec}(i') + \textsc{vec}(i') - \textsc{vec}(i) + \textsc{vec}(i) - \textsc{orn}(X)\| \\
&\le \|\textsc{orn}(X') - \textsc{vec}(i')\| + \|\textsc{vec}(i') - \textsc{vec}(i)\| + \|\textsc{vec}(i) - \textsc{orn}(X)\| \\
&\le (1 - \|\textsc{vec}(i')\|) + \sqrt{d}\eta_v + \frac{\delta}{1+\delta} \\
&\le \frac{\varepsilon}{4} + \frac{\varepsilon}{8} + \frac{\varepsilon}{8} \\
&= \frac{\varepsilon}{2}.
\end{aligned}$$

Similarly we can show that $\|\textsc{orn}(Y') - \textsc{orn}(Y)\|_\infty \le \varepsilon/2$. This proves P4 for Γ'.

Such a trajectory Γ' (and thus a path Π') can be obtained by the TC-graph method. In constructing the graph, an edge is added if (i) it is a (μ, τ)-bang, (ii) the bang does not diverge from W by more than $\varepsilon\rho/2$, and (iii) the L_2-norms of the velocities of the bang fall into $[1-\varepsilon/4, 1+\varepsilon/8]$. Since μ and τ are $O(\varepsilon)$, the number of edges in this graph is bounded by $O(L^d(1/\varepsilon)^{6d-1})$, and thus so is the running time. This completes the proof of the lemma. □

Notice that we do not explicitly constrain the velocities of the tracking trajectory Γ'. This allows us to apply the tracking lemma (Lemma A.1). However, it happens that $\|v_{\Gamma'}(t)\|$ falls into a small range of $[1-\varepsilon/4, 1+\varepsilon/8]$ by being able to track closely a trajectory Γ whose velocities are fixed to be 1 in L_2-norm. By upper bounding the accelerations and lower bounding the velocities of Γ', we are able to bound the curvature of Π'.

3.3. Approximating with obstacles. Let W be a d-dimensional configuration space of size L with a set Ω of obstacles. Let $\mathcal{B}$ be the box decomposition of W, as described in section 2.3.1. Let Π be an optimal $3l$-safe 1-constrained path from position X to position Y.

As we did in the proof of the safe loose-tracking theorem (Theorem 2.11), we can divide Π into segments of paths, $\Pi_{U_0U_1} \| \dots \| \Pi_{U_{m-1}U_m}$, such that $U_0 = X$, $U_m = Y$, and each U_i is the position where Π first exits $\xi(U_{i-1})$ for $1 \le i \le m$. Each segment $\Pi_{U_iU_{i+1}}$ is a 1-constrained path from U_i to U_{i+1} and lies inside $\xi(U_i)$. These are the paths we need to approximate.

We define the set of CS grid states, the canonical extended boxes, the canonical starting states, and the canonical ending states in the same way as we did in the previous sections, except that we let $\mathcal{V}$ be the set of *unit* vectors that are uniformly spaced with spacing δ. If $\delta = O(\epsilon)$ is chosen small enough, for any unit vector v, there is a unit vector $v' \in \mathcal{V}$ such that $\|v' - v\|_\infty \le \epsilon/2$. Thus $\mathcal{V}$ suffices for the curvature-constrained case, since if we consider U_i as a state then $\|\textsc{vec}(U_i)\| = 1$ for all U_i's along Π. The following corollary can be derived from the correcting lemma (Lemma 2.6).

Corollary 3.2. *Fix a constant $c > 1$ and let $\rho_c = 1/(c\kappa)$, where $\kappa > 0$ is arbitrary. Let Π be a κ-constrained path from position I to position F. Given any $\rho > 0$ and $\varepsilon > 0$ and given any two positions U and V, if $\rho > \rho_c$, $\|\textsc{loc}(F) - \textsc{loc}(I)\|_\infty \ge \rho$, $U \in ngb(I, \varepsilon\rho/2, \varepsilon/2)$, and $V \in ngb(F, \varepsilon\rho/2, \varepsilon/2)$, we can construct a path Π' from U to V by correcting Π such that Π' satisfies the following properties:*

P1. $L(\Pi') = (1 + e\varepsilon)L(\Pi)$,

P2. Π' *is* $((1+e\varepsilon)^2/(1-e\varepsilon)^2)\kappa$*-constrained,*

P3. $d(\Pi', \Pi) \le (17/16)\varepsilon\rho$,

where $e = 4c\sqrt{d}$.

The consequence of Lemma 3.1 and Corollary 3.2 is that we are able to precompute paths which approximate U_{ii+1}'s and store them in the connection tables. Similar to what we did for the kinodynamic case, we can prove a version of the loose-tracking lemma (Lemma 2.8) and the safe loose-tracking theorem (Theorem 2.11) for the curvature-constrained case. Since $|\mathcal{V}| = O((1/\epsilon)^{d-1})$ (as opposed to $O((1/\epsilon)^d)$ for the kinodynamic case), the number of edges in the CS graph is reduced to $O((1/\epsilon)^{4d-4})$.

Combining the above, and choosing small enough $\epsilon = O(\varepsilon)$, we can obtain the following result.

Theorem 3.3. *Fix an $l > 0$ and an $\varepsilon > 0$. After some precomputation, we can achieve the following.*

Let W be a d-dimensional space of size L and let Ω be a set of obstacles with a

total of n vertices. Given any two positions X and Y, we can compute a collision-free $(1+\varepsilon)$-constrained path from a position $X' \in ngb(X, \varepsilon l, \varepsilon)$ to a position $Y' \in ngb(Y, \varepsilon l, \varepsilon)$, such that the path length is at most $(1+\varepsilon)$ times the length of an optimal 1-constrained $3l$-safe path from X to Y.

The running time of our algorithm is $O(nN + N \log N (1/\varepsilon)^{4d-4})$, where $N = O((L/l)^d)$.

4. Conclusions. In this paper we have presented a faster approximation algorithm for the kinodynamic motion-planning problem. Contrary to the previous approximation algorithms which all use a uniform discretization in time, our method employs a nonuniform discretization in the configuration space. The discretization is nonuniform in that it is coarser in regions which are farther from all obstacles. The nonuniform discretization leads to a smaller search space and thus a faster algorithm. Moreover, our method is sensitive to the distribution of obstacles in the configuration space. It is expected to perform better (i.e., faster) than the given theoretical time bound in cases where the obstacles are sparsely or unevenly distributed. In developing the approximation algorithm, we utilize a hierarchical decomposition of the configuration space. We also developed the idea of using trajectories precomputed in the absence of obstacles as building blocks to construct trajectories in the presence of obstacles. Finally, we have applied this algorithm to give the first-known polynomial-time approximation algorithm for the curvature-constrained shortest-path problem in three and higher dimensions. The computed paths may have curvatures slightly larger (but can be arbitrarily close to) the given curvature bound.

It should be pointed out that, though improved, the time complexity of our approximation algorithm is still too high for the method to have real-world applications. At this point, the proposed method and results are of pure theoretical interest.

One future research direction is to give a more precise bound on N, the number of boxes in the box decomposition. Instead of describing N as a function of L, the size of the configuration space, we would prefer to describe N as a function of some parameters that describe the obstacle scene, for example, the aspect ratios of the obstacles.

In the kinodynamic motion-planning problem, we only considered *Cartesian robots*, i.e., robots whose inertia tensor is constant (see [15] for a more precise definition). We believe that our approach can also be applied to more general robots with *open kinematic chains*. In order to do this, we need to generalize our correcting lemma (Lemma 2.6) to open chains.

A key further problem is to determine cases of kinodynamic motion-planning problems that we can solve in closed forms, or for which we can give sufficient characterizations for developing fast algorithms. An example along this line is the case of planning for a point robot moving on a plane amid polygonal obstacles and with decoupled kinodynamic constraints. It is characterized in [9] that the minimum-time trajectory is a sequence of segments, where each segment is a "bang-bang" control between two obstacle boundary points. It is interesting to investigate whether such characterizations extend to coupled cases and higher dimensions.

The complexity of the kinodynamic motion-planning problem in two dimensions is still open.

Appendix. The *TC*-graph method. For the sake of completeness, we describe the gist of the tracking lemma (Lemma A.1) and the TC-graph method in this section.

A trajectory Γ' is said to *track* another trajectory Γ to a tolerance (η_x, η_v) if for

all $t \in [0, T]$,

$$\|p_\Gamma(t) - p_{\Gamma'}(t)\|_\infty \leq \eta_x \text{ and} \tag{A.1}$$

$$\|v_\Gamma(t) - v_{\Gamma'}(t)\|_\infty \leq \eta_v. \tag{A.2}$$

Notice that (A.1) implies that $d(\Gamma', \Gamma) \leq \eta_x$.

A *τ-bang* is a trajectory segment of time duration τ during which a *constant* acceleration is applied.[2] A *τ-bang trajectory* is a trajectory consisting of a sequence of τ-bangs. The set of bang trajectories is a restricted set of trajectories. But they suffice to track any nonrestricted trajectories if the acceleration set used by the bang trajectories has some *advantage* over the acceleration set used by the nonrestricted trajectories. Next we define the notion of advantage more formally.

Let $\mathcal{P}$ and $\mathcal{Q}$ be two sets of accelerations. For any acceleration $a \in \mathcal{P}$ and any direction given by a d-length vector σ of 1's and -1's, if there exists an acceleration $b \in \mathcal{Q}$ such that

$$\sigma^j(b^j - a^j) \geq \kappa_l \tag{A.3}$$

for $1 \leq j \leq d$, then $\mathcal{Q}$ is said to have a *uniform κ_l advantage* over $\mathcal{P}$ (α^j means the jth element of a vector α). The tracking lemma relates the parameter τ to the uniform advantage κ_l and the tracking tolerance (η_x, η_v).

LEMMA A.1 (tracking lemma [15]).[3] *Let $\mathcal{P}$ and $\mathcal{Q}$ be two sets of accelerations such that for each $a \in \mathcal{Q}$, $\|a\| \leq 1$, and $\mathcal{Q}$ has a uniform κ_l advantage over $\mathcal{P}$.*

Let Γ be a trajectory that uses $\mathcal{P}$. Let (η_x, η_v) be a tracking tolerance. There exists a time step τ, and a τ-bang trajectory Γ' that uses $\mathcal{Q}$ such that Γ' tracks Γ to tolerance (η_x, η_v).

Moreover, it is sufficient that

$$\tau = O(\min(\eta_v, \sqrt{\eta_x \kappa_l})). \tag{A.4}$$

Let $\mathcal{A}$ (resp., $\mathcal{A}_\epsilon$) be the set of accelerations whose L_2-norms are bounded by 1 (resp., $1/(1+\epsilon)^2$). Next we show how we can choose a finite set of accelerations such that this set has a uniform advantage over $\mathcal{A}_\epsilon$. Given a parameter μ, a set of grid-points of $\mathcal{A}$ with spacing μ is defined to be

$$\{a = (i_1\mu, \ldots, i_d\mu) \mid i_1, \ldots, i_d = 0, \pm 1, \pm 2, \ldots, a \in \mathcal{A}\}. \tag{A.5}$$

Let $\mathcal{A}_\mu$ be the set of *boundary* grid-points[4] (see Figure A.1; the dark dots represent the boundary grid-points in two dimensions). It is shown in [15] that if μ is chosen

[2] Here we slightly abuse the notion of a *bang*. A bang usually means that its acceleration should be *extremal* in some sense.

[3] This is a simplified version of the tracking lemma presented in [15]. In [15], $\mathcal{Q}$ is a set of *instantaneous accelerations* that depends on the current state, and may be a subset of the set of allowed accelerations. This is because applying certain accelerations may violate the velocity constraint. In the context where we apply this tracking lemma, we do not explicitly bound the velocities of the tracking trajectory. This means that the set of instantaneous accelerations equals the set of all allowed accelerations.

[4] In [15], two approximation algorithms, the true-extremal algorithm and the near-extremal algorithm, are described. They differ in the way of choosing a discretized acceleration set and in the way of defining bangs. The description here follows from the near-extremal algorithm.

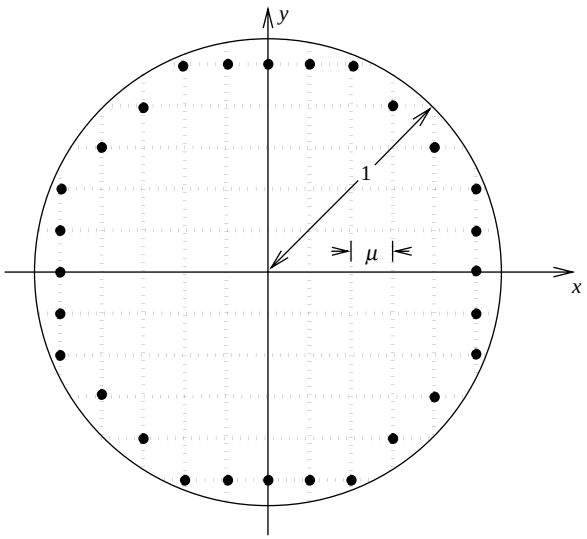

FIG. A.1. *The acceleration set $\mathcal{A}_\mu$ in two dimensions.*

such that

$$\mu \le \kappa_l \le \frac{\epsilon}{4\sqrt{d}}, \tag{A.6}$$

then $\mathcal{A}_\mu$ has a uniform advantage of κ_l over $\mathcal{A}_\epsilon$. Notice that $|\mathcal{A}_\mu| = O(d(1/\mu)^{d-1})$.

A τ-bang (resp., τ-bang trajectory) is a (μ,τ)-*bang* (resp., (μ,τ)-*bang trajectory*) if the acceleration set used is $\mathcal{A}_\mu$. Given a tracking tolerance (η_x,η_v) and any $\epsilon > 0$, there exist μ (satisfying (A.6)) and τ (satisfying (A.4)) such that for any $(1/(1+\epsilon)^2, 1/(1+\epsilon))$-trajectory Γ, there exists a (μ,τ)-bang trajectory Γ' (also a $(1,1)$-trajectory) that tracks Γ to a tolerance of (η_x,η_v). To approximate any given $(1,1)$-trajectory Γ to within a factor of $(1+\epsilon)$ in time length, we first time-rescale Γ to a $(1/(1+\epsilon)^2, 1/(1+\epsilon))$-trajectory Γ', with time length extended by a factor of $(1+\epsilon)$. Since there exists a (μ,τ)-bang trajectory Γ'' that tracks Γ' to a tolerance of (η_x,η_v), Γ'' approximates Γ in that $T(\Gamma'') \le (1+\epsilon)\,T(\Gamma)$. But Γ'' does not track Γ to the tolerance of (η_x,η_v). However, $d(\Gamma'',\Gamma) \le \eta_x$. This is because Γ' and Γ trace the same path and $d(\Gamma'',\Gamma') \le \eta_x$. Also the two end states of Γ'' are close to the two end states of Γ, respectively.

Having discovered the existence of a tracking bang trajectory, the next question is how to compute one. What makes it more difficult is that most of the time, the original $(1,1)$-trajectory Γ is not given except in its initial and final states. The *TC*-graph method transforms this problem to that of finding a shortest path in a directed graph. (In the following, we only describe the *TC*-graph method in the absence of obstacles, where we do not have to do collision-free checking.) The *TC* graph G is roughly as follows: (i) the *root node* of G approximates the initial state of Γ; (ii) a directed edge corresponds to a (μ,τ)-bang whose velocities are also bounded by 1 in L_2-norm; the weight of the edge is always τ; (iii) the graph is generated and explored from the root node in a breadth-first manner, and the search terminates when either a node approximating the final state is found or when no new nodes aregenerated.

Note the following:

- The size of G is finite (see the following analysis).
- The breadth-first search produces a trajectory whose time length is no more than $(1+\epsilon)\,T(\Gamma)$. The breadth-first search suffices for finding a shortest path since each edge has a uniform weight of τ.
- Suppose that Γ lies within a subset W of the configuration space. Since there exists a bang trajectory Γ'' satisfying $d(\Gamma'', \Gamma') \leq \eta_x$, then $d(\Gamma'', W) \leq \eta_x$. We can find such a trajectory by considering only those edges whose corresponding bangs do not diverge from W by more than η_x. Notice that it still holds that $T(\Gamma'') \leq (1+\epsilon)\,T(\Gamma)$.

Each node of G corresponds to a state. By carefully choosing the initial velocity, we can bound the number of possible velocities by $O((1/(\mu\tau))^d)$ and the number of possible locations by $O((L/(\mu\tau^2))^d)$, where L is the size of W. Thus the total number of nodes is bounded by

$$O\left(\left(\frac{L}{\mu^2\tau^3}\right)^d\right). \tag{A.7}$$

Each node can have at most $O(d(1/\mu)^{d-1})$ outgoing edges (because it can have at most this many choices of accelerations), thus the total number of graph edges is

$$O\left(\frac{dL^d}{\mu^{3d-1}\tau^{3d}}\right). \tag{A.8}$$

This also bounds the running time.

If we set

$$\eta_x = \epsilon\rho/2 \text{ and } \eta_v = \epsilon/2, \tag{A.9}$$

where $\rho = O(1)$, we obtain Corollary 2.2. Notice that since $\tau = O(\epsilon)$ and $\mu = O(\epsilon)$, the running time is $O(L^d(1/\epsilon)^{6d-1})$.

ALLOCATING BANDWIDTH FOR BURSTY CONNECTIONS*

JON KLEINBERG†, YUVAL RABANI‡, AND ÉVA TARDOS§

Abstract. In this paper, we undertake the first study of statistical multiplexing from the perspective of approximation algorithms. The basic issue underlying statistical multiplexing is the following: in high-speed networks, individual connections (i.e., communication sessions) are very *bursty*, with transmission rates that vary greatly over time. As such, the problem of packing multiple connections together on a link becomes more subtle than in the case when each connection is assumed to have a fixed demand.

We consider one of the most commonly studied models in this domain: that of two communicating nodes connected by a set of parallel edges, where the rate of each connection between them is a random variable. We consider three related problems: (1) stochastic load balancing, (2) stochastic bin-packing, and (3) stochastic knapsack. In the first problem the number of links is given and we want to minimize the expected value of the maximum load. In the other two problems the link capacity and an allowed *overflow probability* p are given, and the objective is to assign connections to links, so that the probability that the load of a link exceeds the link capacity is at most p. In bin-packing we need to assign each connection to a link using as few links as possible. In the knapsack problem each connection has a value, and we have only one link. The problem is to accept as many connections as possible.

For the stochastic load balancing problem we give an $O(1)$-approximation algorithm for arbitrary random variables. For the other two problems we have algorithms restricted to on-off sources (the most common special case studied in the statistical multiplexing literature), with a somewhat weaker range of performance guarantees.

A standard approach that has emerged for dealing with probabilistic resource requirements is the notion of *effective bandwidth*—this is a means of associating a fixed demand with a bursty connection that "represents" its distribution as closely as possible. Our approximation algorithms make use of the standard definition of effective bandwidth and also a new one that we introduce; the performance guarantees are based on new results showing that a combination of these measures can be used to provide bounds on the optimal solution.

Key words. combinatorial optimization, approximation algorithms, statistical multiplexing, effective bandwidth

line of work has been directed towards the development of *approximation algorithms* and *competitive on-line algorithms* for admission control and virtual circuit routing problems (see the survey by Plotkin [16]). The network model in this line of work represents the links of the network as edges of fixed *capacity* and connections as pairs of vertices with a fixed *bandwidth demand* between them. The algorithms and their analysis are motivated by this network flow perspective.

In fact, however, traffic in high-speed networks based on asynchronous transfer mode (ATM) and related technologies tends to be extremely *bursty*. The transmission rate of a single connection can vary greatly over time; there can be infrequent periods of very high *peak rate*, while the *average rate* is much lower.

One can try to avoid this issue by assigning each connection a demand equal to its maximum possible rate. The use of such a conservative approximation will ensure that edge capacities are never violated. But much of the strength of ATM comes from the advantage of *statistical multiplexing*—the packing of uncorrelated, bursty connections on the same link. In particular, suppose one is willing to tolerate a low rate of packet loss due to occasional violations of the link capacity. As the "peak" states of different connections coincide only very rarely, one can pack many more connections than is possible via the above worst-case approach and still maintain a very low rate of packet loss due to overflow.

Queueing theorists recently have devoted a great deal of study to the analysis of statistical multiplexing (see the book edited by Kelly, Zachary, and Zeidins [13]). Typically, this work models a single connection either as a discrete random variable X, with $\Pr[X = s]$ indicating the fraction of the time that the connection transmits at rate s, or as a finite-state Markov chain with a fixed transmission rate for each state. (A much-discussed case is when X is an *on-off source*. In our context, such a connection is equivalent to a weighted Bernoulli trial.) This line of work has concentrated primarily on the case of point-to-point transmission across a set of parallel links; this allows one to study the packing and load balancing issues that arise without the added complication of path selection in a large network.

One of the main concepts that has emerged from this work has been the development of a notion of *effective bandwidth* for bursty connections. This is based on the following natural idea. Suppose one is willing to tolerate a rate p of overflow on each link. One first assigns a number $\beta_p(X)$ to each connection (i.e., random variable) X, indicating the "effective" amount of bandwidth required by this connection. One then uses a standard packing or load balancing algorithm to assign connections to links, using the single number $\beta_p(X)$ as the *demand* of the connection X. This notion of effective bandwidth is indeed what underlies the modeling of routing problems as network flow questions.

Consensus has more or less been reached (see Kelly [12]) on a specific formula for β_p, first studied by Hui [10]: a scaled logarithm of the moments-generating function of X. One of its attractions is that packing according to $\beta_p(X)$ always provides a relatively *conservative estimate* in the following sense: If the sum of the effective bandwidths of a set of independent connections does not exceed the link capacity, then the probability that the sum of their transmission rates exceeds twice the capacity at any instant is at most p.

Problems studied in this paper. In this paper, we undertake the first study of the issues inherent in statistical multiplexing from the perspective of approximation algorithms. We are motivated primarily by the following fact: the queueing theoretical work discussed above does not attempt to prove that its methods, based on

effective bandwidth, provide solutions that are *near-optimal* on all (or even on typical) instances. Indeed, researchers have recognized that claims about the power of the effective bandwidth approach depend critically on a number of fundamental assumptions about the nature of the underlying traffic (e.g., de Veciana and Walrand [18]). Thus an analysis of statistical multiplexing problems in the framework of approximation algorithms can provide tools for understanding the performance guarantees that can be attained in this domain.

We mentioned above that the model studied in this area concentrates primarily on the case of two communicating nodes connected by a set of parallel edges. Thus, the problem of assigning bursty *connections* to *edges* is equivalent to that of assigning (bursty) *items* to *bins*. As a result, we have a direct connection between the standard questions addressed in statistical multiplexing and stochastic versions of some of the classical resource allocation problems in combinatorial optimization. We design and analyze approximation algorithms for the following fundamental problems:

Stochastic load balancing. An *item* is a discrete random variable. We are given items $X_1, \ldots, X_n$. We want to assign each item to one of the bins $1, \ldots, m$ so as to minimize the *expected maximum weight* in any bin. That is, we want to minimize

$$\mathrm{E}\left[\max_i \sum_{X_j \in B_i} X_j\right],$$

where B_i is the set of items assigned to bin i.

Stochastic bin-packing. We are given items as above, and we define the *overflow probability* of a subset of these items to be the probability that their sum exceeds 1. We are also given a number $p \geq 0$. We want to determine the minimum number of bins (of capacity 1) that we need in order to pack all the items, so that the overflow probability of the items in each bin is at most p.

Stochastic knapsack. We are given $p \geq 0$ and a set of items $X_1, \ldots, X_n$, with item X_i having a *value* v_i. We want to find a subset of the items of maximum value, subject to the constraint that its overflow probability is at most p.

Thus, the above problems provide us with a very concrete setting in which to try assessing the power of various approaches to the statistical multiplexing of bursty connections. These problems are also the natural stochastic analogues of some of the central problems in the area of approximation algorithms; and hence we feel that their approximability is of basic interest.

Of course, each of these problems is NP-hard, since the versions in which each item X_i is *deterministic* (i.e., takes a single value with probability 1) correspond to the *minimum makespan*, *bin-packing*, and *knapsack* problems, respectively. However, the stochastic versions introduce considerable additional complications. For example, we show that even *given* a set of items, determining its overflow probability is $\#P$-complete (see section 2).

Moreover, we also show that simple approaches such as (i) applying Hui's definition of effective bandwidth [10] to the items, and then (ii) running a standard algorithm for the case of deterministic weights (e.g., Graham's lowest-fit makespan algorithm or first-fit for bin packing) can lead to results that are very far from optimal. Indeed, we show in section 2 that in a certain precise sense there is no "direct" use of effective bandwidth that can provide approximation results as strong as those we obtain.

1.1. Our results. This paper provides the first approximation algorithms for these load balancing and packing problems with stochastic items. Our algorithms make use of effective bandwidth, and their analysis is based on new results showing, roughly, that it is possible to define a notion of *effective bandwidth* that can be used to obtain bounds on the value of the optimum.

However, the relationships between the effective bandwidth and the optimum are quite subtle. In particular, while Hui's definition is a useful ingredient in our algorithm for the case of load balancing, we show in the cases of bin-packing and knapsack that it is *necessary* to use a definition of effective bandwidth that is *different* from the standard one. Our new effective bandwidth function β' has a number of additional properties that make its analysis particularly tractable. In particular, it was through β' that we were able to establish our basic relations between the function β and the value of the optimum for the case of load balancing.

Load balancing. Perhaps our strongest result is for the load balancing problem: we provide a constant-factor approximation algorithm for the optimum load for arbitrary random variables. With a somewhat larger constant, we can modify our algorithm to work in an *on-line* setting, in which items arrive in sequence and must be assigned to bins immediately.

Let us give some indication of the techniques underlying this algorithm. First, we mentioned above that the standard effective bandwidth β_p comes with an *upper bound* guarantee: if the sum of the effective bandwidths of a set of items is bounded by 1, then the probability that the total load of these items exceeds 2 is at most p. (This fact is due originally to Hui [10] and has been extended and generalized by Kelly [11], Elwalid and Mitra [4], and others.)

Our proof of the constant approximation ratio uses a new *lower bound* guarantee for effective bandwidth. Suppose we have a set of random variables $X_1, \ldots, X_n$, so that each X_i is a weighted Bernoulli trial taking on the values 0 and 2^{-i} for an integer $0 \leq i \leq \log\log p^{-1}$. We show that there is an absolute constant $C \leq 7$ so that if the sum of the effective bandwidths of the X_i is at least C, then the probability that their sum exceeds 1 is *at least* p.

A number of issues must be resolved in order to use these bounds in the design and analysis of our algorithm. First, the upper bound guarantee holds only under some restricting assumptions on the item sizes, which are not necessarily valid for our input. Therefore, we have to handle *exceptional* items separately. Second, our lower bound concerns overflow probabilities, whereas our objective function is the expected maximum load in any bin. Finally, we have to use this lower bound in the setting of arbitrary random variables, despite the fact that the concrete result itself applies only to a restricted type of random variable.

Bin-packing and knapsack. In the case of the bin-packing and knapsack problems we consider primarily on-off sources. In our context, such a connection is equivalent to a weighted Bernoulli trial. Our emphasis on on-off sources is in keeping with the focus of much of the literature (see, e.g., the book [13]). With somewhat weaker performance guarantees, we can also handle the more general case of high-low sources: connections whose rates are always one of two positive values.

For the bin-packing problem with on-off items we give an algorithm that finds a solution with at most $O(\sqrt{\frac{\log p^{-1}}{\log\log p^{-1}}})B^* + O(\log p^{-1})$ bins, where B^* is the minimum possible number of bins. For the knapsack problem we provide an $O(\log p^{-1})$-approximation algorithm. We also provide constant-factor approximation algorithms

for both problems, in which case one is allowed to relax either the size of the bin or the overflow probability by an arbitrary constant $\varepsilon > 0$. Our algorithm for bin-packing can be modified to work in an *on-line* setting, in which items arrive in sequence and must be assigned to bins immediately.

Our algorithms are based on a notion of effective bandwidth, but not the standard one in the literature. In particular, the guarantee provided by the standard definition is not strong enough for the bin-packing and knapsack problems: it says that if the sum of the effective bandwidths of a set of items is bounded by 1, then the probability that the total load of these items exceeds 2 is at most p. While such a guarantee is strong enough for the load balancing problem—a load of 2 is within a constant factor of a load of 1—it is inadequate for the bin-packing and knapsack problems, which fix hard limits on the size of each bin. Stronger guarantees without exceeding the link capacity were provided by Hui [10], Kelly [11], and Elwalid and Mitra [4] using large overflow buffers. We provide such stronger guarantees without resorting to overflow buffers. In particular, for items of large peak rate (the most difficult case for the standard definition β), we make use of our new effective bandwidth β' to provide the desired performance guarantee.

1.2. Connections with stochastic scheduling. Although we have so far expressed things in the context of bursty traffic in a network, our result on load balancing also resolves a natural problem in the area of *stochastic scheduling*.

There is a large literature on scheduling with stochastic requirements; the recent book on scheduling theory by Pinedo [15] gives an overview of the important results known in this area. In a stochastic scheduling problem, the job processing times are represented by random variables; typical assumptions are that these processing times are independent and identically distributed, and that the distribution is Poisson or exponential. For some of these cases, algorithms have been developed that guarantee an asymptotically optimal schedule with high probability (e.g., Weiss [19, 20]).

We can naturally view our load balancing problem as a scheduling problem on m identical machines (the bins), with a set of n stochastic jobs (the items). Since the problem contains the NP-hard deterministic version as a special case, we cannot expect to find an optimal solution. What our load balancing result provides is a constant approximation for the minimum makespan problem on m identical machines, when the processing time of each job can have an *arbitrary* distribution.

One distinction that arises in these scheduling problems is the following: must all the jobs be loaded onto their assigned machines immediately, or can we perform an assignment adaptively, learning the processing times of earlier jobs as they finish? Our model, since it is motivated by a circuit-routing application, takes the first approach. This is also the approach taken by, e.g., Lehtonen [14], who considers the special case of exponentially distributed processing times; that work left the case of general distributions—which we handle here—as an open problem.

2. Preliminary results and examples. For much of the paper, we will be discussing random variables that are *Bernoulli trials*. We say that a random variable X is a *Bernoulli trial of type* (q, s) if X takes the value s with probability q and the value 0 with probability $1 - q$.

The load balancing, bin-packing, and knapsack problems are all NP-complete even when all items are *deterministic* (i.e., they assume a single value with probability 1). As mentioned above, the introduction of stochastic items leads to new sources of intractability.

THEOREM 2.1. *Given Bernoulli trials $X_1, \ldots, X_n$, where X_i is of type (q_i, s_i), it is #P-complete to compute* $\Pr[\sum_i X_i > 1]$.

Proof. Membership in $\#P$ is easy to verify. We prove $\#P$-hardness by a reduction from the problem of counting the number of feasible solutions to a knapsack problem. That is, given numbers $y_1, \ldots, y_n$ and a bound B, we want to know how many subsets of $\{y_1, \ldots, y_n\}$ add up to at most B. We make two modifications to this problem which do not affect its tractability:

(i) We assume that $B = 1$.

(ii) We consider the complementary problem of counting the number of subsets of $\{y_1, \ldots, y_n\}$ that sum to more than B.

Thus, given $y_1, \ldots, y_n$, we create Bernoulli trials $X_1, \ldots, X_n$ such that X_i is of type $(\frac{1}{2}, y_i)$. Let $p = \Pr[\sum_i X_i > 1]$. The theorem follows from the fact that the number of subsets of $\{y_1, \ldots, y_n\}$ that sum to more than 1 is equal to $p \cdot 2^n$. □

The use of effective bandwidth is a major component in the design of our approximation algorithms. We now give some examples to show that no "direct" use of effective bandwidth will suffice in order to obtain the approximation guarantees presented in later sections. These examples also provide intuition for some of the issues that arise in dealing with stochastic items.

First we consider the load balancing problem. A natural approximation method one might consider here is Graham's lowest-fit algorithm applied to the expected values of the items. However, this fails to achieve a constant-factor approximation. This is a consequence of the following much more general fact. Let γ be any function from random variables to the nonnegative real numbers. If $X_1, \ldots, X_n$ are random variables, and ϕ is an assignment of them to m bins, we say that ϕ is γ-optimal if it minimizes the maximum sum of the γ-values of the items in any one bin.

THEOREM 2.2. *For every function γ as above, there exist $X_1, \ldots, X_n$ and a γ-optimal assignment ϕ of $X_1, \ldots, X_n$ to m bins such that the load of ϕ is $\Omega(\log m / \log\log m)$ times the optimum load.*

Proof. For an arbitrary function γ, we consider just two kinds of distributions: a Bernoulli trial of type $(m^{-\frac{1}{2}}, 1)$ and a Bernoulli trial of type $(1, 1)$. (This latter distribution is simply a deterministic item of weight 1.) By rescaling, assume that γ takes the value 1 on Bernoulli trials of type $(1, 1)$ and the value $am^{-\frac{1}{2}}$ on Bernoulli trials of type $(m^{-\frac{1}{2}}, 1)$. We consider two cases.

Case 1. $a \leq \frac{\varepsilon \log m}{\log\log m}$ for some sufficiently small constant ε. In this case, we consider the following γ-optimal assignment: one item of type $(1, 1)$ in each of the $m - \sqrt{m}$ bins, and $\sqrt{m}/a$ items of type $(m^{-\frac{1}{2}}, 1)$ in each of the remaining $\sqrt{m}$ bins. With high probability, at least $\frac{\varepsilon \log m}{\log\log m}$ of the latter type of item will be on in the same bin, and hence the load of this assignment is $\Omega(\log m / \log\log m)$. By placing at most one item of each type in every bin, one can obtain a load of 2 for this problem.

Case 2. $a > \frac{\varepsilon \log m}{\log\log m}$. In this case, consider the following γ-optimal assignment ϕ: $C\sqrt{m}\log m$ items of type $(m^{-\frac{1}{2}}, 1)$ in each of $m - 1$ bins, for a sufficiently large constant C, and $aC \log m$ items of type $(1, 1)$ in the mth bin. Thus, the load of ϕ is at least $aC \log m$. However, with high probability, the maximum load in the first $m - 1$ bins will be $\Theta(\log m)$, and hence the assignment that evenly balances the items of both types has load $O((1 + \frac{a}{m}) \log m)$. This is better by a factor of $\Omega(\frac{am}{a+m})$. □

We now discuss a similar phenomenon in the case of bin-packing. Let us say that a packing of items into bins is *incompressible* if merging any two of its bins results in an infeasible packing. For the problem of packing deterministic items, a basic fact is that any incompressible packing is within a factor of 2 of optimal. In contrast, we can

show the existence of a set of stochastic items that can be packed in only two bins, but for which there is an *incompressible* packing using $\Omega(p^{-\frac{1}{2}})$ bins.

THEOREM 2.3. *Consider a bin-packing problem with overflow probability p. There exist sets of weighted Bernoulli trials S_1 and S_2 with the following properties.*

(i) $|S_1| = |S_2| = \Omega(p^{-\frac{1}{2}})$.

(ii) *All the items of S_1 can be packed in a single bin.*

(iii) *All the items of S_2 can be packed in a single bin.*

(iv) *One cannot pack one item from S_1 and two from S_2 together in one bin.*

Thus there is a packing of $S_1 \cup S_2$ in two bins, but the packing that uses $\Omega(p^{-\frac{1}{2}})$ and places one item from each set in each bin is incompressible.

Proof. Let p be the given overflow probability, q a real number slightly greater than p, and ε a small constant. One can verify that the above properties hold for the following two sets of weighted Bernoulli trials: S_1 consists of $\varepsilon p^{-\frac{1}{2}}$ items of type $(q, 1-\sqrt{p})$; S_2 consists of $\varepsilon p^{-\frac{1}{2}}$ items of type $(1, \sqrt{p})$. □

COROLLARY 2.4. *No algorithm which simply looks at a single "effective bandwidth" number for each item can provide an approximation ratio better than $\Omega(p^{-\frac{1}{2}})$.*

Proof. Note the behavior of any effective bandwidth function γ in the example of the above theorem. If $X \in S_1$ and $Y \in S_2$, then we have just argued that there exists a set of items whose effective bandwidths add up to $\gamma(X) + 2\gamma(Y)$ and which cannot be packed into one bin. But the entire set of items can be packed into two bins; and its total effective bandwidth is $\varepsilon p^{-\frac{1}{2}}[\gamma(X) + \gamma(Y)]$. This example also shows that the first-fit heuristic applied to a given item ordering can use a number of bins that is $\Omega(p^{-\frac{1}{2}})$ times optimal. □

The effective bandwidth we use. As discussed in the introduction, we will use both the standard definition of effective bandwidth β_p and a new *modified effective bandwidth* β'_p that turns out to be necessary in the case of bin-packing and is also used in proving our lower bounds on optimality for the load balancing problem. For a random variable X, one defines [10, 12]

$$\beta_p(X) = \frac{\log \mathrm{E}[p^{-X}]}{\log p^{-1}}. \tag{2.1}$$

For a Bernoulli trial X of type (q, s), we define its *modified effective bandwidth* by

$$\beta'_p(X) = \min\{s, sqp^{-s}\}. \tag{2.2}$$

For a set of random variables $\mathcal{R}$, we will use the notation $\beta_p(\mathcal{R}) = \sum_{X \in \mathcal{R}} \beta_p(X)$ and $\beta'_p(\mathcal{R}) = \sum_{X \in \mathcal{R}} \beta'_p(X)$.

We first give an inequality relating our modified effective bandwidth to the standard one. The proof follows from elementary calculus.

PROPOSITION 2.5. *For a Bernoulli trial X, $\beta_p(X) \le \beta'_p(X)$.*

Proof. First, we establish the following claim.

(A) *For $a \ge 1$, define $f(x) = a^x - 1$ and $g(x) = xa^x \ln a$. Then $f(x) \le g(x)$ for all $x \in [0, 1]$.*

We prove (A) by noting that

$$\lim_{x \to 0} \frac{f(x)}{g(x)} = 1,$$

and $f'(x) \le g'(x)$ for all $x \in [0, 1]$.

Now if X is of type (q, s), then we have

$$\beta_p(X) = \frac{\log\left(qp^{-s} + (1-q)\right)}{\log p^{-1}} = \frac{\log\left(1 + q(p^{-s}-1)\right)}{\log p^{-1}}.$$

To prove the proposition, it is sufficient to show that $\beta_p(X) \le s$ and $\beta_p(X) \le sqp^{-s}$. The first of these statements follows by taking logarithms base p^{-1} of the inequality $qp^{-s} + (1-q) \le p^{-s}$. To show the second, note that by Taylor's inequality

$$\beta_p(X) \le \frac{q(p^{-s}-1)}{\log p^{-1}},$$

and by fact (A)

$$\frac{q(p^{-s}-1)}{\log p^{-1}} \le qsp^{-s}. \qquad \square$$

3. Stochastic load balancing. Let $X_1, X_2, \ldots, X_n$ be mutually independent random variables taking nonnegative real values. We shall refer to them as *items*. Let $\phi : \{1, \ldots, n\} \to \{1, \ldots, m\}$ be a function assigning each item X_i to one of m *bins*. We define the *load* of the assignment ϕ, denoted $\mathcal{L}(\phi)$, to be the expected maximum load on any bin; that is, $\mathcal{L}(\phi) = \mathrm{E}[\max_i \sum_{j \in \phi^{-1}(i)} X_j]$. We are interested in designing approximation algorithms for the problem of minimizing $\mathcal{L}(\phi)$ over all possible assignments ϕ. Note that the maximum of the expectations would be easy to approximate by simply load balancing the expectations.

3.1. The algorithm for on-off items. In this subsection we present an $O(1)$-approximation algorithm for the case of weighted Bernoulli trials; we then extend this to handle arbitrary distributions in the following subsection. For a Bernoulli trial of type (q, s), we can further assume that s is a power of 2—by reducing all item sizes to the nearest power of 2 we lose only a factor of 2 in the approximation ratio.

Our load balancing algorithm is on-line. It proceeds through iterations; in each iteration it maintains a current estimate of the optimum load, which will always be correct to within a constant factor. An iteration can end in one of two ways: the input can come to an end, or the iteration can *fail*. In the latter case, the estimate of the optimum is doubled, and a new iteration begins.

For ease of notation, the algorithm rescales all modified sizes that it sees so that the estimate in the current iteration is always equal to 1. An item X_i of type (q_i, s_i) is said to be *exceptional* if $s_i > 1$, and *normal* otherwise. Throughout the algorithm, we define $p = m^{-1}$ (recall that m is the number of bins) and C to be an absolute constant. ($C = 18$ is sufficient.) One iteration proceeds as follows; suppose that item X_i has just been presented.

(1) For each bin j, let B_j denote the set of all nonexceptional items from this iteration that have been assigned to j.
(2) If X_i is normal, then we assign it to the bin j with the smallest value of $\beta_p(B_j)$. If this would cause $\beta_p(B_j)$ to exceed C, then the iteration *fails*.
(3) Suppose X_i is exceptional. If the total *expected* size of all exceptional items seen in this iteration (including X_i) exceeds 1, then the iteration *fails*. Otherwise, X_i is assigned to an arbitrary bin.

To prove that this algorithm provides a constant-factor approximation, we show that (i) if an iteration does not fail, then the load of the resulting assignment is within a constant factor of the estimate for that iteration; and (ii) if iteration fails, then

the load of any assignment must be at least a constant times the estimate for that iteration. We start with (ii).

Lower bounding the optimal solution. First we prove a lower bound on the optimal solution to the load balancing problem. This lower bound is the main new technical contribution of this part, and will be used also in analyzing the bin-packing and knapsack algorithm in the next two sections. In this subsection we state and prove the lower bound for the special case of weighted Bernoulli trials. (In section 3.2 we show how the general case follows from the special case.) Assume that $X_1, X_2, \ldots, X_n$ are independent Bernoulli trials such that X_i is of type (q_i, s_i). We will sometimes say that "item X_i is on" to refer to the event that $X_i = s_i$.

We use the following basic claim repeatedly.

CLAIM 3.1. *Let $\mathcal{E}_1, \ldots, \mathcal{E}_k$ be independent events, with $\Pr[\mathcal{E}_i] = q_i$. Let $\mathcal{E}'$ be the event that at least one of these events occurs. Let $q \leq 1$ be a number such that $\sum_i q_i \geq q$. Then $\Pr[\mathcal{E}'] \geq \frac{1}{2}q$.*

Proof. Let $\bar{q} = \frac{1}{k}\sum_i q_i$.

$$\Pr[\mathcal{E}'] = 1 - \prod_i (1 - q_i) \geq 1 - (1 - \bar{q})^{\left(\frac{1}{\bar{q}}\sum_i q_i\right)}$$

$$\geq 1 - e^{-\sum_i q_i} \geq 1 - e^{-q} \geq q - \frac{1}{2}q^2 \geq \frac{1}{2}q. \qquad \square$$

Our key technical lower bound is in the following lemma. Here $p \in [0,1]$ is a target probability (in this section we use $p = m^{-1}$).

LEMMA 3.2. *Let $X_1, \ldots, X_n$ be Bernoulli trials of types $(q_1, s_1), \ldots, (q_n, s_n)$, respectively, such that $\log^{-1} p^{-1} \leq s_i \leq 1$ for each i, and each s_i is an inverse power of 2. If $\sum_i \beta'_p(X_i) \geq 7$, then $\Pr[\sum_i X_i \geq 1] \geq p$.*

Proof. Our goal is to modify the given set of Bernoulli trials so as to obtain a new problem in which (i) the probability of the sum exceeding 1 is no greater than originally and (ii) the probability of the sum exceeding 1 is at least p.

If there is any X_i for which $\beta'_p(X_i) = s_i$, we lower q_i until $q_i = p^{s_i}$. This preserves the assumption that $\sum_i \beta'_p(X_i) \geq 7$.

Let s be an inverse power of two, and consider the set $W^{(s)}$ of items X_i for which $s_i = s$. We partition $W^{(s)}$ into sets $W_1^{(s)}, \ldots, W_{r_s}^{(s)}$ such that for all $j = 1, 2, \ldots, r_s - 1$, $2p^s \leq \sum_{i|X_i \in W_j^{(s)}} q_i \leq 3p^s$ and $\sum_{i|X_i \in W_{r_s}^{(s)}} q_i < 2p^s$. This can be done because $q_i \leq p^s$ for all $X_i \in W^{(s)}$. We define a set $V^{(s)}$ of Bernoulli trials $Y_1^{(s)}, \ldots, Y_{r_s-1}^{(s)}$, each of type (p^s, s). Intuitively, each $Y_j^{(s)}$ approximates well the behavior of $\sum_{X_i \in W_j^{(s)}} X_i$. In particular, we show that the former is stochastically dominated by the latter. We will prove the following:

(A) $\Pr[\sum_s \sum_j Y_j^{(s)} \geq 1] \leq \Pr[\sum_i X_i \geq 1]$;

(B) $\beta'_p(\cup_s V^{(s)}) \geq 1$;

(C) $\Pr[\sum_s \sum_j Y_j^{(s)} \geq 1] \geq p$.

The claim clearly follows from (A) and (C).

To prove (A), we show that $\Pr[\sum_{X_i \in W_j^{(s)}} X_i \geq s] \geq p^s = \Pr[Y_j^{(s)} \geq s]$. The expression on the left-hand side is simply the probability that any of the items in $W_j^{(s)}$ is on; by Claim 3.1, the fact that $\sum_{i|X_i \in W_j^{(s)}} q_i \geq 2p^s$, and the fact that $p^s \leq \frac{1}{2}$, this probability is at least p^s, and (A) follows.

To prove (B), notice that ${\beta'}_p(W_{r_s}^{(s)}) \le 2p^s sp^{-s} = 2s$, and for $1 \le j < r_s$, ${\beta'}_p(W_j^{(s)}) \le 3p^s sp^{-s} = 3s$. On the other hand, ${\beta'}_p(Y_j^{(s)}) = p^s sp^{-s} = s$. Thus ${\beta'}_p(V^{(s)}) \ge \frac{1}{3}({\beta'}_p(W^{(s)}) - 2s)$. Hence

$$\begin{aligned}{\beta'}_p(\cup_s V^{(s)}) &= \sum_s {\beta'}_p(V^{(s)}) \ge \sum_s \frac{{\beta'}_p(W^{(s)}) - 2s}{3} \\ &= \frac{1}{3}\sum_s {\beta'}_p(W^{(s)}) - \frac{2}{3}\sum_s s \ge 1,\end{aligned}$$

where the last inequality follows from the fact that $\sum_s {\beta'}_p(W^{(s)}) \ge 7$, and $\sum_s s \le 2$ because s only takes on the values of inverse powers of 2.

To prove (C), recall that for all j, s, ${\beta'}_p(Y_j^{(s)}) = p^s sp^{-s} = s$. Now, let V denote a subset of $\cup_s V^{(s)}$ consisting of items whose sizes sum to 1. That such a set exists follows from (B) and the fact that all sizes are inverse powers of 2. Let $\{Y_1', \ldots, Y_\ell'\}$ denote the items in V, and let $s_1', \ldots, s_\ell'$ denote their sizes, respectively. Note that the probability that Y_i' is on is equal to $p^{s_i'}$.

The probability of the event $\sum_s \sum_j Y_j^{(s)} \ge 1$ is at least as large as the probability that all items in V are on. But this latter probability is equal to $\prod_{i=1}^{\ell} p^{s_i'} = p$. ∎

The lower bound for exceptional items follows by an argument using Claim 3.1.

LEMMA 3.3. *Let $X_1, \ldots, X_n$ be such that $L \le s_1 \le \cdots \le s_n$ and $\sum_i q_i s_i \ge L$. Then for all ϕ, we have $\mathcal{L}(\phi) \ge \frac{1}{2}L$.*

Proof. Without loss of generality, we may assume $\sum_i q_i s_i = L$. Let $q_i' = \sum_{j \ge i} q_j$. Let $\mathcal{E}_i$ denote the event that at least one item among $\{X_j\}_{j \ge i}$ is on, and let $q_i'' = \Pr[\mathcal{E}_i]$. Note that because $\sum_i q_i s_i = L$ and $s_i \ge L$ for all i, we have $\sum_i q_i \le 1$ and hence $q_i' \le 1$ for all i. Thus, by Claim 3.1, $q_i'' \ge \frac{1}{2}q_i'$. Write $s_0 = 0$ and $q_{n+1}' = 0$.

Observe that $\sum_i q_i s_i = \sum_i q_i'(s_i - s_{i-1})$, because each s_i is counted with a multiplier of q_i on the right-hand side.

Since $\Pr[X_i \text{ is on } \textit{and} \text{ not } \mathcal{E}_{i+1}] = q_i'' - q_{i+1}''$, we have

$$\mathrm{E}[\max\{X_1, \ldots, X_n\}] \ge \sum_i s_i(q_i'' - q_{i+1}'') = \sum_i q_i''(s_i - s_{i-1}).$$

Thus for any assignment ϕ we have

$$\begin{aligned}\mathcal{L}(\phi) &\ge \mathrm{E}[\max\{X_1, \ldots, X_n\}] \ge \sum_i q_i''(s_i - s_{i-1}) \\ &\ge \frac{1}{2}\sum_i q_i'(s_i - s_{i-1}) = \frac{1}{2}\sum_i q_i s_i = \frac{1}{2}L.\end{aligned}$$ ∎

Our main lower bound for the load balancing problem is the following lemma.

LEMMA 3.4. *Suppose that for all i, s_i is an inverse nonnegative integral power of 2 (so $s_i \le 1$). Further suppose that $\sum_i {\beta'}_{m^{-1}}(X_i) \ge 17m$. Then, for all ϕ, $\mathcal{L}(\phi) = \Omega(1)$.*

Proof. Let ϕ be an arbitrary assignment of the items to bins. Let $B_1, \ldots, B_m$ denote the sets of items assigned to bins $1, \ldots, m$, respectively. Apply the following construction: as long as some set B_i' contains a subset$S$ with ${\beta'}_{m^{-1}}(S) \ge 8$, we

put aside a minimal subset S with this property. Note that ${\beta'}_{m^{-1}}(S) \leq 9$ as the bandwidth of a single item of size at most 1 never exceeds 1. When we can no longer find such a subset, then the set of remaining items R has ${\beta'}_{m^{-1}}(R) \leq 8m$. Thus, this construction produces at least m subsets, such that each is assigned to a single bin by ϕ. We denote the first m of these subsets by $W_1, \ldots, W_m$.

Call a Bernoulli trial X of type (q, s) *small* if $s < 1/\log p^{-1}$. Using the fact that small items have $p^{-s} \leq 2$, we can see that the effective bandwidth ${\beta'}_p(X)$ of a small item is at most twice its expectation $\mathrm{E}[X] = qs$. Call a set W_i *dense* if the set of small items $S_i \subseteq W_i$ has ${\beta'}_{m^{-1}}(S_i) \geq 1$. If there exists a dense set W_i, then the expected size of W_i is at least $\frac{1}{2}$. Since $\mathcal{L}(\phi)$ is at least as large as the expected size of W_i, $\mathcal{L}(\phi) \geq \frac{1}{2}$ and the lemma follows.

Thus, we consider the case in which no W_i is dense. Let $W_i' \subseteq W_i$ denote the set of items in W_i which are not small. Since W_i is not dense, ${\beta'}_{m^{-1}}(W_i') \geq 7$. By Lemma 3.2, the probability that size of W_i' exceeds 1 is at least m^{-1}. Hence the probability that *some* W_i' exceeds 1 is at least $1 - (1 - m^{-1})^m \geq 1 - e^{-1}$. Since $\mathcal{L}(\phi) \geq \mathrm{E}[\max\{W_1', \ldots, W_m'\}]$, the lemma follows. □

Recall that the algorithm maintains a current estimate. The iteration fails if the total effective bandwidth of the small and normal items in a bin would exceed a constant C (we use $C = 18$) or if the total expected size of all exceptional items seen in this iteration exceeds 1.

THEOREM 3.5. *Let W denote the set of items presented to the algorithm in an iteration that fails. For any assignment ϕ of W to a set of m bins we have $\mathcal{L}(\phi) = \Omega(1)$, where 1 is the estimate for the iteration.*

Proof. Let ϕ be an arbitrary assignment of items in W to bins. An iteration can fail in one of two ways: either because the expected total size of exceptional items exceeds 1, or because the assignment of the new item to any bin j would cause $\beta_p(B_j)$ to exceed C.

In the first case, Lemma 3.3 implies that $\mathcal{L}(\phi) \geq \frac{1}{2}$. Concerning the second case, consider the moment at which the iteration fails. We have $\sum_j \beta_p(B_j) \geq m(C - 1)$ (because the new item's size, and therefore its effective bandwidth, cannot exceed 1). Recalling that $C \geq 18$, Lemma 3.4 asserts that $\mathcal{L}(\phi) = \Omega(1)$. □

Upper bounding the solution obtained. The following proposition is essentially due to Hui [10], who stated it with $a = 2$ and $b = 1$. We give a short proof for the sake of completeness.

PROPOSITION 3.6 (see [10]). *Let $X_1, \ldots, X_n$ be independent random variables, and $X = \sum_i X_i$. Let $a > b$. If $\sum_i \beta_p(X_i) \leq b$, then $\Pr[X \geq a] \leq p^{a-b}$.*

Proof. First, if $\sum_i \beta_p(X_i) \leq b$, then $\sum_i \log \mathrm{E}[p^{-X_i}] \leq \log p^{-b}$ and hence $\prod_i \mathrm{E}[p^{-X_i}] \leq p^{-b}$.

Thus we have $\Pr[X \geq a] = \Pr[p^{-X} \geq p^{-a}] \leq p^a \mathrm{E}[p^{-X}] = p^a \prod_i \mathrm{E}[p^{-X_i}] \leq p^{a-b}$, where the first inequality follows from Markov's inequality, the equation from the independence of the X_i, and the last inequality from inequality above. □

LEMMA 3.7. *Consider the assignment produced by any iteration of the algorithm. The load of this assignment is $O(1)$. (Recall that sizes are scaled so that 1 is the estimate for that iteration.)*

Proof. The expected size of the sum of exceptional items placed in this iteration is at most 1, so they only add at most 1 to the expected maximum load.

Let $S_j = \sum_{X_i \in B_j} X_i$. Let $x \geq 0$. As $\beta_p(B_j) \leq C$, $\Pr[S_j > x + C] \leq m^{-x}$ by Proposition 3.6. Let $S^* = \max\{S_1, \ldots, S_m\}$. We have$\Pr[S^* \geq y] \leq \sum_j \Pr[S_j \geq y]$.

Hence

$$\begin{aligned}\mathrm{E}[S^*] &= \int_0^\infty \Pr[S^* \geq x]dx \leq C + 1 + \int_{C+1}^\infty \Pr[S^* \geq x]dx \\ &= C + 1 + \int_1^\infty \Pr[S^* \geq x + C]dx \\ &\leq C + 1 + \int_1^\infty m \cdot m^{-x}dx \\ &= C + 1 + m\frac{1}{m \ln m} = C + O(1),\end{aligned}$$

from which the lemma follows. □

Since the estimates increase geometrically, a consequence of Lemma 3.7 is the following theorem.

THEOREM 3.8. *Let ϕ_A be the assignment produced by the algorithm. Then $\mathcal{L}(\phi_A) = O(1)$, where item sizes are scaled so that 1 is the estimate for the final iteration.*

Combining Theorems 3.8 and 3.5, we get our main result.

THEOREM 3.9. *The algorithm provides a constant-factor approximation to the minimum load.*

3.2. Extension to arbitrary distributions. We may assume that the only values taken on by our random variables are powers of 2. If not, other values are rounded down to a power of 2. As in the previous section, this increases our approximation guarantee by a factor of 2 at most. Call a random variable that only takes values that are powers of 2 *geometric*. By the following claim we can reduce the problem for geometric items to the problem for Bernoulli trial items, which we have already solved.

LEMMA 3.10. *Let X be a geometric random variable. Then there exists a set of independent Bernoulli trials $Y_1, \ldots, Y_k$, with $Y = \sum_i Y_i$, such that $\Pr[X = s] = \Pr[s \leq Y < 2s]$.*

Proof. Suppose that X takes the value s_i with probability q_i for $i = 1, \ldots, k$. Suppose that $s_1 > s_2 > \cdots > s_k$. We define Y_i to be of type (q_i', s_i), where

$$q_i' = \frac{q_i}{(1 - q_1 - \cdots - q_{i-1})}.$$

Notice that the events $X = s_i$, $i = 1, \ldots, k$, are mutually exclusive, and therefore q_i' is simply $\Pr[X = s_i \mid X \leq s_i]$. The set $\{q_i'\}$ is the solution to

$$\begin{aligned}q_1 &= q_1', \\ q_2 &= (1 - q_1')q_2', \\ q_3 &= (1 - q_1')(1 - q_2')q_3', \\ &\vdots \\ q_k &= \left(\prod_{i=1}^{k-1}(1 - q_i')\right) q_k',\end{aligned}$$

and hence

$$\Pr[\max_j Y_j = s_i] = q_i' \prod_{j=1}^{i-1}(1 - q_j') = q_i = \Pr[X = s_i].$$

As $s_i > \sum_{j>i} s_j$, the claim follows. □

The algorithm is essentially the same as before. It uses the standard definition of effective bandwidth (Equation (2.1)), which applies to any distribution. The only change arises from the fact that we must define what we mean by "exceptional" in this case. Each item X_i is now divided into an *exceptional part* $X_i \cdot \mathbf{1}_{\{X_i>1\}}$ and a *nonexceptional part* $X_i \cdot \mathbf{1}_{\{X_i\leq 1\}}$. When the expected total value of all exceptional parts exceeds 1, the iteration fails; before this, exceptional parts are (necessarily) just packed together with their nonexceptional parts.

THEOREM 3.11. *The algorithm provides a constant-factor approximation to the minimum load.*

Proof. Recall that in the case of Bernoulli trials exceptional items could be packed in any bin. The upper bound argument follows as before, using Proposition 3.6 for the nonexceptional parts of the items.

The lower bound argument requires the approximation of each item by a sum of Bernoulli trials using Lemma 3.10. We replace each item X_i of a geometric random variable by the corresponding independent Bernoulli trials and apply the lower bound of the previous subsection to the resulting set of Bernoulli trials. □

4. Bin packing with stochastic on-off items. In this section we consider the *bin packing problem* with independent weighted Bernoulli trials, which we will refer to as "items." In addition we are given an allowed probability of overflow p. The problem is to pack the items into as few bins of size 1 each as possible, so that in each bin the probability that the total size of the items in the bin exceeds 1 is at most p. We assume throughout that $p \leq \frac{1}{8}$; this is consistent with routing applications, where p is much smaller than this [4].

We develop approximation algorithms parameterized by a number ε, $0 < \varepsilon < \frac{1}{2}$. Our results show that a solution whose value is within a factor of $O(\varepsilon^{-1})$ to optimal can be obtained if we relax either the bin size or the overflow probability. That is, we compare the performance of our algorithm to the optimum for a slightly smaller bin size or overflow probability. Using these results we then give an approximation algorithm without relaxing either the bin size or the overflow probability. Our algorithms will be on-line, as before.

The basic outline of the method is as follows. As in the load balancing algorithm, we will classify items according to their sizes. For the case with relaxed sizes and/or probabilities, an item will be *small* if $s_i \leq 1/\log_2 p^{-1}$, *large* if $s_i \geq \frac{1}{2}\varepsilon$ for the parameter ε, and *normal* otherwise. We pack using the expectation for small items, using the effective bandwidth $\beta_p(X)$ for normal items, and we develop techniques for packing large items based on our version of the effective bandwidth $\beta'_p(X)$. It can in fact be shown that the standard definition of effective bandwidth is not adequate for obtaining a strong enough approximation ratio.

For a large item of type (q_i, s_i), we effectively discretize its size, and work with its *effective size* $\bar{s}_i$; this is the reciprocal of the minimum number of copies of weight s_i that will overflow a bin of size 1: $\bar{s}_i^{-1} = \min\{j : js_i > 1\}$. Notice that $\bar{s}_i < s_i$ for all i.

An algorithm with relaxed bin size and probability. We start by describing a simpler version of the algorithm in which we relax both the bin size and the overflow probability. Each bin will contain items only of the same type (small, normal, or large). Each item is assigned a *weight*, according to which it is packed. Bins of each type can be packed according to any on-line bin-packing heuristic, applied to the weights; to be concrete, we will assume that the first-fit heuristic is being used.

Small items are given a weight equal to their expectation. A bin with small items will be packed so that its total weight does not exceed $\frac{1}{6}$. Each normal item X is assigned a weight of $\beta_p(X)$. A bin of normal items will be packed so that its total weight does not exceed ε.

The set of large items can have at most $\lceil 2\varepsilon^{-1} \rceil$ different effective sizes. They are classified into groups by the following two criteria.

(i) Each bin will only contain items of the same effective size.

(ii) We say that a large item X_i of type (q_i, s_i) and effective size $\bar{s}$ has *large probability* if $q_i \geq p^{\bar{s}}$ and *normal probability* otherwise. No bin will contain items of both large and normal probabilities.

We pack large probability items in bins so that fewer than $\frac{1}{\bar{s}}$ are in any bin. We pack normal probability items so that the sum of the probabilities of items in a bin does not exceed $p^{\bar{s}}/\bar{s}e$ where $e \approx 2.7..$ is the base of the natural logarithm. We now argue that the algorithm yields a feasible packing in bins of size $1 + \varepsilon$.

First we consider large items. If a bin contains items of effective size $\bar{s} = \frac{1}{k}$, then it will overflow if and only if at least k items are on. This implies that bins with large probability items do not overflow even if all items are on. Large items with normal probability are handled by the following lemma, which involves an analysis of our modified effective bandwidth.

LEMMA 4.1. *Let $X_1, \ldots, X_n$ be independent Bernoulli trials of types $\{(q_i, s_i)\}$, and assume that the effective size $\bar{s}_i = \bar{s}$ and $q_i \leq p^{\bar{s}}$ for all i. Let $X = \sum_i X_i$, and assume that $\sum_i q_i \leq p^{\bar{s}}/\bar{s}e$. Then $\Pr[X \geq 1] \leq p$.*

Proof. We get overflow in a bin if and only if at least k items are on, where $k = \frac{1}{\bar{s}}$. Let $\mathcal{I}$ denote the set of all items. For a set of items $S \subseteq \mathcal{I}$ of size k, the probability that all items in S are on is $\prod_{i \in S} q_i$. Thus the probability of overflow is at most

$$\sum_{S \subseteq I, |S|=k} \prod_{i \in S} q_i. \tag{4.1}$$

We claim that this formula is maximized for a given sum of probabilities $\sum_i q_i$ if all probabilities q_i are all the same. To see this, suppose that we have two items X_i, X_j with different probabilities, and consider modified items with probabilities $q_i' = q_j' = \frac{1}{2}(q_i + q_j)$. We now observe that the sum of probabilities has remained the same, but the probability of overflow is larger: the terms of (4.1) that contain 0 or 1 of the values q_i, q_j contribute in total the same as before, and terms containing both are each increased.

Assume now that all items have the same probability q. The sum of the probabilities of items is at most $p^{\bar{s}}/\bar{s}e$; hence, the number of these items is at most $p^{\bar{s}}/\bar{s}qe$. Now the probability that k items are on is bounded by

$$\binom{p^{\bar{s}}/q\bar{s}e}{1/\bar{s}} q^{\frac{1}{\bar{s}}} \leq \left(\frac{p^{\bar{s}}}{q}\right)^{\frac{1}{\bar{s}}} q^{\frac{1}{\bar{s}}} = p;$$

the inequality follows from the estimate $\binom{n}{k} \leq (\frac{en}{k})^k$. □

The feasibility for small items follows easily from Chernoff bounds.

LEMMA 4.2. *If $X_1, \ldots, X_k$ be independent Bernoulli trials of types $(q_1, s_1), \ldots, (q_k, s_k)$, such that $s_i \leq \frac{1}{\log_2 p^{-1}}$, and $\sum_i \mathrm{E}[X_i] \leq \frac{1}{6}$, then $\Pr[\sum_i X_i \geq 1] < p$.*

Proof. We use Chernoff bounds to bound the probability that the sum exceeds 1. With $\mu = \frac{1}{6} \log p^{-1}$, we have $\Pr[\sum_i X_i > 1] < (e^{5/6}/6)^{6\mu} < 2^{-6\mu} = p$. □

For the normal items, we apply Proposition 3.6 with $a = 1 + \varepsilon$ and $b = \varepsilon$.

We state this special case here for easy reference.

LEMMA 4.3. *Let $X_1, \ldots, X_n$ be independent random variables, and $X = \sum_i X_i$. Let $\varepsilon > 0$. If $\sum_i \beta_p(X_i) \le \varepsilon$, then $\Pr[X \ge 1 + \varepsilon] \le p$.*

THEOREM 4.4. *The on-line algorithm finds a packing of items in bins with the property that for each bin, the probability that the total size of the items in that bin exceeds $1 + \varepsilon$ is at most p.*

Note that large and small items are also feasible with bin size 1; it is only the normal items that require the relaxed bin size.

To prove the approximation ratio, we need to lower-bound the optimum. For small items, Chernoff bounds are sufficient; for normal items and large items of a given effective size we make use of a more careful analogue of Lemma 3.2.

Lemmas 4.7 and 4.8 will show that on large items of a given effective size the number of bins used by our algorithm is at most a constant factor away from the minimum possible. Since there are only $\lceil 2\varepsilon^{-1} \rceil$ different large effective sizes, this implies a bound of $O(\varepsilon^{-1})$ on large items. Lemma 4.6 shows that normal items with large total effective size (more than $5(1 + 2\varepsilon)$) have overflow probability more than $p^{1+3\varepsilon}$. This will imply that the number of bins used for normal items is at most an $O(\varepsilon^{-1})$ factor away from optimal. Finally, small items are again handled directly with Chernoff bounds.

LEMMA 4.5. *Let $p < \frac{1}{2}$ and $X_1, \ldots, X_k$ be independent Bernoulli trials of types (q_1, s_1), ..., (q_k, s_k), such that $s_i \le \log_2 p^{-1}$. If $\sum_i \mathrm{E}[X_i] \ge 4$, then $\Pr[\sum_i X_i > 1] > p$.*

Proof. We use Chernoff bounds to bound the probability that the sum exceeds 1. With $\mu = 4 \log p^{-1}$, we have

$$\Pr\left[\sum_i X_i \le 1\right] \le e^{-\frac{1}{2}\left(\frac{3}{4}\right)^2 \mu} < p,$$

and hence $\Pr[\sum_i X_i > 1] > 1 - p \ge p$. □

Next we consider normal items. In the load-balancing algorithm we proved a lower bound for effective bandwidth in Lemma 3.2; here we require a stronger version of this lemma. For later use we state the lemma with a parameter δ. Here we will use it with $\delta = 1$.

LEMMA 4.6. *Let $X_1, \ldots, X_k$ be independent Bernoulli trials of types $(q_1, s_1), \ldots, (q_k, s_k)$, such that $s_i \ge \frac{1}{\log_2 p^{-1}}$, and $\sum_i \beta_p(X_i) \ge (3\delta + 2)(1 + 2\varepsilon)$; then*

$$\Pr\left[\sum_i X_i > \delta\right] > p^{\delta(1+2\varepsilon)+\varepsilon}.$$

Proof. Recall that $\beta_p(X) \le {\beta'}_p(X)$ for all Bernoulli trials; hence we have that $\sum_i {\beta'}_p(X_i) \ge (3\delta + 2)(1 + 2\varepsilon)$. Further, we will round up the size of each Bernoulli trial X_i to an integer power of $1 + \varepsilon$. Let X_i' denote the resulting rounded item, and let (q_i, s_i') denote its type. Rounding up cannot decrease the effective bandwidth, so we have that $\sum_i {\beta'}_p(X_i') \ge (3\delta + 2)(1 + 2\varepsilon)$.

Next we prove an analogue of Lemma 3.2 for the rounded items. We claim that with probability more than $p^{\delta(1+2\varepsilon)+\varepsilon}$, the total size of the rounded items exceeds $\delta(1 + \varepsilon)$. Notice that this implies that the total size of the original items exceeds δ with probability more than $p^{\delta(1+2\varepsilon)+\varepsilon}$. The proof is analogous to the proof of Lemma 3.2.

We may assume without loss of generality that $q_i \le p^{s_i}$ for all i. Now we have that

$$\sum_i q_i s_i p^{-s_i} \ge (3\delta + 2)(1 + 2\varepsilon). \tag{4.2}$$

We define the sets of items $W^{(s)}$ for each size s; partition $W^{(s)}$ into sets $W_1^{(s)}, \ldots, W_{r_s}^{(s)}$ such that $2p^s \le \sum_{X_i \in W_j^{(s)}} q_i < 3p^s$ for $j = 1, \ldots, r_s - 1$; and define the set $V^{(s)}$ of Bernoulli trials $Y_1^{(s)}, \ldots, Y_{r_s-1}^{(s)}$, each of type (p^s, s), as in the proof of Lemma 3.2.

Next we want to argue that (i) the probability of the sum $\sum_{j,s} Y_j^{(s)}$ exceeding $\delta(1+\varepsilon)$ is no greater than the probability of $\sum_i X_i'$ exceeding $\delta(1+\varepsilon)$, and (ii) the probability of the sum $\sum_{j,s} Y_j^{(s)}$ exceeding $\delta(1+\varepsilon)$ is at least $p^{\delta(1+2\varepsilon)+\varepsilon}$.

To argue part (i) we show as before, using Claim 3.1, that $\Pr[\sum_{X_i' \in W_j^{(s)}} X_i' \ge s] \ge p^s = \Pr[Y_j^{(s)} \ge s]$. The fact that $p^s \le 1/2$ follows from the assumption that $s_i \ge 1/\log_2 p^{-1}$ for all i.

To show part (ii) we claim, using the notation from the proof of Lemma 3.2, that $\beta'_p(\cup_s V^{(s)}) > \delta(1+\varepsilon)$. To prove this, we note that as before we have $\beta'_p(V^{(s)}) > \frac{\beta'_p(W^{(s)}) - 2s}{3}$. Hence

$$\begin{aligned}\beta'_p(\cup_s V^{(s)}) &= \sum_s \beta'_p(V^{(s)}) > \sum_s \frac{\beta'_p(W^{(s)}) - 2s}{3} = \frac{1}{3}\left(\sum_s \beta'_p(W^{(s)}) - 2\sum_s s\right) \\ &= \frac{1}{3}\left(\sum_s \beta'_p(W^{(s)}) - 2(1+\varepsilon)\right) \ge \delta(1+2\varepsilon),\end{aligned}$$

since $\sum_s \beta'_p(W^{(s)}) \ge (3\delta+2)(1+2\varepsilon)$ by (4.2), and $\sum_s s \le (1+\varepsilon)$ since s only takes on values that are integer powers of $(1+\varepsilon)$ and at most ε.

We complete the proof of the lemma by showing $\Pr[\sum_s \sum_j Y_j^{(s)} > \delta(1+\varepsilon)] \ge p^{\delta(1+2\varepsilon)+\varepsilon}$. Note that for all j, s, $\beta'_p(Y_j^{(s)}) = p^s s p^{-s} = s$. Now, let V denote a subset of $\cup_s V^{(s)}$ consisting of items whose sizes sum to a number in $(\delta(1+2\varepsilon), \delta(1+2\varepsilon)+\varepsilon)$; such a set can be chosen as we have shown above that the sum of all sizes in $\cup_s V^{(s)}$ is at least $\delta(1+2\varepsilon)$, and all sizes are at most ε. Let $\{Y_1', \ldots, Y_\ell'\}$ denote the items in V, with $s_1', \ldots, s_\ell'$ denoting their sizes. Note that the probability that Y_i' is on is equal to $p^{s_i'}$.

The probability of the event

$$\sum_s \sum_j Y_j^{(s)} \ge \delta(1+2\varepsilon) > \delta(1+\varepsilon)$$

is at least as large as the probability that all items in V are on. But this latter probability is equal to

$$\prod_{i=1}^{\ell} p^{s_i'} = p^{\sum_{i=1}^{\ell} s_i'} > p^{\delta(1+2\varepsilon)+\varepsilon}. \qquad \square$$

Next we consider a group of large items of effective size s. The packing created by the algorithm is clearly optimal for items of large probability.

LEMMA 4.7. *If $\frac{1}{s}$ large probability items of effective size s are in the same bin, then the probability of overflow is more than p.*

Proof. Let $X_1, \ldots, X_s$ denote $\frac{1}{s}$ large probability items of effective size s. Note that if all $\frac{1}{s}$ items are on, then the total size exceeds the bin size 1. The probability of item i is $q_i > p^s$ for all i. The probability that all s items are on is therefore at least $\prod_i q_i > (p^s)^{\frac{1}{s}} = p$. □

Finally, consider large items of a given effective size and normal probability.

LEMMA 4.8. *Let $X_1, \ldots, X_k$ be independent Bernoulli trials of effective size s and probability $q_1, \ldots, q_k$, such that $s \geq \frac{1}{\log_2 p^{-1}}$; $q_i \leq p^s$ for all i, and $\sum_i q_i \geq 3p^s/s$. Then $\Pr[\sum_i X_i > 1] > p$.*

Proof. We need to argue that the probability that at least $\frac{1}{s}$ of the items are on exceeds p. We partition the set of items into sets $W_1, \ldots, W_{r+1}$ such that

$$2p^s < \sum_{X_i \in W_j} q_i \leq 3p^s$$

for $j = 1, \ldots, r$, and $r \geq \frac{1}{s}$. This is possible as $\sum_i q_i \geq 3p^s/s$ and $q_i \leq p^s$ for each i.

By the assumption that $p^s \leq \frac{1}{2}$, Claim 3.1 implies that in any set W_j for $j = 1, \ldots, r$ the probability that at least one of the items is on the set is more than p^s. Now the probability that at least one item is on in each of the first $\frac{1}{s}$ groups is more than $(p^s)^{\frac{1}{s}} = p$. This implies the lemma. □

Now we are ready to prove the general bound.

THEOREM 4.9. *For a parameter $\varepsilon \geq \frac{1}{\log_2 p^{-1}}$, the above on-line algorithm finds a packing of items in bins of size $1 + \varepsilon$ such that the number of bins used is at most $O(\varepsilon^{-1})$ times the minimum possible number of bins in any packing with bin size 1 and overflow probability at most $p^{1+3\varepsilon}$.*

Proof. We show that the number of bins used by our algorithm for small, normal, and large items is within $O(\varepsilon^{-1})$ of optimal.

First, suppose we use B bins for small items. Each bin is packed up to an expected value of at least $\frac{1}{6} - \frac{1}{\log p^{-1}}$ since packing an extra small item in the bin would exceed the expected value of $\frac{1}{6}$. It follows that the total expected value of all small items is at least $\frac{B(\log p^{-1} - 6)}{6 \log p^{-1}}$. Hence, if fewer than $\frac{B(\log p^{-1} - 6)}{24 \log p^{-1}}$ bins are used, some bin will overflow with probability exceeding p, by Lemma 4.5.

Next, suppose we use B bins for normal items. Each bin is packed up to a β_p-value of at least $\frac{1}{2}\varepsilon$ since adding a new normal item to a bin would exceed the total β_p value of ε, and each normal item has β_p value at most $\frac{1}{2}\varepsilon$. Therefore, the total β_p-value of normal items is at least $\frac{1}{2}\varepsilon B$. Hence, if fewer than $\frac{\varepsilon B}{10(1+2\varepsilon)}$ bins of size 1 are used for normal items, then Lemma 4.6 implies that some bin will overflow with probability exceeding p.

Finally, we consider large items of a given effective size. We show that we are within a constant factor of optimal on this set of items, where the constant does not depend on ε; thus, since there are only $\lceil 2\varepsilon^{-1} \rceil$ different effective sizes, our packing of large items will be within $O(\varepsilon^{-1})$ of optimal. First, Lemma 4.7 implies that for each effective size, the number of bins used for large items of large probability is optimal. Now suppose that we use B bins for large items of normal probability and a given effective size s. Then the total probability of this set of items is at least $Bp^s/2se$. Therefore, if fewer than $B/6e$ bins were used for this set of items, the items in at least one bin would have total probability more than $3p^s/s$, and by Lemma 4.8 the probability of overflow would exceed p. □

Algorithms with either relaxed bin size or probability. In fact, we can obtain the same approximation ratios (up to a constant factor) by only relaxing *either* the bin size or the overflow probability, but not both. Since the relaxed guarantees were only needed for normal items, the idea is to slightly "inflate" or "deflate" the size of the normal items that we present to the above algorithm and argue that we still do not lose too much in comparison to the optimum.

THEOREM 4.10. *There is a constant c such that for any parameter $\varepsilon \geq \frac{c}{\log p^{-1}}$ the following holds. There is an on-line polynomial time algorithm that finds a packing of items in bins of size* 1 *with overflow probability p, such that the number of bins used is at most $O(\varepsilon^{-1})$ times the minimum number of bins in any packing with bin sizes* 1 *and overflow probability at most $p^{1+\varepsilon}$.*

Proof. As just noted, the analysis for large and small items follows as before. The trouble with applying the previous analysis for normal items, of course, is that the packing created by the algorithm above might overflow bins of size exactly 1.

Here, we continue to use the effective bandwidth to pack normal items; however, for each normal item of type (q_i, s_i), we present the algorithm with an *inflated item* of type $(q_i, s_i(1+\varepsilon))$. We also set the threshold for large items at $\frac{1}{2}\varepsilon(1+\varepsilon)$, so that inflated items remain normal. Lemma 4.3 implies that the probability that the total sizes of the inflated items exceeds $1+\varepsilon$ is at most p; hence, the probability that the total size of the original items exceed 1 is at most p. For the lower bound on the optimum, we apply Lemma 4.6 to the inflated items, with $\delta = 1+\varepsilon$ to conclude that if the total effective bandwidth of the inflated items is sufficiently large then the probability that these items overflow a bin of size $1+\varepsilon$ is at least $p^{(1+\varepsilon)(1+2\varepsilon)+\varepsilon} \geq p^{1+5\varepsilon}$. Finally, we observe that a set of inflated items overflows a bin of size $1+\varepsilon$ if and only if the original items overflow a bin of size 1.

To get the bound claimed in the theorem, we must run the above algorithm with a parameter $\varepsilon' = \frac{1}{5}\varepsilon$. □

THEOREM 4.11. *For a parameter $\varepsilon \geq \frac{1}{\log_2 p^{-1}}$, there is a polynomial time algorithm that finds a packing of items in bins of size $1+\varepsilon$ with overflow probability p such that the number of bins used is at most $O(\varepsilon^{-1})$ times the minimum possible number of bins in any packing with bin sizes* 1 *and overflow probability at most p.*

Proof. We use an algorithm similar to that of Theorem 4.10, except that now we decrease the size of each normal item by a factor of $1-\varepsilon$. Lemma 4.3 implies that the decreased sized items do not overflow a bin of size $1+\varepsilon$, and hence the original items do not overflow a bin of size $\frac{1+\varepsilon}{1-\varepsilon} \leq 1+4\varepsilon$.

To obtain the lower bound, we want to prove that if the total effective bandwidth of the decreased sized items is sufficiently large, then the probability that the total size of these items exceeds $1-\varepsilon$ is at least p. This will imply that the total size of the original items is at least 1 with probability at least p. The proof follows from Lemma 4.6 applied to the decreased item sizes and $\delta = \frac{1-\varepsilon}{1+\varepsilon}$.

To get the bound claimed in the theorem, we must run the above algorithm with a parameter $\varepsilon' = \frac{1}{2}\varepsilon$. □

An algorithm without relaxing bin size or probability. In this section we use the results above to obtain an approximation algorithm without relaxing either the bin size or the capacity. In fact, our algorithm will simply be the on-line algorithm from the previous section, with $\varepsilon = \frac{1}{\log_2 p^{-1}}$. Thus, there will be no items classified as *normal*—only small and large. One can give a weak analysis of this algorithm as follows: since the relaxed probabilities and sizes were only required for normal items, this algorithm produces a packing that is with $O(\varepsilon^{-1}) = O(\log p^{-1})$ times the

optimum with bin size 1 and overflow probability p.

Our goal in this section is to give a more involved analysis of the same algorithm, showing that its performance is actually much better than this: it produces a packing with $O(\sqrt{\frac{\log p^{-1}}{\log\log p^{-1}}})B^* + O(\log p^{-1})$ bins, where B^* is the optimum number of bins required (with size 1 and overflow probability p).

The main step of the analysis is the following extension of Lemma 3.2.

LEMMA 4.12. *Let* $\varepsilon = \frac{1}{6}\sqrt{\frac{\log\log p^{-1}}{\log p^{-1}}}$. *If* $X_1, \ldots, X_k$ *are independent Bernoulli trials of types* $(q_1, s_1), \ldots, (q_k, s_k)$, $\varepsilon \geq s_i \geq \frac{1}{\log_2 p^{-1}}$, *and* $\sum_i {\beta'}_p(X_i) \geq 7\varepsilon^{-1}$, *then* $\Pr[\sum_i X_i > 1] > p$.

The proof relies heavily on our modified effective bandwidth, with a grouping scheme as in the proof of Lemma 3.2. However, we cannot afford to analyze the groups in each effective size separately; thus we require a combinatorial argument which analyzes the antichain of minimal collections of groups that would cause the bin to overflow.

Before proving this lemma, we require a simple combinatorial fact. Let S be a set of size n, let $k \leq \ell \leq n$, and let $\mathcal{F}_{k\ell}$ denote the collection of all subsets of S whose size is at least k and at most ℓ. We say that $\mathcal{I} \subseteq \mathcal{F}_{k\ell}$ is an *antichain* if no set in $\mathcal{I}$ contains any other set, and a *maximal antichain* if it is maximal with this property.

CLAIM 4.13. *Assume* $k \leq \ell \leq \frac{n}{2}$. *Then the number of elements in a maximal antichain* $\mathcal{I} \subset \mathcal{F}_{k\ell}$ *is at least* $\binom{n}{k}/\binom{\ell}{k}$.

Proof. Consider a maximal antichain $\mathcal{A}$. Each k-element set S must be contained in one of the sets T of the maximal antichain $\mathcal{A}$. An antichain element T can contain up to $\binom{\ell}{k}$ k-element subsets, and there are altogether $\binom{n}{k}$ k-element sets. This implies the claim. □

Proof of Lemma 4.12. The proof starts out analogous to the proof of Lemma 4.6. We round item sizes up to a power of $(1+\varepsilon)$ and assume without loss of generality that all items have normal probability, i.e., $q_i \leq p^{s_i}$. Then we have that $\sum_i q_i s_i p^{-s_i} \geq 7\varepsilon^{-1}$.

We partition the set of items into sets $W_j^{(s)}$ for each size s such that $2p^s \leq \sum_{X_i \in W_{(s)}^j} q_i \leq 3p^s$ for $j = 1, \ldots, r_s$; and define the set $V^{(s)}$ of Bernoulli trials $Y_1^{(s)}, \ldots, Y_{r_s-1}^{(s)}$, each of type (p^s, s), as in the proof of Lemma 3.2. As before we have that ${\beta'}_p(V^{(s)}) \geq \frac{{\beta'}_p(W^{(s)}) - 2s}{3}$. Further $\sum_s s \leq 1+\varepsilon$, hence we get that ${\beta'}_p(\cup_s V^{(s)}) \geq 2\varepsilon^{-1}$. Note also that ${\beta'}_p(\cup_s V^{(s)}) \leq \frac{1}{2}{\beta'}_p(\cup_s W^{(s)}) \leq \frac{7}{2}\varepsilon^{-1}$.

Next we form groups $G_1, \ldots, G_k$ from the items in $\cup_s V^{(s)}$ so that in each group G_j for $j = 1, \ldots, k$ the sum of the sizes is in the range $[\varepsilon, 2\varepsilon)$ and $k \geq \frac{7}{2}\varepsilon^{-2}$. This is possible as each item has size at most ε, so we can form groups of the right size, and the number of groups that can be formed is at least ε^{-2}, since ${\beta'}_p(\cup_s V^{(s)}) \geq \frac{7}{2}\varepsilon^{-1}$, and the effective bandwidth of each item in $\cup_s V^{(s)}$ is equal to its size by definition (since $p^s s p^{-s} = s$). Moreover, the number of groups formed is at most $\varepsilon^{-1} \cdot {\beta'}_p(\cup_s V^{(s)}) \leq \frac{7}{2}\varepsilon^{-2}$.

A subset $\mathcal{I} \subseteq \{1, \ldots, k\}$ is called *critical* if it is minimal subset to the property that the total size of the items in $\cup_{j\in\mathcal{I}} G_i$ exceeds 1. We note the following facts:

- The number of groups in a critical set is at least $1 + \frac{\varepsilon^{-1}}{2}$ and at most $1 + \varepsilon^{-1}$.
- The probability that all items are on in the groups of a critical set is at least $p^{1+2\varepsilon}$. This follows from the facts that the total size of items in the groups of a critical set is at most $1 + 2\varepsilon$, and each item in $\cup_j G_j$ of size s has

probability p^s.

- The number of critical sets is at least $\frac{1}{2}(\frac{\varepsilon^{-1}}{2})^{-\frac{\varepsilon^{-1}}{2}}$. To see this consider the set of critical sets. The critical sets form a maximal antichain. We want to use Claim 4.13 for this antichain. From the first fact we see that the claim should be applied to $1+\frac{\varepsilon^{-1}}{2} \le 1+\varepsilon^{-1} \le \frac{k}{2}$. We have that $k \ge \varepsilon^{-2}$; therefore, the number of critical sets is at least

$$\binom{\varepsilon^{-2}}{1+\frac{\varepsilon^{-1}}{2}} \Big/ \binom{1+\varepsilon^{-1}}{1+\frac{\varepsilon^{-1}}{2}}.$$

  To get the claimed bound above, we bound $\binom{1+\varepsilon^{-1}}{1+\frac{\varepsilon^{-1}}{2}} \le 2^{1+\varepsilon^{-1}}$, and $\binom{\varepsilon^{-2}}{1+\frac{\varepsilon^{-1}}{2}} \ge (2\varepsilon-1)^{\frac{\varepsilon^{-1}}{2}}$.

We say that a group is *on* if all elements of the group are on, and the group is *off* if at least one element in the group is not on. The probability that a group is on is at least p^ε and at most $p^{2\varepsilon}$. Consider a critical set $\mathcal{I}$. The probability that all groups not in $\mathcal{I}$ are off is at least

$$(1-p^\varepsilon)^k = (1-p^\varepsilon)^{\frac{7}{2}\varepsilon^{-2}} \ge e^{-\frac{\frac{7}{2}\varepsilon^{-2}}{p^{-\varepsilon}}}.$$

By the choice of ε we have that

$$\varepsilon^{-2} = 36 \cdot \frac{\log p^{-1}}{\log\log p^{-1}}$$

and $p^{-\varepsilon} = e^{\Theta(\sqrt{\log p^{-1} \log\log p^{-1}})}$, and so $\frac{7}{2}\varepsilon^{-2} \le p^{-\varepsilon}$ and the probability that all groups not in $\mathcal{I}$ are off is at least e^{-1}.

Now, the probability of overflow is at least the sum, over all critical sets $\mathcal{I}$, of the probability that the groups which are on are precisely those in $\mathcal{I}$. Thus, by the above bounds, we have all

$$\Pr\left[\sum_i X_i \ge 1\right] \ge \frac{1}{2}\left(\frac{\varepsilon^{-1}}{2}\right)^{-\frac{\varepsilon^{-1}}{2}} p^{1+2\varepsilon}\frac{1}{e}.$$

Finally, since $p \ge (18\varepsilon^2)^{(\varepsilon^{-2}/18)}$, it is straightforward to see that

$$\frac{1}{2}\left(\frac{\varepsilon^{-1}}{2}\right)^{-\frac{\varepsilon^{-1}}{2}} p^{2\varepsilon}\frac{1}{e} > 1. \qquad \square$$

This lemma allows us to give a stronger analysis of our algorithm: although the algorithm only recognizes small and large items, our analysis further partitions the large items depending on whether their sizes are smaller or larger than $\varepsilon = \frac{1}{6}\sqrt{\frac{\log\log p^{-1}}{\log p^{-1}}}$. For large items with sizes below ε, we apply Lemma 4.12.

THEOREM 4.14. *The above algorithm finds a packing of items in bins of size* 1 *with overflow probability* p *such that the number of bins used is at most* $O(\sqrt{\frac{\log p^{-1}}{\log\log p^{-1}}})\, B^* + O(\log p^{-1})$*, where* B^* *is the minimum possible number of bins.*

Proof. Although the algorithm only recognizes small and large items, our analysis makes use of three types of items. Let $\varepsilon = \frac{1}{6}\sqrt{\frac{\log\log p^{-1}}{\log p^{-1}}}$, and say that an item of type

(q, s) is *large* if $s \geq \frac{1}{2}\varepsilon^{-1}$, *small* if $s \leq \log p^{-1}$, and *normal* otherwise. By earlier arguments, the algorithm is within a constant factor of optimal on small items and within an $O(\varepsilon^{-1})$ factor on large items. The problem is that the algorithm treats normal items as though they were large and packs them according to ${\beta'}_p$ applied to their effective sizes. Since there are $\Theta(\log p^{-1})$ different effective sizes of normal items, our analysis cannot consider each effective size separately. Thus, we use Lemma 4.12.

As before, we distinguish (normal) items as having *large* or *normal* probability. By giving up a factor of 2, we can still afford to analyze bins with items of normal probability separately from those with items of large probability. We say that a bin with large probability items of effective size s is *filled* if there are $\frac{1}{s} - 1$ items in the bin. For each effective size there is at most one bin of large probability items that is not filled. For a bin with normal probability items we say that the bin is *filled* if the total probability of the items in the bin is at least $p^s/2se$ (half of the maximum possible). Again, for each effective size there is at most one bin of normal probability items that is not filled. So the number of nonfilled bins of normal items is $O(\log p^{-1})$.

Next we consider filled bins. We claim that the total ${\beta'}_p$-value in a filled bin is at least $\frac{1}{2e}$. To show this, we first recall that the effective size is smaller than the real size, and that effective bandwidth is monotone in the size. This implies that a large probability item X of effective size s has effective bandwidth ${\beta'}_p(X) \geq s$. Therefore, the effective bandwidth of a bin filled with large probability items of effective size s is at least $s(\frac{1}{s} - 1) = 1 - s$. A small probability item X of probability q and effective size s has effective bandwidth at least ${\beta'}_p(X) \geq sqp^{-s}$, and so the effective bandwidth of a bin filled with normal probability items of effective size s is at least $\frac{p^s}{2es} p^{-s} s = \frac{1}{2e}$.

If our algorithm produces B filled bins, then the total effective bandwidth over all items in filled bins is at least $\frac{B}{2e}$. Lemma 4.12 implies that any packing of these items with fewer than $\frac{\varepsilon B}{14e}$ bins would result in at least one bin with too high an overflow probability. Thus the number of bins used for normal sized items is at most $O(\varepsilon^{-1})B^* + O(\log p^{-1})$, and we are finished. □

It is natural to ask whether this analysis can be further tightened to show that the same algorithm is in fact producing a packing with $O(B^*) + O(\log p^{-1})$ bins. In fact this is not possible; this is contained in the following theorem.

THEOREM 4.15. *There exist instances in which B^* is arbitrarily large, and the above algorithm uses more than $B^* \cdot \Omega(\log\log\log\log p^{-1})$ bins.*

Proof. Let b be an arbitrarily large constant, let $k = \frac{\ln\ln p^{-1}}{\ln\ln\ln p^{-1}}$, and let J be the set of all prime numbers less than or equal to k. For $r \in J$ and $1 \leq i \leq b$, let X_r^i be a Bernoulli trial of type $(p^{1/r}, 1/r)$.

First, we claim that the set of items $S^i = \{X_r^i : r \in J\}$ can be packed in a single bin. To prove this, consider any set $S' \subset S$ whose sizes sum to a number strictly greater than 1; call such a set *large*. Since the sizes of the items in S' have denominators that are pairwise relatively prime, the sum of these sizes must be at least $1 + 1/k!$. Thus we have

$$\Pr[S \text{ overflows}] \leq \sum_{large\, S' \subset S} \Pr[S' \text{ is on}] \leq 2^k p^{1+1/k!} \leq p,$$

with the last inequality following from the fact that

$$k < \frac{1}{k!} \ln p^{-1}.$$

Thus, the set of all items can be packed in b bins.

Now consider the packing produced by our algorithm. Of the items of size r, it will pack at most r in each bin. Thus, the total number of bins it produces will be at least

$$\sum_{r \in J} \frac{b}{r} = \Theta(b \log\log k) = \Theta(b \log\log\log\log p^{-1}). \qquad \square$$

The form of the final bound suggests that it is possible that our analysis could be tightened further, albeit not to provide a constant ratio.

5. The knapsack problem. Finally, we consider the knapsack problem. First we consider a simple version of the knapsack problem with items $X_1, X_2, \ldots, X_n$ that are independent Bernoulli trials. Each item has a value v_i, and we are given a knapsack size, say 1, and an allowed probability of overflow p. The problem is to find a set of items of maximum value such that the probability that the total size of the set exceeds 1 is at most p.

The lower bounds and techniques developed in the previous section yield similar results for the knapsack problem. We distinguish items by their sizes (small, normal, and large), we group large items by their effective size, and we distinguish large and small probability items just as in the previous section. The solution we construct for the knapsack problem only contains one type of item (either small, normal, or large with a given effective bandwidth). We will look for a near-optimal solution in each of these groups and select the best alternative. Thus, we can show the following.

THEOREM 5.1. *Let $X_1, \ldots, X_n$ be independent Bernoulli trials.*

- *There is a polynomial time algorithm that finds a solution to the knapsack problem with items $X_1, \ldots, X_n$ of value at least an $O(\log p^{-1})$ fraction of the optimum.*
- *For any $\varepsilon > 0$, there is a polynomial time algorithm that finds a solution to the knapsack problem, using knapsack size $1 + \varepsilon$ and overflow probability p, of value at least an $O(\varepsilon^{-1})$ fraction of the maximum possible with a knapsack of size 1 and overflow probability p.*
- *For any $\varepsilon > 0$, there is a polynomial time algorithm that finds a solution to the knapsack problem, using knapsack size 1 and overflow probability p, of value at least an $O(\varepsilon^{-1})$ fraction of the maximum possible with a knapsack of size 1 and overflow probability $p^{1+\varepsilon}$.*

Proof. For small items we use a knapsack approximation algorithm to find a set of items of approximately maximum value with at most a total of $\frac{1}{2}$ expected value.

For normal items we use a knapsack approximation algorithm to find a set of items of approximately maximum value with at most a total of ε total effective bandwidth. As in the previous section, we need to increase or decrease the item sizes by a factor of $(1 + \varepsilon)$ before computing the effective bandwidth depending on the type of result desired.

We group large items according to their effective size. For large items of effective size s we either (i) take the (at most) $\frac{1-s}{s}$ items of largest value; or (ii) use a knapsack approximation algorithm on the large items of normal probability to find a set of approximately maximum value with a total probability of at most $\frac{p^s}{es}$.

To prove the lower bound we note that the optimal value of a deterministic knapsack problem grows only linearly with the knapsack size, as long as new items of larger size are not considered. Our approximation algorithm is simply the greedy algorithm, which either (i) takes the single most valuable item, or (ii) orders the items

in decreasing order of value divided by weight (i.e., expectation, effective bandwidth, or probability) and greedily fills the knapsack in this order.

FACT 5.2. *Consider a deterministic knapsack problem where the knapsack has size* 1*, and all items have size at most* 1*.*

- *The value of the solution obtained by the above greedy method is at least a* $\frac{1}{2}$ *of the optimal.*
- *For any* $c > 1$*, the value of the optimal solution with knapsacks of size* 1 *is at least a fraction of* $\frac{1}{2c}$ *of the optimal value with knapsack size* c*.*

For small items Lemma 4.2 implies that the resulting knapsack solution is feasible, and Lemmas 5.2 and 4.2 imply that its value is within a constant factor of the optimal packing of small items.

For normal items we use Lemma 4.3 to show either that (1) the packing obtained is feasible with a knapsack of size $1 + \varepsilon$ or (2) if we increased sizes before computing the effective bandwidth, then it is feasible with a knapsack of size 1. Lemmas 5.2 and 4.6 imply that the packing obtained is within an $O(\varepsilon^{-1})$ factor of any packing of normal items with either (1) a knapsack of size 1 and overflow probability at most p or (2) a knapsack of size 1 and overflow probability at most $p^{1+\varepsilon}$.

For large items of effective size s, Lemma 4.1 shows that the solution is feasible, and Lemmas 4.7 and 4.8 and Fact 5.2 imply that the solution is within a constant factor to any packing using items of effective size s.

In total we get an $O(1)$ approximation algorithm for small items, and items of a given effective size. There are $O(\varepsilon^{-1})$ different effective sizes. For normal items, we get an $O(\varepsilon^{-1})$ approximation. The approximation ratio of the best solution among these options is the sum of the approximation ratios of the special cases. Thus, the theorem follows. □

Extension to other distributions. Next we extend the solution to a distribution that is somewhat more general than the on-off distribution we have been considering so far. We assume that each item is parameterized by numbers lo, hi, and q, where the item is of size hi with probability q and of size $lo \leq hi$ otherwise. This kind of item is a simple model of a bursty communication, with lo being the normal rate of transmission and hi being a burst that occurs with probability q.

Consider the optimal knapsack packing. Assume we used items $X_1, \ldots, X_k$ in the packing, and let $g = \sum_i lo_i$. The idea is that we guess the value of g in the optimal solution, and for every guess we look for packings that are feasible and in which the total of the lo values is at most g.

We define small items depending on the size $s_i = hi_i - lo_i$ of the probabilistic part, limiting the value s_i to be at most half of what it was for the size in the case of Bernoulli trials. We pack small items using expectation, subject to the the fact that the total expectation is at most $\frac{1}{2}$, and we use Lemmas 4.2 and 4.5 and Fact 5.2 to see that the value of the packing is within a constant factor of the maximum possible using small items.

We define normal items also using $s_i = hi_i - lo_i$ and pack normal items using the effective bandwidth. However, to compute the right effective bandwidth for normal items we need to know $1 - g$, the amount of space left for the probabilistic part of the items, since the effective bandwidth formula assumed that the bin size is 1, so we will have to rescale the bin size to apply the formula. Notice, however, that it suffices to know $1 - g$ roughly up to a factor of $1 + \varepsilon$.

Notice that it is essentially no loss of generality to assume that $g \leq \frac{1}{2}$. Among items with lo values above $\frac{1}{2}$ at most one can be in the knapsack, so we can either

pack a single one of these items in the knapsack by itself or assume that we are not using any of them. For items with $lo \leq \frac{1}{2}$ the restriction that $g \leq \frac{1}{2}$ will not change the optimum value by more than a small constant factor. Therefore, we need only to consider $O(\varepsilon^{-1})$ different values for g to obtain an $O(\varepsilon^{-1})$ approximate solution the optimal value of a solution using normal items.

In the case of Bernoulli trials we used the greedy method to pack items in each category into a knapsack using expectation, effective size, or the probability depending on whether we considered items that are small, normal, or large. Here we cannot use the greedy method to find a solution to the resulting deterministic problem, as we have to consider an extra parameter, the sum of the lo values. We use the following method instead.

A deterministic *two-dimensional knapsack problem* is defined by a set of items $X_1, \ldots, X_n$, each with a value v_i, size s_i, and weight w_i. In addition, we are given a knapsack size S and a weight limit W. The problem is to find a subset $\mathcal{I}$ of items of maximum total value so that the total size $\sum_{i \in \mathcal{I}} s_i$ is at most S and the total weight $\sum_{i \in \mathcal{I}} w_i$ is at most W.

LEMMA 5.3. *A simple greedy algorithm yields a constant factor approximation for the two-dimensional knapsack problem. Using dynamic programming we can obtain a* $1 + \delta$*-approximation for any fixed value* $\delta > 0$.

Proof. First notice that it is no loss of generality to assume that the size S and the weight limit W are both 1.

Consider items that have both size and weight at most $\frac{1}{2}$. We claim that the following greedy method provides an approximation: Find a greedy solution to maximizing using the sum $s_i + w_i$ as size, i.e., this greedy algorithm approximates the maximum possible value subject to the limit that the total size *plus* the total weight is at most 1. The optimal solution has size at most 1 and weight at most 1, so the sum of the total size and weight is at most 2. Hence, by Fact 5.2, the value obtained is at least $\frac{1}{4}$th of the optimal.

For items that have either size above $\frac{1}{2}$ or weight above $\frac{1}{2}$ at most 2 can fit in a knapsack, so we can get the optimal solution by trying all pairs.

The better of the two solutions obtained has a value of at least $\frac{1}{5}$th of the optimum. □

Next we consider large items. The definition of effective size is also related to $1 - g$: The effective size of an item of type (hi, lo, q) is defined as $\bar{s}$, where $\frac{1}{\bar{s}} = \min\{j : j(hi - lo) > 1 - g\}$, the number of copies the probabilistic part of this item can fit in a knapsack of size $1 - g$. Given an estimate for the value g, we group large items according to their effective size and pack items of one effective size using the two-dimensional knapsack problem above. As before, we separate items of identical effective size, depending on whether they have large or normal probability. For large probability items of effective size s, we need at most $\frac{1}{s} - 1$ items of total lo value at most g and maximum total value. For normal probability items one dimension is the lo value, where the total lo value is limited to g, and the other dimension is the probability, bounded by p^s/se. In both cases we can use Lemma 5.3 to obtain a knapsack solution.

Next we consider the issue of how many different estimates we have to consider in order to get a near-optimal solution using large items. Depending on the value of g the effective size of an item can change. Each item can have at most ε^{-1} different effective sizes, and hence it creates at most ε^{-1} different "cut-off" values for g. Hence, the grouping of large items changes for at most $n\varepsilon^{-1}$ discrete values of g, where n

is the number of large items. This implies that it suffices to try $O(n\varepsilon^{-1})$ different g values in order to get an approximately optimal solution.

The above discussion proves the following theorem.

THEOREM 5.4. *Let $X_1, \ldots, X_n$ be independent trials of the type defined above.*

- *There is a polynomial time algorithm that finds a solution to the knapsack problem with items $X_1, \ldots, X_n$ of value at least an $O(\log p^{-1})$ fraction of the optimum.*
- *For any $\varepsilon > 0$, there is a polynomial time algorithm that finds a solution to this knapsack problem using a knapsack size $1 + \varepsilon$ and overflow probability at most p of value at least an $O(\varepsilon^{-1})$ fraction of the maximum possible with a knapsack of size 1 and overflow probability p.*
- *For any $\varepsilon > 0$, there is a polynomial time algorithm that finds a solution to this knapsack problem using a knapsack size 1 and overflow probability p of value at least an $O(\varepsilon^{-1})$ fraction of the maximum possible with a knapsack of size 1 and overflow probability $p^{1+\varepsilon}$.*

Bin-packing with other distributions. Using the knapsack result and set-cover we get a bin-packing algorithm for independent items of type (lo, hi, q). To get a solution to the bin-packing problem we repeatedly take the maximum number of items possible to include in a single bin. The result is an $O(\log n)$ extra factor in the approximation ratio.

COROLLARY 5.5. *Let $X_1, \ldots, X_n$ be independent trials of the type defined above.*

- *There is a polynomial time algorithm that finds a solution to the bin-packing problem with items $X_1, \ldots, X_n$ using at most $O(\log p^{-1} \log n)$ times the minimum possible number of bins.*
- *For any $\varepsilon > 0$, there is a polynomial time algorithm that finds a solution to this bin-packing problem using bins of size $1 + \varepsilon$ and overflow probability at most p with a number of bins that is at most $O(\varepsilon^{-1} \log n)$ times the minimum possible with bins of size 1 and overflow probability p.*
- *For any $\varepsilon > 0$, there is a polynomial time algorithm that finds a solution to this bin-packing problem using bins size 1 and overflow probability p with at most $O(\varepsilon^{-1} \log n)$ times as many bins as the minimum possible with bins of size 1 and overflow probability $p^{1+\varepsilon}$.*

6. Extensions to general networks. The model we have been considering—two nodes communicating over a set of parallel links—is a common one in the study of bursty traffic. However, it is interesting to consider the extent to which one can carry over the results developed here to the problem of routing bursty connections in a general network. The model for a general network follows directly from the discussion in the introduction: we are given a graph $G = (V, E)$ with capacities $\{c_e\}$ on the edges, and source-sink pairs (s_i, t_i) indicating connection requests in the network. For each source-sink pair, we are given a random variable X_i corresponding to the demand of that connection; a *routing* is a choice of a path P_i in G for each connection (s_i, t_i).

There are several options for how one might want to model the *capacity constraints* for a problem of this type; we define two main possibilities here. Suppose we are given an allowed overflow probability p.

(i) The *link-based overflow constraint* requires that for each edge e, we have $\Pr[\sum_{i:e \in P_i} X_i > c_e] \leq p$.

(ii) The *connection-based overflow constraint* requires that for each connection

(s_i, t_i), we have

$$\Pr\left[\exists e \in P_i : \sum_{i:e\in P_i} X_i > c_e\right] \leq p.$$

One can argue that from the perspective of providing guaranteed quality of service to users in a network, the *connection-based overflow constraint* is more natural. In this section we use this model.

Now suppose we are in a "high-capacity" setting in which the capacity of every edge exceeds the *peak* bandwidth rate of every connection X_i by a factor of $c\log(p^{-1}|E|)$ for an appropriate constant c. Let us define the *value* of a set of connections to be the sum of their expectations; we consider the problem of accepting a set of connections of maximum value. We run the on-line algorithm of Awerbuch, Azar, and Plotkin [2], using $\mathrm{E}[X_i]$ as the demand for connection (s_i, t_i) and $\frac{1}{4}c_e$ as the capacity of edge e. The analysis of [2] can then be used to show the following.

LEMMA 6.1. *For any constant γ there is a constant C such that, if k denotes the total value of connections accepted by the algorithm, then in any routing of a set of connections of value at least $C(\log|E|)k$, there is some edge e carrying a total expected value greater than γc_e.*

THEOREM 6.2. *The set of connections accepted by the above algorithm satisfies the connection-based overflow constraints, and the total value of the connections accepted is within an $O(\log|E|)$ factor of the off-line optimum on the graph G.*

Proof. Without loss of generality, we may assume that the minimum edge capacity in the network is 1. Recall our assumption that the peak rate of any connection X is at most $1/(c\log(p^{-1}|E|))$; thus, for each connection X, the effective bandwidth $\beta_{p|E|^{-1}}(X)$, with respect to probability $\frac{p}{|E|}$, is at most $2\mathrm{E}[X]$. Now Proposition 3.6 implies that our routing satisfies the link-based overflow constraint with probability $\frac{p}{|E|}$ and hence the connection-based overflow constraints with probability p.

To compare our performance to that of the optimum, we use Lemma 6.1 with $\gamma = 8$. Further, we give up a constant factor in the approximation ratio and use Lemma 3.10 to model each connection. Using the notation of the lemma we model a connection X as a sum of of independent Bernoulli trials $\frac{1}{2}Y = \sum_i \frac{1}{2}Y_i$ whose peak rates are inverse powers of two, such that $Y \leq X$ and $\mathrm{E}(Y) \leq \frac{1}{2}\mathrm{E}(X)$.

Lemma 4.5 shows that such a routing violates the link-based overflow constraint on edge e, and hence any path through the edge e violates the connection-based overflow constraint. It follows that our routing is within $O(\log|E|)$ of optimal. ∎

We note that the analysis of [2] also allows us to provide performance guarantees in terms of more general notions of "value."

MOTION PLANNING OF LEGGED ROBOTS*

JEAN-DANIEL BOISSONNAT†, OLIVIER DEVILLERS†, AND SYLVAIN LAZARD‡

Abstract. We study the problem of computing the free space $\mathcal{F}$ of a simple legged robot called the spider robot. The body of this robot is a single point and the legs are attached to the body. The robot is subject to two constraints: each leg has a maximal extension R (accessibility constraint) and the body of the robot must lie above the convex hull of its feet (stability constraint). Moreover, the robot can only put its feet on some regions, called the foothold regions. The free space $\mathcal{F}$ is the set of positions of the body of the robot such that there exists a set of accessible footholds for which the robot is stable. We present an efficient algorithm that computes $\mathcal{F}$ in $O(n^2 \log n)$ time using $O(n^2\alpha(n))$ space for n discrete point footholds where $\alpha(n)$ is an extremely slowly growing function ($\alpha(n) \leqslant 3$ for any practical value of n). We also present an algorithm for computing $\mathcal{F}$ when the foothold regions are pairwise disjoint polygons with n edges in total. This algorithm computes $\mathcal{F}$ in $O(n^2\alpha_8(n)\log n)$ time using $O(n^2\alpha_8(n))$ space. ($\alpha_8(n)$ is also an extremely slowly growing function.) These results are close to optimal since $\Omega(n^2)$ is a lower bound for the size of $\mathcal{F}$.

Key words. legged robots, computational geometry, motion planning

1. Introduction.

Although legged robots have already been studied in robotics [13, 14], only a very few papers consider the motion planning problem amidst obstacles [9, 8, 2]. In [9, 8], some heuristic approaches are described, while, in [2], efficient and provably correct geometric algorithms are described for a restricted type of legged robot, the so-called spider robot to be defined precisely below, and for finite sets of point footholds.

A *legged robot* consists of a body with legs. Each leg has one end attached to the body and the other end (called the foot) that can lie on the ground (or move in space between two positions on the ground). Compared to the classic piano movers problem, legged robots introduce new types of constraints. We assume that the environment consists of regions in the plane, called *foothold regions*, where the robot can safely put its feet. A *foothold* is a point in a foothold region. The legged robot must satisfy two different constraints: the accessibility and the stability constraints. A foothold is said to be *accessible* from a *placement* (position of the body of the robot) if it can be reached by a leg of the robot. A placement is called *stable* if there exist accessible footholds and if the center of mass of the robot lies above the convex hull of these accessible footholds. The set of stable placements is clearly relevant for planning the motion of a legged robot: we call this set the *free space* of the legged robot. Note that a legged robot has at least four legs; three legs ensure the stability of a placement and a fourth leg permits the motion of the robot.

A first simple instance of a legged robot is the *spider robot* (see Figure 1.1). The spider robot was inspired by Ambler, developed at Carnegie Mellon University [1].

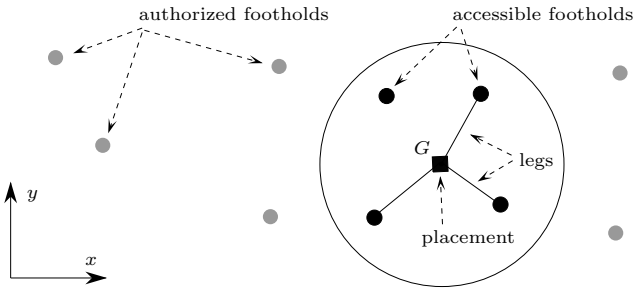

FIG. 1.1. *The spider robot.*

The body of the spider robot is a single point in the Euclidean plane, and all its legs are attached to the body. The legs are retractable and their lengths may vary between 0 and a constant R. We also assume that the center of mass of the robot is its body. It follows that a placement is stable if the body of the robot lies above the convex hull of the accessible footholds.

The constraint that the body of the spider robot lies in the plane (instead of in three dimensions) is not really restrictive. Indeed, consider a legged robot for which that constraint is relaxed. Then, if a placement (x, y, z) of such a legged robot is stable, then any placement (x, y, z'), $0 \leqslant z' \leqslant z$, is also stable. Reciprocally, it can be shown that if (x, y) is in the interior of the free space of the spider robot, then there exists $z > 0$ such that (x, y, z) is a stable placement of the corresponding legged robot.

The problem of planning the motion of a spider robot has already been studied by Boissonnat et al. [2]. However, their method assumes that the set of footholds is a finite set of points and cannot be generalized to more complex environments. This paper proposes a new method for computing the free space of a spider robot in the presence of polygonal foothold regions. This method is based on a transformation between this problem and the problem of moving a half-disk amidst obstacles. Our method requires the computation of some parts of the free space of the half-disk. These computations are rather technical and complicated. Consequently, for the sake of clarity, we first present our algorithm for the simple case of discrete footholds, and then we show how it can be generalized to the case of polygonal foothold regions.

Once the free space of the spider robot has been computed, it can be used to find trajectories and sequences of legs assignments allowing the robot to move from one point to another. Indeed, once the free space is known, a trajectory of the body can be found in the free space. Then, a sequence of legs assignments can be computed as follows (see [2] for details). Given an initial legs assignment, the body of the robot moves along its trajectory until it crosses the convex hull of its (three) feet that are on the ground, or one leg reaches its maximal extension. Then, a suitable foothold is found for the fourth leg and one leg leaves its foothold.

The paper is organized as follows: some notations and results of [2] are recalled in the next section. Section 3 shows the transformation between the spider robot problem and the half-disk problem. We present in section 4 our algorithm for computing the free space of a spider robot for a discrete set of footholds. Section 5 shows how to extend the algorithm to polygonal foothold regions.

2. Notations and previous results. In sections 2, 3, and 4, $\mathcal{S}$ denotes a discrete set of distinct footholds $\{s_1, \ldots, s_n\}$ in the Euclidean plane. ($\mathcal{S}$ will denote

in section 5 a set of disjoint polygonal regions.) Point G denotes the body of the robot (in the same plane) and $[0, R]$ is the length range of each leg. The free space $\mathcal{F}$ is the set of all stable placements of G. A placement is said to be at the *limit of stability* if it lies on the boundary of the convex hull of its accessible footholds. Notice that $\mathcal{F}$ is a closed set and contains the placements at the limit of stability.

Let C_i denote the circle of radius R centered at s_i. $\mathcal{A}$ is the arrangement of the circles C_i for $1 \leqslant i \leqslant n$, i.e., the subdivision of the plane induced by the circles. This arrangement plays an important role in our problem and we will express the complexity results in term of $|\mathcal{A}|$, the size of $\mathcal{A}$. In the worst case, $|\mathcal{A}| = \Theta(n^2)$, but if k denotes the maximum number of disks that can cover a point of the plane, among the disks of radius R centered at the s_i, it can be shown that $|\mathcal{A}| = O(kn)$ [15]. Clearly k is not larger than n and in case of sparse footholds, $|\mathcal{A}|$ may be linearly related to the number of footholds.

For any set $\mathcal{E}$, let $\partial(\mathcal{E})$ denote its boundary, $\mathrm{CH}(\mathcal{E})$ its convex hull, $int(\mathcal{E})$ its relative interior,[1] $clos(\mathcal{E})$ its closure, and $compl(\mathcal{E})$ its complementary set. Let S^1 denote the set of angles $\mathbb{R}/2\pi\mathbb{Z}$. We denote by $x = y[p]$ the equality of x and y modulo p. We say in the following that two objects *properly intersect* if and only if their relative interiors intersect.

The algorithm described in [2] is based on the following observation: for G in a cell Γ of $\mathcal{A}$, the set of footholds that can be reached by the robot is fixed; the portion of Γ that belongs to $\mathcal{F}$ is exactly the intersection of Γ with the convex hull of the footholds that can be reached from Γ. Therefore, the edges of $\partial(\mathcal{F})$ are either circular arcs belonging to $\mathcal{A}$ or portions of line segments joining two footholds. Moreover, a vertex of $\partial(\mathcal{F})$ incident to two straight edges is a foothold (see Figure 2.1). The complexity of $\mathcal{F}$ has been proved to be $|\mathcal{F}| = \Theta(|\mathcal{A}|)$ [2].

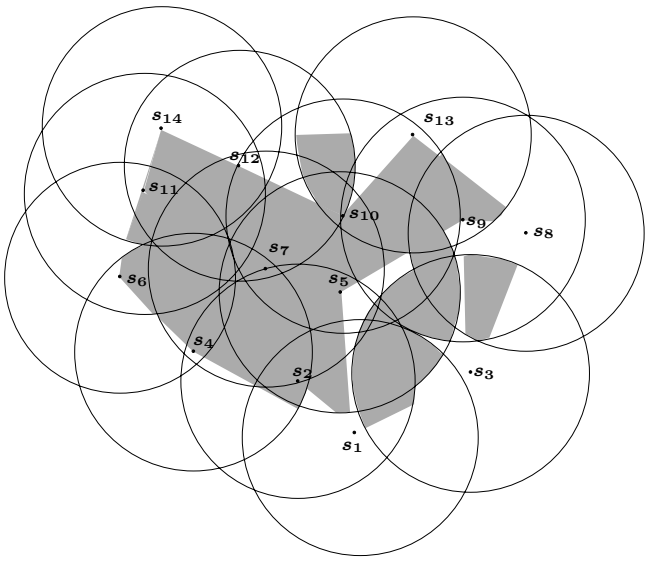

FIG. 2.1. *An example of the free space of a spider robot.*

[1] The relative interior of a set $\mathcal{E}$ in a space E is the interior of $\mathcal{E}$ in the space $\mathcal{E}$ for the topology induced by E. For example, the relative interior of a closed line segment in $\mathbb{R}^3$ is the line segment without its endpoints, though its interior in $\mathbb{R}^3$ is empty.

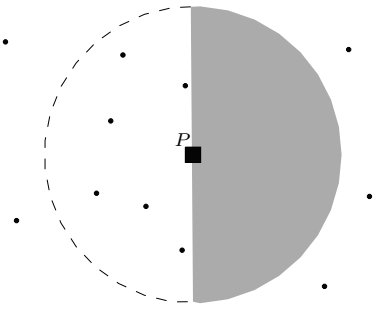

FIG. 3.1. *A placement which is not stable.*

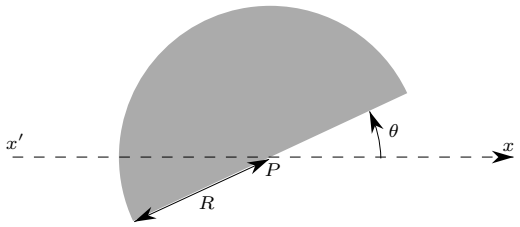

FIG. 3.2. $HD(P, \theta)$.

The algorithm presented in [2] computes the free space $\mathcal{F}$ in $O(|\mathcal{A}| \log n)$ time. It uses sophisticated data structures allowing the off-line maintenance of convex hulls.

The algorithm described in this paper has the same time complexity, uses simple data structures, and can be extended to the case where the set $\mathcal{S}$ of footholds is a set of polygonal regions and not simply a set of points. For simplicity, we consider first the case of point footholds and postpone the discussion on polygonal foothold regions to section 5.

General position assumption. To simplify the presentation of this paper, we make the following general position assumptions. All these hypotheses can be removed by a careful analysis. Recall that we consider here that the set of footholds is discrete.

No two footholds lie at distance exactly R or $2R$. Among the circles $C_1, \ldots, C_n$ and the line segments joining two footholds, the intersection between three circles, or two circles and a line segment, or one circle and two line segments is empty.

3. From spider robots to half-disk robots. In this section, we establish the connection between the free space of the spider robot and the free space of a half-disk robot moving by translation and rotation amidst n point obstacles.

THEOREM 3.1. *The spider robot does not admit a stable placement at point P if and only if there exists a half-disk (of radius R) centered at P that does not contain any foothold of $\mathcal{S}$ (see Figure* 3.1*).*

Proof. Let $\mathcal{R}$ be the set of all the footholds that are reachable from placement P. By definition, P is not stable if and only if the convex hull of $\mathcal{R}$ does not contain P (see Figure 3.1). That is equivalent to saying that there exists an open half-plane through P containing $\mathcal{R}$ or that there exists a closed half-disk of radius R centered at P which does not contain any foothold. □

DEFINITION 3.2. *Let $HD(P,\theta)$ be the half-disk of radius R centered at P (see Figure 3.2) defined by*

$$\begin{cases} (x-x_P)^2+(y-y_P)^2 \leqslant R^2, \\ (x-x_P)\sin\theta-(y-y_P)\cos\theta \leqslant 0. \end{cases}$$

DEFINITION 3.3. *For all $s_i \in \mathcal{S}$ $(1 \leqslant i \leqslant n)$, let*

$$\mathcal{H}_i = \{(P,\theta) \in \mathbb{R}^2 \times S^1 \mid P \in HD(s_i,\theta)\},$$
$$\mathcal{H} = \bigcup_{i=1}^{n} \mathcal{H}_i,$$
$$\mathcal{C}_i = C_i \times S^1.$$

$\mathcal{H}_i$ will be called the helicoidal volume centered at s_i (see Figure 3.3).

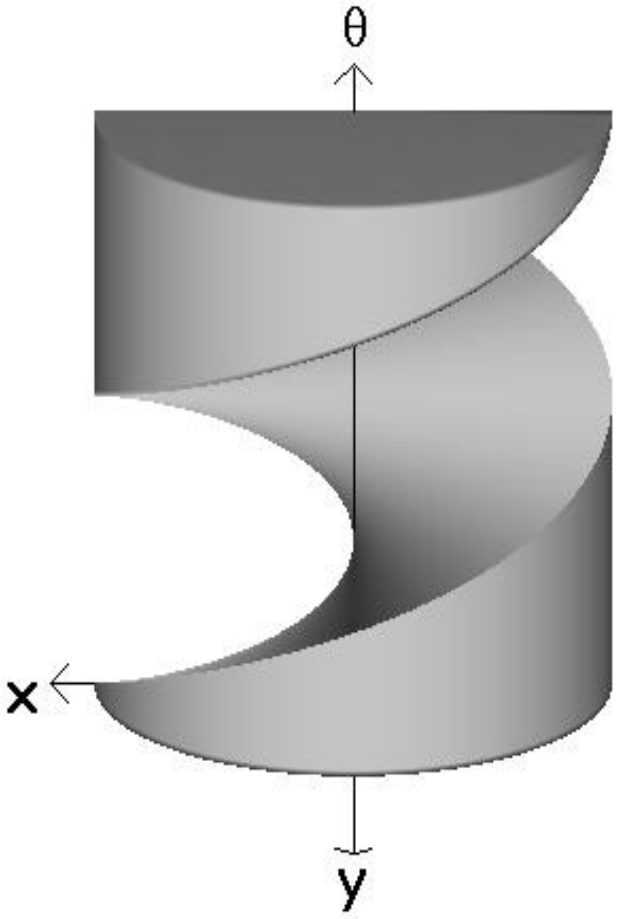

FIG. 3.3. *Helicoidal volume $\mathcal{H}_i$.*

Notice the typographical distinction between the circle C_i defined in $\mathbb{R}^2$ and the torus $\mathcal{C}_i$ defined in $\mathbb{R}^2 \times S^1$. For convenience, we will often identify S^1 and the interval $[0, 2\pi]$ of $\mathbb{R}$. This allows us to draw objects of $\mathbb{R}^2 \times S^1$ in $\mathbb{R}^3$ and to speak of the θ-axis. Π_{θ_0} denotes the "plane" $\{(P,\theta) \in \mathbb{R}^2 \times S^1 \mid \theta = \theta_0\}$.

DEFINITION 3.4. *The free space $\mathcal{L}$ of a half-disk robot moving by translation and rotation amidst the set of obstacles $\mathcal{S}$ is the set of $(P,\theta) \in \mathbb{R}^2 \times S^1$ such that the half-disk $HD(P,\theta+\pi)$ does not intersect $\mathcal{S}$.*

PROPOSITION 3.5. $\mathcal{L} = compl(\mathcal{H})$.

Proof. For all $\theta \in S^1$, the set $\mathcal{L} \cap \Pi_\theta$ is the free space of the half-disk $HD(P,\theta+\pi)$ moving by translation only amidst the obstacle $s_1,\ldots,s_n$. Since the set of points P such that $HD(P,\theta+\pi)$ contains an s_i is $HD(s_i,\theta)$, $\mathcal{L} \cap \Pi_\theta$ is the complementary set of the union of the $HD(s_i,\theta)$. Thus, $\mathcal{L}$ is the complementary set of the union of the $\mathcal{H}_i$, that is $\mathcal{H}$. □

Let $p_{//\theta}$ denote the mapping (called "orthogonal projection"): $\mathbb{R}^2 \times S^1 \longrightarrow \mathbb{R}^2, (P,\theta) \mapsto P$.

THEOREM 3.6. $\mathcal{F} = compl(p_{//\theta}(compl(\mathcal{H})))$.

Proof. By definition of $\mathcal{L}$, $p_{//\theta}(\mathcal{L})$ is the set of points $P \in \mathbb{R}^2$ such that there exists an angle $\theta \in S^1$ such that the half-disk $HD(P,\theta)$ does not intersect $\mathcal{S}$. By Theorem 3.1, it is equivalent to say that there exists $\theta \in S^1$ such that $HD(P,\theta)$ does not intersect $\mathcal{S}$, or that P is not a stable placement of the spider robot. Thus, $p_{//\theta}(\mathcal{L})$ is the set of points P, where the robot does not admit a stable placement, i.e., $\mathcal{F} = compl(p_{//\theta}(\mathcal{L}))$. The result then follows from Proposition 3.5. □

Remark 3.7. $compl(p_{//\theta}(compl(\mathcal{H}))) \times S^1$ is the largest "cylinder" included in $\mathcal{H}$, whose axis is parallel to the θ-axis (in grey in Figure 3.4). The basis of this cylinder is $\mathcal{F}$.

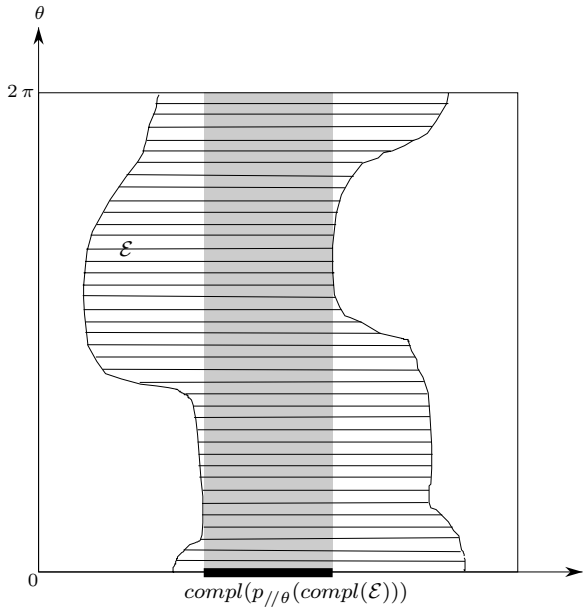

FIG. 3.4. $compl(p_{//\theta}(compl(\mathcal{E})))$.

Remark 3.8. The results of this section do not depend on the fact that the footholds are discrete points. For more general foothold regions, we simply need to replace the helicoidal volumes by their analogue. This will be done in section 5.

4. Computation of $\mathcal{F}$. In this section, we propose an algorithm for computing $\mathcal{F}$ based on Theorem 3.6.

A first attempt to use Theorem 3.6 may consist of computing $\mathcal{L} = compl(\mathcal{H})$ and projecting it onto the horizontal plane. The motion planning of a convex polygonal robot in a polygonal environment has been extensively studied (see, for example, [10, 11]). Such algorithms can be generalized to plan the motion of a half-disk. It should lead to an algorithm of complexity $O(n\lambda_s(n)\log n)$, where $\lambda_s(n)$ is an almost linear function of n. The projection can be done using classical techniques, such as projecting all the faces of $\mathcal{L}$ and computing their union. Since the complexity of the three-dimensional object $\mathcal{L}$ is not directly related to the complexity of its projection, this approach does not provide a combinatorial bound on $\mathcal{F}$. However, if we assume $|\mathcal{F}| = O(\lambda_s(|\mathcal{A}|))$ (which will be proved in this paper), the time complexity of the algorithm of Kedem Sharir, and Toledo is $O(n\lambda_s(n)\log n + \lambda_s(|\mathcal{A}|)\log^2 n)$.

In this paper, we present a direct computation of $\mathcal{F}$. This approach provides an upper bound on the size of $\mathcal{F}$, namely $|\mathcal{F}| = O(\lambda_s(|\mathcal{A}|))$. It also provides an algorithm for computing $\mathcal{F}$ in $O(\lambda_s(|\mathcal{A}|)\log n)$ time. As in [16] and contrary to [11], the algorithm proposed here is sensitive to $|\mathcal{A}|$ which is usually less than quadratic. Another advantage of our direct computation is to avoid the explicit construction of the three-dimensional object $\mathcal{L}$ which is useless for our application. Our algorithm manipulates only two-dimensional arrangements or lower envelopes, and we provide a detailed description of the curves involved in the construction.

Let us now detail the computation of $\mathcal{F}$ in the case of point footholds. We know that each arc of the boundary $\partial(\mathcal{F})$ of $\mathcal{F}$ is either a straight line segment belonging to a line joining two footholds or an arc of a circle C_i (see section 2). The circular arcs $\partial(\mathcal{F}) \cap C_i$ are computed first (sections 4.1, 4.2, and 4.3) and are linked together with the line segments in a second step (sections 4.4 and 4.5).

4.1. Computation of $\partial(\mathcal{F}) \cap \mathcal{A}$. In what follows, the *contribution* of an object X to another object Y is $X \cap Y$. We compute the contribution of each circle C_{i_0}, $i_0 = 1, \ldots, n$, to $\partial(\mathcal{F})$ in turn. Recall that $\mathcal{C}_{i_0}$ denotes the torus $C_{i_0} \times S^1$. The contribution of each circle C_{i_0} to $\partial(\mathcal{F})$ will be obtained by computing the intersection of all the $\mathcal{H}_i$, $i = 1, \ldots, n$, with the torus $\mathcal{C}_{i_0}$. Let $\mathcal{Z}_i$, $i = 1, \ldots, n$, denote these intersections:

$$\mathcal{Z}_i = \mathcal{H}_i \cap \mathcal{C}_{i_0}.$$

We first show how to compute the contribution of C_{i_0} to $\partial(\mathcal{F})$ in term of the $\mathcal{Z}_i$ and leave the studies of the shape and properties of $\mathcal{Z}_i$ to section 4.2. Figures 4.1 and 4.2 show some (hatched) $\mathcal{Z}_i \subset \mathcal{C}_{i_0}$ ($i \neq i_0$), where $\mathcal{C}_{i_0}$ is parameterized by (u, θ) (u and θ parameterize C_{i_0} and S^1, respectively); the dark grey region shows $\mathcal{Z}_{i_0}$.

PROPOSITION 4.1. *The contribution of C_{i_0} to $\partial(\mathcal{F})$ is*

$$C_{i_0} \cap \partial(\mathcal{F}) = compl(p_{//\theta}(compl(\cup_i \mathcal{Z}_i))) \setminus int(compl(p_{//\theta}(compl(\cup_{i \neq i_0} \mathcal{Z}_i)))).$$

Proof. Since $\mathcal{F}$ is a closed set, $C_{i_0} \cap \partial(\mathcal{F}) = [C_{i_0} \cap \mathcal{F}] \setminus [C_{i_0} \cap int(\mathcal{F})]$. According to Theorem 3.6, $\mathcal{F} = compl(p_{//\theta}(compl(\mathcal{H})))$. One can easily prove that for any set $\mathcal{E} \in \mathbb{R}^2 \times S^1$, $int(compl(\mathcal{E})) = compl(clos(\mathcal{E}))$, $clos(compl(\mathcal{E})) = compl(int(\mathcal{E}))$, and $clos(p_{//\theta}(\mathcal{E})) = p_{//\theta}(clos(\mathcal{E}))$. It then follows from the expression of $\mathcal{F}$ that $int(\mathcal{F}) = compl(p_{//\theta}(compl(int(\mathcal{H}))))$.

Recall that for any sets $X, Y \in \mathbb{R}^2 \times S^1$, $compl(X \cap Y) = compl(X) \cup compl(Y)$, $p_{//\theta}(X \cup Y) = p_{//\theta}(X) \cup p_{//\theta}(Y)$, and $compl(X \cup Y) = compl(X) \cap compl(Y)$. That implies

$$compl(p_{//\theta}(compl(X \cap Y))) = compl(p_{//\theta}(compl(X))) \cap compl(p_{//\theta}(compl(Y))).$$

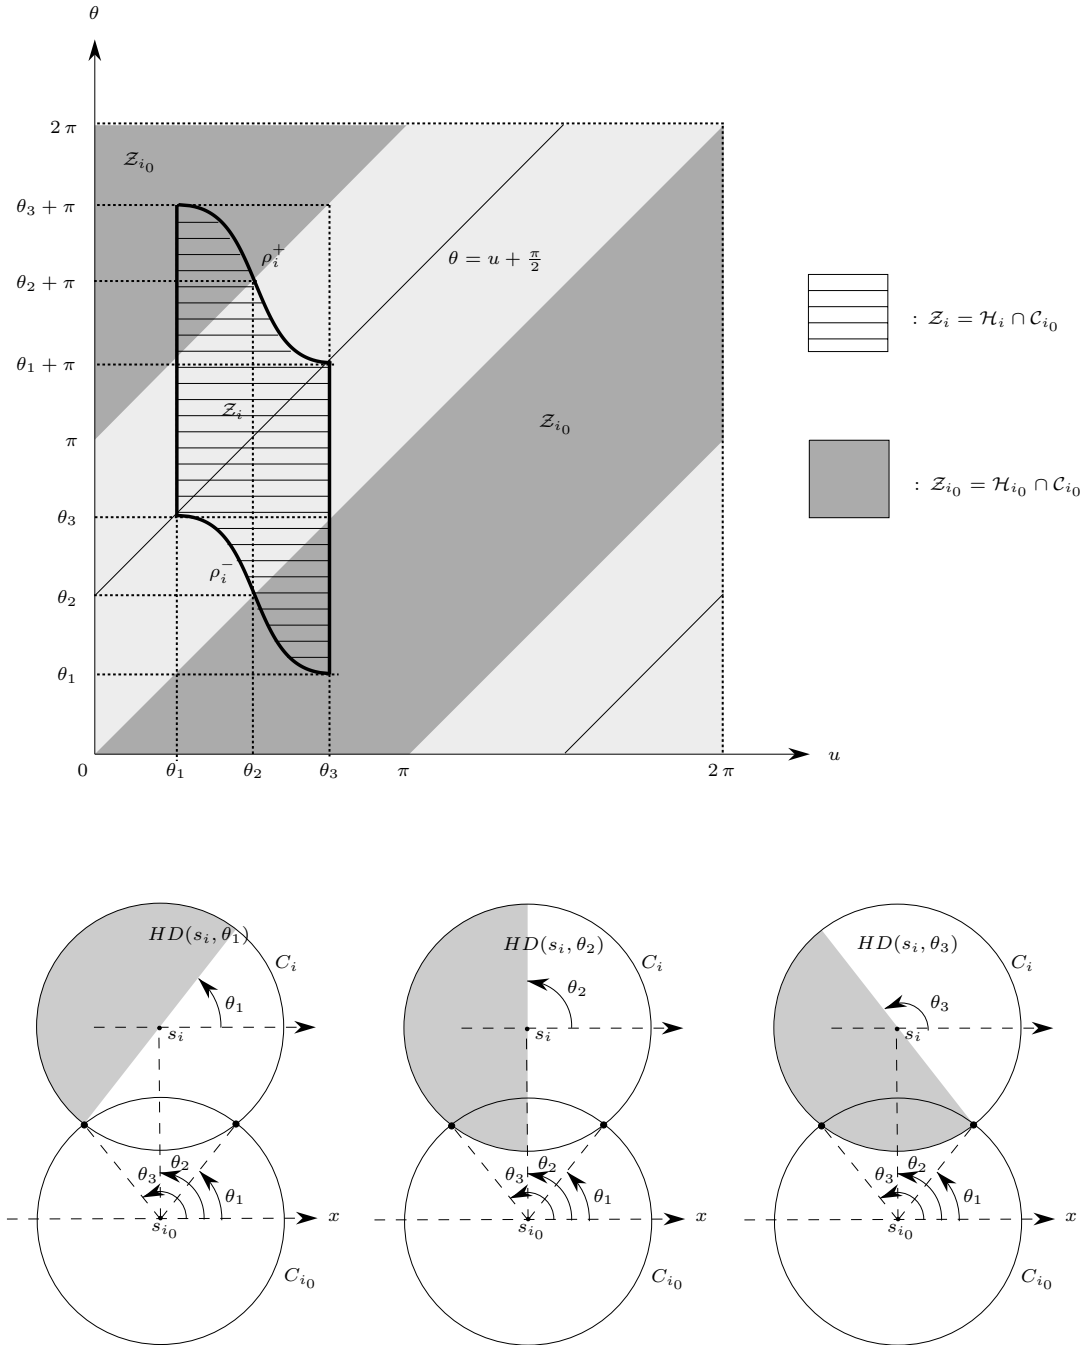

FIG. 4.1. *Example of* $\mathcal{Z}_i$ *for* $\|s_{i_0}s_i\| = \sqrt{2}\,R$ *and some corresponding critical positions of* $HD(s_i, \theta)$.

We now consider that equation with X equal to $\mathcal{H}$ or $int(\mathcal{H})$, and Y equal to the torus $\mathcal{C}_{i_0}$. Since $compl(p_{//\theta}(compl(\mathcal{C}_{i_0})))$ is the circle C_{i_0}, we get

$$compl(p_{//\theta}(compl(\mathcal{H} \cap \mathcal{C}_{i_0}))) = \mathcal{F} \cap C_{i_0} \quad \text{and}$$
$$compl(p_{//\theta}(compl(int(\mathcal{H}) \cap \mathcal{C}_{i_0}))) = int(\mathcal{F}) \cap C_{i_0}.$$

Since $\mathcal{H} = \cup_{i=1}^{n} \mathcal{H}_i$ and $\mathcal{Z}_i = \mathcal{H}_i \cap \mathcal{C}_{i_0}$ by definition, $\mathcal{H} \cap \mathcal{C}_{i_0} = \cup_{i=1}^{n} \mathcal{Z}_i$ and $int(\mathcal{H}) \cap \mathcal{C}_{i_0} = \cup_{i=1}^{n} (int(\mathcal{H}_i) \cap \mathcal{C}_{i_0})$. By the general position assumption, no two footholds lie at distance $2R$, thus for $i \neq i_0$, $int(\mathcal{H}_i) \cap \mathcal{C}_{i_0} = int(\mathcal{Z}_i)$.[2] As $int(\mathcal{H}_{i_0}) \cap \mathcal{C}_{i_0} = \emptyset$, we get $int(\mathcal{H}) \cap \mathcal{C}_{i_0} = \cup_{i \neq i_0} int(\mathcal{Z}_i)$. The study of the shape of $\mathcal{Z}_i$ will yield (see Lemma 4.8) that $\cup_{i \neq i_0} int(\mathcal{Z}_i) = int(\cup_{i \neq i_0} \mathcal{Z}_i)$. Therefore, $int(\mathcal{F}) \cap C_{i_0} = compl(p_{//\theta}(compl(int(\cup_{i \neq i_0} \mathcal{Z}_i)))) = int(compl(p_{//\theta}(compl(\cup_{i \neq i_0} \mathcal{Z}_i))))$ and $\mathcal{F} \cap C_{i_0} = compl(p_{//\theta}(compl(\cup_i \mathcal{Z}_i)))$. Using $C_{i_0} \cap \partial(\mathcal{F}) = [C_{i_0} \cap \mathcal{F}] \setminus [C_{i_0} \cap int(\mathcal{F})]$, we get the result. □

Thus, the contribution of C_{i_0} to $\partial(\mathcal{F})$ comes from the computation of $\cup_i \mathcal{Z}_i$ and $\cup_{i \neq i_0} \mathcal{Z}_i$.

Geometrically, $compl(p_{//\theta}(compl(\cup_i \mathcal{Z}_i)))$ is the vertical projection (along the θ-axis) of the largest vertical strip Σ_{i_0} included in $\cup_i \mathcal{Z}_i$ (see Figure 4.2). Similarly, $compl(p_{//\theta}(compl(\cup_{i \neq i_0} \mathcal{Z}_i)))$ is the projection of the largest vertical strip Σ'_{i_0} included in $\cup_{i \neq i_0} \mathcal{Z}_i$. Thus, $\partial(\mathcal{F}) \cap C_{i_0}$ is the vertical projection onto C_{i_0} of the vertical strip $\Sigma_{i_0} \setminus int(\Sigma'_{i_0})$.

In order to compute $\mathcal{F}$ efficiently, we need to compute the union of the regions $\mathcal{Z}_i$ efficiently. More precisely, we will show that the union of the regions $\mathcal{Z}_i$ can be computed in $O(k_{i_0} \log k_{i_0})$ time, where k_{i_0} is the number of helicoidal volumes $\mathcal{H}_i$ intersecting $\mathcal{C}_{i_0}$.

This is possible because the $\mathcal{Z}_i$ have special shapes that allow us to reduce the computation of their union to the computation of a small number of lower envelopes of curves drawn on $\mathcal{C}_{i_0}$, with the property that two of them intersect at most once. The geometric properties of the $\mathcal{Z}_i$ are discussed in section 4.2, and in section 4.3 we present and analyze the algorithm for constructing $\partial(\mathcal{F}) \cap C_{i_0}$.

4.2. Properties of the $\mathcal{Z}_i$. Here we study the regions $\mathcal{Z}_i = \mathcal{H}_i \cap \mathcal{C}_{i_0}$. Recall that we parameterize $\mathcal{C}_{i_0} = C_{i_0} \times S^1$ by (u, θ), where u and θ parameterize C_{i_0} and S^1, respectively. ($u = 0$ corresponds to the point of C_{i_0} with maximum x-coordinate.) Figures 4.1 and 4.2 show examples of such regions $\mathcal{Z}_i$. For convenience, we will use the vocabulary of the plane when describing objects on the torus $\mathcal{C}_{i_0}$. For instance, the curve drawn on the torus $\mathcal{C}_{i_0}$ with equation $a\,\theta + b\,u + c = 0$ will be called a line. The line $u = u_0$ will be called vertical and oriented according to increasing θ. Lower and upper will refer to this orientation. The discussion below considers only nonempty regions $\mathcal{Z}_i$ (such that $\|s_{i_0} s_i\| < 2R$).

First we introduce some notations. Let $HC_i(\theta)$ be the half-circle of the boundary of $HD(s_i, \theta)$, i.e., $HC_i(\theta) = C_i \cap HD(s_i, \theta)$. Let $r_i(\theta)$ be the spoke of C_i that makes an angle θ with the x-axis, i.e., $r_i(\theta) = \{s_i + \lambda \vec{u}_\theta \mid \lambda \in [0, R]\}$, where $\vec{u}_\theta$ is the unit

[2] Recall that *int* denotes the relative interior, thus $int(\mathcal{H}_i)$ is the interior of $\mathcal{H}_i$ in $\mathbb{R}^2 \times S^1$, but $int(\mathcal{Z}_i)$ denotes the interior of $\mathcal{Z}_i$ in $\mathcal{C}_{i_0}$.

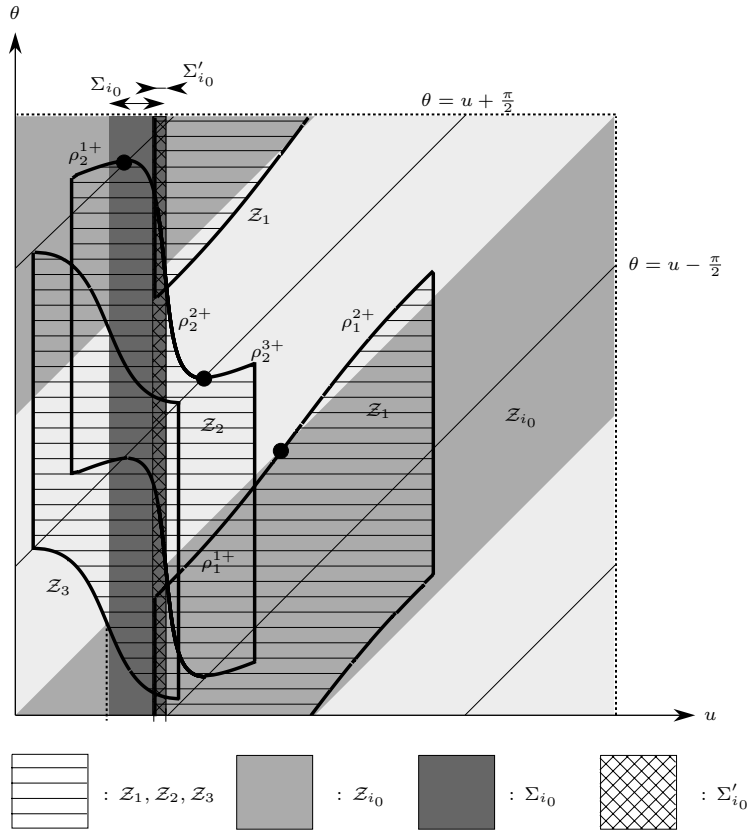

FIG. 4.2. *Contribution of C_{i_0} to $\partial(\mathcal{F})$ ($0 < \|s_1 s_{i_0}\| < R$, $R \leqslant \|s_2 s_{i_0}\| < \sqrt{2}\,R$, $\sqrt{2}\,R \leqslant \|s_3 s_{i_0}\| < 2R$).*

vector whose polar angle is θ. The boundary of $\mathcal{H}_i$ is composed of the following three patches:

$$\begin{aligned}\mathcal{T}_i &= \{(HC_i(\theta), \theta) \in \mathbb{R}^2 \times S^1\},\\ \mathcal{R}_i^+ &= \{(r_i(\theta), \theta) \in \mathbb{R}^2 \times S^1\},\\ \mathcal{R}_i^- &= \{(r_i(\theta + \pi), \theta) \in \mathbb{R}^2 \times S^1\}.\end{aligned}$$

Let ρ_i^- and ρ_i^+ denote the curves $\mathcal{R}_i^- \cap \mathcal{C}_{i_0}$ and $\mathcal{R}_i^+ \cap \mathcal{C}_{i_0}$, respectively. Since $\mathcal{R}_i^-$ and $\mathcal{R}_i^+$ are translated copies of one another, i.e., $\mathcal{R}_i^- = \mathcal{R}_i^+ \pm (0, 0, \pi)$, we have the following lemmas.

LEMMA 4.2. *ρ_i^- and ρ_i^+ are translated copies of one another, i.e.,*

$$\rho_i^+ = \{(u, \theta) \in S^1 \times S^1 \mid (u, \theta - \pi) \in \rho_i^-\} = \{(u, \theta) \in S^1 \times S^1 \mid (u, \theta + \pi) \in \rho_i^-\}.$$

LEMMA 4.3. *The curves $\rho_i^\pm$ are monotone in u.*

Proof. Assume for a contradiction that a curve $\rho_i^\pm$ is not monotone in u. Then there exists u and $\theta \neq \theta'$ in S^1 such that (u, θ) and (u, θ') parameterize points of $\rho_i^\pm$. By the definition of $\mathcal{R}_i^\pm$, it then follows that the point $U \in C_{i_0}$ parameterized by u belongs to the two spokes $r_i(\theta)$ (or $r_i(\theta+\pi)$) and $r_i(\theta')$ (or $r_i(\theta'+\pi)$). The intersection between any two of these spokes is exactly s_i. Thus, $U = s_i$, which contradicts (since

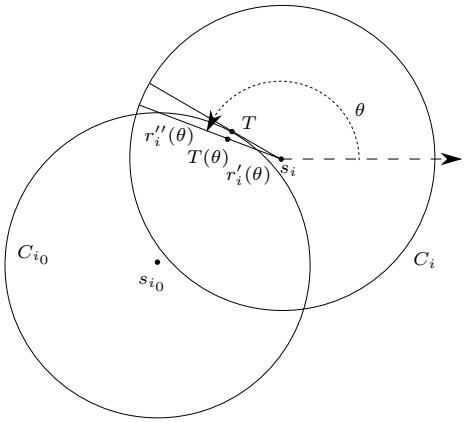

FIG. 4.3. *For the definition of $r_i'(\theta)$ and $r_i''(\theta)$.*

$U \in C_{i_0}$) the general position assumption saying that the distance between s_i and s_{i_0} is not R. □

LEMMA 4.4. *The region $\mathcal{Z}_{i_0}$ is the subset of $\mathcal{C}_{i_0}$ parameterized by $\{(u,\theta) \in S^1 \times S^1 \mid \theta \leqslant u \leqslant \theta + \pi\}$ (shown in grey in Figures* 4.1 *and* 4.2*).*

Proof. For any $\theta \in S^1$, the intersection between $\mathcal{H}_{i_0}$ and the "horizontal plane" Π_θ is the half-disk $HD(s_{i_0}, \theta)$. Similarly, the intersection between $\mathcal{C}_{i_0}$ and that plane is C_{i_0}. Thus, the intersection between $\mathcal{Z}_{i_0}$ and Π_θ is $HC_{i_0}(\theta)$, which is parameterized on C_{i_0} by $\{u \in S^1 \mid \theta \leqslant u \leqslant \theta + \pi\}$. That intersection is actually on the plane Π_θ and is therefore parameterized on $\mathcal{C}_{i_0}$ by $\{(u,\theta) \in S^1 \times S^1 \mid \theta \leqslant u \leqslant \theta + \pi\}$. □

PROPOSITION 4.5. *$\mathcal{Z}_i$ is a connected region bounded from below by ρ_i^- and from above by ρ_i^+, i.e., $\mathcal{Z}_i = \{(u,\theta) \in S^1 \times S^1 \mid \exists x \in [0,\pi], (u, \theta - x) \in \rho_i^-, (u, \theta - x + \pi) \in \rho_i^+\}$ (see Figures* 4.1 and 4.2*).*

Proof. By cutting $\mathcal{C}_{i_0}$ and $\mathcal{H}_i$ by the "horizontal plane" Π_θ, we get that a point parameterized by (u,θ) on $\mathcal{C}_{i_0}$ belongs to $\mathcal{H}_i$ if and only if the point U parameterized by u on C_{i_0} belongs to $HD(s_i,\theta)$. Since $HD(s_i,\theta)$ can be seen as the union of the spokes $\{r_i(\theta+\gamma) \mid \gamma \in [0,\pi]\}$, $(u,\theta) \in \mathcal{Z}_i$ if and only if there exists $\gamma \in [0,\pi]$ such that $U \in r_i(\theta+\gamma)$, or, equivalently, $U \in r_i(\theta - x + \pi)$ with $x = \pi - \gamma \in [0,\pi]$. Since $\mathcal{R}_i^- = \{(r_i(\theta - x + \pi), \theta - x) \mid \theta - x \in S^1\}$, it follows from $U \in r_i(\theta - x + \pi)$ that the point of $\mathcal{C}_{i_0}$ parameterized by $(u, \theta - x)$ belongs to $\mathcal{R}_i^-$ and thus to $\rho_i^- = \mathcal{R}_i^- \cap \mathcal{C}_{i_0}$. From Lemma 4.2, we get that the point parameterized by $(u, \theta - x + \pi)$ belongs to ρ_i^+. Therefore, $\mathcal{Z}_i$ is a connected region bounded from below by ρ_i^- and from above by ρ_i^+. □

We want to compute the union of the $\mathcal{Z}_i$ by computing the "lower envelope"[3] of the lower edges ρ_i^-, and the "upper envelope" of the upper edges ρ_i^+. Unfortunately it is impossible to do so because some upper edges ρ_i^+ may be "below" or intersect some lower edges ρ_j^-. However, we can subdivide the regions $\mathcal{Z}_i$ into blocks $\mathcal{Z}_i^k$, $k \in \mathcal{K}$, and separate these blocks into two sets Ω_1 and Ω_2 such that the union of the $\mathcal{Z}_i^k$ in Ω_1 (respectively, Ω_2) is the region bounded from above by the upper envelope of the upper edges of the $\mathcal{Z}_i^k \in \Omega_1$ and bounded from below by the lower envelope of the lower edges of the $\mathcal{Z}_i^k \in \Omega_1$ (respectively, Ω_2). Such property can be realized by showing that all the upper edges of the $\mathcal{Z}_i^k \in \Omega_1$ belong to the strip $\{(u,\theta) \in S^1 \times [u + \frac{\pi}{2}, u + \frac{3\pi}{2}]\}$ and

[3]Note that the lower and upper envelopes of curves in $S^1 \times S^1$ are not actually defined.

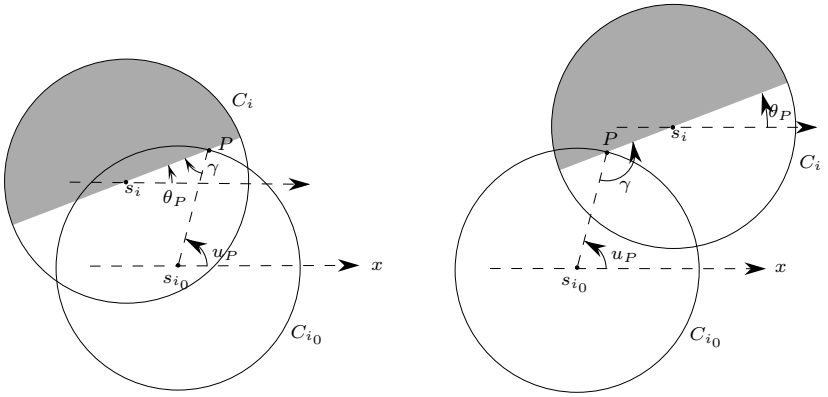

FIG. 4.4. *For the proof of Proposition* 4.6.

all the lower edges of the $\mathcal{Z}_i^k \in \Omega_1$ belong to the strip $\{(u,\theta) \in S^1 \times [u - \frac{\pi}{2}, u + \frac{\pi}{2}]\}$. (A similar property is shown for Ω_2.) Note that the upper and lower envelopes are then defined since they are considered in $S^1 \times \mathbb{R}$.

We subdivide $\mathcal{Z}_i$ into blocks $\mathcal{Z}_i^k$ when $R < \|s_{i_0}s_i\| < \sqrt{2}\,R$. That subdivision is performed such that the upper and lower edges of the $\mathcal{Z}_i^k$ are θ-monotone. Recall that the upper edge ρ_i^+ of $\mathcal{Z}_i$ is the intersection of $\mathcal{R}_i^+ = \{(r_i(\theta),\theta) \mid \theta \in S^1\}$ and $\mathcal{C}_{i_0}$. The spoke $r_i(\theta)$ intersects C_{i_0} twice (for some θ) when $R < \|s_{i_0}s_i\| < \sqrt{2}\,R$, which implies that ρ_i^+ is not θ-monotone. We cut the spoke $r_i(\theta)$ into two pieces such that each piece intersects C_{i_0} at most once. Let T be the intersection point between C_{i_0} and on one of the two lines passing through s_i and tangent to C_{i_0} (see Figure 4.3). Let $T(\theta)$ be the point on $r_i(\theta)$ at distance $\|s_iT\|$ from s_i. Cutting $r_i(\theta)$ at $T(\theta)$ defines two subspokes $r_i'(\theta)$ and $r_i''(\theta)$ that intersect C_{i_0} in at most one point each; without loss of generality, let $r_i'(\theta)$ denote the subspoke joining s_i to $T(\theta)$. The set of $\theta \in S^1$ for which $r_i'(\theta)$ intersects C_{i_0} is clearly connected but the set of $\theta \in S^1$ for which $r_i''(\theta)$ intersects C_{i_0} consists of two connected components. We denote by ρ_i^{2+} the intersection $\{(r_i'(\theta),\theta) \mid \theta \in S^1\} \cap \mathcal{C}_{i_0}$ and by ρ_i^{1+} and ρ_i^{3+} the two connected components of the intersection $\{(r_i''(\theta),\theta) \mid \theta \in S^1\} \cap \mathcal{C}_{i_0}$ (see Figure 4.2). Since $r_i'(\theta)$ and $r_i''(\theta)$ intersect C_{i_0} at most once for any $\theta \in S^1$, the curves ρ_i^{1+}, ρ_i^{2+}, and ρ_i^{3+} are θ-monotone. The lower edges ρ_i^{k-}, $k = 1,2,3$, can be defined similarly or in a simpler way as the translated copies of ρ_i^{k+}, $k = 1,2,3$, i.e., $\rho_i^{k-} = \{(u,\theta) \in S^1 \times S^1 \mid (u,\theta+\pi) \in \rho_i^{+k}\}$. We denote by $\mathcal{Z}_i^k$, $k = 1,2,3$, the subset of $\mathcal{Z}_i$ bounded from above by ρ_i^{k+} and from below by ρ_i^{k-}.

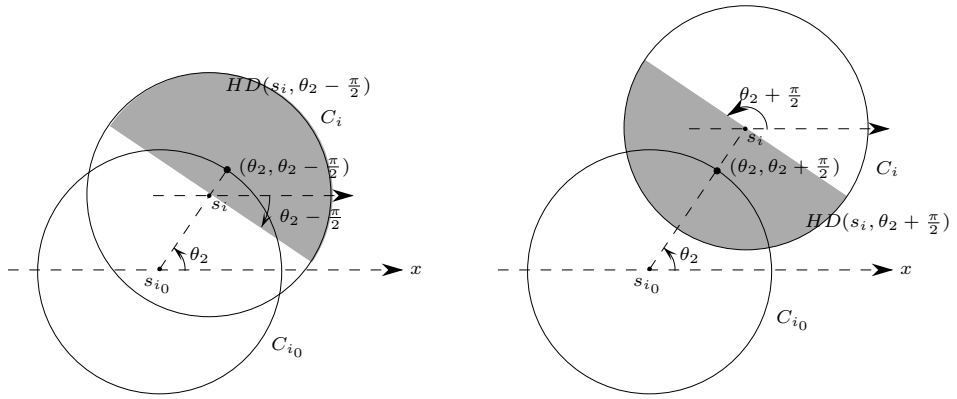
We can now prove the following proposition that will allow us to compute the union of the $\mathcal{Z}_i$ by computing the upper and lower envelopes of their upper and lower edges.

PROPOSITION 4.6. *If $0 \leqslant \|s_{i_0}s_i\| < R$, the line $\theta = u - \frac{\pi}{2}$ properly intersects $\mathcal{Z}_i$, and the lines $\theta = u \pm \frac{\pi}{2}$ properly intersect neither ρ_i^+ nor ρ_i^-.*

If $R < \|s_{i_0}s_i\| < \sqrt{2}\,R$, the line $\theta = u + \frac{\pi}{2}$ properly intersects $\mathcal{Z}_i^2$, and the line $\theta = u - \frac{\pi}{2}$ properly intersects $\mathcal{Z}_i^1$ and $\mathcal{Z}_i^3$. Furthermore, the lines $\theta = u \pm \frac{\pi}{2}$ properly intersect none of the edges ρ_i^{1+}, ρ_i^{1-}, ρ_i^{2+}, ρ_i^{2-}, ρ_i^{3+}, and ρ_i^{3-}.

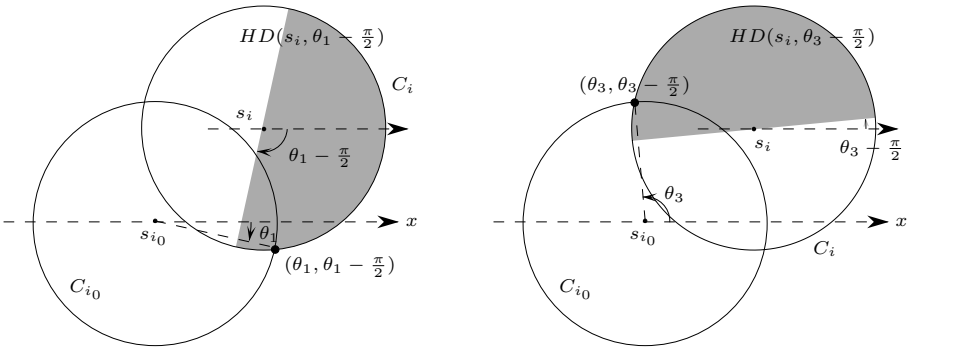
If $\sqrt{2}\,R \leqslant \|s_{i_0}s_i\| < 2R$, the line $\theta = u + \frac{\pi}{2}$ properly intersects $\mathcal{Z}_i$, and the lines $\theta = u \pm \frac{\pi}{2}$ properly intersect neither ρ_i^+ nor ρ_i^-.

Proof. Let (u_P,θ_P) parameterize a point of a curve ρ_i. Let P denote the point



(a): $0 < \|s_{i_0} s_i\| < R$, $(\theta_2, \theta_2 - \frac{\pi}{2}) \in \mathcal{Z}_i$

(b): $R < \|s_{i_0} s_i\| < 2R$, $(\theta_2, \theta_2 + \frac{\pi}{2}) \in \mathcal{Z}_i$



(c): $R < \|s_{i_0} s_i\| < \sqrt{2}\, R$, $(\theta_1, \theta_1 - \frac{\pi}{2}) \in \mathcal{Z}_i^1$

(d): $R < \|s_{i_0} s_i\| < \sqrt{2}\, R$, $(\theta_3, \theta_3 - \frac{\pi}{2}) \in \mathcal{Z}_i^3$

FIG. 4.5. *For the proof of Proposition* 4.6: *section of* $\mathcal{H}_i$ *and* $\mathcal{C}_{i_0}$ *by the "planes"* $\Pi_{\theta_2 - \frac{\pi}{2}}$, $\Pi_{\theta_2 + \frac{\pi}{2}}$, $\Pi_{\theta_1 - \frac{\pi}{2}}$, *and* $\Pi_{\theta_3 - \frac{\pi}{2}}$, *respectively.*

of C_{i_0} with parameter u_P and $\gamma = \angle(\overrightarrow{Ps_{i_0}}, \overrightarrow{Ps_i})$ $[2\pi]$ (see Figure 4.4). One can easily show that $\gamma = \theta_P - u_P[\pi]$. We prove that $\gamma \neq \frac{\pi}{2}$ $[\pi]$, except possibly when (u_P, θ_P) is an endpoint of ρ_i (or ρ_i^k when $R < \|s_{i_0} s_i\| < \sqrt{2}\, R$), which implies, since $\gamma = \theta_P - u_P[\pi]$, that the lines $\theta = u \pm \frac{\pi}{2}$ intersect neither ρ_i^+ nor ρ_i^- (respectively, neither ρ_i^{k+} nor ρ_i^{k-}), except possibly at their endpoints.

Case 1. $0 \leqslant \|s_{i_0} s_i\| < R$. Since s_i belongs to the disk of radius R centered at s_{i_0}, $\gamma \in (-\frac{\pi}{2}, \frac{\pi}{2})$ for any $P \in C_{i_0}$ (see Figure 4.4). Thus, the lines $\theta = u \pm \frac{\pi}{2}$ properly intersect neither ρ_i^+ nor ρ_i^-. Finally, the point of $\mathcal{C}_{i_0}$ $(\theta_2, \theta_2 - \frac{\pi}{2})$, where $\theta_2 = \angle(\vec{x}, \overrightarrow{s_{i_0} s_i})$ $[2\pi]$, belongs to the line $\theta = u - \frac{\pi}{2}$ and also to the relative interior of $\mathcal{Z}_i$ since it belongs to the interior of $\mathcal{H}_i$ (see Figure 4.5a). Therefore, the line $\theta = u - \frac{\pi}{2}$ properly intersects $\mathcal{Z}_i$.

Case 2. $R < \|s_{i_0} s_i\| < \sqrt{2}\, R$. Let (u_{P_1}, θ_{P_1}) parameterize the point connecting ρ_i^{1+} and ρ_i^{2+} and (u_{P_2}, θ_{P_2}) parameterize the point connecting ρ_i^{2+} and ρ_i^{3+}. Let P_1 and P_2 denote the points of C_{i_0} parameterized by u_{P_1} and u_{P_2}, respectively. According to the construction of ρ_i^{1+}, ρ_i^{2+}, and ρ_i^{3+}, the tangent lines to C_{i_0} at P_1 and P_2 pass through s_i. At most two tangent lines to C_{i_0} pass through s_i, thus P_1 and P_2 are the only points of C_{i_0} where $\gamma = \frac{\pi}{2}$ $[\pi]$. Since ρ_i^+ is u-monotone by Lemma 4.3,

(u_{P_1}, θ_{P_1}) and (u_{P_2}, θ_{P_2}) are the only points of ρ_i^+ where $\gamma = \frac{\pi}{2}$ $[\pi]$. Therefore, the lines $\theta = u \pm \frac{\pi}{2}$ do not properly intersect ρ_i^{k+}, $k = 1, 2, 3$. Similarly, the lines $\theta = u \pm \frac{\pi}{2}$ do not properly intersect ρ_i^{k-}, $k = 1, 2, 3$.

Let θ_1 and θ_3 be the parameters on C_{i_0} of the intersection points between C_{i_0} and C_i (see Figures 4.5c and d); to differentiate θ_1 from θ_3, assume without loss of generality that, for any $\varepsilon > 0$ small enough, the points of C_{i_0} parameterized by $\theta_1 + \varepsilon$ and $\theta_3 - \varepsilon$ are in the disk of radius R centered at s_i. Then, the points $(\theta_1, \theta_1 - \frac{\pi}{2})$ and $(\theta_3, \theta_3 - \frac{\pi}{2})$ of $\mathcal{C}_{i_0}$ belong to $\mathcal{Z}_i^1$ and $\mathcal{Z}_i^3$ (or to $\mathcal{Z}_i^3$ and $\mathcal{Z}_i^1$), respectively (see Figures 4.5c and d). However, these points do not belong to the relative interior of $\mathcal{Z}_i^1$ and $\mathcal{Z}_i^3$ (because they lie on the border of $HD(s_i, \theta_1 - \frac{\pi}{2})$ and $HD(s_i, \theta_3 - \frac{\pi}{2})$). Nevertheless, there clearly exists $\varepsilon > 0$ small enough such that the point parameterized by $\theta_1 + \varepsilon$ (respectively, $\theta_3 - \varepsilon$) on C_{i_0} belongs to the interior of the half-disk $HD(s_i, \theta_1 - \frac{\pi}{2} + \varepsilon)$ (respectively, $HD(s_i, \theta_3 - \frac{\pi}{2} - \varepsilon)$). Thus, the points $(\theta_1 + \varepsilon, \theta_1 + \varepsilon - \frac{\pi}{2})$ and $(\theta_3 - \varepsilon, \theta_3 - \varepsilon - \frac{\pi}{2})$ of $\mathcal{C}_{i_0}$ belong to the relative interior of $\mathcal{Z}_i^1$ and $\mathcal{Z}_i^3$, respectively. Therefore, the line $\theta = u - \frac{\pi}{2}$ properly intersects $\mathcal{Z}_i^1$ and $\mathcal{Z}_i^3$.

On the other hand, $(\theta_2, \theta_2 + \frac{\pi}{2})$ (where $\theta_2 = \angle(\vec{x}, \overrightarrow{s_{i_0} s_i})$ $[2\pi]$) belongs to relative interior of $\mathcal{Z}_i^2$ because the point of C_{i_0} parameterized by θ_2 belongs to the relative interior of the subspoke $r_i'(\theta_2 + \pi)$ (see Figure 4.5b) which belongs to interior of $HD(s_i, \theta_2 + \frac{\pi}{2})$. Therefore, the line $\theta = u + \frac{\pi}{2}$ properly intersects $\mathcal{Z}_i^2$.

Case 3. $\sqrt{2}\, R \leqslant \|s_{i_0} s_i\| < 2R$. Since $r_i(\theta)$ intersects C_{i_0} at most once, $\gamma \in [\frac{\pi}{2}, \frac{3\pi}{2}]$ (see Figure 4.4). Moreover, $\gamma = \frac{\pi}{2}$ $[\pi]$ only when $\|s_{i_0} s_i\| = \sqrt{2}\, R$, but then P is at distance R from s_i which implies that (u_P, θ_P) is an endpoint of ρ_i. Thus, the lines $\theta = u \pm \frac{\pi}{2}$ intersect neither ρ_i^+ nor ρ_i^-, except possibly at their endpoints. Finally, the point $(\theta_2, \theta_2 + \frac{\pi}{2})$ of $\mathcal{C}_{i_0}$ (where $\theta_2 = \angle(\vec{x}, \overrightarrow{s_{i_0} s_i})$ $[2\pi]$) belongs to the line $\theta = u + \frac{\pi}{2}$ and also to the relative interior of $\mathcal{Z}_i$ (see Figures 4.5b and 4.1). Therefore, the line $\theta = u + \frac{\pi}{2}$ properly intersects $\mathcal{Z}_i$. □

By Proposition 4.6, we can compute the union $\cup_{i \neq i_0} \mathcal{Z}_i$ by separating the $\mathcal{Z}_i$, $\mathcal{Z}_i^k$ into two sets Ω_1 and Ω_2 (where $\mathcal{Z}_i$, $\mathcal{Z}_i^k$ belongs to Ω_1 if and only if ρ_i^+, ρ_i^{k+} belongs to the strip $\{(u, \theta) \in S^1 \times [u + \frac{\pi}{2}, u + \frac{3\pi}{2}]\}$ and ρ_i^-, ρ_i^{k-} belongs to the strip $\{(u, \theta) \in S^1 \times [u - \frac{\pi}{2}, u + \frac{\pi}{2}]\}$) and by computing the union of the $\mathcal{Z}_i$, $\mathcal{Z}_i^k$ in Ω_1 (respectively, Ω_2) by computing the upper envelope of their upper edges and the lower envelope of their lower edges. In order to compute efficiently these upper and lower envelopes, we show that the curves ρ_i^+, ρ_i^-, ρ_i^{k+}, and ρ_i^{k-} intersect each other at most once. However, we need for that purpose to split the regions $\mathcal{Z}_i$ when $0 < \|s_{i_0} s_i\| < R$ into two blocks $\mathcal{Z}_i^1$ and $\mathcal{Z}_i^2$ separated by the vertical line $u = \theta_2 = \angle(\vec{x}, \overrightarrow{s_{i_0} s_i})$; it also remains to split the θ-interval (or the u-interval) over which ρ_i is defined into two intervals of equal length over which $\rho_i^{1\pm}$ and $\rho_i^{2\pm}$ are defined (see Figure 4.2). Note that Proposition 4.6 still holds if we replace (when $0 < \|s_{i_0} s_i\| < R$) $\mathcal{Z}_i$ by $\mathcal{Z}_i^k$ and $\rho_i^\pm$ by $\rho_i^{k\pm}$, $k = 1, 2$.

For consistency, we split $\mathcal{Z}_{i_0}$ into two blocks $\mathcal{Z}_{i_0}^1$ and $\mathcal{Z}_{i_0}^2$ separated by a vertical line (chosen arbitrarily, say $u = \pi$). Also for consistency, the curves $\rho_i^\pm$ when $\sqrt{2}\, R \leqslant \|s_{i_0} s_i\| < 2R$ are occasionally denoted in what follows by $\rho_i^{1\pm}$.

LEMMA 4.7. *Let ρ_i' and ρ_j' be some connected portions of $\rho_i^\pm$ and $\rho_j^\pm$, respectively $(i \neq j)$. If ρ_i' or ρ_j' is monotone in θ and defined over a θ-interval smaller than π, then ρ_i' and ρ_j' intersect at most once.*

Proof. Let (u_I, θ_I) be a point of intersection between ρ_i' and ρ_j' and I be the point of the circle C_{i_0} with parameter u_I. Since ρ_i' is a portion of the intersection between $\mathcal{C}_{i_0}$ and $\mathcal{R}_i^\pm$, I is a point of intersection between C_{i_0} and the diameter of $HD(s_i, \theta_I)$. Therefore, the line passing through s_i and I has slope θ_I.

By applying the same argument to ρ'_j, we obtain that s_i and s_j belong to the same straight line of slope θ_I. Therefore, if ρ'_i and ρ'_j intersect twice, at (u_I, θ_I) and (u_J, θ_J), then $\theta_I = \theta_J[\pi]$. It follows, if ρ'_i or ρ'_j is defined over a θ-interval smaller than π, that $\theta_I = \theta_J[2\pi]$. Furthermore, if ρ'_i or ρ'_j is monotone in θ, then (u_I, θ_I) and (u_J, θ_I) are equal. □

LEMMA 4.8. *For all i, j, $int(\mathcal{Z}_i) \cup int(\mathcal{Z}_j) = int(\mathcal{Z}_i \cup \mathcal{Z}_j)$.*

Proof. We assume that $i \neq j$ because otherwise the result is trivial. One can easily show that $int(\mathcal{Z}_i) \cup int(\mathcal{Z}_j) \neq int(\mathcal{Z}_i \cup \mathcal{Z}_j)$ only if the boundaries of $\mathcal{Z}_i$ and $\mathcal{Z}_j$ partially coincide, i.e., the dimension of $\partial(\mathcal{Z}_i) \cap \partial(\mathcal{Z}_j)$ is 1.

By Proposition 4.5, $\partial(\mathcal{Z}_i)$ consists of the edges ρ_i^+ and ρ_i^- and of two vertical line segments joining the endpoints of ρ_i^+ and ρ_i^- when these endpoints exist (which is the case when $i \neq i_0$). Moreover, these vertical line segments are clearly supported by the vertical lines $u = \theta_1$ and $u = \theta_3$, where θ_1 and θ_3 parameterize on C_{i_0} the points of intersection between C_{i_0} and C_i (see Figure 4.1).

By Lemma 4.7, the edges $\rho_i^\pm$ and $\rho_j^\pm$ do not partially coincide. By the general position assumption, no three distinct circles C_{i_0}, C_i, and C_j have a common intersection point. Thus, for any $i \neq j$, $C_{i_0} \cap C_i$ and $C_{i_0} \cap C_j$ are disjoint. Therefore, the vertical lines $\partial(\mathcal{Z}_i) \setminus \{\rho_i^+, \rho_i^-\}$ and $\partial(\mathcal{Z}_j) \setminus \{\rho_j^+, \rho_j^-\}$ do not partially coincide. Finally, since $\rho_i^\pm$ is nowhere partially supported by a vertical line by Lemma 4.3, $\rho_i^\pm$ and the vertical lines $\partial(\mathcal{Z}_j) \setminus \{\rho_j^+, \rho_j^-\}$ do not partially coincide. □

PROPOSITION 4.9. *Any two curves among the curves $\rho_i^{k\pm}$ intersect at most once (where $k \in \{1, 2\}$ if $0 \leqslant \|s_{i_0} s_i\| < R$, $k \in \{1, 2, 3\}$ if $R < \|s_{i_0} s_i\| < \sqrt{2}\, R$, and $k = 1$ if $\sqrt{2}\, R \leqslant \|s_{i_0} s_i\| < 2R$).*

Proof. By Lemma 4.7, it is sufficient to prove that all the curves $\rho_i^{k\pm}$, $i \neq i_0$ are monotone in θ and defined over θ-intervals smaller than π. Indeed, the curves $\rho_{i_0}^{1+}$, $\rho_{i_0}^{1-}$, $\rho_{i_0}^{2+}$, and $\rho_{i_0}^{2-}$ clearly do not pairwise intersect more than once, by Lemma 4.4.

If $0 < \|s_{i_0} s_i\| < R$, any spoke of C_i intersects C_{i_0} at most once. Hence, $\rho_i^\pm$ is monotone in θ. $\rho_i^\pm$ is defined over a θ-interval greater than π but smaller than 2π. Since we have split that interval in two equal parts, $\rho_i^{1\pm}$ and $\rho_i^{2\pm}$ are defined over a θ-interval smaller than π (see $\mathcal{Z}_1$ in Figure 4.2).

If $R < \|s_{i_0} s_i\| < \sqrt{2}\, R$, the θ-interval where $r_i(\theta)$ (or $r_i(\theta + \pi)$) intersects C_{i_0} is smaller than π, which implies that ρ_i is defined over a θ-interval smaller than π. The curves ρ_i^{k+}, $k = 1, 2, 3$, are defined as the connected components of $\{(r'_i(\theta), \theta) \mid \theta \in S^1\} \cap \mathcal{C}_{i_0}$ and $\{(r''_i(\theta), \theta) \mid \theta \in S^1\} \cap \mathcal{C}_{i_0}$. Since the subspokes $r'_i(\theta)$ and $r''_i(\theta)$ intersect C_{i_0} at most once for any $\theta \in S^1$, the curves ρ_i^{k+}, $k = 1, 2, 3$, are θ-monotone.

If $\sqrt{2}\, R \leqslant \|s_{i_0} s_i\| < 2R$, $r_i(\theta)$ (and also $r_i(\theta + \pi)$) intersects C_{i_0} in at most one point, which proves that ρ_i is monotone in θ. Furthermore, the θ-interval where ρ_i is defined is smaller than π because the θ-interval where $r_i(\theta)$ (or $r_i(\theta + \pi)$) intersects C_{i_0} is smaller than π. □

4.3. Construction of $\partial(\mathcal{F}) \cap C_{i_0}$. We first show how to compute $\cup_i \mathcal{Z}_i$. Let Ω_1 and Ω_2 be the following sets of $\mathcal{Z}_i^k$:

$$\Omega_1 = \{\mathcal{Z}_i \mid \sqrt{2}\, R \leqslant \|s_{i_0} s_i\| < 2R\} \cup \{\mathcal{Z}_i^2 \mid R < \|s_{i_0} s_i\| < \sqrt{2}\, R\},$$
$$\Omega_2 = \{\mathcal{Z}_i^1, \mathcal{Z}_i^2 \mid 0 \leqslant \|s_{i_0} s_i\| < R\} \cup \{\mathcal{Z}_i^1, \mathcal{Z}_i^3 \mid R < \|s_{i_0} s_i\| < \sqrt{2}\, R\}.$$

By Proposition 4.6, the line $\theta = u + \frac{\pi}{2}$ properly intersects all the $\mathcal{Z}_i^k \in \Omega_1$ but the lines $\theta = u \pm \frac{\pi}{2}$ properly intersect none of their upper and lower edges ρ_i^{k+} and ρ_i^{k-}. Thus, the regions $\mathcal{Z}_i^k \in \Omega_1$ can be seen as regions of $\{(u, \theta) \in S^1 \times [u - \frac{\pi}{2}, u + \frac{3\pi}{2}]\}$

such that all their upper edges ρ_i^{k+} lie in $\{(u,\theta) \in S^1 \times [u+\frac{\pi}{2}, u+\frac{3\pi}{2}]\}$ and all their lower edges ρ_i^{k-} lie in $\{(u,\theta) \in S^1 \times [u-\frac{\pi}{2}, u+\frac{\pi}{2}]\}$. Therefore, the union of the $\mathcal{Z}_i^k \in \Omega_1$ is the region of $\{(u,\theta) \in S^1 \times [u-\frac{\pi}{2}, u+\frac{3\pi}{2}]\}$ bounded from above by the upper envelope of their ρ_i^{k+} and bounded from below by the lower envelope of their ρ_i^{k-}. Similarly, the union of the $\mathcal{Z}_i^k \in \Omega_2$ is the region of $\{(u,\theta) \in S^1 \times [u-\frac{3\pi}{2}, u+\frac{\pi}{2}]\}$ bounded from above by the upper envelope of the ρ_i^{k+} and bounded from below by the lower envelope of the ρ_i^{k-}.

The union of Ω_1 and Ω_2, which is $\cup_i \mathcal{Z}_i$, can be achieved by computing, on one hand, the intersection between the upper edge chain of $\cup_{\mathcal{Z}_i^k \in \Omega_1} \mathcal{Z}_i^k$ with the lower edge chain of $\cup_{\mathcal{Z}_i^k \in \Omega_2} \mathcal{Z}_i^k$ (which both belong to $\{(u,\theta) \in S^1 \times S^1 \mid \theta \in [u+\frac{\pi}{2}, u+\frac{3\pi}{2}]\}$), and on the other hand, the intersection between the upper edge chain of $\cup_{\mathcal{Z}_i^k \in \Omega_2} \mathcal{Z}_i^k$ with the lower edge chain of $\cup_{\mathcal{Z}_i^k \in \Omega_1} \mathcal{Z}_i^k$ (which both belong to $\{(u,\theta) \in S^1 \times S^1 \mid \theta \in [u-\frac{\pi}{2}, u+\frac{\pi}{2}]\}$). These intersections can simply be performed by following the two edge chains for u from 0 to 2π, since they are monotone in u by Lemma 4.3.

Let us analyze the complexity of the above construction. The k_{i_0} helicoidal volumes $\mathcal{H}_i$ that intersect $\mathcal{C}_{i_0}$ can be found in $O(k_{i_0})$ amortized time once the Delaunay triangulation of the footholds has been computed, which can be done in $O(n \log n)$ time [6, 17]. By Proposition 4.9, the upper and lower envelopes can be computed in $O(k_{i_0} \log k_{i_0})$ time using $O(k_{i_0}\alpha(k_{i_0}))$ space where α is the pseudo inverse of Ackerman's function [7]. Also by Proposition 4.9, the union of Ω_1 and Ω_2 can be done in linear time in the size of the edge chains, that is $O(k_{i_0}\alpha(k_{i_0}))$ time. Thus, we can compute $\cup_i \mathcal{Z}_i$ in $O(k_{i_0} \log k_{i_0})$ time using $O(k_{i_0}\alpha(k_{i_0}))$ space after $O(n \log n)$ preprocessing time. We can compute $\cup_{i \neq i_0} \mathcal{Z}_i$ similarly by removing $\mathcal{Z}_{i_0}^1$ and $\mathcal{Z}_{i_0}^2$ from Ω_2.

The contribution of C_{i_0} to $\partial(\mathcal{F})$ is, according to Proposition 4.1, $C_{i_0} \cap \partial(\mathcal{F})$ $= \mathit{compl}(p_{/\!/\theta}(\mathit{compl}(\cup_i \mathcal{Z}_i))) \setminus \mathit{int}(\mathit{compl}(p_{/\!/\theta}(\mathit{compl}(\cup_{i \neq i_0} \mathcal{Z}_i))))$. By Remark 3.7, $\mathit{compl}(p_{/\!/\theta}(\mathit{compl}(\cup_i \mathcal{Z}_i)))$ and $\mathit{compl}(p_{/\!/\theta}(\mathit{compl}(\cup_{i \neq i_0} \mathcal{Z}_i)))$ are the projections onto C_{i_0} of the largest vertical strips Σ_{i_0} and Σ'_{i_0} included in $\cup_i \mathcal{Z}_i$ and $\cup_{i \neq i_0} \mathcal{Z}_i$, respectively (see Figure 4.2). These projections are easily computed because the edges of $\cup_i \mathcal{Z}_i$ and $\cup_{i \neq i_0} \mathcal{Z}_i$ are monotone with respect to u (Lemma 4.3). These projections, and therefore the computation of $C_{i_0} \cap \partial(\mathcal{F})$, can thus be done in linear time and space in the size of $\cup_i \mathcal{Z}_i$ and $\cup_{i \neq i_0} \mathcal{Z}_i$, that is $O(k_{i_0}\alpha(k_{i_0}))$.

Moreover, we label an arc of $\partial(\mathcal{F})$ either by i if the arc belongs to the circle C_i or by (i,j) if the arc belongs to the straight line segment $[s_i, s_j]$. The labels of the edges of $\partial(\mathcal{F})$ incident to C_{i_0} can be found as follows, without increasing the complexity. An arc of $\partial(\mathcal{F}) \cap C_{i_0}$ corresponds to a vertical strip $\Sigma_{i_0} \setminus \Sigma'_{i_0}$. An endpoint P of such an arc is the projection of a vertical edge or the projection of a point of intersection between two curved edges. In the first case, P is the intersection of C_{i_0} with some C_i and in the second case, P is the intersection of C_{i_0} with some line segment $[s_i, s_j]$. By the general position assumption, among the circles $C_1, \ldots, C_n$ and the line segments joining two footholds, the intersection between three circles, two circles and a line segment, or one circle and two line segments is empty. Thus, P is the intersection between C_{i_0} and either a unique C_i or a unique line segment $[s_i, s_j]$. Therefore, the edge of $\partial(\mathcal{F})$ incident to C_{i_0} at P is either a circular arc supported by C_i or a line segment supported by $[s_i, s_j]$. Hence, the labels of the edges of $\partial(\mathcal{F})$ incident to C_{i_0} can be found at no extra cost during the construction.

Since $\mathcal{A}$ is the arrangement of the circles of radius R centered at the footholds, $\sum_{i_0=1}^{n} k_{i_0} = O(|\mathcal{A}|)$. The above considerations yield the following theorem.

THEOREM 4.10. *We can compute $\partial(\mathcal{F}) \cap \mathcal{A}$ and the labels of the edges of $\partial(\mathcal{F})$ incident to the arcs of $\partial(\mathcal{F}) \cap \mathcal{A}$ in $O(|\mathcal{A}| \log n)$ time using $O(|\mathcal{A}|\alpha(n))$ space.*

4.4. Computation of the arcs of $\partial(\mathcal{F})$ issued from a foothold. The previous section has shown how to compute all the vertices of $\mathcal{F}$ that are incident to at least one circular arc. It remains to find the vertices of $\mathcal{F}$ incident to two straight edges. As we have seen in section 2, a vertex of $\mathcal{F}$ incident to two straight edges of $\partial(\mathcal{F})$ is a foothold. Furthermore, considering a foothold s_{i_0} in a cell Γ of $\mathcal{A}$, s_{i_0} is a vertex of $\mathcal{F}$ incident to two straight edges of $\partial(\mathcal{F})$ if and only if s_{i_0} is a vertex of the convex hull of the footholds reachable from s_{i_0}. The k'_{i_0} footholds contained in the disk of radius R centered at s_{i_0} can be found in $O(k'_{i_0})$ amortized time because we have already computed the Delaunay triangulation of the footholds [6, 17]. Thus, we can decide if s_{i_0} is a vertex of the convex hull of these k'_{i_0} footholds in $O(k'_{i_0})$ time and space. When s_{i_0} is a vertex of the convex hull, we can also find the two edges of the convex hull adjacent to s_{i_0} in $O(k'_{i_0})$ time and space. As the sum of the k'_i for $i \in \{1, \ldots, n\}$ is bounded by the size of $\mathcal{A}$, we obtain the following theorem.

THEOREM 4.11. *The footholds belonging to $\partial(\mathcal{F})$ and the labels of the arcs of $\partial(\mathcal{F})$ issued from these footholds can be found in $O(|\mathcal{A}|)$ time and space.*

4.5. Construction of $\mathcal{F}$.

THEOREM 4.12. *The free space of the spider robot can be computed in $O(|\mathcal{A}| \log n)$ time using $O(|\mathcal{A}|\alpha(n))$ space.*

Proof. By Theorem 4.10, we have computed all the circular arcs of $\partial(\mathcal{F})$ and the labels of the edges of $\partial(\mathcal{F})$ incident to them. By Theorem 4.11, we have computed all the vertices of $\partial(\mathcal{F})$ that are incident to two straight edges of $\partial(\mathcal{F})$ and the label of these two edges. It remains to sort the vertices of $\partial(\mathcal{F})$ that appear on the line segments $[s_i, s_j]$. We only consider the line segments $[s_i, s_j]$ such that the corresponding label (i, j) appears during previous computations. Then, we sort the vertices of $\partial(\mathcal{F})$ that belong to each such relevant line. Since $|\partial(\mathcal{F})| = \Theta(|\mathcal{A}|)$ [2], sorting all these vertices can be done in $O(|\mathcal{A}| \log n)$ time. A complete description of $\partial(\mathcal{F})$ then follows easily. □

5. Generalization to polygonal foothold regions.

5.1. Introduction and preliminaries. We consider now the case where the set of footholds is no longer a set of points but a set $\mathcal{S}$ of pairwise disjoint polygonal regions bounded by n line segments $e_1, \ldots, e_n$. Clearly, $\mathcal{S}$ is a subset of the free space $\mathcal{F}$ of the spider robot. Let $\mathcal{F}_e$ denote the free space of the spider robot using as foothold regions only the edges $e_1, \ldots, e_n$. Suppose that the spider robot admits a stable placement outside $\mathcal{S}$ with its feet inside some polygonal footholds; then the placement remains stable if it retracts its legs on the boundary of these polygonal regions. Hence, $\mathcal{F} = \mathcal{F}_e \cup \mathcal{S}$. We show how to compute $\mathcal{F}_e$.

As observed in Remark 3.8, the results of section 3 remain true if the foothold regions are line segments provided that $\mathcal{H}_i$ is replaced by $\mathcal{H}_{e_i}$, the generalized helicoidal volume defined by (see Figure 5.1)

$$\mathcal{H}_{e_i} = \{(P, \theta) \in \mathbb{R}^2 \times S^1 \mid P \in HD(s, \theta),\ s \in e_i\}.$$

The helicoidal volume associated to a point site s_i will be, henceforth, denoted by $\mathcal{H}_{s_i}$.

Similarly, we define the generalized circle C_{e_i} as the set of points at distance R from e_i. Let $\mathcal{A}_e$ denote the arrangement of the n generalized circles $C_{e_1}, \ldots, C_{e_n}$. Notice that $|\mathcal{A}_e| = \Theta(n^2)$.

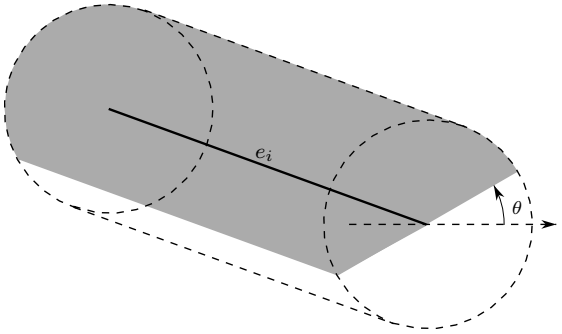


FIG. 5.1. *Section of $\mathcal{H}_{e_i}$ by the "plane" Π_θ.*

Each arc of the boundary $\partial(\mathcal{F}_e)$ of $\mathcal{F}_e$ is either an arc of C_{e_i} corresponding to a maximal extension of one leg or an arc corresponding to placements at the limit of stability of the spider robot. Similar to what we did in section 4, we compute first the contribution of each C_{e_i} to $\partial(\mathcal{F}_e)$ (section 5.2). Thereafter, we compute the arcs of $\partial(\mathcal{F}_e)$ that correspond to placements where the spider robot is at the limit of stability (section 5.3). Finally, we show how to construct $\mathcal{F}_e$ (and $\mathcal{F}$) in section 5.4.

Figure 5.2 shows an example of free space $\mathcal{F}_e$ for polygonal foothold regions.

5.2. Computation of $\partial(\mathcal{F}_e) \cap \mathcal{A}_e$. We compute the contribution to $\partial(\mathcal{F}_e)$ of each generalized circle C_{e_i} in turn. We consider the contribution of $C_{e_{i_0}}$ to $\partial(\mathcal{F}_e)$ for some $i_0 \in \{1, \ldots, n\}$. $C_{e_{i_0}}$ is composed of two half-circles and two straight line segments. In order to compute the contribution of $C_{e_{i_0}}$ to $\partial(\mathcal{F}_e)$, first we evaluate the contribution of the half-circles and then the contribution of the straight line segments. For convenience, we will not compute the contribution of the half-circles to $\partial(\mathcal{F}_e)$ but the contribution of the whole circles. Similarly, we will compute the contribution of the whole straight lines supporting the line segments of $C_{e_{i_0}}$.

Let s_{i_0} and s'_{i_0} denote the two endpoints of the line segment e_{i_0}, and let $C_{s_{i_0}}$ and $C_{s'_{i_0}}$ denote the unit circles centered at s_{i_0} and s'_{i_0}, respectively. Let l_{i_0} and l'_{i_0} denote the two straight line segments of $C_{e_{i_0}}$, and L_{i_0} and L'_{i_0} their supporting lines. We show how to compute the contributions of $C_{s_{i_0}}$ and L_{i_0} to $\partial(\mathcal{F}_e)$; the contributions of $C_{s'_{i_0}}$ and L'_{i_0} can be computed likewise.

Let $\mathcal{C}_{s_{i_0}} = C_{s_{i_0}} \times S^1$ and $\mathcal{L}_{i_0} = L_{i_0} \times S^1$. Basically, we compute $\partial(\mathcal{F}_e) \cap C_{s_{i_0}}$ and $\partial(\mathcal{F}_e) \cap L_{i_0}$, as explained in section 4.1, by computing $\cup_i(\mathcal{H}_{e_i} \cap \mathcal{C}_{s_{i_0}})$, $\cup_{i \neq i_0}(\mathcal{H}_{e_i} \cap \mathcal{C}_{s_{i_0}})$, $\cup_i(\mathcal{H}_{e_i} \cap \mathcal{L}_{i_0})$, and $\cup_{i \neq i_0}(\mathcal{H}_{e_i} \cap \mathcal{L}_{i_0})$. The properties of the new regions $\mathcal{Z}_{e_i} = \mathcal{H}_{e_i} \cap \mathcal{C}_{s_{i_0}}$ and $\mathcal{Y}_{e_i} = \mathcal{H}_{e_i} \cap \mathcal{L}_{i_0}$ are different though similar to the properties of $\mathcal{Z}_{s_i} = \mathcal{H}_{s_i} \cap \mathcal{C}_{s_{i_0}}$ described in section 4.2. The analysis of $\mathcal{Z}_{e_i}$ and $\mathcal{Y}_{e_i}$ is subdivided into two parts: first, we consider the line D_i supporting e_i and we examine the regions $\mathcal{Z}_{D_i} = \mathcal{H}_{D_i} \cap \mathcal{C}_{s_{i_0}}$ and $\mathcal{Y}_{D_i} = \mathcal{H}_{D_i} \cap \mathcal{L}_{i_0}$, where $\mathcal{H}_{D_i}$ is the generalized helicoidal volume induced by D_i,

$$\mathcal{H}_{D_i} = \{(P, \theta) \in \mathbb{R}^2 \times S^1 \mid P \in HD(s, \theta),\ s \in D_i\}.$$

Then we deduce $\mathcal{Z}_{e_i}$ (respectively, $\mathcal{Y}_{e_i}$) from $\mathcal{Z}_{D_i}$, $\mathcal{Z}_{s_i}$, and $\mathcal{Z}_{s'_i}$ (respectively, $\mathcal{Y}_{D_i}$, $\mathcal{Y}_{s_i} = \mathcal{H}_{s_i} \cap \mathcal{L}_{i_0}$, and $\mathcal{Y}_{s'_i}$), where s_i and s'_i are the two endpoints of e_i. Thereafter, we compute the contribution of $C_{e_{i_0}}$ to $\partial(\mathcal{F}_e)$ in a way similar to what we did in section 4.3. The following theorem sums up these results.

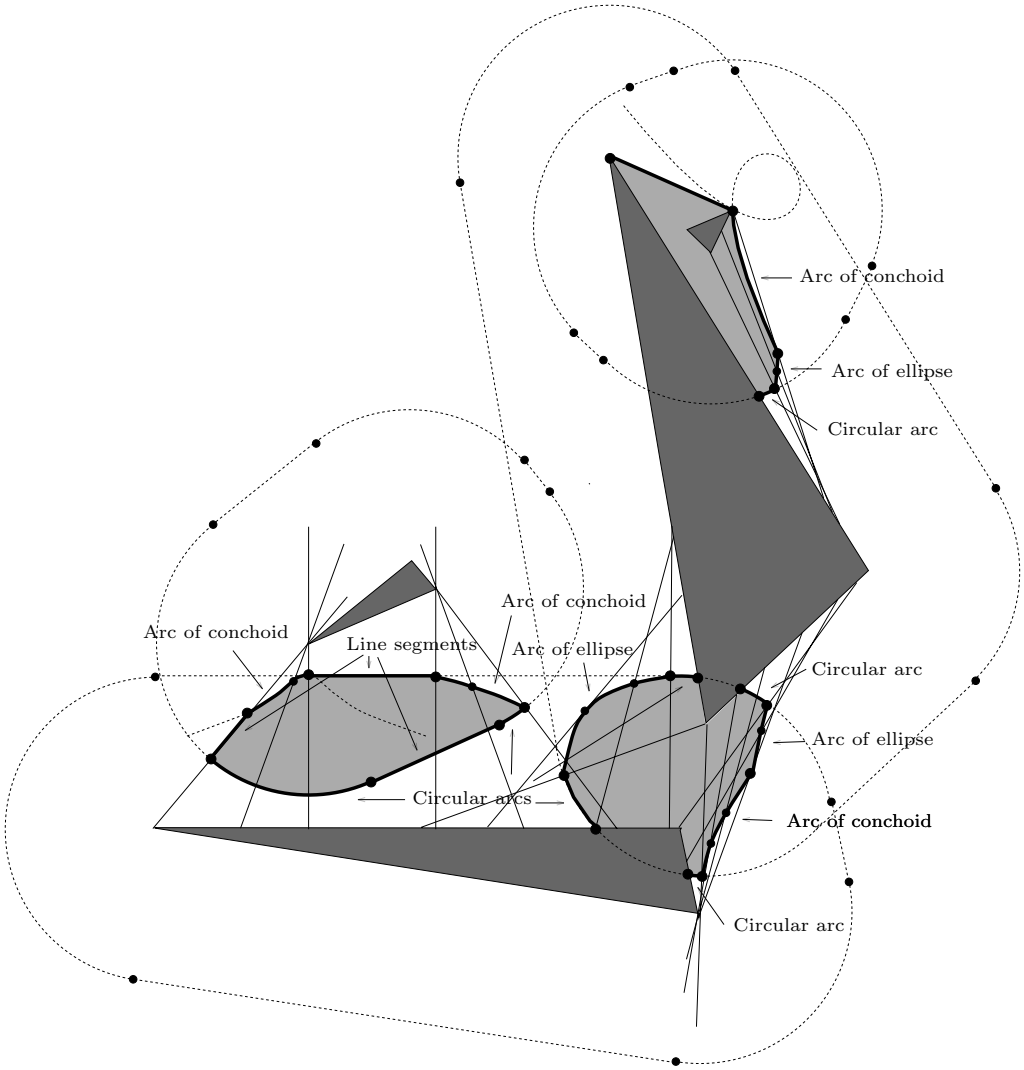

FIG. 5.2. *Example of free space $\mathcal{F}_e$ for polygonal foothold regions. The polygonal foothold regions are shown in dark grey. The other parts of $\mathcal{F}_e$ are in light grey. The C_{e_i} and some arcs of conchoid are dashed. All the line segments touching the polygons in two points are of length $2R$ and represent the ladder introduced in section* 5.3.

THEOREM 5.1. *We can compute $\partial(\mathcal{F}_e) \cap \mathcal{A}_e$ and the labels of the edges of $\partial(\mathcal{F}_e)$ incident to the arcs of $\partial(\mathcal{F}_e) \cap \mathcal{A}_e$ in $O(|\mathcal{A}_e|\alpha_7(n)\log n)$ time using $O(|\mathcal{A}_e|\alpha_8(n))$ space.*

The proof of this theorem, omitted here, is a direct generalization of the proof of Theorem 4.10. Details are given in [5] and [12].

5.3. Arcs of $\partial(\mathcal{F}_e)$ corresponding to the placements where the spider robot is at the limit of stability. We now have to compute the edges of $\mathcal{F}_e$ that do not belong to $\mathcal{A}_e$. The arcs of $\partial(\mathcal{F}_e) \cap \mathcal{A}_e$ correspond to placements at the limit of accessibility of the spider robot, and vice versa. Thus, other edges of $\mathcal{F}_e$ correspond to

placements at the limit of stability of the spider robot. We denote by $\partial(\mathcal{F}_e)_{stab}$ the set of those edges. A placement P of the spider robot is at the limit of stability if and only if there exists a closed half-disk of radius R centered at P that does not contain any foothold except at least two footholds located on the diameter of the half-disk such that P is between these footholds (see Figure 5.3). Therefore, the edges of $\partial(\mathcal{F}_e)_{stab}$ are portions of the curves drawn by the midpoint of a ladder of length $2R$ moving by translation and rotation such that the ladder touches the boundary of the foothold regions in two points but does not intersect the interior of the foothold regions. Hence, the edges of $\partial(\mathcal{F}_e)_{stab}$ are supported by the projection (onto $\mathbb{R}^2$) of the edges of the boundary of the free space of the ladder moving by translation and rotation amidst the foothold regions considered as obstacles, i.e., the set of $(P,\theta) \in \mathbb{R}^2 \times \mathbb{R}/\pi\mathbb{Z}$ such that the ladder of length $2R$ that has its midpoint at P and makes an angle θ with the x-axis does not properly intersect the interior of the foothold regions. According to [16], the edges of the boundary of the free space of the ladder can be computed in $O(|\mathcal{A}_e| \log n)$ time using $O(|\mathcal{A}_e|)$ space. The projection (onto $\mathbb{R}^2$) of each edge can easily be computed in constant time. Thus, we can compute, in $O(|\mathcal{A}_e| \log n)$ time and $O(|\mathcal{A}_e|)$ space (using [16]), a set of curves in $\mathbb{R}^2$ that contains the arcs of $\partial(\mathcal{F}_e)$ that correspond to placements at the limit of stability of the spider robot. However, it remains to compute the portions of these curves that belong to $\partial(\mathcal{F}_e)$.

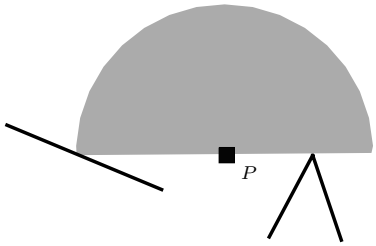

FIG. 5.3. *Example of placement P at the limit of stability.*

5.3.1. Notations and definitions. The relative interior of an e_i is called a *wall*. An endpoint of an e_i is called a *corner* (when several walls share an endpoint, we define only one corner at that point). The *ladder* is a line segment of length $2R$. A *placement* of the ladder is a pair $(P,\theta) \in \mathbb{R}^2 \times \mathbb{R}/\pi\mathbb{Z}$, where P is the location of the midpoint of the ladder and θ is the angle between the x-axis and the ladder. A *free placement* of the ladder is a placement where the ladder does not properly intersect the walls or partially lies on some walls and does not properly intersect the others. (If none of the polygonal regions of $\mathcal{S}$ are degenerated into line segments or points, then a free placement of the ladder is a placement where the ladder does not intersect the interior of the polygonal regions of $\mathcal{S}$.) A *placement of type corner-ladder* is a placement of the ladder such that the relative interior of the ladder touches a *corner*. A *placement of type wall-endpoint* is a placement of the ladder such that an endpoint of the ladder touches a *wall*. A *placement of type corner-endpoint* is a placement of the ladder such that an endpoint of the ladder touches a corner. We now define *k-contact placements* of the ladder.

A 1-*contact placement* is a free placement of type corner-ladder or wall-endpoint. A 2-*contact placement* is either the combination of two 1-contact placements or a free placement of type corner-endpoint. A 2-contact placement is said to be of type (corner-ladder)^2, (corner-ladder, wall-endpoint), (wall-endpoint)^2, or (corner-

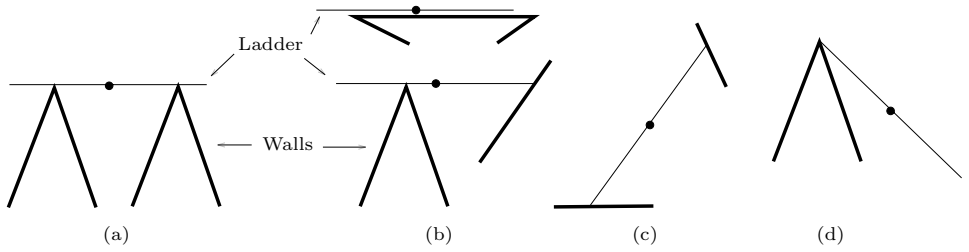

FIG. 5.4. *Examples of* 2*-contact placements of type* (a): *(corner-ladder)*^{2}, (b): *(corner-ladder, wall-endpoint),* (c): *(wall-endpoint)*^{2} *and* (d): *(corner-endpoint).*

endpoint), in accordance to the types of placements involved in the 2-contact placement (see Figure 5.4). Given two walls (respectively, a wall and a corner, two corners, one corner), the set of 2-contact placements induced by these two walls (respectively, the wall and the corner, the two corners, the single corner) is called a 2-*contact curve*. The type of a 2-contact curve is the type of the 2-contact placement defining the curve. Note that the 2-contact curves are defined in $\mathbb{R}^2 \times \mathbb{R}/\pi\mathbb{Z}$. A 3-*contact placement* is a combination of a 1-contact placement and a 2-contact placement. The types of 3-contact placements are naturally given by (corner-ladder)^3, (corner-endpoint, wall-endpoint). With this definition, we unfortunately cannot guarantee that all the 2-contact curves end at 3-contact placements. Indeed, a 2-contact curve defined by the ladder sliding along a wall (see Figure 5.4b) ends on one side (if no other wall blocks the sliding motion) at a 2-contact placement of type (corner-endpoint), where the ladder is collinear with the wall, without properly intersecting it. In order to ensure that all the 2-contact curves end at 3-contact placements, we consider these 2-contact placements as 3-contact placements and denote their type by (corner-endpoint, $\|$). A k-*contact placement*, $k > 3$, is the combination of p 1-contact placements, q 2-contact placements, and r 3-contact placements such that $p + 2q + 3r = k$.

Now, we define a 2-*contact tracing* as the projection onto $\mathbb{R}^2$ of a 2-contact curve. Similarly as above, we define the types of the 2-contact tracings. Notice that, to any point P on a given 2-contact tracing $\mathcal{K}$ corresponds a unique placement (P, θ) on the 2-contact curve that projects onto $\mathcal{K}$. It follows that to any point P on a 2-contact tracing $\mathcal{K}$ corresponds a unique pair (M, N) of points of contact between the ladder at (P, θ) and the walls (M and N are equal when $\mathcal{K}$ is a 2-contact tracing of type (corner-endpoint)); when P is an endpoint of $\mathcal{K}$, a 3-contact placement corresponds to P, however, (M, N) is uniquely defined by continuity. The points M and N are called the *contact points corresponding to* $P \in \mathcal{K}$. We also define the three contact points corresponding to a 3-contact placement.

A 2-contact tracing is a straight line segment, an arc of ellipse, an arc of conchoid, or a circular arc. Indeed (see Figures 5.5, 5.6, 5.7, and 5.8), a 2-contact tracing of type (corner-endpoint) is a circular arc; a 2-contact tracing of type (wall-endpoint)^2 is an arc of ellipse; a 2-contact tracing of type (corner-ladder, wall-endpoint) is an arc of conchoid (see [5]); and a 2-contact tracing of type (corner-ladder)^2 is a straight line segment. As we said before, we can compute all these 2-contact tracings in $O(|\mathcal{A}_e| \log n)$ time using $O(|\mathcal{A}_e|)$ space [16], and it remains to compute the portions of these curves that belong to $\partial(\mathcal{F}_e)$.

5.3.2. Overview. We first show that only some portions of the 2-contact tracings correspond to positions at the limit of stability of the spider robot (section 5.3.3).

These portions are called the relevant 2-contact tracings. Then, we prove that we do not have to take into consideration the intersections between the relative interior of relevant 2-contact tracings (Proposition 5.2). We also show that, if a point A is an endpoint of several relevant 2-contact tracings, only two of them can support edges of $\partial(\mathcal{F}_e)_{stab}$ in the neighborhood of A (Propositions 5.3). Finally (section 5.3.4), we compute a graph whose edges are relevant 2-contact tracings and where the degree of each node is at most two. This graph induces a set Δ of curves supporting $\partial(\mathcal{F}_e)_{stab}$ (Theorem 5.4) that will allow us to compute $\partial(\mathcal{F}_e)_{stab}$ in section 5.4.

5.3.3. Relevant 2-contact tracings. As mentioned above, a placement P of the spider robot is at the limit of stability if and only if there exists a closed half-disk of radius R centered at P that does not contain any foothold except at least two footholds located on the diameter of the half-disk, one on each side of P. Thus, a point P of a 2-contact tracing $\mathcal{K}$ belongs to an arc of $\partial(\mathcal{F}_e)_{stab}$ only if P lies between the two contact points corresponding to $P \in \mathcal{K}$. The portions of the 2-contact tracings for which that property holds are called the *relevant 2-contact tracings*. The other portions are called the *irrelevant 2-contact tracings*. We now show how to compute the relevant 2-contact tracings for each type of contact. Let $\mathcal{K}$ denote a 2-contact tracing, let $P \in \mathcal{K}$ and let M and N be the two contact points corresponding to $P \in \mathcal{K}$. In Figures 5.5, 5.6, 5.7, and 5.8, the walls and the relevant 2-contact tracings are thick, the irrelevant 2-contact tracings are dashed thick, and the ladder is thin.

Type (corner-endpoint): $\mathcal{K}$ is a circular arc, and M and N coincide with one endpoint of the ladder. Thus, all the 2-contact tracings of type (corner-endpoint) are wholly irrelevant.

Type (wall-endpoint)^2: $\mathcal{K}$ is an arc of ellipse, M and N are the endpoints of the ladder, and thus, P lies between them. Therefore, all the 2-contact tracings of type (wall-endpoint)^2 are wholly relevant.

Type (corner-ladder, wall-endpoint): $\mathcal{K}$ is an arc of conchoid. If the distance between the corner and the wall is greater than R, then $\mathcal{K}$ is wholly relevant.

Otherwise, if that distance is smaller than R, then the two relevant portions and the irrelevant portion of $\mathcal{K}$ are incident to the corner involved in the type of $\mathcal{K}$.

Notice that if the corner is an endpoint of the wall (see Figure 5.4b), then $\mathcal{K}$ degenerates into a line segment, and the irrelevant portion of $\mathcal{K}$ is the portion which is not supported by the wall.

Type (corner-ladder)^2: $\mathcal{K}$ is a line segment. If the distance between the two corners is greater than R, then $\mathcal{K}$ is wholly relevant; otherwise, the portion of $\mathcal{K}$ which is relevant is the line segment joining the two corners.

We now show that the intersections between the relative interiors of the relevant 2-contact tracings are not interesting for the spider robot motion problem. We recall that if a vertex A of $\partial(\mathcal{F}_e)$ belongs to $\mathcal{A}_e$, then we know by Theorem 5.1 the labels of the edges of $\partial(\mathcal{F}_e)$ incident to A. Otherwise, if $A \notin \mathcal{A}_e$, then the two edges of $\partial(\mathcal{F}_e)$ that end at A correspond to placements at the limit of stability of the spider robot.

PROPOSITION 5.2. *Any vertex A of $\partial(\mathcal{F}_e)$, such that $A \notin \mathcal{A}_e$, is an endpoint of the two relevant 2-contact tracings supporting the edges of $\partial(\mathcal{F}_e)$ ending at A.*

Proof. Since the two edges of $\partial(\mathcal{F}_e)$ that end at A correspond to placements at the limit of stability of the spider robot, they are both supported by some relevant 2-contact tracings. Thus, we only have to prove that A is an endpoint of these two relevant 2-contact tracings.

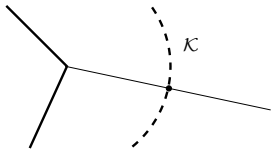

FIG. 5.5. *Irrelevant* 2*-contact tracing of type (corner-endpoint), i.e., circular arc.*

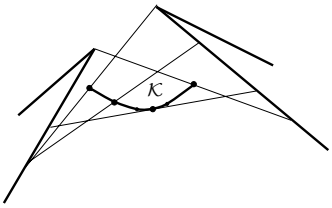

FIG. 5.6. *Relevant* 2*-contact tracing of type (wall-endpoint)*^{2}*, i.e., arc of ellipse.*

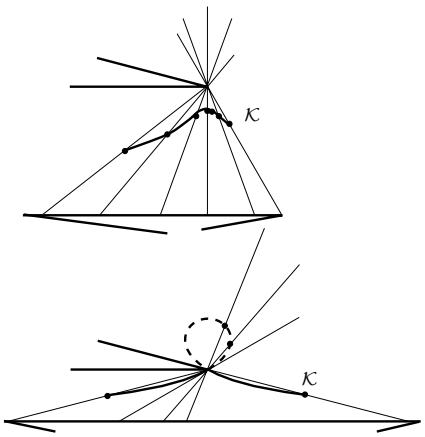

FIG. 5.7. *Relevant, and partially relevant,* 2*-contact tracings of type (corner-ladder, wall-endpoint), i.e., arcs of conchoid.*

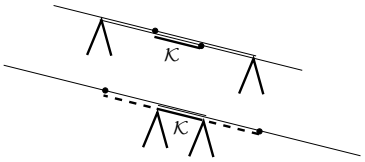

FIG. 5.8. *Relevant, and partially relevant,* 2*-contact tracings of type (corner-ladder)*^{2}*.*

Let $\mathcal{K}_1$ and $\mathcal{K}_2$ be these two relevant 2-contact tracings and assume for a contradiction that A is not an endpoint of $\mathcal{K}_1$ (nothing is assumed for A with respect to $\mathcal{K}_2$). Let $L_1 = (A, \theta_1)$ (respectively, $L_2 = (A, \theta_2)$) be the placement of the ladder that correspond to $A \in \mathcal{K}_1$ (respectively, $A \in \mathcal{K}_2$) and let M_1 and N_1 (respectively, M_2 and N_2) be the corresponding contact points (see Figure 5.9). First, notice that $L_1 \neq L_2$. Indeed, otherwise, L_1 is at least a 3-contact placement, and then A must be an endpoint of $\mathcal{K}_1$, which contradicts our assumption.

By the definition of the relevant 2-contact tracings, A is between M_1 and N_1. Moreover, A cannot be equal to M_1 or N_1 since A is not an endpoint of $\mathcal{K}_1$. It follows that neither M_2 nor N_2 is equal to A, because otherwise L_1 would be a 3-contact placement. Therefore, A is strictly between M_1 and N_1 and strictly between M_2 and N_2. Thus, A is strictly inside the polygon $(M_1M_2N_1N_2)$.

On the other hand, since $A \notin \mathcal{A}_e$, A does not belong to any C_{e_i}, and therefore, the walls supporting M_1, N_1, M_2, and N_2 intersect the open disk D_A of radius R centered at A. Thus, there exist four points M_1', N_1', M_2', and N_2' on these walls and in D_A that are close enough to M_1, N_1, M_2, and N_2, respectively, to ensure that A belongs to the interior of the polygon $(M_1'M_2'N_1'N_2')$. Since the distances from A to M_1', N_1', M_1', and N_2', are strictly smaller than R, A belongs to the interior of $\mathcal{F}_e$. This contradicts our assumption that A is a vertex of $\partial(\mathcal{F}_e)$ and yields the result. □

Consider now the adjacency graph $\mathcal{G}$ of the relevant 2-contact tracings such that two relevant 2-contact tracings are connected in $\mathcal{G}$ if and only if they have a common

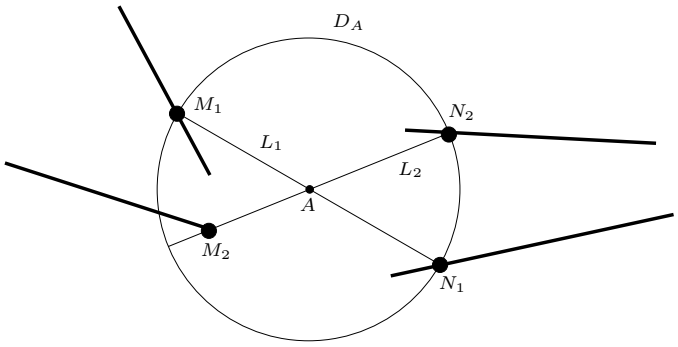

FIG. 5.9. *For the proof of Proposition* 5.2.

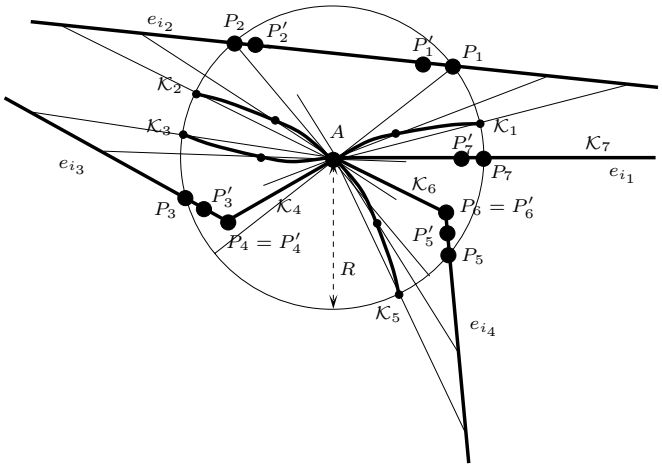

FIG. 5.10. *Relevant* 2*-contact tracings* $\mathcal{K}_1, \ldots, \mathcal{K}_7$ *ending at* A. $\mathcal{K}_1, \mathcal{K}_2, \mathcal{K}_3$, *and* $\mathcal{K}_5$ *are* 2*-contact tracings of type (corner-ladder, wall-endpoint) (i.e., arcs of conchoid).* $\mathcal{K}_7$ *is a degenerated* 2*-contact tracing of type (corner-ladder, wall-endpoint) (i.e., a line segment).* $\mathcal{K}_4$ *and* $\mathcal{K}_5$ *are* 2*-contact tracings of type (corner-ladder)*^{2} *(i.e., line segments).*

endpoint (the intersections between the relative interiors of the relevant 2-contact tracings are not considered). Notice that, given the set of relevant 2-contact tracings, $\mathcal{G}$ can be easily computed in $O(|\mathcal{A}_e| \log n)$ time. Now, given two vertices of $\partial(\mathcal{F}_e) \cap \mathcal{A}_e$ that are connected along $\partial(\mathcal{F}_e)$ by arcs of $\partial(\mathcal{F}_e)_{stab}$, we want to compute these arcs. For computing these arcs, we cannot simply use the graph $\mathcal{G}$ because the degree of some nodes of $\mathcal{G}$ may be arbitrarily large (see Figure 5.10). We show in the next proposition that we can deduce from $\mathcal{G}$ a graph $\mathcal{G}^*$ such that the degree of each node of $\mathcal{G}^*$ is at most two and that $\mathcal{G}^*$ supports any portion of $\partial(\mathcal{F}_e)$ which is the concatenation of arcs of $\partial(\mathcal{F}_e)_{stab}$.

We consider four hypotheses (H1,...,H4) that obviate the need to consider degenerate cases. They are not essential but substantially simplify the proof of the following proposition. The first three hypotheses are made to ensure that the degree of each vertex of the free space of the ladder is 3.

(H1) The line segments $e_1, \ldots, e_n$ compose the boundary of a set of nondegenerated polygons (i.e., no polygon is reduced to a line segment or to a point).

(H2) The ladder does not admit any 4-contact placement.

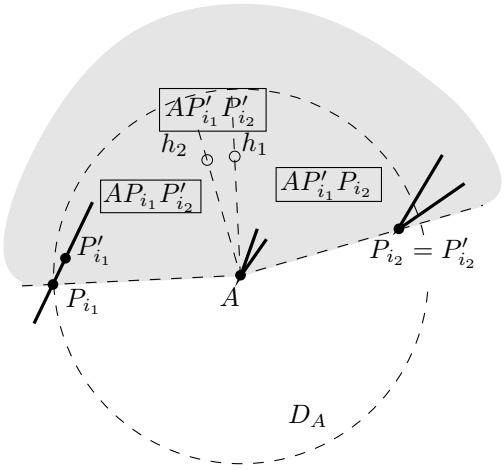

FIG. 5.11. *Wedge $P_{i_1}AP_{i_2}$ is in $\mathcal{F}_e$ near A.*

(H3) The arc (of conchoid) drawn by an endpoint of the ladder when its other endpoint moves along a wall while the ladder remains in contact with a corner is not tangent to any other wall.

(H4) The ladder does not admit any 3-contact placement when its midpoint is located at a corner.

PROPOSITION 5.3. *For any node A of $\mathcal{G}$ of degree k such that $A \notin \mathcal{A}_e$, at most two relevant 2-contact tracings can support $\partial(\mathcal{F}_e)$ in a sufficiently small neighborhood of A. Moreover, we can determine these at most two curves in $O(k \log k)$ time using $O(k)$ space.*

Proof. Let $A \notin \mathcal{A}_e$ be a node of $\mathcal{G}$ of degree k. We assume that $k > 2$, otherwise Proposition 5.3 is trivial. Let $\mathcal{K}_1, \ldots, \mathcal{K}_k$ be the relevant 2-contact tracings that end at A and let $L_i = (A, \phi_i)$ be the placement of the ladder that corresponds to $A \in \mathcal{K}_i$. D_A is the open disk of radius R centered at A. We distinguish two cases whether A is a corner or not.

Case 1. A is a corner. (See Figure 5.10.)

The 2-contact tracing $\mathcal{K}_i$ involves at least another contact than the corner-ladder contact at A. This contact cannot be of type corner-endpoint by (H4). If the contact is of type wall-endpoint, we define P_i as the contact point between this wall and the ladder at placement L_i (see Figure 5.11). Since $A \notin \mathcal{A}_e$, the wall must intersect D_A and we define P'_i as a point close to P_i in that intersection. If the contact is of type corner-ladder, we define $P_i = P'_i$ as the corner (distinct from A) involved in this contact (notice that $P_i = P'_i \in D_A$ by (H4)).

Fact. For all $i \neq j$, $\phi_i \neq \phi_j$.

Otherwise, $L_i = L_j$ is a 3-contact placement contradicting (H4).

Fact. A is a nonflat vertex of CH$(A, P_1, \ldots, P_k)$ or belongs to the interior of $\mathcal{F}_e$.

Assume that $A \in \partial(\mathcal{F}_e)$. Then A lies on the boundary of CH$(A, P_1, \ldots, P_k)$ because otherwise the P'_i provides footholds such that the spider robot can move in a neighborhood of A. Furthermore, A must be a nonflat vertex of CH$(A, P_1, \ldots, P_k)$ by (H4).

Assume now that $A \in \partial(\mathcal{F}_e)$, and let P_{i_1} and P_{i_2} be the two vertices of CH$(A, P_1, \ldots, P_k)$ such that P_{i_1}, A, and P_{i_2} are consecutive along the boundary of CH$(A,$

$P_1, \ldots, P_k$) (see Figure 5.11). We will exhibit a stable placement for the spider robot at any position P inside the intersection of the wedge $P_{i_1}AP_{i_2}$ and a neighborhood of A. Let h_1 and h_2 be two points in the wedge $P_{i_1}AP_{i_2}$ such that the wedges $P_{i_1}Ah_1$ and $h_2AP_{i_2}$ are right (see Figure 5.11).

— If P is in the wedge $P_{i_1}Ah_2$ and is close enough to A, the footholds A, P_{i_1}, and P'_{i_2} yield a stable placement for the spider robot.

— If P is in the wedge h_2Ah_1 and is close enough to A, the footholds A, P'_{i_1}, and P'_{i_2} yield a stable placement for the spider robot.

— If P is in the wedge $h_1AP_{i_1}$ and is close enough to A, the footholds A, P'_{i_1}, and P_{i_2} yield a stable placement for the spider robot.

Fact. $\mathcal{K}_i$, $i \notin \{i_1, i_2\}$, *cannot support an edge of* $\partial(\mathcal{F}_e)$ *incident to* A.

We assume that $A \in \partial(\mathcal{F}_e)$, because otherwise the claim is obvious. It follows that A is a nonflat vertex of $\mathrm{CH}(A, P_1, \ldots, P_k)$. A 2-contact tracing $\mathcal{K}_i$, $i \notin \{i_1, i_2\}$ cannot be an arc of ellipse, because otherwise L_i is a 3-contact placement (because A is a corner here) contradicting (H4). Then, $\mathcal{K}_i$ can be either the segment AP_i or an arc of conchoid. If $\mathcal{K}_i$ is an arc of conchoid, then, by the general properties of conchoids (see [5]), $\mathcal{K}_i$ is tangent to the segment AP_i at A. Thus, $\mathcal{K}_i$ is always tangent to the segment AP_i at A. The point P_i strictly belongs to the wedge $P_{i_1}AP_{i_2}$, because we have shown that $\phi_i \notin \{\phi_{i_1}, \phi_{i_2}\}$. Thus, in a neighborhood of A, $\mathcal{K}_i$ is strictly inside the wedge $P_{i_1}AP_{i_2}$ and thus strictly inside $\mathcal{F}_e$. Therefore, $\mathcal{K}_i$ cannot support $\partial(\mathcal{F}_e)$ in a neighborhood of A.

Hence, by sorting the P_i by their polar angles around A, we can determine, in $O(k \log k)$ time, if A is a nonflat vertex of $\mathrm{CH}(A, P_1, \ldots, P_k)$ and, if so, determine i_1 and i_2. If A is a nonflat vertex of $\mathrm{CH}(A, P_1, \ldots, P_k)$, then only $\mathcal{K}_{i_1}$ and $\mathcal{K}_{i_2}$ can support an edge of $\partial(\mathcal{F}_e)$ incident to A. Otherwise, A belongs to the interior of $\mathcal{F}_e$ and none of the 2-contact tracings $\mathcal{K}_1, \ldots, \mathcal{K}_k$ can support an edge of $\partial(\mathcal{F}_e)$ incident to A.

Case 2. A is not a corner.

Fact. If there exists $i \neq j$ *such that* $\phi_i \neq \phi_j$, *then* A *belongs to the interior of* $\mathcal{F}_e$.

For each relevant 2-contact placement $L_i = (A, \phi_i)$, there exists two contact points M_i and N_i on each side of A at distance less than or equal to R. Since A is not a corner, neither M_i nor N_i is equal to A, thus A belongs to the relative interior of the segment M_iN_i. When $\phi_i \neq \phi_j$, it follows that A belongs to the interior of the polygon $(M_iM_jN_iN_j)$ (see Figure 5.9). Similarly as in the proof of Proposition 5.2, since $A \notin \mathcal{A}_e$, there exist four footholds M'_i, N'_i, M'_j, N'_j in D_A and in some neighborhoods of M_i, N_i, M_j, N_j, respectively, such that A belongs to the interior of the polygon $(M'_iM'_jN'_iN'_j)$. Thus, A belongs to the interior of $\mathcal{F}_e$.

Hence, if there exists $i \neq j$ such that $\phi_i \neq \phi_j$, none of the 2-contact tracings $\mathcal{K}_1, \ldots, \mathcal{K}_k$ can support an edge of $\partial(\mathcal{F}_e)$ incident to A. We now assume that $\phi_i = \phi_j$ $\forall i, j$.

Fact. There are at most six 2*-contact tracings incident to* A.

The general position hypothesis (H2) forbids k-contacts for $k > 3$; thus A corresponds to a 3-contact placement. The three possible choices of two contacts among three give three 2-contact tracing intersecting in A and thus six arcs incident to A.

Fact. There are three 2*-contact tracings incident to* A.

If the 3-contact placement L is of type (corner-endpoint, $\|$), then there are only three 2-contact tracings incident to A that are two circular arcs and one line segment. Otherwise, it comes from the general position hypotheses (H1), (H2), and (H3) (designed to ensure that property) that a 2-contact tracing cannot be valid on both side

of the 3-contact, i.e., on one side of the 3-contact placement, the placements are not free. The proof that the hypotheses ensured that fact is detailed in [5].

Fact. There are two relevant 2*-contact tracings incident to* A.

Since A is not a corner, at the 3-contact placement L, two contact points are on the same side of A. Thus, only two of the three 2-contact tracings incident to A are relevant. □

5.3.4. Construction of Δ. Now consider the graph $\mathcal{G}$ and each node A in turn. If $A \in \mathcal{A}_e$, we disconnect all the edges of $\mathcal{G}$ that end at A. Notice that for each such node A, we know, by Theorem 5.1, whether $A \in \partial(\mathcal{F}_e)$ and, in such a case, the labels of the edges of $\partial(\mathcal{F}_e)$ incident to A. If $A \notin \mathcal{A}_e$, we disconnect the edges ending at A except those (at most two) that may support $\partial(\mathcal{F}_e)$ in a neighborhood of A (see Proposition 5.3). In this way, we obtain a graph $\mathcal{G}^*$ such that the degree of each node is one or two. We consider each connected component of this new graph as a curve. Let Δ be this set of curves. These curves are represented in $\mathcal{G}^*$ as chains (open or closed). Even if a curve is not simple, it follows that there exists a natural order along the curve. Then, according to Propositions 5.2 and 5.3, we get the following theorem.

THEOREM 5.4. *We can compute, in* $O(|\mathcal{A}_e| \log n)$ *time using* $O(|\mathcal{A}_e|)$ *space, a set* Δ *of curves that support the edges of* $\partial(\mathcal{F}_e)$ *corresponding to placements at the limit of stability of the spider robot. Moreover, any portion* $\mathcal{P}$ *of* $\partial(\mathcal{F}_e)$ *either intersects* $\mathcal{A}_e$ *or belongs to a unique curve of* Δ.

5.4. Construction of $\mathcal{F}_e$ and $\mathcal{F}$. We can now construct $\mathcal{F}_e$ and $\mathcal{F}$. Let $\lambda_k(n)$ denote the maximum length of the Davenport–Schinzel sequence of order k on n symbols and $\alpha_k(n) = \lambda_k(n)/n$. Note that $\alpha_3(n) = \alpha(n)$.

THEOREM 5.5. *Given, as foothold regions, a set of* n *nonintersecting straight line segments that satisfies* (H1), (H2), (H3), *and* (H4), *we can compute the free space* $\mathcal{F}_e$ *of the spider robot in* $O(|\mathcal{A}_e|\alpha_8(n) \log n)$ *time using* $O(|\mathcal{A}_e|\alpha_8(n))$ *space.*

Proof. By Theorem 5.1, we can compute the contribution of $\mathcal{A}_e$ to $\partial(\mathcal{F}_e)$ and the label of the edges of $\partial(\mathcal{F}_e)$ incident to them in $O(|\mathcal{A}_e|\alpha_7(n) \log n)$ time using $O(|\mathcal{A}_e|\alpha_8(n))$ space. By Theorem 5.4, we can compute, in $O(|\mathcal{A}_e| \log n)$ time using $O(|\mathcal{A}_e|)$ space, a set Δ of curves that support the edges of $\partial(\mathcal{F}_e)$ that do not belong to $\mathcal{A}_e$. Moreover, any portion $\mathcal{P}$ of $\partial(\mathcal{F}_e)$ such that $\mathcal{P} \cap \mathcal{A}_e = \emptyset$ belongs to a unique curve of Δ. Thus, by sorting all the vertices of $\partial(\mathcal{F}_e) \cap \mathcal{A}_e \cap \Delta$ on the relevant curves of Δ, we obtain all the edges of $\partial(\mathcal{F}_e)$ that belong to a connected component of $\partial(\mathcal{F}_e)$ intersecting $\mathcal{A}_e$. Indeed, for each vertex $A \in \partial(\mathcal{F}_e) \cap \mathcal{A}_e \cap \Delta$, we know, in a neighborhood of A, the portion of the curve of Δ that belongs to $\partial(\mathcal{F}_e)$ because we can simply determine, for each edge, a side of the edge that belongs to $\mathcal{F}_e$. (The contact points corresponding to the edges determine a side that necessarily belongs to $\mathcal{F}_e$.)[4] Then it is an easy task to deduce all the connected components of $\partial(\mathcal{F}_e)$ that intersect $\mathcal{A}_e$.

It remains to compute the connected components of $\partial(\mathcal{F}_e)$ that do not intersect $\mathcal{A}_e$. Each of these components must be a closed curve of Δ. Moreover, all the curves of Δ belong to $\mathcal{F}_e$. Thus, according to Theorem 5.4, any closed curve $\mathcal{K}$ of Δ that does not intersect $\mathcal{A}_e$ is either a connected component of $\partial(\mathcal{F}_e)$ or is strictly included in $\mathcal{F}_e$. Therefore, by considering, in addition, all the closed curves of Δ that do not intersect $\mathcal{A}_e$, we finally obtain a set Ψ of closed curves that contains $\partial(\mathcal{F}_e)$ such that any curve of Ψ is either a connected component of $\partial(\mathcal{F}_e)$ or is strictly included in $\mathcal{F}_e$.

[4] Observe that when the edge belongs to $\mathcal{F}_e$, its two sides belong to $\mathcal{F}_e$.

At last, as we can simply determine, for each curve of Ψ, a side of the edge that belongs to $\mathcal{F}_e$, we can easily deduce from Ψ the free space $\mathcal{F}_e$. That concludes the proof since all these computations can be done in $O(|\mathcal{A}_e|\alpha_8(n)\log n)$ time using $O(|\mathcal{A}_e|\alpha_8(n))$ space. □

As we said at the beginning of section 5, the free space of the spider robot using as foothold regions a set of polygonal regions is obtained by adding these polygonal regions to $\mathcal{F}_e$. This does not increase the geometric complexity of the free space the complexity of the computation. Thus, we get the following theorem.

THEOREM 5.6. *Given a set of pairwise disjoint polygonal foothold regions with n edges in total that satisfies* (H1), (H2), (H3), *and* (H4), *we can compute the free space $\mathcal{F}$ of the spider robot in $O(|\mathcal{A}_e|\alpha_8(n)\log n)$ time using $O(|\mathcal{A}_e|\alpha_8(n))$ space.*

The function $\alpha_8(n)$ is extremely slowly growing and can be considered as a small constant in practical situations. This result is almost optimal since, as shown in [2], $\Omega(|\mathcal{A}_e|)$ is a lower bound for the size of $\mathcal{F}$.

6. Conclusion. We have seen in Theorem 4.12 that, when the foothold regions are n points in the plane, the free space of the spider robot can be computed in $O(|\mathcal{A}|\log n)$ time using $O(|\mathcal{A}|\alpha(n))$ space, where $\alpha(n)$ is the pseudo inverse of Ackerman's function and $\mathcal{A}$ the arrangement of the n circles of radius R centered at the footholds. By [2] the size of $\mathcal{F}$ is known to be $\Theta(|\mathcal{A}|)$. The size of $\mathcal{A}$ is $O(n^2)$ but it has been shown in [15] that $|\mathcal{A}| = O(kn)$, where k denotes the maximum number of disks of radius R centered at the footholds that can cover a point of the plane. Thus, in case of sparse footholds, the sizes of $\mathcal{A}$ and $\mathcal{F}$ are linearly related to the number of footholds.

When the foothold regions are polygons with n edges in total, the free space of the spider robot can be computed in $O(|\mathcal{A}_e|\alpha_8(n)\log n)$ time using $O(|\mathcal{A}_e|\alpha_8(n))$ space, where $n\alpha_k(n) = \lambda_k(n)$ is the maximum length of a Davenport–Schinzel sequence of order k on n symbols, and $\mathcal{A}_e$ is the arrangement of the n curves consisting of the points lying at distance R from the straight line edges. Note that the size of $\mathcal{A}_e$ is $O(n^2)$.

It should be observed that, in the case of point footholds, our algorithm implies that $O(|\mathcal{A}|\alpha(n))$ is an upper bound for $|\mathcal{F}|$. However, this bound is not tight since $|\mathcal{F}| = \Theta(|\mathcal{A}|)$ [2]. In the case of polygonal footholds, our analysis implies that $O(|\mathcal{A}_e|\alpha_8(n))$ is an upper bound for $|\mathcal{F}|$. We leave as an open problem to close the (small) gap between this upper bound and the $\Omega(|\mathcal{A}_e|)$ lower bound.

Once the free space $\mathcal{F}$ is known, several questions can be answered. In particular, given two points in the same connected component of $\mathcal{F}$, the algorithm in [2] computes a motion of the spider robot, i.e., a motion of the body and a corresponding sequence of legs assignments that allows the robot to move from one point to the other.

The motion planning problem for other types of legged robots remains to be studied. The case where all the legs are not attached at the same point on a polygonal/polyhedral body is particularly relevant. A spider robot for which all the legs are not of the same length is also an interesting model.

Acknowledgment. We would like to thank Joseph O'Rourke for helpful comments.

TIGHT FAULT LOCALITY*

SHAY KUTTEN† AND DAVID PELEG‡

Abstract. This paper lays a theoretical foundation for scaling fault tolerant tasks to large and diversified networks such as the Internet. In such networks, there are always parts of the network that fail. On the other hand, various subtasks interest only parts of the network, and it is desirable that those parts, if nonfaulty, do not suffer from faults in other parts. Our approach is to refine the previously suggested notion of fault local algorithms (that was best suited for global tasks) for which the complexity of recovering was proportional to the number of faults. We refine this notion by introducing the concept of *tight fault locality* to deal with problems whose complexity (in the absence of faults) is sublinear in the size of the network. For a problem whose time complexity on an n-node network is $T(n)$ (where possibly $T(n) = o(n)$), a tightly fault local algorithm recovers a legal global state in $O(T(x))$ time when the (unknown) number of faults is x.

This concept is illustrated by presenting a general transformation for maximal independent set (MIS) algorithms to make them tightly fault local. In particular, our transformation yields an $O(\log x)$ randomized mending algorithm and an $\exp(O(\sqrt{\log x}))$ deterministic mending algorithm for MIS. The methods used in the transformation may be of interest by themselves.

1. Introduction.

1.1. The problem. Many parallel models assume that information can be collected from all processors quickly. In real computer networks, however, communication is local; hence it takes at least diameter time to collect all information, leading to *global* (i.e., linear in the number of nodes) running times on worst-case topologies. Consequently, Linial and others (cf. [L92, AGLP]) promoted the notion of *local* algorithms, namely, algorithms that require the collection of data only from small neighborhoods. We refer to these algorithms also as *sublinear*, since their running time is sublinear in the diameter (or the number of nodes).

The use of sublinear or local algorithms is becoming more and more essential in order for solutions to scale to the emerging huge networks of today, e.g., the Internet. However, one striking characteristic of the research on distributed fault tolerance is that usually faults are corrected *globally*, i.e., by algorithms involving the entire system. In other cases, the running time of the correction algorithm is the same as that of the algorithm for recomputing the function from scratch (cf. [ACS94, AGLP]). Fast and local fault correction is the topic of the current paper.

We first describe the types of faults dealt with in this paper. The global state of a distributed system can be represented as a vector whose components are the local

states of the various nodes of the system. A transient fault in one node may change the node's state to some other local state that still looks legal. However, the global state may no longer be legal. Intensive research efforts were invested in dealing with this situation and bringing the system to a correct legal state. A common methodology is based on separating the task into two distinct subtasks, *detection* and *correction*. In this paper we concentrate on the development of fault-local variants for the correction phase.

The study of fault-local algorithms was initiated in [KP95], where the following basic question was raised. Consider a problem Π on graphs, whose solutions are representable as a function $\mathcal{V}$ from the inputs of the network vertices to their outputs. The set of legal solutions of Π on a given graph G is denoted by $\Pi(G)$. Consider a distributed network, whose nodes collectively store the representation of some solution $\mathcal{V} \in \Pi(G)$ of the problem Π on graph G. Suppose that at time t_0, the memory content stored at some subset F of the network nodes is distorted due to some transient failures. As a result, while the stored values still look locally legal, the global representation of $\mathcal{V}$ has changed into some inconsistent function $\mathcal{V}'$ that is no longer valid.

It is clear that, if the problem Π is computable, then investing sufficient computational efforts it is possible to *mend* the function, namely, change the values at some of (or all) the nodes and reconstruct a valid representation of a (possibly different) solution of the same type, $\mathcal{V}' \in \Pi(G)$. The question raised in [KP95] was whether it is possible to take advantage of the relative rarity of faults and distributively mend the function in time complexity dependent on the number of *failed nodes*, $|F|$, rather than on the size of the entire network, n. This operation (if and when possible) was termed *fault-local mending*. The problem Π is *fault locally T-mendable* if, following the occurrence of faults in a set F of nodes, the solution can be mended in $O(T(|F|))$ time. A problem Π is *fault-locally mendable* if there exists some complexity function T such that Π is fault-locally T-mendable.

Note, though, that this definition of [KP95] makes no special requirements of the function T. For example, an easy-to-solve problem Π (say, solvable from scratch by an algorithm of complexity log-logarithmic in n) may be considered fault-locally mendable if it is fault-locally T-mendable for a highly costly function T (say, doubly exponential in $|F|$).

In [KP95] it is shown that the actual situation is not all that bad for global (linear) functions. First, *every* (computable) problem is fault locally mendable. Moreover, every problem is fault locally $c|F| \log |F|$-mendable for a small constant c. Hence the complexity of mending is close to linear in $|F|$.

Fault-local mending may make a lot of sense *especially* for local functions, since faults are very often of extremely *local* nature and involve only a small number of hosts. (For example, the famous crash of the ARPANET, Internet's former incarnation, was caused by a single node giving all other nodes wrong routing information [R81].) Moreover, systems reliability has been increasing, so the number of faults grows much more slowly than the network sizes, especially in domains (or localities) of the network that employ high security and quality standards.

Yet, the motivating observation of the current paper is that for easy-to-solve (or sublinear) local problems, fault-local mending can still be very bad in the worst case. As our illustrative example, we take Π to be the problem of computing the MIS of the graph. MIS enjoys a randomized logarithmic time algorithm [L86]. Recomputing the MIS from scratch using Luby's algorithm will only take logarithmic time, whereas

the running time of the mending algorithm of [KP95] will be exponentially higher if $|F|$ is large. Hence for such sublinear problems we may hope to be able to do much better, although this may require a more careful definition as well as a more elaborate algorithm.

Toward this goal, we now introduce the new notion of *tight* fault-local mending. If the cost of computing Π from scratch on an n-vertex network is $\Omega(T(n))$ and Π is fault locally T-mendable, then we say that Π is *tightly locally mendable* (or simply *tightly mendable*). If Π is only fault locally $poly(T)$-mendable, then we say that Π is *near-tightly locally mendable*. For randomized algorithms we use analogous terminology. In particular, if $T(n)$ is the complexity of a randomized algorithm for computing Π, then we say that Π is randomly locally T-mendable. The notion of tightness is defined similarly.

We should point out two inherent limitations of any kind of mending, or recovery in general (including, of course, the fault-local approach). First, note that the precise value of the original function $\mathcal{V}$ may not be recoverable, since we do not necessarily know the fault configuration, namely, which nodes suffered faults, or even how many faults occurred. (In fact, it is possible for the faults to change the global state to look precisely as some other legal solution $\mathcal{V}'$, in which case no problem will ever be detected!) Note that this limitation applies, of course, to any kind of correction.

While considered here as a limitation, it should be pointed out that viewed from another angle, our definition of *tight* fault locality implies a property that looks stronger than the one stated. This property can serve as another way to view the difference between fault locality and tight fault locality.

Consider a fault locally T-mendable problem Π. Suppose that we started from a legal solution $\mathcal{V}$ and through failures at a set of nodes F reached an illegal function $\mathcal{V}'$. As discussed above, there is no way for the mending algorithm to know which nodes suffered faults or what the original solution was. It follows that the mending algorithm is forced to mend $\mathcal{V}'$ to the legal solution $\mathcal{V}''$ *closest* to $\mathcal{V}'$; otherwise it might be too costly if $|F|$ were small. This may in fact be cheaper in some cases than returning to the original $\mathcal{V}$. The definition of a "close" solution for tightly fault local algorithm is different (stronger) than previous definitions.

Put more formally, let $d(\mathcal{V}, \mathcal{V}')$ denote the Hamming distance between the two solutions $\mathcal{V}$ and $\mathcal{V}'$, namely, the number of nodes on which they disagree:

$$d(\mathcal{V}, \mathcal{V}') = |\{v \mid \mathcal{V}(v) \neq \mathcal{V}'(v)\}|.$$

For a problem Π, a graph G and a function $\mathcal{V}'$, let $\mathit{diff}(\mathcal{V}', \Pi, G)$ denote the distance of $\mathcal{V}'$ from $\Pi(G)$:

$$\mathit{diff}(\mathcal{V}', \Pi, G) = \min\{d(\mathcal{V}', \mathcal{V}) \mid \mathcal{V} \in \Pi(G)\}.$$

Clearly, if $\mathcal{V}'$ is obtained from $\mathcal{V} \in \Pi(G)$ through failures in a set of nodes F, then $\mathit{diff}(\mathcal{V}', \Pi, G)$ is bounded from above by $|F|$. Our observation implies that the complexity of mending a given faulty solution $\mathcal{V}'$ of Π must thus be $O(T(\mathit{diff}(\mathcal{V}', \Pi, G)))$, even if, in fact, the number of faults $|F|$ is much larger than $O(T(\mathit{diff}(\mathcal{V}', \Pi, G)))$. This is due to the fact that we cannot eliminate the possibility that indeed $\mathcal{V}''$ was the original solution, rather than $\mathcal{V}$, so we must assume the case that allows us the smallest cost for correction. Note that this does not always imply that the number of nodes whose state can be changed by the mending algorithm is $O(T(\mathit{diff}(\mathcal{V}', \Pi, G)))$, since changing the states of a large number of nodes may not take a large amount of time, e.g., in the case that they are "packed" in a small neighborhood.

Considered from this point of view, our tightly fault-local mending techniques can be thought of as facilitating an approach defined formally and promoted in [DH95] as a basic goal of any algorithm for adjusting to topological changes and faults. That paper suggests the idea that the recovery algorithm should bring the system from its currently faulty global state to a "closest" global state. However, the definition of closeness in [DH95] is somewhat different; they count the *number* of nodes by which the states differ, rather than the *complexity* (as a function of that number) of reaching from one state to the other. Note also that achieving the goal of [DH95] does not imply a fault-local algorithm and thus, of course, it does not imply a tightly fault-local algorithm. For example, the algorithm presented there for achieving closeness performs a global computation even in response to a single change and is thus *not* fault local.

The second inherent limitation of fault-local mending has to do with the specific representation of the solution function $\mathcal{V}$ in the network. A crucial observation is that if the function is represented *minimally*, then fault-local mending may be impossible (see [KP95]). Hence any solution approach must be based on making use of additional data structures at the various nodes, typically storing information about the local states of their neighbors. It should be clear that the use of such data structures does not by itself suffice to solve the problem. In fact, it may increase its complexity, since any additional data stored at the nodes of the system is just as prone to erasure or distortion due to faults as is the basic data.

1.2. Contributions. In this paper, we define the concept of *tight fault locality* to better capture the desired performance of a mending algorithm for sublinear functions. We focus mainly on the MIS problem and examine its fault-locality properties. An MIS of G is a maximal set $M \subseteq V$ of nodes such that no two nodes in M are neighbors. This is a degenerate case of an input/output function, which has no input. That is, a solution $\mathcal{V}$ is actually a Boolean function of the vertices whose value is $\mathcal{V}(v) = 1$ if v belongs to the MIS, and 0 otherwise, and given a graph G, the set of legal solutions $MIS(G)$ contains precisely those functions $\mathcal{V}$ that represent an MIS of G. Transient faults may change some 0's to 1's (such that the resulting set $\mathcal{V}'$ is no longer independent) and some 1's to 0's (such that the resulting set is no longer maximal).

The MIS problem has been intensively studied before in the context of understanding the nature of sublinear distributed algorithms. A number of sublinear algorithms exist for it, and hence it is a natural candidate for demonstrating the concepts and transformation technique presented in this paper. Moreover, MIS is of special interest in the context of fault-local mending due to the fact that it is used as a paradigm for several purposes in a distributed system. One example is for scheduling access to nearby resources [L80] (a generalization of the drinking philosophers problem [CM84]), e.g., a communication channel. It models a setting in which whenever one node accesses a resource, its neighbors are prevented from using that resource.

Our results concerning MIS are the following. We present a generic mending algorithm for MIS, named $Mend$. This algorithm employs an MIS construction procedure P as a subroutine, and we denote the resulting algorithm by $Mend[P]$. The properties of this algorithm depend on the particular procedure chosen. First, employing the randomized algorithm of [L86], MIS_L, as our MIS procedure, we demonstrate that the MIS problem is randomly locally $\log|F|$-mendable. That is, if only $|F|$ faults occurred, then the expected running time of the randomized mending algorithm, $T_{Mend[L]}$, is only $O(\log|F|)$ rather than $O(\log n)$. Thus the (randomized expected) complexity of

locally mending MIS is as good as that of the best (randomized expected) algorithm known for distributively computing MIS from scratch.

Since we have no nontrivial lower bound on the (randomized or deterministic) complexity of distributed MIS, the above result serves only to show that MIS is randomly *near*-tightly locally mendable. Actually, we show a more general result, namely, that the existence of any randomized MIS algorithm whose time complexity is a "reasonably nice" function T (to be defined precisely later) implies that MIS is randomly locally T-mendable. This implies, in particular, that if the true randomized complexity of MIS is such a nice function, then MIS is randomly tightly locally mendable.

As for deterministic mending we show similar results. Specifically, relying on the deterministic algorithm of [PS92], MIS_{PS}, as our MIS procedure, we show that MIS is fault locally $2^{O(\sqrt{\log |F|})}$-mendable; i.e., the expected running time of the mending algorithm with this procedure, $Mend[PS]$, is $T_{Mend[PS]} = 2^{O(\sqrt{\log |F|})}$. Again, we show a general result stating that the existence of any deterministic MIS algorithm with "reasonably nice" time complexity T implies that MIS is fault locally $poly(T)$-mendable. This implies, in particular, that if the true deterministic complexity of MIS is such a nice function, then MIS is near-tightly locally mendable.

The methods proposed here for mending MIS can be applied also for obtaining near-tight mending algorithms for a number of other problems, such as coloring and scheduling problems.

Note that the results listed above establish with certainty only the existence of *near*-tightly locally mendable problems. (Of course, problems that can be checked and computed in $O(1)$ time are trivially tightly mendable. Such problems are presented in [NS93].)

1.3. Related work. The problem of distributed fault correction has been the subject of much research in the area of *dynamic networks*, where the most common type of faults is the crash of a communication link. An approach with mostly theoretical appeal was to run a global "reset" protocol that enables restarting the computation from scratch [F79, AAG87]. Another approach, more common in practice, is to disseminate every piece of local information globally, so that any global function (e.g., routing) can be corrected (when faults or changes occur) by every node, simply by computing the new value from the known global information [MRR80, CGKK95]. Note that in both approaches, every node must participate in the modification process for every topological change, e.g., the addition or the crash of a single node; hence their worst-case complexity is not very attractive. However, when the number of changes is small, the update approach may lead to considerable savings in communication for many problems, since most of the information does not need to be redistributed. It is argued [ACK90] that the reset approach can be avoided, since other approaches can be made more efficient even in the worst case.

In [ACK90], a spanning tree is maintained rather than recomputed. When a tree edge fails, the algorithm replaces it by a single other tree edge (if possible), keeping the rest of the tree intact. This property is called there *path preservation*, and it is argued that it keeps the routing on the tree intact for every route that does not use the failed edge. Similar examples appear in [CP87, CK85, NS93, MNS95, DH95]. In [DH95] this idea was generalized and formalized as a requirement that an illegal global state is corrected to a global state that is the "closest." A general global algorithm (*superstabilization*) is presented there to perform this task for any problem if the number of detectable faults is precisely 1. This correctness notion, however,

is not related to complexity: the *superstabilizing* general algorithm given therein has an $\Omega(diameter)$ running time even when only one fault occurs (hence it is not fault local). Thus, the intuition captured by [DH95] may prove a good generalization for the *path preservation* (i.e., formalizing the intuitive notion of small disruption), and fault locality formalizes another intuitive notion—that of efficiency. On the other hand, the definition of *tight fault locality*, introduced in the current paper, attempts to capture both of these intuitive notions.

All of the previous approaches mentioned above are more suitable for global (linear) problems; and even for those problems they (with the exception of the fault local approach of [KP95]) consume at least $\Omega(diameter)$ time, even for a small number of faults. This means that even one fault can cause a global computation. Moreover, these approaches (especially reset) are mainly suitable for a distributed system that cannot produce "useful work" when some of its nodes suffer a transient fault. A more dynamic solution to the MIS problem, in which the system corrects itself as locally as possible, letting undamaged regions of the system operate as usual in the meantime, appears in [ACS94]. However, the running time of that correction algorithm is the same as that of recomputing the function from scratch. On the other hand, the algorithm in [ACS94] is based on less synchrony assumptions than those used in this paper; in particular, it is not assumed there that all the nodes start the algorithm at the same time or that the network is synchronous.

A generalization of dynamic networks to deal with self-stabilization is proposed in [AKY90]. The reset algorithms in this context (e.g., [AKY90, APV91, AV91, AK93, APVD94]) suffer from the same disadvantages mentioned above. Other models deal with other (sometimes even stronger) types of faults, or try to treat several kinds of faults simultaneously [GP93, DH95]. Other models studied in the literature allow efficient algorithms through imposing various restrictions; e.g., only one fault may occur at a time, or the network is a complete graph, etc.

2. Preliminaries.

2.1. Model and definitions. We model a distributed system as a graph $G = (V, E)$, where V is the set of the system (or network) nodes, $|V| = n$, and E is the set of links. Nodes communicate by sending messages over the links. The network is synchronous; that is, communication proceeds in rounds, where in every round each node receives all the messages sent to it from its neighbors in the previous round, and sends messages to some of its neighbors. Moreover, we assume that all faults occur simultaneously at time t_0. To focus on time complexity, we adopt the model employed in previous studies of locality issues [GPS87, L92], in which message complexity is abstracted away by allowing the transmission of arbitrary size messages in a single time unit. (Our messages are nevertheless not very large.)

We consider the problem of mending an MIS of a given graph G. The MIS is represented distributively by a vector of bits $\mathcal{M} = (\mathcal{M}_{v_1}, \ldots, \mathcal{M}_{v_n})$, with each node v storing its own bit $\mathcal{M}_v$, such that $\mathcal{M}_v = 1$ iff v is in the MIS. Denote by $\mathcal{S}(\mathcal{M}) = \{v \mid \mathcal{M}_v = 1\}$ the set induced by $\mathcal{M}$. Hereafter, we shall occasionally use $\mathcal{M}$ for the MIS $\mathcal{S}(\mathcal{M})$, where the intention is clear from the context.

Our approach allows a more general representation, in which in addition to the output bit $\mathcal{M}_v$ each node v may maintain an additional data structure $\mathcal{D}_v$, which is a function of $\mathcal{M}$ and the particular algorithm. Note that $\mathcal{M}$ is a part of the definition of the problem, whereas different algorithms may use different definitions (and different value ranges) for $\mathcal{D}_v$.

We distinguish two important global states: the one just before the faults and the one just after. Let $\mathcal{M}_v^*$ be the representation of the MIS before the faults, and let $\mathcal{M}_v$ be the current representation of the MIS (after the faults). Likewise, let $\mathcal{D}_v^*$ be the data structure stored at v before the faults, and let $\mathcal{D}_v$ be the current structure stored at v. Thus $\mathcal{M}_v$ and $\mathcal{D}_v$ are the inputs for the mending task. (Clearly, $\mathcal{M}_v^*$ and $\mathcal{D}_v^*$ are not known to v.)

Formally, the set F of faulty nodes and the set H of healthy nodes are defined, respectively, as

$$F = \{v \mid \mathcal{M}_v \neq \mathcal{M}_v^* \text{ or } \mathcal{D}_v \neq \mathcal{D}_v^*\} \quad \text{and} \quad H = \{v \mid \mathcal{M}_v = \mathcal{M}_v^* \text{ and } \mathcal{D}_v = \mathcal{D}_v^*\}.$$

If the resulting set $\mathcal{S}(\mathcal{M})$ is not an MIS on a given graph, then there are two possible types of violations. A node v is said to be *uncovered* if neither v nor any of its neighbors are in $\mathcal{S}(\mathcal{M})$. A node v is said to be *collided* if both v and one of its neighbors are in $\mathcal{S}(\mathcal{M})$.

DEFINITION 2.1. *The* conflict set *of the assignment $\mathcal{M}$, denoted $\mathcal{C}(\mathcal{M})$, is the set of nodes that can detect locally that $\mathcal{S}(\mathcal{M})$ is not a legal MIS, namely, the uncovered nodes and the collided nodes.*

Finally, we need a few definitions concerning the immediate surroundings of sets of nodes. Let $\Gamma_i(v)$ be the set of all nodes whose distance from v in G is less than or equal to i. For a set of nodes W, let $\Gamma_i(W) = \bigcup_{w \in W} \Gamma_i(w)$. The *complement* of a set of nodes $U \subseteq V$ is defined to be

$$Co(U) = V \setminus U.$$

The *i-border* of the set U is defined to be the set of nodes in the i most external layers of U or, formally,

$$Border_i(U) = \Gamma_i(Co(U)) \cap U.$$

$Border_1(U)$ is denoted simply $Border(U)$.

2.2. Utilizing MIS procedures. To date, the precise complexity of distributed MIS is not known. Hence to cast our results in as general a form as we can, we describe our mending algorithm using any distributed MIS procedure as a black box. We are interested in showing that MIS is tightly locally mendable (or at least near-tightly locally mendable). We can prove that subject to the assumption that the complexity of the optimal algorithm is a "reasonably nice" function. To establish that, we show that the existence of any MIS algorithm whose time complexity is a "reasonably nice" function T implies that MIS is fault-locally T-mendable in the randomized case and fault-locally $poly(T)$-mendable in the deterministic case.

More precisely, by a "reasonably nice" complexity function we mean the following. A function $T : N \mapsto N$ is said to be *sublogarithmic* if it is nondecreasing and positive for $n \geq 1$, and in addition it satisfies the following condition:

$$\text{(SL1)} \qquad \forall x, y, \qquad T(xy) \leq T(x) + T(y).$$

The function T is *superlogarithmic* if instead of (SL1), it satisfies

$$\text{(SL2)} \qquad \forall x, y, \qquad T(xy) > T(x) + T(y).$$

Note that the log function is sublogarithmic and, in fact, most complexity functions likely to be used are either sublogarithmic or superlogarithmic. (Our results may

possibly hold also for functions that are neither sublogarithmic nor superlogarithmic, but this is left for further research.)

First consider deterministic MIS procedures. Our definition of "reasonable" complexity allows any deterministic MIS procedure MIS_D whose complexity $T_{MIS_D}(n)$ is either sublogarithmic or superlogarithmic. This applies, in particular, to the currently best known procedure, due to [PS92] (whose complexity is superlogarithmic).

LEMMA 2.2 (see [PS92]). *There exists a deterministic distributed algorithm MIS_{PS} for computing an MIS on an n-vertex graph in time $T_{MIS_{PS}}(n) = 2^{O(\sqrt{\log n})}$.*

(Note that $2^{O(\sqrt{\log n})}$ is asymptotically larger than any polylogarithmic function in n but smaller than n^{ϵ} for any $\epsilon > 0$.)

In our mending algorithm, we invoke an MIS procedure only for a prescribed number of steps τ, on some region G' of the graph, of size n'. If $\tau \geq T_{MIS_D}(n')$, then the procedure will indeed halt with the correct output. If this requirement does not hold, then we assume that the output is arbitrary.

We now turn to randomized MIS procedures. Since the best known randomized MIS algorithm is of expected time complexity $O(\log n)$, we need only consider procedures of sublogarithmic complexity. Consequently, we shall concentrate on randomized Las Vegas type MIS procedures MIS_R whose expected time complexity $T_{MIS_R}(n)$ is sublogarithmic. Relying on Markov's inequality, we will in fact make use of a corresponding Monte Carlo variant of the procedure, $MIS_R(\tau)$, in which the procedure is halted after τ steps. Based on well known techniques, it is easy to show the following properties.

LEMMA 2.3. *Given a randomized Las Vegas MIS procedure MIS_R of expected time complexity $T_{MIS_R}(n)$, there exists a constant $\tilde{c} \geq 1$, such that whenever executing the corresponding Monte Carlo variant $MIS_R(\tau)$ with $\tau \geq \tilde{c} \cdot T_{MIS_R}(n)$, the output is a legal MIS with probability* 3/4.

We point out that our randomized mending algorithm is nevertheless a Las Vegas algorithm. Also, note that again our requirement applies in particular to the currently best known randomized procedure due to [L86].

LEMMA 2.4 (see [L86]). *There exists a randomized distributed algorithm MIS_L for computing an MIS on an n-vertex graph in expected time $T_{MIS_L}(n) = O(\log n)$.*

3. Overview of the solution. A first naive solution one may suggest for the problem of mending an MIS assignment is to have the nodes in the conflict set $\mathcal{C}(\mathcal{M})$ run an MIS protocol, without involving the rest of the nodes of the graph. The problem with this approach is that, even assuming it is possible to efficiently correct $\mathcal{M}$ in such a way,[1] this alone cannot guarantee that the complexity of the mending process is bounded as a function of the number of corrupted nodes, since the conflict set might be much larger than the set of corrupted nodes. Consequently, in our solution every node stores information about its state at neighboring nodes. The obvious difficulty is that the data stored at a node for its neighbors might get corrupted just as easily as its own data. Moreover, simple voting schemes (if the node consults many neighbors) run into difficulties. See [KP95, LPRS93, P96].

We start by presenting a simplified solution for the case that $|F|$ is known in advance. First we describe the local data structures $\mathcal{D}_v$ employed in our solution. In addition to the output bit $\mathcal{M}_v$, each node v will store a bit $\mathcal{D}_v(u) = \mathcal{M}_u$ for each node u whose distance from v in the graph is 2 or less. Formally, $\mathcal{D}_v = \{\mathcal{D}_v(u) \in \{0,1\} \mid u \in \Gamma_2(v)\}$.

[1] It is probably not, since it entails solving the problem of MIS completion, which is NP-Hard.

Given $|F|$, partition the nodes into two sets: a set `Big` consisting of the nodes v whose distance-2 neighborhood $\Gamma_2(v)$ contains more than $2|F|$ nodes, and a set `Small` containing the rest. Each of these sets will be treated separately.

The output of a node v in `Big` is determined by a *majority vote* among its 2-neighbors (including itself), based on the value stored for v in their data structures. If the result of this vote is different than $\mathcal{M}_v$, then v changes its $\mathcal{M}_v$ accordingly. (The reasons for which we look at the distance-2 neighborhood of nodes rather than simply their direct neighborhoods will become clear later.) Note that following this vote the original correct value of $\mathcal{M}^*_v$ for any v in `Big` is recovered.

Now consider all the nodes in `Small`. Some of them may now belong to the conflict set $\mathcal{C}$. Denote this subset by $\hat{C} = \mathcal{C} \cap \texttt{Small}$. Notice that it is not enough to run an MIS algorithm for the nodes in $\hat{C}$ only, since some of them have neighbors in the complement $Co(\hat{C})$, and a combination of an arbitrary new MIS in $\hat{C}$ and the original MIS $\mathcal{M}$ in $Co(\hat{C})$ does not necessarily form a legal MIS. One would thus like to select a special kind of MIS in $\hat{C}$, namely, one that is constrained by the values of the original MIS $\mathcal{M}$ in $Co(\hat{C})$. More specifically, a node v in $\hat{C}$ whose neighbor w in $Co(\hat{C})$ has $\mathcal{M}_w = 1$ is not allowed to output $\mathcal{M}_v = 1$, and likewise, uncovered nodes in $Co(\hat{C})$ may impose a 1 value on their neighbors in $\hat{C}$.

Unfortunately, solving such a constrained MIS even by a sequential algorithm is NP-Hard. To overcome this difficulty, we resort to a more relaxed method of fusing the new MIS constructed for $\hat{C}$ to the existing one on $Co(\hat{C})$. We first employ a procedure that selects a subset L of some of the nodes in $Co(\hat{C})$ that are at distance 1 or 2 from $\hat{C}$. For L produced by this procedure, the original MIS $\mathcal{M}$ restricted to the resulting set $Co(\hat{C} \cup L)$ has the nice property that it is "shielded" from the influence of fusing to it a new MIS assignment on $\hat{C} \cup L$, no matter what MIS values are chosen for $\hat{C} \cup L$. More specifically, consider a node v in $Co(\hat{C} \cup L)$ that borders with $\hat{C} \cup L$. Then in the MIS $\mathcal{M}$ defined on $Co(\hat{C} \cup L)$, the value of v is $\mathcal{M}_v = 0$, and, moreover, v has a neighbor u in $Co(\hat{C} \cup L)$ such that $\mathcal{M}_u = 1$. We say that $\mathcal{M}$ is a *shielded MIS* on $Co(\hat{C} \cup L)$. Therefore, as we now compute a new MIS assignment on $\hat{C} \cup L$, it is easy to see that no matter what this MIS assignment is, its fusing together with $\mathcal{M}$ in $Co(\hat{C} \cup L)$ yields a legal MIS in G.

As for time complexity, the execution time of this protocol is bounded by ensuring that the size of $\hat{C} \cup L$ is $O(|F|)$. (The dependence on the particular MIS procedure used for computing the new MIS assignment on this region is discussed in the next subsection.) For bounding $|L|$, we rely on the fact that L consists of nodes that are in the 2-neighborhood of nodes in $\hat{C}$. This ensures that $|L| = O(|F|)$ as a result of our choice to include in $\hat{C}$ only nodes with small 2-neighborhoods. This is an additional reason for treating nodes with large 2-neighborhoods separately, through direct majority vote.

We now turn to the general case, where it is not assumed that $|F|$ is known. In this case, our algorithm runs in phases, performing a search on the number of faults $|F|$. In phase i it is "guessed" that the number $|F|$ of faults is not larger than some λ_i. The precise definition of λ_i, given later, depends on the complexity of the MIS procedure used and is aimed at preventing the number of phases from appearing as a multiplicative factor in the complexity of the algorithm.

Several things can go wrong when the guess is too small. One minor problem is that since F is larger than guessed (in the first few phases), the size of the conflict set $\mathcal{C}_i$ may also be larger than anticipated; hence, the MIS computation on $\mathcal{C}_i \cup L_i$ may be too long. An easy way to prevent that from happening is to execute the

MIS computation in the i's phase only for the time that would have been needed for this computation had the size of $\mathcal{C}_i$ indeed been λ_i. That is, phase i is run for $O(T_{MIS_R}(\lambda_i))$ time in the randomized case or $O(T_{MIS_D}(\lambda_i))$ in the deterministic case.

A more severe problem is that the computations carried out in the first phases may increase the number of "currently faulty" nodes. That is, denoting by F_i the set of nodes v whose MIS value $\mathcal{M}_v$ at the beginning of the ith phase is different from their original value $\mathcal{M}_v^*$, while $F_1 = F$, the set F_2 is affected by the outcome of phase 1: The assignment of new MIS values to the nodes of the conflict set $\mathcal{C}_1$ in phase 1 may cause many nodes whose original value was correct to erroneously change their value, thus making the set F_2 much larger than F and causing many new conflicts to show up in phase 2 and so on. This is the case even if phase 1 is terminated after the fixed time bound.

The only way to completely wipe out the influence of the previous phase would be to make all participating nodes return to their initial values. Indeed, this operation is applied at nodes that decide at the end of a phase to participate in subsequent phases (using the initial values, saved in variables $\mathcal{M}_v^{sav}$). But applying such a reinitialization operation globally may be highly time consuming, since it may happen that the assignment in the neighborhood of some nodes in the conflict set $\mathcal{C}_i$ is consistent at the end of the phase, and hence these nodes are ready to terminate, while some other nodes observe inconsistencies, implying the necessity of another phase. Therefore, reinitialization of all nodes requires broadcast of a message from the latter nodes to the former, which may be time consuming.

It is therefore necessary to ensure two things: first, that the algorithm is able to detect that the guess was wrong, and, second, that the operations of the algorithm under the wrong guess did not cause "too much damage." We achieve this behavior by attempting to prevent seemingly faulty nodes from participating in the voting process and gaining undue influence. Toward that end, we introduce one additional "screening" step before performing our votes. The idea is that nodes with a suspiciously high number of conflicts with neighbors (where "high" here is relative to the phase) will be "guessed" faulty and consequently will be barred from participating in the voting. It is important to note that despite the possibility of nonvoters, the votes carried at the nodes of `Big` will still require a strict majority, namely, more than half of the entire 2-neighborhood (not just of the voters).

4. MIS completions. Formally, the problem of *relaxed MIS completion* requires us to compute an MIS, given a partial MIS assignment. It is permitted to change any part of the partial MIS assignment, as long as the end result is a legal MIS. Note that the only difference between this problem and the problem of MIS is that the complexity of this problem may be lower, due to the given partial information. We comment that in our specific solution, the only values of the given partial MIS assignment U that may be changed are at the set $Border_2(U)$.

4.1. Shielded MIS, fringed MIS, and shielded kernels. We now describe a distributed procedure Rel_Comp$(G, W, \mathcal{M}, \tau)$ that, given a graph G, a subset W of the vertices, a partial MIS assignment $\mathcal{M}$ on W (possibly with some uncovered nodes on the border of W), and a time bound τ, computes a relaxed completion of $\mathcal{M}$ on the rest of the graph (with minimal penetration to the region of W). The procedure makes use of an MIS procedure, which can be either deterministic or randomized and is applied only for τ steps.

Definition 4.1. *Given a graph $G = (V, E)$, a subset $U \subseteq V$, and an MIS $\mathcal{R}$ on the subgraph induced by U, we say that $\mathcal{R}$ is a* Shielded MIS *for U if it contains no*

1. Initialize U to be W.
2. Let $X = \{v \in \mathit{Border}(U) \mid \mathcal{M}_v = 1\}$, and eliminate the nodes of X from U.
3. Let $Y = \{v \in U \mid v \text{ is uncovered}\}$, and eliminate the nodes of Y from U.
4. Define $\mathcal{R} = \{v \in U \mid \mathcal{M}_v = 1\}$.
5. Output $(\mathcal{R}, U)$.

FIG. 1. *Procedure* SHIELD_MIS$(G, W, \mathcal{M})$.

nodes from Border(U).

DEFINITION 4.2. *Given a graph $G = (V, E)$, a set $W = \{v_1, \ldots, v_k\} \subset V$, and an* independent set *assignment $\mathcal{M} = (\mathcal{M}_{v_1}, \ldots, \mathcal{M}_{v_k})$ on W, we have that the set $\mathcal{S}(\mathcal{M})$ is a* fringed-MIS *of W if it is maximal everywhere except possibly on its border; namely, the only violations that prevent it from being a legal MIS involve nodes v in Border(W) that are uncovered.*

This definition is motivated by the fact that our mending problem leads to situations where some of the MIS was ruined, yet other segments remain intact. These segments now form a fringed-MIS, since although no changes have occurred on these nodes themselves, their border nodes may become uncovered due to changes in their neighbors.

DEFINITION 4.3. *Given a graph $G = (V, E)$ and a subset $W = \{v_1, \ldots, v_k\} \subset V$, a* shielded kernel *for W is a pair of subsets $(\mathcal{R}, U)$ such that*

1. *$\mathcal{R} \subseteq U \subseteq W$,*
2. *U contains (at least) all the internal layers of W up to the last two layers, namely, $W \setminus \mathit{Border}_2(W) \subseteq U$, and*
3. *$\mathcal{R}$ is a shielded MIS for U.*

Figure 1 describes a procedure SHIELD_MIS that, given a graph G, a set of nodes W, and a fringed-MIS $\mathcal{M}$ on W, generates a shielded kernel $(\mathcal{R}, U)$ for W. Figure 2 illustrates the operation of the procedure. (The procedure is sequential; we discuss its distributed implementation later.)

LEMMA 4.4. *Procedure* SHIELD_MIS *provides a shielded MIS for the given problem and requires $O(1)$ time for a distributed implementation.*

Proof. Property 1 in the definition of shielded MIS is guaranteed trivially by the procedure. For property 2, we need to argue that every node that is eliminated from U belongs to the external two layers of W. For the first elimination step, step 2, this is immediate. For the second elimination step, step 3, the claim follows from the fact that $\mathcal{M}$ is a fringed MIS; hence initially it could have uncovered nodes only on its border, and step 2 could introduce new uncovered nodes only in one of the two external layers of W.

It remains to prove property 3. We first argue that $\mathcal{R}$ forms an MIS on U. Since $\mathcal{S}(\mathcal{M})$ is a fringed MIS on W, and no new 1-valued nodes were introduced, there are no collision violations in $\mathcal{R}$. Step 3 directly guarantees that U has no uncovered nodes. Hence $\mathcal{R}$ is an MIS on U.

Finally, we need to argue that $\mathcal{R}$ contains no nodes from U's border. Assume, to the contrary, that $\mathcal{R}$ contains some node v from the border of U. If v was also on the border of W, then it should have been erased from U in step 2. Therefore, necessarily v was an internal node of W and was brought to the border of U due to the elimination of some of its neighbors. But step 2 eliminates only nodes v with $\mathcal{M}_v = 1$, none of which could have been a neighbor of v (since otherwise $\mathcal{M}$ contains a collision), and step 3 eliminates only nodes whose neighbors w in U all have $\mathcal{M}_w = 0$;

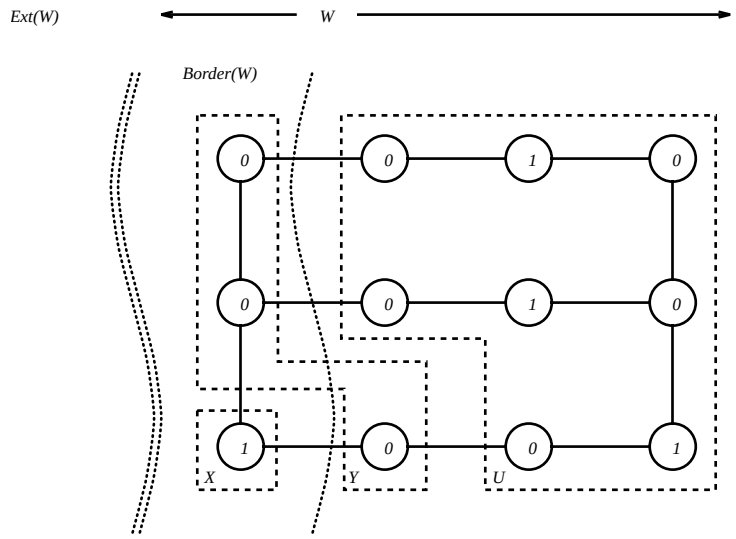

FIG. 2. *The operation of Procedure* SHIELD_MIS *on a set W with a fringed-MIS $\mathcal{M}$. ($\mathcal{M}$ is not an MIS because the upper left corner node is uncovered.)*

1. Applying Procedure SHIELD_MIS$(G, W, \mathcal{M})$, obtain a shielded kernel $(\mathcal{R}, U)$ for W.
2. Let $Q = Co(U)$.
3. Apply an MIS procedure to the subgraph induced by Q for τ steps, and get an MIS $\mathcal{R}'$.
   This can be a deterministic procedure MIS_D or a Monte Carlo type procedure $MIS_R(\tau)$.
4. Output $\mathcal{R} \cup \mathcal{R}'$ as an MIS for the entire graph.

FIG. 3. *Procedure* REL_COMP$(G, W, \mathcal{M}, \tau)$.

hence again none of them could be a neighbor of v, a contradiction. □

4.2. Using shielded MIS for relaxed MIS completion. We now use the procedure given in the previous section for deriving a procedure REL_COMP for relaxed completion of a given fringed MIS. We are given a graph $G = (V, E)$, a subset $W = \{v_1, \ldots, v_k\} \subset V$, and a fringed-MIS assignment $\mathcal{M} = (\mathcal{M}_{v_1}, \ldots, \mathcal{M}_{v_k})$ on W. Procedure REL_COMP is described in Figure 3, and its properties are stated in the following lemma.

LEMMA 4.5.

1. *Procedure* REL_COMP *reassigns MIS values only at the nodes of a set Q restricted to $Co(W) \cup Border_2(W)$.*
2. *If a deterministic MIS procedure MIS_D is used, and the time limit τ satisfies $\tau \geq T_{MIS_D}(|Q|)$, then procedure* REL_COMP *provides a relaxed MIS completion for $\mathcal{M}$.*
3. *If a randomized MIS procedure $MIS_R(\tau)$ is invoked, and the time limit τ satisfies $\tau \geq \tilde{c} \cdot T_{MIS_R}(|Q|)$ (for the constant $\tilde{c}$ of Lemma* 2.3*), then procedure* REL_COMP *provides a relaxed MIS completion with probability* 3/4.

4. *The time complexity of Procedure* Rel_Comp *is* $O(\tau)$.

Proof. The fact that $\mathcal{R}$ is a shielded MIS for U guarantees that it can be combined without conflicts with the MIS $\mathcal{R}'$ computed for the complement of U to yield an MIS for the entire graph. The time complexity of the procedure is composed of that of procedure Shield_MIS, which is $O(1)$, and the time complexity of the MIS procedure on Q, which is limited to τ steps. The bound on the failure probability in the randomized case follows from Lemma 2.3. □

4.3. Distributed implementation. While the description of the procedure Rel_Comp and its subprocedure Shield_MIS is given in "sequential" form, it is clear that both procedures have a straightforward distributed implementation. The only delicate point is that these procedures are to be initiated (as we shall see later) simultaneously not only by the nodes of the set W, but also by some nodes of its complement, $Co(W)$. This does not create any special difficulties, though, since the exact time duration for all the computations is known to all the nodes in the graph. Moreover, these initiators are neighbors of W, and thus the nodes in W which perform the procedure get the initiation messages within a constant time.

5. MIS correction algorithm. We are now ready to describe our mending algorithm for the MIS problem. The algorithm, *Mend*, is given below in Figure 4. The algorithm starts by saving the input values of $\mathcal{M}$ and the data structure $\mathcal{D}$ in variables $\mathcal{M}^{sav}$ and $\mathcal{D}^{sav}$. Let $\mathcal{D}_v^{sav}(v) = \mathcal{M}_v^{sav}$. These input values will be used from time to time throughout the execution. The variables $\mathcal{M}$ and $\mathcal{D}$ will be used for recording the output of the computation. Specifically, whenever a node v selects a new value for its MIS assignment, it stores it in $\mathcal{M}_v$ as well as in $\mathcal{D}_w(v)$ at every node $w \in \Gamma_2(v)$.

The algorithm makes use of a *record inconsistency graph* G_{RI} defined on V, whose edges identify pairs of nodes of which one must be faulty. The edges of this graph are determined on the basis of an inconsistency between the $\mathcal{M}$ value of a node and the recorded value for that node in the data structure stored at a neighbor. Formally, this graph is defined as follows.

Definition 5.1. *The (undirected)* record inconsistency *graph* G_{RI} *consists of the following edges. For every two nodes* $u, w \in V$*, the edge* (u, w) *is included in* G_{RI} *if one of the following conditions holds:*

1. $\mathrm{dist}(u, w) \leq 2$ *and* $\mathcal{M}_u^{sav} \neq \mathcal{D}_w^{sav}(u)$ *or vice versa,*
2. $\mathcal{D}_u^{sav}(x) \neq \mathcal{D}_w^{sav}(x)$ *for some common distance-2 neighbor* x *of* u *and* w *(i.e.,* $x \in \Gamma_2(u) \cap \Gamma_2(w)$*).*

Note that G_{RI} can be constructed distributively in constant time, as each node can find out which other nodes neighbor it in G_{RI}. For every node v, let $\deg_{RI}(v)$ denote v's degree in G_{RI}.

As outlined earlier, the algorithm conducts majority votes to determine the output of some nodes, using their neighbors' data structures. However, a node v with high $\deg_{RI}(v)$ (where "high" here is w.r.t. the current phase) is "guessed" to be faulty and is not allowed to vote. In addition, the algorithm maintains a set `Detected` of nodes that detected a local inconsistency in their own initial output (i.e., every node v such that $\mathcal{M}_v^{sav} = 1$ and $\mathcal{D}_v^{sav}(w) = 1$ for some neighbor w, as well as every node v such that $\mathcal{M}_v^{sav} = 0$ and $\mathcal{D}_v^{sav}(w) = 0$ for every neighbor w). Since the nodes in `Detected` are known to be faulty, they too do not vote.

In each phase i, the algorithm separates nodes with large neighborhoods from ones with small neighborhoods using a threshold λ_i. The sequence $\{\lambda_i\}$ will be fixed

on a global *start* signal **do**

1. **For** every node v, set $\mathcal{M}_v^{sav} \leftarrow \mathcal{M}_v$ and $\mathcal{D}_u^{sav}(v) \leftarrow \mathcal{D}_u(v)$ **for** every $u \in \Gamma_2(v)$.
2. **For** $i = 1$ to J_{max} **do** (* i.e., when $\lambda_i \leq n$ *)
   (a) **For** every node $v \in \mathtt{Big}_i$ that has a collision or uncoverage conflict with some neighbors (with the current $\mathcal{M}$ values), perform a vote on the value of $\mathcal{M}_v$ among the voting nodes in its 2-neighborhood as follows:
      i. **Let** $\mathcal{M}_v \leftarrow 0$ if $|\{w \in \mathtt{Vot}_i(v) \mid \mathcal{D}_w^{sav}(v) = 0\}| > \gamma(v)/2$.
      ii. **Let** $\mathcal{M}_v \leftarrow 1$ if $|\{w \in \mathtt{Vot}_i(v) \mid \mathcal{D}_w^{sav}(v) = 1\}| > \gamma(v)/2$.
      iii. **If** neither of the two votes has the majority (* due to nonvoters *)
      v marks itself and its neighbors in $\mathtt{Vot}_i(v)$ "nonparticipating" (and leaves $\mathcal{M}_v$ unchanged).
   (b) Let $\mathtt{NP}_i$ be the set of nonparticipating nodes.
   (c) **for** every participating node $v \in \mathtt{Small}_i \setminus \mathtt{NP}_i$ **do**:
   If v has a collision with a "participating" neighbor $w \in \mathtt{Big}_i$ (namely, $\mathcal{M}_v = \mathcal{M}_w = 1$), then let $\mathcal{M}_v = \mathcal{M}_v^{sav}$.
   (d) **Let** $\mathcal{C}_i = (\mathcal{C}(\mathcal{M}) \cap \mathtt{Small}_i) \setminus \mathtt{NP}_i$.
   (* Participating nodes that are in $\mathtt{Small}_i$ and in the conflict set induced by the current $\mathcal{M}$. *)
   (e) **If** $\mathcal{C}_i \neq \emptyset$ then the nodes of $\mathcal{C}_i$ **invoke** Procedure REL_COMP$(G, V \setminus \mathcal{C}_i, \mathcal{M}, \tau_i)$ for $\tau_i = T_{MIS_D}(\lambda_{i+3})$ in the deterministic case, and $\tau_i = \tilde{c} \cdot T_{MIS_R}(\lambda_{i+3})$ in the randomized case.
   (f) **for** every node v whose $\mathcal{M}_v$ has changed, **let** $\mathcal{D}_u(v) = \mathcal{M}_v$ **for** every $u \in \Gamma_2(v)$.
3. (* Handling the case that all phases failed. *)
   In the randomized case only: if any conflict still exists then invoke a Las Vegas variant of Algorithm MIS_R.

FIG. 4. *Algorithm Mend.*

later, as a function of the specific MIS procedure used. The only requirement imposed on the choice of this sequence is that it must be *quadratically growing*, namely, satisfy

$$\lambda_{i+1} \geq \lambda_i^2$$

(thus the length of the sequence is smaller than $\log \log n$). This choice also determines the value of J_{max}, the number of phases in the algorithm. (J_{max} is taken to be the first i such that $\lambda_i \geq n$.)

For the algorithm and analysis, we use the following definitions. Let

$$\mathtt{NV}_i = \{v \mid \deg_{RI}(v) > \lambda_i\} \cup \mathtt{Detected} \qquad \text{and} \qquad \mathtt{Vot}_i(v) = \Gamma_2(v) \setminus \mathtt{NV}_i$$

(standing, respectively, for "nonvoting" and "voters"). For every node v, let $\gamma(v) = |\Gamma_2(v)|$. Let

$$\mathtt{Big}_i = \{v \in V \mid \gamma(v) > 2\lambda_i\} \qquad \text{and} \qquad \mathtt{Small}_i = \{v \in V \mid \gamma(v) \leq 2\lambda_i\}.$$

6. Correctness and analysis of the main algorithm. We first describe the general structure of the proof. In Lemma 6.5 (using Lemma 6.4) we show that for a sufficiently large i, phase i computes a valid MIS. However, the complexity depends

on the size of the set F_i of "currently faulty" nodes whose output $\mathcal{M}_v$ at the beginning of phase i is different than the original value $\mathcal{M}_v^*$. Note that these could be either faulty nodes or healthy nodes that erroneously computed a new $\mathcal{M}_v$ during previous phases. In Lemmas 6.1 and 6.2 we show that the number of such nodes F_i in phase i is not much larger than the number of faults F. First, in Lemma 6.1 we show that the number of nodes participating in computing an MIS in phase i is not much larger than the number of (low-degree) nodes in F_i. Then in Lemma 6.2 we show that the number of (low-degree) nodes in F_{i+1} is not much larger than the number of nodes that participated in the MIS in phase i.

LEMMA 6.1. *In any phase i, the set $\mathcal{C}_i$ satisfies $|\mathcal{C}_i| = O(|F| + |F_i \cap \texttt{Small}_i| \cdot \lambda_i)$.*

Proof. Consider a phase i. Partition the set $\mathcal{C}_i$ defined in step 2d into $\mathcal{C}_F = (F \cup F_i) \cap \mathcal{C}_i$ and $\mathcal{C}_H = (H \cap H_i) \cap \mathcal{C}_i$. Clearly, $|\mathcal{C}_F|$ is bounded by $|F| + |F_i \cap \texttt{Small}_i|$, since $\mathcal{C}_i \subseteq \texttt{Small}_i$. It is therefore sufficient to bound $|\mathcal{C}_H|$.

The notion of *accusation* is defined as follows. Each node in conflict must accuse some node. In particular, for every $v \in \mathcal{C}_i$, the set of nodes accused by v, denoted $\texttt{Accuse}(v)$, is $\{w \mid (v,w) \in E, \mathcal{M}_v = \mathcal{M}_w = 1\}$ if v is collided, and $\{w \mid \mathcal{D}_v^{sav}(w) = 1\}$ if v is uncovered.

We now argue that $\emptyset \neq \texttt{Accuse}(v) \subseteq F_i$ for every node $v \in \mathcal{C}_H$. To see that $\texttt{Accuse}(v)$ is nonempty, for an uncovered v, note that since v is in both H and H_i, necessarily $\mathcal{M}_v^* = \mathcal{M}_v^{sav} = \mathcal{M}_v = 0$, and v's records $\mathcal{D}_v^{sav}$ are identical to the original $\mathcal{D}_v^*$. Hence these records must show a neighbor w such that $\mathcal{D}_v^{sav}(w) = 1$; hence $w \in \texttt{Accuse}(v)$. The argument for a collided v is similar. To see that each node w accused by v is in F_i, note that since $v \in H \cap H_i$, $\mathcal{D}_v^{sav}(w)$ agrees with $\mathcal{M}_w^*$, and hence $\mathcal{M}_w \neq \mathcal{M}_w^*$; hence $w \in F_i$.

Consequently, partition the set $\mathcal{C}_H$ into two sets, the set ACC_BIG_i of nodes $v \in \mathcal{C}_H$ that accuse some neighbor $w \in F_i \cap \texttt{Big}_i$, and the set ACC_SMALL_i of nodes $v \in \mathcal{C}_H$ for which $\texttt{Accuse}(v) \subseteq F_i \cap \texttt{Small}_i$. To bound $|\mathcal{C}_H|$, we separately bound $|\text{ACC\_BIG}_i|$ and $|\text{ACC\_SMALL}_i|$.

CLAIM A. $|\text{ACC\_BIG}_i| \leq |F|$.

Proof. Consider a node $v \in \text{ACC\_BIG}_i$, and arbitrarily associate with it one particular node $w_v \in F_i \cap \texttt{Big}_i \cap \texttt{Accuse}(v)$. Observe that w_v cannot be a nonparticipating node, since if $w_v \in \texttt{NP}_i$ then v should have been nonparticipating as well. (See step 2(a)iii in the algorithm.) We use this observation later on to show that w_v has many faulty voting neighbors.

Consider a node $w \in \texttt{Big}_i$. Group the neighbors of w into the following sets. Let $\Gamma^F(w)$ denote the set of 2-neighbors x of w such that $x \in F \setminus \texttt{NV}_i$ and $\mathcal{D}_x^{sav}(w) = \mathcal{M}_w$. Note that $\Gamma^F(w) \subseteq \Gamma_2(w) \cap (F \setminus \texttt{NV}_i)$. Let $\Gamma^{AB}(w)$ denote the nodes $v \in \text{ACC\_BIG}_i$ for which $w = w_v$. Note that by the definition of ACC_BIG and of w, $\Gamma^{AB}(w) \subseteq H$. Let $\gamma^Z(w) = |\Gamma^Z(w)|$ for any appropriate Z.

Since the majority vote carried by w was won by the nodes of $\Gamma^F(w)$, the voting rule used to determine $\mathcal{M}_w$ (step 2(a)), combined with the fact that $w \in \texttt{Big}_i$, imply that

$$\gamma^F(w) > \gamma(w)/2 \geq \lambda_i. \tag{1}$$

Observe that each node of $\Gamma^F(w)$ is connected to each node of $\Gamma^{AB}(w)$ in G_{RI}. This follows from the fact that by the definitions of $\Gamma^F(w)$ and $\Gamma^{AB}(w)$, each node $y \in \Gamma^F(w)$ is at distance 4 or less from each node $z \in \Gamma^{AB}(w)$ (since both y and z are 2-neighbors of w), and in addition, y's record regarding w's bit is erroneous while z's record is correct; hence $\mathcal{D}_y(w) \neq \mathcal{M}_w^* = \mathcal{D}_z(w)$, so y and z are connected by an edge in G_{RI}.

Let $c_F(w)$ denote the number of edges connecting the nodes of $\Gamma^F(w)$ to the nodes of $\Gamma^{AB}(w)$ in G_{RI}. As $c_F(w)$ is bounded (for w to be a voting node), we conclude that not too many nodes can be corrupted, since each corruption "costs" distinct λ_i edges in G_{RI}. More precisely,

$$c_F(w) \geq \gamma^F(w) \cdot \gamma^{AB}(w).$$

Combined with (1), it follows that $c_F(w) \geq \lambda_i \cdot \gamma^{AB}(w)$. Hence

$$\begin{aligned} |\textsc{Acc\_Big}_i| &= \sum_{w \in \mathtt{Big}_i} \gamma^{AB}(w) \;\leq\; \frac{1}{\lambda_i} \sum_{w \in \mathtt{Big}_i} c_F(w) \\ &\leq \frac{1}{\lambda_i} \sum_{x \in F \setminus \mathtt{NV}_i} \deg_{RI}(x) \;\leq\; \frac{1}{\lambda_i} \cdot (\lambda_i \cdot |F \setminus \mathtt{NV}_i|) \;\leq\; |F|. \end{aligned}$$

(The second inequality holds since the sets $\Gamma^{AB}(w)$ are distinct for different w's, and hence the numbers $c_F(w)$ count distinct edges. The third inequality relies on the definition of $\mathtt{NV}$.) □

Claim B. $|\textsc{Acc\_Small}_i| \;\leq\; 2\lambda_i |F_i \cap \mathtt{Small}_i|$.

Proof. By definition of $\textsc{Acc\_Small}_i$, each $v \in \textsc{Acc\_Small}_i$ has a neighbor in $F_i \cap \mathtt{Small}_i$ (namely, the node it accuses). It follows that $\textsc{Acc\_Small}_i \subseteq \Gamma(F_i \cap \mathtt{Small}_i)$. But the neighborhood of every $v \in F_i \cap \mathtt{Small}_i$ is of size $|\Gamma(v)| \leq 2\lambda_i$ by definition of $\mathtt{Small}_i$. Hence

$$|\textsc{Acc\_Small}_i| \;\leq\; |\Gamma(F_i \cap \mathtt{Small}_i)| \;\leq\; 2\lambda_i |F_i \cap \mathtt{Small}_i|. \qquad \square$$

The lemma now follows immediately from Claims A and B. □

Lemma 6.2. *In any phase i, the set F_i satisfies $|F_i \cap \mathtt{Small}_i| = O(|F| \cdot \lambda_{i+1})$, and the set $\mathcal{C}_i$ satisfies $|\mathcal{C}_i| = O(|F| \cdot \lambda_i \cdot \lambda_{i+1})$.*

Proof. The second claim follows from the first claim and the previous lemma as

$$|\mathcal{C}_i| \;\leq\; O(|F| + |F_i \cap \mathtt{Small}_i| \cdot \lambda_i) \;\leq\; O(|F| \cdot \lambda_{i+1} \cdot \lambda_i).$$

The first claim is proved by induction on i. The claim is clear for the beginning of phase $i = 1$. Now assume the claim for phase i and look at the beginning of phase $i + 1$. Nodes enter $F_{i+1} \cap \mathtt{Small}_{i+1}$ (if they are not in F_i) either from $\Gamma_2(\mathcal{C}_i)$ (as a result of performing MIS) or as a result of moving from $\mathtt{Big}_i$ to $\mathtt{Small}_{i+1}$. The first of those sources is bounded by noting that $\mathcal{C}_i \subseteq \mathtt{Small}_i$, so

$$|\Gamma_2(\mathcal{C}_i)| \;\leq\; 2\lambda_i |\mathcal{C}_i| \;\leq\; O(\lambda_i \cdot (|F| \cdot \lambda_{i+1} \cdot \lambda_i)) \;\leq\; O(|F| \cdot \lambda_{i+2}).$$

(The last inequality follows from the assumption that the sequence $\{\lambda_i\}$ is quadratically growing.)

As for the second, note that a node $v \in \mathtt{Big}_i$ that was not participating in the previous phase enters phase $i + 1$ with its initial value $\mathcal{M}_v^{sav}$. (Note that it was a nonparticipating node in all the previous phases.) Hence the number of such nodes joining $F_{i+1} \cap \mathtt{Small}_i$ is bounded by $|F|$. Also, the number of nodes in $F \cap \mathtt{Big}_i$ that join F_{i+1} is also bounded by $|F|$.

It remains to consider nodes $v \in H \cap \mathtt{Big}_i$ that have participated in the previous phase i. For such a node v, getting the wrong value (causing it to enter F_{i+1}) necessitates the influence of at least $\gamma(v)/2$ neighbors from $F \setminus \mathtt{NV}_i$, and thus it incurs a contribution of at least λ_i to $\sum_{x \in F \setminus \mathtt{NV}_i} \deg_{RI}(x)$ in G_{RI}. But the above sum is

bounded from above by $\lambda_i \cdot |F \setminus \mathtt{NV}_i|$. Thus the number of nodes in $\mathtt{Big}_i$ that can be influenced in such a way is bounded by $|F \setminus \mathtt{NV}_i| \leq |F|$. ∎

LEMMA 6.3. *Let i be such that $\lambda_i \geq |F|$. Then $\mathtt{NV}_i$ contains only nodes from F.*

Proof. A node $v \in H$ can be adjacent only to nodes of F in G_{RI}; hence its degree in this graph is at most $\deg_{RI}(v) \leq |F|$. Therefore, $\mathtt{NV}_i$ does not contain it by definition. ∎

LEMMA 6.4. *Let i be such that $\lambda_i \geq |F|$. Then*

(a) *every node w in $\mathtt{Big}_i$ is participating; and*

(b) *the voted value for $\mathcal{M}_w$ equals $\mathcal{M}^*_w$.*

Proof. Such a node w has at least $\gamma(w) \geq 2\lambda_i + 1$ neighbors (including itself), out of which at most λ_i are in F. By the previous lemma, none of its healthy neighbors from H can be in $\mathtt{NV}_i$. Thus, at least $\gamma(v) - \lambda_i > \gamma(v)/2$ do vote for a value for $\mathcal{M}_w$ which is equal to $\mathcal{M}^*_w$. The lemma follows. ∎

LEMMA 6.5. *If $|F| \leq \lambda_i$, then at the end of phase i, if the algorithm uses a deterministic MIS procedure MIS_D then $\mathcal{M}$ is a valid MIS assignment, and if it uses a randomized MIS procedure MIS_R then $\mathcal{M}$ is a valid MIS assignment with probability* 3/4.

Proof. Suppose that $|F| \leq \lambda_i$. By Lemma 6.4 all the nodes in $\mathtt{Big}_i$, as well as their neighbors, are participating nodes. Moreover the nodes in $\mathtt{Big}_i$ start then with their values from $\mathcal{M}^*$. As for the nodes in $\mathtt{Small}_i$, since they all are participating, a valid MIS is reached if Procedure REL_COMP computes a valid MIS.

By Lemma 6.1, the set $\mathcal{C}_i$ of nodes involved in MIS conflicts after step 2(a) of the algorithm satisfies $|\mathcal{C}_i| = O(|F| \cdot \lambda_i \cdot \lambda_{i+1})$. Since $\mathcal{C}_i \subseteq \mathtt{Small}_i$ and $Q \subseteq \Gamma_2(\mathcal{C}_i)$ (where Q is the set defined in step 2 of Procedure REL_COMP, namely, the expansion of the set $\mathcal{C}_i$), it follows that

$$|Q| \leq |\mathcal{C}_i| \cdot 2\lambda_i \leq |F| \cdot 2\lambda_i \cdot \lambda_i \cdot \lambda_{i+1} \leq 2\lambda_i^3 \lambda_{i+1} \leq \lambda_{i+3}.$$

Hence the time required to compute MIS on Q by MIS_D is $T_{MIS_D}(|Q|) \leq T_{MIS_D}(\lambda_{i+3})$, and hence the expected time required to compute MIS on Q by MIS_R is $T_{MIS_R}(|Q|) \leq T_{MIS_R}(\lambda_{i+3})$. Given the choice of time limit prescribed for the ith phase in step 2(e), Lemma 4.5 guarantees that a valid MIS assignment is produced with certainty in the deterministic case, and with probability 3/4 in the randomized case. ∎

We are now ready to give the main results.

LEMMA 6.6. *Given a deterministic distributed procedure MIS_D, if $T_{MIS_D}(n)$ is sublogarithmic or superlogarithmic, then for a suitable choice of the sequence $\{\lambda_i\}$, Algorithm $Mend[MIS_D]$ reaches a legal MIS assignment in time $T_{Mend[MIS_D]} = O(T_{MIS_D}(|F|^c))$ for some constant $c \geq 1$ (with $c = 1$ for the sublogarithmic case).*

Proof. Each of the two cases is handled separately. Consider first the case that $T_{MIS_D}(n)$ is superlogarithmic. Then we fix $\lambda_i = 2^{2^i}$. Note that this choice satisfies the quadratic growth requirement.

Let J be the first phase satisfying $\lambda_J \geq |F|$. By the previous lemma, the algorithm will halt on phase J. The total time consumed by phases 1 through J is bounded by

$$T_{Mend[MIS_D]} \;=\; \sum_{j=1}^{J} T_{MIS_D}(\lambda_{j+3}) \;=\; \sum_{j=1}^{J} T_{MIS_D}\left(2^{2^{j+3}}\right).$$

By the superlogarithmic assumption (SL2),

$$T_{Mend[MIS_D]} \;\leq\; T_{MIS_D}\left(\prod_{j=1}^{J} 2^{2^{j+3}}\right) \;=\; T_{MIS_D}\left(2^{\sum_{j=1}^{J} 2^{j+3}}\right) \;\leq\; T_{MIS_D}\left(2^{2^{J+4}}\right).$$

By the choice of J it follows that $|F| \geq 2^{2^{J-1}}$, and hence

$$T_{Mend[MIS_D]} \leq T_{MIS_D}\left(2^{2^{J-1}\cdot 2^5}\right) \leq T_{MIS_D}(|F|^{32}).$$

Next, consider the case that $T_{MIS_D}(n)$ is sublogarithmic. Then we fix $\lambda_i = T^{-1}_{MIS_D}(2^i)$. This choice satisfies the quadratic growth requirement as well. To show this, we rely on the fact that since T_{MIS_D} is sublogarithmic, its inverse $T \equiv T^{-1}_{MIS_D}$ is *superexponential*; i.e., it satisfies

$$T(x+y) \geq T(x)T(y). \tag{SE}$$

Therefore, $\lambda_{i+1} = f(2^{i+1}) \geq f(2^i)^2 = \lambda_i^2$.

Letting J be the first phase satisfying $\lambda_J \geq |F|$, we have that the total time consumed by the algorithm (that again halts on phase J) is bounded by

$$T_{Mend[MIS_D]} = \sum_{j=1}^{J} T_{MIS_D}(\lambda_{j+3}) = \sum_{j=1}^{J} T_{MIS_D}(T^{-1}_{MIS_D}(2^{j+3})) = \sum_{j=1}^{J} 2^{j+3} \leq 2^{J+4}.$$

By the choice of J it follows that $|F| \geq \lambda_{J-1}$, and hence by choice of λ_i and the fact that T_{MIS_D} is nondecreasing, $T_{MIS_D}(|F|) \geq T_{MIS_D}(\lambda_{J-1}) = 2^{J-1}$. Consequently,

$$T_{Mend[MIS_D]} \leq 32 \cdot 2^{J-1} \leq 32 \cdot T_{MIS_D}(|F|). \qquad \square$$

COROLLARY 6.7. *The MIS problem is fault locally $2^{O(\sqrt{\log |F|})}$-mendable.*

Proof. Use Procedure MIS_{PS} of [PS92] in the mending algorithm. By Lemmas 2.2 and 6.6, Algorithm $Mend[PS]$ mends MIS in time

$$T_{Mend[PS]} = O(T_{MIS_{PS}}(|F|^c)) = O(2^{\sqrt{\alpha \log |F|^c}}) = 2^{O(\sqrt{\log |F|})}$$

(using constant c from Lemma 6.6 and for some constant α). $\square$

COROLLARY 6.8. *Let the time complexity of the MIS problem be $T^*_D(n)$. If $T^*_D(n)$ is sublogarithmic, then MIS is tightly locally mendable. If $T^*_D(n)$ is superlogarithmic, then MIS is near-tightly locally mendable.* $\square$

LEMMA 6.9. *Given a randomized distributed procedure MIS_R, if $T_{MIS_R}(n)$ is sublogarithmic, then for a suitable choice of the sequence $\{\lambda_i\}$, Algorithm $Mend[MIS_R]$ reaches a legal MIS assignment in expected time $O(T_{MIS_R}(|F|))$.*

Proof. As in the sublogarithmic case of Lemma 6.6, we fix $\lambda_i = T^{-1}_{MIS_R}(2^i)$. Letting J be the first phase satisfying $\lambda_J \geq |F|$, we have that the time consumed by the first J phases is bounded in the same way as in that proof, yielding a bound of

$$T_1 \leq 32\tilde{c} \cdot T_{MIS_R}(|F|).$$

By Lemma 6.5, the algorithm will halt on any phase $i \geq J$ with probability $3/4$. Hence the algorithm will reach the execution of phase $J+k$ with probability $1/4^k$. The total expected time consumed by phases $J+1$ and on is therefore bounded by

$$T_2 = \sum_{k>0} \frac{1}{4^k} \cdot \tilde{c} \cdot T_{MIS_R}(\lambda_{J+k+3}) = \sum_{k>0} \frac{1}{4^k} \cdot \tilde{c} \cdot 2^{J+k+3} = \tilde{c} \cdot 2^{J+3} \sum_{k>0} \frac{1}{4^k} \cdot 2^k \leq \tilde{c} \cdot 2^{J+3}.$$

Again, by the choice of J it follows that $|F| \geq \lambda_{J-1}$, and hence by choice of λ_i and the fact that T_{MIS_R} is nondecreasing, $T_{MIS_R}(|F|) \geq T_{MIS_R}(\lambda_{J-1}) = 2^{J-1}$. Consequently,

$$T_2 \leq 16\tilde{c} \cdot 2^{J-1} \leq 16\tilde{c} \cdot T_{MIS_R}(|F|).$$

Finally, the algorithm will get to the final step of executing the Las Vegas procedure MIS_R only if all phases failed. This will happen with probability $1/4^k$ for $k = J_{max} - J$, and in that case, the algorithm will require an additional time $T_{MIS_R}(n)$; hence the contribution of this step to the expected time complexity is

$$T_3 \leq \frac{1}{4^k} \cdot T_{MIS_R}(n) \leq \frac{1}{4^k} \cdot T_{MIS_R}(\lambda_{J_{max}}) \leq \frac{1}{4^k} \cdot 2^{J_{max}} = \frac{2^J}{2^k} \leq \frac{T_{MIS_R}(|F|)}{2^{k-1}}.$$

Overall, the expected time complexity of the algorithm is bounded by

$$T_{Mend[MIS_R]} = T_1 + T_2 + T_3 = O(T_{MIS_R}(|F|))$$

as required. □

COROLLARY 6.10. *The MIS problem is randomly locally* $\log |F|$*-mendable.*

Proof. Use Procedure MIS_L of [L86] in the mending algorithm. By Lemmas 2.4 and 6.9, Algorithm $Mend[L]$ mends MIS in time $T_{Mend[L]} = O(T_{MIS_L}(|F|)) = O(\log |F|)$. □

COROLLARY 6.11. *Let the randomized expected time complexity of the MIS problem be* $T^*_R(n)$*. If* $T^*_R(n)$ *is sublogarithmic,*[2] *then MIS is randomly tightly locally mendable.* □

Space and communication complexity. The dominating factor in the size of the storage required is the data structure $\mathcal{D}_v(u) = \mathcal{M}_u$, storing, at each node v, a bit for each node u whose distance from v in the graph is 2 or less. This storage requirement decreases with the decreased density of the graph. In the worst case it implies $O(n)$ bits per node. The dominating factor in the communication is the voting according to $\mathcal{D}_v(u)$, where, in the worst case, each node may receive a vote from every other node. Every vote travels at most over two edges, leading to a total bit communication complexity of $O(n^2)$.

7. Discussion.

7.1. Distributed termination of the algorithm. Lemmas 6.6 and 6.9 discuss the time until a legal MIS assignment is reached. It may seem as if even after reaching a legal state, nodes still need to test in subsequent phases that they are not in conflict. Even if this had been the case, we would still consider it a reasonable requirement, since in many contexts one needs to address the problem of *fault detection* and not just fault *correction*. For instance, in the approach of self-stabilization, correction is said to have been achieved once a legal state is reached, yet all nodes must continue to periodically test the legality of their state.

Still, for completeness, we mention that our algorithm can be implemented in such a way that nodes that do not detect a conflict at the end of some phase and do not need to take any further steps in the algorithm, unless notified of conflicts by other nodes which are still active. Thus if the nodes which take steps at some phase i are not in any conflict, and have no neighbors in any conflict, at the end of phase i, then no node will take steps in any phase larger than i. (One should not confuse the action of taking steps, though, with the status of "nonparticipating" determined in step 2(a)iii in the algorithm; "nonparticipating" nodes nevertheless took some steps to determine that they are "nonparticipating.")

The required modification to the algorithm is described and analyzed in detail in [KP94].

[2] Recall that it is at most logarithmic.

7.2. Summary and open problems. The results presented in this paper are mainly of theoretical nature, since the solution is limited in a number of ways. In particular, it is not asynchronous, and, moreover, nodes are not allowed to start at arbitrary (and different) times. Even more desirable would be to have a self-stabilizing solution. Some initial steps in this direction have been taken in [KP96]. Finally, tight mendability is proved only under the assumption that the complexity of MIS is a function that "behaves nicely." (Nevertheless, even without this assumption it is known that MIS is at least nearly tightly mendable.) It would be interesting to remove that assumption.

Despite these limitations of our specific solution, it is our belief that the proposed general *approach* may be of considerable practical significance. Toward that goal, a number of necessary steps must be taken to remove the limitations discussed above. In addition, although demonstrated only for MIS, questions related to mendability and tight mendability can be asked for other distributed problems. In particular, it is desirable to apply our approach to real-life protocols.

Of course, one can think also of generalizations of our work to other models, defined by different characteristics; e.g., one can study tight fault locality in shared memory with, e.g., atomic registers. Related questions can be asked in the context of interactive tasks (as opposed to input–output tasks). These are tasks that run forever, guaranteeing certain properties (e.g., that each node enters a critical section often).

Finally, questions similar to the one asked in this paper can be raised in *nondistributed* contexts as well. For example, tight mending is meaningful also for sequential data structures. There, it forms a generalization of the area of dynamic data structures [Fre85, T83], in which one assumes that F (rather than 1 or n) changes occurred, and studies the complexity of updating the data structure.

Summary of main notation.

$G = (V, E)$—a graph representing the system, with node set V, $|V| = n$, and link set E.
$Mend[P]$—a mending algorithm for MIS, employing an MIS construction procedure P.
T_{Mend}—the running time of algorithm $Mend$.
$\mathcal{M} = (\mathcal{M}_{v_1}, \ldots, \mathcal{M}_{v_n})$—a given MIS vector.
$\mathcal{S}(\mathcal{M})$—the set induced by $\mathcal{M}$.
$\mathcal{D}_v$—an additional data structure maintained by node v.
$\mathcal{M}^*_v$, $\mathcal{D}^*_v$—the MIS bit and the data structure stored at v before the faults.
$\mathcal{M}_v$, $\mathcal{D}_v$—the MIS bit and the data structure stored at v after the faults.
F, H—the sets of faulty and healthy nodes.
$\mathcal{C}(\mathcal{M})$—the conflict set.
$\Gamma_i(W)$—the i-neighborhood of W.
$Co(U)$—the complement of U (w.r.t. V).
$Border_i(U)$—the i-border of U.
`Big`, `Small`—the sets of nodes v s.t. $|\Gamma_2(v)| > 2|F|$ (respectively, $|\Gamma_2(v)| \leq 2|F|$) for a given $|F|$.
$\hat{C}$—the set of conflicting nodes in `Small`.
F_i—the set of faulty nodes at the beginning of the ith phase.
G_{RI}—the record inconsistency graph.
$\deg_{RI}(v)$—v's degree in G_{RI}.
`Detected`—the set of nodes that detected a local inconsistency in their initial output.

λ_i—a quadratically growing sequence.
$\mathtt{NV}_i$—the nonvoting nodes in phase i.
$\mathtt{Vot}_i(v)$—the phase i voters in $\Gamma_2(v)$.
$\gamma(v) = |\Gamma_2(v)|$.
$\mathtt{Big}_i$, $\mathtt{Small}_i$—the sets of nodes with $\gamma(v) > 2\lambda_i$ (resp., $\gamma(v) \leq 2\lambda_i$).
$\mathcal{C}_F$—the conflicting nodes which are faulty (now or at the beginning).
$\mathcal{C}_H$—the conflicting nodes which are healthy (now and at the beginning).
$\mathtt{Accuse}(v)$—the nodes accused by v.
w_v—the faulty accused node associated with v.
Acc_Big_i—the set of nodes in $\mathcal{C}_H$ that accuse some neighbor in $F_i \cap \mathtt{Big}_i$.
Acc_Small_i—the set of nodes in $\mathcal{C}_H$ that accuse only neighbors from $F_i \cap \mathtt{Small}_i$.
$\Gamma^F(w)$—the set of 2-neighbors x of w such that $x \in F \setminus \mathtt{NV}_i$ and $\mathcal{D}_x^{sav}(w) = \mathcal{M}_w$.
$\Gamma^{AB}(w)$—the nodes $v \in \text{Acc\_Big}_i$ for which $w = w_v$.
$\gamma^Z(w) = |\Gamma^Z(w)|$ (for any appropriate Z).
$c_F(w)$—the number of edges connecting the nodes of $\Gamma^F(w)$ to the nodes of $\Gamma^{AB}(w)$ in G_{RI}.

Acknowledgments. It is a pleasure to thank Hadas Shachnai and Moti Yung for helpful discussions and Esther Jennings for her useful comments on an earlier draft. Thanks are also due to two anonymous referees, whose remarks have helped to improve the presentation of the paper.

CONVERGENCE CRITERIA FOR GENETIC ALGORITHMS*

DAVID GREENHALGH† AND STEPHEN MARSHALL‡

Abstract. In this paper we discuss convergence properties for genetic algorithms. By looking at the effect of mutation on convergence, we show that by running the genetic algorithm for a sufficiently long time we can guarantee convergence to a global optimum with any specified level of confidence. We obtain an upper bound for the number of iterations necessary to ensure this, which improves previous results. Our upper bound decreases as the population size increases. We produce examples to show that in some cases this upper bound is asymptotically optimal for large population sizes. The final section discusses implications of these results for optimal coding of genetic algorithms.

Key words. genetic algorithms, convergence criteria, upper bounds, probability, optimal coding

1. Introduction.

Genetic algorithms are robust search mechanisms based on underlying genetic biological principles. Having been established as a valid approach to problems requiring efficient and effective search, genetic algorithms are increasingly finding widespread application in business, scientific, and engineering circles (Goldberg (1989)). These algorithms are computationally simple yet powerful in their search for improvement. They work on a wide range of discrete search spaces and are very versatile, as few assumptions are needed about these spaces. However, perhaps because of this versatility, relatively little mathematical theory is available concerning the performance of these algorithms.

Genetic algorithms comprise three basic mechanisms: reproduction, crossover, and mutation. Typically the discrete space to be searched is coded as a set of binary strings of length γ. These strings are analogous to chromosomes. An initial population of n strings is chosen. For simplicity n is taken to be even. The goal of the genetic algorithm is to find the maximum of some objective function f (called the fitness function) defined on the search space.

A simple genetic algorithm is described in Goldberg (1989). Starting with the original population, a new population of n strings is selected in three stages. First, a new set of n strings (not necessarily distinct) is chosen from the original n strings by selecting each member of the population with probability proportional to its fitness. This is called reproduction. Second, the new set of strings is mated (paired) at random. For each pair crossover occurs with probability χ. If crossover occurs, then a position between 1 and $\gamma - 1$ is chosen at random, and the first half of the first string in the pair is matched with the second half of the second string, and the second half of the first string is matched with the first half of the second to give a new pair (like chromosomes). Third, each bit of each string in the new population is independently flipped (changed from zero to one or vice versa) with probability μ. This is called uniform mutation. Usually the crossover probability χ and the mutation probability

μ are small. A typical value of μ is less than 0.05. More complex genetic algorithms may have nonuniform crossover rates between iterations, or nonuniform mutation rates between iterations, or both. Other possibilities include more complex crossover schemes (for example, multiple point crossover) and mutation schemes (for example, mutation of blocks of digits altogether simultaneously).

The process of reproduction probabilistically ensures that individuals of high fitness are preferentially maintained in the population, while crossover and mutation are necessary to introduce the diversity needed to ensure that the entire sample space is reachable and avoid becoming stuck at suboptimal solutions. In fact mutation on its own is sufficient to introduce such diversity. The idea is that after a large number of iterations the population should consist mainly of individuals very close to the optimal solution. When the genetic algorithm has finished, the fitness of each member of the population is evaluated and the member corresponding to the maximum fitness taken as the optimum member of the search space.

However, with this method it is possible for the optimal solution to be seen and then disappear, if it appears in some population and then is lost due to mutation or crossover. A more effective method, which requires very little extra effort and is commonly used, is to save at each stage the population member of maximal fitness which has been seen so far (in either the initial population or one of the end of iteration populations up to now). This is updated each time that the fitnesses for a population are calculated. This is sometimes called a queen bee or elitist approach.

Heuristically genetic algorithms appear in practice to work well, but there is little mathematical analysis underpinning their performance. One key problem area is how to decide when to stop. A simplistic approach (but one that is often taken) is to stop after a (large) arbitrary fixed number of iterations. A slightly more sophisticated approach is described by de Jong (1975), who defines the on-line performance (describing on-going performance) as the average of all fitness functions evaluated up to and including the current trial. The off-line performance (describing convergence) is a running average of the best performance values to a particular time. A more sophisticated alternative to stopping after a fixed number of iterations is to stop after either the on-line or, preferably, the off-line performance appears to have stabilized.

As genetic algorithms are stochastic search algorithms it is never possible to guarantee that an optimal solution (in general there may be more than one) has been seen after a fixed number of iterations. There is always a probability that we have not seen an optimal solution. However, we can examine a sort of convergence in probability. Given a fixed probability δ $(0 < \delta < 1)$ we may ask what is the smallest number of iterations required to guarantee that we have seen an optimal solution with probability δ. We denote this number by $t(\delta)$.

2. Genetic algorithms as Markov chains. Previous work has succeeded in deriving bounds for this quantity $t(\delta)$ by modeling genetic algorithms as Markov chains. Vose and Liepins (1991) show how genetic algorithms can be expected to display punctuated equilibria, often appearing to converge to false suboptimal solutions for relatively long times before moving on to better solutions. This behavior is often seen in practice. Thus convergence criteria such as de Jong's on-line and off-line performance can often be misleading. Nix and Vose (1992) characterize genetic algorithms as Markov chains. They show that if the state variable is taken to be the current population, then the Markov chain is ergodic if and only if the mutation probability μ is strictly positive. Hence a steady state behavior exists and it is not possible for the Markov chain to be trapped at a suboptimal solution indefinitely.

Aytug and Koehler (1996) use this Markov chain formulation to find bounds for $t(\delta)$. For $x \geq 0$ define INT$[x]$ to be the smallest integer greater than or equal to x. The show that $t_2(\delta) \leq t(\delta) \leq t_1(\delta)$ where

$$t_1(\delta) = \text{INT}\left[\frac{\ln(1-\delta)}{\ln[1-\min\{(1-\mu)^{\gamma n}, \mu^{\gamma n}\}]}\right]$$

and

$$t_2(\delta) = \text{INT}\left[\max_j \left\{\frac{\ln(1-\delta)}{\ln[\rho(Q - Qe_j e_j^T)]}\right\}\right].$$

In the definition of $t_2(\delta)$ the maximum is taken over all states of the Markov chain, Q is the Markov chain transition matrix, and e_j is the jth unit vector. $\rho(A)$ denotes the spectral radius of a matrix A. The lower bound is difficult to evaluate, but the upper bound gives an easily computed sufficient condition that after $t_1(\delta)$ iterations we have seen the optimal solution with probability at least δ.

Although simple genetic algorithms use binary coding it is sometimes advantageous to use a nonbinary coding. This time each element of the space to be searched is represented by a vector in $\{0, 1, 2, \ldots, K-1\}^\gamma$, called a K-string of length γ. Reproduction and crossover proceed as before. For mutation, each digit of each population member independently mutates with probability μ. When a digit mutates it changes to one of the other $K-1$ digits, chosen at random. The case $K = 2$ is the binary case. Goldberg (1989) has argued for binary over higher cardinality representations for maximizing implicit parallelism in genetic processing. Notwithstanding this argument, practitioners report better performance with nonbinary representations in many applications (Davis, 1991). Aytug, Bhattacharrya, and Koehler (1996) extend their results from binary representations to alphabets of cardinality $K = 2^x$ (i.e., alphabets whose cardinality is a power of 2) to show that in a cardinality K genetic algorithm the number of iterations necessary to see all populations with probability δ is bounded above by

$$t_1(\delta) = \text{INT}\left[\frac{\ln(1-\delta)}{\ln\left[1-\min\left\{(1-\mu)^{\gamma n}, \left(\frac{\mu}{K-1}\right)^{\gamma n}\right\}\right]}\right].$$

For $K = 2$ this upper bound reduces to the one obtained by Aytug and Koehler (1996). Note that Aytug, Bhattacharrya, and Koehler (1996) incorrectly define INT$[x]$ as the smallest integer greater than (as opposed to greater than or equal to) x. The correct definition is given in Aytug and Koehler (1996).

The bounds of Aytug, Bhattacharrya, and Koehler assume that with specified probability they have seen every population and hence every optimal solution. This is a huge overkill. Aytug and Koehler believe tighter bounds could be derived by establishing a way where all population members (not all populations) are seen at least once with a specified probability. In fact a very simple argument along the suggested lines enables us to improve Aytug, Bhattacharrya, and Koehler's upper bound.

3. Main results.

THEOREM 1.

$$t(\delta) \leq \tilde{t}_1(\delta) = \text{INT}\left[\frac{\ln(1-\delta)}{n \ln\left[1 - \min\left\{(1-\mu)^{\gamma-1}\left(\frac{\mu}{K-1}\right), \left(\frac{\mu}{K-1}\right)^{\gamma}\right\}\right]}\right].$$

Proof. See the appendix.

Note that the only properties of the crossover function used in the proof of Theorem 1 are in (b), where we show that if after crossover we have exactly one copy of the optimal string $\underline{e}^*$ and one nonoptimal string, they agree in at most $\gamma - 2$ digits. The arguments used to show this do not depend on the crossover scheme having a one-point crossover or a uniform crossover rate. Thus our results are equally valid if our crossover scheme is a multiple point crossover or has a nonuniform crossover rate or both. The arguments also hold for any selection process which at each stage selects n strings (possibly including some replicated ones) from an original population of n strings. However, although our results hold for a wide variety of genetic algorithm models, they do not hold for the general case given by Vose, where mutation masks and crossover masks are employed instead of rates. The mixing probability formula was first given in Vose and Wright (1995) and generalized to the general cardinality case in Koehler, Bhattacharrya, and Vose (1997).

It is straightforward to show this bound is always an improvement on $t_1(\delta)$.

LEMMA 1.

$$\tilde{t}_1(\delta) \leq t_1(\delta).$$

Proof. If $\mu \leq \frac{K-1}{K}$, $1-\mu \geq \frac{\mu}{K-1}$. Then for $n = 1$, $t_1(\delta) = \tilde{t}_1(\delta)$, whence the result follows as $\tilde{t}_1(\delta)$ is decreasing in n and $t_1(\delta)$ increasing in n. If $\mu > \frac{K-1}{K}$, $1-\mu < \frac{\mu}{K-1}$ and it is straightforward to show that for $n = 1$, $t_1(\delta) > \tilde{t}_1(\delta)$. The result follows similarly to above.

Thus our bound $\tilde{t}_1(\delta)$ is significantly tighter than the previous one. In addition it decreases as the population size n increases, whereas $t_1(\delta)$ increases with n. This is intuitively correct as increasing the population size means that there is a greater probability of the optimum being present in any given population. On the other hand the total number of possible combinations of populations will be larger, and it will therefore take significantly more iterations to encounter all of them. Moreover our results hold for alphabets of arbitrary cardinality, whereas the results of Aytug, Bhattacharrya, and Koehler require that the cardinality K be a power of 2.

In practice the mutation rate μ is usually small so that μ^γ is often very small. In this case, using the approximation $\ln(1+x) \approx x$ for x small and $\text{INT}[x] \approx x$ for x large, then the original bound may be approximated as

$$t_1(\delta) \approx -\frac{(K-1)^{\gamma n} \ln(1-\delta)}{\mu^{\gamma n}}$$

if $t_1(\delta)$ is large and the new bound as

$$\tilde{t}_1(\delta) \approx -\frac{(K-1)^{\gamma} \ln(1-\delta)}{n\mu^{\gamma}} \tag{1}$$

if $\tilde{t}_1(\delta)$ is large. The ratio is therefore

$$\frac{t_1(\delta)}{\tilde{t}_1(\delta)} \approx n \left(\frac{\mu}{K-1} \right)^{-\gamma(n-1)}.$$

As a numerical example we take $K = 2$, $\gamma = 10$, $\mu = 0.2$, $n = 15$, and $\delta = 0.9$ giving $t_1(\delta)$ as approximately 1.6×10^{105} iterations, whereas for the same figures $\tilde{t}_1(\delta)$ is very much smaller at 1.5×10^6 iterations. Indeed if we double the population size to $n = 30$, the new bound reduces by half to 7.5×10^5 and the old bound almost squares to 1.1×10^{210}.

Aytug, Bhattacharrya, and Koehler (1996) show that the bound $t_1(\delta)$ is minimized at $n = 1$ and $\mu = \frac{K-1}{K}$. It is straightforward to show that for fixed n our new upper bound $\tilde{t}_1(\delta)$ is also minimized at $\mu = \frac{K-1}{K}$ for $\gamma \geq 2$ and at $\mu = 1$ for $\gamma = 1$. This says that as the bound is based only on mutation, it gives the best bound when the process is diffusing most rapidly, which happens when $\mu = \frac{K-1}{K}$ for $\gamma \geq 2$ and when $\mu = 1$ for $\gamma = 1$. This is also true for the upper bound of Aytug, Bhattacharrya, and Koehler for the most practically relevant situation where $\gamma \geq 2$. However, if $\gamma = 1$, then Aytug and Koehler's upper bound is still maximized at $\mu = \frac{K-1}{K}$. It is similarly straightforward to show that $\tilde{t}_1(\delta)$ is monotone increasing in n for μ fixed. This says that as the population size increases, our search naturally becomes more efficient at finding the optimal solution. At $n = 1$, having seen every population is equivalent to having seen that every member of the search space and the two bounds are the same.

Theorem 1 assumes a uniform mutation rate, where at each stage each digit mutates independently. These results may carry over to different mutation schemes by reworking the calculations and redoing some of the proofs. For example, suppose that at iteration i each digit of each population member mutates independently at random with probability μ_i. If μ_i is bounded above away from one and below away from zero, so that $\mu_1 > \mu_i > \mu_2$ for some $\mu_1 < 1$ and $\mu_2 > 0$, then it is straightforward to modify the proof of Theorem 1 to show that

$$t(\delta) \leq \text{INT} \left[\frac{\ln(1-\delta)}{n \ln \left[1 - \min \left\{ (1-\mu_1)^{\gamma-1} \left(\frac{\mu_1}{K-1} \right), \left(\frac{\mu_2}{K-1} \right)^{\gamma} \right\} \right]} \right].$$

We can obtain a better bound (again by modifying the argument of Theorem 1) to show that $t(\delta) \leq T_1$, where T_1 is the smallest integer such that

$$\sum_{i=1}^{T_1} \ln \left[1 - \min \left\{ (1-\mu_i)^{\gamma-1} \left(\frac{\mu_i}{K_1} \right), \left(\frac{\mu_i}{K-1} \right)^{\gamma} \right\} \right] \leq \frac{\ln(1-\delta)}{n}.$$

In most practical situations each μ_i will be small. In such circumstances define $\tilde{T}_1$ to be the smallest integer T such that

$$\sum_{i=1}^{T} \mu_i^{\gamma} \geq -\frac{(K-1)^{\gamma} \ln(1-\delta)}{n}.$$

Then, using similar approximations to the ones made in deriving (1), we deduce that T_1 can be approximated by $\tilde{T}_1$ if each μ_i is sufficiently small.

Theorem 1 gives an upper bound $\tilde{t}_1(\delta)$ for $t(\delta)$, the number of iterations necessary to ensure that we have seen the optimal solution with probability δ. This is an improvement on previous upper bounds. A natural question is whether this bound can be reduced further. Of course for specific objective functions the genetic algorithm will usually perform much better than our upper bound. However, the following examples exhibit circumstances where no further improvement is possible, and our upper bound is asymptotically optimal (for large n). Thus with a completely general objective function and population size it is not possible to improve on our result. The first example shows that no better bound can be obtained for the range $\mu \leq \frac{K-1}{K}$, the second that none can be obtained for the range $\mu \geq \frac{K-1}{K}$.

Example 1. Consider an objective function f defined on all K-strings of length γ to be ε everywhere apart from the origin $\underline{0} = (0, 0, 0, \ldots, 0)$ and the vector $\underline{e} = (K-1, K-1, K-1, \ldots, K-1)$, $0 < \varepsilon < 1$, $f(\underline{0}) = 1$, and $f(\underline{e}) = 2$. There is a nonzero uniform mutation rate μ. For the sake of definiteness we assume a nonzero uniform crossover rate with a single point crossover, although our argument would work equally well with a nonuniform crossover rate or multiple point crossover or both. At the selection phase individuals are selected in proportion to their fitness. We start with an initial population of n $\underline{0}$'s.

RESULT 1. *Consider Example* 1 *for* $\mu \leq \frac{K-1}{K}$. *Then*

(2)
$$\tilde{t}_1(\delta) \geq t(\delta) > \text{INT}\left[\frac{\ln(1-\delta)}{n\ln\left[1-\left(\frac{\mu}{K-1}\right)^{\gamma}\right] + \ln(1-\theta^n) - n\ln(1+(n-1)\varepsilon)}\right] - 1,$$

where

$$\theta = 1 - \frac{(1-\mu)^{\gamma}}{1-\left(\frac{\mu}{K-1}\right)^{\gamma}} \qquad (0 < \theta < 1).$$

The proof of Result 1 is given in the appendix. Result 1 shows that the bound of Theorem 1 is optimal in the following sense. Pick $\varepsilon_n = \frac{1}{n^3}$ (so ε depends on n). Then as $\ln(1+x) \leq x$ for $x \geq 0$, $0 \leq n\ln(1+(n-1)\varepsilon_n) \leq \frac{n(n-1)}{n^3} \leq \frac{1}{n}$ for all n. As $n \to \infty$, $\tilde{t}_1(\delta)$ tends to zero as $\frac{1}{n}$, and θ^n tends to zero exponentially fast. Hence it is straightforward to show that for $\mu \leq \frac{K-1}{K}$ and n large enough

$$\left|\frac{\ln(1-\delta)}{n\ln\left[1-\left(\frac{\mu}{K-1}\right)^{\gamma}\right]} - \frac{\ln(1-\delta)}{n\ln\left[1-\left(\frac{\mu}{K-1}\right)^{\gamma}\right] + \ln(1-\theta^n) - n\ln(1+(n-1)\varepsilon_n)}\right| \leq \tilde{t}_1(\delta)\frac{-2}{n^2\ln\left[1-\left(\frac{\mu}{K-1}\right)^{\gamma}\right]},$$

which tends to zero at a much faster rate than $\tilde{t}_1(\delta)$ does. A consequence of this result is that provided that n is very large then the upper bound in (2) is one plus the lower bound for almost all values of δ; so in this case, $\tilde{t}_1(\delta)$ gives an arbitrarily close approximation to $t(\delta)$.

The idea behind Example 1 is that we have a population initially consisting of all $\underline{0}$'s. At each iteration the optimum solution may appear in the population by direct mutation for some $\underline{0}$ in one step. Otherwise, provided that at least one $\underline{0}$ remains at the end of this iteration and ε is very small, after reproduction we are almost certainly back to the initial population of n $\underline{0}$'s (ignoring small terms in ε). Thus the only way the optimum can appear in the population is by direct mutation of one of the population members. This argument breaks down if, in any iteration, all of the population members simultaneously mutate away from $\underline{0}$ in one iteration, but none of them mutates to the optimum. However, by making n large enough, we can make the probability of this happening arbitrarily small, and provided that we choose $\varepsilon_n = \frac{1}{n^3}$, the small terms in ε can still be neglected. Thus if n is large enough, $\tilde{t}_1(\delta)$ can be made as close as we like to $t(\delta)$.

Our second example shows a similar result when $\mu \geq \frac{K-1}{K}$.

Example 2. Consider an objective function f defined on all K-strings on length γ to be ε everywhere apart from $\underline{e}_0 = (0, K-1, K-1, \ldots, K-1)$ and $\underline{e} = (K-1, K-1, K-1, \ldots, K-1)$, $0 < \varepsilon < 1$, $f(\underline{e}_0) = 1$, and $f(\underline{e}) = 2$. There is a nonzero uniform mutation rate μ. Again for the sake of definiteness we assume a nonzero uniform crossover rate with a single crossover, although our argument would work equally well with a nonuniform crossover rate or multiple crossover or both. The selection phase and the initial population are the same as in Example 1.

RESULT 2. *Consider Example* 2 *for* $\mu \geq \frac{K-1}{K}$. *Then if* n *is large enough*

(3)

$$\tilde{t}_1(\delta) \geq t(\delta) > \text{INT}\left[\frac{\ln(1-\delta)}{n\ln\left[1-(1-\mu)^{\gamma-1}\left(\frac{\mu}{K-1}\right)\right] + \ln(1-\theta^n) - n\ln(1+(n-1)\varepsilon)}\right] - 1,$$

where

$$\theta = 1 - \frac{(1-\mu)^{\gamma}}{1-(1-\mu)^{\gamma-1}\left(\frac{\mu}{K-1}\right)} \qquad (0 < \theta < 1).$$

The proof of Result 2 is similar to that of Result 1. Similarly to Result 1 this can be used to show that if $\varepsilon_n = \frac{1}{n^3}$, then for $\mu > \frac{K-1}{K}$, as n becomes very large $\tilde{t}_1(\delta)$ again gives a very close approximation to $t(\delta)$ for almost all values of δ and so is asymptotically optimal for large n.

4. Implications for coding of genetic algorithms. Aytug, Bhattacharrya, and Koehler (1996) discuss the implications of their upper bound for the practical problem of coding genetic algorithms. They ask: given a problem whose domain can be represented with a coding of cardinality K, what is the best choice of coding? In other words, should one use binary or a higher cardinality coding for a given problem? The answer to this question is given by the following theorem (Aytug, Bhattacharrya, and Koehler, 1996).

THEOREM 2. *If $t_1(\delta)$ iterations guarantee that an optimal solution has been found with probability δ by using binary coding, to guarantee the same worst-case level of confidence in $t_1(\delta)$ or fewer iterations by using $K = 2^x$ cardinality coding, the mutation rate of the higher cardinality genetic algorithm (μ_K) has to satisfy*

$$\mu_K \geq \mu_2^x(2^x - 1),$$

where $\mu_2 \leq 0.5$ is the mutation rate used in binary coding.

This theorem shows that when an optimal mutation rate $\mu_2 = 0.5$ is used for a binary genetic algorithm, if the same problem is re-encoded using a higher cardinality alphabet (and thus a correspondingly shorter string length) in the worst case, the re-encoded genetic algorithm cannot perform better than the binary genetic algorithm and can just match the worst case performance of the binary genetic algorithm by operating with mutation rate $\mu_K = \frac{K-1}{K}$. However, Aytug, Bhattacharrya, and Koehler show that for a lower binary genetic algorithm mutation rate we can achieve a better upper bound, and hence a better worst-case performance with the re-encoded higher cardinality genetic algorithm, even if the mutation rate for the re-encoded genetic algorithm is lower than that of the binary genetic algorithm. In other words, the re-encoded genetic algorithm not only can just match the performance of the binary genetic algorithm at the optimal binary mutation rate but can also outperform it even with a mutation rate lower than that of the binary genetic algorithm if the binary genetic algorithm mutation rate is nonoptimal. Because the functional forms of the worst-case upper bounds obtained by Aytug, Bhattacharrya, and Koehler (1996) are very similar to our own, provided that $\mu_2 \leq 0.5$ and $\gamma \geq 2$, it is straightforward to show that the same results hold using the new improved upper bounds derived in this paper (provided $\gamma \geq 2$, as will be the case for all practical applications). In fact it is also straightforward to show that similar results hold when $\gamma = 1$ with two minor modifications. First, for $\gamma = 1$ using our new bounds, Theorem 2 holds without any restriction on the value of μ_2. Second, if the optimal mutation rate $\mu_2 = 1$ is used for the binary genetic algorithm, in the worst case the re-encoded genetic algorithm always performs worse than the binary genetic algorithm, even when operating with the optimal re-encoded genetic algorithm mutation rate $\mu_K = 1$.

5. Summary and conclusions. Genetic algorithms are a robust search method for finding global optima of functions which mimic the biological principles of sexual reproduction. They have increasing practical applications in many areas (Goldberg (1989), Harvey and Marshall (1996)). Although they appear to perform well in practice, there is not a great deal of mathematical work underpinning their performance. One reason for this is they make few assumptions about the underlying state space. While this gives them great flexibility it makes general results hard to obtain. The NFL (no free lunch) work of Wolpert and Macready (Wolpert and Macready (1995), Wolpert (1996), Salomon (1997)) is a framework that addresses the core aspects of search, focusing on the connection between fitness functions and effective search algorithms. The key result is the No Free Lunch Theorem, which states that averaged over all problems, all search algorithms perform equally. This result implies that if we are comparing a genetic algorithm to some other algorithm (e.g., simulated annealing or even random search) and the genetic algorithm performs better on some class of problems, then the other algorithm necessarily performs better on problems outside the class. Thus it is essential to incorporate knowledge of the problem into the search algorithm.

In this paper we have examined questions of convergence. We ask how long must

a genetic algorithm run for it to be reasonably certain that we have seen the optimal solution. A naive approach is just to run the genetic algorithm for a large, fixed number of iterations, but there is no guarantee that this will be successful. A better approach is to look at the on-line and off-line performances, but as the work of Vose and Liepins (1991) shows that genetic algorithms can often appear to converge to false optima, this method may also give a misleading result.

Previous work of Aytug, Bhattacharrya, and Koehler has examined this question using the theory of Markov chains. Taking the state variable to be the current genetic algorithm population they show that the Markov chain is ergodic. They also show that given any probability $\delta < 1$, by running the genetic algorithm for sufficiently long, it is possible to guarantee that we have seen the optimal solution with probability δ and obtain an upper bound for the time necessary to do this. We have examined this problem using the simpler approach of looking at the effect of mutation on the convergence of the genetic algorithm. We also showed that by running the genetic algorithm for long enough we can guarantee convergence to the global optimum with any prespecified level of confidence and obtained a much lower bound for the number of iterations necessary to do this. Moreover our bound has the desirable property that it decreases as the population size increases (and the genetic algorithm gets more effective), whereas the bounds of Aytug, Bhattacharrya, and Koehler increase with increasing population size. The upper bounds we obtain are much smaller than those of Aytug, Bhattacharrya, and Koehler for realistic parameter values. Nevertheless they are still large, and for most practical problems the effect of reproduction and crossover, combined with some smoothness of the objective function, will mean that in practice the genetic algorithm converges much faster, although as discussed above it is difficult to say how much faster. The question therefore arises of whether it is possible to improve on these results further. We have produced examples to show that in general it is not possible to improve further on our upper bound, at least if the population size is sufficiently large. In the final section we showed that the results of Aytug, Bhattacharrya, and Koehler on optimal coding of genetic algorithms carry over with our new improved upper bounds.

Note that the proof of Theorem 1 assumed that the objective or fitness function had a unique global maximum attained for exactly one string. In general we will not know whether this is true. If there are several distinct strings where the objective function attains its maximum value, then the proof of Theorem 1 is still valid, but in this case we expect the genetic algorithm to converge faster than our bound. If we know in advance the number of strings where the fitness function attains its maximum value and this number of strings is greater than one, then it is possible to improve further on our upper bound (with this restricted class of objective functions). This is a possible area for future research. In general we will not know this information and, as we have shown in our paper, in the general case the bound which we have found will be asymptotically optimal.

Note added in proof. During the review of this manuscript we were informed by a referee that Aytug and Koehler submitted a paper in December 1996 to the *INFORMs Journal on Computing* (Aytug and Koehler (1999)) which gives similar results to this paper for the binary case and the more general results are contained in a working paper by Aytug, Koehler, and Bhattacharrya. We have seen Aytug and Koehler's paper but have not yet seen this working paper. The results are similar, but the proofs in our manuscript were simpler. These results were derived independently, to the best of our knowledge; as yet, neither of these papers has been published.

Appendix. *Proof of Theorem* 1. We assume that the objective function has a unique global optimum value corresponding to a unique string $\underline{e}^*$ and work out the probability that we have seen this value $\underline{e}^*$ by the end of the tth iteration. There is no loss of generality in this assumption. If the objective function attains its global optimum value at several distinct strings, then we arbitrarily choose one as $\underline{e}^*$ and our proof will still be valid (although in this case we would expect the genetic algorithm to actually converge faster).

(i) $1 - \mu \geq \frac{\mu}{K-1}$.

Given a member of the search space which agrees with the optimal string $\underline{e}^*$ in y digits, the probability that it mutates to this optimal string under mutation alone in one step is

$$(1-\mu)^y \left(\frac{\mu}{K-1}\right)^{\gamma-y} \geq \left(\frac{\mu}{K-1}\right)^{\gamma}.$$

Hence the probability that it does not mutate to $\underline{e}^*$ under mutation alone in one step is at most

$$\left(1 - \left(\frac{\mu}{K-1}\right)^{\gamma}\right).$$

Although this bound involves only the mutation operator it holds whatever happens in the reproduction and crossover phases. To see this, note that reproduction and crossover happen before mutation. Thus whatever happens in the reproduction and crossover phases immediately before mutation, we end up with a population of n strings and the probability that any specified one does not mutate to $\underline{e}^*$ in the mutation stage is at most

$$\left(1 - \left(\frac{\mu}{K-1}\right)^{\gamma}\right).$$

In t iterations of the genetic algorithm there are nt independent mutations. Hence if P_t is the probability that the optimum has been seen after t iterations,

$$P_t \geq 1 - \left(1 - \left(\frac{\mu}{K-1}\right)^{\gamma}\right)^{nt}$$

(whatever happens in the reproduction and crossover phases).

Choosing t_1 such that

$$1 - \left(1 - \left(\frac{\mu}{K-1}\right)^{\gamma}\right)^{nt_1} \geq \delta \tag{A.1}$$

guarantees that the optimum has been seen after t_1 steps with probability at least δ (therefore $t_1 \geq t(\delta)$). (A.1) can be rewritten

$$t_1 \geq \frac{\ln(1-\delta)}{n \ln\left[1 - \left(\frac{\mu}{K-1}\right)^{\gamma}\right]}, \tag{A.2}$$

and therefore (A.2) implies $t_1 \geq t(\delta)$. Thus

$$t(\delta) \leq \tilde{t}_1(\delta) = \mathrm{INT}\left[\frac{\ln(1-\delta)}{n \ln\left[1 - \left(\frac{\mu}{K-1}\right)^{\gamma}\right]}\right],$$

and the result of Theorem 1 follows in this case.

(ii) $\frac{\mu}{K-1} \geq 1-\mu$.

In t iterations of the genetic algorithm the mutation operator is applied in total nt times to the population members occurring after reproduction and crossover. If the optimal solution has not yet been seen in either the initial population or the populations at the end of each iteration, consider the population members immediately before mutation; that is, after reproduction and crossover. These can be divided naturally into pairs according to which crossover they come from. For each pair either of the following cases occurs.

(a) Neither string in the pair is $\underline{e}^*$. Suppose that the strings in the pair agree with $\underline{e}^*$ in y_1 and y_2 digits, respectively, where $0 \leq y_1 \leq \gamma - 1$ and $0 \leq y_2 \leq \gamma - 1$. For $i = 1,\ 2$ the probability that the ith member of the pair mutates to $\underline{e}^*$ in one step is

$$(1-\mu)^{y_i}\left(\frac{\mu}{K-1}\right)^{\gamma-y_i} \geq (1-\mu)^{\gamma-1}\left(\frac{\mu}{K-1}\right).$$

Hence the probability that neither string in the pair mutates to the optimal string is at most

$$\left(1-(1-\mu)^{\gamma-1}\frac{\mu}{K-1}\right)^2.$$

(b) Exactly one member of the pair is $\underline{e}^*$. The pair must have been obtained by crossover from two distinct population members, neither of which was $\underline{e}^*$. Suppose that the pair before crossover agreed with $\underline{e}^*$ in z_1 and z_2 digits, respectively, where $0 \leq z_1 \leq \gamma - 1$ and $0 \leq z_2 \leq \gamma - 1$. In this case $\gamma \geq 2$ and the other member of the pair after crossover must agree with $\underline{e}^*$ in $z_1 + z_2 - \gamma \leq \gamma - 2$ digits. Hence the probability that neither member of the pair after crossover mutates to $\underline{e}^*$ is

$$\begin{aligned}&(1-(1-\mu)^{\gamma})\left(1-(1-\mu)^{z_1+z_2-\gamma}\left(\frac{\mu}{K-1}\right)^{2\gamma-z_1-z_2}\right)\\ &\quad\leq (1-(1-\mu)^{\gamma})\left(1-(1-\mu)^{\gamma-2}\left(\frac{\mu}{K-1}\right)^2\right)\end{aligned}$$

as

$$\begin{aligned}(1-\mu)^{\gamma-2}\left(\frac{\mu}{K-1}\right)^2 &\leq (1-\mu)^{y_1+y_2-\gamma}\left(\frac{\mu}{K-1}\right)^{2y-\gamma_1-\gamma_2}\\ &\leq \left(1-(1-\mu)^{\gamma-1}\left(\frac{\mu}{K-1}\right)\right)^2,\end{aligned}$$

using the inequality

$$2(1-\mu)^{\gamma-1}\left(\frac{\mu}{K-1}\right) \leq (1-\mu)^{\gamma} + (1-\mu)^{\gamma-2}\left(\frac{\mu}{K-1}\right)^2.$$

As the pair of strings immediately before mutation is obtained from reproduction followed by crossover, it is not possible for both strings in this pair to be $\underline{e}^*$. This is because we have supposed that $\underline{e}^*$ has not yet appeared in the initial population or any of the end of iteration populations.

Combining the results of (a) and (b) we deduce that $1 - P_t$, the probability the optimal string has not been seen in the end of iteration populations by t iterations, is less than

$$\left(1 - (1-\mu)^{\gamma-1}\left(\frac{\mu}{K-1}\right)\right)^{nt}.$$

Arguing as in the case where $1 - \mu > \frac{\mu}{K-1}$ we deduce that

$$t(\delta) \leq \tilde{t}_1(\delta) = \text{INT}\left[\frac{\ln(1-\delta)}{n\ln\left[1 - (1-\mu)^{\gamma-1}\left(\frac{\mu}{K-1}\right)\right]}\right].$$

This completes the proof of Theorem 1.

Proof of Result 1. Consider what happens at the first iteration of the genetic algorithm. Reproduction and crossover have no effect on the initial population. After mutation either of the following cases occur.

(i) The optimal string has been seen with probability

$$1 - \left(1 - \left(\frac{\mu}{K-1}\right)^{\gamma}\right)^{n}.$$

(ii) The optimal string has not been seen and no $\underline{0}$'s remain. This is equivalent to saying that all n population members neither mutate to the optimal string nor stay unchanged and occurs with probability

$$\left(1 - \left(\frac{\mu}{K-1}\right)^{\gamma} - (1-\mu)^{\gamma}\right)^{n}.$$

(iii) The optimal string has not been seen and at least one $\underline{0}$ remains. This occurs with probability

$$\left(1 - \left(\frac{\mu}{K-1}\right)^{\gamma}\right)^{n} - \left(1 - \left(\frac{\mu}{K-1}\right)^{\gamma} - (1-\mu)^{\gamma}\right)^{n}.$$

Provided that at least one $\underline{0}$ remains and no $\underline{e}$'s are present at the end of iteration k, then in the next iteration of the genetic algorithm after reproduction the population again consists entirely of $\underline{0}$'s with probability at least $(\frac{1}{1+(n-1)\varepsilon})^n$. Hence as

Prob(Optimal string not seen after t iterations)

$\geq$ Prob(Optimal string not seen, and at least one $\underline{0}$ remains in all t iterations),

$$\begin{aligned}
&1 - P_t \\
&\geq \left[\left(\left\{1 - \left(\frac{\mu}{K-1}\right)^{\gamma}\right\}^{n} - \left\{1 - \left(\frac{\mu}{K-1}\right)^{\gamma} - (1-\mu)^{\gamma}\right\}^{n}\right)\right]^{t}\left(\frac{1}{1+(n-1)\varepsilon}\right)^{n(t-1)} \\
&\geq \left[\left(\left\{1 - \left(\frac{\mu}{K-1}\right)^{\gamma}\right\}^{n} - \left\{1 - \left(\frac{\mu}{K-1}\right)^{\gamma} - (1-\mu)^{\gamma}\right\}^{n}\right)\left(\frac{1}{1+(n-1)\varepsilon}\right)^{n}\right]^{t}.
\end{aligned}$$

Choosing t_1 so that

(A.3)

$$\delta > 1 - \left[\left(\left\{ 1 - \left(\frac{\mu}{K-1} \right)^{\gamma} \right\}^n - \left\{ 1 - \left(\frac{\mu}{K-1} \right)^{\gamma} - (1-\mu)^{\gamma} \right\}^n \right) \left(\frac{1}{1+(n-1)\varepsilon} \right)^n \right]^{t_1}$$

guarantees that the optimum has been seen after t_1 steps with probability strictly less than δ (so $t(\delta) > t_1$). (A.3) can be rewritten

(A.4)

$$t_1 < \frac{\ln(1-\delta)}{\ln\left[\left\{ 1 - \left(\frac{\mu}{K-1} \right)^{\gamma} \right\}^n - \left\{ 1 - \left(\frac{\mu}{K-1} \right)^{\gamma} - (1-\mu)^{\gamma} \right\}^n \right] - n \ln(1+(n-1)\varepsilon)}$$

and therefore (A.4) implies $t_1 < t(\delta)$. Thus $t(\delta)$ is greater than

$$\mathrm{INT}\left[\frac{\ln(1-\delta)}{\ln\left[\left\{ 1 - \left(\frac{\mu}{K-1} \right)^{\gamma} \right\}^n - \left\{ 1 - \left(\frac{\mu}{K-1} \right)^{\gamma} - (1-\mu)^{\gamma} \right\}^n \right] - n \ln(1+(n-1)\varepsilon)} \right] - 1,$$

$$= \mathrm{INT}\left[\frac{\ln(1-\delta)}{n \ln\left[1 - \left(\frac{\mu}{K-1} \right)^{\gamma} \right] + \ln(1-\theta^n) - n \ln(1+(n-1)\varepsilon)} \right] - 1,$$

where

$$\theta = 1 - \frac{(1-\mu)^{\gamma}}{1 - \left(\frac{\mu}{K-1} \right)^{\gamma}} \qquad (0 < \theta < 1).$$

A MORE EFFICIENT APPROXIMATION SCHEME FOR TREE ALIGNMENT*

LUSHENG WANG†, TAO JIANG‡, AND DAN GUSFIELD§

Abstract. We present a new polynomial time approximation scheme (PTAS) for tree alignment, which is an important variant of multiple sequence alignment. As in the existing PTASs in the literature, the basic approach of our algorithm is to partition the given tree into overlapping components of a constant size and then apply local optimization on each such component. But the new algorithm uses a clever partitioning strategy and achieves a better efficiency for the same performance ratio. For example, to achieve approximation ratios 1.6 and 1.5, the best existing PTAS has to spend time $O(kdn^5)$ and $O(kdn^9)$, respectively, where n is the length of each leaf sequence and d, k are the depth and number of leaves of the tree, while the new PTAS only has to spend time $O(kdn^4)$ and $O(kdn^5)$. Moreover, the performance of the PTAS is more sensitive to the size of the components, which basically determines the running time, and we obtain an improved approximation ratio for each size. Some experiments of the algorithm on simulated and real data are also given.

1. Introduction.

Multiple sequence alignment is one of the fundamental and most challenging problems in computational molecular biology [1, 2, 5, 13]. It plays an essential role in the solution of many problems such as searching for highly conserved subregions among a set of biological sequences and inferring the evolutionary history of a family of species from their molecular sequences. For example, most methods for phylogeny reconstruction based on sequence data assume a given multiple sequence alignment.

An important approach to multiple sequence alignment is the *tree alignment* method. Suppose that we are given k sequences and a *rooted phylogenetic tree* containing k leaves, each of which is labeled with a unique given sequence. The goal is to construct a sequence for each internal node of the tree such that the *cost* of the resulting *fully labeled* tree is minimized. Here, the cost of the fully labeled tree is the total cost of its edges, and the cost of an edge is the *mutational distance* (or *weighted edit distance*) between the two sequences associated with both ends of the edge.

The biological interpretation of the model is that the given tree represents the evolutionary history (known from means other than sequence analysis or postulated

in a phylogeny reconstruction experiment) which has created the molecular (DNA, RNA, or amino acid) sequence written at the leaves of the tree. The leaf sequences are ones found in organisms existing today, and the sequences to be determined for the internal nodes of the tree represent inferred sequences that may have existed in the ancestral organisms. It should be emphasized that the tree is almost always binary in biological applications.

To see how the above is related to multiple sequence alignment, we demonstrate by an example that the sequences inferred for the internal nodes actually induce a mutiple alignment of the given k sequence. Such a multiple sequence alignment is believed to expose evolutionarily significant relationships among the sequences, according to the maximum parsimony principle.

Example 1. Consider four sequences ACTG, ATCG, GCCA, and GTTA, and the tree shown in Figure 1.1(a) connecting these sequences. Suppose that the internal sequences are reconstructed as in (b). For each edge of the tree in (b) we can construct a pairwise alignment of the two sequences associated with the edge, with a cost equal to the mutational distance of the sequences. Then we can induce a multiple alignment that is *consistent* with all six pairwise alignments by "merging" the pairwise alignments incrementally as in [3], taking the spaces into consideration. For example, from the given pairwise alignments of sequences s_1, h_1 and of sequences s_2, h_1, we can obtain a multiple alignment of s_1, s_2, h_1 as shown in (d). The final induced multiple alignment of the four leaf sequences is shown in (e) (if we ignore everything below the dashed line).

Tree alignment is also a key step in a particular phylogeny reconstruction method called *generalized parsimony* [10, 12]. The basic strategy of generalized parsimony is to start with a tree consisting of two leaves and grow the tree by gradually inserting the rest of the leaves (labeled with sequences) at the edges. To add a leaf, we consider insertion at all possible edges of the current tree and use tree alignment to test which edge will result in a most parsimonious tree (i.e., one with the smallest cost).

Tree alignment is known to be NP-hard [14]. Many heuristic algorithms have been proposed in the literature [1, 7, 8, 10, 11], and some approximation algorithms with guaranteed relative error bounds have been reported recently. In particular, a polynomial time approximation scheme (PTAS) is presented in [15], and an improved version is given in [16]. Both PTASs partition the tree into overlapping constant size components, label the leaves of each such component in some way, and then apply local optimization on each component, i.e., compute an optimal tree alignment for each component. The PTAS in [16] achieves an approximation ratio $1 + \frac{2}{t} - \frac{2}{t \times 2^t}$, i.e., it produces a fully labeled tree with cost at most $1 + \frac{2}{t} - \frac{2}{t \times 2^t}$ times the optimal cost, when the running time is $O(kdn^{2^{t-1}+1})$, where k is the number of the given sequences, n is the length of each given sequence, d is the depth of the given phylogeny, and t is a parameter to control the number of sequences involved in a local optimization as well as the performance ratio. For any fixed t, a local optimization aligns a tree with $2^{t-1}+1$ leaves (i.e., sequences), which takes $O(n^{2^{t-1}+1})$ time [9]. Thus the more accurate the algorithm is, the more time it consumes. Since in practice n is at least 100, the bottleneck of the time efficiency is the time spent on local optimization. At present, we can expect to optimally align up to eight sequences of length 200 at a time, as demonstrated by the software package MSA for a similar multiple alignment problem [4]. Thus the above PTASs are still far from being practical.

In this paper, we further improve the PTAS in [16]. The new approximation scheme adopts a more clever partitioning strategy and has a better time efficiency for

the same performance ratio. For any fixed r, where $r = 2^{t-1} + 1 - q$ and $0 \leq q \leq 2^{t-2} - 1$, the new PTAS runs in time $O(kdn^r)$ and achieves an approximation ratio of $1 + \frac{2^{t-1}}{2^{t-2}(t+1)-q}$. Here the parameter r represents the "size" of local optimization. In particular, when $r = 2^{t-1}+1$, its approximation ratio is simply $1+\frac{2}{t+1}$. A comparison of the performance of the new PTAS and the PTAS in [16] for small values of t and r is given in Table 1.1. Note that the new PTAS yields an improved approximation ratio for *every* size of local optimization, whereas the previous PTAS does not. This is because the previous partitioning and analysis method works only when the size of local optimization has the form of one plus some power of two, and the new method works for any size. Hence to achieve a ratio 1.5, the new PTAS requires running time $O(kdn^5)$, while the old PTAS would require running time $O(kdn^9)$.

Although the new PTAS is only a small improvement to the previous PTASs in terms of the feasible approximation ratios it can provide, it still represents a concrete

step towards constructing a practical approximation algorithm for tree alignment with provable performance bounds, which could be extremely useful in sequence analysis. The new partitioning strategy is also much more flexible and has the potential of leading to even better analytical bounds than what is reported here. We observe that the bounds listed in Table 1.1 do not appear to be tight for either PTAS, and a better analysis technique may also reduce the approximation ratio by a significant amount.

The paper is organized as follows. We review the uniform lifting technique developed in [16] in section 2. Sections 3 and 4 present the new approximation scheme and its analysis, respectively. Finally we describe an implementation of the PTAS and perform some tests on simulated and real data in section 5.

Remark 1.1. There are many ways to define the mutational distance $D(s, s')$ between sequences s and s'. In this paper, we need only assume that the distance is a *metric*. That is, it satisfies

1. *positive definiteness*: $D(s, s') \geq 0$ and $D(s, s) = 0$;
2. *symmetry*: $D(s, s') = D(s', s)$;
3. *triangle inequality*: $D(s, s') \leq D(s, s'') + D(s'', s')$ for any sequence s''.

2. Uniformly lifted trees and the general approach. Before we discuss the new algorithm, let us introduce some useful concepts and results. Let T be a binary (phylogenetic) tree such that each of its leaves is labeled with a given sequence. For convenience, convert T to an *ordered* tree by specifying the children of each internal as left and right children, arbitrarily. A *loaded* tree for T is a tree in which each internal node is also assigned a sequence label (not necessarily a given sequence). A loaded tree is called a *lifted* tree if the sequence label of every internal node v equals the sequence label of some child of v. Figure 2.1(a) exhibits a lifted tree. A lifted tree is called a *uniformly* lifted tree if, for each level, either every internal node at that level receives its sequence label from its left child or every internal node at that level receives its sequence label from its right child. In other words, the lifting choices for the internal nodes at the same level are uniform. Figure 2.1(b) exhibits a uniformly lifted tree.

Let d denote the depth of the tree T. Then there are 2^d different uniformly lifted trees for T. We use a vector $V = (x_1, \ldots, x_d)$ to denote the uniform lifting choices for all levels, where $x_i = R$ or L corresponds to lifting the sequence of the left child or the right child at ith level. For any vector V, $T(V)$ denotes the uniformly lifted tree for T specified by V. For each internal node v, the path from v to the leaf whose sequence label is lifted to v is called the *lifting path* of v. Observe that, every node on the lifting path of v (including v) is assigned the identical sequence.

The following results are proven in [16]. Let $T^{\min}$ denote an optimal loaded tree for T.

THEOREM 2.1. *The average cost of the 2^d uniformly lifted trees for T is at most twice the cost of $T^{\min}$.*

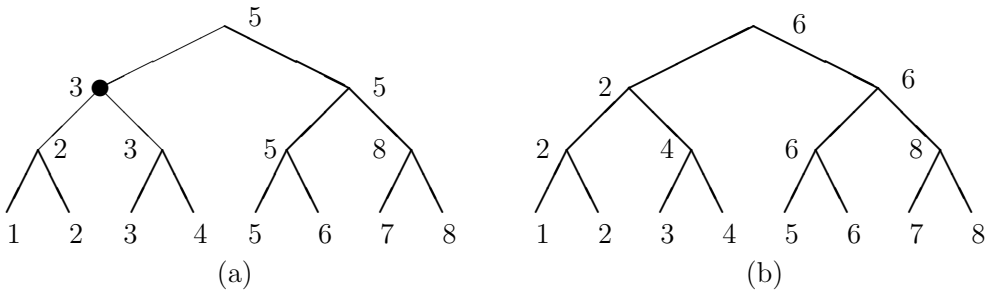

FIG. 2.1. (a) *A lifted tree.* (b) *A uniform lifted tree.*

COROLLARY 2.2. *There exists a uniformly lifted tree for T with a cost at most twice the cost of $T^{\min}$.*

An optimal uniformly lifted tree can be computed in $O(kd + kdn^2)$ time by a straightforward bottom-up dynamic programming, where k is the number of leaves in T and n is the length of each given sequence [16].

Observe that given any lifted tree, we may further reduce its cost by keeping the lifted sequences on some nodes and reconstructing the sequences on the other (internal) nodes to minimize the cost of the edges incident upon these (latter) nodes. For example, based on the lifted sequences 2, 3, 5, we can compute a sequence for the dark circled node in Figure 2.1(a) such that the total cost of the three thin edges is minimized. The new sequence should in general yield a loaded tree with a smaller cost. This suggests the idea of partitioning a (uniformly) lifted tree into a collection of overlapping components, keeping the lifted sequences at the leaves of these components intact, and optimally reconstructing the sequences for the internal nodes in each component, i.e., doing a local optimization on each component. The computation can be done in polynomial time as long as each component has a constant size.

Both PTASs in [15, 16] are based on this idea and partition the tree simply by cutting at levels separated by a fixed constant distance. Our new algorithm also follows the same general approach, but we use a more sophisticated and flexible partitioning strategy.

3. The new partitioning strategy and algorithm. Our algorithm involves partitioning a uniformly lifted tree into many overlapping components, each of which is a binary tree by itself. Let us first describe the structure of the components used in a partition.

A degree-1 node in a tree is called a *terminal*. For a fixed constant r, we consider components of r terminals. If $2^{t-2} + 1 \leq r < 2^{t-1} + 1$ for some positive integer t, a component contains t levels of nodes, where the top level contains only one terminal, called the *head*, the other $t - 1$ levels form a complete binary tree, and the bottom two levels contain $r - 1$ leaves. (See Figure 3.1.) Such a component will be referred to as a *basic component* of a partition, to avoid ambiguity. The terminals (i.e., the head and leaves) of a basic component are called its *boundary nodes*. Note that the child of the head could be either the left or right child. A basic component is of *L-type* (or *R-type*) if it uses the left (or right, respectively) child of the head.

Let T be a phylogeny, V a uniform lifting choice vector, and $T(V)$ the corresponding uniformly lifted tree. Suppose that r is an integer such that $2^{t-2}+1 \leq r \leq 2^{t-1}+1$.

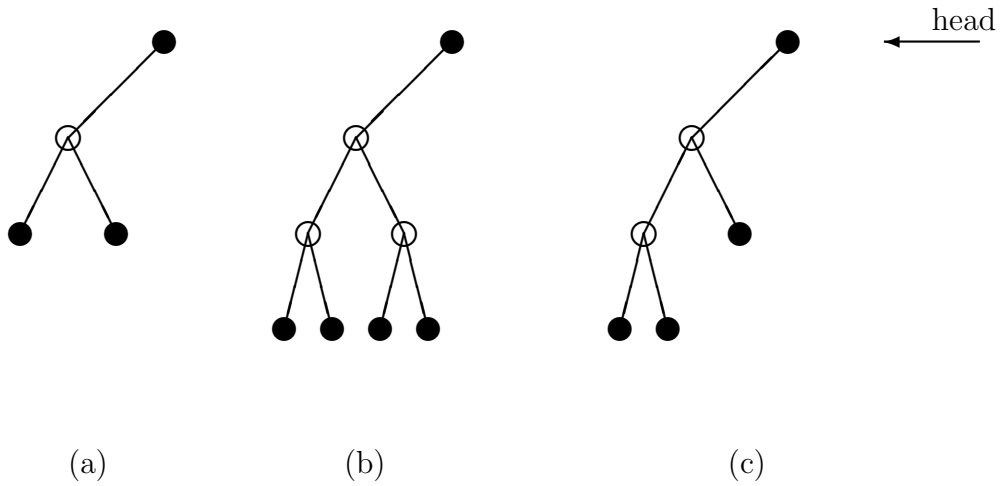

FIG. 3.1. *The L-type basic components for* (a) $r = 3$, (b) $r = 5$, *and* (c) $r = 4$. *The boundary nodes of a basic component are dark circled.*

For every uniform lifting choice vector V, we can obtain t partitions $P_0, P_1, \ldots, P_{t-1}$ of $T(V)$ as follows. Observe that to define a partition, it suffices to specify the heads of the basic components involved and the type of each basic component. First consider $i = 0, 1, \ldots, t-2$.

1. P_i has a (deformed) basic component at the top of $T(V)$, which consists of 2^i leaves at the ith level. (The root of the tree is at level 0, and the ith level is below the $(i-1)$th level. See Figures 3.2 and 3.3.)
2. All nodes on the lifting path of each leaf and each head of every basic component are heads, and the leaves of the basic components are heads.
3. The type of each basic component is identical to the lifting choice at its head as given in V. In other words, the basic component is of L-type (R-type) iff its head receives its sequence from the left child.

The partition P_{t-1} is defined similarly except that its top basic component part is a complete binary tree with $r-1$ leaves instead. Figures 3.2, 3.3, and 3.4 give an example of the partitions P_0, P_1, P_2 when $r = 4$.

Given a partition P_i, if we preserve the sequences uniformly lifted to all the boundary nodes and optimally reconstruct the sequences on rest of the nodes (i.e., the internal nodes of each basic component) to minimize the cost of each basic component, we obtain a loaded tree, which will simply be called an (r, i)-*tree*. We use $T(V)_{r,i}$ to denote the (r, i)-tree obtained from the uniformly lifted tree $T(V)$. An *optimal* r-*tree* is some (r, i)-tree $T(V)_{r,i}$ with the smallest cost among all possible i and V. For any loaded tree T_1, $C(T_1)$ denotes its cost. For any tree T_1, denote the set of internal nodes of T_1 as $I(T_1)$ and the set of leaves of T_1 as $L(T_1)$, and for each $a \in L(T_1)$, T_1^a denotes the unique $(r, 0)$-tree for T_1 such that the sequence label of leaf a is lifted to the root of T_1.

Now let us begin to describe our algorithm. We will first assume that T is a full binary tree and then extend the construction to arbitrary binary trees. Let v be a node of T. The subtree of T rooted at v consisting of all descendants of v is denoted as T_v. Note that, since we assume that T is a full binary tree, lifting the sequence of a, for any $a \in L(T_v)$, to v uniquely determines a uniform lifting choice for T_v.

Let T' be the top basic component of T_v^a and v' the child of v that is on the

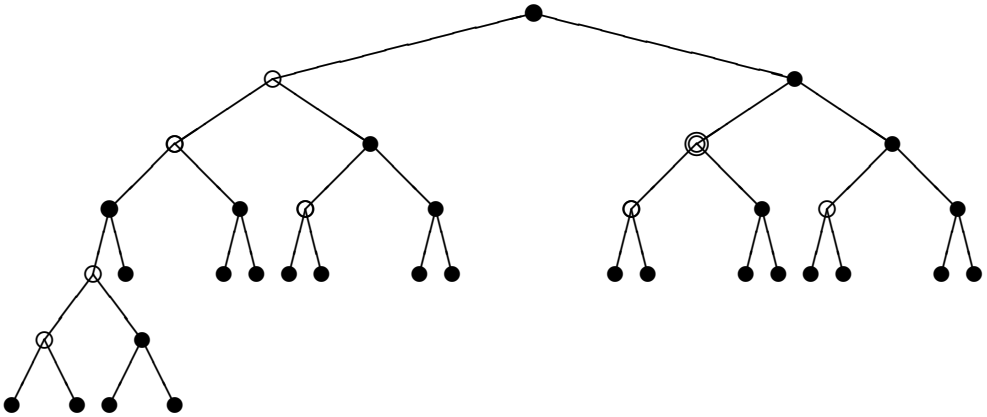

FIG. 3.2. *The partition P_0 when $r = 4$. The uniform lifting choice is $(R, R, \ldots, R)$. The dark circled nodes are boundary nodes of the basic components.*

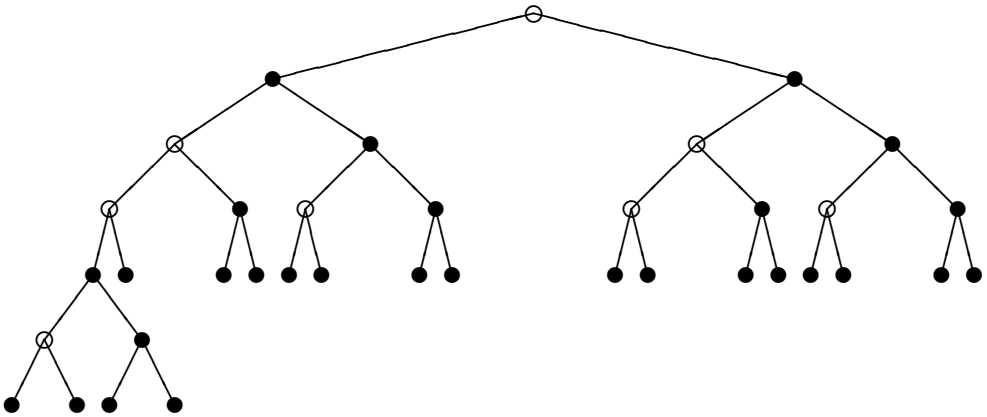

FIG. 3.3. *The partition P_1 when $r = 4$. The uniform lifting choice is $(R, R, \ldots, R)$.*

lifting path of v in T_v^a. Observe that a uniquely determines the sequences lifted to the boundary nodes of T'. The cost of the $(r, 0)$-tree for T_v^a can be computed using the recurrence equation

$$C(T_v^a) = C(T') + \sum_{u \in L(T')} C(T_u^{a(u)}) + C(T_{v'}^a), \tag{3.1}$$

where $a(u)$ is the leaf whose sequence is lifted to u and $a(u)$ is uniquely determined by a. (See Figure 3.5.)

Hence we can compute the values $C(T_v^a)$ for all v and a inductively by traversing the tree bottom-up. Note that, for each pair v and a, computing (3.1) requires $O(r + n^r)$ time, where n is the length of the sequences, given the value of $C(T_u^{a(u)})$ for each $u \in L(T')$ and the value of $C(T_{v'}^a)$. Thus, computing $C(T_v^a)$ for all pairs v and a requires $O((r + n^r) \cdot \sum_{v \in T} |L(T_v)|)$ time. Since each leaf a appears in at most d different $L(T_v)$s, where d is the depth of T, totally we need $O(rkd + kdn^r)$ time. Similarly, the cost of an (r, i)-tree $T_{r,i}^a$ obtained by lifting the sequence label of leaf a

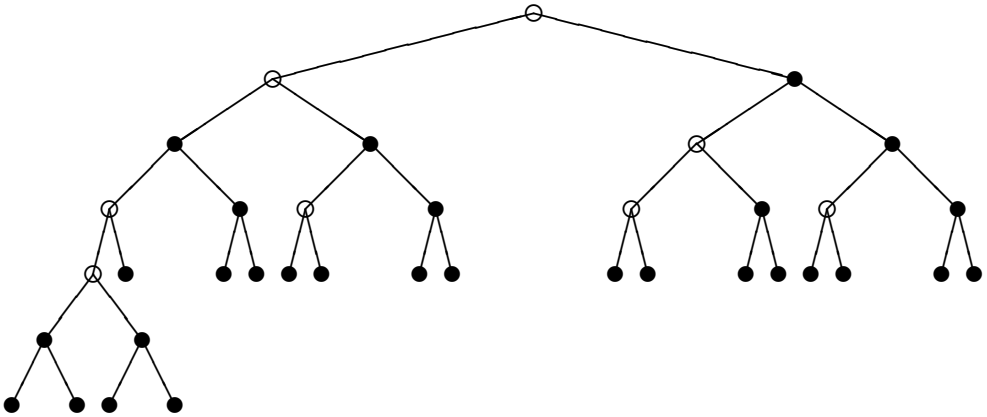

FIG. 3.4. *The partition P_2 when $r = 4$. The uniform lifting choice is $(R, R, \ldots, R)$.*

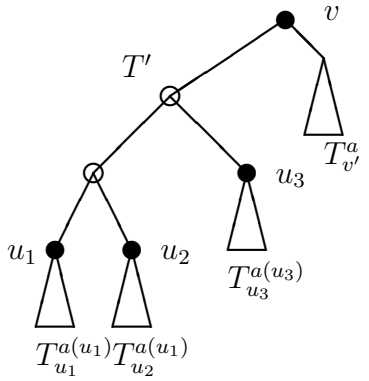

FIG. 3.5. *An illustration for the recurrence equation* (3.1).

to the root of T can be computed as follows:

$$C(T^a_{r,i}) = C(T'_i) + \sum_{v \in L(T'_i)} C(T^{a(v)}_v), \tag{3.2}$$

where T'_i is the top basic component of partition P_i and $a(v)$ is the leaf whose sequence is lifted to v as determined by the choice of a.

The above algorithm only works for full binary trees since, in general, lifting from a leaf a to a node v does not completely determine the uniform lifting choice for the subtree T_v if a is not at the bottom level of T_v. In particular, in arbitrary binary trees, lifting from leaf a to node v does not uniquely determine the leaf $a(u)$ being lifted to the node u for any internal node u that is lower than v, hence invalidating the recurrence equation (3.1).

To extend the algorithm to arbitrary binary trees without losing any time efficiency, we need the notion of an *extension* of a phylogeny. An unlabeled (ordered) tree T_1 *extends* another unlabeled (ordered) tree T_2 if T_2 can be obtained from T_1 by contracting some subtrees to single leaves. Clearly, if T_1 extends T_2, then each leaf of T_2 uniquely corresponds to a subtree of T_1. The *minimal extension* of a set of unlabeled trees is the (unique) unlabeled tree with the fewest edges that extends every tree in

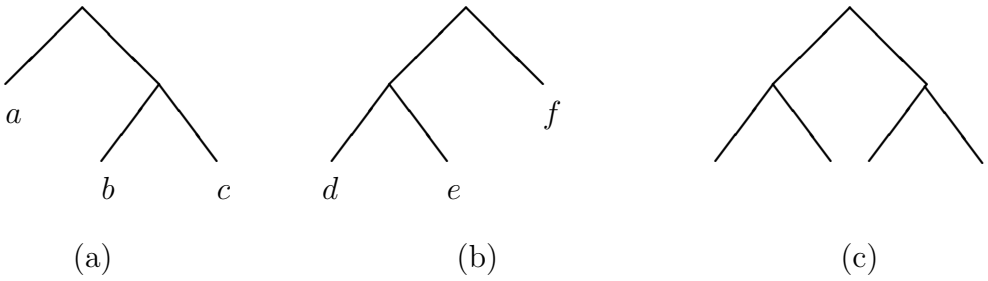

FIG. 3.6. *The minimal extension of the structures of the trees in* (a) *and* (b) *is shown in* (c).

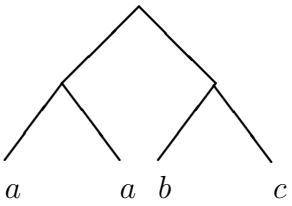

FIG. 3.7. *An extension of the tree in Figure* 3.6(a).

the set. A (partially) leaf-labeled tree T_1 extends another (partially) leaf-labeled tree T_2 if (i) the structure of T_1 extends the structure of T_2; and (ii) for each leaf v of T_2, the subtree of T_1 corresponding to v has all its leaves assigned the same label as that of v. Figure 3.6 gives an example of the minimal extension of two unlabeled trees, and Figure 3.7 shows an extension of the leaf-labeled tree in given Figure 3.6(a).

Now we are ready to generalize the algorithm to an arbitrary binary tree T. Let v be an internal node of T. Denote $T_{v,t-1}$ as the tree consisting of the top t levels of the subtree T_v. To compute $C(T_v^a)$ for each $a \in L(T_v)$, we first extend the tree $T_{v,t-1}$, which is in general a partially leaf-labeled tree, to a full binary (partially leaf-labeled) tree $T'_{v,t-1}$ with 2^{t-1} leaves. Let $v_1, \ldots, v_{2^{t-1}}$ be the leaves of this extended tree. For each v_i, $i = 1, \ldots, 2^{t-1}$, we extend T_{v_i} to obtain a leaf-labeled tree T'_{v_i} such that the structure of T'_{v_i} is the minimal extension of the structures of all $T_{v_1}, \ldots, T_{v_{2^{t-1}}}$. Note that $T'_{v,t-1}$ has 2^{t-1} leaves $v_1, \ldots, v_{2^{t-1}}$ that are the roots of subtrees $T'_{v_1}, \ldots, T'_{v_{2^{t-1}}}$. Denote the tree containing $T_{v,t-1}$ at the top and $T'_{v_1}, \ldots, T'_{v_{2^{t-1}}}$ at the bottom as $ET(v)$. We compute the cost $C(ET(v)^a)$ for each $a \in L(ET(v))$ first.

Suppose that $C(T_u^a)$ has been computed for each $u \in T_{v,t-1}$, where $u \neq v$ and $a \in L(T_u)$. We can easily compute the cost $C(ET(v)_u^a)$ of the $(r,0)$-tree $ET(v)_u^a$ for each $u \in T_{v,t-1}$, where $u \neq v$ and $a \in L(ET(v)_u)$ as follows:

$$C(ET(v)_u^a) = C(T_u^b), \qquad \text{where } a \in L(ET(v)_b). \tag{3.3}$$

Observe that the subtrees $T'_{v_1}, \ldots, T'_{v_{2^{t-1}}}$ of $ET(v)$ all have the same structure. Thus, lifting the sequence of a, for any $a \in L(ET(v))$, to v uniquely determines from where each node of $ET(v)_{v,t-1}$ receives its lifted sequence. Since $ET(v)_{v,t-1}$ extends the top basic component of $ET(v)^a$, lifting the sequence of leaf a, $a \in L(ET(v))$, to v uniquely determines from where each leaf of the top basic component of $ET(v)^a$ receives its lifted sequence. Therefore, we can compute the cost $C(ET(v)^a)$ for each $a \in L(ET(v))$ using the recurrence equation (3.1).

```

11.         Compute C(T^a_v) using equation 3.4.
12.   end
13. for each i = 0, 1, ..., t − 1
14.    Compute C(T^a_{r,i}) for every a ∈ L(T).
15. Find i, a so that C(T^a_{r,i}) is minimized.
16. Compute a loaded tree from C(T^a_{r,i}) by back-tracing.
17. end.
```

FIG. 3.8. *The algorithm to compute an optimal r-tree.*

Once we have the cost $C(ET(v)^a)$ for each $a \in L(ET(v))$, we can compute $C(T_v^a)$ easily for each $a \in L(T_v)$ by "reversing" (3.3) as follows:

$$C(T_v^a) = \min_{b \in L(ET(v)_a)} C(ET(v)^b). \tag{3.4}$$

The time complexity of the algorithm can be analyzed as follows. Since the structure of T_v extends the structure of all subtrees $T_{v_1}, \ldots, T_{v_{2^{t-1}}}$, $|L(T'_{v_i})| \leq |L(T_v)|$ for each i, $1 \leq i \leq 2^{t-1}$. Thus, the extended tree $ET(v)$ can be computed in $O(r|L(T_v)|)$ time for each $v \in T$. Hence totally it requires at most $O(\sum_{v \in T} r|L(T_v)|)$ time to construct all the $ET(v)$s. Since each leaf of T appears in at most d $L(T_v)$s, $O(\sum_{v \in T} r|L(T_v)|) = O(rd|L(T)|) = O(rkd)$. Computing (3.3) and (3.4) takes merely a traversal of $ET(v)$ each. Hence the algorithm still runs in time $O(rkd + kdn^r)$ on arbitrary binary trees. The complete algorithm is summarized in Figure 3.8.

4. The analysis of the algorithm. Given an arbitrary binary phylogeny T, we can extend T into a full binary tree $\hat{T}$. Obviously, any loaded tree for T can be extended to a loaded tree with the same cost for $\hat{T}$. Conversely, given any loaded tree for $\hat{T}$, we can obtain a loaded tree for T with equal or smaller cost by pruning appropriate subtrees and contracting nodes with only one child. The last operation will not increase the cost by the triangle inequality. Thus for the analysis we may assume that the given tree T is a full binary tree. For convenience, we number the levels from top to bottom. That is, the root is at level 0, and the level below level i is level $i + 1$.

First, let us find a good upper bound for the cost of an (r, i)-tree $T(V)_{r,i}$ for an arbitrary uniform lifting choice V. Again, let $T^{\min}$ be an optimal loaded tree for T. For each node $v \in T$, let $s(v)$ denote the sequence label of v in $T^{\min}$. We can modify $T(V)_{r,i}$ by replacing the sequence label of each nonterminal node with the sequence $s(v)$ to obtain a loaded tree $T(V)'_{r,i}$. Clearly, the cost of $T(V)'_{r,i}$ is at least that of $T(V)_{r,i}$. So, it suffices to upper bound the cost of $T(V)'_{r,i}$.

There are four types of edges in the loaded tree $T(V)'_{r,i}$:

1. the edges whose both ends are assigned an identical lifted sequence;
2. the edges with ends assigned distinct lifted sequences;
3. the edges whose both ends are assigned sequences from $T^{\min}$;
4. the edges with one end assigned a sequence from $T^{\min}$ and the other assigned a lifted sequence.

(See again Figure 3.2.) Obviously each type 1 edge costs zero and each type 3 edge (u, v) costs $D(s(u), s(v))$. Let (u, v) be a type 4 edge, where u is assigned a sequence from $T^{\min}$ and v is assigned a lifted sequence according to V. The cost of the edge (u, v) is upper bounded by

$$D(s(u), s(v)) + C(P_{v,V}),$$

where $P_{v,V}$ denotes the lifting path of node v in the uniformly lifted tree $T(V)$ and $C(P_{v,V})$ is the cost of the path $P_{v,V}$ in the optimal tree $T^{\min}$. Observe that type 2 edges may only appear at the bottom level of the tree. Hence a type 2 edge can be viewed as a degenerate type 4 edge, with the lower end (which is a leaf) of the edge being the node assigned a sequence from $T^{\min}$, and can be treated similarly to the type 4 edges. For convenience, call $D(s(u), s(v))$ and $C(P_{v,V})$ the *first* and *second* parts of the cost of edge (u, v) in $T(V)$, respectively. For each internal node v in $T(V)_{r,i}$, the path from v to the leaf whose sequence label is lifted to v is called the *lifting path* of v in $T(V)_{r,i}$. Call each internal node on a lifting path in $T(V)_{r,i}$ of some node v a *lifted* node. A lifted node is *heavy* if it is involved in two type 4 edges, and is *light* if it is involved in one type 4 edge. For a light node v, the cost of the lifted path $P_{v,V}$ is charged once in the above upper bound as the second part, whereas for a heavy node v, the cost of the lifted path $P_{v,V}$ is charged twice. A *maximal* lifting path is a lifting path in $T(V)_{r,i}$ which cannot be further extended. Notice that each maximal lifting path contains at most one heavy node at the upper end of the path. Since every edge in a maximal lifting path has type 1 and thus zero cost, we can charge one of the $C(P_{v,V})$s for a heavy node v to $C(T^{\min})$, obtaining the following upper bound for the cost $T(V)_{r,i}$:

$$C(T(V)_{r,i}) \le C(T^{\min}) + \sum_{v \text{ is a lifted node}} C(P_{v,V}). \tag{4.1}$$

To further bound the total cost of the lifting paths, we need the following lemmas.

LEMMA 4.1 (see [15, 16]). *Let T be a binary tree such that every internal node has exactly two children. For each leaf $l \in L(T)$, there exists a mapping π_l from the internal nodes of T to its leaves such that* (i) *for each internal node v, $\pi(v)$ is a descendant leaf of v,* (ii) *the paths from nodes v to their images $\pi(v)$ are edge-disjoint, and* (iii) *moreover, there is an* unused *path from the root of T to the leaf l that is edge-disjoint from all the paths in* (ii).

In other words, Lemma 4.1 says that a binary tree can be decomposed into a set of edge-disjoint paths from internal nodes to leaves, with one path for each nonroot internal node and two paths for the root. Let $C(\pi)$ denote the cost of the paths induced by mapping π in the tree $T^{\min}$.

LEMMA 4.2. *There exist mappings $\{\pi_l | l \in L(T)\}$ such that*

$$\sum_{V} \sum_{v \in I(T)} C(P_{v,V}) \le \sum_{l \in L(T)} C(\pi_l) \le 2^d C(T^{\min}),$$

where d is the depth of T.

Proof. We prove it by induction on d, the depth of the tree. Recall that T is a full binary tree. The lemma obviously holds for $d = 1$. Suppose that it holds for $d \leq q$. Consider a tree T with $d = q + 1$. Let v_0 be the root of T and v_L and v_R the left and right children of v_0. Recall that T_{v_L} and T_{v_R} denote the subtrees rooted at v_L and v_R, respectively. Then the depth of T_{v_j} $(j = L, R)$ is q. Let $\mathcal{V}$ be the set of lifting choices for T, and $\mathcal{V}_j$ the set of lifting choices for T whose first component is j. Clearly $\mathcal{V} = \mathcal{V}_L \cup \mathcal{V}_R$. By the inductive hypothesis, for each $j = L, R$, there exist mappings $\{\pi_l | l \in L(T_{v_j})\}$ for the subtree T_{v_j} such that

$$\sum_{V \in \mathcal{V}_j} \sum_{v \in I(T_{v_j})} C(P_{v,V}) \leq \sum_{l \in L(T_{v_j})} C(\pi_l).$$

For each mapping π_l, $l \in L(T_{v_j})$, there is an unused path from v_j to the leaf l of T_{v_j}. For any leaf l, let P_l be the path from the root v_0 of T to the leaf l. Number the leaves of T from left to right as $l_1, \ldots, l_{2^{q+1}}$. It is easy to see that for any $h = 1, \ldots, 2^q$, the mappings π_{l_h} and $\pi_{l_{2^q+h}}$ and the path P_{l_h} form a mapping for tree T, denoted $\pi^{h,1}$, with an unused path from v_0 to l_{2^q+h}, and symmetrically the mappings π_{l_h} and $\pi_{l_{2^q+h}}$ and the path $P_{l_{2^q+h}}$ form a mapping for tree T, denoted $\pi_{h,2}$, with an unused path from v_0 to l_h. Thus, we have

$$\begin{aligned}
\sum_{V \in \mathcal{V}} \sum_{v \in I(T)} C(P_{v,V}) &= 2 \cdot \left[\sum_{j=L}^{R} \sum_{V \in \mathcal{V}_j} \sum_{v \in I(T_{v_j})} C(P_{v,V}) \right] + \sum_{V \in \mathcal{V}} C(P_{v_0,V}) \\
&\leq \sum_{h=1}^{2^{q+1}} 2 \cdot C(\pi_{l_h}) + C(P_{l_h}) \\
&\leq \sum_{h=1}^{2^q} \sum_{j=1}^{2} C(\pi_{l_h}) + C(\pi_{l_{2^q+h}}) + C(P_{l_{(j-1)2^q+h}}) \\
&\leq \sum_{h=1}^{2^q} \sum_{j=1}^{2} C(\pi_{h,j}) \\
&\leq 2^{q+1} C(T^{\min}). \qquad \square
\end{aligned}$$

Since, there are 2^d distinct uniform lifting choices, the average cost of each $\sum_{v \in I(T)} C(P_{v,V})$ is at most $C(T^{\min})$. Observe that Theorem 2.1 follows immediately from inequality (4.1) and Lemma 4.2, since in a uniformly lifted tree $T(V)$, every internal node is a lifted node. Now we are ready to derive the required upper bound for an optimal r-tree and hence the performance ratio of our approximation algorithm. To simplify the presentation, consider first the case when $r = 2^{t-1} + 1$ for some $t \geq 1$.

4.1. The performance ratio when $r = 2^{t-1}+1$. Let $y_i(j)$ denote the number of boundary nodes at level j of an (r, i)-tree, where $0 \leq i \leq t-1$ and $0 \leq j \leq d$. It is easy to see that $y_0(j)$ can be computed by the recurrence equation

$$y_0(j) = y_0(j-1) + 2^{t-1} y_0(j-t), \tag{4.2}$$

where $t \leq j \leq d$. The initial values are $y_0(0) = \cdots = y_0(t-1) = 1$.

Let $x_i(j) = \frac{y_i(j)}{2^j}$ be the fraction of the nodes on level j of an (r,i)-tree that are boundary nodes, where $0 \le i \le t-1$ and $0 \le j \le d$. From (4.2), we have

$$x_0(j) = \frac{x_0(j-1) + x_0(j-t)}{2}, \tag{4.3}$$

where $t \le j \le d$. The initial values are $x_0(j) = 2^{-j}$ for each $j = 0, 1, \ldots, t-1$. Moreover, it is easy to see that

$$x_i(j) = x_{i-1}(j-1) = \cdots = x_0(j-i) \tag{4.4}$$

for any $i \le j \le d$ and $x_i(j) = 0$ for any $0 \le j < i$. The next lemma is a key to our bound. This gives a complete recurrence relation for all $x_i(j)$.

LEMMA 4.3.

$$2x_0(j) + \sum_{i=1}^{t-1} x_i(j) \le 2.$$

Proof. Define $f(j) = 2x_0(j) + \sum_{i=1}^{t-1} x_i(j)$. From (4.3) and (4.4), we obtain

$$f(j+1) - f(j) = 2x_0(j+1) - x_0(j) - x_0(j-t+1) = 0$$

for $j \ge t-1$. Based on the given initial values, we have

$$f(j) = f(t-1) = 2x_0(t-1) + x_0(t-2) + \cdots + x_0(0) = 2$$

for $j \ge t-1$. It is also easy to see that $f(j) < f(t-1)$ for any $j < t-1$. ∎

Combining inequality (4.1) and Lemmas 4.2 and 4.3, we have the following lemma.

LEMMA 4.4.

$$2 \cdot \sum_{V=(L,\ldots,L)}^{(R,\ldots,R)} C(T(V)_{r,0}) + \sum_{V=(L,\ldots,L)}^{(R,\ldots,R)} C(T(V)_{r,1}) + \cdots + \sum_{V=(L,\ldots,L)}^{(R,\ldots,R)} C(T(V)_{r,t-1}) \le (t+1)2^d C(T^{\min}) + 2 \cdot 2^d C(T^{\min}).$$

The left-hand side of the above inequality consists of $(t+1)2^d$ distinct (r,i)-trees. That is, the average cost of each of these (r,i)-trees is $1 + \frac{2}{t+1} C(T^{\min})$. Thus we can conclude that there exists an (r,i)-tree with cost at most $1 + \frac{2}{t+1} C(T^{\min})$.

THEOREM 4.5. *When $r = 2^{t-1} + 1$, the performance ratio of the algorithm in Figure 3.8 is $1 + \frac{2}{t+1}$.*

4.2. The performance ratio for an arbitrary *r*. Assume that $r = 2^{t-1} + 1 - q$ for some integer q, $0 \le q < 2^{t-2}$. Define variables $y_i(j)$ and $x_i(j)$ as before, and consider $y_0(j)$ and $x_0(j), j \ge t$ first. There are three types of boundary nodes at level j. Recall that each basic component consists of a head and a complete binary tree with $r-1$ leaves.

1. There are $(2^{t-1} - 2q)y_0(j-t)$ boundary nodes which are at the lowest level of some basic components.
2. There are $qy_0(j-t+1)$ boundary nodes which are at the second lowest level of some basic components.
3. There are $y_0(j-1)$ remaining boundary nodes which are on some lifting paths.

The above three types of boundary nodes are disjoint. (Note that each node in classes 1 and 2 is always shared by two adjacent basic components, whereas each node in class 3 is only involved in one basic component.) Therefore, we have recurrence equation

$$y_0(j) = y_0(j-1) + qy_0(j-t+1) + (2^{t-1} - 2q)y_0(j-t)$$

for $j \geq t$. Hence

$$x_0(j) = \frac{1}{2}x_0(j-1) + \frac{2q}{2^t}x_0(j-t+1) + \frac{2^{t-1}-2q}{2^t}x_0(j-t) \tag{4.5}$$

for $j \geq t$. The initial values are

$$x_0(j) = \frac{1}{2^j} \quad \text{for} \quad j = 0, 1, \ldots, t-2,$$
$$x_0(t-1) = \frac{q+1}{2^{t-1}}.$$

Again, it is easy to see that

$$x_i(j) = x_{i-1}(j-1) \tag{4.6}$$

for any $i = 1, \ldots, t-2$, and

$$y_{t-1}(j) = (2^{t-1} - 2q)y_0(j-t+1) + qy_0(j-t+2).$$

From the last equation, we have

$$x_{t-1}(j) = \frac{2^{t-1}-2q}{2^{t-1}}x_0(j-t+1) + \frac{2q}{2^{t-1}}x_0(j-t+2). \tag{4.7}$$

Observing that $x_i(j) = 0$ for any $j < i$, the above gives a complete recursive definition of all $x_i(j)$.

LEMMA 4.6.

$$2^t x_0(j) + 2^{t-1}x_1(j) + \cdots + 2^{t-1}x_{t-3}(j) + (2^{t-1} - 2q)x_{t-2}(j) + 2^{t-1}x_{t-1}(j) \leq 2^t.$$

Proof. Define

$$f(j) = 2^t x_0(j) + 2^{t-1}x_1(j) + \cdots + 2^{t-1}x_{t-3}(j) + (2^{t-1} - 2q)x_{t-2}(j) + 2^{t-1}x_{t-1}(j).$$

From (4.6) and (4.7), we have, for $j \geq t-1$,

$$f(j) = 2^t x_0(j) + 2^{t-1}x_0(j-1) + \cdots + 2^{t-1}x_0(j-t+2) + (2^{t-1} - 2q)x_0(j-t+1). \tag{4.8}$$

From (4.5) and (4.8), we obtain $f(j+1) - f(j) = 0$. Plugging the initial values of $x_0(j)$ in (4.8), we have

$$\begin{aligned} f(j) &= f(t-1) \\ &= 2^t x_0(t-1) + 2^{t-2}x_0(j-1) + \cdots + 2^{t-1}x_0(1) + (2^{t-1} - 2q)x_0(0) \\ &= 2(q+1) + 2 + \cdots + 2^{t-2} + (2^{t-1} - 2q) = 2^t \end{aligned}$$

for any $j \geq t-1$. It is easy to verify that $f(j) < f(t-1)$ for any $j < t-1$. ∎

Similar to Lemma 4.4, we have the following lemma.

LEMMA 4.7.

$$\begin{aligned} 2^t \sum_{V=(L,\ldots,L)}^{(R,\ldots,R)} C(T(V)_{r,0}) + 2^{t-1} \sum_{V=(L,\ldots,L)}^{(R,\ldots,R)} C(T(V)_{r,1}) + \cdots + 2^{t-1} \sum_{V=(L,\ldots,L)}^{(R,\ldots,R)} C(T(V)_{r,t-3}) \\ + \quad (2^{t-1} - 2q) \sum_{V=(L,\ldots,L)}^{(R,\ldots,R)} C(T(V)_{r,t-2}) + 2^{t-1} \sum_{V=(L,\ldots,L)}^{(R,\ldots,R)} C(T(V)_{r,t-1}) \\ \leq \quad (2^{t-1}(t+1) - 2q) 2^d C(T^{\min}) + 2^t \cdot 2^d C(T^{\min}). \end{aligned}$$

Noting that the left-hand side of the above inequality consists of $(2^{t-1}(t+1)-2q)2^d$ distinct (r,i)-trees, we have the main theorem of this section.

THEOREM 4.8. *Suppose that* $r = 2^{t-1} + 1 - q$, *where* $0 \leq q < 2^{t-2}$. *The performance ratio of the algorithm in Figure* 3.8 *is* $1 + \frac{2^{t-1}}{2^{t-2}(t+1)-q}$.

5. Discussions.

5.1. Further improvement. Note that an approximate solution produced by the algorithm in Figure 3.8 still uses sequences lifted from the leaves as sequence labels for some internal nodes. Such a solution can be further improved with the iterative method proposed by Sankoff, Cedergren, and Lapalme [10].

To illustrate the iterative method in [10], consider the phylogeny in Figure 5.1, which contains nine given species on its nine leaves. To improve the cost of a loaded tree, we divide the phylogeny into seven 3-components as shown in Figure 5.1, each consisting of a center and three terminals. Local optimization is done for every 3-component based on the labels of its three terminals. The new center label can then be used to update the center label of an overlapping 3-component. The algorithm converges since each local optimization reduces the cost of the tree by at least one. Thus if the process is repeated often enough, every 3-component will become optimal. Empirical results show that the algorithm produces a reasonably good loaded tree within five iterations [10].

If we are able to handle local optimization of size r, $r \geq 3$, we may extend the above iterative method to components with r terminals. Augmenting the algorithm in Figure 3.8 with the iterative method should result in an improved performance. We do not have an error bound analysis for the combined method at this point that is better than the bound given in section 4. However, there is a good way to estimate the error bound of this combined method for a particular input.

5.2. Estimating the error bound for an instance. Theorem 2.1 says that the average cost of the uniformly lifted trees is at most twice that of an optimal solution. Thus, a half of the average cost is a lower bound of the optimal cost. Let $C_{avg}(I)$ be the cost of the average cost of the uniformly lifted trees for some instance I, and let $X(I)$ be the cost of the solution obtained by the combination of the approximation algorithm in Figure 3.8 and the iterative method above for the input I. Then $X(I)$ is at most $\frac{2X(I)}{C_{avg}(I)}$ times the optimum. This suggests a way to estimate the error bound for a particular instance. In [6], an algorithm to compute the average cost of the uniformly lifted trees is proposed. The running time of the algorithm is $O(kdn^2)$. It is demonstrated that this lower bound is reasonably tight.

5.3. Some experimental results. We have implemented our algorithm in C and run the program on a small example from [10]. The given tree topology is shown in Figure 5.1. Each terminal is labeled with an RNA S_5 sequence. The score scheme

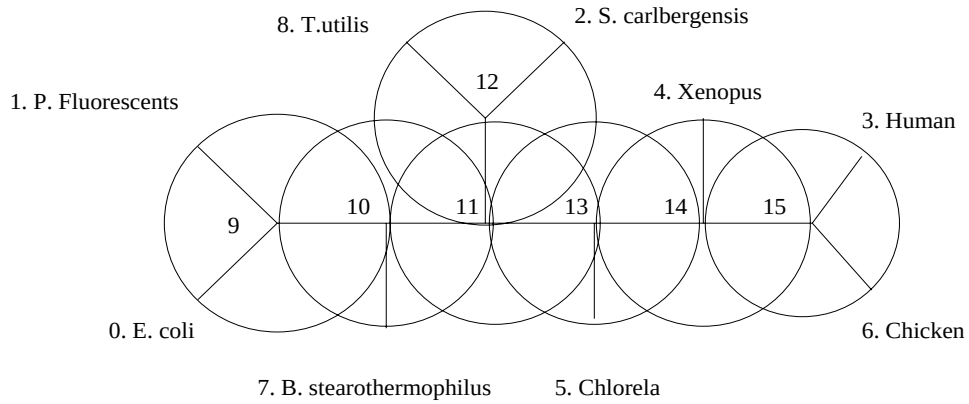

FIG. 5.1. *A phylogeny with nine species, which is divided into seven* 3*-components.*

is the same as in [10]. For $r = 3$, we select the root in the middle of the edge (13,14) and the cost of the corresponding loaded tree is 332.75. For $r = 4$, the same root gives a loaded tree with cost 322.5. Such a cost changes a bit if we try other roots. The average cost of the uniformly lifted trees is 461.6 [6]. Thus we can conclude that the costs of the solutions for $r = 3$ and 4 are at most 1.442 and 1.397 times the optimal for this example. We then use the iterative method of [10] to further improve the solution. The costs are further reduced from 332.75 and 322.5 to 321.25 and 298.25, respectively.

BEYOND COMPETITIVE ANALYSIS*

ELIAS KOUTSOUPIAS† AND CHRISTOS H. PAPADIMITRIOU‡

Abstract. The competitive analysis of online algorithms has been criticized as being too crude and unrealistic. We propose refinements of competitive analysis in two directions: The first restricts the power of the adversary by allowing only certain input distributions, while the other allows for comparisons between information regimes for online decision-making. We illustrate the first with an application to the paging problem; as a byproduct we characterize completely the work functions of this important special case of the k-server problem. We use the second refinement to explore the power of lookahead in server and task systems.

Key words. online algorithms, competitive analysis, paging problem, metrical task systems

1. Introduction.

The area of *online algorithms* [14, 10] shares with complexity theory the following characteristic: Although its importance cannot be reasonably denied (an algorithmic theory of decision-making under uncertainty is of obvious foundational significance and practical relevance), certain aspects of its basic premises, modeling assumptions, and results have been widely criticized with respect to their realism and relation to computational practice. In this work we revisit some of the most often voiced criticisms of *competitive analysis* (the basic framework within which online algorithms have been heretofore studied and analyzed) and propose and explore some better-motivated alternatives.

In competitive analysis, the performance of an online algorithm is compared against an all-powerful adversary on a worst-case input. The *competitive ratio* of a problem—the analogue of worst-case asymptotic complexity for this area—is defined as

$$R = \min_A \max_x \frac{A(x)}{\mathrm{opt}(x)}. \tag{1}$$

Here A ranges over all online algorithms, x ranges over all "inputs," opt denotes the optimum offline algorithm, while $A(x)$ is the cost of algorithm A when presented with input x. This clever definition is both the weakness and strength of competitive analysis. It is a strength because the setting is clear, the problems are crisp and sometimes deep, and the results are often elegant and striking. But it is a weakness for several reasons. First, in the face of the devastating comparison against an all-powerful offline algorithm, a wide range of online algorithms (good, bad, and mediocre) fare equally badly; the competitive ratio is thus not very informative and fails to discriminate or to suggest good approaches. Another aspect of the same problem is that, since a worst-case input decides the performance of the algorithm, the optimal algorithms are often unnatural and impractical and the bounds too pessimistic to be informative

in practice. Even enhancing the capabilities of the online algorithm in obviously desirable ways (such as a limited lookahead capability) brings no improvement to the ratio (this is discussed more extensively later). The main argument for competitive analysis over the classical approach (minimize the expectation) is that *the distribution is usually not known.* However, competitive analysis takes this argument way too far: It assumes that *absolutely nothing* is known about the distribution, that *any distribution* of the inputs is in principle possible; the worst-case "distribution" prevailing in competitive analysis is, of course, a worst-case input with probability one. Such complete powerlessness seems unrealistic to both the practitioner (we always know, or can learn, *something* about the distribution of the inputs) and the theoretician of another persuasion (the absence of a prior distribution, or some information about it, seems very unrealistic to a probabilist or mathematical economist).

The *paging problem,* perhaps the most simple, fundamental, and practically important online problem, is a good illustration of all these points. An unreasonably wide range of deterministic algorithms (both the good-in-practice LRU and the empirically mediocre FIFO) have the same competitive ratio—k, the amount of available memory. Even algorithms within more powerful *information regimes*—for example, any algorithm with lookahead $\ell > 0$ pages—provably can fare no better. Admittedly, there have been several interesting variants of the framework that were at least partially successful in addressing some of these concerns. *Randomized* paging algorithms have more realistic performance [5, 11, 13]. Some alternative approaches to evaluating online algorithms were proposed in [1, 12] for the general case and in [2, 6, 7, 15] specifically for the paging problem.

In this paper we propose and study two refinements of competitive analysis which seem to go a long way toward addressing the concerns expressed above. Perhaps more importantly, we show that these ideas give rise to interesting algorithmic and analytical problems (which we have only begun to solve in this paper).

Our first refinement, *the diffuse adversary model*, removes the assumption that we know nothing about the distribution—without resorting to the equally unrealistic classical assumption that we know all about it. *We assume that the actual distribution D of the inputs is a member of a known class Δ of possible distributions.* That is, we seek to determine, for a given class of distributions Δ, the performance ratio

$$R(\Delta) = \min_A \max_{D \in \Delta} \frac{\mathcal{E}_D(A(x))}{\mathcal{E}_D(\mathrm{opt}(x))}. \tag{2}$$

That is, the adversary picks a distribution D among those in Δ, so that the expected, under D, performance of the algorithm and the offline optimum algorithm are as far apart as possible. Notice that, if Δ is the class of all possible distributions, (1) and (2) coincide since the worst possible distribution is the one that assigns probability one to the worst-case input and probability zero everywhere else. Hence the diffuse adversary model is indeed a refinement of competitive analysis.

In the paging problem, for example, the input distribution specifies, for each page a and sequence of page requests ρ, $\mathrm{Prob}(a|\rho)$—the probability that the next page fault is a, given that the sequence so far is ρ. It is unlikely that an operating system knows this distribution precisely. On the other hand, it seems unrealistic to assume that any distribution at all is possible. For example, suppose that the next page request *is not predictable with absolute certainty:* $\mathrm{Prob}(a|\rho) \leq \epsilon$, for all a and ρ, where ϵ is a real number between 0 and 1 capturing the inherent uncertainty of the request sequence. This is a simple, natural, and quite well-motivated assumption; call

the class of distributions obeying this inequality Δ_ϵ. An immediate question is, What online algorithm achieves the optimal competitive ratio $R(\Delta_\epsilon)$?

As it turns out, the answer is quite interesting. The optimum online algorithm is *robust*—that is, the same for all ϵ's—and turns out to be a familiar algorithm that is also very good in practice: LRU. It is noteworthy that LRU emerges from the analysis as the unique "natural" optimal algorithm, although there are other algorithms that may also be optimal. An important byproduct of our analysis is that, extending the work in [9], we completely characterize the work functions of the paging special case of the k-server problem.

In a preliminary version of this work that appeared in [8], we incorrectly stated that the competitive ratio $R(\Delta_\epsilon)$ is given by a simple Markov chain of $(k+\frac{1}{\epsilon})^{k-1}$ states. In fact, the answer is more complicated. The competitive ratio is given by the "optimal" Markov chain from a family of $k^{(k+\frac{1}{\epsilon})^{k-1}}$ Markov chains of $(k+\frac{1}{\epsilon})^{k-1}$ states each.

The second refinement of competitive analysis that we are proposing deals with the following line of criticism: In traditional competitive analysis, the all-powerful adversary frustrates not only interesting algorithms, but also powerful *information regimes.* The classical example is again from paging: In paging, the best competitive ratio of any online algorithm is k. But what if we have an online algorithm *with a lookahead of ℓ steps*, that is, an algorithm that knows the immediate future? It is easy to see that any such algorithm must fare equally badly as algorithms without lookahead. In proof, consider a worst-case request sequence, $abdc\ldots$, and take its $(\ell+1)$*-stuttered version*, $a^{\ell+1}b^{\ell+1}d^{\ell+1}c^{\ell+1}\ldots$. It is easy to see that an algorithm with lookahead ℓ is as powerless in the face of such a sequence as one without a lookahead. Once more, the absolute power of the adversary blurs practically important distinctions. Still, lookahead is obviously a valuable feature of paging algorithms. How can we use competitive analysis to evaluate its power? Notice that this is not a question about the effectiveness of a single algorithm, but about *classes of algorithms*, about the power of *information regimes*—ultimately, about the value of information.

To formulate and answer this and similar questions we introduce our second refinement of competitive analysis, which we call *comparative analysis.* Suppose that $\mathcal{A}$ and $\mathcal{B}$ are classes of algorithms—typically but not necessarily $\mathcal{A}\subseteq\mathcal{B}$; that is, $\mathcal{B}$ is usually a broader class of algorithms, a more powerful information regime. The *comparative ratio* $R(\mathcal{A},\mathcal{B})$ is defined as follows:

$$R(\mathcal{A},\mathcal{B})=\max_{B\in\mathcal{B}}\min_{A\in\mathcal{A}}\max_{x}\frac{A(x)}{B(x)}. \tag{3}$$

This definition is best understood in terms of a game-theoretic interpretation: $\mathcal{B}$ wants to demonstrate to $\mathcal{A}$ that it is a more powerful class of algorithms. To this end, $\mathcal{B}$ proposes an algorithm B among its own. In response, $\mathcal{A}$ comes up with an algorithm A. Then $\mathcal{B}$ chooses an input x. Finally, $\mathcal{A}$ pays $\mathcal{B}$ the ratio $A(x)/B(x)$. The larger this ratio, the more powerful $\mathcal{B}$ is in comparison to $\mathcal{A}$. Notice that if we let $\mathcal{A}$ be the class of online algorithms and $\mathcal{B}$ the class of all algorithms—online or offline—then (1) and (3) coincide, and $R(\mathcal{A},\mathcal{B})=R$. Hence comparative analysis is indeed a refinement of competitive analysis.

We illustrate the use of comparative analysis by attacking the question of the power of lookahead in online problems of the "server" type: If $\mathcal{L}_\ell$ is the class of all algorithms with lookahead ℓ, and $\mathcal{L}_0$ is the class of online algorithms, then we show

that, in the very general context of *metrical task systems* [3], we have

$$R(\mathcal{L}_0, \mathcal{L}_\ell) = 2\ell + 1,$$

(that is, the ratio is at most $2\ell + 1$ for all metrical task systems, and it is exactly $2\ell + 1$ for some), while in the more restricted context of paging,

$$R(\mathcal{L}_0, \mathcal{L}_\ell) = \min\{\ell + 1, k\}.$$

2. Diffuse adversaries. The competitive ratio for a diffuse adversary[1] is given in (2). In order to make the analysis independent of the initial conditions, we shall allow an additive constant in the numerator. More precisely, a deterministic online algorithm A is c-competitive against a class Δ of input distributions if there exists a constant d such that for all distributions $D \in \Delta$,

$$\mathcal{E}_D(A(x)) \leq c \cdot \mathcal{E}_D(\mathrm{opt}(x)) + d. \tag{4}$$

The competitive ratio of the algorithm A is the infimum of all such c's. Finally, the competitive ratio $R(\Delta)$ of the class of distributions is the minimum competitive ratio achievable by an online algorithm. It is important to observe that Δ is a class of acceptable conditional probability distributions; each $D \in \Delta$ is the distribution of the relevant part of the world conditioned on the currently available information. One can easily extend the definition to randomized online algorithms. However, in this work, we deal only with deterministic online algorithms.

In the case of the paging problem with a set of pages M, Δ is a set of probability distributions on page sequences M^*. An equivalent and perhaps more natural way to describe Δ is by a set of conditional probability distributions, that is, functions of the form $D : M^* \times M \mapsto [0, 1]$, where for all $\rho \in M^*$ $\sum_{a \in M} D(a|\rho) \leq 1$; the sum may be less than 1 because the adversary may choose to end the sequence. In the game-theoretic interpretation, as the sequence of requests ρ develops, the adversary chooses the values of $D(a|\rho)$ from those available in Δ to maximize the ratio. Since we deal with deterministic algorithms, the adversary knows precisely the past decisions of A, but the adversary's choices may be severely constrained by Δ. It is indicative of the power of the diffuse adversary model that most of the proposals for a more realistic competitive analysis are simply special cases of it. For example, the locality of reference in the paging problem [2, 6] is captured by the diffuse adversary model where Δ consists of the following conditional probability distributions: $D(a|\rho b) = 0$ if there is *no* edge from b to a in the *access graph* and $D(a|\rho b) = 0$ or 1 otherwise. Similarly, the Markov paging model [7] and the statistical adversary model [12] are also special cases of the diffuse adversary model. In the first case, the class Δ of distributions contains only one conditional distribution D with $D(\cdot|\rho b) = D(\cdot|b)$, and in the latter case $D \in \Delta$ assigns probability one to some request sequence that satisfies the statistical adversary restriction.

In this section we apply the diffuse adversary model to the paging problem. We shall focus on the class of distributions Δ_ϵ, which contains all functions $D : M^* \times M \mapsto [0, \epsilon]$—that is to say, all conditional distributions with no value exceeding ϵ. But first, we diverge in order to give a useful characterization of work functions for the paging problem.

[1] Diffuse adversaries are not related to the diffusion processes in probability theory which are continuous path Markov processes.

2.1. The structure of paging work functions. Since the paging problem is the k-server problem on uniform metric spaces, certain key concepts from the k-server theory will be very useful (see [9, 4] for a more detailed exposition).

DEFINITION 2.1. *Let k denote the number of page slots in fast memory, and let M be the set of pages. A* configuration *is a k-subset of M; we denote the set of all configurations by C. The* work function *associated with a sequence $\rho \in M^*$, w_ρ (or simply w when ρ is not important or understood from context) is a function $w_\rho : C \mapsto \Re^+$, defined as follows: $w_\rho(X)$ is the optimum number of page replacements when the sequence of requests is ρ and the final memory configuration is X.*

Notice that in some cases, for example, when a configuration X does not contain the last request, some page replacements may occur not because of page faults but because we insist that the final configuration is X.

Henceforth we use the symbols $+$ and $-$ to denote set union and set difference, respectively. Also, we represent unary sets with their element, e.g., we write a instead of $\{a\}$. Finally, we denote the cardinality of a set S by $|S|$.

DEFINITION 2.2. *If w is a work function, define the* support *of w to be all configurations $X \in C$ such that there is no $Y \in C$, different from X, with $w(X) = w(Y) + |X - Y|$.*

Intuitively, the values of w on its support completely determine w: if S is the support, then $w(X) = \min_{Y \in S}\{w(Y) + |X - Y|\}$. Furthermore, we can safely assume that the optimal offline algorithm (or adversary) is in a configuration of the support. To see this consider two configurations X and Y with $w_\rho(X) = w_\rho(Y) + |X - Y|$. Then the optimal offline algorithm has no advantage being in configuration X instead of configuration Y after servicing ρ; it can move from Y to X without exceeding the cost of being at X. In other words, an optimal offline algorithm that replaces a page only when it is necessary is always in a configuration of the support.

The following lemmas, specific to the paging problem and not true in general for the k-server problem, characterize all possible work functions by determining the structure of their support. A similar, but more complicated, characterization is implicit in the work of [11]. The first lemma states that all configurations in the support have the same value, and hence what matters is the support itself, not the values of w on it.

LEMMA 2.3. *The support of a work function w contains only configurations on which w achieves its minimum value.*

Proof. Toward a contradiction assume that there is a configuration A in the support of w such that $w(A) > \min_X w(X)$. Choose now a configuration B with $w(A) > w(B)$ that minimizes $|B - A|$. By the quasi-convexity condition in [9], there are $a \in A - B$ and $b \in B - A$ such that

$$w(A) + w(B) \geq w(A - a + b) + w(B - b + a).$$

Since $w(A) > w(B)$, this holds only if either $w(A) > w(A - a + b)$ or $w(A) > w(B - b + a)$. In the first case, we get that $w(A) = w(A - a + b) + 1$ and this contradicts the assumption that A is in the support of w. The second case also leads to a contradiction since it violates the choice of B with minimum $|B - A|$, because $|(B - b + a) - A| = |B - A| - 1$. □

Since the configuration of the optimal offline algorithm is always in the support, Lemma 2.3 shows that the offline cost to service a request is simply the increase (0 or 1) of the minimum value of a work function. As a result, it can be determined online when the adversary has a page fault.

The next lemma determines the structure of the support.

LEMMA 2.4. *For each work function w there is an increasing sequence of sets $S_1 \subsetneq S_2 \subsetneq \cdots \subsetneq S_k$, with $S_1 = \{r\}$ the most recent request, such that the support of w is precisely*

$$\{X : |X \cap S_j| \geq j \text{ for all } j\}.$$

We postpone the proof of the lemma to introduce some new definitions. We will call a k-tuple $S = (S_1, S_2, \ldots, S_k)$ of the lemma a *signature* of w. A signature of w completely determines its support. But it doesn't have to be unique. For example, a work function whose support consists of only one configuration $\{a_1, \ldots, a_k\}$ has $k!$ signatures (for each permutation σ let $S_j = \{a_{\sigma_1}, \ldots, a_{\sigma_j}\}$). We define the *type* of w to be the k-tuple $\mathbb{P} = (|S_1| = 1, |S_2|, \ldots, |S_k|)$. Although a work function may have many signatures, its type is unique; it is easy to see that a work function has more than one signature only when there is a $j > 1$ such that $|S_i| = i$ for $1 \leq i \leq j$.

We now prove Lemma 2.4.

Proof of Lemma 2.4. The proof is by induction on the length of the request sequence. The basis case is obvious: Let $S_j = \{a_1, \ldots, a_j\}$, where $\{a_1, \ldots, a_k\}$ is the initial configuration. For the induction step assume that we have a signature $(S_1, S_2, \ldots, S_k)$ of w, and let w' be the resulting work function after request r.

Consider first the case that r belongs to S_t and not to S_{t-1} for some $t \in \{2, 3, \ldots, k\}$. Since there is at least one configuration in the support of w that contains the request r, the minimum value of w' is the same as the minimum value of w. Therefore, the support of w' is a subset of the support of w. It consists of the configurations that belong to the support of w and contain the most recent request r. It is easy now to verify that w' has the following signature:

$$\begin{aligned} S'_1 &= \{r\}; \\ S'_i &= S_{i-1} + r, \qquad 2 \leq i \leq t; \\ S'_i &= S_i, \qquad t < i \leq k. \end{aligned}$$

If, on the other hand, the request r does not belong to S_k, the minimum value of w' is one more than the minimum value of w. In this case, the support of w' consists of all configurations in the support of w where one point has been replaced by the request r, i.e., a server has been moved to service r. Consequently, a signature of w' is given by

$$\begin{aligned} S'_1 &= \{r\}; \\ S'_i &= S_i + r, \qquad 1 < i \leq k. \end{aligned}$$

The induction step now follows. □

Note that the converse of the lemma, not needed in what follows, also holds: Any such tower of S_j's defines a reachable work function, that is, there exists w_ρ for some ρ with signature S.

We define the *canonical ordering* to be a permutation of all pages such that page a precedes page b when a has been requested more recently than b. Furthermore, pages that have not been requested are ordered according to a fixed ordering (for example, the lexicographic ordering). For example, if the canonical ordering after request sequence ρ is $a_1 \ldots a_m$, then ρ has the form $\ldots a_4(a_3|a_2|a_1)^* a_3(a_2|a_1)^* a_2(a_1)^* a_1$. An obvious property of the canonical ordering is that a new request a_j doesn't change the ordering except from the movement of a_j to the front.

It follows from the proof of Lemma 2.4 that if we know the canonical ordering $a_1 a_2 \dots$ and the type $(p_1, \dots, p_k)$ of a work function w, we can determine a signature $(S_1, \dots, S_k)$ of the work function: S_i consists of the first p_i pages of the canonical ordering, i.e., $S_i = \{a_1, \dots, a_{p_i}\}$. We will call this signature the *canonical signature* of w.

For a type $\mathbb{P} = (p_1 = 1, p_2, \dots, p_k)$ that corresponds to a canonical signature $S = (S_1, S_2, \dots, S_k)$, we will denote by $\mathbb{P}_j$ the type that results from a request in $S_{j+1} - S_j$. From the proof of Lemma 2.4, we get

$$\begin{aligned}
&\mathbb{P}_0 = \mathbb{P},\\
&\mathbb{P}_1 = (1, p_1 + 1, p_3, p_4, \dots, p_k),\\
&\mathbb{P}_2 = (1, p_1 + 1, p_2 + 1, p_4, \dots, p_k),\\
&\quad\vdots\\
&\mathbb{P}_{k-1} = (1, p_1 + 1, p_2 + 1, p_3 + 1, \dots, p_{k-1} + 1), \text{ and}\\
&\mathbb{P}_k = (1, p_2 + 1, p_3 + 1, \dots, p_k + 1).
\end{aligned}$$

The first type $\mathbb{P}_0$ corresponds to a request in S_1 and the last type to a request not in S_k. We will also use the following notation: For types $\mathbb{P} = (p_1, p_2, \dots, p_k)$ and $\mathbb{Q} = (q_1, q_2, \dots, q_k)$ we write $\mathbb{P} \le \mathbb{Q}$ (or $\mathbb{Q} \ge \mathbb{P}$) if for all $j = 1, 2, \dots, k$: $p_j \le q_j$. We also write $\mathbb{P} \trianglelefteq \mathbb{Q}$ (or $\mathbb{Q} \trianglerighteq \mathbb{P}$) if for all $j = 1, 2, \dots, k-1$: $p_j \le q_{j+1}$. The motivation for this notation is the relation between $\mathbb{P}_{k-1}$ and $\mathbb{P}_k$: $\mathbb{P}_{k-1} \trianglerighteq \mathbb{P}_k$. In addition, $\mathbb{P}_0 \ge \mathbb{P}_1 \ge \mathbb{P}_2 \ge \cdots \ge \mathbb{P}_{k-1} \trianglerighteq \mathbb{P}_k$.

We can now state the following crucial property of work functions.

LEMMA 2.5. *Let ρ and ρ' be two request sequences that result in the same canonical ordering. Let $\mathbb{P}$ and $\mathbb{Q}$ be the types of the two work functions $w = w_\rho$ and $w' = w_{\rho'}$, respectively. If $\mathbb{P} \le \mathbb{Q}$, then any configuration in the support of w is also in the support of w'. Furthermore, if $\mathbb{P} \trianglelefteq \mathbb{Q}$, then for any configuration in the support of w there is configuration in the support of w' that differs in at most one position.*

Proof. Let $S = (S_1, S_2, \dots, S_k)$ and $S' = (S'_1, S'_2, \dots, S'_k)$ be the canonical signatures of w and w'. The first case of the lemma, when $\mathbb{P} \le \mathbb{Q}$, is trivial since $S_j \subset S'_j$, $j = 1, 2, \dots, k$. For the second case, when $\mathbb{P} \trianglelefteq \mathbb{Q}$, it suffices to handle the "largest" possible $\mathbb{P}$, so we may assume that $S_{j-1} = S'_j$, for $j = 3, \dots, k-1$. Consider now a configuration X in the support of w. We will show that there is a configuration Y in the support of w' such that $|Y - X| \le 1$. Let x_k be the last page of X in the canonical ordering. Also, let b be the first page of the canonical ordering not in $X - x_k$. We claim that $Y = X - x_k + b$, which differs in at most one position from X, is in the support of w'. Notice first that Y contains the page in S_1. It also contains the second page of the canonical ordering because either this page is in $X - x_k$ or it is equal to b. It remains to show that $|Y \cap S'_j| \ge j$, for $j = 3, \dots, k$. There are two cases to consider: The first case, when $|X \cap S_{j-1}| \ge j$, follows from the fact that x_k is in S'_j $(= S_{j-1})$ only if b is in S'_j. For the second case, when $|X \cap S_{j-1}| = j - 1$, it suffices to note that $b \in S'_j$ but $x_k \notin S'_j$. □

2.2. Optimality of LRU. We now turn to the Δ_ϵ diffuse adversary. Our goal in this section is to show that LRU has optimal competitive ratio against a diffuse adversary. The usual approach to show that an online algorithm has optimal competitive ratio is to compute its ratio and then show that every other algorithm has no smaller competitive ratio. The difficulty here is that we cannot compute the competitive ratio of LRU. Thus we have to compare LRU directly with any other online algorithm. More precisely, we have to show that for any online algorithm A and any adversary

(conditional probability distribution) $D \in \Delta_\epsilon$, there is an adversary $D' \in \Delta_\epsilon$ such that the competitive ratio of A against D' is at least the competitive ratio of LRU against D. We have to face the problem that D may be very complicated and A may be erratic.

We attack the problem in two steps. First, we "standardize" the class of adversaries, by showing that it suffices to consider only a class of adversaries which we call *conservative* (to be defined shortly). In particular, we will show that for any $D \in \Delta_\epsilon$ there is a better conservative adversary $\hat{D} \in \Delta_\epsilon$ against LRU, i.e., LRU has a competitive ratio against $\hat{D}$ that is no less than that against D. Second, we show that for any conservative $D \in \Delta_\epsilon$ against LRU, there is a conservative adversary $D' \in \Delta_\epsilon$ against A, such that the competitive ratio of LRU against D is at most the competitive ratio of A against D'.

To understand why LRU is optimal against diffuse adversaries and to motivate the notion of conservatives adversaries, we start by asking what property an optimal online algorithm must have. Intuitively, if $(S_1, \ldots, S_k)$ is a signature of the current work function w, an optimal online algorithm should prefer to have in its fast memory pages from S_i instead of pages not in S_i. The intuition is that pages in S_i are more valuable to the offline algorithm than pages not in S_i, because a configuration from the support of w remains in the support when we replace any page not in S_i with a page in S_i; the converse does not hold in general. LRU does exactly this. In fact, LRU keeps in its fast memory the first k pages of the canonical ordering (with appropriate initialization).

The same intuition suggests that the adversary should prefer as next request a page $a \in S_i$ to a page $b \notin S_i$; the only exception being when a is in the online cache and b is not. In this case, it is unclear which page (a or b) the adversary should choose because of the following trade-off: On the one hand, b is more favorable because it increases the online cost, whereas a does not. On the other hand, a is more favorable since either the resulting support is larger or b increases the offline cost. The above intuition suggests the notion of conservative adversary. A conservative adversary assigns probability that favors pages with smaller rank in the canonical ordering among the pages in the online cache and similarly for the pages not in the online cache. To be more precise, fix a request sequence ρ that results in canonical ordering $a_1 a_2 \ldots$ and configuration C of an online algorithm A. A conservative adversary against A assigns probabilities with the property that for every $a_i, a_j \in C$ with $i < j$, a_j receives positive probability, $D(a_j|\rho) > 0$, only if a_i receives maximum probability, $D(a_i|\rho) = \epsilon$. Similarly for pages $a_i, a_j \notin C$. Thus the probabilities $D(\cdot|\rho)$ are completely determined by the total probability z assigned to pages in C. We add an additional constraint, although the proofs do not call for it: At most one page receives probability that is not zero or ϵ (equivalently either z or $1 - z$ is an integral multiple of ϵ). For example, if $\epsilon = 1/5$, the online cache C consists of pages $1, 3, 4, 5$ of the canonical ordering, and $z = 2/5$, then pages $1, 2, 3, 6, 7$ receive probability ϵ.

It seems reasonable that an optimal adversary against LRU is conservative and indeed we are going to prove shortly that this is the case. For other online algorithms, however, conservative adversaries may not be optimal, especially for "unreasonable" and highly suboptimal online algorithms. A central idea of our proof is to disregard this problem. Even if conservative adversaries are not optimal against an online algorithm A, it suffices to show that there is a conservative adversary that forces a competitive ratio no less than the ratio of LRU. We now show that an optimal adversary against LRU is conservative.

LEMMA 2.6. *For any $D \in \Delta_\epsilon$, there is a conservative adversary $\hat{D} \in \Delta_\epsilon$ such that the competitive ratio of LRU against $\hat{D}$ is at least the competitive ratio of LRU against D.*

Proof. The proof is by induction on the number of requests. To facilitate induction, we use a strong inductive hypothesis. First, we allow any initial work function (instead of the work function whose support contains only one configuration). Let $\mathrm{opt}(\rho, \mathbb{P}, C)$ be the optimal cost to service ρ when the initial work function has type $\mathbb{P}$ and canonical ordering C. For simplicity, in our notation we use only the type of work functions and we write $\mathrm{opt}(\rho, \mathbb{P})$ instead of $\mathrm{opt}(\rho, \mathbb{P}, C)$. Notice also that the initial type does not affect the behavior of LRU at all, so we can simply write $\mathrm{LRU}(\rho)$ to denote the cost of *LRU* for the sequence request ρ.

Second, since we don't know the competitive ratio of LRU, we simply use the fact that the competitive ratio is positive (although we could safely assume a competitive ratio at least 1). More precisely, the inductive hypothesis is that for any $D \in \Delta_\epsilon$, any n, and any $c > 0$ there is a conservative $\hat{D}$ such that $\mathcal{E}_D(LRU(x_n) - c \cdot \mathrm{opt}(x_n, \mathbb{P})) \leq \mathcal{E}_{\hat{D}}(LRU(x_n) - c \cdot \mathrm{opt}(x_n, \mathbb{P}))$, where $\mathbb{P}$ is the type of the initial work function and x_n denotes a sequence of length n drawn from the conditional probability distribution D or $\hat{D}$. Equivalently, we will show that there is a conservative D that maximizes

$$\psi(D, n, \mathbb{P}) = \mathcal{E}_D(LRU(x_n) - c \cdot \mathrm{opt}(x_n, \mathbb{P})). \tag{5}$$

We use induction on the number of requests n. For $n = 0$, there is nothing to prove. Assume now that the induction hypothesis holds for $n-1$ and let D be a distribution that maximizes $\mathcal{E}_D(LRU(x_n) - c \cdot \mathrm{opt}(x_n, \mathbb{P}))$. If D is not conservative, we will show how to alter it to get a conservative adversary $\hat{D}$ that also maximizes $\psi(\hat{D}, n, \mathbb{P})$.

The proof proceeds as follows: Although D may not be conservative, by induction it becomes conservative after the first request. So, we want to show that the first request is also "conservative." Denote by D_j the resulting conditional distribution when the first request is the jth request a_j of the canonical ordering, i.e., $D_j(\cdot|\rho) = D(\cdot|a_j\rho)$. Let also $\mathbb{P}^{(j)}$ denote the type of the work function that results after request a_j. If $(S_1, \ldots, S_k)$ is the initial canonical signature, then

$$\psi(D, n, \mathbb{P}) = \sum_{j \geq 1} D(a_j) \cdot \left[\psi(D_j, n-1, \mathbb{P}^{(j)}) + I(j > k) - c \cdot I(a_j \notin S_k) \right], \tag{6}$$

where $D(a_j) = D(a_j|\varepsilon)$ is the probability assigned to page a_j conditioned on the empty sequence ε, and $I(\phi)$ is the indicator function that takes value 1 when ϕ is true and 0 otherwise. The last two terms inside the sum of the right-hand side correspond to the online and the offline cost for the first request. By induction, we can replace D_j with a conservative $\hat{D}_j$ without decreasing the right-hand side of (6). So, without loss of generality, we assume that the distributions D_j are conservative.

If we fix the conditional distributions D_j, the optimal probabilities for the first request can be computed as follows: order the pages in decreasing $\psi(D_j, n-1, \mathbb{P}^{(j)}) + I(j > k) - c \cdot I(a_j \notin S_k)$ value, assign probability ϵ to the first $\lfloor 1/\epsilon \rfloor$ pages, and assign the remaining probability (which of course is less than ϵ) to the next page.

We simply want to guarantee that the probabilities are assigned in a conservative manner. Equivalently, if $i < j \leq k$ (both a_i and a_j are in LRU's cache) or when

$k < i < j$ (neither a_i nor a_j are in LRU's cache), it suffices to show that

$$\psi(D_i, n-1, \mathbb{P}^{(i)}) + I(i > k) - c \cdot I(a_i \notin S_k) \geq \psi(D_j, n-1, \mathbb{P}^{(j)}) + I(j > k) - c \cdot I(a_j \notin S_k). \tag{7}$$

We first consider the case of $i < j \leq k$. The crucial point for establishing (7) is that we can assume

$$\psi(D_i, n-1, \mathbb{P}^{(i)}) \geq \psi(D_j, n-1, \mathbb{P}^{(j)}). \tag{8}$$

To see this, let us consider the adversary $\hat{D}$ that is identical to D but when the first request is a_i, it continues like D_j instead of D_i (taking into account the difference in the canonical orderings). Formally, if $b_1 b_2 \ldots$ is the canonical ordering that results when the first request is a_j and $b'_1 b'_2 \ldots$ when the first request is a_i, then $\hat{D}(b'_l | a_i b'_{l_1} \ldots b'_{l_m}) = D(b_l | a_j b_{l_1} \ldots b_{l_m})$. We then have $\psi(\hat{D}, n, \mathbb{P}) = \psi(D, n, \mathbb{P}) + D(a_i)(\psi(D_j, n-1, \mathbb{P}^{(i)}) - \psi(D_i, n-1, \mathbb{P}^{(i)}))$.

But since $\mathbb{P}^{(i)} \geq \mathbb{P}^{(j)}$, we can apply Lemma 2.5 and get $\mathrm{opt}(x_{n-1}, \mathbb{P}^{(i)}) \leq \mathrm{opt}(x_{n-1}, \mathbb{P}^{(j)})$, which in turn implies that $\psi(D_j, n-1, \mathbb{P}^{(i)}) \geq \psi(D_j, n-1, \mathbb{P}^{(j)})$. Thus $\psi(\hat{D}, n, \mathbb{P}) \geq \psi(D, n, \mathbb{P}) + D(a_i)(\psi(D_j, n-1, \mathbb{P}^{(j)}) - \psi(D_i, n-1, \mathbb{P}^{(i)}))$. If (8) does not hold, then $\psi(\hat{D}, n, \mathbb{P}) \geq \psi(D, n, \mathbb{P})$; hence, $\hat{D}$ maximizes ψ and of course has the desired property (8).

Combining (8) and the fact that $I(i > k) = I(j > k) = I(a_i \notin S_k) = I(a_j \notin S_k) = 0$, we get that (7) holds for $i < j \leq k$.

Inequality (7) holds for $k < i < j$. An identical argument as above establishes it for the case of $a_i, a_j \in S_k$ or $a_i, a_j \notin S_k$. The remaining case, when $a_i \in S_k$ and $a_j \notin S_k$, is treated similarly. In this case, we have that $\mathbb{P}^{(i)} \trianglerighteq \mathbb{P}^{(j)}$, which implies $\mathrm{opt}(x_{n-1}, \mathbb{P}^{(i)}) \leq \mathrm{opt}(x_{n-1}, \mathbb{P}^{(j)}) + 1$. The last inequality implies $\psi(D_i, n-1, \mathbb{P}^{(i)}) \geq \psi(D_j, n-1, \mathbb{P}^{(j)}) - c$, and together with the facts that $I(i > k) = I(j > k) = 1$, $I(a_i \notin S_k) = 0$, and $I(a_j \notin S_k) = 1$, we get (7). □

The above lemma establishes that the best adversary against LRU is conservative. We can now proceed to the second part of the proof that LRU has optimal competitive ratio. We will show that for any online algorithm A and any conservative adversary $D \in \Delta_\epsilon$ against LRU, there is an adversary $D' \in \Delta_\epsilon$ against A such that the competitive ratio of LRU against D is at most the competitive ratio of A against D'. The main idea for constructing a D' is by enforcing the online cost of LRU against D to be equal to the online cost of A against D'. This allows us to compare the competitive ratios of LRU and A, simply by comparing the corresponding offline costs.

Given D, how can we design D' so that cost of LRU against D is equal to the cost of A against D'? For the first request it is obvious: the probability that D' assigns to pages in the cache of A should be equal to the probability that D assigns to pages in LRU's cache. But for the second and subsequent requests, the situation depends on previous requests (the outcome of random experiments). In general, a conservative adversary against an algorithm B corresponds to an (infinite) rooted tree T with outdegree $\lceil 1/\epsilon \rceil$ such that each node v has weight $z(v)$ in $[0, \min\{k\epsilon, 1\}]$; furthermore, either $z(v)$ or $1 - z(v)$ is an integral multiple of ϵ. Paths on this tree correspond to request sequences and the values $z(v)$ are the total probability assigned by the adversary to pages in the online cache. More precisely, a request sequence is produced by starting at the root and descending down the tree. At a node v the adversary assigns probabilities in a conservative manner so that the total probability assigned to pages of the current cache of B is $z(v)$. Since the adversary is conservative, at most $l = \lceil 1/\epsilon \rceil$

pages receive nonzero probability. Let $r_1, \ldots, r_l$ be these pages (first the pages in the current cache of B and then the pages outside the cache in the canonical order). If the next request (the outcome of the random experiment) is r_j, the adversary moves to the jth child of v and repeats the process to produce the next request. We will call this conservative adversary the *adversary based on T against B* and we will denote it by $D_{T(B)}$. Notice that the conditional probability distribution $D_{T(B)}$ depends on the online algorithm B (for another algorithm B' it may be different). It also depends on the initial configuration of B, although for simplicity we omit this dependence in our notation.

It is now simple to design D' so that the expected cost of A against D' is equal to the expected cost of LRU against D: if T is the tree such that $D = D_{T(\mathrm{LRU})}$, then $D' = D_{T(A)}$. It suffices to show that the expected optimum cost against D is no less than the expected optimum cost against D'. More precisely, we will show that the expected offline cost to service a request sequence of length n produced by $D_{T(\mathrm{LRU})}$ is no less than the offline cost to service a request sequence of length n produced by $D_{T(A)}$.

We will use induction on the length n of the request sequence. In order to facilitate induction, we generalize the problem by assuming any initial work function. As in the proof of Lemma 2.6, our notation will include only the type of the work function. More precisely, let $h_{T(A)}(n, \mathbb{P})$ denote the expected offline cost to service a request sequence of length n produced by the conditional distribution $D_{T(A)}$ when the initial work function has type $\mathbb{P}$. We will show that for every $\mathbb{P}$: $h_{T(\mathrm{LRU})}(n, \mathbb{P}) \geq h_{T(A)}(n, \mathbb{P})$. But first, we need the following simple lemma.

LEMMA 2.7. *For all conservative adversaries T, if $\mathbb{P} \leq \mathbb{Q}$, then $h_{T(LRU)}(n, \mathbb{P}) \geq h_{T(LRU)}(n, \mathbb{Q})$, and if $\mathbb{P} \trianglelefteq \mathbb{Q}$, then $h_{T(LRU)}(n, \mathbb{P}) + 1 \geq h_{T(LRU)}(n, \mathbb{Q})$.*

Proof. The crucial observation is that LRU does not depend on the initial type of the work function, but only on the initial canonical ordering. An immediate consequence is that the conditional probability distribution $T(\mathrm{LRU})$ is independent of the initial work function. Consider first the case of $\mathbb{P} \leq \mathbb{Q}$. By Lemma 2.5, the offline cost to service a request sequence starting with a work function w of type $\mathbb{P}$ cannot be less than the offline cost to service the same request sequence starting with a work function w' of type $\mathbb{Q}$ and the same canonical ordering with w. Therefore, $h_{T(\mathrm{LRU})}(n, \mathbb{P}) \geq h_{T(\mathrm{LRU})}(n, \mathbb{Q})$. The other case, $\mathbb{P} \trianglelefteq \mathbb{Q}$, is handled similarly. □

We are now ready to show that the expected offline cost of a request sequence produced by a tree T is maximized when the online algorithm is the LRU algorithm.

LEMMA 2.8. *For every tree T and every online algorithm A, $h_{T(LRU)}(n, \mathbb{P}) \geq h_{T(A)}(n, \mathbb{P})$.*

Proof. By induction on n. For $n = 0$, the lemma is trivially true. Assume that the lemma holds for $n-1$. Denote by T_j the subtree rooted at the jth child of the root of T. Let r_A and r_{LRU} be the request that is produced when the adversary descends to T_j for algorithms A and LRU, respectively. Let also $\mathbb{P}_{i_A}$, $\mathbb{P}_{i_{\mathrm{LRU}}}$ denote the resulting type after requests r_A and r_{LRU}. It is important to notice that $i_A \leq i_{\mathrm{LRU}}$; this is the only property of algorithm A used in the proof.

Child j is chosen with probability that depends on the value $z(v)$, where v is the root of T. This probability is ϵ for all values of j except of one child when $1/\epsilon$ is not an integer. Obviously, $h_{T(A)}(n, \mathbb{P})$ is equal to the expected value of $h_{T_j(A)}(n-1, \mathbb{P}_{i_A})$ plus the offline cost for the first request; the offline cost is 0 when $i_A < k$ and it is 1 when $i_A = k$. In other words $h_{T(A)}(n, \mathbb{P}) = E[h_{T_j(A)}(n-1, \mathbb{P}_{i_A}) + I(i_A = k)]$. A similar expression holds also for $h_{T(LRU)}(n, \mathbb{P})$. It suffices therefore to show that for

all j: $h_{T_j(A)}(n-1,\mathbb{P}_{i_A}) + I(i_A = k) \le h_{T_j(LRU)}(n-1,\mathbb{P}_{i_{\mathrm{LRU}}}) + I(i_{\mathrm{LRU}} = k)$.

We consider three cases according to the values of i_A and i_{LRU}. In the first case, $i_A \le i_{\mathrm{LRU}} < k$, we get

$$\begin{aligned} h_{T_j(A)}(n-1,\mathbb{P}_{i_A}) + I(i_A = k) &= h_{T_j(A)}(n-1,\mathbb{P}_{i_A}) \\ &\le h_{T_j(\mathrm{LRU})}(n-1,\mathbb{P}_{i_A}) \\ &\le h_{T_j(\mathrm{LRU})}(n-1,\mathbb{P}_{i_{\mathrm{LRU}}}) \\ &= h_{T_j(\mathrm{LRU})}(n-1,\mathbb{P}_{i_{\mathrm{LRU}}}) + I(i_{\mathrm{LRU}} = k), \end{aligned}$$

where the first inequality follows from the induction hypothesis and the second one from Lemma 2.7, because $\mathbb{P}_{i_A} \ge \mathbb{P}_{i_{\mathrm{LRU}}}$. In the second case, $i_A < i_{\mathrm{LRU}} = k$, we get $h_{T_j(A)}(n-1,\mathbb{P}_{i_A}) + I(i_A = k) = h_{T_j(A)}(n-1,\mathbb{P}_{i_A}) \le h_{T_j(\mathrm{LRU})}(n-1,\mathbb{P}_{i_A}) \le h_{T_j(\mathrm{LRU})}(n-1,\mathbb{P}_{i_{\mathrm{LRU}}}) + 1 = h_{T_j(\mathrm{LRU})}(n-1,\mathbb{P}_{i_{\mathrm{LRU}}}) + I(i_{\mathrm{LRU}} = k)$. Again, the first inequality follows from the induction hypothesis and the second one from Lemma 2.7, because $\mathbb{P}_{i_A} \trianglerighteq \mathbb{P}_{i_{\mathrm{LRU}}}$. Finally, the third case, $i_A = i_{\mathrm{LRU}} = k$, is handled similarly: $h_{T_j(A)}(n-1,\mathbb{P}_{i_A}) + I(i_A = k) = h_{T_j(A)}(n-1,\mathbb{P}_{i_A}) + 1 \le h_{T_j(\mathrm{LRU})}(n-1,\mathbb{P}_{i_{\mathrm{LRU}}}) + 1 = h_{T_j(\mathrm{LRU})}(n-1,\mathbb{P}_{i_{\mathrm{LRU}}}) + I(i_{\mathrm{LRU}} = k)$. □

The above lemmas establish the main result of this section.

THEOREM 2.9. *For any ϵ, LRU has optimal competitive ratio $R(\Delta_\epsilon)$ for the paging diffuse adversary model.*

The above lemmas, however, do not provide any efficient way to estimate the competitive ratio $R(\Delta_\epsilon)$. The approach suggested by the lemmas is to nondeterministically guess the optimal conservative adversary and then compute the competitive ratio of LRU against this adversary. A conservative adversary is determined by the values $z(v)$ that are multiples of ϵ when $1/\epsilon$ is an integer; it is slightly more complicated when $1/\epsilon$ is not an integer. For a given conservative adversary, the competitive ratio of LRU is given by a finite Markov chain; the states of the Markov chain are all reachable types and there are at most $(k+1/\epsilon)^{k-1}$ such types. This approach provides a doubly exponential algorithm (approximately $k^{(k+1/\epsilon)^{k-1}}$) to compute $R(\Delta_\epsilon)$. It is an interesting open problem to determine $R(\Delta_\epsilon)$ as a function of ϵ. For the extreme values of ϵ, we know that $R(\Delta_1) = k$ and $\lim_{\epsilon\to 0} R(\Delta_\epsilon) = 1$. In the first case, the adversary has complete power and in the second case, it suffers a page fault in almost every step. Recently, Young [16] estimated $R(\Delta_\epsilon)$ within (almost) a factor of two; $R(\Delta_\epsilon)$ is between $\Phi(\epsilon,k) - 1$ and $2\Phi(\epsilon,k)$, where $\Phi(\epsilon,k) = 1 + \sum_{i=1}^{k-1} 1/\max\{1/\epsilon - i, 1\}$ (this is approximately $\ln \frac{1}{1-(k-1)\epsilon}$ for $\epsilon > 1/k$, and $k + 1 - 1/\epsilon$ otherwise).

Even for the simplest case of $k = 2$, determining the competitive ratio is not trivial. Here we give a lower bound which we believe is exact. This is the competitive ratio against the conservative adversary that always assigns nonzero probability to exactly one page from the pages in the online fast memory.

PROPOSITION 2.10. *For $k = 2$, if $n = 1/\epsilon - 1$ is an integer, then*

$$R(\Delta_\epsilon) \ge \frac{\sum_{i=0}^{n} n^i/i!}{\sum_{i=0}^{n-1} n^i/i!} \in [1 + \sqrt{\epsilon}/2, 1 + 2\sqrt{\epsilon}].$$

Proof. Consider the conservative adversary that always assigns probability ϵ to pages of the current canonical ordering with rank $1, 3, 4, \ldots, 1/\epsilon + 1$. Notice that page 2 is assigned zero probability. The request on the page of rank 1 is identical to the previous request and does not change anything. Thus, this adversary is equivalent to the adversary that assigns probability $\delta = \epsilon/(1-\epsilon) = 1/n$ to pages with rank $3, 4, \ldots, 1/\epsilon + 1$.

Let $(1, p_2)$ be the type of the current work function. The following table summarizes the possibilities of the next request, together with the probability, the resulting type, and the associated online and offline cost for servicing the request.

Request	Probability	Type	Online cost	Offline cost
$3 \dots p_2$	$(p_2 - 2)\delta$	$(1, 2)$	1	0
$p_2 + 1 \dots 1/\delta + 2$	$1 - (p_2 - 2)\delta$	$(1, p_2 + 1)$	1	1

In summary, the competitive ratio is given by a Markov chain M_δ with states the types $(1, p_2)$ for $p_2 = 2, 3, \dots, 1/\delta + 2$. The transition probabilities from state $(1, p_2)$ are given in the above table. It is not difficult to see that the Markov process is identical to the following random process: In each phase repeatedly choose uniformly a number from $\{1, 2, \dots, n\}$, where $n = 1/\delta$; a phase ends when a number is chosen twice. The state $(1, p_2)$ of M_δ corresponds to the case that $p_2 - 2$ numbers have been drawn. This random process is a generalization of the well-known *birthday* problem in probability theory. A phase corresponds to a cycle in the Markov chain that starts (and ends) at state with type $(1, 2)$. The expected offline cost per phase is equal to the length of a phase minus one (all transitions in the cycle have offline cost one except the last one). Similarly, the expected online cost per phase is equal to the length of a phase (all transitions have online cost one). It is not hard now to verify the expression for $R(\Delta_\epsilon)$.

For the purpose of bounding the expected length of a phase, notice that each of the first $\sqrt{n}$ numbers has probability at most $1/\sqrt{n}$ to end the phase. In contrast, each of the next $\sqrt{n}$ numbers has probability at least $1/\sqrt{n}$ to end the phase. Elaborating on this observation we get that R_ϵ is in the interval $[1 + \sqrt{\epsilon}/2, 1 + 2\sqrt{\epsilon}]$.

Numerical evaluations suggest that the value of R_ϵ is approximately $1 + 0.8\sqrt{\epsilon}$, when $\epsilon \to 0$. □

A preliminary version of this work [8] had an incorrect proof of optimality of LRU. The proof was based on the unjustified assumption that a conservative adversary that achieves optimal competitive ratio against LRU assigns probability ϵ to exactly one page in the online fast memory. As was pointed out to us by Neal Young (see also [16]), this assumption does not hold in general.

An important open problem is to determine the competitive ratio of known paging algorithms against a diffuse adversary. The most important direction is to estimate the competitive ratio of FIFO. The recent work of Young [16] estimates the competitive ratio of marking algorithms—both LRU and FIFO are marking algorithms—almost within a factor of 2. He gives similar bounds for randomized algorithms. Our proof of the optimality of LRU seems to suggest that for certain values of ϵ, the competitive ratio of FIFO is not optimal. In particular, FIFO does not always keep in its fast memory the first k pages of the canonical ordering or an equivalent set of pages. This then is an indication that a conservative adversary may force FIFO to have larger cost than LRU. We conjecture that FIFO is suboptimal for some values of ϵ. If indeed this is the case, it will add some extra validity to the paging diffuse adversary model, in the sense that the model can actually distinguish between LRU and FIFO.

3. Comparative analysis. Online algorithms deal with the relations between *information regimes*. Formally but briefly, an information regime is the class of all functions from a domain D to a range R that are constant within a fixed partition of D. Refining this partition results in a richer regime. Traditionally, the literature on online algorithms has been preoccupied with comparisons between two basic information regimes: the *online* and the *offline* regime (the offline regime corresponds to the fully

refined partition). As we argued in the introduction, this has left unexplored several intricate comparisons between other important information regimes.

Comparative analysis is a generalization of competitive analysis allowing comparisons between arbitrary information regimes, via the comparative ratio defined in (3). Naturally, such comparisons make sense only if the corresponding regimes are rich in algorithms—single algorithms do not lend themselves to useful comparisons. As in the case of the competitive ratio for the diffuse adversary model, we usually allow an additive constant in the numerator of (3).

We apply comparative analysis in order to evaluate the power of *lookahead* in task systems. An online algorithm for a metrical task system has lookahead ℓ if it can base its decision not only on the past but also on the next ℓ requests. All online algorithms with lookahead ℓ comprise the information regime $\mathcal{L}_\ell$. Thus, $\mathcal{L}_0$ is the class of all traditional online algorithms.

Metrical task systems [3] are defined on some metric space $\mathcal{M}$; a server resides on some point of the metric space and can move from point to point. Its goal is to process online a sequence of tasks $T_1, T_2, \ldots$. The server is free to move to any position before processimg a task, although it has to pay the distance. The cost $c(T_j, a_j)$ for processing a task T_j is determined by the task T_j and the position a_j of the server while processing the task. The total cost for processing the sequence is the sum of the distance moved by the server plus the cost of servicing each task T_j, $j = 1, 2, \ldots$.

THEOREM 3.1. *For any metrical task system, $R(\mathcal{L}_0, \mathcal{L}_\ell) \leq 2\ell + 1$. Furthermore, there are metrical task systems for which $R(\mathcal{L}_0, \mathcal{L}_\ell) = 2\ell + 1$.*

Proof. Trivially the theorem holds for $\ell = 0$. Assume that $\ell > 0$ and fix an algorithm B in $\mathcal{L}_\ell$. We shall define an online algorithm A without lookahead whose cost on any sequence of tasks is at most $2\ell + 1$ times the cost of B. Algorithm A is a typical online algorithm in comparative analysis: it tries to efficiently "simulate" the more powerful algorithm B. In particular, A knows the position of B ℓ steps ago. In order to process the next task, A moves first to B's last known position, and then processes the task greedily, that is, with the minimum possible cost.

Let $T_1, T_2, \ldots$ be a sequence of tasks and let $b_1, b_2, \ldots$ be the points where algorithm B processes each task and $a_1, a_2, \ldots$ the corresponding points for algorithm A. For simplicity, we define also points $b_j = a_j = a_0$ for negative j's.

Then the cost of algorithm B is

$$\sum_{j \geq 1} \left(d(b_{j-1}, b_j) + c(T_j, b_j) \right)$$

and the cost of algorithm A is

$$\sum_{j \geq 1} \left(d(a_{j-1}, b_{j-\ell}) + d(b_{j-\ell}, a_j) + c(T_j, a_j) \right). \tag{9}$$

Recall that in order to process the jth task, algorithm A moves to B's last known position $b_{j-\ell}$ and then processes the task greedily, that is, $d(b_{j-\ell}, a_j) + c(T_j, a_j)$ is the minimum. In particular,

$$d(b_{j-\ell}, a_j) + c(T_j, a_j) \leq d(b_{j-\ell}, b_j) + c(T_j, b_j).$$

From this, the fact that costs are nonnegative, and the triangle inequality we get

$$\begin{aligned} d(a_{j-1}, b_{j-\ell}) &\leq d(a_{j-1}, b_{j-\ell-1}) + d(b_{j-\ell-1}, b_{j-\ell}) \\ &\leq d(b_{j-1}, b_{j-\ell-1}) + c(T_{j-1}, b_{j-1}) + d(b_{j-\ell-1}, b_{j-\ell}). \end{aligned}$$

We can now bound the cost of algorithm A in (9) by

$$\sum_{j\geq 1}\left(d(b_{j-1},b_{j-\ell-1})+c(T_{j-1},b_{j-1})+d(b_{j-\ell-1},b_{j-\ell})+d(b_{j-\ell},b_j)+c(T_j,b_j)\right). \tag{10}$$

Using the triangle inequalities of the form

$$d(b_i,b_{i+2})\leq d(b_i,b_{i+1})+d(b_{i+1},b_{i+2}),$$

we can expand $d(b_{j-\ell-1},b_{j-1})\leq d(b_{j-\ell-1},b_{j-\ell})+\cdots+d(b_{j-2},b_{j-1})$ and similarly we can expand $d(b_{j-\ell},b_j)$. Observe now that each term $d(b_{i-1},b_i)$ appears in (10) $2\ell+1$ times and each term $c(T_i,b_i)$ appears twice. We can therefore conclude that the cost of algorithm A is at most

$$\sum_{j\geq 1}\left((2\ell+1)d(b_{j-1},b_j)+2c(T_j,b_j)\right)\leq(2\ell+1)\sum_{j\geq 1}\left(d(b_{j-1},b_j)+c(T_j,b_j)\right).$$

The last expression is $(2\ell+1)$ times the cost of algorithm B.

To show the converse, we consider a task system with metric space $\mathcal{M}$ a (rooted) binary tree, where the distance between adjacent vertices is 1. Let B be the "greedy" algorithm with lookahead ℓ. In other words, B services the next task in such a way that minimizes the total cost to service the next ℓ tasks. Consider now an algorithm A with no lookahead. We will describe a sequence of tasks $T_1,T_2,\ldots$ that force a comparative ratio $2\ell+1$ for A against B. For this, let a_{j-1} be the position where A services the task T_{j-1}. With appropriate initialization, assume that a_{j-1} is at depth $j+\ell$. The next task T_j has infinite cost on all vertices except for the 2^ℓ vertices that are on depth $j+\ell+1$ and on distance $2\ell+1$ from the current position a_{j-1}. (To move to one of these vertices A must move up to level j and then down to level $j+\ell+1$.) The cost of T_j on these vertices is 0. Thus, the cost for A to service each such task is $2\ell+1$, while the cost for B is 1. (Using its lookahead power, it simply walks down the tree.)

We remark here that although the above lower bound uses an infinite metric space, a finite metric space that looks locally like a binary tree can also be used. In particular, consider a butterfly (the FFT graph) of $2\ell+2$ levels and identify the first and last levels. Then we can embed the infinite binary tree into this graph in such a way that every subtree of $\ell+1$ levels is embedded isometrically (in a distance-preserving manner). We conclude that there are task systems with metric spaces of $2^{O(\ell)}$ points and comparative ratio $2\ell+1$. We leave it as an interesting open problem to determine the comparative ratio for smaller metric spaces. □

Of course, for certain task systems the comparative ratio may be less than $2\ell+1$. For the paging problem, it is $\min\{\ell+1,k\}$.

THEOREM 3.2. *For the paging problem*

$$R(\mathcal{L}_0,\mathcal{L}_\ell)=\min\{\ell+1,k\}.$$

Proof. Let $n=\min\{\ell,k-1\}$ and let B be an algorithm for the paging problem in the class $\mathcal{L}_\ell$, that is, with lookahead ℓ. Without loss of generality we assume that B moves pages only to service requests. Consider the followingonline algorithm A which

is a generalization of LRU:

> To service a request r not in its fast memory, A evicts a page that is not one of the n most recent distinct requests (including r). Among the remaining pages, A chooses to evict a page such that the resulting configuration is as close as possible to the last known configuration of B. A does nothing for requests in its fast memory.

To show that the comparative ratio of A is $n+1$, it suffices to show that for every $n+1$ consecutive page faults of A, B suffers at least one page fault. This can be achieved by showing that after each subsequence of requests that causes n page faults to A and no page fault to B, both algorithms are in the same configuration. To do this, we show by induction on the number of requests the stronger claim that after a subsequence of requests that cause c page faults to A and no fault to B, the configurations of A and B differ by at most $n - c$ pages.

Fix a request sequence $\rho = r_1 r_2 \dots$ and let $A_0, A_1, \dots$ and $B_0 = A_0, B_1, \dots$ be the configurations of A and B that service ρ. The base of the induction is trivial. Assume that the induction hypothesis holds for $t-1$. We have to deal with a few cases. First of all, when $r_t \in A_{t-1}$, A suffers no page fault and the inductive step follows from the fact that $|A_t - B_t| \leq |A_{t-1} - B_{t-1}|$. Similarly, when the request $r_t \notin B_{t-1}$, B suffers a page fault and $|A_t - B_t| \leq |A_{t-1} - B_{t-1}|$, which is at most n by the induction hypothesis. Assume now that $r_t \in B_{t-1} - A_{t-1}$. Let x_t be the page evicted by A to service r_t. It is easy to see that if $x_t \notin B_{t-1}$, then $|A_t - B_t| = |A_{t-1} - B_{t-1}| - 1$. The final and more complicated case is when $x_t \in B_{t-1}$. By the definition of algorithm A, x_t is not one of the n most recent requests and consequently x_t is also in B_{t-n}. It follows that $A_{t-1} \subseteq B_{t-n} + \{r_{t-n+1}, \dots, r_{t-1}\}$ (otherwise A would not choose $x_t \in B_{t-n}$ to evict) and

$$A_t \subseteq B_{t-n} + \{r_{t-n+1}, \dots, r_{t-1}, r_t\}.$$

We also have the obvious relation

$$B_t \subseteq B_{t-n} + \{r_{t-n+1}, \dots, r_{t-1}, r_t\}.$$

(Recall that we assumed that B moves pages only to service requests.) If B suffered no page fault during the last c requests, i.e., $B_t = B_{t-1} = \cdots B_{t-c}$, the set $B_{t-n} + \{r_{t-n+1}, \dots, r_{t-1}, r_t\}$ has cardinality at most $k + n - c$. We conclude that $|A_t \cup B_t| \leq k + n - c$, which implies the desired $|A_t - B_t| \leq n - c$.

To show that $\min\{\ell + 1, k\}$ is a lower bound of the comparative ratio, let B be a variant of the optimal offline algorithm adapted to lookahead ℓ. More precisely, B never evicts one of the next n requests. Fix a set of $k+1$ pages. Clearly, for every request sequence ρ, B suffers at most one page fault for every $n+1$ consecutive requests. The lower bound follows because for any algorithm A, there is a request sequence ρ such that A suffers a page fault for every request. □

4. Open problems. We introduced two refinements of competitive analysis, the diffuse adversary model and comparative analysis. Both restrict the power of the adversary: the first by allowing only certain input distributions and the second by restricting the refinement of the adversary's information regime. In general, we believe that the only natural way to deal with uncertainty is by designing algorithms that perform well in the worst world which is compatible with the algorithm's knowledge.

There are a lot of interesting open problems suggested by this approach. The most important open problem is to determine the competitive ratio of FIFO for the paging

diffuse adversary model. As mentioned above, we conjecture that FIFO is in general suboptimal. There are numerous other applications of these two frameworks for evaluating online algorithms. We simply mention here two challenging open problems.

The Markov diffuse adversary. Consider again the paging problem. Suppose that the request sequence is the output sequence of an unknown *Markov chain* (intuitively, the program generating the page requests) with at most s states, which we can only partially observe via its output. That is, the output $f(q)$ of a state q of the unknown Markov process is a page in M. The allowed distributions Δ are now all output distributions of s-state Markov processes with output. We may want to restrict our online algorithms to ones that do not attempt to exhaustively learn the Markov process. One way to do this would be to bound the length of the request sequence to $O(s)$. A better way, however, is to require the additive constant d in (4) to be independent of s. We believe that this is a useful model of paging whose study and solution may enhance our understanding of the performance of actual paging systems.

The power of vision. Consider two robots, one with vision α (its visual sensors can detect objects in distance α) and the other with vision β, $\beta > \alpha$. We want to measure the disadvantage of the first robot in navigating or exploring a terrain against the second robot. Naturally, comparative analysis seems the most appropriate framework for this type of problem. Different restrictions on the terrain and the objective of the robot result in different problems but we find the following simple problem particularly challenging: On the plane, there are n objects (points). The objective of the robot is to construct a map of the plane, i.e., to find the position of all n objects. We ask what the comparative ratio $R(\mathcal{V}_\alpha, \mathcal{V}_\beta)$ for this problem is, where $\mathcal{V}_\alpha$ and $\mathcal{V}_\beta$ denote the information regimes of vision α and β, respectively.

ON THE DIFFICULTY OF DESIGNING GOOD CLASSIFIERS*

MICHELANGELO GRIGNI†, VINCENT MIRELLI‡, AND CHRISTOS H. PAPADIMITRIOU§

Abstract. We consider the problem of designing a near-optimal linear decision tree to classify two given point sets B and W in $\Re^n$. A linear decision tree defines a polyhedral subdivision of space; it is a classifier if no leaf region contains points from both sets. We show hardness results for computing such a classifier with approximately optimal depth or size in polynomial time. In particular, we show that unless NP = ZPP, the depth of a classifier cannot be approximated within any constant factor, and that the total number of nodes cannot be approximated within any fixed polynomial. Our proof uses a simple connection between this problem and graph coloring and uses the result of Feige and Kilian on the inapproximability of the chromatic number. We also study the problem of designing a classifier with a single inequality that involves as few variables as possible and point out certain aspects of the difficulty of this problem.

1. Introduction.

Classifying point sets in $\Re^n$ by linear decision trees is of great interest in pattern analysis and many other applications [4, 5, 14]. Typically, in such a problem we are given a set W of *white* points and a set B of *black* points in $\Re^n$, and we must produce a linear decision tree which classifies them. That is, the tree defines a linear decision at each internal node, such that for each leaf ℓ of this tree, either only white or only black points lead the algorithm to ℓ. We call such a linear decision tree a *classifier*. In many situations W and B are not given explicitly but implicitly in terms of concepts, images of objects, etc.

The problem is already well studied. Constructing a size-optimal classifier is NP-complete even in three dimensions [10]; in high dimensions it is NP-complete even for constant size trees [2, 16]. There is much algorithmic work toward computing classifiers that meet various local optimality conditions [4, 17], but very little is known about how well such local optima approximate the optimal solution. An exception is the use of random sampling to find near-optimal splitting planes in low dimensions [10].

In this paper we prove some very strong negative results on high-dimensional classifying trees (the important case in practice). We point out a simple connection between the problem of designing optimal linear classifying trees and the classical problem of *coloring a graph*. Given a graph G, we construct its geometric realization; roughly speaking, the white points are the vertices of the graph arranged at the corners of a simplex, and the black points correspond to the edges of the graph, with each black point placed at the midpoint between the two endpoints of its edge. It is not

hard to prove then that the optimum size of any classifier is the chromatic number of the graph $\chi(G)$, while the optimum depth is $\log_2(\chi(G)+1)$. We then use the result of Feige and Kilian [8] on the inapproximability of the chromatic number to obtain the following two results.

THEOREM 1.1. *Unless NP = ZPP, no polynomial-time algorithm for optimizing the number of nodes in a classifier can approximate the optimum within any fixed polynomial. For $\epsilon > 0$ and large enough dimension n, the approximation ratio is no better than $n^{1-\epsilon}$.*

THEOREM 1.2. *Unless NP = ZPP, no polynomial-time algorithm for optimizing the depth a classifier can have approximation ratio better than any fixed constant.*

Here ZPP is the class of problems solved by polynomial expected-time *randomized* algorithms with neither false negatives nor false positives. NP = ZPP is a situation almost as unthinkable as NP = P. In the next section we prove these two results.

Finally, in section 3 we look at another aspect of the difficulty of optimizing classifiers: Suppose that the two point sets can be separated by a *single* linear inequality, but we want to find the inequality that separates them *and involves as few variables as possible*. This situation is of interest when we use functions of the points as additional coordinates to facilitate classification [4, 11]. We point out that variants of this problem are hard for various levels of the *W hierarchy* [3, 6], which implies that (unless an unlikely collapse occurs), they cannot be solved in polynomial time even if the optimum sought is small (bounded by any very slowly growing function).

2. Definitions and proofs. Let $W, B \subseteq \Re^n$ be two point sets. A *linear classifying tree* for W and B is a decision tree with internal nodes of the form $\sum_{i=1}^{n} a_i x_i > b$, each with two branches, the *true* branch and the *false* branch. A leaf ℓ of such a tree corresponds in a straightforward way to a convex cell in a subdivision of $\Re^n$, call it $C(\ell)$, containing all points that satisfy (or falsify) the inequality in each internal node I that is an ancestor of ℓ in the tree, and such that ℓ is in the *true* (respectively, *false*) subtree of I.

There are two important measures of the difficulty of such a classifier. The first is the *number of internal nodes* of the tree and corresponds to the program size of the classifier. The other is the *depth* of the tree and corresponds to the running time of the decision algorithm. We denote by $d(W, B)$ the depth of the classifier for W and B that has the smallest possible depth among all such classifiers; similarly, $n(W, B)$ is the optimum number of internal nodes.

For example, a classifier for the two 2-dimensional point sets W and B shown in Figure 2.1(a) is shown in Figure 2.1(b). The subdivisions corresponding to the leaves are also shown in Figure 2.1(a). It has depth two, and a total of three nodes. Here it is easy to see that $d(W, B) = 2$ and $n(W, B) = 2$; thus the tree shown is optimal with respect to depth, but not with respect to the number of nodes.

Let $G = (V, E)$ be any graph, with vertices $V = \{v_1, \ldots, v_n\}$ and edges $E = \{e_1, \ldots, e_m\}$. Consider the following two point sets in $\Re^n$ (indeed, on the $(n-1)$-dimensional hyperplane $\sum_{i=1}^{n} x_i = 1$): the white set $W(G) = \{w_1, \ldots, w_n\}$, where w_i is the ith elementary basis vector (that is, $(w_i)_i = 1$ and all other coordinates are zero); and the black set $B(G) = \{b_1, \ldots, b_m\}$, with $b_k = \frac{1}{2}(w_i + w_j)$, where $e_k = \{v_i, v_j\}$. In other words, the white points are the nodes of G placed at the vertices of the simplex, while the black points are the edges of G, each placed at the midpoint of its two endpoints.

The chromatic number of G, $\chi(G)$, is the smallest number of colors that can be used to color the nodes of G so that no two adjacent nodes have the same color;

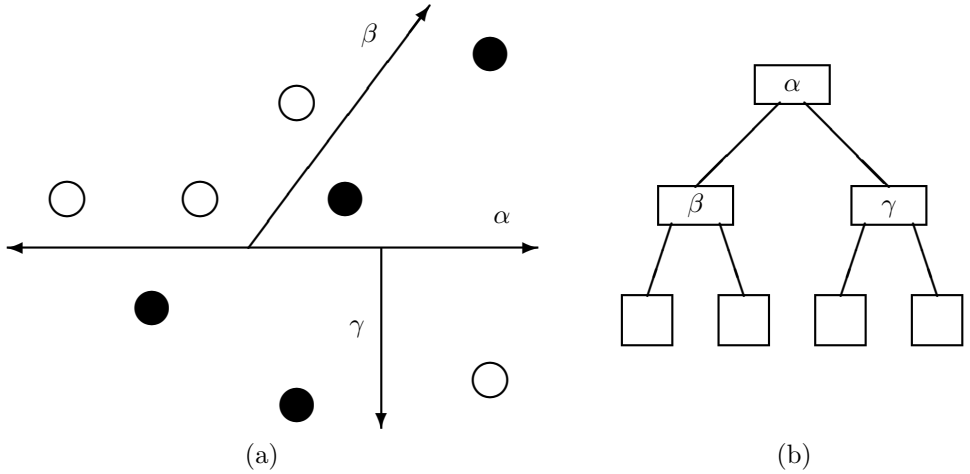

FIG. 2.1. *A 2-dimensional classifier.*

equivalently, it is the smallest number of independent sets that can be used to cover all nodes of G.

The following two lemmas now characterize the complexity of classifying $W(G)$ and $B(G)$ in terms of $\chi(G)$.

LEMMA 2.1. $n(W(G), B(G)) = \chi(G)$.

Proof. Consider any white leaf ℓ in any decision tree for $W(G), B(G)$. Since its cell $C(\ell)$ is convex, it follows that the nodes of G it contains share no edge, because otherwise the corresponding black midpoint would also be in $C(\ell)$. Thus, $C(\ell)$ contains an independent set of G. Since the leaves of the decision tree must cover all nodes of G, there are at least $\chi(G)$ white leaves in any decision tree. In addition there must be at least one black leaf, and hence there are at least $\chi(G) + 1$ leaves overall, and at least $\chi(G)$ internal nodes. It follows that $n(W(G), B(G)) \geq \chi(G)$.

For the other direction let $S_1, \ldots, S_{\chi(G)}$ be the independent sets in the optimum coloring of G. We can construct a decision tree with $\chi(G)$ internal nodes, of which the kth has the inequality $\sum_{v_i \in S_k} x_i \geq \frac{2}{3}$, with the *true* branch leading to a white leaf and the *false* branch leading to either the $k+1$st internal node or a black leaf if $k = \chi(G)$. It is easy to see that this is a classifier for $W(G), B(G)$, and hence $n(W(G), B(G)) \leq \chi(G)$. □

LEMMA 2.2. $\lceil \log_2(\chi(G) + 1) \rceil \leq d(W(G), B(G)) \leq \lceil \log_2(\chi(G) + 1) \rceil + 1$.

Proof. The lower bound follows from the previous lemma, since $d(W, B) \geq \lceil \log_2(n(W, B) + 1) \rceil$. For the upper bound, consider the optimum coloring of G with $\chi(G)$ colors. We let V_1 be the union of the first $\lfloor \frac{\chi(G)}{2} \rfloor$ color classes, and let V_2 be the remaining nodes of G. Our first inequality is $\sum_{v_i \in V_1} x_i \geq \frac{1}{3}$, and it separates the white nodes in two subgraphs, each with about half the chromatic number. Continuing the same way we arrive at nodes that contain white nodes that are independent, plus certain black nodes; these can be separated with one more internal node. The total depth is thus $\lceil \log_2 \chi((G) + 1) \rceil + 1$. □

To prove Theorems 1.1 and 1.2 from the lemmas, we now need only the following result of Feige and Kilian [8], building on earlier results of Lund and Yannakakis [15] and Fürer [9].

THEOREM 2.3. *Unless NP = ZPP, no polynomial-time algorithm for approximat-*

ing the chromatic number of a graph with n nodes can have an approximation ratio better than $n^{1-\epsilon}$ for a fixed $\epsilon > 0$ and large enough n.

In other words, for a given efficient algorithm and $\epsilon > 0$, there are graphs with chromatic number n^{ϵ}, such that the algorithm cannot find a coloring better than $n^{1-\epsilon}$. Theorem 1.1 then follows from Lemma 2.1 and Theorem 2.3, and Theorem 1.2 follows from Lemma 2.2 and Theorem 2.3.

3. Single linear decisions. In this section we point out aspects of the difficulty of classifier optimization that hold even in the case in which W and B are *separable*, that is, *there is a single linear inequality that separates W from B* (in other words, the optimum classifying tree has just one internal node). In this case we are interested in minimizing *the number of variables that are actually needed in the decision node.*

Naturally, the interesting classification problems are not linearly separable; however, the separable case is practically interesting because it arises when we introduce "extra variables" to make classification possible. For example, one may introduce low-degree monomials (products of variables) or radial basis functions (simple functions of the distance from a point) [11, 13] and then construct a linear decision tree treating the outputs of these functions as new variables. Or one could even allow more costly special-purpose classifying heuristics and also treat their outputs as variables. It is clear that any disjoint finite sets W and B may be separated given enough such extra functions, so the real question is how to minimize their number and cost. Besides the obvious consideration of computational efficiency, by the principle of *Occam's razor* we expect that optimal classifiers of this sort are in some sense "better-quality" classifiers.

We wish thus to solve the following problem: We are given two point sets $W, B \subseteq \Re^n$ that we know are separable by a single hyperplane. We are asked to find the hyperplane $\sum_{i=1}^{n} a_i x_i \geq b$ that separates W from B, and such that $|\{i : a_i \neq 0\}|$ is minimized. In another version (better suited for modeling the case of extra functions), the first $m < n$ variables are *free*, and we wish to minimize $|\{i > m : a_i \neq 0\}|$.

We next make a very useful simplification—we assume that $B = \{0\}$ (that is, there is only one black point, the origin): Given any classification problem W, B we can transform it into an equivalent classification problem $W - B, \{0\}$, where $W - B = \{w - b : w \in W \text{ and } b \in B\}$ is the *Minkowski difference*. Thus, we seek the hyperplane that separates a given point set W from the origin and has the smallest number of nonzero coefficients (respectively, excluding the coefficients of the first m variables). We call these problems the *smallest separating inequality problem* and its *version with free variables.*

Both versions of this problem are easily seen to be NP-complete. In this section we point out their high *parameterized complexity*. In [3, 6] a theory of parameterized complexity has been initiated. The issue is whether a minimization problem of the form "given instance x and integer parameter k, is the optimum k or less?" can be solved in time, say, $O(n^p)$, where n is the size of the input x, and the hidden constants (but not p) may depend on k. For some problems, such as bandwidth and node cover, such algorithms are possible; for others, no such algorithms are known. These latter problems classify into a hierarchy of classes, denoted $W[1], W[2], \ldots$, plus an ultimate class $W[P]$. Hardness of a problem (via "parameterized reductions" appropriate for these problems; see [3]) for such a class is evidence that the problem does not have a polynomial algorithm even when the parameter is severely bounded. The higher the class, the more devastating the evidence of intractability.

THEOREM 3.1. *The smallest separating inequality problem is hard for $W[2]$, and*

its version with free variables is hard for $W[P]$.

Proof. For $W[2]$-hardness we shall reduce the $W[2]$-complete *hitting set problem* [1, 12] to the minimum separating hyperplane problem. In the hitting set problem we are given a family $F = \{S_1, \ldots, S_k\}$ of subsets of some set $\{1, 2, \ldots, n\}$, and a parameter p, and we are asked to determine whether there is a set H, $|H| \leq p$, such that $H \cap S_i \neq \emptyset$ for all i. From F we construct a set of points $W = \{w_1, \ldots, w_k\} \subseteq \Re^n$, where w_i is the characteristic vector of S_i. Let $\sum_{i=1}^{n} a_i x_i = 1$ be a hyperplane separating W from the origin, and let $H = \{i : a_i \neq 0\}$. If $H \cap S_i = \emptyset$ for some i, then the hyperplane fails to separate w_i from the origin, and hence the nonzero coordinates of the hyperplane must be a hitting set. Conversely, for any hitting set H, the hyperplane $\sum_{i \in H} x_i = \frac{1}{2}$ separates W from the origin. This completes the proof of the first part.

For the second part, we shall reduce to the version of the problem with free variables the $W[P]$-complete *minimum monotone circuit value problem* [7]. In it we are given a monotone circuit, and a parameter k, and we wish to determine whether there is an input vector with k or fewer 1's that makes the output of the circuit 1. Given such a circuit with n gates, of which all but the first m are input gates, we construct the following point set W in $\Re^n$: If i is the output gate, we add to W the point $-e_i$—recall that e_i is the unit vector in the ith coordinate. If i is an OR gate with inputs j and ℓ, then we add to W the point $e_i - e_j - e_\ell$. If i is an AND gate with inputs j and ℓ, then we add to W the points $e_i - e_j$ and $e_i - e_\ell$. This completes the construction. It is not very hard to argue that there is a hyperplane separating W from the origin with k or fewer nonzero coefficients in its last $n - m$ coordinates, if and only if the given circuit has a satisfying truth assignment with k or fewer positive inputs. □

Acknowledgment. We wish to thank Mihalis Yannakakis for an interesting discussion on this problem.

TWO-PROVER PROTOCOLS—LOW ERROR AT AFFORDABLE RATES*

URIEL FEIGE† AND JOE KILIAN‡

Abstract. We introduce the *miss-match* form for two-prover one-round proof systems. Any two-prover one-round proof system can be easily modified so as to be in miss-match form. Proof systems in miss-match form have the "projection" property that is important for deriving hardness of approximation results for NP-hard combinatorial optimization problems.

Our main result is an upper bound on the number of parallel repetitions that suffice in order to reduce the error of miss-match proof systems from p to ϵ. This upper bound depends only on p and on ϵ (polynomial in $1/(1-p)$ and in $1/\epsilon$). Based on previous work, it follows that for any $\epsilon > 0$, NP has two-prover one-round proof systems with logarithmic-sized questions, constant-sized answers, and error at most ϵ.

As part of our proof we prove upper bounds on the influence of random variables on multivariate functions, which may be of independent interest.

1. Introduction.

A two-prover one-round proof system [6] is a protocol by which two provers jointly try to convince a computationally limited probabilistic verifier that a common input belongs to a prespecified language. The verifier selects a pair of questions at random. Each prover sees only one of the two questions and sends back an answer. The verifier evaluates a predicate on the common input and the two questions and answers, and accepts or rejects according to the output of the predicate. For inputs in the language, the provers have a strategy (where a strategy for a prover is a function from incoming messages to outgoing messages) that always causes the verifier to accept. For inputs not in the language, regardless of the strategy used by the provers, the verifier accepts with probability at most ϵ. The smaller the value of ϵ, known as the *error*, the greater the verifier's confidence in the result of the proof system.

The class MIP(2,1) denotes those languages L accepted by a two-prover one-round proof system with a probabilistic polynomial-time verifier. More generally, an MIP(2,1) *game* is one in which a verifier engages in a single round of communication with two cooperating but not communicating players (the provers); the verifier determines based on the messages and its private coin tosses whether the players win. Similarly, in an MIP(2,1) *proof system*, "yes" instances (when $x \in L$) give rise to trivial games, in which the provers can always win (we only consider proof systems with perfect completeness) and "no" instances give rise to nontrivial games in which the provers can win with probability at most $\epsilon < 1$. We call ϵ the *error* of the proof

system. Reducing the error in MIP(2,1) proof systems (while preserving triviality for "yes" instances) is a subtle issue. A natural approach is to repeat an MIP(2,1) protocol n times and accept only if all executions are accepting. Ideally, one would hope that this method would reduce the error to ϵ^n. This is indeed true if each execution is performed with a fresh pair of provers, requiring n pairs of provers, or if the executions are performed sequentially (each prover must answer each question online before seeing the question for the next execution), requiring n rounds of communication. However, parallel repetition—in which there are only two provers and one round, and each prover sends out its answers only after receiving all its questions—is not guaranteed to reduce the error to ϵ^n [15]. Much work was invested in trying to analyze the rate at which parallel repetition reduces the error in MIP(2,1) proof systems (see, e.g., [15, 22, 7, 13, 14]).

We analyze a specific class of MIP(2,1) proof systems which we call *miss-match* proof systems. In the basic one-round proof system, the question to the first prover is composed of two "half questions" (α_1, α_2), and the first prover replies with two "half answers" (β_1, β_2). Based on $\alpha_1, \alpha_2, \beta_1$, and β_2, the verifier makes an initial decision on whether to reject or provisionally accept, pending the results of its interaction with the second prover. This acceptance predicate depends on the specific proof system and may differ from one miss-match proof system to another. The common feature of all miss-match proof systems is the way in which the second prover is used to confirm a decision to accept. Here the verifier has two options. The first, *miss* option, is to ask the second prover a null question λ, ignore the second prover's answer, and accept. The second, the *match*, is to ask the second prover one of the two half questions α_i sent to the first prover and to accept only if the second prover's answer β matches (i.e., is equal to) the half answer β_i given by the first prover. The verifier chooses its question to the second prover uniformly from $\{\alpha_1, \alpha_2, \lambda\}$. For formal definitions, see section 2.

Our main result is an upper bound, for proof systems in the miss-match form, on the number of parallel repetitions that suffice in order to reduce the error from an initial value of p to a desired value of ϵ. This upper bound is polynomial in $1/(1-p)$ and in $1/\epsilon$.

Though our upper bound applies only to proof systems in miss-match form, it can be used in order to reduce the error from one constant to another in any MIP(2,1) proof system. The reason is that any MIP(2,1) proof system can be easily transformed into miss-match form (see Proposition 3.1), with only constant overhead in communication and randomness, and insignificant loss in the error p. In [2] it was shown that any NP-language has an MIP(2,1) proof system with logarithmic-size questions and constant-size answers. The error p for these proof systems is a constant less than 1 but larger than $\frac{1}{2}$. Our main result implies that the error can be reduced to any constant $\epsilon > 0$, while increasing the question and answer sizes by only a multiplicative constant factor. We remark that these error-reducing transformations preserve triviality; on "yes" instances of the proof system the provers can always make the verifier accept.

A major application of MIP(2,1) proof systems for NP is to prove hardness of approximation results. Decreasing the error of an MIP(2,1) proof system often translates into stronger hardness of approximation results (cf. [12, 5, 4]).

Our analysis of parallel repetition of MIP(2,1) proof systems in miss-match form is based in part on an analysis of the influence of random variables on an arbitrary function. This part is presented in a self-contained way in section 4 and may be of independent interest. Essentially, we present an exact formulation of the intuition

that for any function, knowing the value of an α-fraction of the input variables (chosen at random) is expected to give at most an α-fraction of the information regarding the output of the function. Here, we measure "information" in terms of the variance of the function. Theorem 4.3 is an essentially optimal version of a lemma that appeared in the conference version of this paper [12]. It was developed with the help of Leonid Gurvits, who gave the first proof, based on Fourier analysis. In section 4, we present a more elementary proof of this theorem.

1.1. Related work. A preliminary version of this paper appeared in [12]. In discussing related work, we distinguish between work done prior to the preliminary version and work done since. We also discuss the improvements of the current version over the preliminary one.

Prior work. MIP(2,1) proof systems were introduced by Ben-Or, Goldwasser, Kilian, and Wigderson [6]. A major result there was a two-prover perfect zero-knowledge proof system for NP. The authors remarked that parallel repetition of these proof systems preserves zero-knowledge properties, but the issue of its effect on the error was not touched upon. Initial beliefs that n parallel repetitions reduce the error from ϵ to ϵ^n were refuted by an explicit example in [15]. Since then, the problem of error reduction for MIP(2,1) proof systems has attracted much attention, because of both the intellectual challenge and the potential applications of these proof systems. Applications were initially made to cryptography [18], and later to the design of efficient probabilistically checkable proofs and to proving hardness results for approximating NP-hard optimization problems [2, 20, 3].

Initially, bounds on the rate by which parallel repetition reduces the error in MIP(2,1) proof systems were obtained only in special cases (see, e.g., [8, 18]). In this respect, the result most related to our current work was the method of [7, 10] that can reduce the error in any MIP(2,1) proof system from $p > 1/2$ to $1/2 + \epsilon$ with an overhead that depends only on p and ϵ. Our work on miss-match proof systems gives a result of similar flavor that extends to arbitrarily small errors.

The most successful approach for reducing the error was through algebraic techniques [9, 19, 13]. These techniques may dramatically change the structure of the original protocol, but thereafter the analysis of error reduction becomes relatively simple and the rate of error reduction becomes exponential. Algebraic techniques became the method of choice for reducing the error in MIP(2,1) proof systems.

Our preliminary version. The preliminary version of our paper [12] had two parts. The first part, on which the current version is based, analyzed the effect of parallel repetition on MIP(2,1) proof systems of a certain form, which we called *confuse-or-compare*. The second part showed how to preserve the zero-knowledge property when algebraic error reduction techniques are applied. We shall not discuss this second part further, nor shall we discuss zero-knowledge.

Confuse-or-compare proof systems give the verifier two options of what to do with the second prover, similar to the case of miss-match proof systems. The "compare" option is identical to the "match" option. The "confuse" option was our original version of the "miss" option. Rather than send the second prover the null question, the verifier sends him a random half question γ, unrelated to α_1 and α_2. As with the miss option, the verifier ignores the second prover's answer if the confuse option is employed. The results presented for the confuse-or-compare proof systems were qualitatively similar to the results presented here for miss-match proof systems, and the analysis was slightly simpler. The reason we switched from confuse-or-compare to miss-match will be explained shortly.

The main point of the results in [12] was that they provided a way of reducing the error from one constant to another with only constant overhead. In contrast, known algebraic error reduction techniques require more than a constant overhead in modifying the original proof system. Using the confuse-or-compare proof systems, previously known hardness of approximation results could be derived under weaker complexity assumptions (e.g., under the assumption that $P \neq NP$ instead of the assumption that NP does not have quasi-polynomial algorithms). Additional results in [12] included further strengthening of hardness of approximation results for *clique* and *chromatic number*, based on observations regarding which parameters of proof systems are really relevant to obtaining such results.

Results obtained since. Concurrently with our preliminary work in [12], Verbitsky proved that for any MIP(2,1) proof system, parallel repetition can reduce the error to be arbitrarily small. However, the method of analysis used by Verbitsky does not give useful bounds on the number of repetitions needed [22]. Subsequently, Raz proved the following parallel repetition theorem, which gives almost tight bounds on the rate of error reduction by parallel repetition.

Parallel repetition theorem (*see* [21]). For any MIP(2,1) proof system with error ϵ there exists some constant $\alpha > 0$ (that depends on ϵ and on the answer length of the proof system) such that the error obtained by n parallel repetitions is at most $\epsilon^{\alpha n}$.

Raz's theorem is strongest when the initial error and answer length are constant, as then α is just some other constant. This is indeed the case in the places where the use of error reduction by transformation to a confuse-or-compare proof system was suggested, and hence Raz's theorem could replace the results of [12] in all suggested applications. Moreover, as was pointed out in [5, 4], Raz's theorem has the further advantage of not introducing the confuse rounds. Certain efficient constructions in the theory of probabilistically checkable proofs [4] (leading to better inapproximability ratios for NP-hard optimization problems) require that the underlying MIP(2,1) proof system have the "projection" property: the answer of the second prover is a function of the answer of the first prover. This indeed holds for compare rounds, but does not hold for confuse rounds. Even though the verifier ignores the answer of the second prover on the confuse rounds, the second prover cannot tell which are the confuse rounds, and for this reason cannot be used by the construction of Bellare, Goldreich, and Sudan [4]. With Raz's theorem, the problem does not arise because the confuse rounds are not needed in order to reduce the error.

Despite the above, the confuse-or-compare structure does offer advantages that cannot be achieved by straight parallel repetition. There are families of MIP(2,1) proof systems for which the number of parallel repetitions required in order to reduce the error from 3/4 to 1/8 is not bounded by any constant [14]. However, as will be discussed in section 3, any MIP(2,1) proof system with error at most 3/4 can be converted to one in miss-match form, with error at most 11/12, and then amplified by parallel repetition to achieve any constant error. This method uses only a constant number of "black box" invocations of the original proof system. Thus, we have an alternative generic amplification method that in some cases works substantially better than parallel repetition.

The current version. The main disadvantage of the confuse-or-compare structure, not having the projection property, is circumvented in the current version of the paper. Here the confuse-or-compare structure is replaced by the miss-match structure, which does have the projection property (as explained in section 2). This makes our results applicable for the construction of [4]. We analyze error reduction by parallel repetition

for miss-match proof systems and show that the number of repetitions that is required in order to reduce the error from p to ϵ is some constant that depends only on p and ϵ. Our analysis follows closely our preliminary analysis in [12], with a slight twist toward the end. (The inspiration for this slight twist came from [16].) We also improve our analysis of the influence of random variables on a function. This stronger analysis was developed with the help of Leonid Gurvits and gives essentially tight bounds. (Our previous bounds gave away unnecessary logarithmic terms.) In the current version of the paper, we omit discussion of applications of our results to the construction of efficient probabilistically checkable proofs and to obtaining hardness of approximation results. The reader is referred to [4] for this purpose.

For further discussion on error reduction by parallel repetition, see [11]. For a discussion on the influence of variables on Boolean functions, see [17].

2. Definitions. Two-prover one-round proof systems are often modeled as a game between a verifier and two cooperating but not communicating provers. It is not an adversarial game, as the strategy of the verifier is fixed in advance. Rather, it is a cooperative game with two players (provers) who coordinate a joint strategy that gives them the highest probability of winning. Modeling MIP(2,1) proof systems as games suppresses the language recognition aspects of these proof systems, but preserves the concept of error in a proof system and the issue of how error can be reduced. One may best think of a game as an instantiation of an MIP(2,1) proof system on a single input that is not in the given language. We use the following notation.

$G = G(X, Y, Q, \pi, A, B, V)$ - a two-prover one-round game;
X - set of questions to prover P_1;
Y - set of questions to prover P_2;
A - set of answers available to P_1;
B - set of answers available to P_2;
π - probability distribution on $X \times Y$;
Q - support of π. $Q \subseteq X \times Y$;
V - acceptance predicate on (X, Y, A, B).

Game G proceeds as follows. The verifier selects at random a question pair $(x, y) \in Q$, according to probability distribution π. Question x is sent to P_1, who replies with an answer $P_1(x) \in A$. Question y is sent to P_2, who replies with an answer $P_2(y) \in B$. (We identify the name of a prover and the strategy that it employs.) The verifier then evaluates a predicate $V(x, y, P_1(x), P_2(y))$ and accepts if the predicate is satisfied. The goal of the provers is to select a strategy (namely, two functions, one for each prover, specifying an answer to each possible question) that maximizes the probability that the verifier accepts. The probability that the verifier accepts under the optimal strategy of the provers is denoted by $\omega(G)$. If $\omega(G) = 1$ the provers are said to have a *perfect strategy* for G, and the game G is *trivial*. For nontrivial games, $\omega(G)$ is also called the *error* of the game. We shall be interested only in nontrivial games.

An *n-fold parallel repetition* of game G is a new game, denoted by G^n, played on n coordinates, corresponding to playing n versions of game G in parallel. The questions and answers are now n-vectors, the ith element corresponding to the ith game. The verifier treats each coordinate of G^n as an independent copy of the original game G and accepts in G^n only if it would have accepted all the n copies of G. The support set of G^n is $Q^n \subseteq X^n \times Y^n$, the answer sets are A^n and B^n. The verifier selects n question pairs $(x_i, y_i) \in Q$ independently, each according to the probability distribution π. We

denote $\vec{x} = x_1 x_2 \cdots x_n$ and $\vec{y} = y_1 y_2 \cdots y_n$. (Hence $\vec{x} \in X^n$ and $\vec{y} \in Y^n$.) A strategy for the provers is $2n$ functions, $P_1^i : X^n \longrightarrow A$ and $P_2^i : Y^n \longrightarrow B$, where $1 \leq i \leq n$. The acceptance predicate is $V^n = \bigwedge_{i=1}^n V(x_i, y_i, P_1^i(\vec{x}), P_2^i(\vec{y}))$. That is, the verifier accepts if all n copies of the original game G are accepting.

Observe that even though the verifier treats each coordinate of G^n independently, the provers may not. In particular, the answer a prover gives in coordinate i may depend on the questions that the prover receives in other coordinates. For this reason, it is not true in general that $\omega(G^n) = (\omega(G))^n$.

We shall often refer to the following special classes of games. A game is *uniform* if π is uniform on Q. A game is *free* if it is uniform and has full support, i.e., $Q = X \times Y$. (The term *free* was introduced in [8].) A game has the *projection* property if the question to prover P_2 is a projection of the question to prover P_1, and the verifier accepts only if the answer of prover P_2 is a projection of the answer to prover P_1. More formally, the question sets are of the form $X = X_1 \times X_2 \times \cdots \times X_k$ for some k, and $Y = \bigcup_{i=1}^k X_i$, where the sets X_i are disjoint. The support of the probability distribution π includes only pairs $(x, y) \in X \times Y$ for which y is x_i for some $i \in \{1, 2, \ldots, k\}$, where x_i is the ith component of the question $x = (x_1, x_2, \ldots, x_k)$. The answer sets are of the form $A = A_1 \times A_2 \times \cdots \times A_k$ for the same k as above, and $B = \bigcup_{i=1}^k A_i$, where the sets A_i are disjoint. The acceptance predicate V is a conjunction of two parts $V = V_1 \wedge V_2$. One is a predicate $V_1(X, A)$ that ignores the communication with P_2. The other is $V_2(X, Y, A, B)$, which accepts only if the answer of P_2 is precisely the ith component of the answer of P_1, where i is the same coordinate on which the question y is a projection of the question x. We observe that games with the projection property may be uniform, but cannot be free (unless the cardinality of X is one).

We are now ready to define *miss-match* games. These are games with the projection property, also satisfying the following requirements. The question set to prover P_1 is $X = X_1 \times X_2 \times \{\lambda\}$, where λ is a character which the reader can interpret as saying "a miss." Hence the question set to P_2 is $Y = X_1 \bigcup X_2 \bigcup \{\lambda\}$. The probability distribution π is arbitrary on $X_1 \times X_2$, and uniform with respect to selecting which of the three components of $x \in X$ to choose as y. Hence we shall often refer to π as a probability distribution over $X_1 \times X_2$. The answer set for prover P_1 is $A = A_1 \times A_2 \times \{\lambda\}$. Hence the answer set for P_2 is $B = A_1 \bigcup A_2 \bigcup \{\lambda\}$. Since the third component of the question to P_1 is $\{\lambda\}$ and the third component of his answer is $\{\lambda\}$, the acceptance predicate V_1 is defined only on $(X_1 \times X_2, A_1 \times A_2)$. The full acceptance predicate is $V = V_1 \wedge V_2$, where V_2 is the predicate for the projection property. Observe that the projection property forces P_2 to answer λ with a λ.

When the question to P_2 is λ we say that it is a *miss*. When the question to P_2 is in $X_1 \bigcup X_2$ we say that it is a *match*. When a miss-match game is repeated many times in parallel, some of the rounds will be miss rounds and the others will be match rounds. Though there is no advantage in introducing a miss when the game is played only once, our analysis of the error of the repeated game will make use of the presence of the miss rounds.

3. Preliminaries and main results. Though miss-match games are a restricted form of games, any other MIP(2,1) game can be easily transformed into a miss-match game. Let $G(X, Y, Q, \pi, A, B, V)$ be an arbitrary game. Then its miss-match version $G' = G'(X', Y', Q', \pi', A', B', V')$ is as follows:

- $X' = X \times Y \times \{\lambda\}$;
- π' is identical to π over $X \times Y$;

- $A' = A \times B \times \{\lambda\}$.

Recall that $V' = V_1 \wedge V_2$. V_1 is identical to V on (X, Y, A, B). The rest of the parameters (Y', Q', B', V_2) are implicit from G' being a miss-match game. Note that if G is trivial, then G' is trivial.

PROPOSITION 3.1. *For the games G and G' as described above, $\omega(G') \leq \frac{\omega(G)+2}{3}$.*

Proof. Recall that in G', prover P_2 receives questions $y' \in X \bigcup Y \bigcup \{\lambda\}$. Fix an arbitrary deterministic strategy for P_2 in G'. (P_2's strategy can be made deterministic without loss of generality.) For every question $x \in X$, this fixes a unique answer $a \in A$, and for every question $y \in Y$, this fixes a unique answer $b \in B$. Observe that the provers in the original game G can follow this strategy, and then the probability that V is satisfied is at most $\omega(G)$. Now fix an arbitrary strategy for P_1, who receives questions $x' \in X \times Y \times \{\lambda\}$. Use the strategies of P_1 and P_2 in order to partition all questions x' to P_1 into two classes. The first class contains those x' for which P_1's answers in $A \times B$ agree with P_2's fixed strategy. The second class contains those x' for which at least one of P_1's two answers in $A \times B$ disagrees with P_2's fixed strategy. Let q denote the probability that x' is from the first class; x' is from the second class with probability $(1-q)$. The joint probability that x' is from the first class and V_1 is satisfied is at most q and is also at most $\omega(G)$. (Otherwise, the provers for the original game can win with probability higher that $\omega(G)$.) Hence this joint probability is at most $\min[q, \omega(G)] \leq (\omega(G) + 2q)/3$. The joint probability that x' is from the second class and V_2 is satisfied is at most $\frac{2}{3}(1-q)$: whenever x' is from the second class (probability $(1-q)$), there is a $1/3$ chance of the inconsistent answer being detected. Thus, the acceptance probability is at most $(2 + \omega(G))/3$, the sum of these upper bounds. □

For a miss-match game G', we say that prover P_1 has a *projection strategy* if, for every two questions $x = (x_1, x_2, \lambda)$ and $x' = (x'_1, x'_2, \lambda)$ and their respective answers $a = (a_1, a_2, \lambda)$ and $a' = (a'_1, a'_2, \lambda)$, it holds that $a_1 = a'_1$ whenever $x_1 = x'_1$, and $a_2 = a'_2$ whenever $x_2 = x'_2$. Let the *basic error* $p(G')$ be the maximum probability that V_1 is satisfied, where the maximum is taken over all projection strategies of P_1. For miss-match games, we will find it more convenient to work with p rather than ω. Note that when transforming an arbitrary game G to a miss-match game G', there is a correspondence between deterministic strategies for G and projection strategies for G'. We thus obtain the following simple relation between $p(G')$ and $\omega(G)$.

PROPOSITION 3.2. *For G and G' as above, $p(G') = \omega(G)$.*

Propositions 3.1 and 3.2 imply that $\omega(G') \leq \frac{p(G')+2}{3}$.

The following theorem is our main result.

THEOREM 3.3. *Let G' be an arbitrary miss-match game with basic error $p < 1$. Then $\omega((G')^n) \leq \epsilon$, whenever $n \geq c/((1-p)\epsilon)^c$, where $c \geq 0$ is a universal constant independent of G', p, n, and ϵ.*

Using Proposition 3.2 and the fact that for any miss-match game G', $p(G') \leq \omega(G')$, we can restate Theorem 3.3 in terms of the original win probabilities.

COROLLARY 3.4. *For G' an arbitrary miss-match game, $\omega((G')^n) \leq \epsilon$ when $n \geq c/((1-\omega(G'))\epsilon)^c$, where $c \geq 0$ is some universal constant independent of G', p, and ϵ. Furthermore, for G an arbitrary nontrivial MIP(2,1) game, $\omega((G')^n) \leq \epsilon$ when $n \geq c/((1-\omega(G))\epsilon)^c$, where G' is obtained by transforming G as described above.*

We remark that the proof of our theorem is robust enough to support simple modifications to the notion of a miss-match game. (These modifications change only the value of the constant c.) In particular, the requirement that $X = X_1 \times X_2 \times \{\lambda\}$ can be relaxed to $X = X_1 \times X_2 \times \cdots \times X_k \times \{\lambda\}$ for any fixed k, and the requirement

that the question to P_2 is chosen uniformly from the $k+1$ parts of the question to P_1 can be relaxed to any other distribution with full support.

To appreciate Theorem 3.3, one should contrast it with the following theorem of [14].

Feige–Verbitsky theorem (*see* [14]). There exists an infinite family $\mathcal{G}$ of free games such that $\omega(G) \leq 3/4$ for every $G \in \mathcal{G}$, and for any n there is some $G \in \mathcal{G}$ with $\omega(G^n) \geq 1/8$.

Hence Theorem 3.3 does not hold for arbitrary games, and there is something special in the miss-match form that makes it work. Miss-match games have two ingredients—the miss (sending an occasional λ to P_2) and the match (the projection property). It turns out that the miss property alone does not suffice in order to prove Theorem 3.3. The constant $1/2$ in the following proposition is arbitrary and can be replaced with any other constant.

PROPOSITION 3.5. *Let $\lambda \circ G$ denote a modification of a game G in which, with probability $1/2$, the question to P_2 is replaced by λ, and the verifier accepts. For any* free *game G, and for any integer $n \geq 1$, $\omega((\lambda \circ G)^n) \geq \omega(G^n)$.*

Proof. Fix an optimal strategy S for P_1 and P_2 in G^n. Based on S, we design a randomized strategy for the provers in $(\lambda \circ G)^n$. P_1 deterministically answers each question of $(\lambda \circ G)^n$ with the answer that P_1 would have given on the same question using strategy S. P_2 uses the following randomized strategy. Independently, in each coordinate on which P_2 receives a λ in $(\lambda \circ G)^n$, prover P_2 replaces λ by a question $y \in Y$ chosen uniformly at random. As a result, the question that P_2 receives in $(\lambda \circ G)^n$ is transformed into a randomly distributed question in G^n. Moreover, the assumption that G is a free game implies that the question pair that P_1 and P_2 now hold is distributed uniformly at random over all question pairs of the game G^n. Hence if the provers use strategy S, then the probability that the verifier of G^n accepts (taken over the choice of question to P_1 and transformed question to P_2) is at least $\omega(G^n)$. Indeed, P_2 answers the transformed question according to strategy S. □

COROLLARY 3.6. *There exists an infinite family $\mathcal{G}$ of free games such that $\omega(\lambda \circ G) \leq 7/8$ for every $G \in \mathcal{G}$, and for any n there is some $G \in \mathcal{G}$ with $\omega((\lambda \circ G)^n) \geq 1/8$.*

Proof. Apply Proposition 3.5 to the family of games from the Feige–Verbitsky theorem [14] cited above. □

Corollary 3.6 implies that there are families of games that have the miss property yet for which parallel repetition does not yield the error reduction obtained in Theorem 3.3. We were unable to resolve the question of whether the projection property alone makes Theorem 3.3 work or whether the combination of projection and miss is required.

We now give some intuition to explain why having miss rounds facilitates error reduction through parallel repetition. To win several parallel games with high probability, the provers must coordinate their strategies very carefully. A miss round disrupts this coordination: each prover has less understanding about what the other prover knows. Unfortunately, we know of no direct, easily motivated way of analyzing this effect.

We now give some intuition for the proof of Theorem 3.3. First, we actually analyze the error rate of G^{4n}, not G^n; the difference between n and $4n$ is easily swallowed up by an appropriate choice of c. In the analysis, out of the $4n$ rounds of G^{4n}, we concentrate only on n rounds, of which only $m \ll n$ are match rounds and the rest are miss rounds. (In fact, our analysis is somewhat simplified if we start directly with a proof system that has n rounds, of which m rounds chosen at random are match

rounds, and $n - m$ rounds are miss rounds.) Oversimplifying, P_1 has two possible modes of behavior. One is to employ a projection strategy for all n rounds, answering each round independently, and within each round using a projection strategy. The other is to base the answer in any particular round on the questions in all other rounds. If P_1 employs a projection strategy, then he is not using the fact that rounds are repeated in parallel, and standard Chernoff bounds imply that the probability of simultaneous success on all rounds is low. If P_1 does not employ a projection strategy, then his answers on the m match rounds highly depend on the questions received on the $n - m$ miss rounds. But prover P_2 receives only a λ on the miss rounds and has no idea what P_1 receives. So P_2 cannot know how to answer the match rounds in a way that indeed produces a match.

The rest of the paper is organized as follows. The proof of the main theorem itself appears in section 6. Prior to the proof, in sections 4 and 5, we present some general properties of multivariate functions. In section 4 we study the influence of a small number of random variables on the value of a function. This is related to the information available to the second prover, who sees only the questions on m match rounds, regarding the output of the first prover on these m rounds, which is a function of the questions of all n rounds. In section 5 we characterize the "gray area" between the two extreme strategies for the first prover in the simplified overview above: the projection strategy and a strategy in which the answer in each round is highly influenced by the questions in all other rounds. We show that in some exact sense, there is no gray area in between.

4. The influence of random variables on a function. The results of this section were developed with the help of Leonid Gurvits.

Let Q be a finite set and let $x_i \leftarrow \pi_i$ denote a random variable $x_i \in Q$ chosen at random according to probability distribution π_i over Q. Let $\pi = \pi_1 \times \pi_2 \times \cdots \times \pi_n$ be a product distribution over Q^n, and let $x \leftarrow \pi$ denote a random n-vector chosen according to probability distribution π. That is, for each coordinate i of x, $x_i \leftarrow \pi_i$, independently of the other coordinates of x. Let $f : Q^n \to \mathcal{R}^\ell$ be a function whose values are points in ℓ-dimensional real space, and let the *mean* $\mu[f, \pi]$ of f under π denote the expectation of f over the choice of $x \leftarrow \pi$ (which is the center of mass of the points in $\mathcal{R}^\ell$ if probability is interpreted as mass). That is,

$$\mu[f, \pi] \stackrel{\text{def}}{=} \mathrm{E}_{x \leftarrow \pi}[f(x)] = \sum_x \pi(x) f(x).$$

Similarly, we define the variance $\sigma^2[f, \pi]$ by

$$\sigma^2[f, \pi] \stackrel{\text{def}}{=} \mathrm{E}_{x \leftarrow \pi}\left[(f(x) - \mu[f, \pi])^2\right] = \mathrm{E}_{x \leftarrow \pi}[f(x)^2] - \mu[f, \pi]^2.$$

Let $[n]$ denote the set of integers from 1 to n. For $m \le n$, we will be interested in m-vectors $\vec{\imath} \in [n]^m$ in which all coordinates are distinct and ascending. Thus, $\vec{\imath}$ denotes an m-element subset of $[n]$. As a convention, $\vec{\imath} \leftarrow [n]^m$ denotes a vector chosen uniformly at random from all vectors of $[n]^m$ with distinct ascending entries. Let $\vec{q}$ denote a vector in Q^m. Let $x[\vec{\imath}]$ denote the projection of x to the coordinates indexed by $\vec{\imath}$ ($x[i]$, for scalar i, is interpreted in the obvious manner).

DEFINITION 4.1. *An m-block $B = (\vec{\imath}, \vec{q})$ is a sequence of m pairs (i_j, q_j) (for $1 \le j \le m$), where $q_j \in Q$, $i_j \in [n]$, and $i_j < i_k$ when $j < k$. In our intended use, an m-block specifies the values of m of the input variables for an n-variate function.*

A vector $x \in Q^n$ *satisfies* the m-block B if for every pair $(i_j, q_j) \in B$, $x_{i_j} = q_j$. For a fixed m-block B, let the conditional mean $\mu[f, \pi|B]$ denote the expectation of

$f(x)$ when x is chosen at random according to π, conditioned on x satisfying B. Let $B \overset{m}{\leftarrow} \pi$ denote an m-block $(\vec{i}, \vec{q})$ chosen at random, where $\vec{i} \leftarrow [n]^m$, and each entry of q_j of $\vec{q}$ is chosen independently according to π_{i_j}.

Clearly, for any function f, the expectation of the conditional mean is the same as the mean. That is, $\mathrm{E}_{B \overset{m}{\leftarrow} \pi} \mu[f, \pi|B] = \mu[f, \pi]$. We shall show that if m is small compared to n, then for most choices of an m-block B, the conditional mean is close to the mean. In other words, the value of x on m random coordinates is unlikely to significantly influence the mean of $f(x)$. Our analysis is essentially tight.

We define the *inner product* of two vectors u and v by $\langle u, v \rangle \overset{\text{def}}{=} \sum u_i v_i$ and the *norm* of vector x by $\|x\| \overset{\text{def}}{=} \sqrt{\langle x, x \rangle}$.

DEFINITION 4.2. *For a function $f : Q^n \to \mathcal{R}^\ell$ and probability distribution π, the* m-variance $\sigma^2[f, \pi, m]$ *is the mean square distance between the mean of f and the conditional mean of f. Formally,*

$$\sigma^2 [f, \pi, m] \overset{def}{=} \mathrm{E}_{B \overset{m}{\leftarrow} \pi} \left[\| \mu [f, \pi|B] - \mu [f, \pi] \|^2 \right].$$

By the linearity of expectation and of the inner product operation, it can be easily verified that $\mathrm{E}_{B \overset{m}{\leftarrow} \pi}[\|\mu[f, \pi|B] - \mu[f, \pi]\|^2] = \mathrm{E}_{B \overset{m}{\leftarrow} \pi}[\|\mu[f, \pi|B]\|^2] - \|\mu[f, \pi]\|^2$, giving an alternative formulation of the variance which we shall often use. To simplify notation, we use the convention that v^2 is interpreted as $\|v\|^2$ whenever v is a vector.

The m-variance generalizes the notion of the variance in the sense that when $m = n$ (that is, the input as a whole is revealed), $\sigma^2[f, \pi, n] = \mathrm{E}_{x \leftarrow \pi}[\|f(x)\|^2] - \|\mu[f, \pi]\|^2 = \sigma^2[f, \pi]$. Intuitively, the m-variance is related to the influence that a random set of m variables has on the value of a function.

For simple examples of the concept of m-variance, consider the following Boolean functions, where $n > 1$, π is uniform over $\{0, 1\}^n$, and x_i denotes the ith variable (coordinate) of x. The parity function $f(x) = \sum_{i=1}^n x_i (\mathrm{mod}\ 2)$ has zero m-variance for all $m \leq n - 1$, since as long as one variable remains unknown, the parity function remains balanced. The majority function, $f(x) = 1$ iff $\sum_{i=1}^n x_i \geq n/2$, has 1-variance $\Theta(1/n)$, because knowing the value of one variable biases the majority function by $\Theta(1/\sqrt{n})$. More generally, the k-majority function, $f(x) = 1$ iff $\sum_{i=1}^k x_i \geq k/2$, also has 1-variance $\Theta(1/n)$ for any k, because with probability k/n the sampled variable is among the k variables on which the majority is computed, and then it biases their majority by $\Theta(1/\sqrt{k})$.

Note that if the function f depends only on one variable, then $\sigma^2[f, \pi, m] = m\sigma^2[f, \pi]/n$, since a block B influences the value of f if it contains the distinguished variable (which happens with probability m/n), and then it completely determines the value of the function. The following theorem generalizes this to arbitrary functions.

THEOREM 4.3. *Let $f : Q^n \to \mathcal{R}^\ell$ be an arbitrary function and let π be an arbitrary product probability distribution on Q^n. Then for any m, where $1 \leq m \leq n$, the m-variance of f satisfies*

$$\sigma^2 [f, \pi, m] \leq \frac{m}{n} \sigma^2 [f, \pi].$$

Proof. We first concentrate on $f : Q^n \to \mathcal{R}$; we relax this restriction later.

In our computations of expectations and variances, x_i is always distributed according to π_i. We will at times specify a set of variables in the subscript of an expectation {variance}; this denotes taking the expectation {variance} over the choice of all the variables in the subscript, where each variable x_i is independently distributed according to π_i.

Given a subset of the variable indices, $S = \{i_1, \ldots, i_k\}$, we define f_S by

$$f_S(x_{i_1}, \ldots, x_{i_k}) = \mathrm{E}_{x_j : j \notin S}[f(x_1, \ldots, x_n)].$$

That is, f_S gives the expected value of f conditioned on the values of $x_{i_1}, \ldots, x_{i_k}$. We define $\pi_S = (\pi_{i_1}, \ldots, \pi_{i_k})$ and $\sigma^2[f, \pi, S]$ by

$$\sigma^2[f, \pi, S] \stackrel{\text{def}}{=} \sigma^2[f_S, \pi_S] = \mathrm{E}_{x_i : i \in S}[f_S(x_{i_1}, \ldots, x_{i_k})^2] - \mu[f, \pi]^2, \tag{4.1}$$

where the latter equality follows from $\mu[f, \pi] = \mu[f_S, \pi_S]$.

By definition, $\sigma^2[f, \pi, m] = \mathrm{E}_S[\sigma^2[f, \pi, S]]$, where S is distributed uniformly over m-element subsets of $[n]$. The crux of our proof is to upper bound $\sigma^2[f, \pi, S]$ by a quantity I_S whose expected value (over the choice of S) is $(m/n)\sigma^2[f, \pi]$. Let $P = i_1, \ldots, i_n$ be an arbitrary ordering of the variables. We define

$$I_{i_j} = \sigma^2[f, \pi, \{i_1, \ldots, i_j\}] - \sigma^2[f, \pi, \{i_1, \ldots, i_{j-1}\}]$$

and

$$I_S = \sum_{i \in S} I_i.$$

When P is unclear we write $I_i(P)$. It follows via a telescoping sum that $\sigma^2[f, \pi] = \sum_i I_i$; by the linearity of expectation, it follows that $\mathrm{E}_S[I_S] = (m/n) \sum_i I_i$, hence $\mathrm{E}_S[I_S] = (m/n)\sigma^2[f, \pi]$. The theorem, restricted to the case where the range of f is $\mathcal{R}$, then follows immediately from Lemma 4.4 below.

To extend the proof to the case that the range of f is $\mathcal{R}^\ell$, consider an arbitrary orthonormal basis for $\mathcal{R}^\ell$. Now view f as ℓ different functions $f_1, \ldots, f_\ell$, where $f_i(x)$ is the projection of $f(x)$ on the ith basis vector. For each function f_i separately, the range is just $\mathcal{R}$, and hence the theorem holds. As the square of the distance of two points in $\mathcal{R}^\ell$ is the sum of squares of their distances when projected to the ℓ basis vectors, the theorem follows also for f. □

LEMMA 4.4. *For any ordering P on $\{1, \ldots, n\}$, $\sigma^2[f, \pi, S] \leq I_S$.*

For our purposes, a single P that works for all S would suffice, but considering an arbitrary P will be useful in the proof. Before proving Lemma 4.4, we prove a useful, presumably known inequality on variances.

PROPOSITION 4.5. *Let $f : Q^2 \longrightarrow R$ be an arbitrary function and let (x, y) be distributed according to an arbitrary product probability distribution on Q^2. Then*

$$\sigma_x^2[\mathrm{E}_y[f(x, y)]] \leq \mathrm{E}_y[\sigma_x^2[f(x, y)]].$$

Proof. We first observe that for any function $g(y)$, the function $f'(x, y) = f(x, y) + g(y)$ satisfies $\sigma_x^2[f'(x, y)] = \sigma_x^2[f(x, y)]$ for all y, and $\mathrm{E}_y[f'(x, y)] = \mathrm{E}_y[f(x, y)] + \mathrm{E}_y[g(y)]$ for all x. It follows that $\sigma_x^2[\mathrm{E}_y[f(x, y)]] \leq \mathrm{E}_y[\sigma_x^2[f(x, y)]]$ iff $\sigma_x^2[\mathrm{E}_y[f'(x, y)]] \leq \mathrm{E}_y[\sigma_x^2[f'(x, y)]]$, since both quantities are unchanged by this translation. We therefore assume without loss of generality that for all y, $\mathrm{E}_x[f(x, y)] = 0$; if not, translate by $g(y) = -\mathrm{E}_x[f(x, y)]$. It follows that $\mathrm{E}_x \mathrm{E}_y[f(x, y)] = 0$, and hence that

$$\sigma_x^2[\mathrm{E}_y[f(x, y)]] = \mathrm{E}_x \mathrm{E}_y[f(x, y)^2].$$

Similarly, it follows that

$$\begin{aligned} \mathrm{E}_y[\sigma_x^2[f(x, y)]] &= \mathrm{E}_y \mathrm{E}_x[f(x, y)^2] \\ &= \mathrm{E}_x \mathrm{E}_y[f(x, y)^2]. \end{aligned}$$

Fixing x, we have $\sigma_y^2[f(x,y)] = \mathrm{E}_y[f(x,y)^2] - \mathrm{E}_y[f(x,y)]^2$. Hence, by the positivity of the variance, $\mathrm{E}_y[f(x,y)]^2 \le \mathrm{E}_y[f(x,y)^2]$. The proposition follows. □

Proof of Lemma 4.4. When S is a prefix of P, then by the definitions and a telescoping sum it follows that $\sigma^2[f,\pi,S] = I_S$. To show the inequality for arbitrary S, we make incremental changes $P \to P'$ such that $I_S(P') \le I_S(P)$, finally obtaining an ordering Q that contains S as a prefix. Then, $I_S(Q) = \sigma^2[f,\pi,S]$ and $I_S(Q) \le I_S(P)$, implying the lemma.

For ease of exposition, we assume without loss of generality that $P = 1,\ldots,n$. We consider the ordering

$$P' = 1,\ldots,i-2,i,i-1,i+1,\ldots,n,$$

where $i \in S$ and $i-1 \notin S$. That is, we move a variable indexed by S one step closer to the beginning of the ordering, moving it past a variable that is not in S. Clearly, a sequence of such operations can be used to move all the variables of S to the beginning of the sequence. It remains to show that $I_S(P') \le I_S(P)$. Clearly, $I_j(P') = I_j(P)$ for $j \notin \{i-1,i\}$. It thus suffices to show that $I_i(P') \le I_i(P)$, since I_{i-1} does not affect I_S.

Let $A = \{1,\ldots,i\}$, $B = \{1,\ldots,i-1\}$, $C = \{1,\ldots,i-2,i\}$, and $D = \{1,\ldots,i-2\}$. Expanding out the definitions, we obtain,

$$\begin{aligned} I_i(P) = {} & \left(\mathrm{E}_{x_1,\ldots,x_{i-2}}\mathrm{E}_{x_{i-1}}\mathrm{E}_{x_i}[f_A(x_1,\ldots,x_i)^2] - \mu[f,\pi]^2\right) \\ & - \left(\mathrm{E}_{x_1,\ldots,x_{i-2}}\mathrm{E}_{x_{i-1}}[f_B(x_1,\ldots,x_{i-1})^2] - \mu[f,\pi]^2\right). \end{aligned}$$

Given $x_1,\ldots,x_{i-2}$, we define $g(x_{i-1},x_i) = f_A(x_1,\ldots,x_i)$. Noting that

$$f_B(x_1,\ldots,x_{i-1}) = \mathrm{E}_{x_i}[f_A(x_1,\ldots,x_i)],$$

we obtain,

$$I_i(P) = \mathrm{E}_{x_1,\ldots,x_{i-2}}\mathrm{E}_{x_{i-1}}[\sigma_{x_i}^2[g(x_{i-1},x_i)]].$$

By similar manipulations, we obtain

$$\begin{aligned} I_i(P') &= \left(\mathrm{E}_{x_1,\ldots,x_{i-2}}\mathrm{E}_{x_i}[f_C(x_1,\ldots,x_{i-2},x_i)^2] - \mu[f,\pi]^2\right) \\ &\quad - \left(\mathrm{E}_{x_1,\ldots,x_{i-2}}[f_D(x_1,\ldots,x_{i-2})^2] - \mu[f,\pi]^2\right) \\ &= \mathrm{E}_{x_1,\ldots,x_{i-2}}[\sigma_{x_i}^2[\mathrm{E}_{x_{i-1}}[g(x_{i-1},x_i)]]]. \end{aligned}$$

However, by Proposition 4.5 it follows that for all $x_1,\ldots,x_{i-2}$,

$$\sigma_{x_i}^2[\mathrm{E}_{x_{i-1}}[g(x_{i-1},x_i)]] \le \mathrm{E}_{x_{i-1}}[\sigma_{x_i}^2[g(x_{i-1},x_i)],$$

implying the lemma. □

Theorem 4.3 has the following useful corollary, that we shall use repeatedly in subsequent parts of the paper.

COROLLARY 4.6. *Let Q and A be finite sets, let $f : Q^n \to A$ be an arbitrary function, and let π be an arbitrary product probability distribution on Q^n. Then the influence of a random m-block on the probability that $f(x)$ attains any particular value $a \in A$ is bounded as follows:*

$$\mathrm{E}_{B \overset{m}{\leftarrow} \pi}\left[\sum_{a \in A}\left(\Pr_{x \leftarrow (Q^n,\pi)}[f(x) = a] - \Pr_{x \leftarrow (\pi|B)}[f(x) = a]\right)^2\right] \le m/n.$$

Proof. By the linearity of expectation, it suffices to show that

$$\sum_{a\in A} \mathrm{E}_{B\overset{m}{\leftarrow}\pi}\left[\left(\Pr_{x\leftarrow\pi}\left[f\left(x\right)=a\right]-\Pr_{x\leftarrow(\pi|B)}\left[f\left(x\right)=a\right]\right)^2\right]\le m/n. \tag{4.2}$$

For each $a \in A$, define $f_a : Q^n \to \{0,1\}$ by $f_a(x) = 1$ if $f(x) = a$ and $f_a(x) = 0$ otherwise. For any distribution D, we have $\mu[f_a, D] = \Pr_{x\leftarrow D}[f(x) = a]$. By Definition 4.2, we can write the left-hand side of (4.2) as $\sum_{a\in A}\sigma^2[f_a,\pi,m]$. By Theorem 4.3, $\sigma^2[f_a,\pi,m] \le \frac{m}{n}\sigma^2[f_a,\pi]$. Now, $\sigma^2[f_a,\pi] = p_a(1-p_a) \le p_a$, where $p_a = \Pr_{x\leftarrow\pi}[f(x) = a]$, so

$$\sum_{a\in A}\sigma^2[f_a,\pi,m] \le \frac{m}{n}\sum_{a\in A} p_a = \frac{m}{n}. \qquad \square$$

5. Correlations within multivalued functions. Let Q and A be finite sets, let $f : Q^n \to A^n$ be a function, and let π be a probability distribution over Q, extended as a product distribution π^n over Q^n. Recall that $\vec{\imath} \in [n]^m$ denotes a vector of m distinct, ascending entries in $\{1,\ldots,n\}$, the notion of an m-block $(\vec{\imath},\vec{q})$, and the projection notation from section 4. Let $\Pr[\vec{a}|(\vec{\imath},\vec{q})]$ denote the probability that $f(x)[\vec{\imath}] = \vec{a}$, conditioned on $x[\vec{\imath}] = \vec{q}$ (i.e., the probability is taken over $x \leftarrow (Q^n, \pi^n|(\vec{\imath},\vec{q}))$). This notation is extended in a natural way to $\Pr[\vec{a}|(\vec{\imath},\vec{q})(i,q)]$ (in which case the conditioning is done on one coordinate more than the projection), and to $\Pr[\vec{a},a|(\vec{\imath},\vec{q})(i,q)]$ for $a \in A$. Throughout we use the convention that i has to be distinct from all coordinates of $\vec{\imath}$.

DEFINITION 5.1. *For a parameter $\varepsilon > 0$, the m-triple $(\vec{\imath},\vec{q},\vec{a})$ is* alive *if $\Pr[\vec{a}|(\vec{\imath},\vec{q})] \ge \varepsilon$. The m-block $(\vec{\imath},\vec{q})$ is* alive *if for some $\vec{a}$ the m-triple $(\vec{\imath},\vec{q},\vec{a})$ is alive.*

DEFINITION 5.2. *An m-block $(\vec{\imath},\vec{q})$ $(1-\eta)$-*determines *a pair (i,q) if for every live m-triple $(\vec{\imath},\vec{q},\vec{a})$ there exists $a \in A$ such that*

$$\Pr\left[\vec{a},a|\left(\vec{\imath},\vec{q}\right)(i,q)\right] \ge (1-\eta)\Pr\left[\vec{a}|\left(\vec{\imath},\vec{q}\right)(i,q)\right].$$

The above inequality may be thought of in terms of conditional probability. Conditioned on $x[\vec{\imath},i] = \vec{q},q$ and $f(x)[\vec{q}] = \vec{a}$, $f(x)[i] = a$ with probability at least $(1-\eta)$.

DEFINITION 5.3. *An m-block $(\vec{\imath},\vec{q})$ is* $(1-\eta)$-good *if it is alive and* $(1-\eta)$-determines *a randomly chosen pair (i,q) ($i \leftarrow ([n]-\vec{\imath})$ and $q \leftarrow \pi$) with probability at least $1-\eta$.*

It is useful to consider the "majority answer" guess for the value of $f(x)$ at some coordinate, given partial information about x and $f(x)$.

DEFINITION 5.4. *Given $(\vec{\imath},\vec{q},\vec{a})$, we define* $\mathrm{maj}(i,q)$ *to be the most likely (breaking ties lexicographically) value for $f(x)[i]$, over the choice of x, conditioned on $x[\vec{\imath}] = \vec{q}$, $f(x)[\vec{\imath}] = \vec{a}$, and $x[i] = q$.*

A good block $(\vec{\imath},\vec{q})$ has the property that for any live $(\vec{\imath},\vec{q},\vec{a})$ a large fraction of the other answers are expected to agree with the majority answer defined above.

The following proposition will be used in the proof of our main theorem.

PROPOSITION 5.5. *Suppose that $(\vec{\imath},\vec{q})$ is $(1-\eta)$-good, for $\eta < \frac{1}{2}$, and that $(\vec{\imath},\vec{q},\vec{a})$ is alive. Then $f(x)[i] = \mathrm{maj}(i,q)$ with probability at least $1 - 2\eta/\varepsilon$ in the following experiment:*

1. *Choose x according to π^n, conditioned on $x[\vec{\imath}] = \vec{q}$ and $f(x)[\vec{\imath}] = \vec{a}$.*
2. *Choose i uniformly from $[n] - \vec{\imath}$.*
3. *Let $q = x[i]$.*

Proof. Consider the experiment of choosing (i,q) by $i \leftarrow ([n]-\vec{\imath})$, $q = x[i]$, conditioned on $x[\vec{\imath}] = \vec{q}$ but *not* conditioned on $f(x)[\vec{\imath}] = \vec{a}$. Since $(\vec{\imath},\vec{q})$ is good, by Definition 5.3, (i,q) fails to be $(1-\eta)$-determined by $(\vec{\imath},\vec{q})$ with probability at most η. The probability that it fails to be $(1-\eta)$-determined, conditioned on $f(x)[\vec{\imath}] = \vec{a}$, is at most $\eta/\Pr(f(x)[\vec{\imath}] = \vec{a}) \le \eta/\varepsilon$. Hence, (i,q) is $(1-\eta)$-determined with probability $1-\eta/\varepsilon$, conditioned on $x[\vec{\imath}] = \vec{q}$ and $f(x)[\vec{\imath}] = \vec{a}$. By Definition 5.2, there is some a such that under this same conditioning (and additionally conditioning on $x[i] = q$) $f(x)[i] = a$ with probability at least $(1-\eta)$; by the definition of maj and the above, we have that $f(x)[i] = \mathrm{maj}(i,q)$ with probability at least

$$(1-\eta/\varepsilon)\,(1-\eta) \ge 1 - 2\eta/\varepsilon. \qquad \square$$

Intuitively, for any function $f : Q^n \to A^n$, either the value of the projection of $f(x)$ on a random coordinate can be guessed with high confidence by looking only at the same coordinate of x, or else, when one looks at the value of x at m random coordinates, errors build up, making it improbable to simultaneously guess correctly the projection of $f(x)$ on the respective m coordinates. The following lemma builds upon this intuition.

LEMMA 5.6. *For $m < n/2$, $n > 2^{10}\eta^{-4}\varepsilon^{-8}$, $\eta \le \frac{1}{2}$, and $m > 2^5\eta^{-2}\varepsilon^{-4}$, there exists a* good *block size k, $1 \le k \le m$, such that one of the following two conditions holds:*

1. *The probability that a random k-block $(\vec{\imath},\vec{q}) \overset{k}{\leftarrow} \pi^n$ is alive is at most ε.*
2. *If one chooses $(\vec{\imath},\vec{q})$ at random from the live k-blocks, $(\vec{\imath},\vec{q})$ will be $(1-\eta)$-good with probability at least $(1-\varepsilon)$. That is,*

$$\Pr_{(\vec{\imath},\vec{q}) \overset{k}{\leftarrow} \pi^n}\left[(\vec{\imath},\vec{q}) \text{ is } (1-\eta)\text{-good} \mid (\vec{\imath},\vec{q}) \text{ live}\right] \ge 1-\varepsilon.$$

Proof. For each j, $1 \le j \le n/2$, let E_j denote the following expectation:

$$E_j = \mathrm{E}_{(\vec{\imath},\vec{q})}\left[\sum_{\vec{a}\in A^j} \Pr\left[\vec{a}\right|(\vec{\imath},\vec{q})\left]^2\right],$$

where the expectation is taken over the choice of random j-block $(\vec{\imath},\vec{q})$. For every j, $0 < E_j \le 1$.

Let us give some insight on what E_j is measuring. Given $(\vec{\imath},\vec{q})$, the summation term measures the predictability of $\vec{a}$: if $\vec{a}$ is completely determined by $(\vec{\imath},\vec{q})$, the summation will be 1; if $\vec{a}$ is uniformly distributed with N possible values, the summation will be $1/N$. There are two competing considerations governing the relationship between E_j and E_{j+1}. Having more questions, and hence more answers, tends to fragment the set of possible answer vectors, causing E_j to be larger than E_{j+1}. However, seeing more questions may give so much information about the answers that the answer vectors are less fragmented. For example, if questions (q_1,q_2) are answered by (q_2,q_1), then E_1 may be quite small and $E_2 = 1$. We will show that, for our choice of parameters, if j is not a good block size, then the former consideration dominates; quantitatively, $E_j - E_{j+1} \ge 1/m$. Hence if there is no good block size between 1 and m, then $E_1 - E_{m+1} \ge 1$, a contradiction.

In order to lower bound $E_j - E_{j+1}$, we introduce a hybrid quantity:

$$E_j^* = \mathrm{E}_{(\vec{\imath},\vec{q})(i,q)}\left[\sum_{\vec{a}\in A^j} \Pr\left[\vec{a}\right|(\vec{\imath},\vec{q})\,(i,q)\left]^2\right],$$

where the expectation is taken over the choice of random j-block $(\vec{\imath},\vec{q})$ and random pair (i,q) $(i \notin \vec{\imath})$.

Let us give some more insight. E_j^* measures the average predictability of $\vec{a}$ given $(\vec{\imath},\vec{q})$ and an additional pair (i,q). Our proof proceeds as follows. First, we show that E_j^* is not much larger that E_j. The idea is that a random (i,q) is not likely to have much influence on $\vec{a}$, and hence knowing (i,q) will not make $\vec{a}$ that much more predictable on average. We then show that if j is not a good block size, then E_{j+1} is significantly smaller than E_j^*. That is, given $(\vec{\imath},\vec{q})$ and (i,q), $(\vec{a},a)$ is significantly harder to predict on average than just $\vec{a}$. Combining these relations between E_j, E_j^*, and E_{j+1}, we show that E_{j+1} is significantly smaller than E_j when $j \le n/2$ is not a good block size.

It follows from the above definitions that

$$E_j^* - E_j = \mathrm{E}_{(\vec{\imath},\vec{q})}\left[\mathrm{E}_{(i,q)}\left[\sum_{\vec{a}\in A^j} \Pr\left[\vec{a}\right|\left(\vec{\imath},\vec{q}\right)(i,q)\right]^2 - \Pr\left[\vec{a}\right|\left(\vec{\imath},\vec{q}\right)]^2\right]\right] \tag{5.1}$$

and

$$E_j^* - E_{j+1} = \mathrm{E}_{(\vec{\imath},\vec{q})(i,q)}\left[\sum_{\vec{a}\in A^j}\left(\Pr\left[\vec{a}\right|\left(\vec{\imath},\vec{q}\right)(i,q)\right]^2 - \sum_{a\in A}\Pr\left[\vec{a},a\right|\left(\vec{\imath},\vec{q}\right)(i,q)\right]^2\right)\right]. \tag{5.2}$$

PROPOSITION 5.7. *For any block size $j \le n/2$ (whether good or not),*

$$E_j^* - E_j \le \frac{2}{\sqrt{n-j}} \le \sqrt{\frac{8}{n}}$$

.

Proof. Fix a j-block $(\vec{\imath},\vec{q})$. The value of $\vec{a}$ is now a function of $n-j$ variables. Let ℓ denote the cardinality of A and consider the vector $v \in \mathcal{R}^{\ell^j}$ of probabilities $\Pr[\vec{a}|(\vec{\imath},\vec{q})]$. Then $\|v\|^2 = \sum_{\vec{a}\in A^j}(\Pr[\vec{a}|(\vec{\imath},\vec{q})])^2 \le 1$. Now fix also a pair (i,q) and consider the vector $u \in \mathcal{R}^{\ell^j}$ of probabilities $\Pr[\vec{a}|(\vec{\imath},\vec{q})(i,q)]$. Then $\|u\|^2 = \sum_{\vec{a}\in A^j}\Pr[\vec{a}|(\vec{\imath},\vec{q})(i,q)]^2 \le 1$, and by the triangle inequality, $\|u+v\| \le 2$. Moreover,

$$\begin{aligned}\sum_{\vec{a}\in A^j}\left(\Pr\left[\vec{a}\right|\left(\vec{\imath},\vec{q}\right)(i,q)\right]^2 - \Pr\left[\vec{a}\right|\left(\vec{\imath},\vec{q}\right)]^2\right) &= \|u\|^2 - \|v\|^2 = \langle (u+v),(u-v)\rangle \\ &\le \|u+v\|\cdot\|u-v\| \le 2\|u-v\|.\end{aligned}$$

By convexity and Corollary 4.6 (with $m=1$) we obtain

$$\mathrm{E}_{(i,q)}\left[\|u-v\|\right]^2 \le \mathrm{E}_{(i,q)}\left[\|u-v\|^2\right] \le \frac{1}{n-j}.$$

Combining this with the previous inequality yields

$$\mathrm{E}_{(i,q)}\left[\sum_{\vec{a}\in A^j}\left(\Pr\left[\vec{a}\right|\left(\vec{\imath},\vec{q}\right)(i,q)\right]^2 - \Pr\left[\vec{a}\right|\left(\vec{\imath},\vec{q}\right)]^2\right)\right] \le \frac{2}{\sqrt{n-j}}.$$

The proposition follows by taking expectations over $(\vec{\imath},\vec{q})$. ∎

PROPOSITION 5.8. *If block size $j \le n/2$ is not good, then $E_j^* - E_{j+1} \ge \eta^2\varepsilon^4/8$.*

Proof. Clearly, for any j-block $(\vec{\imath},\vec{q})$ and any pair (i,q) with $i \notin \vec{\imath}$, and any $\vec{a} \in A^j$,

$$\Pr\left[\vec{a}\right|\left(\vec{\imath},\vec{q}\right)(i,q)\left]^2 \;\ge\; \sum_{a\in A} \Pr\left[\vec{a},a\right|\left(\vec{\imath},\vec{q}\right)(i,q)\left]^2\right. . \tag{5.3}$$

When(i,q) is not $(1-\eta)$-determined by $(\vec{\imath},\vec{q})$, then strict inequality holds. We quantify the effect of these inequalities. First, we show that with a reasonably large probability, some useful events occur.

PROPOSITION 5.9. *Suppose that $j \le n/2$ is not a good block size. Let $(\vec{\imath},\vec{q})$ be a randomly chosen j-block and let (i,q) be a randomly chosen pair with $i \notin \vec{\imath}$. Then with probability at least $\eta\varepsilon^2/2$, there will exist some $\vec{a}$ such that*

1. *(For all $a \in A$)*$\Pr[\vec{a},a|(\vec{\imath},\vec{q})(i,q)] \le (1-\eta)\Pr[\vec{a}|(\vec{\imath},\vec{q})(i,q)]$*, and*
2. $\Pr[\vec{a}|(\vec{\imath},\vec{q})(i,q)] \ge \varepsilon/2$.

We defer the proof of Proposition 5.9 and proceed to analyzing its consequences. We first use a straightforward convexity argument to show that for $(\vec{\imath},\vec{q})$, (i,q), and $\vec{a}$ satisfying the conclusions of Proposition 5.9,

$$\sum_{a\in A} \Pr\left[\vec{a},a\right|\left(\vec{\imath},\vec{q}\right)(i,q)\left]^2\right. \le \left(1-2\eta+2\eta^2\right)\cdot \Pr\left[\vec{a}\right|\left(\vec{\imath},\vec{q}\right)(i,q)\left]^2\right. .$$

In general, if one wants to maximize $X_1^2+\cdots+X_k^2$ subject to $X = X_1+\cdots+X_k$, where all quantities are positive, it always helps to subtract from smaller values in order to add to larger values. Given the added constraint that $X_i \le (1-\eta)X$, the maximum is attained by setting $X_1 = (1-\eta)X$, $X_2 = \eta X$, and all the rest equal to 0, giving $X_1^2+\cdots+X_k^2 = (1-2\eta+2\eta^2)X^2$.

This implies (when $\eta \le 1/2$) that

$$\Pr\left[\vec{a}\right|\left(\vec{\imath},\vec{q}\right)(i,q)\left]^2 - \sum_{a\in A} \Pr\left[\vec{a},a\right|\left(\vec{\imath},\vec{q}\right)(i,q)\left]^2\right. \ge \eta\cdot \Pr\left[\vec{a}\right|\left(\vec{\imath},\vec{q}\right)(i,q)\left]^2\right. \ge \eta\cdot(\varepsilon/2)^2. \tag{5.4}$$

By (5.3), (5.1), and (5.4), each $((\vec{\imath},\vec{q}),(i,q))$ that satisfies the condition of Proposition 5.9 contributes at least $\eta(\varepsilon/2)^2 = \eta\varepsilon^2/4$ times the probability of the event occurring to $E_j^* - E_{j+1}$. Thus the good events contribute at least $(\eta\varepsilon^2/2)(\eta\varepsilon^2/4) = \eta^2\varepsilon^4/8$ to $E_j^* - E_{j+1}$. (Recall that all the other $((\vec{\imath},\vec{q}),(i,q))$ terms contribute nonnegatively, by (5.3).) □

Proof of Proposition 5.9. The statement of the proposition considers $\vec{a}$ such that (among other properties) $\Pr[\vec{a}|(\vec{\imath},\vec{q})(i,q)] \ge \varepsilon/2$. We first show that if we modify this property, asking instead that $\Pr[\vec{a}|(\vec{\imath},\vec{q})] \ge \varepsilon$, then such $\vec{a}$ exist with sufficiently high probability. We then show it unlikely that an $\vec{a}$ exists that has the modified property but not the original property.

If j is not a good block size, then the probability that $(\vec{\imath},\vec{q})$ is alive is at least ε, and conditioned on being alive, the probability that $(\vec{\imath},\vec{q})$ is not good is again at least ε. Thereafter, the probability that $(\vec{\imath},\vec{q})$ does not $(1-\eta)$-determine a random (i,q) is at least η. Assume that all three of these events occur (this has probability at least $\eta\varepsilon^2$). Then because $(\vec{\imath},\vec{q})$ is alive and $(\vec{\imath},\vec{q})$ does not $(1-\eta)$-determine (i,q), there is some $\vec{a}$ such that $\Pr[\vec{a}|(\vec{\imath},\vec{q})] \ge \varepsilon$ and, for every $a \in A$,

$$\Pr\left[\vec{a},a\right|\left(\vec{\imath},\vec{q}\right)(i,q)\left] \le (1-\eta)\Pr\left[\vec{a}\right|\left(\vec{\imath},\vec{q}\right)(i,q)\left]\right. .$$

It remains to bound the probability that for some $\vec{a}$, $\Pr[\vec{a}|(\vec{\imath},\vec{q})] \geq \varepsilon$ but $\Pr[\vec{a}|(\vec{\imath},\vec{q})(i,q)] < \varepsilon/2$. We say that $((\vec{\imath},\vec{q}),(i,q))$ is *discardable* if, for some $\vec{a}$, $\Pr[\vec{a}|(\vec{\imath},\vec{q})] - \Pr[\vec{a}|(\vec{\imath},\vec{q})(i,q)] \geq \varepsilon/2$. Note that if $\Pr[\vec{a}|(\vec{\imath},\vec{q})] \geq \varepsilon$ and $((\vec{\imath},\vec{q}),(i,q))$ is not discardable, then $\Pr[\vec{a}|(\vec{\imath},\vec{q})(i,q)] \geq \varepsilon/2$. We show that discardable $((\vec{\imath},\vec{q}),(i,q))$ occur with probability at most $\eta\varepsilon^2/2$; combined with the above bound, this implies the proposition.

Consider a live j-block $(\vec{\imath},\vec{q})$ and define a function $g : Q^{n-j} \to A^j$ that receives as an argument the value of an input x on the coordinates other than $\vec{\imath}$, and outputs the value of $f(x)$ on the coordinates indexed by $\vec{\imath}$. By Corollary 4.6,

$$\mathrm{E}_{(i,q)\leftarrow(Q,\pi)}\left[\sum_{\vec{a}\in A^j}\left(\Pr_{x\leftarrow(Q^n,\pi^n|(\vec{\imath},\vec{q}))}\left[g\left(x\right)=\vec{a}\right]-\Pr_{x\leftarrow(Q^n,\pi^n|(\vec{\imath},\vec{q})(i,q))}\left[g\left(x\right)=\vec{a}\right]\right)^2\right]$$
$$\leq 1/\left(n-j\right)\leq 2/n.$$

Using Markov's inequality and simple manipulations, it follows that the probability (over the choice of (i,q)) that there is any $\vec{a}$ with $\Pr[\vec{a}|(\vec{\imath},\vec{q})]-\Pr[\vec{a}|(\vec{\imath},\vec{q})(i,q)] \geq \varepsilon/2$ is at most $(2/n)/(\varepsilon/2)^2 = 8/\varepsilon^2 n$. For $n > 16/\eta\varepsilon^4$ this probability is at most $\eta\varepsilon^2/2$. □

Finally, we conclude the proof of Lemma 5.6. From Propositions 5.7 and 5.8 we obtain that $E_j - E_{j+1} \geq \eta^2\varepsilon^4/8 - \sqrt{\frac{8}{n}}$. For $j \leq m \leq n/2$ and $n > 2^{10}\eta^{-4}\varepsilon^{-8}$, $E_j - E_{j+1} \geq \eta^2\varepsilon^4/32$. For $m > 2^5\eta^{-2}\varepsilon^{-4}$, this difference is more than $1/m$ and the lemma follows. □

6. Proof of the main theorem. For notational convenience we write the initial miss-match game as G rather than G'. For ease of exposition, rather than consider G^n, we shall consider a related game that we denote by $\hat{G}$, which is derived from G^n by conditioning that there be exactly m match rounds. Hence $\hat{G}$ contains n parallel rounds of G, with the restriction of having exactly m match rounds and $n-m$ miss rounds, where $m < n/2$ will be determined later. The locations of the match rounds is random. Proposition 6.1 implies that upper bounding the error for $\hat{G}$ will suffice to prove our main theorem, though with a different value for c (that "swallows up" the difference between $4n$ and n).

PROPOSITION 6.1. *For $\hat{G}$ as described above, $\omega(\hat{G}) \geq \omega(G^{4n}) - 4e^{-n/32}$.*

Proof. We describe a probability measure on strategies $P = (p_1, p_2)$ for the provers in $\hat{G}$. Each strategy corresponds to a particular way in which the game $\hat{G}$ can be completed to a game G^{4n}. Let p_k denote the probability that G^{4n} has exactly k match rounds, conditioned on it having at least m match rounds and at least $n-m$ miss rounds (the latter condition is equivalent to having at most $3n+m$ match rounds).

We can view such a completion as the following random process:

1. The provers uniformly choose a set $S \subset [4n]$ indexing the n rounds into which they place the rounds of $\hat{G}$.
2. The provers choose $k \in [m, 3n+m]$ according to the probability measure $\Pr[k] = p_k$.
3. The provers uniformly choose a set $M \subseteq [4n] \setminus S$ of size $k-m$. For each round indexed by M the provers agree on the questions for match rounds, generated according to G.
4. For all the remaining rounds (not indexed by S or M), the provers agree on the questions for miss rounds, generated according to G.

The provers, prior to the start of the protocol, jointly sample one member P from the space of completion strategies.

When a prover receives a list of n questions in the game $\hat{G}$, the prover uses the agreed upon completion to embed these as part of a list of $4n$ questions in the game G^{4n}; then the prover employs the optimal strategy of the game G^{4n} and sends back only the n answers that correspond to the original questions of $\hat{G}$. It can readily be seen that the probability that V accepts is at least the probability that the optimal strategy for G^{4n} wins, given the distribution on the questions. This distribution is the "usual" distribution for G^{4n}, conditioned on there being at least m match rounds and $n-m$ miss rounds. By standard Chernoff bounds, the probability that there are less than $n-m$ miss rounds or less than m match rounds out of $4n$ rounds is at most $4e^{-n/32}$; this probability is negligible compared to ϵ when n is sufficiently large. Hence the expected probability of winning is at least $\omega(G^{4n}) - 4e^{-n/32}$, where expectation is taken over the random choice of completion strategy and random questions for $\hat{G}$.

Finally, by averaging, there is at least one deterministic strategy P that ensures probability of acceptance of at least $\omega(G^{4n}) - 4e^{-n/32}$ in the game $\hat{G}$. □

We now prove Theorem 3.3 by showing that $\omega(\hat{G}) \leq \epsilon$.

Proof. Fix a (deterministic) strategy (p_1, p_2) for $\hat{G}$ with highest probability of success for the two provers. This strategy is a pair of functions $p_1 : (X_1 \times X_2)^n \rightarrow (A_1 \times A_2)^n$ and $p_2 : (X_1 \bigcup X_2 \bigcup \{\lambda\})^n \rightarrow (A_1 \bigcup A_2)^m$. Observe that once p_1 is fixed, the function p_2 is characterized using the maximum likelihood principle. That is, on seeing the sequence $\vec{q}$ of n questions, it is best for P_2 to consider all possible sequences of n questions to P_1 that are consistent with P_2 receiving $\vec{q}$, compute the answers of P_1 on the match rounds for each of these sequences, and then answer the match rounds of $\vec{q}$ in a way identical to the most likely answer sequence by P_1 (breaking ties arbitrarily).

Let $Q = X_1 \times X_2 \times \{1,2\}$, let $A = A_1 \bigcup A_2$, and let π' be a probability distribution over Q that agrees with π over $X_1 \times X_2$ and is uniform over $\{1,2\}$ (that is, choose the first two coordinates according to π and then choose the last coordinate uniformly from $\{1,2\}$). Based on p_1 we define the function $f : Q^n \rightarrow A^n$, described as follows. For an input in Q^n, first strip off the last component of each coordinate, obtaining an input in $(X_1 \times X_2)^n$. Then compute the output of p_1 on the stripped input. This will be a vector in $(A_1 \times A_2)^n$. Finally, for each coordinate in this output vector, save only one of its two components (either the one in A_1 or the one in A_2), based on the respective value of the $\{1,2\}$ component of the original input vector. The function f corresponds to what P_2 would need to respond if all rounds were match rounds. In $\hat{G}$ some rounds are miss rounds, and our analysis will concentrate on coordinates of f that correspond to match rounds.

Recall the notion of a k-block from section 4. Assume that $m < n/2$. (We will enforce this condition in our choice of m.) Applying Lemma 5.6 with respect to f and probability distribution $(\pi')^n$, we have a *good* block of size $k \leq m$ in the sense defined in Lemma 5.6. (We shall expand on this below.) Fix this k for the rest of the proof.

For the purpose of our proof, we describe a three-step procedure by which the verifier selects the questions to the two provers in the n rounds. It can easily be verified that this three-step procedure induces the correct probability distribution on the questions.

Step 1. Select at random a k-block $(\vec{\imath}, \vec{q}) \stackrel{k}{\leftarrow} (\pi')^n$ for f. That is, select at random k distinct rounds, and in each such round select a question pair from $X_1 \times X_2$ with probability π (to be sent to P_1), and an index uniformly from $\{1,2\}$ specifying which half is sent to P_2. This specifies k match rounds.

Step 2. From the remaining rounds, select at random an $(m-k)$-block, B, specifying $m-k$ additional match rounds.

Step 3. Make the remaining $n-m$ rounds miss rounds. Select the questions to P_1 for these $n-m$ rounds. (P_2 receives λ on these rounds.)

To outline the rest of the analysis, we describe five events, at least one of which will occur when the verifier accepts. For each event, we bound the probability that the event occurs and that the verifier accepts. Although these events are not independent, we can conservatively bound the probability that the verifier accepts by the sum of the individual bounds.

Consider the k-block $(\vec{\imath}, \vec{q})$ selected by the verifier in Step 1, and consider the eventual answer $\vec{a}$ that P_2 gives on his respective half questions on the rounds specified by $\vec{\imath}$. Based on $(\vec{\imath}, \vec{q})$ and on function f, consider a new function $g : Q^{n-k} \to A^k$ that gives the value of f on the k coordinates specified by $\vec{\imath}$ as a function of the remaining $n-k$ coordinates of the input. For the verifier to accept, P_2 must give the same answers on these half questions. There are two cases:

1. The answer $\vec{a}$ of P_2 was an unlikely answer for P_1, in the sense that $\Pr_{x \leftarrow (\pi')^{n-k}}[g(x) = \vec{a}] < \varepsilon$, where $\varepsilon < \epsilon$ will be chosen later. There are two subcases to consider, depending on whether $\vec{a}$ continues to be an unlikely answer even after the $(m-k)$-block B is chosen.
   (a) $\Pr_{x \leftarrow ((\pi')^{n-k}|B)}[g(x) = \vec{a}] < 2\varepsilon$. This subcase is handled by Event 1.
   (b) $\Pr_{x \leftarrow ((\pi')^{n-k}|B)}[g(x) = \vec{a}] \geq 2\varepsilon$. This subcase is handled by Event 2.
2. $\Pr_{x \leftarrow (\pi')^{n-k}}[g(x) = \vec{a}] \geq \varepsilon$. This implies that the k-block $(\vec{\imath}, \vec{q})$ is alive (with respect to f). We have two subcases.
   (a) The k-block $(\vec{\imath}, \vec{q})$ is not $(1-\eta)$-good, where the precise value of η will be chosen later. This is handled by Event 3.
   (b) The k-block $(\vec{\imath}, \vec{q})$ is $(1-\eta)$-good. There are two subcases depending on the number of the remaining coordinates that are answered by P_1 according to the majority strategy. The subcase that this number is small is handled by Event 4, and the subcase that this number is large is handled by Event 5.

We now describe and analyze these events in greater detail.

Event 1. If $\Pr_{x \leftarrow ((\pi')^{n-k}|B)}[g(x) = \vec{a}] < 2\varepsilon$, we say that Event 1 occurs and assume that the verifier accepts with probability 2ε. This is indeed an upper bound on the acceptance probability in this case, because the verifier accepts only if P_1 and P_2 answer identically these k questions, and $\Pr[g(x) = \vec{a}]$ measures the probability (over the choices of the questions to P_1 in the miss rounds) that P_1 answers the same way as P_2 does. (Note that P_2's answer $\vec{a}$ is determined by $(\vec{\imath}, \vec{q})$ and B.) The contribution of Event 1 to the total acceptance probability is 2ε. (Note that we need not bound the probability of an event if we can bound the error probability conditioned on the event.)

Event 2. The outcome of Step 1 is a k-block $(\vec{\imath}, \vec{q})$. Event 2 happens when

1. $\Pr_{x \leftarrow (\pi')^{n-k}}[g(x) = \vec{a}] < \varepsilon$, and
2. $\Pr_{x \leftarrow ((\pi')^{n-k}|B)}[g(x) = \vec{a}] \geq 2\varepsilon$.

It follows that

$$\Pr_{x \leftarrow ((\pi')^{n-k}|B)}[g(x) = \vec{a}] - \Pr_{x \leftarrow (\pi')^{n-k}}[g(x) = \vec{a}] \geq \varepsilon.$$

We show that this happens with low probability, thus bounding the probability that Event 2 occurs and the verifier accepts. (Note that we do not need to consider the probability that the verifier accepts if we can bound the probability of the event.)

For function g, we apply Corollary 4.6 to bound the influence of Step 2 (in which an additional $(m-k)$-block is selected), obtaining

$$\mathrm{E}_{B \overset{m-k}{\leftarrow} (\pi')^{m-k}} \left[\sum_{\vec{a} \in A^k} \left(\Pr_{x \leftarrow (\pi')^{n-k}} [g(x) = \vec{a}] - \Pr_{x \leftarrow ((\pi')^{n-k} | B)} [g(x) = \vec{a}] \right)^2 \right] \leq (m-k)/(n-k) \leq m/n.$$

Now, if Event 2 occurs, then there is some $\vec{a}$ that contributes ε^2 to the above summation term. Note that all the other terms in the summation are nonnegative. By Markov's inequality, the probability of Event 2, taken over the choice of B, is at most $m/n\varepsilon^2$.

Event 3. Event 3 is the event that $(\vec{i}, \vec{q})$, selected in Step 1, is alive but not $(1-\eta)$-good. We upper bound the probability of Event 3 by ε as follows. Recall that k was selected to be good with respect to (f, π') in the sense of Lemma 5.6. Hence, either $(\vec{i}, \vec{q})$ is alive with probability at most ε or it is the case that live $(\vec{i}, \vec{q})$ fail to be $(1-\eta)$-good with probability at most ε. In either case, the probability that $(\vec{i}, \vec{q})$ is alive but not $(1-\eta)$-good is at most ε.

To define Events 4 and 5, recall the notion of *majority answer* from Definition 5.4. We introduced the notation $\mathrm{maj}(i, q)$ to denote the most likely value for $f(x)[i]$ when $x[i] = q \overset{\text{def}}{=} (q_1, q_2, b)$ (also conditioned on $x[\vec{i}] = \vec{q}$ and $f(x)[\vec{i}] = \vec{a}$). In our case, this corresponds to P_1's most likely bth half answer on coordinate i when $x[i] = q$. For $j \in \{1, 2\}$, we extend this notation to $\mathrm{maj}(i, q, j)$ to denote P_1's most likely jth half answer on coordinate i when $x[i] = q$. Note that j need not be equal to b.

Event 4. Event 4 occurs when

1. $(\vec{i}, \vec{q})$ is *alive* and *good*;
2. $\Pr_{x \leftarrow (\pi')^{n-k}}[g(x) = \vec{a}] \geq \varepsilon$; and
3. given $(\vec{i}, \vec{q}, \vec{a})$, less than a $1 - 2\eta/\delta$ fraction of the $2(n-k)$ remaining half answers of P_1 equal their respective majority answer, $\mathrm{maj}(i, q, j)$. Here, δ is a parameter that will be chosen later.

Note that for a fixed k-block $(\vec{i}, \vec{q})$, at most $1/\varepsilon$ different $\vec{a}$ may satisfy this condition. We shall concentrate on an arbitrary one such $\vec{a}$ and later multiply the probability of acceptance by a factor of $1/\varepsilon$.

The k-block $(\vec{i}, \vec{q})$ is good and the triple $(\vec{i}, \vec{q}, \vec{a})$ is alive. By Proposition 5.5, the following experiment succeeds with probability $\alpha \geq 1 - 2\eta/\varepsilon$.

1. Choose i uniformly from $[n] - \vec{i}$ and choose z according to $(\pi')^n$, conditioned on $z[\vec{i}] = \vec{q}$ and $f(z)[\vec{i}] = \vec{a}$.
2. Let $q = z[i]$. Succeed iff $f(z)[i] = \mathrm{maj}(i, q)$.

Recall that maj is defined with respect to $(\vec{i}, \vec{q}, \vec{a})$.

Let β denote the expected fraction of half answers given by P_1 that are equal to their respective $\mathrm{maj}(i, q, j)$, where the conditioning is as in the definition of Event 4. We will show that $\alpha = \beta$, and hence that $\beta \geq 1 - 2\eta/\varepsilon$. By Markov's inequality, the probability that P_1 gives the majority answer on less than a $1 - 2\eta/\delta$ fraction of the half questions is at most δ/ε. Summing over at most $1/\varepsilon$ possible $\vec{a}$, we have that Event 4 occurs with probability at most δ/ε^2.

It remains to show that $\alpha = \beta$. Given $z = (q_1^1, q_2^1, b^1), (q_1^2, q_2^2, b^2), \ldots$, define $z \backslash b = (q_1^1, q_2^1), (q_1^2, q_2^2), \ldots$ and $b(z) = b^1, b^2, \ldots$. Using the linearity of expectation we can express β as the success probability of the following experiment.

1. Choose i uniformly from $[n]-\vec{\imath}$ and choose z according to $(\pi')^n$, conditioned on $z[\vec{\imath}]=\vec{q}$ and $f(z)[\vec{\imath}]=\vec{a}$.
2. Let $q=z[i]\stackrel{\text{def}}{=}(q_1,q_2,b)$. Choose j uniformly from $\{1,2\}$. Let $(a_1,a_2)=p_1(z\backslash b)[i]$. Succeed iff $a_j=\text{maj}(i,q,j)$.

By the definition of f, we can rewrite the second step in the experiment defining α to be the following:

2. Let $q=z[i]\stackrel{\text{def}}{=}(q_1,q_2,b)$. Choose $j\in\{1,2\}$ as $j=b$. Let $(a_1,a_2)=p_1(z\backslash b)[i]$. Succeed iff $a_j=\text{maj}(i,q,j)$.

Thus, the only difference between the two experiments is in the distribution on j. The experiment for β chooses j uniformly, independently of all other events, whereas the experiment for α chooses $j=b$. We now use the fact that b is not an input to P_1, and hence the answers of P_1 are independent of b.

We can imagine choosing z according to $(\pi')^n$, then conditioning on $(\vec{\imath},\vec{q})$ and then conditioning on $f(z)[\vec{\imath}]=\vec{a}$. Initially, $b(z)$ is uniformly distributed, conditioned on $z\backslash b$. After conditioning on $\vec{q}$, $b(z)[\vec{\imath}]$ is fixed, but $b(z)[[n]-\vec{\imath}]$ remains uniformly distributed over $\{0,1\}^{n-k}$. Now, $f(z)[\vec{q}]$ is completely independent of $b(z)[[n]-\vec{\imath}]$, so further conditioning based on this value has no effect on the distribution of $b(z)[[n]-\vec{\imath}]$. Hence b is uniformly distributed and so is j in the experiment for α.

We established that j is identically distributed in the two experiments. To complete the proof of $\alpha=\beta$ we observe that the correlation between j and b in the experiment defining α is irrelevant to its probability of success, because neither (a_1,a_2) nor $(\text{maj}(i,q,1),\text{maj}(i,q,2))$ depends on b.

Event 5. Event 5 occurs when

1. $(\vec{\imath},\vec{q})$ is *alive* and *good*;
2. $\Pr_{x\leftarrow(\pi')^{n-k}}[g(x)=\vec{a}]\geq\varepsilon$; and
3. given $(\vec{\imath},\vec{q},\vec{a})$, at least a $1-2\eta/\delta$ fraction of the $2(n-k)$ remaining half answers of P_1 equal their respective majority answer, $\text{maj}(i,q,j)$.

It follows that for at least a $1-4\eta/\delta$ fraction of these coordinates, P_1 answers both half questions according to a majority strategy. Which majority strategy is used depends on $\vec{a}$; there are at most $1/\varepsilon$ values of $\vec{a}$ such that $\Pr_{x\leftarrow(Q^{n-k},(\pi')^{n-k})}[g(x)=\vec{a}]\geq\varepsilon$. Fixing $\vec{a}$ and assuming that P_1 plays the majority strategy for a $1-4\eta/\delta$ fraction of the $n-k$ subgames, consider the probability that verifier accepts on each of them. This probability is bounded above by the probability that the verifier accepts on a $1-4\eta/\delta$ fraction of the $n-k$ subgames, when P_1 plays the majority strategy for all $n-k$ subgames.

Fixing a strategy for P_1, whether the verifier accepts or rejects is a function of its random coins, which are chosen independently for each subgame. Since the majority strategy is a projection strategy, for each subgame the probability that the verifier accepts is at most p, independent of any of the other games. We can therefore apply a Chernoff bound (Theorem A.4 in [1]) and conclude that the probability that the verifier accepts in more than a $(1+p)/2$ fraction of the $n-k$ coordinates is at most $e^{-(1-p)^2(n-k)/2}<e^{-(1-p)^2n/4}$. When $\eta<(1-p)\delta/8$, then $(1+p)/2<1-4\eta/\delta$, and Event 5 occurs with probability at most $e^{-(1-p)^2n/4}/\varepsilon$.

Summing up the probabilities for the five events, the verifier accepts with probability at most

$$2\varepsilon+m/n\varepsilon^2+\varepsilon+\delta/\varepsilon^2+e^{-(1-p)^2n/4}/\varepsilon.$$

The various parameters need to satisfy $m<n/2$, $\eta<\frac{1}{2}$, $n>2^{10}\eta^{-4}\varepsilon^{-8}$, and $m>2^5\eta^{-2}\varepsilon^{-4}$ from Lemma 5.6 and $\eta<(1-p)\delta/8$ from Event 5. If $n\geq c/((1-p)\epsilon)^c$,

for a sufficiently large c, then the other parameters can be chosen to make the above expression at most ϵ, as desired. Needless to say, our analysis is not tight. □

Remark. The main difference between the proof of the above theorem in the current version and the preliminary version [12] is in the definition of the function f. In the miss-match case, the function f is based on the strategy of prover P_1, and its definition is a bit complicated. In the confuse-or-compare case [12], the function f was simply the strategy p_2 of prover P_2. The simpler definition for f allowed subsequent arguments to be stated more simply.

Acknowledgments. We thank Leonid Gurvits for his help in proving Theorem 4.3. We thank the referees for numerous useful comments.

MESSAGE MULTICASTING IN HETEROGENEOUS NETWORKS*

AMOTZ BAR-NOY†, SUDIPTO GUHA‡, JOSEPH (SEFFI) NAOR§, AND BARUCH SCHIEBER¶

Abstract. In heterogeneous networks, sending messages may incur different delays on different links, and each node may have a different switching time between messages. The well-studied telephone model is obtained when all link delays and switching times are equal to one unit. We investigate the problem of finding the minimum time required to multicast a message from one source to a subset of the nodes of size k. The problem is NP-hard even in the basic telephone model. We present a polynomial-time algorithm that approximates the minimum multicast time within a factor of $O(\log k)$. Our algorithm improves on the best known approximation factor for the telephone model by a factor of $O(\frac{\log n}{\log \log k})$. No approximation algorithms were known for the general model considered in this paper.

1. Introduction.

The task of disseminating a message from a source node to the rest of the nodes in a communication network is called *broadcasting*. The goal is to complete the task as fast as possible assuming all nodes in the network participate in the effort. When the message needs to be disseminated only to a subset of the nodes, this task is referred to as *multicasting*. Broadcasting and multicasting are important and basic communication primitives in many multiprocessor systems. Current networks usually provide point-to-point communication only between some of the pairs of the nodes in the network. Yet, in many applications, a node in the network may wish to send a message to a subset of the nodes, where some of them are not connected to the sender directly. Due to the significance of this operation, it is important to design efficient algorithms for it.

Broadcast and multicast operations are frequently used in many applications for message-passing systems (see [10]). It is also provided as a communication primitive by several collective communication libraries, such as Express by Parasoft [7] and the message-passing library (MPL) [1, 2] of the IBM SP2 parallel systems. This operation is also included as part of the collective communication routines in the

message-passing interface (MPI) standard proposal [22]. Application domains that use broadcast and multicast operations extensively include scientific computations, network management protocols, database transactions, and multimedia applications. In most of these applications the efficiency depends on the time it takes to complete the broadcast or multicast operations.

There are two basic models in which trivial optimal solutions exist. In the first model, all nodes are assumed to be connected, a node may send a message to at most one other node in each round, and it takes one unit of time (round) for a message to cross a link. Therefore, in each round the number of nodes receiving the message can be doubled. If the target set of nodes is of size k, then this process terminates in $\lceil \log k \rceil$ rounds. In the second model the communication network is represented by an arbitrary graph, where each node is capable of sending a message to all of its neighbors in one unit of time. Here, the number of rounds required to deliver a message to a subset of the nodes is the maximum distance from the source node to any of the nodes in the subset.

The model in which a node may send a message to at most one other node in each round is known as the *telephone* model. It is known that for arbitrary communication graphs, the problem of finding an optimal broadcast in the telephone model is NP-hard [11], even for 3-regular planar graphs [19]. Following the two easy cases given above, it is not hard to verify that in the telephone model two trivial lower bounds hold for the minimum broadcast time. The first one is $\lceil \log n \rceil$, where n denotes the number of nodes in the graph, and the second one is the maximum distance from the source node to any of the other nodes. Research in the past three decades has focused on finding optimal broadcast algorithms for various classes of graphs such as trees, grids, and hypercubes. Also, researchers have looked for graphs with minimum number of links for which a broadcast time of $\lceil \log n \rceil$ can be achieved from any source node. Problems related to broadcast which were extensively investigated are the problems of broadcast multiple messages, gossiping, and computing certain functions on all n inputs in a network. See, e.g., [4, 5, 6, 8, 12, 13, 14, 18, 21, 24, 25].

An assumption central to the telephone model is that both sender and receiver are busy during the whole sending process. That is, only after the receiver received the message, both ends may send the message to other nodes. More realistic models in this context are the postal model [3] and the LogP model [17]. The idea there is that the sender may send another message before the current message is completely received by the receiver, and the receiver is free during the early stages of the sending process. We note that in both the postal model and the LogP model it is assumed that the delay of a message between any pair of nodes is the same.

Optimal solutions for broadcast in the postal model are known for the case of a complete graph and for some other classes of graphs. However, not much is known for arbitrary graphs. In the postal model, researchers have also concentrated on other dissemination primitives and almost always assumed that the communication graph is complete.

1.1. Our results. In this paper we define a more general model based on the postal model and call it the *heterogeneous postal* model. Assume node u sends a message to node v at time 0 and the message arrives at v at time λ_{uv}. The assumption is that u is free to send a new message at time s_u, and v is free from time 0 to time $\lambda_{uv} - r_v$. We call λ_{uv} the *delay* of the link (u, v), s_u the *sending* (or *switching*) time of u, and r_v the *receiving* time of v. By definition, both s_u and r_v are smaller than λ_{uv}. In the single-message multicast problem each node receives no more than a single

message. Thus, for this problem the receiving time has almost no relevance. Because of this, and to keep the presentation clearer, we assume for the rest of the paper that $r_u = s_u$ for all nodes u. Observe that when the delay, sending time, and receiving time are all equal to 1, we obtain the telephone model.

We believe that our framework may be useful to model modern communication networks, where the major components—the processors and the communication links—are not homogeneous. Some processors are faster than others, and some links have more bandwidth than others. These disparities are captured by the different values of the delay and the switching time.

Since finding the minimum multicast time is NP-hard even in the telephone model, we turn our focus to approximation algorithms. The main result we present is an approximation algorithm for computing a multicast scheme in the heterogeneous postal model. The approximation factor is $O(\log k)$, where k denotes the number of processors in the target set. Previous approximation algorithms for multicasting were known only in the telephone model. Kortsarz and Peleg [16] gave an approximation algorithm that produces a solution whose value is bounded away from the optimal solution by an $O(\sqrt{n})$ additive term. This term is quite large, especially for graphs in which the broadcast (multicast) time is polylogarithmic. Later, Ravi [20] gave an algorithm that achieves a multiplicative approximation factor of $O(\frac{\log n \log k}{\log \log k})$.

We also show that it is NP-hard to approximate the minimum broadcast time within a factor of three in a model which is only slightly more complicated than the telephone model.

The rest of the paper is organized as follows. In section 2 we define our model. In section 3 we describe our solution. Finally, in section 4 we show that this problem is hard to approximate by a small constant factor.

2. The model and the problem. We define our model as follows. Let $G = (V, E)$ be an undirected graph representing a communication network, where V is a set of n nodes and E is the set of point-to-point communication links. Let $U \subseteq V$ denote a special set of *terminals*, and let r be a special node termed the *root*. Let the cardinality of the set U be k. To simplify notation assume that $r \in U$.

We associate with each node $v \in V$ a parameter s_v that denotes the sending time. We sometimes refer to s_v as the switching time of v to indicate that this is the time it takes node v to send a new message. In other words, $1/s_v$ is the number of messages node v can send in one round (unit of time). We associate with each node $v \in V$ a parameter r_v that denotes the receiving time. We assume that $r_v = s_v$, for each node v. We associate with each link $(u, v) \in E$ a length λ_{uv} that denotes the communication delay between nodes u and v. By definition, λ_{uv} is greater than both s_u and r_v $(= s_v)$. We can think of the delay λ_{uv} as taking into account the sending time at u and the receiving time at v.

Let the *generalized degree* of node $v \in V$ be the actual degree of v in the graph G multiplied by the switching time s_v. Observe that the generalized degree measures the time it would have taken the node v to send a message to all of its neighbors.

Our goal is to find a minimum-time multicast scheme, that is, a scheme in which the time it takes for all nodes in the set U to receive the message from the root r is minimized. Without loss of generality, we may consider only multicast schemes that are "not lazy," i.e., schemes in which a node that has not finished sending the message to its neighbors (but has already started) is not idle. Such multicast schemes can be represented by an outward directed tree T that is rooted at r and spans all the nodes in U, together with orderings on the edges outgoing from each node in the tree. The

multicast scheme corresponding to such a tree and orderings is a multicast in which each node in the tree upon receiving the message (through its single incoming edge) sends the message along each of its outgoing edges in the specified order. From now on, we refer to the tree in the representation of a multicast scheme as the tree "used" by the scheme.

For a rooted tree T, denote by Δ_T its maximum generalized degree, and by L_T the maximum distance from r to any of the nodes in U (with respect to the lengths λ_{xy} associated with each link (x, y)). By definition, the multicast time of tree T is greater than Δ_T and greater than L_T. Hence, we obtain the following lemma.

LEMMA 1. *Let OPT denote the multicast time of an optimal solution using tree T^*; then $OPT \geq \frac{1}{2}(\Delta_{T^*} + L_{T^*})$*

3. The approximation algorithm. In this section we describe the approximation algorithm for multicasting a message to a set of terminals U from a root node $r \in U$.

The main tool used by our algorithm is a procedure $ComputeCore(U')$ that computes for a given set of terminals U', where $r \in U'$,

(1) a subset $W \subset U'$ which we call the *core* of U', of size at most $\frac{3}{4}|U'|$, where $r \in W$;
(2) a scheme to disseminate a message known to all the nodes in W to the rest of the nodes in U' in time proportional to the minimum multicast time from r to U'.

The algorithm that computes the multicast scheme proceeds in ℓ phases. Let $U_0 = U$. Upon termination, $U_\ell = \{r\}$. In the ith phase, $i = 1, \ldots, \ell$, procedure $ComputeCore(U_{i-1})$ is invoked to compute

(1) the core of U_{i-1}, denoted by U_i;
(2) a scheme to disseminate the message from U_i to the set U_{i-1} in time proportional to the minimum multicast time from r to U_{i-1}.

Since $|U_i| \leq \frac{3}{4} \cdot |U_{i-1}|$ and $|U_0| = k$, we have that $\ell = O(\log k)$. The resulting multicast scheme is given by looking at the rounds of the algorithm in backward order. Namely, starting at $i = \ell$ downwards, in each round of the multicast scheme the message is disseminated from U_i to U_{i-1}. Since $U_\ell \subset U_{\ell-1} \subset \cdots \subset U_0 = U$, each dissemination phase takes time proportional to the minimum multicast time from r to U. It follows that the multicast time is up to $O(\log k)$ times the optimal multicast time.

In the rest of the section we describe the procedure $ComputeCore(U')$. Let OPT be the minimum multicast time from r to U'. Lemma 1 implies that there exists a tree T^* spanning the set U' such that $\Delta_{T^*} + L_{T^*} \leq 2 \cdot OPT$. The procedure $ComputeCore(U')$ has two main parts. In the first part, we find a set of $|U'|$ paths, one for each terminal, where the ith path connects the terminal u_i to another terminal called $Mate(u_i)$. The paths have the following *path properties*:

Length property: The length of each path is at most $4 \cdot (\Delta_{T^*} + L_{T^*})$.

Congestion property: The generalized degree of the nodes in the graph induced by the paths is at most $6 \cdot (\Delta_{T^*} + L_{T^*})$.

In the second part we design a dissemination scheme using the above paths. We do it by transforming the paths into a set of disjoint *spider* graphs—graphs in which at most one node has degree more than two. These spider graphs have the following *spider properties*:

- Each spider contains at least two terminals from U'.
- The set of spiders spans at least half the nodes in U'.
- The diameter of each spider is at most $4 \cdot (\Delta_{T^*} + L_{T^*})$.

- The generalized degree of the *center* of a spider is at most $6 \cdot (\Delta_{T^*} + L_{T^*})$, where the center of a spider is the unique node with degree larger than two, if such exists, or one of the endpoints of the spider otherwise.

Now, for each spider, we arbitrarily select one of the nodes from U' to the core of U'. Note that each such node can multicast the message to the rest of the terminals in its spider in $O(\Delta_{T^*} + L_{T^*})$ time (linear in OPT). We add all the terminals not contained in any of the spiders to the core of U'. We claim that the size of the core is at most $\frac{3}{4}|U'|$. To see this, let x denote the number of spiders and let y be the number of the terminals in all the spiders. It follows that the size of the core is $|U'| - y + x$. By the first spider property we have that $x \leq y/2$ and by the second spider property we get that $y \geq |U'|/2$. Thus,

$$|core(U')| = |U'| - y + x \leq |U'| - \frac{y}{2} \leq |U'| - \frac{1}{4}|U'| = \frac{3}{4}|U'| \ .$$

We now turn to describe each of the two parts of the procedure $ComputeCore(U')$.

3.1. Finding a set of paths. We first claim the following lemma, which is analogous to the "tree-pairing" lemma of Ravi [20].

LEMMA 2. *Let T be a tree that spans a set $U' \subseteq V$, and suppose that $|U'|$ is even. There exists a way to pair the nodes of U' and to find paths (in the tree T) connecting each pair such that*

(1) *the paths are edge disjoint;*
(2) *the length of each path is bounded by $2L_T$;*
(3) *the generalized degree of each node in the graph induced by the paths is at most Δ_T.*

Proof. The tree-pairing lemma [20] states that there exists a pairing such that the paths in T connecting each of the pairs are edge disjoint. Consider these paths. Clearly the length of each of these paths is bounded by $2L_T$. The degree, and hence the generalized degree, of every node in the graph induced by the paths is no more than the (generalized) degree in T since we use only the edges of the tree T. Hence, it is bounded by Δ_T. ∎

The following corollary handles the odd case as well.

COROLLARY 3. *Let T be a tree that spans a set $U' \subseteq V$. There exists a way to pair the nodes of U' and to find paths (in the tree T) connecting each pair such that*

(1) *the length of each path is bounded by $2L_T$;*
(2) *the generalized degree of each node in the graph induced by the paths is at most $2\Delta_T$.*

Proof. The corollary clearly holds if $|U'|$ is even. If $|U'|$ is odd, we pair $|U'| - 1$ of the nodes as in Lemma 2 and pair the last node with any other node. The length of the path connecting the last pair is still bounded by $2L_T$. However, the degree of the subgraph may double up to $2\Delta_T$. ∎

Recall that the tree T^* spans the nodes of U' and $(\Delta_{T*} + L_{T*}) \leq 2 \cdot OPT$. Our objective is to find the set of paths as guaranteed by Corollary 3 with respect to T^*. However, we do not know T^*. Thus, instead, we find a set of *fractional* paths satisfying similar properties. To this end, we write a linear program for finding a set of (fractional) paths that minimizes the sum of two quantities: (1) the maximum over all pairs of the average length of the paths connecting a pair, and (2) the maximum generalized degree of the subgraph induced by the paths connecting the pairs.

The linear program is a variant of multicommodity flow. For each edge (u, v), we define the directed edges (u, v) and (v, u) both of length λ_{uv}. Let $U' = \{v_1, \ldots, v_h\}$.

With each node $v_j \in U'$ we associate commodity j. Node v_j is the source of commodity j and we create an artificial sink t_j with $r_{t_j} = s_{t_j} = 0$. We connect each of the nodes $v' \in U'$, where $v_j \neq v'$, to t_j by a directed edge (v', t_j) of length 0. The objective is to minimize $(L + \Delta)$, where exactly one unit of flow has to be shipped from each v_j to t_j, such that the average length of the flow paths from v_j to t_j is at most $2L$, and the maximum weighted congestion (generalized degree) of the induced subgraph is at most 3Δ.

More formally, let A denote the set of directed edges, and let $f^i(u, v)$ denote the flow of commodity i on directed edge (u, v). The linear programming formulation is as follows.

Minimize $\Delta + L$

subject to:

For all $1 \leq i \leq h$ and $v \in V - \{v_i, t_i\}$:	$\sum_{(u,v)\in A} f^i(u,v) - \sum_{(v,w)\in A} f^i(v,w)$	$=$	$0.$
For all $1 \leq i \leq h$:	$\sum_{(u,t_i)\in A} f^i(u,t_i)$	$=$	$1.$
For all $1 \leq i \leq h$:	$\sum_{(v_i,u)\in A} f^i(v_i,u)$	$=$	$1.$
For all $1 \leq i \leq h$:	$\sum_{(u,v)\in A} f^i(u,v)\lambda_{uv}$	$\leq$	$2L.$
For all $v \in V - \{t_1, \ldots, t_h\}$:	$s_v \cdot \sum_i \sum_{u\in V} \left(f^i(u,v) + f^i(v,u)\right)$	$\leq$	$3\Delta.$
For all $1 \leq i \leq h$:	$f^i(u,v)$	$\geq$	$0.$

We now show that the set of paths guaranteed by Corollary 3 with respect to T^* can be modified so as to obtain an integral solution for the linear program as follows. If $|U'|$ is even, the solution is obtained by using each path connecting a pair (u_i, u_j) to ship one unit of flow from u_j through u_i to t_j, and another unit of flow from u_i through u_j to t_i. The length of each path is bounded by $2L_{T^*}$, and since we use each path twice, the generalized degree is bounded by $2\Delta_{T^*}$. If $|U'|$ is odd, the solution is obtained by using each of the $\frac{1}{2}(|U'| - 1)$ paths connecting the first $|U'| - 1$ nodes of U' twice (once in each direction), and using the path connecting the last node in U' to its mate to ship flow out of this node. The length of each path is still bounded by $2L_{T^*}$. However, because of the additional path, the degree is only bounded by $3\Delta_{T^*}$.

It follows that the value of the objective function for this solution is $\Delta_{T^*} + L_{T^*}$, and thus the linear program is guaranteed to find a solution whose value is upper bounded by this value. Let L_T and Δ_T denote the values of the length and congestion in the optimal solution of the above linear program.

The optimal solution is a "fractional" solution in the sense that the (unit) flow of each commodity is split between several flow paths. We round the fractional solution into an integral solution using an algorithm proposed by Srinivasan and Teo [23]. This algorithm builds on a theorem proved by Karp et al. [15]. For completeness, and

since the details are slightly different, we now describe the rounding of the fractional solution.

THEOREM 4 (see [15]). *Let A be a real valued $r \times s$ matrix, and y be a real valued s-vector. Let b be a real valued vector such that $Ay = b$. Let t be a positive real number such that in every column of A,*

(1) *the sum of all positive entries $\leq t$; and*

(2) *the sum of all negative entries $\geq -t$.*

Then, we can compute (in polynomial time) an integral vector $\bar{y}$ such that for every i, either $\bar{y}_i = \lfloor y \rfloor$ or $\bar{y}_i = \lceil y \rceil$ and $A\bar{y} = \bar{b}$, where $\bar{b}_i - b_i < t$.

We now show how to find an integral flow of congestion at most $6\Delta_T + 4L_T$, where each flow path (of each commodity) has length at most $4L_T$. We first decompose the flow into (polynomially many) flow paths. If any path in this decomposition is longer than $4L_T$, we discard it. We observe that since the average length is less than $2L_T$, discarding these long paths leaves at least half of a unit of flow between each pair (v_i, t_i). We scale the flows appropriately such that the total flow to each t_i is exactly 1. This can at most double the flow on an edge, and the total congestion is now at most $6\Delta_T$.

Let $P_1, P_2, \ldots$ denote the length-bounded flow paths. Denote the set of nodes in a path P_i by $V(P_i)$ and the set of edges by $E(P_i)$. Let $f(P_i)$ denote the amount of flow pushed on path P_i. Define the set $\mathcal{P}^j$ as the set of all paths that carry flow of the jth commodity. Observe that each path belongs to exactly one $\mathcal{P}^j$. The linear system $Ay = b$ needed for Theorem 4 is defined by the following linear equations, where the ith equation corresponds to the ith row of A and the ith element of b.

$$\begin{array}{lrcl} \text{For each } v & s_v \cdot \displaystyle\sum_{i:\, v \in V(P_i)} f(P_i) & \leq & 6\Delta_T; \\ \text{for all } j & -4L_T \cdot \displaystyle\sum_{i:\, P_i \in \mathcal{P}^j} f(P_i) & = & -4L_T. \end{array}$$

The second set of inequalities captures the fact that the flow on all the paths corresponding to commodity j is exactly 1. Now the sum of the positive entries in a column is

$$\sum_{v \in V(P_i)} s_v \leq \sum_{(v,w) \in E(p_i)} \lambda_{vw} + s_{t_j} = (\text{length of path } P_j) \leq 4L_T \ .$$

The second part of the inequality follows since $s_v \leq \lambda_{vw}$ for all v, w and $s_{t_j} = 0$. The sum of the negative entries in a column is at most $4L_T$; this follows due to the fact that each P_i belongs to exactly one $\mathcal{P}^j$. Invoking Theorem 4 gives us a set of paths such that

$$\begin{array}{lrcl} \text{for each } v & s_v \cdot \displaystyle\sum_{i:\, v \in V(P_i)} \bar{f}(P_i) & < & 6\Delta_T + 4L_T; \\ \text{for all } j & -4L_T \cdot \displaystyle\sum_{i:\, P_i \in \mathcal{P}^j} \bar{f}(P_i) & < & 0. \end{array}$$

The second set of inequalities implies that each commodity has at least one flow path. So we have a set of flow paths such that the congestion is at most $6\Delta_T + 4L_T$ and their length is at most $4L_T$. Since $\Delta_T + L_T \leq \Delta_{T^*} + L_{T^*}$ these paths satisfy the length and congestion properties as desired.

3.2. Finding a spider decomposition. We now show how to obtain a spider decomposition satisfying the spider properties previously defined. Recall that we are now given a set of paths connecting each terminal u_j with another terminal $Mate(u_j)$, and that this set of paths satisfies the length and congestion properties.

We find a set of at least $|U'|/2$ *trees* that satisfy the following properties which are similar to the spider properties.

- Each tree spans at least two terminals from U'.
- The diameter of each tree is at most $4L_T \leq 4 \cdot (\Delta_{T^*} + L_{T^*})$.
- The generalized degree of each node in each of the trees is at most $6\Delta_T + 4L_T \leq 6(\Delta_{T^*} + L_{T^*})$.

Before showing how to find these trees, we show how to transform them into the required spiders. Repeatedly, consider the tree edges, and remove a tree edge if it separates the tree into two subtrees such that either both subtrees contain at least two terminals or one of them contains no terminals. (In this case this subtree is removed as well.) Repeat this process until no more edges can be removed. The process terminates since the number of edges is finite. Observe that upon termination if a connected component is not a spider, then another edge could be deleted. Thus, we get the following claim.

Claim 5. *When the process terminates, each connected component is a spider.*

Clearly, all the terminals spanned by the trees are also spanned by the spiders. The diameter of each of these spiders is at most $4L_T$, since the distance between every pair of nodes in U' spanned by a tree is at most $4L_T$ to begin with. Also, the generalized degree of the "center" of the spider is at most the generalized degree of its originating tree since we have not introduced any new edges in the process. We conclude that the spiders satisfy the desired spider properties.

Now, we show how to find the required trees. Define G_p to be the undirected graph induced by the paths from each terminal to its mate. Observe that a spanning forest of this graph may not satisfy the required diameter property above, and hence some extra refinement is necessary.

For each node u in G_p, find a unique terminal in U' that is closest to u (with respect to the lengths λ_{xy} associated with each link (x, y)). Ties are broken arbitrarily.

We modify the paths starting at each terminal as follows. From each terminal u begin tracing the path connecting u to $Mate(u)$. At some node v along this path, the closest terminal to v will not be u. We are guaranteed to encounter such a node because the closest node to $Mate(u)$ is $Mate(u)$ itself. From this node v trace the path to its closest terminal. This creates a path from u to another terminal denoted $NewMate(u)$. Note that $NewMate(u)$ may be different from $Mate(u)$. However, we are guaranteed that the path from u to $NewMate(u)$ is not longer than the path from u to $Mate(u)$ and thus bounded by $4L_T$.

Define an auxiliary directed graph H on the set of terminals U' with the set of edges $(u \rightarrow NewMate(u))$ for $u \in U'$. By definition each node in H has outdegree one. Thus, each connected component of (the undirected skeleton of) H contains exactly one directed cycle. Discard one edge from each such connected component to make it a rooted tree in which all edges are oriented towards the root. (The root is unique since the outdegree of each node is one.) Note that every nontrivial strongly connected component of H is a cycle. Thus, this can be done just by discarding an arbitrary edge from each strongly connected component of H. Let H' be the resulting forest.

Define the level of a node in H' to be the number of edges in the path to it from the root of its component. (We flip the direction of the edges in H' for the purpose

of measuring distances.) Distinguish between nodes of even level and nodes of odd level. Each edge of H' goes either from an odd-level node to an even-level node or vice-versa.

Consider two collections of stars in H'. One collection consisting of edges from odd-level nodes to even-level nodes, and the other consisting of edges from even-level nodes to odd-level nodes. Every terminal with positive indegree and outdegree (in H') is spanned by a star in each one of the two collections. Every terminal with either indegree or outdegree zero (in H') is spanned by a star in only one of the two collections. However, by a simple pigeonhole argument, at least one of the collections spans at least half of the terminals.

Consider such a collection. First, note that each star in this collection induces an undirected tree in the original graph when replacing each star edge by its originating path. We now claim the following.

LEMMA 6. *The induced trees of any two stars belonging to the same collection are node disjoint.*

Proof. To obtain a contradiction assume they are not disjoint. Then there exist two distinct terminals with the same even or odd parity, say, u and v, such that $NewMate(u) \neq NewMate(v)$, but the paths traced from u to $NewMate(u)$ and from v to $NewMate(v)$ have a common node x. Consider the terminal chosen by x as its closest terminal. We distinguish between two cases.

Case 1. The terminal chosen by x is u. Then u must be $NewMate(v)$, contradicting the fact that u and v are of the same parity. The case where v is the chosen terminal of x is symmetric.

Case 2. The terminal chosen by x is $NewMate(u)$. Then $NewMate(v)$ must be the same as $NewMate(u)$, a contradiction. The case where $NewMate(v)$ is the chosen terminal of x is symmetric. □

It is easy to see that the trees induced by the stars in the collection satisfy the required properties. This concludes the construction.

4. Hardness of approximations. In this section we show that the best possible approximation factor of the minimum broadcast time in the heterogeneous postal model is $3 - \epsilon$. We show this hardness result even for a restricted model in which $s_i \in \{0, 1\}$ and $\lambda_{uv} \in \{1, d\}$ for some constant d. Note that when $s_i = 0$, node u_i can broadcast the message concurrently to all of its neighbors. The proof is by a reduction to the set cover problem. In the unweighted version of the set cover problem we are given a set U of elements and a collection S of subsets of U. The goal is to find the smallest number of subsets from S whose union is the set U. Feige [9] proved the following hardness result.

LEMMA 7. *Unless* $NP \subseteq DTIME(n^{\log \log n})$, *the set cover problem cannot be approximated by a factor which is better than* $\ln n$, *and hence it cannot be approximated within any constant factor.*

In our proof, we will only use the fact that it is NP-hard to approximate the optimal set cover within any constant factor.

THEOREM 8. *It is NP-hard to approximate the minimum broadcast time of any graph within a factor of* $3 - \epsilon$.

Proof. Assume to the contrary that there exists an algorithm that violates the claim of the theorem for some ϵ. We show how to approximate the set cover problem within a constant factor using this algorithm.

To approximate the set cover problem we "guess" the size of the optimal set cover and use our approximate minimum broadcast time algorithm to check our guess. Since

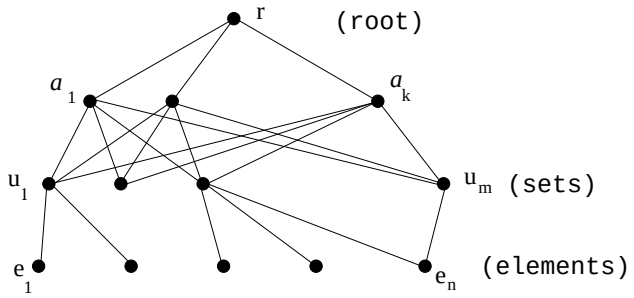

FIG. 1. *The graph G.*

the size of the optimal set cover is polynomial, we need to check only a polynomial number of guesses.

Consider an instance of set cover $I = (U, S)$, where U is the set of elements, and S a collection of subsets of U. Let $|U| = n$ and $|S| = m$. Let the guess on the size of the optimal set cover be k. We construct the following graph G (see Figure 1). The graph G consists of $1 + n + m + k$ vertices: a distinguished root vertex r, vertices $e_1, \ldots, e_n$ corresponding to the elements of U, vertices $u_1, \ldots, u_m$ corresponding to the subsets, and k additional vertices $a_1, \ldots, a_k$.

The root r has switching time $s(r) = 0$ and is connected to $a_1, \ldots, a_k$ by edges with delay $\lambda_{ra_\ell} = 1$. Each vertex a_ℓ has switching time $s(a_\ell) = 1$ and is connected to all u_j with delay $\lambda_{a_\ell u_j} = 1$. Each vertex u_j has switching time $s(u_j) = 0$ and is connected to a vertex e_i iff the jth set contains the ith element. The delay of such an edge is $\lambda_{u_j e_i} = d$, where $d > \frac{4-2\epsilon}{\epsilon}$ is a constant. Each vertex e_i has switching time $s(e_i) = 1$. Finally, to complete the instance of the multicasting problem, the target multicast set consists of all vertices e_i.

We first show that if there is a set cover of size k, then there is a multicast scheme of length $d + 2$. After time 1, all the vertices a_ℓ receive the message. After time 2, all the vertices u_j corresponding to sets which are in this cover receive the message. This is possible since all a_ℓ are connected to all u_j. Finally, these vertices send the message to all the elements that they cover. Since $s(u_j) = 0$ and $\lambda_{u_j e_i} = d$, it follows that the multicast time is $d + 2$.

Suppose that the algorithm for the multicasting problem completes the multicasting at time t. By the contradiction assumption, its approximation factor is $3 - \epsilon$. Since by our guess on the size of the set cover the optimal multicast time no more than $d+2$, we have $t \leq (3-\epsilon)(d+2) = 3d+6-2\epsilon-\epsilon d < 3d+6-2\epsilon-4+2\epsilon = 3d+2$. The strict inequality follows from the choice of d.

We first claim that all the vertices u_j that participate in the multicast receive the message from some a_ℓ. Otherwise there exists a vertex $e_{i'}$ that received the message via a path of a type $(r, a_\ell, u_j, e_i, u_{j'}, e_{i'})$. This means that $e_{i'}$ received the message at or after time $3d + 2 > t$. Our second claim is that each vertex a_ℓ sends the message to at most $2d$ vertices u_j. This is because the $(2d + 1)$st vertex would receive the message at time $2d + 2$ and would not be able to help in the multicast effort that is completed before time $3d + 2$.

Combining our two claims we get that the multicasting was completed with the help of $2dk$ vertices u_j. The corresponding $2dk$ sets cover all the elements e_i. This violates Lemma 7, which states that the set cover problem cannot be approximated within any constant factor. □

Remark. In our proof we considered a restricted model in which the switching time may get only two possible values and the delay may get only three possible values (assuming that when an edge does not exist, then the delay is infinity). Observe that this hardness result does not apply to the telephone model, in which the switching time is always 1 and the delay is either 1 or infinity. We have similar hardness results for other special cases. However, none of them is better than 3 and all use similar techniques.

Acknowledgment. We thank David Williamson for his helpful comments.

COMPLEXITY OF SOME PROBLEMS CONCERNING VARIETIES AND QUASI-VARIETIES OF ALGEBRAS*

CLIFFORD BERGMAN† AND GIORA SLUTZKI‡

Abstract. In this paper we consider the complexity of several problems involving finite algebraic structures. Given finite algebras **A** and **B**, these problems ask the following. (1) Do **A** and **B** satisfy precisely the same identities? (2) Do they satisfy the same quasi-identities? (3) Do **A** and **B** have the same set of term operations?

In addition to the general case in which we allow arbitrary (finite) algebras, we consider each of these problems under the restrictions that all operations are unary and that **A** and **B** have cardinality two. We briefly discuss the relationship of these problems to algebraic specification theory.

Key words. variety, quasi-variety, clone, term-equivalence, computational complexity, logarithmic space, polynomial space, hyperexponential time, nondeterminism

1. Introduction.

There are several relationships between mathematical structures that might be considered "fundamental." First and foremost is certainly the isomorphism relation. Questions about isomorphic structures occur throughout mathematics and apply to universal algebras, topological spaces, graphs, partially ordered sets, etc. Many other relationships are more specialized. For example, given two graphs **G** and **H**, one may wish to know whether **H** is a subgraph of **G** or perhaps a minor of **G**.

Properly formulated, questions about these relationships give rise to complexity questions. Generally speaking, we must impose some sort of finiteness assumption on the structures in question so that notions of computational complexity make sense. The complexity of various isomorphism problems has received a great deal of attention. The graph isomorphism problem has been intensively studied, partly because its exact relationship to the classes **P** and **NP** is still unknown, and partly because it provides a paradigm for other problems of unknown complexity status. In this case, both graphs are assumed to have finitely many vertices and finitely many edges. With a similar formulation, the isomorphism problem for algebras has the same complexity as does graph isomorphism. More generally, Kozen [17] showed that the isomorphism problem for finitely presented algebras has this same complexity. See [4, 16, 19] for further discussion and references on the isomorphism problem.

In this paper we consider the complexity of three relationships that arise from considerations in universal algebra. Any algebraic structure satisfies certain identities and fails to satisfy others. Roughly speaking, an identity is an equality between two expressions built from the operations of the algebra. Examples of identities are the associative law (which involves one binary operation) and DeMorgan's law (two binary

operations and one unary operation). Identities are one of the primary organizing tools in algebra.

Given two algebras $\mathbf{A}$ and $\mathbf{B}$, we may ask whether they satisfy precisely the same set of identities. Notice that this is a far weaker notion than isomorphism. For example, any algebra satisfies the same identities as each of its direct powers. Nevertheless, if $\mathbf{A}$ and $\mathbf{B}$ satisfy the same identities, then they will be constrained to behave in a similar way. One of our problems, called VAR-EQUIV, is this: Given two finite algebras of the same finite similarity type, determine whether they satisfy the same identities.

This problem has implications for several areas of computer science. *Formal algebraic specifications* are expressions in a language which describe the properties and input-output behavior that a software system must exhibit, without putting any restrictions on the way in which these properties are implemented. This *abstraction* makes formal specifications extremely useful in the process of developing software systems where it serves as a reference point for users, implementers, testers, and writers of instruction manuals. Formal specifications have been applied successfully in deployment of sophisticated software systems; see [33], especially the references there.

Mathematically, formal algebraic specifications are firmly grounded on algebraic concepts, especially ideas, notions, and methods from universal algebra [6]. The relationship between implementation and equational specification corresponds, in algebraic terms, to the relationship between an algebra and a set of identities satisfied by the algebra. Thus, two algebras that satisfy the same identities correspond to a pair of implementations with precisely the same specifications. The computational complexity of these problems, in the universal algebraic framework, is thus quite relevant to the body of research in formal specification theory, and to the construction of supporting tools such as theorem provers and model checkers.

Generalizing the notion of identity, we arrive at a quasi-identity. We shall leave a precise definition for section 2, but crudely speaking, a quasi-identity involves a conjunction of identities and an implication. An example is the left-cancellation law (for, say, a semigroup). In direct analogy with the previous problem we can ask for the complexity of the following. Given two finite algebras of the same finite similarity type, determine whether they satisfy exactly the same quasi-identities. This notion too extends to algebraic specification theory, since "conditional specifications" take the form of quasi-identities.

Our third problem involves the term operations of an algebra. Although an algebra may be endowed with only finitely many basic operations, we can construct many more by composing the basic ones in various combinations. These are called the term operations of the algebra. Two algebras (presumably of different similarity types) are called term-equivalent if they have the same universe and exactly the same set of term operations. In universal algebra, term-equivalent algebras are considered the same "for all practical purposes." The problem we call TERM-EQUIV is that of determining whether two finite algebras are term-equivalent. Returning once again to the realm of specification theory, in this problem we are asking whether a pair of implementations for two entirely different specifications has the property that it exhibits the same input-output behavior. See [25], where this notion is called the "behavioral equivalence of specifications."

Each of these three problems makes sense for arbitrary finite algebras with an arbitrary (but finite) set of basic operations. In addition to this most general formu-

lation, we consider, for each of the three problems, two more restricted settings that, experience tells us, may result in different complexities (see Table 4.1). The first is to require that all basic operations on our algebras be unary. In the second, we only consider algebras of cardinality two.

Unary algebras constitute, from the standpoint of similarity type, the simplest sort of algebraic structure. The set of available term operations is quite small, and the free algebras in the generated variety have a simple structure. Furthermore, (finite) unary algebras capture the algebraic aspects of deterministic (finite-state) automata. (Here, the universe of the algebra corresponds to the set of states, and the similarity type corresponds to the input alphabet of the automata.)

Algebras of cardinality two are, of course, the smallest nontrivial algebras. These are the "Boolean" algebras, and they play an important role in the study of Boolean functions and circuits; see [23] and [32]. For us, the clue that the complexity of our problems will be lower when restricted to two-element algebras comes from the lattice of clones, called Post's lattice [24, 23]. Over a set of cardinality two, the lattice of clones is highly structured and quite manageable. Most of the nice properties of the lattice seem to disappear over larger base sets. One can hope that a good understanding of Post's lattice will lead to the design of more efficient algorithms. Algorithm 7.3 is an example of such an improvement over the "obvious" approach.

The first two sections of this paper are devoted to a development of the necessary background in both universal algebra and complexity theory, for the benefit of those unfamiliar with the basic notions in these fields. In section 3, we formally state the problems we will discuss and outline the major results. Then one section is devoted to each of the three main problems under consideration.

2. Universal algebraic preliminaries. Our primary reference for definitions and basic facts of universal algebra is [20]. Other good references are [5], especially for the material on quasi-varieties, and [10]. Although a bit dated, Taylor's survey in [31] is particularly readable. However, for the benefit of those readers unfamiliar with this material, we give an informal summary of the most important concepts that we will need in this paper.

Let A be a nonempty set and k a nonnegative integer. A k-ary *operation on* A is a function from A^k to A. The integer k is called the *rank* of the operation. Note that if $k = 0$, then $A^k = \{\varnothing\}$, so that a nullary operation is effectively an element of A.

Let F be a set of symbols (called *operation symbols*), and let ρ be a function from F to the nonnegative integers. An *algebra of similarity type* ρ is a structure $\mathbf{A} = \langle A, F^{\mathbf{A}} \rangle$ in which A is a nonempty set and $F^{\mathbf{A}} = \langle f^{\mathbf{A}} : f \in F \rangle$, where each $f^{\mathbf{A}}$ is an operation on A of rank $\rho(f)$. The members of $F^{\mathbf{A}}$ are called the *basic operations* of $\mathbf{A}$, and the set A is called the *universe,* or *underlying set* of $\mathbf{A}$. We will often leave off the superscript $\mathbf{A}$ when no confusion will result. The notation "$\mathbf{A} \sim \mathbf{B}$" will indicate that $\mathbf{A}$ and $\mathbf{B}$ have the same similarity type.

Suppose that $\mathbf{A} = \langle A, F^{\mathbf{A}} \rangle$ and $\mathbf{B} = \langle B, F^{\mathbf{B}} \rangle$ are two algebras of similarity type ρ. A function $\psi\colon B \to A$ is called a *homomorphism* if, for every $f \in F$ and $b_1, \ldots, b_{\rho(f)} \in B$, we have $\psi f^{\mathbf{B}}(b_1, \ldots, b_{\rho(f)}) = f^{\mathbf{A}}(\psi b_1, \ldots, \psi b_{\rho(f)})$. Injective homomorphisms are often called *embeddings.* The algebras $\mathbf{A}$ and $\mathbf{B}$ are *isomorphic,* denoted $\mathbf{A} \cong \mathbf{B}$, if there is a homomorphism from $\mathbf{A}$ to $\mathbf{B}$ that is a bijection. $\mathbf{B}$ is called a *subalgebra* of $\mathbf{A}$ if $B \subseteq A$ and the inclusion map is a homomorphism. Thus $\mathbf{B}$ is isomorphic to a subalgebra of $\mathbf{A}$ if and only if there is an embedding of $\mathbf{B}$ into $\mathbf{A}$.

Let J be a set, and for each $j \in J$ let A_j be a nonempty set. Then the Cartesian product, $\prod_{j \in J} A_j$, is the set of all sequences $a = \langle\, a_j : j \in J \,\rangle$ such that for every

$j \in J$, $a_j \in A_j$. For each $i \in J$, there is a surjective function $\pi_i \colon \prod_{j\in J} A_j \to A_i$ mapping the sequence a to its ith component, a_i. We shall reserve the symbol "π" for these mappings. Suppose now that $\langle\, \mathbf{A}_j : j \in J \,\rangle$ is a sequence of algebras, all of similarity type ρ. Then $\prod_{j\in J} \mathbf{A}_j$ is the algebra (of type ρ) whose universe is the Cartesian product of the sets A_j, with basic operations that act coordinatewise, using the basic operations of each $\mathbf{A}_j$. In other words, if f is a basic operation symbol of rank n and $x_1, x_2, \dots, x_n \in \prod_{j\in J} A_j$, then

$$\pi_i f^{\prod \mathbf{A}_j}(x_1, \dots, x_n) = f^{\mathbf{A}_i}(\pi_i x_1, \dots, \pi_i x_n) \qquad \forall\ i \in J.$$

In addition to the basic operations of an algebra, one can create new operations by composing the basic ones. Specifically, let A be a set, f an n-ary operation on A, and let $g_1, \dots, g_n$ be k-ary operations on A. Then the *generalized composition of f with $g_1, \dots, g_n$,* denoted $f[g_1, \dots, g_n]$, is the k-ary operation that maps the k-tuple $\mathbf{a} = (a_1, \dots, a_k)$ to $f\big(g_1(\mathbf{a}), \dots, g_n(\mathbf{a})\big)$.

For each positive integer n and $1 \le j \le n$ we define the jth n-ary *projection operation* by $p_j^n(x_1, \dots, x_n) = x_j$. In particular, p_1^1 is the identity operation. A *clone* on a set A is a set of operations on A containing all projections and closed under generalized composition. The set of all clones on A is obviously ordered by set-theoretic inclusion. The smallest clone consists of nothing but the projection operations, while the largest clone contains all operations on A. It is easy to see that the intersection of a family of clones on A is again a clone. Therefore, if E is any set of operations on A, we define the *clone on A generated by E* to be

$$\mathrm{Clo}^A(E) = \bigcap \{\, C : E \subseteq C \text{ and } C \text{ a clone on } A \,\}. \tag{2.1}$$

For an algebra $\mathbf{A} = \langle A, F\rangle$, the clone of *term operations of* $\mathbf{A}$ is simply $\mathrm{Clo}^A(F)$, the clone on A generated by F. This is typically denoted $\mathrm{Clo}(\mathbf{A})$. For any positive integer m, the set of m-ary members of $\mathrm{Clo}(\mathbf{A})$ is denoted $\mathrm{Clo}_m(\mathbf{A})$.

While (2.1) serves as a definition of $\mathrm{Clo}(\mathbf{A})$, it does not provide any information as to the contents of this clone. Intuitively, an operation on A is a member of $\mathrm{Clo}(\mathbf{A})$ if and only if it can be built up by generalized composition, from the basic operations of $\mathbf{A}$ and the projections. This is formalized in the following theorem. The proof is straightforward; see [20, Theorem 4.3].

THEOREM 2.1. *Let F be a set of operations on a set A, and let m be a positive integer. The set* $\mathrm{Clo}_m^A(F)$ *of* m-ary *members of* $\mathrm{Clo}^A(F)$ *is the smallest set X of* m-ary *operations on A such that*

(i) $p_i^m \in X$ *for* $i = 1, 2, \dots, m$;
(ii) *if* $f \in F$ *and* $g_1, g_2, \dots, g_{\rho(f)} \in X$, *then* $f[g_1, \dots, g_{\rho(f)}] \in X$.

Just as the basic operations of an algebra $\mathbf{A}$ are instances of the operation symbols, we would like to have syntactic objects that correspond to the term operations of $\mathbf{A}$. One way to do this is as follows.

DEFINITION 2.2. *Let $X = \{x_1, x_2, \dots\}$ be a countably infinite set of variables and $\rho \colon F \to \{0, 1, \dots\}$ a similarity type, with F disjoint from X. The set of* terms of type ρ *is the smallest set T of strings such that*

1. $X \subseteq T$;
2. $\rho^{-1}(0) \subseteq T$;
3. *if* $f \in F$ *and* $t_1, \dots, t_{\rho(f)} \in T$, *then* $f(t_1, \dots, t_{\rho(f)}) \in T$.

A term is n-ary *if the only variables that appear in the string come from* $\{x_1, \dots, x_n\}$.

If $\mathbf{A}$ is an algebra and t is an n-ary term, then we can assign an n-ary term operation $t^{\mathbf{A}}$ to t as follows. If $t = x_i$, then $t^{\mathbf{A}} = (p_i^n)^{\mathbf{A}}$. If $t = f(t_1, \dots, t_k)$,

then $t^{\mathbf{A}} = f^{\mathbf{A}}[t_1^{\mathbf{A}}, \ldots, t_k^{\mathbf{A}}]$. Comparing the assertions in Theorem 2.1 to the above definitions, we see that $\mathrm{Clo}(\mathbf{A}) = \{\, t^{\mathbf{A}} : t \text{ is a term} \,\}$.

An *identity* of type ρ is simply a pair of terms, although we usually write it in the form $s \approx t$. An algebra $\mathbf{A}$ satisfies the identity $s \approx t$ if $s^{\mathbf{A}} = t^{\mathbf{A}}$. In the usual terminology of first-order logic, this is the same as asserting that the model $\mathbf{A}$ satisfies the sentence

$$(\forall x_1)(\forall x_2)\cdots(\forall x_n)\,\big(s(x_1, \ldots, x_n) \approx t(x_1, \ldots, x_n)\big),$$

where s and t are n-ary terms.

For example, if our similarity type consists of two binary operation symbols, $+$ and $*$, then both the commutative law $x + y \approx y + x$ and the distributive law $x * (y + z) \approx (x * y) + (x * z)$ are identities that may or may not hold in any particular algebra. Notice that in this example we have adopted the usual custom of writing binary operations in "infix" form and using variables x, y, z instead of x_1, x_2, x_3.

A *quasi-identity* is a first-order sentence of the form

$$(\forall x_1)\cdots(\forall x_n)\,\Big(\bigwedge_{j=1}^{m} s_j(x_1, \ldots, x_n) \approx t_j(x_1, \ldots, x_n) \longrightarrow u(x_1, \ldots, x_n) \approx v(x_1, \ldots, x_n)\Big),$$

where each s_j, t_j, u, and v is an n-ary term, and "$\bigwedge$" denotes conjunction. Every identity is a quasi-identity, by taking $m = 0$. In the context of algebraic structures, quasi-identities are precisely the universal Horn sentences. An example of a quasi-identity that is not an identity is the left-cancellation law $x * y \approx x * z \to y \approx z$, which holds, for example, in the positive integers under multiplication but not for all integers under multiplication. By contrast, the formula

$$(x \neq 0 \ \wedge \ x * y \approx x * z) \to y \approx z$$

is not a quasi-identity, since we do not permit negation symbols.

Now, fix a similarity type ρ, and let $\mathcal{K}$ be a class of algebras, all of type ρ. $\mathcal{K}$ is called a *variety,* or *equational class,* if there is a set Σ of identities (not necessarily finite) such that $\mathcal{K}$ is exactly the class of all algebras satisfying every identity in Σ. Notice that many familiar classes of algebras are varieties. For example, the class of all groups is a variety if we take our similarity type to consist of one binary, one unary, and one nullary operation, and Σ to consist of the five identities

$$x \cdot (y \cdot z) \approx (x \cdot y) \cdot z, \quad x \cdot e \approx e \cdot x \approx x, \quad x \cdot x^{-1} \approx x^{-1} \cdot x \approx e.$$

A classical theorem due to Birkhoff [3] asserts that a class $\mathcal{K}$ is a variety if and only if $\mathcal{K}$ is closed under the formation of subalgebras, arbitrary products, and homomorphic images. This remarkable fact connects the purely syntactic idea of an equation to the familiar algebraic constructions we discussed earlier.

It is convenient to introduce the following notation. Let $\mathcal{K}$ be a class of algebras of the same similarity type. Then $\mathbf{H}(\mathcal{K}), \mathbf{S}(\mathcal{K})$, and $\mathbf{P}(\mathcal{K})$ denote the class of all

algebras isomorphic to a homomorphic image, subalgebra, and product of members of $\mathcal{K}$, respectively. Thus $\mathcal{K}$ is a variety if and only if $\mathcal{K} = \mathbf{H}(\mathcal{K}) = \mathbf{S}(\mathcal{K}) = \mathbf{P}(\mathcal{K})$.

It is easy to see that the intersection of a family of varieties (all of similarity type ρ) is again a variety. In fact, a defining set of identities will be the union of defining sets for each of the component varieties. Thus we define, for any class $\mathcal{K}$, the *variety generated by* $\mathcal{K}$ to be

$$\mathbf{V}(\mathcal{K}) = \bigcap \{ \mathcal{V} : \mathcal{V} \text{ is a variety and } \mathcal{K} \subseteq \mathcal{V} \}.$$

It is not hard to show that for any class $\mathcal{K}$,

$$\mathbf{V}(\mathcal{K}) = \mathbf{HSP}(\mathcal{K}) = \mathrm{Mod}(\mathrm{Id}(\mathcal{K})). \tag{2.2}$$

In this equation, $\mathrm{Id}(\mathcal{K})$ denotes the set of all identities true in every member of $\mathcal{K}$, and $\mathrm{Mod}(\Sigma)$ denotes the class of all algebras in which every identity in Σ holds. For a single algebra $\mathbf{A}$, it is customary to write $\mathbf{V}(\mathbf{A})$ instead of $\mathbf{V}(\{\mathbf{A}\})$.

Just as a variety is defined by identities, a *quasi-variety* is defined by quasi-identities. Most of the assertions we have made about varieties have analogous formulations for quasi-varieties. For example, there is a Birkhoff-type theorem that states that a class $\mathcal{K}$ is a quasi-variety if and only if it is closed under the formation of subalgebras, products, and ultraproducts. (We will not need the notion of an ultraproduct here. See [5, p. 210].) The *quasi-variety generated by* $\mathcal{K}$ is

$$\mathbf{Q}(\mathcal{K}) = \bigcap \{ \mathcal{Q} : \mathcal{Q} \text{ is a quasi-variety and } \mathcal{K} \subseteq \mathcal{Q} \}.$$

Since every variety is also a quasi-variety, we always have $\mathcal{K} \subseteq \mathbf{Q}(\mathcal{K}) \subseteq \mathbf{V}(\mathcal{K})$, but the reverse inclusions are usually false. For example, let $\mathbb{Z}$ denote the group of integers, and $\mathcal{K} = \{\mathbb{Z}\}$. Then $\mathbf{Q}(\mathcal{K})$ is the class of torsion-free Abelian groups, while $\mathbf{V}(\mathcal{K})$ consists of all Abelian groups. (A group is *torsion-free* if no element except the identity has finite order.)

There is one feature of the quasi-variety notion that deserves special mention. Since we will need it later, we state it formally.

THEOREM 2.3. *Let* $\mathbf{A}$ *be a finite algebra. Then* $\mathbf{Q}(\mathbf{A}) = \mathbf{SP}(\mathbf{A})$.

Proof. Since $\mathbf{A} \in \mathbf{SP}(\mathbf{A}) \subseteq \mathbf{Q}(\mathbf{A})$, it suffices to show that $\mathbf{SP}(\mathbf{A})$ is a quasi-variety. Closure under $\mathbf{S}$ and $\mathbf{P}$ is easy. Closure under ultraproducts boils down to the fact that, since A is finite, an ultraproduct of copies of $\mathbf{A}$ is simply isomorphic to $\mathbf{A}$ again. See [5, Lemma 6.5 and Theorem 2.25]. □

An algebra $\mathbf{B}$ is called *simple* if it has more than one element and every homomorphism with domain B is either injective or trivial (i.e., has a one-element image). For example, a group is simple in this sense if and only if it has exactly two normal subgroups. We will need the following easy result.

PROPOSITION 2.4. *Let* $\mathbf{B}$ *be a simple algebra and* $\mathbf{A}$ *be any algebra of the same similarity type. If* $\mathbf{B} \in \mathbf{SP}(\mathbf{A})$, *then* $\mathbf{B} \in \mathbf{S}(\mathbf{A})$.

Proof. By assumption there is a set I and an embedding $\psi\colon \mathbf{B} \to \mathbf{A}^I$. Pick distinct elements a, b from B. Then $\psi(a) \neq \psi(b)$, so for some $i \in I$, $\psi(a)$ and $\psi(b)$ differ in the ith component. Let π_i be the mapping from $\mathbf{A}^I$ to $\mathbf{A}$ that assigns to each I-tuple its ith coordinate. Then $\pi_i \circ \psi$ is a homomorphism from $\mathbf{B}$ to $\mathbf{A}$ which is nontrivial, since $\pi_i\psi(a) \neq \pi_i\psi(b)$. From the simplicity of $\mathbf{B}$, it follows that $\pi_i \circ \psi$ is an embedding. Hence $\mathbf{B} \in \mathbf{S}(\mathbf{A})$. □

TABLE 3.1
Some complexity classes.

$\mathbf{L} = \mathbf{DSPACE}(\log n)$,	logarithmic space;
$\mathbf{NL} = \mathbf{NSPACE}(\log n)$,	nondeterministic logarithmic space;
$\mathbf{P} = \bigcup_{k\geq 1} \mathbf{DTIME}(n^k)$,	polynomial time;
$\mathbf{NP} = \bigcup_{k\geq 1} \mathbf{NTIME}(n^k)$,	nondeterministic polynomial time;
$\mathbf{PSPACE} = \bigcup_{k\geq 1} \mathbf{DSPACE}(n^k)$,	polynomial space;
$\mathbf{EXPTIME} = \bigcup_{k\geq 1} \mathbf{DTIME}(2^{n^k})$,	exponential time;
$\mathbf{2\text{-}EXPTIME} = \bigcup_{k\geq 1} \mathbf{DTIME}(2^{2^{n^k}})$,	hyperexponential time.

3. Complexity preliminaries. Since this paper deals with the computational complexity of problems in universal algebra, we will include a brief review of the complexity classes used in this paper, mainly for the benefit of those readers unfamiliar with the common notation and terminology used. Consult any of [27, 22, 13, 9] for an in-depth treatment of computational complexity.

Languages (i.e., sets of finite strings over some fixed alphabet) are viewed as encodings of problems. Given a function $f\colon \mathbb{N} \to \mathbb{N}$, we denote by $\mathbf{DTIME}(f(n))$ (respectively, $\mathbf{DSPACE}(f(n))$) the set of all languages decidable by a deterministic Turing machine in time (respectively, space) $O(f(n))$. In an analogous way, the nondeterministic classes $\mathbf{NTIME}(f(n))$ and $\mathbf{NSPACE}(f(n))$ are defined in terms of nondeterministic Turing machines. The complexity classes referred to in this paper are defined in Table 3.1 (see [13]). The class **P** consists of those problems for which it is considered to be feasible to use a computer to find a solution. By contrast, a problem lies in **NP** if a proposed solution can be *verified* in polynomial time.

These classes form a chain of inclusions:

$$\mathbf{L} \subseteq \mathbf{NL} \subseteq \mathbf{P} \subseteq \mathbf{NP} \subseteq \mathbf{PSPACE} \subseteq \mathbf{EXPTIME} \subseteq \mathbf{2\text{-}EXPTIME}. \tag{3.1}$$

Of these the following are known to be proper:

$$\mathbf{NL} \subsetneq \mathbf{PSPACE}, \qquad \mathbf{P} \subsetneq \mathbf{EXPTIME} \subsetneq \mathbf{2\text{-}EXPTIME}. \tag{3.2}$$

All of the other inclusions (except for the obvious ones that follow from (3.2)) represent deep open problems in theoretical computer science, the most famous of which is the seemingly unapproachable $\mathbf{P} \stackrel{?}{=} \mathbf{NP}$ problem.

In addition to the classes listed above, several others are worth noting briefly. First, both **EXPTIME** and **2-EXPTIME** have nondeterministic analogues which could be added to our list. Surprisingly, the same is not true for **PSPACE**. In 1970, Savitch [26] proved that for any function f with $f(n) \geq \log n$, $\mathbf{NSPACE}(f(n)) \subseteq \mathbf{DSPACE}(f(n)^2)$. In particular, $\mathbf{PSPACE} = \mathbf{NPSPACE}$.

Second, for any complexity class **C**, one can define the dual class **co-C**, consisting of those languages (problems) whose *complements* lie in **C**. For example, since the graph-isomorphism problem lies in **NP**, the graph-nonisomorphism problem lies in

co-NP. It is not hard to see that every deterministic class **C** is closed under complements, i.e., **C** = **co-C**. Furthermore, it was shown independently by Immerman and Szelepcsényi [12, 29], that if $f(n) \geq \log n$, then **NSPACE**$(f(n))$ is closed under complements. From this we obtain **NL** = **co-NL**.

Among the most useful tools in complexity theory are the concepts of resource-bounded reducibility and completeness, both borrowed from recursive function theory. Given two languages A and B, we say that A is *polynomial-time, many-one reducible to B,* and we write $A \leq_m^p B$, if there is a polynomial-time computable function f such that

$$x \in A \iff f(x) \in B. \tag{3.3}$$

It is not hard to verify that "$\leq_m^p$" is both reflexive and transitive. A language (i.e., problem) A is $\leq_m^p$*-hard* (or just *hard*) for a class **C** of problems, if for every $C \in \mathbf{C}$, $C \leq_m^p A$. The language A is $\leq_m^p$*-complete* (or just complete) for **C** if A is hard for **C** and $A \in \mathbf{C}$.

Unfortunately, polynomial-time reductions are not useful within the class **P**, since for any nontrivial $A, B \in \mathbf{P}$ we have $A \leq_m^p B \leq_m^p A$. Instead, we must resort to a weaker notion called *log-space reduction.* This simply means that in (3.3), the function f must be computable in logarithmic space.

Since it is generally believed that all of the inclusions in (3.1) are in fact proper, a proof of completeness of a problem A in any of those classes is viewed as providing overwhelming evidence that A does not belong to the immediately preceding class in (3.1). It follows from (3.2) that any problem which is complete for **EXPTIME** (such as our Term-Equiv) fails to lie in **P**. Such a problem is *provably* intractable.

In the problems we will be investigating, the input consists of pairs of finite algebras of *finite similarity type* (i.e., algebras having only finitely many basic operation symbols). Let us be more specific as to the form we assume the input will take. The underlying set of an algebra can be assumed to be $\{0, 1, \ldots, n-1\}$ for some positive integer n. In fact, this set can be represented in the input by its cardinality, which requires $\log n$ bits of storage. (All logarithms will be to the base 2.) A k-ary operation on this set is represented as a table of values or, in other words, a k-dimensional array with both the indices and entries coming from $\{0, 1, \ldots, n-1\}$. Notice that this can be represented in the input stream using $n^k \cdot \log n$ bits.

Let us define the *rank* of an algebra to be the maximum rank of any of its basic operations. Thus an algebra of cardinality n and rank k will require at least $n^k \cdot \log n$ bits to specify.

There are certainly other ways of specifying operations, such as with circuits or Turing machines, but we shall not pursue this idea here. Also, from now on we shall assume that all algebras are finite and of finite similarity type.

4. Discussion of the problems. In this paper we shall consider three equivalence relations on algebraic structures. First, given two algebras **A** and **B** of the same similarity type, is $\mathbf{V}(\mathbf{A}) = \mathbf{V}(\mathbf{B})$? In light of (2.2), this is equivalent to asking whether **A** and **B** satisfy exactly the same identities. Note that this only makes sense if the two algebras have the same similarity type. It was shown in [14] that this problem is decidable. We shall denote this problem Var-Equiv. Thus

$$\text{Var-Equiv} = \{\, (\mathbf{A}, \mathbf{B}) : \mathbf{A} \sim \mathbf{B} \;\&\; \mathbf{V}(\mathbf{A}) = \mathbf{V}(\mathbf{B}) \,\}.$$

Recently, Z. Székely proved that Var-Equiv is **NP**-hard; see [28].

We have an analogous problem for quasi-varieties:

$$\text{QVAR-EQUIV} = \{\, (\mathbf{A}, \mathbf{B}) : \mathbf{A} \sim \mathbf{B} \;\&\; \mathbf{Q}(\mathbf{A}) = \mathbf{Q}(\mathbf{B}) \,\}.$$

The assertion $(\mathbf{A}, \mathbf{B}) \in$ QVAR-EQUIV is equivalent to $\mathbf{A}$ and $\mathbf{B}$ satisfying exactly the same quasi-identities. Surprisingly, even though the logical form of a quasi-identity is much more complicated than that of an identity, QVAR-EQUIV has a relatively low computational complexity compared to VAR-EQUIV. Note that QVAR-EQUIV $\subseteq$ VAR-EQUIV as sets.

The third problem we shall consider is term-equivalence. Two algebras $\mathbf{A}$ and $\mathbf{B}$ are *term-equivalent* if and only if they have the same underlying set and $\mathrm{Clo}(\mathbf{A}) = \mathrm{Clo}(\mathbf{B})$. For this problem, we do not require that $\mathbf{A}$ and $\mathbf{B}$ have the same similarity type, but we do require that they have the same universe:

$$\text{TERM-EQUIV} = \{\, (\mathbf{A}, \mathbf{B}) : A = B \;\&\; \mathrm{Clo}(\mathbf{A}) = \mathrm{Clo}(\mathbf{B}) \,\}.$$

It was shown in [1] that TERM-EQUIV is complete for **EXPTIME**.

There are several restrictions of these problems which are of interest and which turn out to have a lower complexity. In particular, we can bound either the cardinality of the underlying sets or the ranks of the algebras. For example, it was shown in [18] that TERM-EQUIV is complete for **PSPACE** when restricted to *unary algebras,* that is, algebras in which every operation has rank 1. For each of our three problems, we shall consider, in addition to the general case, the subcases obtained by considering only unary algebras and only two-element algebras. We shall denote the subcase by appending a superscript "1" or subscript "2" to the problem. To be precise, let us define

$$U = \{\, \mathbf{A} : \mathbf{A} \text{ is a unary algebra} \,\},$$
$$T = \{\, \mathbf{A} : A = \{0, 1\} \,\}.$$

Then $\mathrm{X}^1 = \mathrm{X} \cap (U \times U)$ and $\mathrm{X}_2 = \mathrm{X} \cap (T \times T)$ for X any one of TERM-EQUIV, VAR-EQUIV, or QVAR-EQUIV.

Our results for each of these nine problems are summarized in Table 4.1. In this

TABLE 4.1
Summary of results.

	QVAR-EQUIV	TERM-EQUIV	VAR-EQUIV
card2	**L**	**NL**	**L**
unary	**NP**	**PSPACE***	**PSPACE**
general	**NP***	**EXPTIME***	**2-EXPTIME**

table, the first row concerns the subcase consisting of two-element algebras, the second concerns the subcase of unary algebras, and the third concerns the general case. Each of the nine entries gives the smallest complexity class known to contain the problem, and a superscript "*" indicates that the result is sharp, i.e., the problem is complete for the given complexity class.

5. The quasi-variety problems. We begin with the problems that ask whether two algebras generate the same quasi-variety. It is sometimes convenient to work with an asymmetric variant of this problem:

$$\text{QVAR-MEM} = \{\, (\mathbf{A}, \mathbf{B}) : \mathbf{A} \sim \mathbf{B} \;\&\; \mathbf{B} \in \mathbf{Q}(\mathbf{A}) \,\}.$$

Since the "**Q**" operator has the usual properties of closure, we obviously have

$$(\mathbf{A},\mathbf{B}) \in \text{QVAR-EQUIV} \iff (\mathbf{A},\mathbf{B}),\ (\mathbf{B},\mathbf{A}) \in \text{QVAR-MEM}. \tag{5.1}$$

It follows that for an instance of size s, membership in QVAR-EQUIV can be tested with two calls to an algorithm for QVAR-MEM, both using inputs of size s. In a natural way, we also have the restricted problems QVAR-MEM^1 and QVAR-MEM$_2$ consisting of pairs of unary and two-element algebras, respectively.

THEOREM 5.1. QVAR-MEM $\in$ **NP**.

Proof. Let $\mathbf{A}$ and $\mathbf{B}$ be a pair of similar, finite algebras. We wish to determine whether $\mathbf{B} \in \mathbf{Q}(\mathbf{A})$. Here is a nondeterministic algorithm. For each unordered pair $\{a,b\}$ of distinct elements of B, guess a function $\psi_{\{a,b\}}\colon B \to A$ such that $\psi_{\{a,b\}}(a) \neq \psi_{\{a,b\}}(b)$. Test whether $\psi_{\{a,b\}}$ is a homomorphism. If it is not, then reject. But if every $\psi_{\{a,b\}}$ passes the homomorphism test, then accept.

To see that our algorithm is correct, suppose that we accept the pair $(\mathbf{A},\mathbf{B})$. Enumerate the doubletons $\{a_i,b_i\}$, $i = 1,2,\dots,n$, of elements of B. Define a function $\psi\colon B \to A^n$ such that the ith coordinate of $\psi(x)$ is $\psi_{\{a_i,b_i\}}(x)$. The fact that every $\psi_{\{a_i,b_i\}}$ is a homomorphism ensures that ψ is a homomorphism. And ψ will be injective since, if $a \neq b$, then $\psi(a)$ and $\psi(b)$ differ in the ith coordinate, where $\{a,b\}$ is the ith pair in our enumeration. It follows that $\mathbf{B}$ is isomorphic to a subalgebra of a direct power of $\mathbf{A}$, and consequently $\mathbf{B}$ lies in the quasi-variety generated by $\mathbf{A}$.

Conversely, suppose that $\mathbf{B} \in \mathbf{Q}(\mathbf{A})$. By Theorem 2.3 there is a set J and an embedding $\psi\colon \mathbf{B} \to \mathbf{A}^J$. Using the notation of the previous paragraph, for each $i = 1,\dots,n$, we have $\psi(a_i) \neq \psi(b_i)$, and hence there is some $j_i \in J$ such that $\psi(a_i)$ and $\psi(b_i)$ differ in their j_ith coordinate. Let $\pi_{j_i}\colon \mathbf{A}^J \to \mathbf{A}$ denote the coordinate projection homomorphism. Then $\psi_{\{a_i,b_i\}} = \pi_{j_i} \circ \psi$ constitutes an appropriate guess. Thus our algorithm will accept the pair $(\mathbf{A},\mathbf{B})$.

Finally, we need to estimate the (nondeterministic) running time of the algorithm. Let s denote the size of the input. A function ψ from B to A can be guessed in time on the order of $|B|\cdot|A|$, which is at most s^2. The verification that ψ is a homomorphism also takes time in $O(s^2)$. The total number of functions we need to construct is $\binom{|B|}{2} \leq s^2$. Thus the total running time lies in $O(s^4)$. □

COROLLARY 5.2. *All of the following lie in* **NP***:* QVAR-EQUIV*,* QVAR-MEM^1*,* QVAR-MEM$_2$*,* QVAR-EQUIV^1*, and* QVAR-EQUIV$_2$*.*

Proof. That QVAR-EQUIV $\in$ **NP** follows from Theorem 5.1 and (5.1). The class **NP** is closed under polynomial-time, many-one reductions. Since QVAR-MEM^1 and QVAR-EQUIV^1 are reducible to (indeed special cases of) QVAR-MEM and QVAR-EQUIV, respectively, they too lie in **NP**. The same argument applies to the two-element versions of the problems. □

We shall improve the bounds on QVAR-MEM$_2$ and QVAR-EQUIV$_2$ in Theorem 5.7 below. But first we consider the **NP**-completeness of the other problems discussed in Corollary 5.2. To do this, we use a transformation from (directed) graphs to unary algebras described in [11]. By a *digraph* we shall mean a structure $\mathbf{G} = \langle G,\theta\rangle$ in which G is a nonempty set and $\theta \subseteq G \times G$. $\mathbf{G}$ is *loopless* if for no x in G do we have $(x,x) \in \theta$.

Let $\mathbf{G} = \langle G,\theta\rangle$ and $\mathbf{H} = \langle H,\tau\rangle$ be digraphs. A morphism from $\mathbf{H}$ to $\mathbf{G}$ is a function $\psi\colon H \to G$ such that $(x,y) \in \tau \implies \big(\psi(x),\psi(y)\big) \in \theta$. $\mathbf{H}$ is a subgraph of $\mathbf{G}$ if $H \subseteq G$ and the inclusion map is a morphism. If $\mathbf{G}_i = \langle G_i,\theta_i\rangle$, $i \in I$ is a family of digraphs, then the product graph is $\langle G,\theta\rangle$, where $G = \prod_{i\in I} G_i$ and $\theta = \{\,(x,y) \in G \times G : (\forall i \in I)\ (x_i,y_i) \in \theta_i\,\}$. Just as for algebras, we use the

operators **S** and **P** to denote closure under the formation of subgraph and product graph, respectively.

Given a digraph $\mathbf{G} = \langle G, \theta \rangle$, we now define an algebra $\mathbf{G}^*$ as follows. The universe of $\mathbf{G}^*$ is the set $G \cup \theta \cup \{u, v\}$ where u and v are points not appearing in either G or θ. $\mathbf{G}^* = \langle\, G^*, f_0, f_1 \,\rangle$, where f_0 and f_1 are unary operations defined by

$$\begin{array}{lll} \forall x \in G & f_0(x) = u, & f_1(x) = v; \\ \forall (x,y) \in \theta & f_0((x,y)) = x, & f_1((x,y)) = y; \\ & f_0(u) = v, & f_1(u) = u, \\ & f_0(v) = v, & f_1(v) = u. \end{array}$$

Furthermore, let $\psi\colon \mathbf{H} \to \mathbf{G}$ be a digraph morphism. We define a function $\psi^*\colon H^* \to G^*$ given by

$$\begin{array}{ll} \forall x \in H & \psi^*(x) = \psi(x); \\ \forall (x,y) \in \tau & \psi^*((x,y)) = (\psi(x),\, \psi(y)); \\ \psi^*(u^H) = u^G, & \psi^*(v^H) = v^G. \end{array}$$

LEMMA 5.3 (see Hedrlín and Pultr [11]). *The assignments $\mathbf{G} \mapsto \mathbf{G}^*$ and $\psi \mapsto \psi^*$ constitute a full and faithful functor from the category of digraphs to that of algebras with two unary operations. In other words, for each pair $\mathbf{H}$, $\mathbf{G}$ of digraphs, and each digraph morphism ψ, the function $\psi^*\colon \mathbf{H}^* \to \mathbf{G}^*$ is a homomorphism, and furthermore, the mapping $\psi \mapsto \psi^*$ is a bijection between the morphisms from $\mathbf{H}$ to $\mathbf{G}$ and the homomorphisms between $\mathbf{H}^*$ and $\mathbf{G}^*$. Also, ψ is an injective map if and only if ψ^* is injective.*

We will show **NP**-completeness of QVAR-MEM[1] by exhibiting a reduction from the problem CLIQUE, which is well known to be complete for **NP**; see [9, p. 194]. For a positive integer n, let $\mathbf{K}_n$ denote the digraph with vertex set $\{1, 2, \ldots, n\}$ and edges $\{\, (x,y) : x \neq y \,\}$. We define

$$\text{CLIQUE} = \{\, (\mathbf{G}, n) : \mathbf{G} \text{ a digraph, } n \geq 1 \text{ and } \mathbf{K}_n \in \mathbf{S}(\mathbf{G}) \,\}.$$

A subset of G isomorphic to some $\mathbf{K}_n$ is called a *clique*.

PROPOSITION 5.4. *Let $\mathbf{G}$ be a loopless digraph and n a positive integer. The following are equivalent.*

(i) $(\mathbf{G}, n) \in$ CLIQUE.
(ii) $\mathbf{K}_n \in \mathbf{SP}(\mathbf{G})$.
(iii) $\mathbf{K}_n^* \in \mathbf{SP}(\mathbf{G}^*)$.

Proof. That (i) implies (ii) is trivial. Now assume (ii), i.e., suppose that ψ is an embedding of $\mathbf{K}_n$ into a power $\mathbf{G}^I$. By Lemma 5.3, we have an injective homomorphism ψ^* from $\mathbf{K}_n^*$ to $(\mathbf{G}^I)^*$. Moreover, it is easy to see that $(\mathbf{G}^I)^*$ is isomorphic to a subalgebra of $(\mathbf{G}^*)^I$. Thus (iii) holds.

Finally, suppose that $\phi\colon \mathbf{K}_n^* \to (\mathbf{G}^*)^I$ is an embedding for some set I. Choose any $i \in I$. Then $\pi_i \circ \phi$ is a homomorphism from $\mathbf{K}_n^*$ to $\mathbf{G}^*$, which, by Lemma 5.3, must be of the form ψ^* for some digraph morphism $\psi\colon \mathbf{K}_n \to \mathbf{G}$. Suppose that x and y are distinct elements of $\mathbf{K}_n$. By definition, there is an edge from x to y; consequently, there must be an edge in $\mathbf{G}$ from $\psi(x)$ to $\psi(y)$. Since $\mathbf{G}$ is assumed to be loopless, it must be the case that $\psi(x) \neq \psi(y)$. Therefore, ψ is injective, so (iii) implies (i). □

It is convenient to introduce one more problem involving the relationship between two algebras. Let

$$\text{SUBALG} = \{\, (\mathbf{A}, \mathbf{B}) : \mathbf{A} \sim \mathbf{B} \;\&\; \mathbf{B} \in \mathbf{S}(\mathbf{A}) \,\}.$$

As with our other problems, SUBALG^1 will refer to the restriction of this problem to the case that $\mathbf{A}$ and $\mathbf{B}$ are unary algebras. It is easy to see that SUBALG and SUBALG^1 lie in **NP** (just guess an injective function and check to see if it is a homomorphism).

THEOREM 5.5. *The problems* QVAR-MEM^1, QVAR-MEM, SUBALG^1, SUBALG, *and* QVAR-EQUIV *are all complete for* **NP**.

Proof. We showed in Theorem 5.1, Corollary 5.2, and the comments just above that all of these problems lie in **NP**. The problem CLIQUE is **NP**-complete, and the transformation $(\mathbf{G}, n) \mapsto (\mathbf{G}^*, \mathbf{K}_n^*)$ can be done in polynomial time. Therefore, we deduce from Proposition 5.4 and Theorem 2.3 that QVAR-MEM^1 is also **NP**-complete. Clearly, QVAR-MEM$^1 \leq_m^p$ QVAR-MEM, so QVAR-MEM is **NP**-complete.

By Lemma 5.3, $(\mathbf{G}, n) \in$ CLIQUE if and only if $(\mathbf{G}^*, \mathbf{K}_n^*) \in$ SUBALG^1. Thus SUBALG^1 and also SUBALG are **NP**-complete. This fact is not new; it was first noted in [21].

To complete the proof, we will reduce SUBALG^1 to QVAR-EQUIV. Given a finite unary algebra $\mathbf{B} = \langle B, F\rangle$, let $\mathbf{B}^+ = \big\langle\, B \cup \{e\},\ F \cup \{p, d\}\,\big\rangle$, where $e \notin B$ and $p, d \notin F$. For each $f \in F$, $f(e) = e$. For all $x, y, z \in B \cup \{e\}$ we define

$$p(x) = e;$$

$$d(x, y, z) = \begin{cases} z & \text{if } x = y, \\ x & \text{if } x \neq y. \end{cases}$$

The ternary operation d is called the *discriminator operation*. It is an easy exercise to check that any algebra with a discriminator among its term operations is simple.

Now, given two finite unary algebras $\mathbf{A}$ and $\mathbf{B}$, we have the following equivalences.

$$\mathbf{B} \in \mathbf{S}(\mathbf{A}) \iff \mathbf{B}^+ \in \mathbf{S}(\mathbf{A}^+) \iff \mathbf{Q}(\mathbf{A}^+) = \mathbf{Q}(\mathbf{A}^+ \times \mathbf{B}^+). \tag{5.2}$$

Clearly, the equivalences in (5.2) imply that SUBALG$^1 \leq_m^p$ QVAR-EQUIV. The first equivalence is an easy verification. We check the second. First suppose that $\mathbf{B}^+ \in \mathbf{S}(\mathbf{A}^+)$. Then both $\mathbf{A}^+$ and $\mathbf{B}^+$ are members of $\mathbf{Q}(\mathbf{A}^+)$ which is closed under products. Therefore, $\mathbf{A}^+ \times \mathbf{B}^+ \in \mathbf{Q}(\mathbf{A}^+)$, so $\mathbf{Q}(\mathbf{A}^+ \times \mathbf{B}^+) \subseteq \mathbf{Q}(\mathbf{A}^+)$. On the other hand, there is an embedding of $\mathbf{A}^+$ into $\mathbf{A}^+ \times \mathbf{B}^+$ given by $x \mapsto (x, e)$. Hence $\mathbf{Q}(\mathbf{A}^+) \subseteq \mathbf{Q}(\mathbf{A}^+ \times \mathbf{B}^+)$.

Conversely, suppose that $\mathbf{Q}(\mathbf{A}^+) = \mathbf{Q}(\mathbf{A}^+ \times \mathbf{B}^+)$. There is an embedding of $\mathbf{B}^+$ into $\mathbf{A}^+ \times \mathbf{B}^+$ such that $x \mapsto (e, x)$. Thus $\mathbf{B}^+ \in \mathbf{Q}(\mathbf{A}^+) = \mathbf{SP}(\mathbf{A}^+)$. However, $\mathbf{B}^+$ is a simple algebra, so by Proposition 2.4, $\mathbf{B}^+ \in \mathbf{S}(\mathbf{A}^+)$. □

Remark. Referring back to the proof of Theorem 5.5, it is tempting to try to prove the **NP**-hardness of QVAR-EQUIV by using (5.1) together with the **NP**-completeness of QVAR-MEM and Corollary 5.2. However, there are difficulties with this line of argument. To take an analogous situation, the subgraph isomorphism problem is **NP**-complete, but the graph isomorphism problem is in **NP** but most probably is not **NP**-complete.

Unfortunately, the method used to reduce SUBALG^1 to QVAR-EQUIV does not produce a unary algebra, so we are not able to show that QVAR-EQUIV^1 is complete for **NP**. We leave it as an open problem.

PROBLEM 5.6. *Is* QVAR-EQUIV^1 *complete for* **NP**? *Is* QVAR-EQUIV$^1 \in$ **P**?

Now we turn to the problem QVAR-EQUIV$_2$. Suppose that $\mathbf{A}$ and $\mathbf{B}$ are two-element algebras. We claim that $\mathbf{B} \in \mathbf{Q}(\mathbf{A})$ if and only if $\mathbf{B} \cong \mathbf{A}$. To see this, note that every two-element algebra is simple. Therefore, by Proposition 2.4, Theorem 2.3, and the fact that $|B| = |A|$, we obtain

$$\mathbf{B} \in \mathbf{Q}(\mathbf{A}) = \mathbf{SP}(\mathbf{A}) \implies \mathbf{B} \in \mathbf{S}(\mathbf{A}) \implies \mathbf{B} \cong \mathbf{A}.$$

The converse, that $\mathbf{B} \cong \mathbf{A} \implies \mathbf{B} \in \mathbf{Q}(\mathbf{A})$, is trivial.

THEOREM 5.7. QVAR-EQUIV$_2$, QVAR-MEM$_2 \in \mathbf{L}$.

Proof. As we argued in the previous paragraph, $(\mathbf{B}, \mathbf{A}) \in$ QVAR-MEM$_2$ if and only if $\mathbf{B} \cong \mathbf{A}$. There are only two bijections from B to A, and each of these can be tested to see if it is a homomorphism. The testing requires just a couple of counters, each of which has a space bound that is logarithmic in the size of the input. Thus QVAR-MEM$_2 \in \mathbf{L}$. Now apply assertion (5.1) to deduce that QVAR-EQUIV$_2$ $\in \mathbf{L}$. □

6. The variety problems. The problem VAR-EQUIV asks: if $\mathbf{A}$ and $\mathbf{B}$ are two algebras of the same similarity type, is $\mathbf{V}(\mathbf{A}) = \mathbf{V}(\mathbf{B})$? As with quasi-varieties, it is convenient to introduce an auxiliary problem, VAR-MEM:

$$\text{VAR-MEM} = \{\, (\mathbf{A}, \mathbf{B}) : \mathbf{A} \sim \mathbf{B} \;\&\; \mathbf{B} \in \mathbf{V}(\mathbf{A}) \,\}.$$

Unlike the situation for quasi-varieties, the problems VAR-EQUIV and VAR-MEM are interchangeable from the perspective of complexity. We have

$$\begin{aligned} (\mathbf{A}, \mathbf{B}) \in \text{VAR-EQUIV} &\iff (\mathbf{A}, \mathbf{B}), (\mathbf{B}, \mathbf{A}) \in \text{VAR-MEM}, \\ (\mathbf{A}, \mathbf{B}) \in \text{VAR-MEM} &\iff (\mathbf{A}, \mathbf{A} \times \mathbf{B}) \in \text{VAR-EQUIV}. \end{aligned} \tag{6.1}$$

The second equivalence follows from the fact that both $\mathbf{A}$ and $\mathbf{B}$ are homomorphic images of $\mathbf{A} \times \mathbf{B}$.

We begin with the two-element problem. The crucial point is the following theorem.

THEOREM 6.1. *Let* $\mathbf{A}$ *and* $\mathbf{B}$ *be two-element algebras of the same similarity type. Then* $\mathbf{V}(\mathbf{A}) = \mathbf{V}(\mathbf{B})$ *if and only if* $\mathbf{A} \cong \mathbf{B}$.

The proof of Theorem 6.1 requires considerably more universal algebra than does the remainder of this paper. For this reason, we have relegated the proof to the appendix.

THEOREM 6.2. VAR-EQUIV$_2 \in \mathbf{L}$.

Proof. From Theorem 6.1, testing whether $(\mathbf{A}, \mathbf{B}) \in$ VAR-EQUIV$_2$ is equivalent to testing $\mathbf{A} \cong \mathbf{B}$. Arguing as we did at the end of section 5, there are only two possible isomorphisms to test. This can be done deterministically in logarithmic space. □

In order to proceed to the remaining two problems, we need some more detailed information on the relationship between clones, terms, and varieties. Let $\mathbf{A} = \langle A, F \rangle$ be an algebra of cardinality n, and let m be a positive integer. An m-ary operation on A, being a function from A^m to A, can also be thought of as an element of the direct power $A^{(A^m)}$. Visualized this way, it is not hard to see that $\mathrm{Clo}_m(\mathbf{A})$ forms a subalgebra of $\mathbf{A}^{(A^m)}$. In fact, Theorem 2.1 can be viewed as asserting that $\mathbf{Clo}_m(\mathbf{A})$ is the subalgebra of $\mathbf{A}^{(A^m)}$ generated by the set $\{p_1^m, \ldots, p_m^m\}$. Notice that we follow our usual typographic convention and print "**Clo**" in boldface when it is to be used as an algebra. Since varieties are closed under the formation of both powers and subalgebras, it follows that both $\mathbf{A}^{(A^m)}$ and $\mathbf{Clo}_m(\mathbf{A})$ lie in $\mathbf{V}(\mathbf{A})$.

Let us be more precise about how this subalgebra could be constructed. For each natural number j, define a set X_j of m-ary operations on A recursively by

$$\begin{aligned} X_0 &= \{p_1^m, p_2^m, \ldots, p_m^m\}, \\ X_{j+1} &= X_j \cup \left\{\, f[g_1, \ldots, g_{\rho(f)}] : f \in F,\ g_1, \ldots, g_{\rho(f)} \in X_j \,\right\}. \end{aligned} \tag{6.2}$$

It is easy to see that $X_0 \subseteq X_1 \subseteq \cdots \subseteq \mathrm{Clo}_m(\mathbf{A})$. Since the total number of m-ary operations on A is $n^{(n^m)}$, there is some index $q < n^{(n^m)}$ such that $X_q = X_{q+1}$. But

the pair of conditions $X_j \supseteq X_0$ and $X_j = X_{j+1}$ are precisely those of Theorem 2.1. Therefore, $X_q = \mathrm{Clo}_m(\mathbf{A})$.

The case of a unary algebra deserves special consideration. Suppose that $\mathbf{A}$ is unary (i.e., has rank 1). While it is true that, technically speaking, $\mathbf{A}$ has term operations of arbitrarily large rank, these operations are trivial in the sense that they only depend on one of their variables. For example, if f is a basic operation of $\mathbf{A}$, then the term operation $f[p_1^2]$ has rank 2. However, this operation maps any pair (x, y) to $f(x)$. Thus $f[p_1^2]$ is "essentially unary." Since there are only n^n possible unary operations, one can easily show that for any m, we always have $X_{n^n-1} = \mathrm{Clo}_m(\mathbf{A})$.

Now one cannot help but notice the similarity between the definition of the sets X_j in (6.2) and that of a term given in Definition 2.2. Of course, if t is an m-ary term, then $t^{\mathbf{A}} \in \mathrm{Clo}_m(\mathbf{A})$, hence, for some $j < n^{(n^m)}$, $t^{\mathbf{A}} \in X_j$. Conversely, if we view each m-ary term as a tree, then every member of X_j is of the form $t^{\mathbf{A}}$ for some term t of height at most j. Let us write $\mathrm{ht}(t)$ to denote the height of the term t. Putting these two observations together, for every m-ary term t, there is a term t' such that $t^{\mathbf{A}} = (t')^{\mathbf{A}}$ and $\mathrm{ht}(t') < n^{(n^m)}$. Following up on our earlier observation, in the special case that $\mathbf{A}$ is unary, the bound on the height of t' can be reduced to n^n no matter what the value of m.

THEOREM 6.3. *Let $\mathbf{A}$ and $\mathbf{B}$ be finite algebras of the same similarity type. Assume that the cardinalities of $\mathbf{A}$ and $\mathbf{B}$ are n and m, respectively. Then the following are equivalent.*

(i) $\mathbf{B} \in \mathbf{V}(\mathbf{A})$.

(ii) *For every pair of terms s and t, each of height at most $n^{(n^m)}$, if $\mathbf{A}$ satisfies the identity $s \approx t$, then so does $\mathbf{B}$.*

(iii) $\mathbf{B}$ *is a homomorphic image of the algebra* $\mathbf{Clo}_m(\mathbf{A})$.

If $\mathbf{A}$ and $\mathbf{B}$ are unary algebras, then the bound $n^{(n^m)}$ in (ii) *can be reduced to n^n.*

Proof. That (i) implies (ii) follows from (2.2). So assume (ii). Enumerate the elements of B as $b_1, \ldots, b_m$. Define a function $\psi\colon \mathrm{Clo}_m(\mathbf{A}) \to B$ as follows. For each $g \in \mathrm{Clo}_m(\mathbf{A})$, choose a term u such that $\mathrm{ht}(u) < n^{(n^m)}$ and $u^{\mathbf{A}} = g$, and define $\psi(g) = u^{\mathbf{B}}(b_1, \ldots, b_m)$. To see that this is well defined, suppose that s is another term with the properties $s^{\mathbf{A}} = g$ and $\mathrm{ht}(s) < n^{(n^m)}$. Then $s^{\mathbf{A}} = g = u^{\mathbf{A}}$, so $\mathbf{A}$ satisfies the identity $s \approx u$. Therefore, by (ii), $\mathbf{B}$ also satisfies the identity $s \approx u$, hence $s^{\mathbf{B}} = u^{\mathbf{B}}$.

The function ψ is surjective since for every $i \leq m$, $b_i = \psi(p_i^m)$. In order to prove (iii), it remains to show that ψ is a homomorphism. So let $g_1, \ldots, g_k \in \mathrm{Clo}_m(\mathbf{A})$, and let f be a basic k-ary operation symbol. There are terms $s_1, s_2, \ldots, s_k$ and t, all of height less than $n^{(n^m)}$ such that $g_i = s_i^{\mathbf{A}}$ for $i = 1, 2, \ldots, k$, and $f^{\mathbf{A}}[g_1, \ldots, g_k] = t^{\mathbf{A}}$. Let r be the term $f(s_1, \ldots, s_k)$. We need to verify that $\psi\big(f^{\mathbf{A}}[g_1, \ldots, g_k]\big) = f^{\mathbf{B}}\big(\psi(g_1), \ldots, \psi(g_k)\big)$. Note that $\mathrm{ht}(r) = 1 + \max_i \mathrm{ht}(s_i) \leq n^{(n^m)}$. Also, $r^{\mathbf{A}} = t^{\mathbf{A}}$ since

$$r^{\mathbf{A}} = f^{\mathbf{A}}[s_1^{\mathbf{A}}, \ldots, s_k^{\mathbf{A}}] = f^{\mathbf{A}}[g_1, \ldots, g_k] = t^{\mathbf{A}}.$$

Therefore, the equation $r \approx t$ holds in $\mathbf{A}$, hence in $\mathbf{B}$, because of the bounds on the heights. Thus $r^{\mathbf{B}} = t^{\mathbf{B}}$. Now, writing $\mathbf{b} = (b_1, \ldots, b_m)$, we compute

$$\begin{aligned}\psi\big(f^{\mathbf{A}}[g_1, \ldots, g_k]\big) &= \psi(t^{\mathbf{A}}) = t^{\mathbf{B}}(\mathbf{b}) = r^{\mathbf{B}}(\mathbf{b}) \\ &= f^{\mathbf{B}}\big(s_1^{\mathbf{B}}(\mathbf{b}), \ldots, s_k^{\mathbf{B}}(\mathbf{b})\big) = f^{\mathbf{B}}\big(\psi(g_1), \ldots, \psi(g_k)\big).\end{aligned}$$

Finally, assume (iii). $\mathbf{Clo}_m(\mathbf{A})$ is a subalgebra of $\mathbf{A}^{A^m}$; consequently, it lies in $\mathbf{V}(\mathbf{A})$. Since every variety is closed under homomorphic images, $\mathbf{B} \in \mathbf{V}(\mathbf{A})$ as well. □

1. $s^A \leftarrow t^A \leftarrow f_0^{\mathbf{A}}$; $\quad s^B \leftarrow t^B \leftarrow f_0^{\mathbf{B}}$.
2. for $i = 1$ to n^n do
3. guess $j, \ell \in \{0, 1, \ldots, k\}$
4. $s^A \leftarrow f_j^{\mathbf{A}} \circ s^A$; $\quad s^B \leftarrow f_j^{\mathbf{B}} \circ s^B$; $\quad t^A \leftarrow f_\ell^{\mathbf{A}} \circ t^A$; $\quad t^B \leftarrow f_\ell^{\mathbf{B}} \circ t^B$
5. if $\big((\forall x, y \in A)\ (s^A(x) = t^A(y))$ and $(\exists x, y \in B)\ (s^B(x) \neq t^B(y))\big)$ or $\big((\forall x \in A)\ (s^A(x) = t^A(x))$ and $(\exists x \in B)\ (s^B(x) \neq t^B(x))\big)$ then **accept**.

ALGORITHM 6.1. *Testing* $(\mathbf{A}, \mathbf{B}) \notin$ VAR-MEM^1.

It is worthwhile to extract just a bit more information from the proof of Theorem 6.3. Notice that in the proof of (ii) implies (iii), we began with an arbitrary enumeration of the elements of B and constructed a homomorphism from $\mathbf{Clo}_m(\mathbf{A})$ onto $\mathbf{B}$. In the language of universal algebra, this is equivalent to the assertion that the algebra $\mathbf{Clo}_m(\mathbf{A})$ is *freely generated* by $X_0 = \{\, p_i^m : 1 \leq i \leq m \,\}$. For our purposes, we can express this property as the following corollary.

COROLLARY 6.4. *Let* $\mathbf{A}$ *and* $\mathbf{B}$ *be algebras as in Theorem* 6.3. *The following are equivalent.*

(i) $\mathbf{B} \in \mathbf{V}(\mathbf{A})$.

(ii) *For some bijection* ψ_0 *of* X_0 *with* B, *there exists a homomorphism* ψ *from* $\mathbf{Clo}_m(\mathbf{A})$ *to* $\mathbf{B}$ *such that* $\psi{\restriction}_{X_0} = \psi_0$.

(iii) *For every bijection* ψ_0 *of* X_0 *with* B, *there exists a homomorphism* ψ *from* $\mathbf{Clo}_m(\mathbf{A})$ *to* $\mathbf{B}$ *such that* $\psi{\restriction}_{X_0} = \psi_0$.

Theorem 6.3 suggests an approach that can be used to test the condition $\mathbf{B} \notin \mathbf{V}(\mathbf{A})$: simply *guess* an identity ϵ and check to see whether $\mathbf{A}$ satisfies ϵ while $\mathbf{B}$ fails to satisfy ϵ. This approach seems to be quite effective—at least for unary algebras. For in this case, we have the improved bound n^n in part (ii) of the theorem.

Let us fix a set $F = \{f_1, \ldots, f_k\}$ of operation symbols, each of rank 1. Also, let us add an additional unary operation symbol f_0 which will always be interpreted as the identity operation. This has no effect on the algebras but will save us a subscript in our analysis. A typical term over F is of the form $f_{i_\ell} f_{i_{\ell-1}} \cdots f_{i_2} f_{i_1}(x)$, where $i_1, i_2, \ldots, i_\ell \in \{0, 1, \ldots, k\}$. The height of this term is ℓ. Since each term involves only one variable, every identity is of one of two possible forms:

$$s(x) \approx t(x) \quad \text{or} \quad s(x) \approx t(y).$$

Notice that the second of these is quite degenerate since it requires that the term operations corresponding to s and t both be constant and, in fact, the same constant. Nevertheless, it must be considered in the analysis.

Now suppose that $\mathbf{A}$ and $\mathbf{B}$ are algebras of type F and of cardinalities n and m, respectively. Algorithm 6.1 is a nondeterministic algorithm that accepts the pair $(\mathbf{A}, \mathbf{B})$ if and only if $\mathbf{B} \notin \mathbf{V}(\mathbf{A})$.

How much space is used by this algorithm? Let $p = \max(n, m)$. Each of the four unary operations can be represented as a vector of length p. Each such vector requires $p \log(p) \leq p^2$ bits. We also need space for the counter i, which ranges from 0 to n^n. Since $\log(n^n) = n \log(n) \leq p^2$, i requires another p^2 bits. It follows that the total amount of space required is on the order of p^2 bits.

What is the size of the input? The algebra $\mathbf{A}$ requires $\log(n) + kn \log(n) > n$ bits. Similarly $\mathbf{B}$ requires at least m bits. The total input size is at least $n + m > p$ bits. It follows that our algorithm's space requirements are bounded above by the square of the size of the input.

1. Create empty table for ψ. Fill in ψ_0.
2. for $j = 0$ to $n^{(n^m)} - 2$ do
3. for $f \in F$ do (*let* $k = \rho(f)$)
4. for $g_1, \ldots, g_k \in X_j$ do
5. $b \leftarrow f^{\mathbf{B}}(\psi(g_1), \ldots, \psi(g_k))$
6. $b' \leftarrow \psi(f^{\mathbf{A}}[g_1, \ldots, g_k])$
7. if $b' = \varnothing$ then insert b into the position for b'
8. else if $b' \neq b$ then
9. **reject**
10. **accept**

ALGORITHM 6.2. *Testing* $(\mathbf{A}, \mathbf{B}) \in$ VAR-MEM.

THEOREM 6.5. VAR-MEM^1 *and* VAR-EQUIV^1 *lie in* **PSPACE**.

Proof. Algorithm 6.1 can be used to test whether $(\mathbf{A}, \mathbf{B})$ lies in the *complement* of VAR-MEM^1. Since the algorithm is nondeterministic, we get VAR-MEM$^1 \in$ **co-NPSPACE**. But from Savitch's theorem [26], **NPSPACE** = **PSPACE**. Furthermore, every deterministic class is closed under complements, so **co-PSPACE** = **PSPACE**. Thus VAR-MEM$^1 \in$ **PSPACE**. Now it follows from the relationships in (6.1) that VAR-EQUIV^1 lies in **PSPACE** as well. □

It is not clear whether this is the best possible bound for these two problems. We leave it as an open question.

PROBLEM 6.6. *Are either* VAR-MEM^1 *or* VAR-EQUIV^1 **PSPACE***-complete?*

One might hope to apply the same techniques used above to the unrestricted problem, VAR-EQUIV. Unfortunately, the resources needed to evaluate an arbitrary term in a given algebra jump dramatically as soon as we allow a binary operation. Our approach instead is to try to construct the homomorphism guaranteed by Theorem 6.3 (iii). However, rather than use the construction given in the proof of that theorem, we will construct a homomorphism ψ recursively, based on (6.2). The best we seem to be able to do is the following hyperexponential bound.

THEOREM 6.7. VAR-EQUIV, VAR-MEM $\in$ **2-EXPTIME**.

Proof. Let $|A| = n > 1$ and $|B| = m$. Let F denote the set of basic operation symbols of $\mathbf{A}$ and $\mathbf{B}$, and let r be the maximum rank of the members of F. In light of Theorem 6.5, we shall assume that $r \geq 2$. It follows from Corollary 6.4 that we can test $\mathbf{B} \in \mathbf{V}(\mathbf{A})$ by choosing an arbitrary bijection $\psi_0 \colon X_0 \to B$ and extending it, if possible, to a homomorphism $\psi \colon \mathbf{Clo}_m(\mathbf{A}) \to \mathbf{B}$. So we fix any bijection ψ_0.

Let us sketch an algorithm for extending (if possible) ψ_0 to a homomorphism ψ. Create a table with two columns. In the left-hand column, list every m-ary operation of A. For each m-ary operation g, the right-hand column will contain $\psi(g)$ if and when it is defined. To begin with, leave every entry in the right-hand column blank, except that, for each $1 \leq i \leq m$, put $\psi_0(p_i^m)$ in the row containing p_i^m.

Now let j be an integer, $0 \leq j < n^{(n^m)} - 1$, and suppose we have successfully defined ψ on X_j. We attempt to extend ψ to X_{j+1}. For each $f \in F$ and each $g_1, \ldots, g_k \in X_j$ (with $k = \rho(f)$), we proceed as follows. Look up $\psi(g_1), \ldots, \psi(g_k)$ in the table and compute $b = f^{\mathbf{B}}(\psi(g_1), \ldots, \psi(g_k))$. Also, compute the operation $f^{\mathbf{A}}[g_1, \ldots, g_k]$. If the entry in the table corresponding to $f^{\mathbf{A}}[g_1, \ldots, g_k]$ is blank, then insert b and continue. If the entry is already equal to b, continue. But if the table contains some value $b' \neq b$, then we terminate the algorithm and reject. See the pseudocode in Algorithm 6.2.

If the algorithm runs to completion without a rejection, then we have successfully

found the extension of ψ_0. A rejection means that ψ does not exist.

We must analyze the time requirements of Algorithm 6.2. As we noted earlier, the algebra $\mathbf{A}$ will require at least $n^r \log n$ bits to represent. Let S denote the size of the input $(\mathbf{A}, \mathbf{B})$. Then $S \geq n^r + m^r > r$. Notice also that $S \geq |F|$ since each operation requires at least one bit.

To prove the theorem, we must show that the time required to run Algorithm 6.2 on the input $(\mathbf{A}, \mathbf{B})$ is bounded above by a function of the form $2^{2^{p(S)}}$ for some polynomial p. Since $O\big(2^{2^{\text{poly}}}\big)$ is closed under sums and products, it suffices to check that we can bound the time required by each step of the algorithm by a member of $O\big(2^{2^{\text{poly}}}\big)$. Observe first that

$$\log(n^{m+1}) = (m+1)\log n \leq (m+1)n \leq S,$$

and hence $n^{m+1} \leq 2^S$. Similarly,

$$\log n^{(n^m)} = n^m \log n \leq n^{m+1} \leq 2^S,$$

so

$$n^{(n^m)} \leq 2^{2^S}. \tag{6.3}$$

Let us go step-by-step through Algorithm 6.2. The initial setup (step 1) requires time on the order of n^m to fill in each entry. Since there are $n^{(n^m)}$ entries, the total time required for this step lies in $O\big(2^{2^{\text{poly}}}\big)$ by inequality (6.3). Steps 2–7 constitute a triply-nested loop. The total number of iterations is at most the product of the upper bounds on the counters in steps 2, 3, and 4. Step 2 requires $n^{(n^m)} \in O\big(2^{2^{\text{poly}}}\big)$ iterations. Step 3 runs from 1 to $|F|$, and we have already observed that $|F| \leq S$. For each value of j (in step 2), step 4 will loop $|X_j|^k$ times. We have $k = \rho(f) \leq r$ and $|X_j| \leq |\mathrm{Clo}_m(\mathbf{A})| \leq n^{(n^m)}$, so an upper bound on the counter is $(n^{(n^m)})^r \leq 2^{2^{rS}}$. Finally, the time required for each trip through the body of the triple-loop is the sum of the times for steps 5–7. Step 7 is negligible. Step 5 requires r lookups in the table for ψ and one lookup in the table for $f^{\mathbf{B}}$. The former takes time $r \cdot n^{(n^m)} \leq S \cdot 2^{2^S}$ which is clearly in $O\big(2^{2^{\text{poly}}}\big)$. The latter requires $m^r \leq S$ program steps. Step 6 is the reverse of step 5: one lookup in ψ (time $\leq n^{(n^m)}$) and $(r+1)n^m$ lookups in operation tables. Thus the running time for the entire algorithm lies in $O\big(2^{2^{\text{poly}}}\big)$. □

Theorem 6.7 provides a rather disappointing bound for VAR-EQUIV. It is also somewhat surprising that there seems to be such a dramatic (i.e., exponential) difference in the complexities of QVAR-EQUIV and VAR-EQUIV (see Table 4.1). Perhaps one can do better.

PROBLEM 6.8. *Is* VAR-EQUIV *complete for* **2-EXPTIME**? *Is* VAR-EQUIV *in* **EXPSPACE**?

As we mentioned earlier, Székely proved in [28] that VAR-EQUIV is **NP**-hard. This result can also be obtained using the construction in Theorem 5.5; see especially the equivalences in (5.2).

7. Term-equivalence. Recall that the algebras $\mathbf{A}$ and $\mathbf{B}$ are term-equivalent if $A = B$ and $\mathrm{Clo}(\mathbf{A}) = \mathrm{Clo}(\mathbf{B})$. From a universal algebraic standpoint, term-equivalent algebras are generally interchangeable. When considering the complexity of the problem TERM-EQUIV, it is convenient, once again, to consider a slightly different problem. Thus we define the problem CLO-MEM to consist of all pairs (F, g) in which $F \cup \{g\}$

is a set of operations on some finite set A and $g \in \mathrm{Clo}^A(F)$. The problem CLO-MEM^1 is similar, but we require all of the operations in $F \cup \{g\}$ to be unary. For the problem CLO-MEM$_2$, the set A has cardinality two.

Historically, CLO-MEM was the first problem, of those discussed in this paper, to be considered in the literature. Kozen proved in 1977 [18] that CLO-MEM^1 is complete for **PSPACE**. In 1982, Friedman proved that CLO-MEM is complete for **EXPTIME** [8]. However, that manuscript was never published. A different proof of this result, as well as a proof that TERM-EQUIV is complete for **EXPTIME**, appears in [1].

Let $\mathbf{A} = \langle A, F\rangle$ and $\mathbf{B} = \langle B, G\rangle$. Then

$$\begin{array}{c} (\mathbf{A}, \mathbf{B}) \in \text{TERM-EQUIV} \\ \Updownarrow \\ A = B \;\&\; (\forall g \in G)(\forall f \in F)\ \big((F, g), (G, f) \in \text{CLO-MEM}\big). \end{array} \tag{7.1}$$

Conversely, if $F \cup \{g\}$ is a set of operations on A, then

$$(F, g) \in \text{CLO-MEM} \iff \big(\langle A, F\rangle, \langle A, F \cup \{g\}\rangle\big) \in \text{TERM-EQUIV}. \tag{7.2}$$

Of course, similar relationships hold for the unary and two-element variants of these problems.

Now it follows easily from (7.2) that CLO-MEM is log-space reducible to TERM-EQUIV. This is true for the general, unary, and two-element variants of the problems. However, a reduction in the other direction is a bit problematic. Let us first consider the general case. Given a pair $(\mathbf{A}, \mathbf{B})$ of size S, equivalence (7.1) tells us that we can test $(\mathbf{A}, \mathbf{B}) \in$ TERM-EQUIV by making several calls to an algorithm for CLO-MEM. The input to each such call will certainly have size at most S hence will run in time at most $2^{p(S)}$ for some polynomial p. Furthermore, there will clearly be at most S such calls. Hence a bound on the running time for TERM-EQUIV will be $S \cdot 2^{p(S)}$ which is still exponential in S. Combining our observations, we conclude that the (general) problem TERM-EQUIV is complete for **EXPTIME** (see Table 4.1).

For CLO-MEM^1 and CLO-MEM$_2$, we need to argue a bit differently, since we will be interested in a space-bound. Let C denote one of these two problems, and let T denote the corresponding term-equivalence problem. Suppose we have an algorithm for C that runs in space $f(x)$ on an input of size x. As is commonplace, we assume that f is a monotonically increasing function. In applying (7.1) to test $(\mathbf{A}, \mathbf{B}) \in$ T, the first call to C will require space bounded above by $O(f(S))$. But subsequent calls to C can reuse the same space. Hence the total space requirement for T is on the order of $\log S + f(S)$. (The $\log S$ term accounts for some counters.)

For the specific case C = CLO-MEM^1, Kozen's result tells us that the function f is a polynomial, so we conclude that TERM-EQUIV^1 is complete for **PSPACE**, as we assert in Table 4.1. When $C =$ CLO-MEM$_2$, we can certainly make the following claim.

LEMMA 7.1. *If $f(S) \in O(\log S)$, then both* CLO-MEM$_2$ *and* TERM-EQUIV$_2$ *lie in* **NL**.

So our remaining task is to prove that $f(S)$ is indeed on the order of $\log S$. In other words, we must find a nondeterministic algorithm for CLO-MEM$_2$ that runs in log-space. To do this, we will take advantage of the very detailed description of the lattice of clones on $\{0, 1\}$ that was discovered by Post in 1941 [24]. This will allow us to check the condition $(F, g) \in$ CLO-MEM$_2$ using a finite number of nondeterministic tests, each of which uses very little space. There have been several more recent

treatments of Post's results. The reader might wish to consult the first chapter of Pippenger's book [23]. All we really need here is a description of the completely meet-irreducible members of the lattice of clones. For this we mostly follow the discussion given in Szendrei [30, pp. 36ff].

Let A be any set, and let k be a positive integer. A subset θ of A^k is called a k-ary *relation on* A. If f is an n-ary operation on A, we say that f *preserves* θ, ($f \mid\!: \theta$) if for all arrays $\langle\, a_{ij} : 1 \le i \le n,\ 1 \le j \le k \,\rangle$ we have

$$(\forall i \le n\ \ \mathbf{a}^i \in \theta) \implies \langle f(\mathbf{a}_1), \ldots, f(\mathbf{a}_k)\rangle \in \theta,$$

where $\mathbf{a}_j = \langle a_{1j}, \ldots, a_{nj}\rangle$ and $\mathbf{a}^i = \langle a_{i1}, \ldots, a_{ik}\rangle$. The relationship $f \mid\!: \theta$ is equivalent to asserting that θ is a subalgebra of the algebra $\langle A, f\rangle^k$. One way to visualize this is to think of the $\langle a_{ij}\rangle$ as forming an $n \times k$ matrix. If each row of the matrix constitutes an element of θ, then the row obtained by applying f to each column is again a member of θ. We extend this notation to multiple operations by defining $F \mid\!: \theta$ if and only if for every $f \in F$ we have $f \mid\!: \theta$.

For a fixed relation θ we define

$$\mathcal{F}^A(\theta) = \{\, f : f \text{ is an operation on } A \text{ and } f \mid\!: \theta \,\}.$$

More generally, if Θ is a set of relations on A (of various ranks), then

$$\mathcal{F}^A(\Theta) = \bigcap_{\theta \in \Theta} \mathcal{F}^A(\theta).$$

We usually omit the superscript "A" if no confusion will result. It is easy to check that for any set A and family Θ, $\mathcal{F}(\Theta)$ is always a clone on A. However, more to the point for us, for every *finite* set A, every clone on A is of the form $\mathcal{F}(\Theta)$ for some (not necessarily finite) family Θ. See [30, Corollary 1.4].

We now restrict our attention to $A = \{0, 1\}$. We define the following relations on A.

$$\begin{aligned}
\nu &= \{\, \langle 0,1\rangle, \langle 1,0\rangle \,\}, & \lambda &= \{\, \langle 0,0\rangle, \langle 0,1\rangle, \langle 1,1\rangle \,\},\\
\mu &= \{\, \langle x,y,z\rangle : z = x \wedge y \,\}, & \chi &= \{\, \langle x,y,z\rangle : z = x \vee y \,\},\\
\varepsilon &= \{\, \langle x,y,z\rangle : x = y \text{ or } y = z \,\}, & \sigma &= \{\, \langle x,y,z,w\rangle : x \oplus y = z \oplus w \,\},\\
\kappa_m &= \{0,1\}^m - \{\langle 1,1,\ldots,1\rangle\} \quad \text{for } m \ge 1,\\
\tilde{\kappa}_m &= \{0,1\}^m - \{\langle 0,0,\ldots,0\rangle\} \quad \text{for } m \ge 1.
\end{aligned}$$

Let $\Sigma_0 = \{\nu, \mu, \chi, \lambda, \varepsilon, \sigma\}$ and, for every $m > 0$, $\Sigma_m = \Sigma_0 \cup \{\, \kappa_j, \tilde{\kappa}_j : j \le m \,\}$. Set $\Sigma = \bigcup_{m \ge 1} \Sigma_m$. From Post's analysis, we get the following theorem.

THEOREM 7.2 (Post). *Let C be a clone on $\{0,1\}$. Then for some family $\Theta \subseteq \Sigma$, $C = \mathcal{F}(\Theta)$.*

Let θ be a fixed k-ary relation on $\{0,1\}$. We first show that there is a simple nondeterministic algorithm for the *complement* of the problem

$$\textsc{Pres}(\theta) = \{\, f : f \text{ an operation on } \{0,1\} \text{ and } f \mid\!: \theta \,\}.$$

Given an n-ary operation f, we guess an $n \times k$ matrix and accept if each row of the matrix lies in θ but the result of applying f to the columns fails to lie in θ. A more formal description is given in Algorithm 7.1.

LEMMA 7.3. *For any fixed relation θ on $\{0,1\}$, $\textsc{Pres}(\theta) \in \mathbf{NL}$.*

1. Let $n = \rho(f)$
2. Guess $a_{ij} \in \{0,1\}$, $1 \le i \le n$, $1 \le j \le k$
3. For $i = 1$ to n do
4. if $\mathbf{a}^i \notin \theta$ then **reject**
5. if $\langle f(\mathbf{a}_1), \ldots, f(\mathbf{a}_k)\rangle \notin \theta$ then **accept**

ALGORITHM 7.1. $f \notin \text{PRES}(\theta)$.

---

1. Let $n = \rho(f)$
2. $\mathbf{x} \leftarrow \langle 1, 1, \ldots, 1\rangle \in \{0,1\}^n$
3. for $i = 1$ to m do
4. guess $\mathbf{a} \in \{0,1\}^n$
5. if $f(\mathbf{a}) = 1$ then $\mathbf{x} \leftarrow \mathbf{x} \wedge \mathbf{a}$ *(coordinatewise conjunction)*
6. else **reject**
7. if $\mathbf{x} = \langle 0, 0, \ldots, 0\rangle$ then **accept**
8. else **reject**

ALGORITHM 7.2. $(f, m) \notin \text{KAPPA}$.

Proof. Algorithm 7.1 provides a test for the complement of PRES(θ). Since **NL** is closed under complements (see [12, 29]), it suffices to show that this algorithm requires only log-space. Since the size of the input (an n-ary operation) is 2^n bits, we must verify that the space requirement of the algorithm lies in $O(n)$. However, the algorithm only requires space for the counters i and j, the Boolean matrix $\langle a_{ij}\rangle$, and k pointers into the table of values for f. Since k is a constant, the total space required is indeed in $O(n)$. □

We will also need a variation of Algorithm 7.1 to handle the κ_m and $\tilde{\kappa}_m$. Algorithm 7.2 gives a procedure that takes as input an operation f and a positive integer m and accepts (nondeterministically) if and only if f does not preserve κ_m. Using the same argument as in Lemma 7.3, we can conclude that

$$\text{KAPPA} = \{\, (f, m) : f \not\colon \kappa_m \,\} \in \mathbf{NL},$$

with an analogous result for $\tilde{\kappa}_m$. Let us remark here that it is not hard to modify Algorithm 7.1 to run in deterministic logarithmic space. However, that modification does not seem to work for KAPPA, so there does not appear to be anything to gain by including the argument here.

Our next task is to put a bound on the size of the family Θ that we need to consider in Theorem 7.2. Notice that, except for the six members of Σ_0, the members of Σ form two infinite sequences, and, furthermore, these two sequences are dual to each other.

LEMMA 7.4. *Let g be an n-ary operation on $\{0,1\}$.*

(i) *For every $m > 1$, if g preserves κ_m, then g preserves κ_{m-1}.*

(ii) *If g preserves κ_n, then g preserves κ_m for all $m > n$.*

The same results hold with $\tilde{\kappa}$ in place of κ.

Proof. Suppose $g \not\colon \kappa_m$. Let $\langle a_{ij}\rangle$ be an $n \times (m-1)$ matrix in which every row is a member of κ_{m-1}. This simply means that no row consists of all 1s. We wish to argue that $\langle g(\mathbf{a}_1), \ldots g(\mathbf{a}_{m-1})\rangle \in \kappa_{m-1}$, i.e., is not all 1s. Create an $n \times m$ matrix by repeating the last column of $\langle a_{ij}\rangle$. Then each row of this new matrix lies in κ_m, so by assumption, the m-tuple $\langle g(\mathbf{a}_1), \ldots, g(\mathbf{a}_{m-1}), g(\mathbf{a}_{m-1})\rangle \in \kappa_m$. Therefore, $\langle g(\mathbf{a}_1), \ldots, g(\mathbf{a}_{m-1})\rangle$ is not equal to $\langle 1, 1, \ldots, 1\rangle$, as desired.

For the second claim, assume that $g \not\colon \kappa_n$ and let $m > n$. Let $\langle a_{ij}\rangle$ be an $n \times m$

```
1. n ← ρ(g)
2. for θ ∈ Σ_n do
3.     if F |: θ then
4.         if not(g |: θ) then reject
5. accept
```

ALGORITHM 7.3. $g \in \mathrm{Clo}(F)$.

matrix in which every row is a member of κ_m. In other words, each row contains a "0." Therefore we can find $1 \le j_1 < j_2 < \cdots < j_n \le m$ such that the $n \times n$ submatrix $\langle a_{ij_k} : 1 \le i \le n,\ 1 \le k \le n\rangle$ retains the property that every row contains a "0." Since $g \mid\!: \kappa_n$, we get $\langle g(\mathbf{a}_{j_1}), \ldots, g(\mathbf{a}_{j_n})\rangle \in \kappa_n$, i.e., for some k, $g(\mathbf{a}_{j_k}) = 0$. Therefore, $\langle g(\mathbf{a}_1), \ldots, g(\mathbf{a}_n)\rangle \in \kappa_m$. □

We can now combine Theorem 7.2 and Lemmas 7.3 and 7.4 to put a finite bound on the work needed in order to test the relationship $g \in \mathrm{Clo}(F)$.

THEOREM 7.5. *Let F be a set of operations on $\{0,1\}$, and let g be an n-ary operation on $\{0,1\}$. Then $g \in \mathrm{Clo}(F)$ if and only if for every $\theta \in \Sigma_n$, $F \mid\!: \theta \implies g \mid\!: \theta$.*

Proof. Suppose first that $g \in \mathrm{Clo}(F)$. Let θ be any relation such that $F \mid\!: \theta$. Since $\mathcal{F}(\theta)$ is a clone, $F \subseteq \mathcal{F}(\theta)$, and $\mathrm{Clo}(F)$ is, by definition, the *smallest* clone containing F, we obtain $\mathrm{Clo}(F) \subseteq \mathcal{F}(\theta)$; hence $g \mid\!: \theta$.

Conversely, suppose the condition holds. By Theorem 7.2, there is some subset Θ of Σ such that $\mathrm{Clo}(F) = \mathcal{F}(\Theta)$. We need to show that for every $\theta \in \Theta$, $g \mid\!: \theta$. If $\theta \in \Sigma_n$, then, since $F \subseteq \mathrm{Clo}(F)$, we have $F \mid\!: \theta$, so $g \mid\!: \theta$ by assumption. So suppose that $\theta \in \Sigma - \Sigma_n$. Then $\theta = \kappa_m$ or $\theta = \tilde{\kappa}_m$ for some $m > n$. Without loss of generality, assume the former. Again, since $F \subseteq \mathrm{Clo}(F) = \mathcal{F}(\Theta)$, we get $F \mid\!: \kappa_m$. By Lemma 7.4(i), $F \mid\!: \kappa_n$; hence $g \mid\!: \kappa_n$ by assumption. Therefore, by Lemma 7.4(ii), $g \mid\!: \kappa_m$. □

Since the family Σ_n is finite, Theorem 7.5 provides an algorithm for testing $g \in \mathrm{Clo}(F)$. Pseudocode is given in Algorithm 7.3. Let us analyze the space requirements for this algorithm. The size of the input is at least 2^n since that is the size of g, and also at least $|F|$ since each operation takes up at least 1 bit. Line 1 can be implemented by setting θ first to each member of Σ_0, followed by $\kappa_1, \tilde{\kappa}_1, \kappa_2, \ldots, \tilde{\kappa}_n$ using a loop. The amount of space needed to manage the loop is in $O(\log n)$.

The notation "$F \mid\!: \theta$" is shorthand for the following code fragment.

```
x ← True
for f ∈ F do
    if not(f |: θ) then x ← False
return x
```

When $\theta \in \Sigma_0$, the test $f \mid\!: \theta$ is implemented using an algorithm for PRES(θ). When $\theta = \kappa_m$ or $\tilde{\kappa}_m$, we use KAPPA or its dual. Clearly, the entire algorithm requires only a couple of counters besides the calls to PRES and KAPPA and hence lies in **NL**. Combining this with Lemma 7.1, we have proved the following theorem.

THEOREM 7.6. *Both* CLO-MEM$_2$ *and* TERM-EQUIV$_2$ *lie in* **NL**.

Once again, it is not clear that these are optimal results, so we pose a problem.

PROBLEM 7.7. *Is* TERM-EQUIV$_2$ *complete for* **NL**? *Does it lie in* **L**?

Appendix. Proof of Theorem 6.1. This appendix provides a proof of Theorem 6.1. In fact, we shall prove a slightly stronger theorem which allows us to conclude that both VAR-EQUIV$_2$ and VAR-MEM$_2$ are members of **L**. The line of argument we

follow was suggested to us by J. Berman. An alternate proof can be obtained from [15, Corollary 2.5], using the fact that every two-element algebra is both term-minimal and strictly simple.

An algebra is called *congruence distributive* if its lattice of congruences is distributive. The algebra is *congruence permutable* if for every pair of congruences α and β we have $\alpha \circ \beta = \beta \circ \alpha$. Here,

$$\alpha \circ \beta = \{\, (x, z) : (\exists y)\ (x, y) \in \alpha \ \&\ (y, z) \in \beta \,\}.$$

A variety is called congruence distributive (respectively, permutable) if every member is congruence distributive (permutable). See [5, Definition 5.8] for a discussion of these two important properties. We also require the following result.

LEMMA A.1 (see Berman [2, Lemma 1]). *Let* $\mathbf{A}$ *be an algebra with universe* $\{0, 1\}$. *Then at least one of the following hold.*

(i) $\mathbf{V}(\mathbf{A})$ *is congruence distributive.*

(ii) $\mathbf{V}(\mathbf{A})$ *is congruence permutable.*

(iii) *Every basic operation of* $\mathbf{A}$ *is one of the following: a conjunction of variables, a disjunction of variables, negation of a variable, a projection operation, or a constant operation.*

An n-ary operation f is "a conjunction of variables" if $f(x_1, \dots, x_n) = x_{i_1} \wedge x_{i_2} \wedge \cdots \wedge x_{i_k}$, where $2 \le k \le n$, $1 \le i_1 < i_2 < \cdots < i_k \le n$ and "$\wedge$" denotes the usual logical "and" operation on $\{0, 1\}$. A disjunction of variables is similar. We write $0' = 1$ and $1' = 0$. The function $f(x_1, \dots, x_n) = x_i'$ is the negation of the variable x_i.

Let Δ denote the equivalence relation on $\{0, 1\}^2$ that identifies the pairs $(0, 0)$ and $(1, 1)$ and the pairs $(0, 1)$ and $(1, 0)$. One way to think of Δ is as the kernel of the exclusive-or function $\{0, 1\}^2 \to \{0, 1\}$. For a fixed algebra $\mathbf{A}$ on $\{0, 1\}$, Δ may or may not be a congruence relation on $\mathbf{A}^2$. By using Lemma A.1, it is not hard to see that Δ is a congruence if and only if $\mathbf{A}$ is Abelian. (See [20, section 4.13], especially Theorem 4.152.) In the case that Δ is indeed a congruence on $\mathbf{A}^2$, we define $\mathbf{A}_\nabla$ to be the algebra $\mathbf{A}^2/\Delta$. Note that it is possible for $\mathbf{A}$ and $\mathbf{A}_\nabla$ to be isomorphic. In fact, $\mathbf{A} \cong \mathbf{A}_\nabla$ if and only if there is an element $e \in \{0, 1\}$ such that $\{e\}$ is a subalgebra of $\mathbf{A}$. (To see this, show that the function $x \mapsto (x, e)/\Delta$ is an isomorphism.) As we shall see, in the case that $\mathbf{A}_\nabla$ exists and is not isomorphic to $\mathbf{A}$, $\mathbf{V}(\mathbf{A}_\nabla)$ is the unique proper, nontrivial subvariety of $\mathbf{V}(\mathbf{A})$.

THEOREM A.2. *Let* $\mathbf{A}$ *and* $\mathbf{B}$ *be algebras on* $\{0, 1\}$ *of the same similarity type, and suppose that* $\mathbf{B} \in \mathbf{V}(\mathbf{A})$. *Then either* $\mathbf{B} \cong \mathbf{A}$ *or* $\mathbf{B} \cong \mathbf{A}_\nabla$.

Proof. Since both $\mathbf{A}$ and $\mathbf{B}$ have cardinality two, they are *strictly simple* algebras, i.e., they are simple and have no proper, nontrivial subalgebras. Suppose first that $\mathcal{V} = \mathbf{V}(\mathbf{A})$ is congruence distributive. Since $\mathbf{B} \in \mathbf{V}(\mathbf{A})$ and $\mathbf{B}$ is simple, we obtain $\mathbf{B} \in \mathbf{HS}(\mathbf{A})$ from Jónsson's lemma [5, Theorem 6.8]. From the strict simplicity of $\mathbf{A}$ we get $\mathbf{B} \cong \mathbf{A}$. Notice that we never obtain the conclusion $\mathbf{B} \cong \mathbf{A}_\nabla$ here. This is not surprising since a congruence distributive variety contains no nontrivial Abelian algebras.

For the remainder of the proof, we assume that $\mathcal{V}$ is not congruence distributive. Suppose that $\mathcal{V}$ is congruence permutable. Then, in particular, $\mathcal{V}$ is congruence modular [5, Theorem 5.10], so by [7, Theorem 12.1] and the strict simplicity of $\mathbf{A}$, $\mathcal{V}$ is an Abelian variety, and hence $\mathbf{A}$ is an Abelian algebra. Therefore, since $\mathbf{B} \in \mathbf{V}(\mathbf{A})$, from [7, Theorem 12.4] we deduce that either $\mathbf{B} \cong \mathbf{A}$ or $\mathbf{B} \cong \mathbf{A}_\nabla$.

So now we are reduced to the case that $\mathcal{V}$ is neither congruence distributive nor congruence permutable. This forces us into case (iii) of Lemma A.1. Each of the

TABLE A.1

$\mathbf{A}$	$\mathbf{A}_\nabla$
$\langle\{0,1\}, '\rangle$	$\langle\{0,1\}, p_1^1\rangle$
$\langle\{0,1\}, ', 0\rangle$	$\langle\{0,1\}, p_1^1, 0\rangle$
$\langle\{0,1\}\rangle$	
$\langle\{0,1\}, 0\rangle$	
$\langle\{0,1\}, 1\rangle$	
$\langle\{0,1\}, 0, 1\rangle$	$\langle\{0,1\}, 0, 0\rangle$

basic operations of $\mathbf{A}$ and of $\mathbf{B}$ must be of one of the types described there. Suppose that $\mathbf{A}$ contains a conjunction of variables among its basic operations. If $\mathbf{A}$ also contains either a disjunction of variables or a negation operation, then $\mathbf{A}$ will have a lattice reduct and consequently $\mathcal{V}$ will be congruence distributive, which contradicts our assumption. Therefore, if $\mathbf{A}$ contains a conjunction of variables, then $\mathbf{A}$ is term-equivalent to a semilattice, possibly with one or two constant operations. However, it is well known that the variety generated by such an algebra has, up to isomorphism, a unique two-element member. Thus we conclude that in this case too, $\mathbf{B} \cong \mathbf{A}$. Obviously, we arrive at the same conclusion if we assume at the outset that $\mathbf{A}$ has a basic operation that is a disjunction of variables.

Now suppose that neither $\mathbf{A}$ nor $\mathbf{B}$ has a conjunction or a disjunction of variables among its basic operations. By looking at the available operations in Lemma A.1 (iii), we conclude that $\mathbf{A}$ is term-equivalent to one of the algebras listed in Table A.1. It is easy to check that for each algebra $\mathbf{A}$ in the table, $\mathbf{A}_\nabla$ exists. Furthermore, in each case, it is obvious that $\mathbf{A}$ and $\mathbf{A}_\nabla$ are the only two-element algebras in $\mathbf{V}(\mathbf{A})$. Using these observations, we obtain the conclusion in the remaining cases. □

Theorem 6.1 follows immediately from Theorem A.2. For if $\mathbf{B}$ and $\mathbf{A}$ generate the same variety, then we certainly have $\mathbf{B} \in \mathbf{V}(\mathbf{A})$, so by Theorem A.2, either $\mathbf{B} \cong \mathbf{A}$ or $\mathbf{B} \cong \mathbf{A}_\nabla$. However, we claim that if $\mathbf{A} \ncong \mathbf{A}_\nabla$, then $\mathbf{A}_\nabla$ always generates a proper subvariety of $\mathbf{V}(\mathbf{A})$, contrary to the assumption that $\mathbf{V}(\mathbf{B}) = \mathbf{V}(\mathbf{A})$. The easiest way to see this is probably just to treat the various cases that arose in Theorem A.2 individually. The case that $\mathbf{V}(\mathbf{A})$ is congruence permutable is discussed in [7]. For the algebras listed in Table A.1, it is a simple matter to find an identity satisfied by $\mathbf{A}_\nabla$ that fails in $\mathbf{A}$. For example, consider the first line of the table. The similarity type consists of a single unary operation symbol, f. Then the identity $f(x) \approx x$ separates $\mathbf{A}$ from $\mathbf{A}_\nabla$.

COROLLARY A.3. VAR-MEM$_2 \in \mathbf{L}$.

Proof. From Theorem A.2, $(\mathbf{A}, \mathbf{B}) \in$ VAR-MEM$_2$ if and only if either $\mathbf{B} \cong \mathbf{A}$ or $\mathbf{B} \cong \mathbf{A}_\nabla$. We have already observed that the former condition can be checked in log-space. To check the latter, it is enough to check the following two maps to see if either is a homomorphism.

$$\mathbf{A}^2 \to \mathbf{B} \qquad (x, y) \mapsto x \oplus y,$$
$$\mathbf{A}^2 \to \mathbf{B} \qquad (x, y) \mapsto x \oplus y \oplus 1.$$

Here $x \oplus y$ is the exclusive-or of x and y. □

Acknowledgments. Finally, we would like to thank Joel Berman, Gary Leavens, and Ross Willard for many helpful discussions on this and related topics.

AN ALGORITHM FOR HEILBRONN'S PROBLEM*

CLAUDIA BERTRAM–KRETZBERG†, THOMAS HOFMEISTER†, AND HANNO LEFMANN†

Abstract. Heilbronn conjectured that given arbitrary n points from the 2-dimensional unit square, there must be three points which form a triangle of area at most $O(1/n^2)$. This conjecture was disproved by a nonconstructive argument of Komlós, Pintz, and Szemerédi [*J. London Math. Soc.*, 25 (1982), pp. 13–24] who showed that for every n there is a configuration of n points in the unit square where all triangles have area at least $\Omega(\log n/n^2)$. Considering a discretization of Heilbronn's problem, we give an alternative proof of the result from [*J. London Math. Soc.*, 25 (1982), pp. 13–24]. Our approach has two advantages: First, it yields a polynomial-time algorithm which for every n computes a configuration of n points where all triangles have area $\Omega(\log n/n^2)$. Second, it allows us to consider a generalization of Heilbronn's problem to convex hulls of k points where we can show that an algorithmic solution is also available.

1. Introduction.

Given a configuration of n points in the 2-dimensional unit square, we can consider the minimum triangle area formed by any three of the n points. Heilbronn's problem consists in finding a configuration of n points which maximizes this minimum area. Denote the maximal possible area by $\Delta^{(3)}(n)$. Heilbronn conjectured that $\Delta^{(3)}(n) = O(1/n^2)$, and the earliest reference mentioning the conjecture is a paper by Roth [12] from 1951; see also the 1976 survey paper [16].

In 1982, Komlós, Pintz, and Szemerédi [9] showed nonconstructively that Heilbronn's conjecture is false. They proved the lower bound $\Delta^{(3)}(n) = \Omega(\log n/n^2)$. The exact order of $\Delta^{(3)}(n)$ is still unknown, but some upper bounds are known. The best one is by Komlós, Pintz, and Szemerédi [8] who showed that $\Delta^{(3)}(n) = O(e^{c\sqrt{\log n}}/n^{8/7})$ for some constant $c > 0$, i.e., $\Delta^{(3)}(n) = O(n^{-8/7+\epsilon})$ for any fixed $\varepsilon > 0$. This result improved upon earlier upper bounds due to Roth [12], [13], [14], [15], [16] and Schmidt [17].

In this paper, we provide a constructive proof of the result by Komlós, Pintz, and Szemerédi. We provide a polynomial-time algorithm which for every n computes a configuration of n points in the unit square where the minimum triangle area is at least $\Omega(\log n/n^2)$. This is done by first discretizing the problem and then transforming it into an independent set problem on hypergraphs.

Designing an algorithm for Heilbronn's problem is interesting because the existence proof of [9] applies a probabilistic argument which uses a continuous distribution for choosing the points in the unit disc (or square) and it involves the evaluation of

integrals. This makes a direct derandomization of the probabilistic argument difficult. To overcome this difficulty, we first discretize the problem. More precisely, we will consider a $T\times T$ grid, where T is of the order of n^α for some $\alpha > 1$. One of the problems introduced by this discretization is that now many triples of grid points lie on a line and form a degenerated triangle (i.e., one of area zero), whereas in the continuous case, the probability of this happening for randomly chosen points is zero.

For every n, our algorithm will find n points in the $T\times T$ grid where every triangle has area at least $\Omega(T^2 \log n/n^2)$. This yields a solution for the problem in the unit square by scaling with a factor of $\Theta(1/T^2)$.

Furthermore, we demonstrate that our approach can be used for a more general problem, first investigated for the special case $k = 4$ by Schmidt [17]. Given a configuration of n points in the unit square, what is the minimum area of the convex hull of k points? Choose n points to maximize this minimum area which we denote by $\Delta^{(k)}(n)$.

It seems that the general case of fixed $k \geq 4$ has not been investigated in the existing literature. We remark that in [5, p. 861] (without proof) the lower bound $\Delta^{(k)}(n) = \Omega(n^{-1-1/k})$ is attributed to Schmidt. However, Schmidt considered in [17] only the case $k = 4$ and proved by analytic arguments that $\Delta^{(4)}(n) = \Omega(1/n^{3/2})$. Here we give a simpler proof of this lower bound. Moreover, our arguments yield a polynomial-time algorithm which for arbitrary fixed $k \geq 4$ computes n points in the unit square where the minimum area of the convex hull of any k points is $\Omega(1/n^{(k-1)/(k-2)})$, i.e., $\Delta^{(k)}(n) = \Omega(1/n^{(k-1)/(k-2)})$. It should be noted (see [17]) that for $k \geq 4$ it is not known whether $\Delta^{(k)}(n) = o(1/n)$.

A generalization of Heilbronn's problem to d dimensions which considers the volumes of $(d + 1)$-simplices has recently been investigated in [2] and [10].

2. Hypergraphs. Heilbronn's problem can be transformed into a problem on hypergraphs. We first recall some basic definitions.

DEFINITION 1. *A hypergraph $\mathcal{G} = (V, \mathcal{E})$ is given by a finite nonempty set V of vertices and a set $\mathcal{E} = \{E_1, \ldots, E_r\}$ of hyperedges $E_i \subseteq V$ with $|E_i| \geq 2$ for $i = 1, \ldots, r$. A hypergraph is called k-uniform if every hyperedge has cardinality k. A subset $V' \subseteq V$ is called independent if no hyperedge E_i is a subset of V'. The average degree of a k-uniform hypergraph is defined by $d_{avg} = |\mathcal{E}| \cdot k/|V|$.*

2-uniform hypergraphs capture the usual concept of undirected simple graphs. For certain types of graphs, e.g., graphs without cycles of small length, very often better estimations on parameters and better algorithms are available than for arbitrary graphs. For hypergraphs, the same is sometimes true. We use the following cycle definition in hypergraphs.

DEFINITION 2. *A 2-cycle in a hypergraph is a pair of hyperedges $E_1 \neq E_2$ such that $|E_1 \cap E_2| \geq 2$.*

Such a pair E_1, E_2 can be seen as a cycle since if $\{v, w\} \subseteq E_1 \cap E_2$, then one can reach w from v via E_1 and return to v via E_2.

We consider the points from the $T\times T$ grid as the vertices of a 3-uniform hypergraph $\mathcal{H}^{(3)}_{T,L}$ whose hyperedges are determined by the parameters T and L as follows. A triple $\{p, q, r\}$ is a hyperedge of $\mathcal{H}^{(3)}_{T,L}$ if the (possibly degenerated) triangle on p, q, r in the $T\times T$ grid has area at most L. We will later choose some $L = \Theta(T^2 \log n/n^2)$.

If V' is an independent set in the hypergraph $\mathcal{H}^{(3)}_{T,L}$, then the corresponding points in the $T\times T$ grid have the property that every triangle has an area bigger than L. It remains to find an independent set V' in $\mathcal{H}^{(3)}_{T,L}$ of size at least $\Omega(n)$.

Computing maximum independent sets in graphs is $\mathcal{NP}$-hard, and it is also hard to find an approximate solution in polynomial time, unless $\mathcal{P}$=$\mathcal{NP}$; see Håstad [6]. The same holds for hypergraphs; see, e.g., [7]. Nevertheless, polynomial-time algorithms for computing independent sets of a guaranteed size are available. We apply such an algorithm, which is based on derandomization through potential functions. For this approach to work, it is crucial to determine the number of hyperedges, i.e., the number of triangles of area at most L in the $T\times T$ grid. Using nothing more but such an upper bound on the number of hyperedges, this approach could be used for a choice of $L = O(T^2/n^2)$. In order to make the approach work for $L = O(T^2 \log n/n^2)$, we have to work harder by counting the number of 2-cycles in the hypergraph. The reason is that for hypergraphs with not too many 2-cycles, the existence of larger independent sets can be shown, and algorithms for finding them are also known.

3. Counting polygons of bounded area. Let $\gcd(h, s)$ denote the greatest common divisor of h and s. The following is a simple fact.

LEMMA 3. *For integers $s \geq 1$, let $F(s) := \sum_{h=1}^{s} \gcd(h, s)$. Then for every $\varepsilon > 0$ there is a constant $c_\varepsilon > 0$ such that $F(s) \leq c_\varepsilon \cdot s^{1+\varepsilon}$.*

Proof. For a given divisor d of s, there are at most s/d numbers $h \in \{1, \ldots, s\}$ such that $\gcd(h, s) = d$. Hence,

$$F(s) \leq \sum_{d \text{ divisor of } s} (s/d) \cdot d = s \cdot \#\text{divisors of s.}$$

The number of divisors of each $s \geq 4$ is at most $s^{c'/(\log\log s)}$ for some positive constant c' (see, for example, [11]). Thus, $F(s) \leq c_\varepsilon \cdot s^{1+\varepsilon}$ for some positive constant c_ε and all $s \geq 1$. □

Given a point p from the $T\times T$ grid, we denote by p_x and p_y its x- and y- coordinate. Define a lexicographic order on the points of the $T\times T$ grid by

$$p <_{lex} q \quad \Leftrightarrow \quad (p_x < q_x) \text{ or } (p_x = q_x \text{ and } p_y < q_y).$$

LEMMA 4. *Let $\varepsilon > 0$ be fixed. The number of degenerated triangles in the $T\times T$ grid is at most $O(T^{4+\varepsilon})$.*

Proof. Let $p_1 <_{lex} p_2 <_{lex} p_3$ be the points of a degenerated triangle. Let $s = (p_3)_x - (p_1)_x$ and $h = (p_3)_y - (p_1)_y$. The number of degenerated triangles with $s = 0$ or $h = 0$ is at most $O(T^4)$, since we can choose one of $O(T)$ lines and one of $O(T^3)$ point triples from that line.

By symmetry, neglecting constant factors, it is now enough to count degenerated triangles with $s \geq h > 0$. If we fix p_1, s, and h (and therefore also p_3), there are exactly $\gcd(h, s) - 1$ many grid points on the line segment between p_1 and p_3. Thus, the number of degenerated triangles is bounded from above by

$$c \cdot T^2 \cdot \sum_{s=1}^{T} \sum_{h=1}^{s} \gcd(h, s) = c \cdot T^2 \cdot \sum_{s=1}^{T} F(s),$$

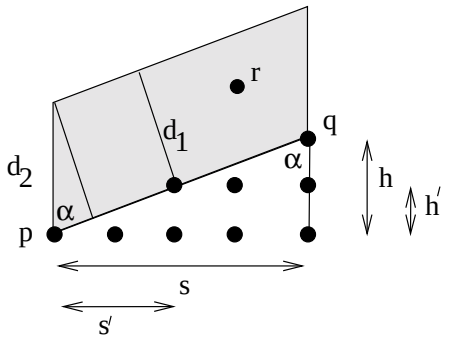
which, by Lemma 3, is at most $c'_\varepsilon \cdot T^2 \cdot \sum_{s=1}^{T} s^{1+\varepsilon} = O(T^{4+\varepsilon})$. □

LEMMA 5. *Let $p <_{lex} q$ be two points from the $T\times T$ grid. Define $s := q_x - p_x$. For every $L > 0$, the following hold.*

(a) *There are at most $4L$ grid points r such that the following three conditions hold simultaneously:*
   (1) $p <_{lex} r <_{lex} q$.
   (2) *The triangle (p, q, r) is nondegenerated.*
   (3) *The area of the triangle (p, q, r) is at most L.*

(b) *The number of grid points r which fulfill conditions* (2) *and* (3) *from* (a) *is at most $12LT/s$ if $s > 0$ and at most $4LT$ if $s = 0$.*

Proof. We first prove (a). By (1) and (2), we have $s > 0$. Assume without loss of generality (w.l.o.g.) that $h := q_y - p_y \geq 0$, since the other case can be dealt with analogously. The situation can be depicted as follows:



Since the area of the triangle (p, q, r) is at most L, and since $p <_{lex} r <_{lex} q$, we know that the point r must lie in some bounded strip above or below the straight line segment between p and q. (The strip is shaded in the above figure.)

Let the side lengths of the strip be d_2 and $\sqrt{s^2 + h^2}$. The width of the strip is given by $d_1 = 2L/\sqrt{s^2 + h^2}$. By a simple geometric argument, we have $d_1/d_2 = s/\sqrt{s^2 + h^2}$, hence $d_2 = 2L/s$.

If $h = 0$, then the number of points r is trivially bounded by $2 \cdot d_2 \cdot s = 4L$. Otherwise, we carefully count the number of grid points in the shaded strip. Assume w.l.o.g. that $p = (0, 0)$. Let $s' = s/\gcd(s, h)$ and $h' = h/\gcd(s, h)$. We count the number of grid points in the shaded strip above the line segment for the x-coordinates $0, \ldots, s'-1$.

For $x = 0$, the integer points from the y-interval $[0, d_2]$ are in the shaded strip. In general, for $x = i$, the integer points from the y-interval

$$\left[\frac{ih'}{s'}, \frac{ih'}{s'} + d_2\right] = \left[\frac{ih'}{s'}, \frac{ih'}{s'} + \frac{2L/\gcd(s, h)}{s'}\right]$$

are in the shaded strip. For every i, this interval contains exactly $D + 1$ numbers of the form m/s', where $D := \lfloor 2L/\gcd(s, h)\rfloor$.

Since h' and s' are relatively prime, the values ih', $i = 0, \ldots, s'-1$, run through all elements modulo s' exactly once. Hence, for every $t \in \{0, \ldots, s'-1\}$, the numbers of points of the form t^*/s' in the shaded strip such that $t^* \equiv t \bmod s'$ are equal.

In general, we have counted $(D+1)s'$ many points; hence there are $(D+1)s'/s' = (D + 1)$ many points of the form t/s' with $t \equiv 0 \bmod s'$ in the shaded strip. This is equal to the number of grid points in that strip. We are allowed to subtract one since the point p would lead to a degenerated triangle.

Since we are interested in the number of grid points in the shaded strip for $x = 0$ to $x = s - 1$, we thus count $D \cdot s/s'$ points. Finally, we have to multiply by two since the strip below the line segment between p and q also needs to be considered. There are some points at the x-coordinate of p which we have unnecessarily taken into account, but this is compensated for by the same number of points which we have not yet counted at the x-coordinate of q. Altogether, we have at most $2D \cdot s/s' = 2 \cdot \gcd(s,h) \cdot \lfloor 2L/\gcd(s,h) \rfloor \leq 4L$ possibilities for the choice of r.

For statement (b) and $s > 0$, we extend the shaded strip over all x-coordinates. Thus, we get a total number which is at most $4L \cdot (T/s + 2) \leq 12LT/s$. For $s = 0$, the bound $4LT$ is trivially obtained. □

LEMMA 6. *Let $\varepsilon > 0$ and $k \geq 3$ be fixed. For $L \geq T^{\frac{k-3}{k-2}+\varepsilon}$, there are at most $O(L^{k-2} \cdot T^4)$ configurations of k points $p_1 <_{lex} \cdots <_{lex} p_k$ in the $T \times T$ grid with a convex hull of area at most L.*

Proof. We divide the configurations into two classes. The first class contains the configurations where all triangles (p_1, p_i, p_k), $i = 2, \ldots, k-1$, are nondegenerated. After p_1 and p_k are chosen, we know by Lemma 5 that there are at most $4L$ candidates for each of $p_2, \ldots, p_{k-1}$ to choose from; hence this class contains at most $O(L^{k-2} \cdot T^4)$ configurations.

A configuration which has a degenerated triangle (p_1, p_i, p_k) can be constructed by first choosing some degenerated triangle (p_1, p_i, p_k) and then choosing $k-3$ more points q with $p_1 <_{lex} q <_{lex} p_k$. For each of those points, we have at most $4L+T$ many candidates. We obtain that there are at most $O(T^{4+\varepsilon} \cdot (L+T)^{k-3})$ many configurations in this class.

If $L \geq T$, the bound from the lemma follows easily. Otherwise, we have at most $O(T^{k+1+\varepsilon})$ many such configurations which meets the bound of the lemma since $L \geq T^{\frac{k-3}{k-2}+\varepsilon}$. □

4. An algorithm for $k = 3$. By Lemma 6, we know that for $L \geq T^{\varepsilon}$, the hypergraph $\mathcal{H}^{(3)}_{T,L}$ contains at most $O(L \cdot T^4)$ many hyperedges and thus its average degree satisfies $d_{avg} = O(L \cdot T^2)$. Just knowing this bound, one is able to provide an algorithm which computes an independent set of size at least $\Omega(T/\sqrt{L})$. We will use such an approach for the case $k \geq 4$ in section 5. For $k = 3$, we can exploit that the number of 2-cycles in $\mathcal{H}^{(3)}_{T,L}$ is not too large. For such hypergraphs, an algorithm which computes larger independent sets is known (see Theorem 8).

LEMMA 7. *Let $\varepsilon > 0$. The number of 2-cycles in the hypergraph $\mathcal{H}^{(3)}_{T,L}$ is at most*

$$O(L^2 \cdot T^4 \cdot \log T + T^{5+\varepsilon} + L \cdot T^5).$$

Proof. Consider a 2-cycle E_1, E_2 and let $\{v, w\} = E_1 \cap E_2$. This corresponds to two triangles which share two points v and w and which both have an area bounded by L. Let $s = w_x - v_x$ and $h = w_y - v_y$. By rotation symmetry (which we account for by an extra constant factor), we can assume that $s > 0$ and $0 \leq h \leq s$.

Let us first assume that the triangles corresponding to E_1 and E_2 both are non-degenerated. Using Lemma 5(b), the number of such pairs of triangles with area at most L can now be bounded from above by

$$C \cdot T^2 \cdot \sum_{s=1}^{T} \sum_{h=0}^{s} \left(\frac{LT}{s}\right)^2 \leq C' \cdot L^2 \cdot T^4 \cdot \sum_{s=1}^{T} \frac{1}{s} = O(L^2 \cdot T^4 \cdot \log T).$$

If both triangles are degenerated, we have four points on a line. By Lemma 4 there are at most $O(T^{5+\varepsilon})$ such configurations. If one of the triangles is nondegenerated and one is degenerated, then we can construct this situation by choosing one of the $O(L \cdot T^4)$ many nondegenerated triangles and choosing one out of at most $O(T)$ possible positions for the fourth point. This yields the bound of the lemma. ∎

The next result is taken from [3] and describes an algorithm for and an extension of a powerful result by Ajtai et al. [1]; compare also Fundia [4].

THEOREM 8 (see [3]). *Let $\mathcal{G} = (V, \mathcal{E})$ be a 3-uniform hypergraph on N vertices with average degree $d_{avg} = 3 \cdot |\mathcal{E}|/N$, where $d_{avg} \to \infty$. Let $t := \sqrt{d_{avg}}$. If the number $s_2(\mathcal{G})$ of 2-cycles in $\mathcal{G}$ satisfies $s_2(\mathcal{G}) \le N \cdot t^{3-\gamma}$ for some constant $\gamma > 0$, then one can find in polynomial time an independent set of size at least $\Omega((N/t) \cdot (\log t)^{1/2})$.*

We are now ready to prove our main theorem for the case $k = 3$.

THEOREM 9. *One can find in polynomial time n points in the unit square such that all triangles have area at least $\Omega(\log n/n^2)$.*

Proof. First, fix some $0 < \gamma < 1/4$ and let $\alpha := 1/(1-2\gamma)$; thus $1 < \alpha < 2$. Let

$$T := \lceil n^\alpha \rceil \quad \text{and} \quad L := \frac{\log n}{n^2} \cdot T^2.$$

From this choice, it follows that $L \ge T^\varepsilon$ for some fixed $\varepsilon > 0$.

Our earlier considerations have shown that the hypergraph $\mathcal{H}^{(3)}_{T,L}$ on $N{=}T^2$ vertices has average degree $d_{avg}{=}O(L \cdot T^2)$, i.e., $t := \sqrt{d_{avg}} = O(L^{1/2} \cdot T)$. However, this is only an upper bound for t. It is useful to distinguish two cases.

Case 1. $t \ge L^{1/2} \cdot T/\log n$.

We show that the conditions of Theorem 8 are fulfilled for the chosen γ. Since $\alpha < 2$, we have $L \cdot \log T/T = \log n \cdot \log T \cdot T/n^2 = o(1)$, and thus the dominating term in Lemma 7 for the number of 2-cycles in $\mathcal{H}^{(3)}_{T,L}$ is $O(L \cdot T^5)$. For the application of Theorem 8, it is enough to show now that $L \cdot T^5/B = o(1)$, where $B := T^2 \cdot (L^{1/2} \cdot T/\log n)^{3-\gamma}$:

$$\begin{aligned} \frac{L \cdot T^5}{T^2 \cdot (L^{1/2} \cdot T/\log n)^{3-\gamma}} &= \frac{T^\gamma}{L^{1/2-\gamma/2}} \cdot (\log n)^{3-\gamma} \\ &= \frac{1}{(\log n)^{1/2-\gamma/2}} \cdot \frac{n^{1-\gamma}}{T^{1-2\gamma}} \cdot (\log n)^{3-\gamma} \\ &= o(1), \end{aligned}$$

since $T^{1-2\gamma} \ge n$. Hence, we can apply Theorem 8. We now use the upper bound $t = O(L^{1/2} \cdot T)$ and obtain in polynomial time an independent set in $\mathcal{H}^{(3)}_{T,L}$ of size at least

$$\Omega\left(\frac{T^2}{t} \cdot \log^{1/2} t\right) = \Omega\left(\frac{T^2}{L^{1/2} \cdot T} \cdot \log^{1/2} n\right) = \Omega\left(\frac{T}{L^{1/2}} \cdot \log^{1/2} n\right) = \Omega(n).$$

Case 2. $t < L^{1/2} \cdot T/\log n$.

We apply the algorithm from Theorem 10 (see section 5) and obtain in polynomial time an independent set in $\mathcal{H}^{(3)}_{T,L}$ of size at least

$$\Omega\left(\frac{T^2}{L^{1/2} \cdot T/\log n}\right) = \Omega\left(\frac{T \cdot \log n}{L^{1/2}}\right) = \Omega\left(n \cdot \log n/(\log n)^{1/2}\right) = \Omega(n).$$

In both cases, the algorithm computes $c \cdot n$ points for some $c > 0$. If $c < 1$, we can adapt the constants and apply the above arguments to some $N = \Theta(n)$ replacing n such that the algorithm indeed finds at least n points where the condition on the triangles also holds. To summarize, we obtain in polynomial time at least n points in the $T \times T$ grid such that every triangle has area at least $c' \cdot T^2 \cdot \log n/n^2$ for some $c' > 0$. By rescaling, i.e., considering the $T \times T$ grid as located in the unit square, we have finished the proof. □

5. An algorithm for $k \geq 4$. For general k, one may consider the following problem: Find n points in the unit square such that the convex hull of every choice of k points among them has an area as large as possible.

Schmidt [17] investigated this problem for the case $k = 4$ and he proved the existence of a configuration on n points which achieves the bound given in Theorem 11 below.

Theorem 10 (Turán's theorem for hypergraphs) gives a lower bound for the independence number $\alpha(\mathcal{G})$ of a hypergraph $\mathcal{G}$ (cf. Spencer [18]), and a linear–time algorithm for achieving this bound is also available. We show that this algorithm can be exploited for Heilbronn's problem if $k \geq 4$.

THEOREM 10 (see [18]). *Let $\mathcal{G} = (V, \mathcal{E})$ be a k-uniform hypergraph, $k \geq 2$, with average degree d_{avg} and $|V| = N$. Let $t := \max\{1, (d_{avg})^{1/(k-1)}\}$. Then one can find in $\mathcal{G}$ in time $O(N + |\mathcal{E}|)$ an independent set of size at least $\Omega(N/t)$.*

We sketch the algorithm behind Theorem 10 for the sake of completeness.

Proof. Let $V = \{v_1, \ldots, v_N\}$. Assign a weight $p_i \in [0, 1]$ to every vertex v_i. Define a potential function F by $F(p_1, \ldots, p_N) = \sum_{i=1}^{N} p_i - \sum_{E \in \mathcal{E}} \prod_{v_i \in E} p_i$.

We have $F(p_1 := 1/t, \ldots, p_N := 1/t) = \frac{N}{t} - \frac{|\mathcal{E}|}{t^k} \geq \frac{k-1}{k} \cdot \frac{N}{t}$. Since F is linear in every p_i, we can set each p_i one after the other to either 0 or 1 without decreasing the potential. Set $V' = \{v_i \in V \mid p_i = 1\}$. If there is still some hyperedge E contained in V', then set $p_j = 0$ for some vertex $v_j \in E$ in this hyperedge. The potential does not decrease. Finally, we obtain an independent set of size at least $\frac{k-1}{k} \cdot \frac{N}{t}$. The running time is $O(N + |\mathcal{E}|)$. □

Theorem 10 and the counting result from Lemma 6 are enough to obtain our result for the generalization of Heilbronn's problem to convex hulls of k points. For the proof of the next theorem, we define a generalization of the hypergraph $\mathcal{H}^{(3)}_{T,L}$: let the vertices of the k-uniform hypergraph $\mathcal{H}^{(k)}_{T,L}$ be the grid points of the $T \times T$ grid and let a hyperedge be in $\mathcal{H}^{(k)}_{T,L}$ iff the area of the convex hull of the corresponding k points is at most L.

THEOREM 11. *For every fixed $k \geq 3$, there is a polynomial-time algorithm which on input n computes a configuration of n points in the unit square such that the convex hull of any k points has area at least $\Omega(1/n^{(k-1)/(k-2)})$.*

Proof. Choose some $0 < \alpha < \alpha' < 2\alpha$. Then for n large enough, there is some integer T with $n^{1+\alpha} \leq T \leq n^{1+\alpha'}$. Let $L := T^2/n^{(k-1)/(k-2)}$. It now holds that

$$L \geq n^{2\alpha + \frac{k-3}{k-2}} \qquad \text{and} \qquad T^{\frac{k-3}{k-2}+\varepsilon} \leq n^{(1+\alpha')(\frac{k-3}{k-2}+\varepsilon)} < n^{\frac{k-3}{k-2}+\alpha'+\varepsilon+\varepsilon\alpha'}.$$

Thus, we can choose some small $\varepsilon > 0$ such that $L \geq T^{\frac{k-3}{k-2}+\varepsilon}$; hence the conditions of Lemma 6 are fulfilled. By choice of L we infer that the average degree of the hypergraph $\mathcal{H}^{(k)}_{T,L}$ satisfies $d_{avg} = O(L^{k-2} \cdot T^2) = O((T^2/n)^{k-1})$.

Applying Theorem 10 with $t = O(T^2/n)$, we obtain in polynomial time an independent set of size at least $\Omega(n)$. For any k of these $\Omega(n)$ points from the $T \times T$ grid,

the area of their convex hull is at least $L = T^2/n^{(k-1)/(k-2)}$. Rescaling yields the desired result. □

6. Open problems. Of course, one would like to know the exact growth rate of $\Delta^{(k)}(n)$ for fixed $k \geq 3$. Hence, it would also be interesting to resolve whether for $k = 4$ or in general for $k \geq 4$ the lower bound on $\Delta^{(k)}(n)$ can also be improved by a logarithmic factor, e.g., by the factor $(\log n)^{1/(k-2)}$. It is also an open problem to determine whether $\Delta^{(k)}(n) = o(1/n)$ holds for fixed $k \geq 4$.

NONMALLEABLE CRYPTOGRAPHY*

DANNY DOLEV†, CYNTHIA DWORK‡, AND MONI NAOR§

Abstract. The notion of *nonmalleable* cryptography, an extension of semantically secure cryptography, is defined. Informally, in the context of encryption the additional requirement is that given the ciphertext it is impossible to generate a *different* ciphertext so that the respective plaintexts are related. The same concept makes sense in the contexts of string commitment and zero-knowledge proofs of possession of knowledge. Nonmalleable schemes for each of these three problems are presented. The schemes do not assume a trusted center; a user need not know anything about the number or identity of other system users.

Our cryptosystem is the first proven to be secure against a strong type of chosen ciphertext attack proposed by Rackoff and Simon, in which the attacker knows the ciphertext she wishes to break and can query the decryption oracle on any ciphertext other than the target.

Key words. cryptography, cryptanalysis, encryption, authentication, randomized algorithms, nonmalleability, chosen ciphertext security, auction protocols, commitment schemes, zero-knowledge

1. Introduction.

The notion of *nonmalleable* cryptography is an extension of semantically secure cryptography. Informally, in the context of encryption the additional requirement is that given the ciphertext it is impossible to generate a *different* ciphertext so that the respective plaintexts are related. For example, consider the problem of *contract bidding*: municipality M has voted to construct a new elementary school, has chosen a design, and advertises in the appropriate trade journals, inviting construction companies to bid for the contract. The advertisement contains a public key E to be used for encrypting bids and a fax number to which encrypted bids should be sent. Company A places its bid of $\$1,500,000$ by faxing $E(15,000,000)$ to the published number over an insecure line. Intuitively, the public-key cryptosystem is *malleable* if, having access to $E(15,000,000)$, company B is more likely to generate a bid $E(\beta)$ such that $\beta \leq 15,000,000$ than company B would be able to do without the ciphertext. Note that company B *need not* be able to decrypt the bid of company A in order to consistently just underbid. In this paper we describe a nonmalleable public-key cryptosystem that prevents such underbidding. Our system does not even require company A to know of the existence of company B. It also does not require the municipality M to know of A or B before the companies bid, nor does it require A or B to have any kind of public key. The system remains nonmalleable even under a very strong type of chosen ciphertext attack, in which the attacker knows the ciphertext she wishes to break (or maul) and can query the decryption oracle on any ciphertext other than the target.

A well-established, albeit implicit, notion of nonmalleability is existential unforgeability of signature schemes [45]. Informally, a signature scheme is existentially unforgeable if, given access to $(m_1, S(m_1)), \ldots, (m_k, S(m_k))$, where $S(m_i)$ denotes a signature on message m_i, the adversary cannot construct a single valid $(m, S(m))$ pair for any *new* message m—even a nonsense message or a function of $m_1, \ldots, m_k$. Thus, existential unforgeability for signature schemes is the "moral equivalent" of nonmalleability for cryptography. We do not construct signature schemes in this paper. However, we introduce the related notion of *public-key authentication* and present a simple method of constructing a provably secure public-key authentication scheme based on any nonmalleable public-key cryptosystem.[1]

Nonmalleability is also important in private-key cryptography. Many common protocols, such as Kerberos or the Andrew Secure Handshake, use private-key encryption as a sort of authentication mechanism: parties A and B share a key K_{AB}. A sends to B the encryption of a nonce N under K_{AB}, and the protocol requires B to respond with the encryption under K_{AB} of $f(N)$, where f is some simple function such as $f(x) = x - 1$. The *unproved and unstated* assumption (see, e.g., [16]) is that seeing $K_{AB}(N)$ doesn't help an imposter falsely claiming to be B to compute $K_{AB}(f(N))$. As we shall see, this is *precisely* the guarantee provided by nonmalleability.

Nonmalleability is a desirable property in many cryptographic primitives other than encryption. For example, suppose researcher A has obtained a proof that $P \neq NP$ and wishes to communicate this fact to professor B. Suppose that, to protect herself, A proves her claim to B in a zero-knowledge fashion. Is zero-knowledge sufficient protection? Professor B may try to steal credit for this result by calling eminent professor E and acting as a *transparent prover*. Any questions posed by professor E to professor B are relayed by the latter to A, and A's answers to professor B are then relayed in turn to professor E. We solve this problem with a *nonmalleable zero-knowledge proof of knowledge.* Researcher A will get proper credit even without knowing of the existence of professor E, and even if professor E is (initially) unaware of researcher A.

Our work on nonmalleability was inspired by early attempts to solve the distributed coin flipping problem. Although $t+1$ rounds are necessary for solving Byzantine agreement in the presence of t faulty processors [33], in the presence of a global source of randomness the problem can be solved in constant expected time [62]. Thus, in the mid 1980s several attempts were made to construct a global coin by combining the individual sources of randomness available to each of the participants in the system. At a very high level, the original attempts involved commitment to coins by all processors, followed by a revelation of the committed values. The idea was that the global coin would be the exclusive-or (or some other function) of the individual committed values. Disregarding the question of how to force faulty processors to reveal their committed values, the original attempts erred because *secrecy was confused with independence*. In other words, the issue was malleability: even though the faulty processors could not know the committed values of the nonfaulty processors, they could potentially force a desired outcome by arranging to commit to a specific function of these (unknown) values.

As the examples show, *secrecy* does not imply *independence*. The goal of nonmalleable cryptography is to *force* this implication.

[1] For more on existentially unforgeable signature schemes, see [27, 45, 60].

1.1. Description of principal results.

Nonmalleable public-key cryptography. Goldwasser and Micali define a cryptosystem to be *semantically secure* if anything computable about the cleartext from the ciphertext is computable without the ciphertext [43]. This powerful type of security may be insufficient in the context of a distributed system, in which the mutual independence of messages sent by distinct parties often plays a critical role. For example, a semantically secure cryptosystem may not solve the contract bidding problem. Informally, a cryptosystem is *nonmalleable* if the ciphertext doesn't help: given the ciphertext it is no easier to generate a *different* ciphertext so that the respective plaintexts are related than it is to do so without access to the ciphertext. In other words, a system is nonmalleable if, for every relation R, given a ciphertext $E(\alpha)$, one cannot generate a different ciphertext $E(\beta)$ such that $R(\alpha, \beta)$ holds any more easily than can be done without access to $E(\alpha)$.[2] We present a public-key cryptosystem that is nonmalleable even against what we call a chosen ciphertext attack in the postprocessing mode (CCA-post) (defined informally in section 2.1 and formally in section 3). Since nonmalleability is an extension of semantic security, this yields the first public-key cryptosystem that is semantically secure against this strong type of chosen ciphertext attack.[3]

Our cryptosystem does not assume a trusted center, nor does it assume that any given collection of users knows the identities of other users in the system. In contrast, all other research touching on this problem of which we are aware requires at least one of these assumptions (e.g., [20, 21, 63]).

Nonmalleable string commitment. A second important scenario for nonmalleability is string commitment. Let A and B run a string commitment protocol. Assume that A is nonfaulty, and that A commits to the string α. Assume that, concurrently, C and D are also running a commitment protocol in which C commits to a string β. If B and C are both faulty, then even though neither of these players knows α, it is conceivable that β may depend on α. The goal of a nonmalleable string commitment scheme is to prevent this.

We present a nonmalleable string commitment scheme with the property that if the players have names (from a possibly unbounded universe), then for all polynomial-time computable relations R our scheme ensures that C is no more likely to be able to arrange that $R(\alpha, \beta)$ holds than it could do without access to the (A, B) interaction. Again, the scheme works even if A is unaware of the existence of C and D. If the players are anonymous, or the names they claim cannot be verified, then again if $\beta \neq \alpha$, then the two strings are no more likely to be related by R.

Intuitively, it is sufficient to require that C know the value to which it is committing in order to guarantee that α and β are unrelated. To see this, suppose C knows β and C also knows that $R(\alpha, \beta)$ holds. Then C knows "something about" α, thus violating the semantic security of the (A, B) string commitment. Proving possession of knowledge requires specifying a *knowledge extractor*, which, given the internal state of C, outputs β. In our case, the extractor has access to the (A, B) interaction, but it cannot rewind A. Otherwise it would only be a proof that *someone* (perhaps A) knows β, but not necessarily that C does.

[2] Clearly, there are certain kinds of relations R that we cannot rule out. For example, if $R(\alpha, \beta)$ holds precisely when $\beta \in E(\alpha)$, then from $E(\alpha)$ it is trivial to compute β, and hence $E(\beta)$, such that $R(\alpha, \beta)$ is satisfied. For formal definitions and specifications see section 2.

[3] For this type of attack it turns out that semantic and nonmalleable security are equivalent, which is not the case for weaker attacks. See section 3.4.2.

Nonmalleable zero-knowledge protocols. Using nonmalleable string commitment as a building block, we can convert any zero-knowledge interaction into a nonmalleable one. In particular we obtain nonmalleable zero-knowledge proofs of possession of knowledge, in the sense of Feige, Fiat, and Shamir [31]. Zero-knowledge protocols [44, 40] may compose in an unexpectedly malleable fashion. A classic example is the so-called "man-in-the-middle" attack (also known as the "intruder-in-the-middle," "Mafia scam," and "chess-masters problem") [24] on an identification scheme, similar in spirit to the transparent intermediary problem described above. Let A and D be nonfaulty parties, and let B and C be cooperating faulty parties (they could even be the same party). Consider two zero-knowledge interactive proof systems, in one A is proving to B knowledge of some string α and in the other C is proving to D knowledge of some string β. The two proof systems may be operating concurrently; since B and C are cooperating, the executions of the (A, B) and (C, D) proof systems may not be independent. Intuitively, nonmalleability says that if C can prove knowledge of β to D while A proves knowledge of α to B, then C could prove knowledge of β without access to the (A, B) interaction. The construction in section 5 yields a nonmalleable scheme for zero-knowledge proof of possession of knowledge.

1.2. Some technical remarks.

Nonmalleability in context. In the scenarios we have been describing, there are (at least) two protocol executions involved: the (A, B) interaction and the (C, D) interaction. Even if both pairs of players are, say, running string commitment protocols, the protocols need not be the same. Similar observations apply to the cases of nonmalleable public-key cryptosystems and nonmalleable zero-knowledge proofs of knowledge. Thus nonmalleability of a protocol really only makes sense with respect to another protocol. All our nonmalleable protocols are nonmalleable with respect to themselves. A more general result is mentioned briefly in section 5.

Identities. One delicate issue is the question of identities. Let α and β be as above. If the players have names, then our commitment and zero-knowledge interaction protocols guarantee that β is independent of α. The names may come from an unbounded universe. Note that there are many possibilities for names: timestamps, locations, message histories, and so on. If the players are anonymous, or the names they claim cannot be verified, then it is impossible to solve the *transparent prover* problem described earlier. However, the faulty prover must be completely transparent: if $\beta \neq \alpha$ then the two strings are unrelated by any relation R. In particular, recall the scenario described above in which (relatively unknown) researcher A seeks credit for the $P \neq NP$ result and at the same time needs protection against the transparent prover attack. Instead of proving knowledge of a witness s that $P \neq NP$, researcher A can prove knowledge of a statement $\alpha = A \circ s$. In this case the only dependent statement provable by professor B is α, which contains the name A. Note that we do not assume any type of authenticated channels.

Computational complexity assumptions. We assume the existence of trapdoor functions in constructing our public-key cryptosystems. The string commitment protocols and the compiler for zero-knowledge interactions require only one-way functions.

2. Definitions and system model. Since nonmalleability is a concept of interest in at least the three contexts of encryption, bit/string commitment, and zero-knowledge proofs, we give a single general definition that applies to all of these. Thus, when we speak of a *primitive* $\mathcal{P}$ we can instantiate any of these three primitives. We

start in section 2.1 by providing definitions for the primitives, as well as for some of the tools we use. Our presentation of the notion of security is nonstandard and we call it *semantic security with respect to relations*. In Theorem 2.4, we show that our version is equivalent to the "traditional" definition. We prefer this version for several reasons:

- It provides a uniform way of treating the security of all the primitives, i.e., the definition of zero-knowledge and semantic security do not *seem* different.
- It generalizes to the nonmalleable case in a natural way, whereas the usual notion of semantic security (provably) does not.

In section 2.2 we provide the definition of nonmalleable security. In section 2.3 we define the system model which is most relevant to those primitives which involve a lot of interaction.

The following definitions and notation are common to all the sections. We use $X \in_R B$ to mean that X is chosen from B at random. If B is a set, then X is simply chosen uniformly at random from the elements of B. If B is a distribution, then $X \in_R B$ means that X is chosen according to B from the support of B.

An *interactive* protocol $(A, B)[c, a, b]$ is an ordered pair of polynomial-time probabilistic algorithms A and B to be run on a pair of interactive Turing machines with common input c and with private inputs a and b, respectively, where any of a, b, c might be null.

We distinguish between the algorithm A and the agent $\psi(A)$ that executes it. We also use $\psi(A)$ to denote a faulty agent that is "supposed" to be running A (that is, that the nonfaulty participants expect to be running A) but has deviated from the protocol. Thus A is the protocol, and $\psi(A)$ is the player.

2.1. Definitions of primitives. In this section, we review the definitions from the literature of probabilistic public-key cryptosystems, string commitment, zero-knowledge interaction, and noninteractive zero-knowledge proof systems, all of which are used as primitives in our constructions. As mentioned above, we provide a unifying treatment of the security of all the primitives.

Probabilistic public-key encryption. A *probabilistic public-key encryption* scheme (see [43]) consists of the following:

- GP, the *key generator*, a probabilistic machine that on unary input 1^n, where n is the security parameter, outputs a pair of strings (e, d) (e is the *public key* and d is the *secret key*);
- E, the encryption function, gets three inputs: the public key e, $b \in \{0, 1\}$, and a random string r of length $p(n)$, for some polynomial p; $E_e(b, r)$ is computable in polynomial time;
- D, the decryption function, gets two inputs: c which is a ciphertext and the private key d which was produced by GP; $D_d(c)$ is computable in expected polynomial time;
- if GP outputs (e, d), then

$$\forall b \in \{0, 1\}\ \forall r \in \{0, 1\}^{p(n)} \quad D_d(E_e(b, r)) = b;$$

- The system has the property of *indistinguishability*: for all polynomial-time machines M, for all $c > 0$ $\exists n_c$ such that (s.t.) for $n > n_c$,

$$|\mathrm{Prob}[M(e, E_e(0, r)) = 1] - \mathrm{Prob}[M(e, E_e(1, r)) = 1]| < \frac{1}{n^c},$$

where the probability is taken over the coin-flips of GP, M and the choice of r.

This definition is for *bit* encryption and the existence of such a method suffices for our constructions. To encrypt longer messages one can concatenate several bit encryptions or use some other method. The definition of indistinguishability in this case becomes that with overwhelming probability over choice of encryption keys e, M cannot find two messages (m_0, m_1) for which it can distinguish with polynomial advantage between encryptions of m_0 and m_1. Formally, we give the following definition.

DEFINITION 2.1. *Let (GP, E, D) be a probabilistic public-key cryptosystem. We say that the system has the property of indistinguishability of encryptions if for all pairs of probabilistic polynomial time machines $(\mathcal{F}, \mathcal{T})$, for all $c > 0$ $\exists n_c$* s.t. *for $n > n_c$,*

$$\Pr\left[|\Pr[\mathcal{T}(e, m_0, m_1, E_e(m_0, r)) = 1] - \Pr[\mathcal{T}(e, m_0, m_1, E_e(m_1, r)) = 1]| \geq \frac{1}{n^c}\right] < \frac{1}{n^c},$$

where the external probability is over the choice of e and the coin-flips of $\mathcal{F}$ (which gets e as input), and each internal probability is taken the coin-flips of $\mathcal{T}$ and the choice of r.

For implementations of probabilistic encryption see [2, 14, 39, 52, 66]. In particular, such schemes can be constructed from *any* trapdoor permutation.

When describing the security of a cryptosystem, one must define what the attack is and what it means to break the system. The traditional notion of breaking (since [43]) has been a violation of semantic security or, equivalently, a violation of indistinguishability. This work introduces the notion of nonmalleable security, and a break will be a violation of nonmalleability. We return to this in section 2.2. We consider three types of attacks against a cryptosystem:

- Chosen plaintext. This is the weakest form of attack that makes any sense against a public-key cryptosystem. The attacker can (trivially) see a ciphertext of any plaintext message (because she can use the public encryption key to encrypt).
- Chosen ciphertext in the sense of [61], sometimes called lunch-break or lunchtime attacks in the literature; we prefer the term chosen ciphertext attack in the *preprocessing* mode, abbreviated CCA-pre. Here, the adversary may access a decryption oracle any polynomial (in the security parameter) number of times. Then the oracle is removed and a "challenge" ciphertext is given to the attacker.
- Chosen ciphertext in the sense of Rackoff and Simon [63]; we prefer the term chosen ciphertext attack in the *postprocessing* mode, abbreviated CCA-post. This is defined formally in section 3. The key point is that the attacker sees the challenge ciphertext *before* the oracle is removed, and can ask the oracle to decrypt any (possibly invalid) ciphertext *except the challenge*.

Our version of semantic security under chosen plaintext attack is the following: Let R be a relation computable in probabilistic polynomial time. We define two probabilities. Let $\mathcal{A}$ be an adversary that gets a key e and produces a distribution $\mathcal{M}$ on messages of length $\ell(n)$ by producing a description (including a specific time bound) of a polynomial-time machine that generates $\mathcal{M}$. $\mathcal{A}$ is then given a *challenge* consisting of a ciphertext $c \in_R E_e(m)$, where $m \in_R \mathcal{M}$ and $E_e(m)$ denotes the set $\{E_e(m, r)$ s.t. $|r| = p(n)\}$. In addition, $\mathcal{A}$ receives a "hint" (or history) about m in the

form of hist(m), where hist is a polynomially computable function. $\mathcal{A}$ then produces a string β. *We assume that the prefix of β is the description of $\mathcal{M}$.*

$\mathcal{A}$ is considered to have succeeded with respect to R if $R(m, \beta)$. Since β contains a description of $\mathcal{M}$, R is *aware* of $\mathcal{M}$ and may decide to accept or reject based on its description. This rules out achieving "success" by choosing a trivial distribution. Let $\pi(\mathcal{A}, R)$ be the probability that $\mathcal{A}$ succeeds with respect to R. The probability is over the choice of e, the coin-flips of $\mathcal{A}$, and the choice of m, so in particular it is also over the choice of $\mathcal{M}$.

For the second probability, we have an adversary simulator $\mathcal{A}'$ who will not have access to the encryption. On input e, $\mathcal{A}'$ chooses a distribution $\mathcal{M}'$. Choose an $m \in_R \mathcal{M}'$ and give hist(m) to $\mathcal{A}'$. $\mathcal{A}'$ produces β. As above, $\mathcal{A}'$ is considered to have succeeded with respect to R if $R(m, \beta)$. Let $\pi'(\mathcal{A}', R)$ be the probability that $\mathcal{A}'$ succeeds.

REMARK 2.2. 1. *In their seminal paper on probabilistic encryption, Goldwasser and Micali separate the power of the adversary into two parts: a message finder that, intuitively, tries to find a pair of messages on which the cryptosystem is weak, and the line tapper, that tries to guess which of the two chosen messages is encrypted by a given ciphertext* [43]. *Accordingly, we have let $\mathcal{A}$ choose the message space $\mathcal{M}$ on which it will be tested. By letting $\mathcal{A}'$ choose $\mathcal{M}'$ (rather than "inheriting" $\mathcal{M}$ from $\mathcal{A}$), we are letting the simulator completely simulate the behavior of the adversary, so in this sense our definition is natural. A second reason for this choice is discussed in section* 3.4.3.

2. *As noted above, the fact that the description of $\mathcal{M}$ or $\mathcal{M}'$ is given explicitly to R prevents $\mathcal{A}'$ from choosing a trivial distribution, e.g., a singleton, since R can "rule out" such $\mathcal{M}$'s.*

DEFINITION 2.3. *A scheme $\mathcal{S}$ for public-key cryptosystems is* semantically secure with respect to relations *under chosen plaintext attack if for every probabilistic polynomial time adversary $\mathcal{A}$ as above there exists a probabilistic polynomial time adversary simulator $\mathcal{A}'$ such that for every relation $R(m, \beta)$ and function hist(m), both computable in probabilistic polynomial time, $|\pi(\mathcal{A}, R) - \pi'(\mathcal{A}', R)|$ is subpolynomial.* In this definition, the chosen plaintext attack is implicit in the definition of $\mathcal{A}$. This is a convention that will be followed throughout the paper.

Note the differences between our definition of semantic security with respect to relations and the original definition of semantic security [43]: in the original definition the challenge was to compute $f(x)$ given $E(x)$, where the function f is not necessarily even recursive. In contrast, here R is a relation and it is probabilistic polynomial time computable. Nevertheless, the two definitions are equivalent, as we prove in Theorem 2.4.[4]

We prove the following theorem for the case of chosen plaintext attacks; the proof carries over to both CCA-preprocessing and CCA-postprocessing.

THEOREM 2.4. *A public-key cryptosystem is semantically secure with respect to relations under chosen plaintext attack if and only if it has the indistinguishability property.*

[4]The literature shows for three versions of semantic security and three corresponding versions of indistinguishability that each version of semantic security is equivalent to the corresponding version of indistinguishability [54, 36]. We are using a fourth version of indistinguishability—a uniform version of the nonuniform one-pass version in [54]. Equivalence of this definition to a corresponding version of semantic security has not been proved in the literature, but we conjecture it holds.

Proof. We first show that if the cryptosystem has the indistinguishability property, then it is semantically secure with respect to relations. Consider the following three experiments. Choose an encryption key e using GP. Given the public key e, $\mathcal{A}$ produces a distribution $\mathcal{M}$. Sample $\alpha_1, \alpha_2 \in_R \mathcal{M}$.

In the first experiment, $\mathcal{A}$ is given hist(α_1) and $E_e(\alpha_1)$ and produces β_1. By definition, for any relation R,

$$\Pr[R(\alpha_1, \beta_1) \text{ holds}] = \pi(\mathcal{A}, R).$$

In the second experiment, $\mathcal{A}$ is given hist(α_1) and $E_e(\alpha_2)$ and produces β_2. Let

$$\chi = \Pr[R(\alpha_1, \beta_2) \text{ holds}].$$

Note that if R is probabilistic polynomial-time computable and $\Pr[R(\alpha_1, \beta_1) \text{ holds}]$ differs polynomially from $\Pr[R(\alpha_1, \beta_2) \text{ holds}]$, where the probabilities are taken over the coin-flips by R, and the random bits used in generating the encryptions (but not over the choice of e, $\mathcal{M}$, and α_1 and α_2), then we can create a distinguisher for encryptions of α_1 and α_2 under encryption key e, so in particular, given e, we have found a pair of messages whose encryptions are easy to distinguish. Thus, with overwhelming probability over choice of e, $\mathcal{M}$, and α_1, α_2, the individual probabilities (with fixed e) are close. It follows that the probabilities $\pi(\mathcal{A}, R)$ and χ (which are aggregated over choice of e) are also close.

For the third experiment, consider an $\mathcal{A}'$ that, on input e, simulates $\mathcal{A}$ on e to get a distribution $\mathcal{M}$. It gives $\mathcal{M}$ as the distribution on which it should be tested. $\mathcal{A}'$ is then given hist(α) for an $\alpha \in_R \mathcal{M}$. $\mathcal{A}'$ generates $\alpha' \in_R \mathcal{M}$ and gives to the simulated $\mathcal{A}$ the hint hist(α) and the encryption $E_e(\alpha')$. The simulated $\mathcal{A}$ responds with some β, which is then output by $\mathcal{A}'$. Note that $\pi'(\mathcal{A}', R) = \chi$. Thus, if the cryptosystem has the indistinguishability property, then $|\pi(\mathcal{A}, R) - \pi'(\mathcal{A}', R)|$ is subpolynomial, so the cryptosystem is semantically secure with respect to relations.

We now argue that if a cryptosystem does not have the indistinguishability property, then it is not semantically secure with respect to relations. If a system does not have the indistinguishability property, then there exists a polynomial time machine M that given the public key can find two messages (m_0, m_1) for which it can distinguish encryptions of m_0 from encryptions of m_1. The specification of $\mathcal{A}$ is as follows: given a key e, $\mathcal{A}$ runs M to obtain (m_0, m_1). Let $\mathcal{M} = \{m_0, m_1\}$, where m_0 and m_1 each has probability $1/2$, be the message distribution on which $\mathcal{A}$ is to be tested. The function hist is the trivial hist$(x) = 1$ for all x. Given an encryption $\gamma \in_R E_e(m)$, where $m \in_R \mathcal{M}$, $\mathcal{A}$ uses M to guess the value of m and outputs β, the resulting guess plus the description of $\mathcal{M}$. The relation R that witnesses the fact that the cryptosystem is not semantically secure with respect to relations is equality plus a test of consistency with $\mathcal{M}$. Recall that the description of $\mathcal{M}$ is provided explicitly, and hence R can also check that $\mathcal{M}$ is of the right form.

Since M is by assumption a distinguisher, having access to the ciphertext γ gives $\mathcal{A}$ a polynomial advantage at succeeding with respect to R over any $\mathcal{A}'$ that does not have access to the ciphertext (which has probability $1/2$). □

Thus, a scheme is semantically secure with respect to relations if and only if it has the indistinguishability property. It follows from the results in [36, 43, 54] that the notions of (traditional) semantic security, indistinguishability, and semantically secure with respect to relations are all equivalent.

String commitment. The literature discusses two types of bit or string commitment: *computational* and *information* theoretic. These terms describe the type of

secrecy of the committed values offered by the scheme. In computational bit commitment, there is only one possible way of opening the commitment. Such a scheme is designed to be secure against a probabilistic polynomial-time receiver and an arbitrarily powerful sender. In information theoretic commitment, it is possible to open the commitment in two ways, but the assumed computational boundedness of the sender prevents him from finding the second way. Such a scheme is designed to be secure against an arbitrarily powerful receiver and a probabilistic polynomial-time prover. We restrict our attention to computational string commitment.

A *string commitment* protocol between sender A and receiver B consists of two stages:

- The *commit* stage. A has a string α to which she wishes to commit to B. She and B exchange messages. At the end of this stage, B has some information that represents α, but B should gain no information on the value of α from the messages exchanged during this stage.
- The *reveal* stage. At the end of this stage, B knows α. There should be only one string that A can reveal.

The two requirements of a string commitment protocol are *binding* and *secrecy*. Binding means that, following the commit stage, A can reveal at most one string. In our scenario we require the binding to be unconditional but probabilistic: with high probability over B's coin-flips, following the commit stage there is at most one string that B accepts (as the value committed) in the reveal stage.

The type of secrecy we require is semantic security. We specify what this means using the notions of security with respect to relations (however, as above, it is equivalent to the "traditional" way of defining semantic security). Let $\mathcal{A}$ be an adversary that produces a distribution $\mathcal{M}$ on strings of length $\ell(n)$ computable in probabilistic polynomial time. A string $\alpha \in_R \mathcal{M}$ is chosen and $\mathcal{A}$ receives $\text{hist}(\alpha)$, where hist is a probabilistic polynomial-time computable function. The commitment protocol is executed, where $\psi(A)$ follows the protocol and $\psi(B)$ is controlled by $\mathcal{A}$. The adversary $\mathcal{A}$ then produces a string β. We assume that the prefix of β is the description of $\mathcal{M}$.

$\mathcal{A}$ is considered to have succeeded with respect to R if $R(\alpha, \beta)$. Let $\pi(\mathcal{A}, R)$ be the probability that $\mathcal{A}$ succeeds with respect to R. The probability is over the coin-flips of $\mathcal{A}$, and the choice of α.

For the second probability, we have an adversary simulator $\mathcal{A}'$ who will not have access to the $(\psi(A), \psi(B))$ execution of the string commitment protocol. $\mathcal{A}'$ chooses a distribution $\mathcal{M}'$. An $\alpha \in_R \mathcal{M}'$ and $\text{hist}(\alpha)$ is given to $\mathcal{A}'$. $\mathcal{A}'$ produces β. As above, $\mathcal{A}'$ is considered to have succeeded with respect to R if $R(\alpha, \beta)$.

DEFINITION 2.5. *A commitment scheme is* semantically secure with respect to relations *if for every probabilistic polynomial-time adversary $\mathcal{A}$ as above there exists a probabilistic polynomial-time adversary simulator $\mathcal{A}'$ s.t. for every probabilistic polynomial-time computable relation $R(\alpha, \beta)$ and function hist(m) computable in probabilistic polynomial time, $|\pi(\mathcal{A}, R) - \pi'(\mathcal{A}', R)|$ is subpolynomial.*

Zero-knowledge interaction. We next present a generalization of a (uniform) zero-knowledge interactive proof of language membership.

Let $(A, B)[a, b]$ be an interactive protocol, where (a, b) belongs to a set Π of legal input pairs to A and B. (In the special case of zero-knowledge proofs of language membership, the valid pairs (a, b) have the property that the prefixes of a and b are the common input $x \in L$.) Roughly speaking, we say that (A, B) is *zero-knowledge* with respect to B if for every polynomial-time bounded B', there exists a simulator that can produce conversations between (A, B') which are indistinguishable from the

actual (A, B') conversation. More accurately, and pursuing the terminology of this section, let $\mathcal{A}$ be an adversary that controls $\psi(B)$. $\mathcal{A}$ chooses a joint distribution $\mathcal{D}$, consistent with Π, on $[a, b]$, and then a pair $[a, b]$ is drawn according to $\mathcal{D}$; $\psi(A)$ gets a, $\psi(B)$ gets b, and the interaction proceeds by $\psi(A)$ following the protocol (while $\psi(B)$'s actions are controlled by $\mathcal{A}$). The result is a transcript T of the conversation between $\psi(A)$ and $\psi(B)$. $\mathcal{A}$ also produces a string σ which contains as a prefix the description of $\mathcal{D}$ (and may contain such information as the state of $\psi(B)$ at the end of the protocol).

Let R be a ternary relation. $\mathcal{A}$ is considered to have succeeded with respect to R if $R([a, b], T, \sigma)$. Let $\pi(\mathcal{A}, R)$ be the probability that $\mathcal{A}$ succeeds with respect to R. The probability is over the coin-flips of $\mathcal{A}$, the coin-flips of $\psi(A)$, and the choice of $[a, b]$.

On the other hand, we have $\mathcal{A}'$ that selects $\mathcal{D}'$ consistent with Π. A pair $[a, b]$ is then drawn according to $\mathcal{D}'$, and $\mathcal{A}'$ receives b. $\mathcal{A}'$ produces a transcript T' and a string σ'. $\mathcal{A}'$ is considered to have succeeded with respect to R if $R([a, b], T', \sigma')$. Let $\pi(\mathcal{A}', R)$ be the probability that $\mathcal{A}$ succeeds with respect to R. The probability is over the coin-flips of $\mathcal{A}'$ and the choice of $[a, b]$.

DEFINITION 2.6. *A protocol (A, B) is zero-knowledge with respect to B if for all probabilistic polynomial-time adversaries $\mathcal{A}$ as above there exists a probabilistic polynomial-time adversary simulator $\mathcal{A}'$ such that for every relation R computable in probabilistic polynomial time $|\pi(\mathcal{A}, R) - \pi'(\mathcal{A}', R)|$ is subpolynomial.*

(If $(a, b) \notin \Pi$, then zero-knowledge is not ensured, but other requirements may hold, depending on the protocol.)

Two interesting examples of zero-knowledge interaction are proof of language membership [44, 40] and proofs of knowledge [31]. Both of these can be based on the existence of string commitment protocols.

Noninteractive zero-knowledge proof systems. An important tool in the construction of our public-key cryptosystem are noninteractive zero-knowledge proof systems (NIZKs). The following explanation is taken almost verbatim from [61]: A (single-theorem) noninteractive proof system for a language L allows one party $\mathcal{P}$ to prove membership in L to another party $\mathcal{V}$ for any $x \in L$. $\mathcal{P}$ and $\mathcal{V}$ initially share a string U of length polynomial in the security parameter n. To prove membership of a string x in $L_n = L \cap \{0, 1\}^n$, $\mathcal{P}$ sends a message p as a proof of membership. $\mathcal{V}$ decides whether to accept or to reject the proof. Noninteractive zero-knowledge proof systems were introduced in [12, 13]. A noninteractive zero-knowledge scheme for proving membership in any language in NP which may be based on *any* trapdoor permutation is described in [32]. Recently, Kilian and Petrank [49, 50] found more efficient implementations of such schemes. Their scheme is for the circuit satisfiability problem. Let k be a security parameter. Assuming a trapdoor permutation on k bits, the length of a proof of a satisfiable circuit of size L (and the size of the shared random string) is $O(Lk^2)$.

The shared string U is generated according to some distribution $\mathcal{U}(n)$ that can be generated by a probabilistic polynomial-time machine. (In all the examples we know of it is the uniform distribution on strings of length polynomial in n and k, where the polynomial depends on the particular protocol, although this is not required for our scheme.)

Let L be in NP. For any $x \in L$, let $WL(x) = \{z |\ z \textit{ is a witness for } x\}$ be the set of strings that witness the membership of x in L. For the proof system to be of any use, $\mathcal{P}$ must be able to operate in polynomial time if it is given a witness $z \in WL(x)$.

We call this the *tractability* assumption for $\mathcal{P}$. In general, z is not available to $\mathcal{V}$.

Let $\mathcal{P}(x, z, U)$ be the distribution of the proofs generated by P on input x, witness z, and shared string U. Suppose that $\mathcal{P}$ sends $\mathcal{V}$ a proof p when the shared random string is U. Then the pair (U, p) is called the conversation. Any $x \in L$ and $z \in WL(x)$ induces a probability distribution $\mathcal{CONV}(x, z)$ on conversations (U, p), where $U \in \mathcal{U}$ is a shared string and $p \in \mathcal{P}(x, z, U)$ is a proof.

For the system to be zero-knowledge, there must exist a simulator Sim which, on input x, generates a conversation (U, p). Let $Sim(x)$ be the distribution on the conversations that Sim generates on input x, let $Sim_U(x) = Sim_U$ be the distribution on the U part of the conversation, and let $Sim_P(x)$ be the distribution on the proof component. In the definitions of [13, 32] the simulator has two steps: it first outputs Sim_U without knowing x, and then, given x, it outputs $Sim_P(x)$. (This requirement, that the simulator not know the theorem when producing U, is not essential for our purposes; however, for convenience, our proof in section 3.3 does assume that the simulator is of this nature.)

Let

$$ACCEPT(U, x) = \{p | \mathcal{V} \text{ accepts on input } U, x, p\},$$

and let

$$REJECT(U, x) = \{p | \mathcal{V} \text{ rejects on input } U, x, p\}.$$

The following is the definition of noninteractive proof systems of [12], modified to incorporate the tractability of $\mathcal{P}$. The uniformity conditions of the system are adopted from Goldreich [35].

DEFINITION 2.7. *A triple $(\mathcal{P}, \mathcal{V}, \mathcal{U})$, where $\mathcal{P}$ is a probabilistic polynomial-time machine, $\mathcal{V}$ is a polynomial-time machine, and $\mathcal{U}$ is a polynomial-time sampleable probability distribution, is a* noninteractive zero-knowledge proof system *for the language $L \in NP$ if the following are present:*

1. Completeness *(if $x \in L$, then $\mathcal{P}$ generates a proof that $\mathcal{V}$ accepts): For all $x \in L_n$, for all $z \in WL(x)$, with overwhelming probability for $U \in_R \mathcal{U}(n)$ and $p \in_R \mathcal{P}(x, z, U)$, $p \in ACCEPT(U, x)$. The probability is over the choice of the shared string U and the internal coin-flips of $\mathcal{P}$.*
2. Soundness *(if $y \notin L$, then no prover can generate a proof that $\mathcal{V}$ accepts): For all $y \notin L_n$ with overwhelming probability over $U \in_R \mathcal{U}(n)$ for all $p \in \{0,1\}^*$, $p \in REJECT(U, y)$. The probability is over the choices of the shared string U.*
3. Zero-knowledge: *There is a probabilistic polynomial-time machine Sim which is a simulator for the system: For all probabilistic polynomial-time machines $\mathcal{C}$, if $\mathcal{C}$ generates $x \in L$ and $z \in WL(x)$, then*

$$|\text{Prob}[\mathcal{C}(w) = 1 | w \in_R Sim(x)] - \text{Prob}[\mathcal{C}(w) = 1 | w \in_R \mathcal{CONV}(x, z)]| < \frac{1}{p(n)}$$

for all polynomials p and sufficiently large n.

In the construction of the nonmalleable cryptosystem in section 3, noninteractive zero-knowledge proof systems are used to prove that encryptions generated under *independent* keys correspond to the *same* plaintext. This is similar to their application in [61].

2.2. Definitions specific to nonmalleability. In any interactive protocol (A, B) for primitive $\mathcal{P}$, party A has an *intended value*. In the case of encryption it is the value encrypted in $\psi(B)$'s public key; in string commitment it is the string to which $\psi(A)$ commits; in a zero-knowledge proof it is the theorem being proved interactively. The intended value is a generalization of the notion of an input. Indeed, when $\psi(A)$ is nonfaulty we may refer to the intended value as an *input* to A. However, we do not know how to define the input to a faulty processor that can, for example, refuse to commit to it. In this case we may need to substitute in a default value. The term *intended value* covers cases like this.

We sometimes refer to $\psi(A)$ as the *sender* and to $\psi(B)$ as the *receiver*. We use the verb *to send* to mean, as appropriate, to send an encrypted message, to commit to, and to prove knowledge of. Intuitively, in each of these cases information is being transmitted, or sent, from the sender to the receiver.

Interactive protocols (A, B), including the simple sending of an encrypted message, are executed in a context, and the participants have access to the history preceding the protocol execution. When $\psi(A)$ has intended value α, we assume both parties have access to $\text{hist}(\alpha)$, intuitively, information about the history that leads to $\psi(A)$ running the protocol with intended value α.

In some cases we also assume an underlying probability distribution $\mathcal{D}$ on intended values, to which both parties have access (that is, from which they can sample in polynomial time).

An *adversarially coordinated* system of interactive protocols

$$\langle (A, B), (C, D),\ \mathcal{A} : \psi(B) \leftrightarrow \psi(C) \rangle$$

consists of two interactive protocols (A, B) and (C, D), an adversary $\mathcal{A}$ controlling the agents $\psi(B)$ and $\psi(C)$, the communication between these agents, and the times at which all agents take steps.

Generally, we are interested in the situation in which $A = C$ and $B = D$, for example, when both interactive protocols are the same bit commitment protocol. Thus, for the remainder of the paper, unless otherwise specified, $(A, B) = (C, D)$, but $\psi(A), \psi(B), \psi(C)$, and $\psi(D)$ are all distinct.

Consider the adversarially coordinated system $\langle (A, B), (C, D),\ \mathcal{A} : \psi(B) \leftrightarrow \psi(C) \rangle$. In an execution of this system, $\psi(A)$ sends an intended value $\alpha \in_R \mathcal{D}$ in its conversation with $\psi(B)$, and $\psi(C)$ sends an intended value β in its conversation with $\psi(D)$. If $\psi(C)$ fails to do so—e.g., fails to respond to a query, is caught cheating, or produces invalid ciphertexts—we take β to be all zeros.

We treat "copying" slightly differently in the context of encryption, which is noninteractive, and in the commitment and zero-knowledge settings, which are interactive. In particular, our results are stronger for encryption, since our construction rules out anything but exact copying of the ciphertext. Thus, seeing the ciphertext does not help the adversary to construct a different encryption of the same message. In the interactive setting we only ensure that if $\alpha \neq \beta$, then the two values are unrelated. We use identities (chosen by the users and not enforced provided by any authentication mechanism) to force α and β to be different. In particular, if the adversary wishes to be a transparent intermediary, then we do not bother to rule out the case in which the adversary commits to or proves exactly the same string as A does, even if it gives a different commitment (to the same value) or a different proof (of the same theorem).

We now formally define the nonmalleability guarantee in the interactive setting. A *relation approximator* R is a probabilistic polynomial-time Turing machine taking

two inputs[5] and producing as output either 0 or 1. The purpose of the relation approximator is to measure the correlation between α and β. That is, R measures how well the adversary manages to make β depend on α. In the interactive settings, we restrict our attention to the special class of relation approximators which on input pairs of the form (x, x) always output 0. The intuition here is that we cannot rule out copying, but, intuitively, this is not the case in which the adversary "succeeds."

When we discuss composition (or parallel execution) we will extend the definition so that the first input is actually a vector V of length k. The intuition here is that C may have access to several interactions with, and values sent by, nonfaulty players. In that case, the approximator must output zero on inputs (V, y) in which y is either a component of V, corresponding to the case in which $\psi(C)$ sends the same value as one of the nonfaulty players (in the case of encryption this is ruled out by the definition of the adversary).

Given a probability distribution on the pair of inputs, there is an a priori probability, taken over the choice of intended values and the coin-flips of R, that R will output 1. In order to measure the correlation between α and β, we must compare R's behavior on input pairs (α, β) generated as described above to its behavior on pairs (α, γ), where γ is sent without access to the sending of α (although as always we assume that $\psi(C)$ has access to $\mathcal{D}$ and hist(α)).

An *adversary simulator* for a commitment (zero-knowledge proof of knowledge) scheme $\mathcal{S}$ with input distribution $\mathcal{D}$ and polynomial-time computable function hist, is a probabilistic polynomial-time algorithm that, given hist, hist(α), and $\mathcal{D}$, produces an intended value γ.

Consider an adversarially coordinated system of interactive protocols $\langle (A, B), (C, D),\ \mathcal{A} : \psi(B) \leftrightarrow \psi(C) \rangle$, where (A, B) and (C, D) are both instances of $\mathcal{S}$, and Π is the set of legal input pairs to the two parties executing $\mathcal{S}$. $\mathcal{A}$ may choose any probabilistic polynomial-time sampleable distribution $\mathcal{D}$ on the joint distribution to all four players,

$$\psi(A), \psi(B), \psi(C), \psi(D),$$

respectively, where the inputs to $\psi(A)$ and $\psi(B)$ are consistent with Π. Let $(\alpha, x, y, \delta) \in_R \mathcal{D}$. For any relation approximator R, let $\pi(\mathcal{A}, R)$ denote the probability, taken over all choices of $\psi(A)$, $\psi(D)$, $\mathcal{A}$, and R, that $\mathcal{A}$, given x, y, hist(α), and participation in the (A, B) execution in which $\psi(A)$ sends α, causes $\psi(C)$ to send β in the (C, D) execution, such that $R(\alpha, \beta)$ outputs 1, *under some specified form of attack.* (Since $\psi(C)$ is under control of the adversary, there is no reason that β should equal y.)

Similarly, for an adversary simulator $\mathcal{A}'$ choosing a joint distribution $\mathcal{D}'$ for all four players where the inputs to $\psi(A)$ and $\psi(B)$ are consistent with Π, for $(\alpha, x, y, \delta) \in_R \mathcal{D}'$, let $\mathcal{A}'$ have access to x, y, and hist(α), and let $\mathcal{A}'$ send γ. Let $\pi'(\mathcal{A}', R)$ denote the probability, taken over the choices of $\mathcal{A}'$, and the choices of R, that $R(\alpha, \gamma) = 1$.

DEFINITION 2.8. *A scheme $\mathcal{S}$ for a primitive $\mathcal{P}$ is nonmalleable with respect to itself under a given type of attack G, if for all adversarially coordinated systems $\langle (A, B), (C, D),\ \mathcal{A} : \psi(B) \leftrightarrow \psi(C) \rangle$, where $(A, B) = (C, D) = \mathcal{S}$, where $\mathcal{A}$ mounts an attack of type G, there exists an adversary simulator $\mathcal{A}'$ such that for all relation approximators R, $|\, \pi(\mathcal{A}, R) - \pi'(\mathcal{A}', R) \,|$ is subpolynomial.*[6]

[5] Sometimes we will need R to take three inputs, the third being in plaintext.

[6] In the previous version of this paper the order of quantifiers was $\forall R \forall \mathcal{A} \exists \mathcal{A}'$, yielding a possibly weaker definition. However, all the constructions in our work satisfy the stronger order of quantifiers given here. Now all our definitions share a common order of quantifiers.

This definition is applicable to *all* three primitives. As stated above, the precise attack against the system is crucial to the definition of $\mathcal{A}$ and hence of $\pi(\mathcal{A}, R)$. In particular, when we discuss encryption in section 3, we will specify the nature of the adversary precisely. The definition makes sense for all types of attack, with the appropriate choices of $\pi(\mathcal{A}, R)$. Finally, we must specify the "unit" which we are trying to protect; i.e., is it a single encryption or several?

REMARK 2.9. *There are three possible interpretations of Definition* 2.8*, according to the running time of* $\mathcal{A}'$*:*

1. $\mathcal{A}'$ *runs in a fixed polynomial time; this is* strict *nonmalleability (we usually drop the appellation "strict").*
2. $\mathcal{A}'$ *runs in* expected *polynomial time; in accordance with Goldreich's taxonomy for zero-knowledge, we call this* liberal [35] *nonmalleability.*
3. *For every* ε *there exists* $\mathcal{A}'$ *running in time polynomial in* n *and* ε^{-1} *such that* $|\pi(\mathcal{A}, R) - \pi'(\mathcal{A}', R)| < \varepsilon$*; this is the* ε-malleability*, this time in analogy to* ε*-knowledge* ([43]; *see also* [29])*.*

Our public-key cryptosystem is strictly nonmalleable. M. Fischlin and R. Fischlin have pointed out that we do not prove strict nonmalleability in our commitment scheme; however, we prove both liberal nonmalleability and ε*-malleability.*

2.3. System model. We assume a completely asynchronous model of computing. For simplicity, we assume FIFO communication links between processors (if the links are not FIFO, then this can be simulated using sequence numbers). We *do not* assume authenticated channels.

We *do not* assume the usual model of a fixed number of mutually aware processors. Rather, we assume a more general model in which a given party does not know which other parties are currently using the system. For example, consider a number of interconnected computers. A user ("agent") can log into any machine and communicate with a user on an adjacent machine, without knowing whether a given third machine is actually in use at all, or if the second and third machines are currently in communication with each other. In addition, the user does not know the set of potential other users, nor need it know anything about the network topology.

Thus, we do not assume a given user knows the identities of the other users of the system. On the other hand, our protocols may make heavy use of user identities. One difficulty is that in general, one user may be able to impersonate another. There are several ways of avoiding this. For example, Rackoff and Simon [63] propose a model in which each sender possesses a secret associated with a *publicly known* identifying key issued by a trusted center.

In the scenario of interconnected computers described above, an identity could be composed of the computer serial number and a timestamp, possibly with the addition of the claimed name of the user. In the absence of some way of verifying claimed identities, *exact copying* of the pair, claimed identity and text, cannot be avoided, but we rule out essentially all other types of dependence between intended values.

We can therefore assume that the intended value α sent by $\psi(A)$ contains as its first component a user identity, which may or may not be verifiable. Fix a scheme $\mathcal{S}$ and an adversarially coordinated system of interactive protocols $\langle (A, B), (C, D), \mathcal{A} : \psi(B) \leftrightarrow \psi(C) \rangle$, where (A, B) and (C, D) are both instances of $\mathcal{S}$, and let α and β be sent by $\psi(A)$ and $\psi(C)$, respectively. Then, whether or not the identities can be checked, if $\mathcal{S}$ is nonmalleable and $\alpha \neq \beta$, then β's dependence on α is limited to dependence on $\text{hist}(\alpha)$. In addition, if the identities can be checked, then $\alpha \neq \beta$.

In order to avoid assumptions about the lengths of intended values sent, we assume

the space of legal values is prefix-free.

3. Nonmalleable public-key cryptosystems. A *public-key cryptosystem* allows one participant, the owner, to publish a public key, keeping secret a corresponding private key. Any user that knows the public key can use it to send messages to the owner; no one but the owner should be able to read them. In this section, we show how to construct nonmalleable public-key cryptosystems. The definitions apply, mutatis mutandi, to private-key cryptosystems. As was done by [45] in 1984 in the context of digital signatures, when defining the security of a cryptosystem one must specify (a) the type of attack considered and (b) what it means to break the cryptosystem.

The cryptosystem we construct is secure against chosen ciphertext attacks. In fact it is secure against a more severe attack suggested by Rackoff and Simon [63] and which we call CCA-post: The attacker knows the ciphertext she wishes to crack while she is allowed to experiment with the decryption mechanism. She is allowed to feed it with any ciphertext she wishes, except for the exact one she is interested in. Thus the attacker is like a student who steals a test and can ask the professor any question, except the ones on the test. This is the first public-key cryptosystem to be provably secure against such attacks. Indeed, (plain) RSA [64] and the implementation of probabilistic encryption based on quadratic residuousity [43] are insecure against CCA-post.

Malleability, as defined in section 2.2, specifies what it means to "break" the cryptosystem. Informally, given a relation R and a ciphertext of a message α, the attacker $\mathcal{A}$ is considered successful if it creates a *ciphertext* of β such that $R(\alpha, \beta) = 1$. The cryptosystem is nonmalleable under a given attack G if for every $\mathcal{A}$ mounting an attack of type G, there is an $\mathcal{A}'$ that, without access to the ciphertext of α, succeeds with similar probability as $\mathcal{A}$ in creating a ciphertext of γ such that $R(\alpha, \gamma) = 1$. Given the notion of semantic security with respect to relations and Theorem 2.4, nonmalleability is clearly an extension of semantic security. See section 3.4.2 for the relationship between nonmalleability and the type of attack.

We now define precisely the power of the CCA-post adversary $\mathcal{A}$. Let R be a polynomial-time computable relation. Let n be the security parameter. $\mathcal{A}$ receives the public key $e \in_R GP(n)$ and can adaptively choose a sequence of ciphertexts $c_1, c_2, \ldots$. On each of them, $\mathcal{A}$ receives the corresponding plaintext. It then produces a distribution $\mathcal{M}$ on messages of length $\ell(n)$, for some polynomial ℓ, by giving the polynomial-time machine that can generate this distribution. $\mathcal{A}$ then receives as a challenge a ciphertext $c \in_R E_e(m)$, where $m \in_R \mathcal{M}$, together with some "side-information" about m in the form of hist(m), where hist is some polynomially computable function. $\mathcal{A}$ then engages in a second sequence of adaptively choosing ciphertexts $c'_1, c'_2, \ldots$. The only restriction is that $c \neq c'_1, c'_2, \ldots$. At the end of the process, $\mathcal{A}$ produces a polynomially bounded length vector of ciphertexts $(f_1, f_2, \ldots)$ not containing the challenge ciphertext c, with each $f_i \in E_e(\beta_i)$, and a *cleartext* string σ which we assume contains a description of $\mathcal{M}$.[7] Let $\beta = (\beta_1, \beta_2, \ldots)$. $\mathcal{A}$ is considered to have succeeded with respect to R if $R(m, \beta, \sigma)$. (We separate β from σ because the goal of the adversary is to produce encryptions of the elements in β.) Let $\pi(\mathcal{A}, R)$ be the probability that $\mathcal{A}$ succeeds where the probability is over the coin-flips of the key generator, $\mathcal{A}, \mathcal{M}$ and

[7] In the public key context, σ serves no purpose other than providing the description of $\mathcal{M}$ as an input to R, since in this situation from any plaintexts $p \in \mathcal{M}$ that are part of σ it is always possible to compute an encryption of σ, so we could always add an additional $f_i \in E_e(p)$ to our vector of ciphertexts. However, we introduce the possibility of including plaintexts p in σ so that the definition can apply to symmetric, or private-key, encryption.

the encryption of m.

Let $\mathcal{A}'$ be an adversary simulator that does not have access to the encryptions or to the decryptions but can pick the distribution $\mathcal{M}'$. On input e, $\mathcal{A}'$ produces $\mathcal{M}'$ and then $m \in_R \mathcal{M}'$ is chosen. $\mathcal{A}'$ receives hist(m) and without the benefit of the chosen ciphertext attack should produce a vector of ciphertexts $(f_1, f_2, \ldots)$, where each $f_i \in E_e(\beta_i)$, and a string σ containing $\mathcal{M}'$. Let $\beta = (\beta_1, \beta_2, \ldots)$. As above, $\mathcal{A}'$ is considered to have succeeded with respect to R if $R(m, \beta, \sigma)$. Let $\pi'(\mathcal{A}', R)$ be the probability that $\mathcal{A}'$ succeeds where the probability is over the coin-flips of the key generator, $\mathcal{A}'$ and $\mathcal{M}'$.

Note that $\mathcal{A}'$ has a lot less power than $\mathcal{A}$: not only does it not have access to the ciphertext encrypting α, but it cannot perform *any* type of chosen ciphertext attack, even in choosing the distribution $\mathcal{M}'$. Note also that as in the definition of semantically secure with respect to relations, the fact that $\mathcal{M}$ is given to R prevents $\mathcal{A}'$ from choosing trivial distributions.

DEFINITION 3.1. *A scheme $\mathcal{S}$ for public-key cryptosystems is nonmalleable with respect to chosen ciphertext attacks in the postprocessing mode (CCA-post attacks), if for all probabilistic polynomial-time adversaries $\mathcal{A}$ as above there exists a probabilistic polynomial-time adversary simulator $\mathcal{A}'$ s.t. for all relations $R(\alpha, \beta, \sigma)$ computable in probabilistic polynomial time, $|\pi(\mathcal{A}, R) - \pi'(\mathcal{A}', R)|$ is subpolynomial.*

Note that the definition does not require R to be restricted (to a relation approximator) as described in section 2.2.

An illustration of the power of nonmalleability under CCA-post attacks is presented in section 3.5, where we discuss an extremely simple protocol for *public-key authentication*, a relaxation of digital signatures that permits an authenticator A to authenticate messages m, but in which the authentication needn't (and perhaps shouldn't!) be verifiable by a third party. The protocol requires a nonmalleable public-key cryptosystem and is simply incorrect if the cryptosystem is malleable.

Simple ideas that do not work. A number of simple candidates for nonmalleable cryptosystems come to mind. Let E be a cryptosystem semantically secure against a chosen ciphertext attack. Assume for concreteness that A wishes to send the message m and B wishes to send "1 + the value sent by A." That is, B, without knowing m, wishes to send $m + 1$.

One "solution" would be to append to $E(m)$ a noninteractive zero-knowledge proof of knowledge of the encrypted value m. The problem with this approach is that the proof of knowledge may itself be malleable: conceivably, given $E(m)$ and a proof of knowledge of m, it may be possible to generate $E(m+1)$ and a proof of knowledge of $m + 1$.

Another frequently suggested approach is to sign each message. Thus, to send a message m, party A sends $(E(m), S_A(E(m)))$, where S_A is a private signing algorithm for which a public verification key is known. There are two problems with this: first, it assumes that *senders* as well as *receivers* have public keys; second, it misses the point: if E is malleable, then B, seeing $(E(m), S_A(E(m)))$, simply ignores the second component, generates $E(m+1)$, say, based on $E(m)$, and sends $(E(m+1), S_B(E(m+1)))$.

Yet another suggestion is to put the signature *inside* the ciphertext: A sends $E(m \circ S_A(m))$. This still suffers from the assumption that A has a public verification key corresponding to S_A, and it again misses the point: B is not trying to produce $E(m+1, S_A(m+1))$, but only $E(m+1 \circ S_B(m+1))$. The unforgeability properties of S_A say absolutely nothing about B's ability to produce an encryption of $S_B(m + 1)$.

One more suggestion is to append an ID to each message and send, for example, $E(A \circ m)$. Again, we do not know how to show that, based only on the semantic security of E against chosen ciphertext attack, seeing $E(A \circ m)$ does not help B to produce $E(B \circ m)$ or $E(B \circ m + 1)$.

Overview of the scheme. The public key consists of 3 parts: (1) a collection of n pairs of keys $\{\langle e_i^0,\ e_i^1\rangle | 1 \le i \le n\}$; (2) a random string U for providing zero-knowledge proofs of consistency in a noninteractive proof system; (3) a universal one-way hash function. U is uniformly distributed because it is to the advantage of its creator (the verifier in the noninteractive zero-knowledge proof) that it should be so.

The process of encryption consists of four parts.

1. An "identity" is chosen for the message by creating a public signature verification key; the corresponding signing key is kept private. The signing key is only used to sign a single message, so a one-time signature scheme may be used here.
2. The message is encrypted under several encryption keys chosen from $\{\langle e_i^0, e_i^1\rangle | 1 \le i \le n\}$ as a function of the public signature verification key chosen in the first step. The selection is made by hashing the public signature verification key using the universal one-way hash function that is part of the public key for the cryptosystem.
3. A (noninteractive zero-knowledge) proof of consistency is provided, showing that the value encrypted under all the selected keys is the same one.
4. The encryptions and the proof are signed using the private signing key chosen in the first step.

When a message is decrypted, the signature verification key comprising the identity is used to verify that the signature is valid; the proof of consistency of encryptions is also checked. Only then is the (now well-defined) plaintext extracted.

The hash function is used only for efficiency; without it we would have to increase n, the number of encryption key pairs $\langle e_i^0,\ e_i^1\rangle$ in the public key for the cryptosystem. Thus, intuitively, the hash function plays a role analogous to the usual role of a hash function in an implementation of a signature scheme; however, we use it to hash the public verification key of the (freshly chosen) signature scheme, rather than the text of a message to be signed. As we will see, the critical point is that every identity chosen yields a distinct set of keys under which consistent encryptions must be created.

The idea of encrypting under several keys and proving consistency appeared in [61]. However, in [61] every plaintext bit is encrypted under *every* public key (there are only two), while here each identity for a message yields a distinct set of keys. Thus, the main changes here to the scheme in [61] are

1. the addition of an "identity" for each message to select a distinct set of keys;
2. using a (hash of the) freshly chosen public signature verification key as the identity;
3. signing the encryptions under the selected keys and the proof of consistency with the (secret) signing key that corresponds to the identity.

To develop some intuition for how the identities are used, consider a hypothetical situation in which all the keys in the pairs $\langle e_i^0,\ e_i^1\rangle$, $i = 1, \ldots, n$, are completely malleable, and suppose further that given an NIZK that one set of encryptions is consistent, it is easy to generate a proof of the true theorem that a set of related encryptions is also consistent.

If (as is the case in [61], where only two keys are used) we were *not* to use

signatures and we were *not* to select a new set of keys for each message (so that an encryption $E(m)$ would be a consistent set of encryptions under *all* the e_i^0 and e_i^1, $i = 1, \ldots, n$, and a proof of consistency), then given an encryption $E(m)$, creating an encryption, say of $2m$, would be easy: use the assumed malleability of all the $e_i^b(m)$ to create encryptions $e_i^b(2m)$, and use the assumed malleability of the NIZK to prove (the true theorem) that the resulting set of encryptions is consistent. We combat this hypothetical attack (which we cannot rule out!) using the identities, as we now describe.

Consider an attacker that has an encryption $\alpha \in_R E(m)$ under our scheme and that wishes to create from it an encryption $\beta \in E(2m)$. Suppose, as above, that the encryption functions e_i^b are completely malleable and that the NIZKs are malleable in the sense previously described. In our case, the attacker must create an identity for the message. Remember that an identity is the public verification key for a signature scheme. The attacker can choose to use the same identity (signature verification key) as in α or a different one. If the identity is preserved, this means that the attacker is using the public signature verification key appearing in α, for which he does not know the corresponding signature key. In this case, while the attacker can exploit the malleability of the e_i^b and the NIZK, in the last step of the encryption process he must forge a signature on the *new* encryptions and *new* proof of consistency—which he cannot do because he does not know the private signing key. On the other hand, if the attacker selects a new identity for β, different than the one used in α, then, since the identity selects the keys e_i^b under which the message is encrypted, for some i the attacker will have in α only $e_i^b(m)$ (and he will *not* have $e_i^{1-b}(m)$), but he will need to create $e_i^{1-b}(2m)$, so there will be no way to exploit the malleability of the encryption schemes e_i^0 and e_i^1. To summarize, nonmalleability comes from the fact that the choice of the subsets and the signature each authenticate the other.

As in [61], anyone can decide whether a ciphertext is legitimate, i.e., decrypts to some meaningful message, by verifying the NIZK proof of consistency and checking, using the signature verification key that comprises its identity, that the message is correctly signed. Thus, no information is ever gained during an attack when the decrypting mechanism rejects an invalid ciphertext.

Intuitively, given $E(\alpha)$, an attacker with access to a decryption mechanism can generate a legal ciphertext $E(\beta)$ and learn β, but nonmalleability implies that an adversary simulator can generate $E(\gamma)$ without access to $E(\alpha)$, where γ is distributed essentially as β is distributed. Thus β is unrelated to α (nonmalleability), and learning β yields no information about α (semantic security).

3.1. The tools. We require a probabilistic public-key cryptosystem that is semantically secure (see section 2.1). Recall that GP denotes the key generator, e and d denote the public and private keys, respectively, and E and D denote, respectively, the encryption and decryption algorithms.

For public keys $e_1, e_2, \ldots, e_n$ a *consistent encryption* is a string w that is equal to

$$E_{e_1}(b, r_1), E_{e_2}(b, r_2), \ldots, E_{e_n}(b, r_n)$$

for some $b \in \{0, 1\}$ and $r_1, r_2, \ldots, r_n \in \{0, 1\}^{p(n)}$, for some polynomial p. The language of consistent encryptions $L = \{e_1, e_2, \ldots, e_n, w | w$ is a consistent encryption$\}$ is in NP. For a given word $w = E_{e_1}(b, r_1)$, $E_{e_2}(b, r_2)$, $\ldots, E_{e_n}(b, r_n)$, the sequence r_1, $r_2, \ldots, r_n$ is a witness for its membership in L. In order to prove consistency we need a *noninteractive zero-knowledge proof system* for L, as defined in section 2.1. Recall that the system consists of a prover, a verifier, and a common random string

U known to both the prover and the verifier and that such a scheme can be based on any trapdoor permutation. Note that the length of U depends only on the security parameter and not on the number of messages to be encrypted over the lifetime of this public key.

The cryptosystem uses a *universal family of one-way hash functions* as defined in [60]. This is a family of functions H such that for any x and a randomly chosen $h \in_R H$ the problem of finding $y \neq x$ s.t. $h(y) = h(x)$ is intractable. The family we need should compress from any polynomial in n bits to n bits. In [65] such families are constructed from any one-way function.

Finally we need a one-time *signature scheme*, which consists of GS, the scheme generator that outputs F, the public key of the signature scheme, and P the private key. Using the private key P any message can be signed in such a way that anyone knowing F can verify the signature and no one who does not know the private key P can generate a valid signature on any message except the one signed. For exact definition and history see [5, 45, 60].

3.2. The nonmalleable public-key encryption scheme. We are now ready to present the scheme $\mathcal{S}$.

Key generation.

1. Run $GP(1^n)$, the probabilistic encryption key generator, $2n$ times. Denote the output by
$$(e_1^0, d_1^0), (e_1^1, d_1^1), (e_2^0, d_2^0), (e_2^1, d_2^1), \ldots, (e_n^0, d_n^0), (e_n^1, d_n^1).$$
2. Generate random reference string U.
3. Generate $h \in_R H$.

The public encryption key is
$$\langle h, e_1^0, e_1^1, e_2^0, e_2^1, \ldots, e_n^0, e_n^1, U \rangle,$$
and the corresponding private decryption key is $\langle d_1^0, d_1^1, d_2^0, d_2^1, \ldots, d_n^0, d_n^1 \rangle$.

Encryption. To encrypt a message $m = b_1 b_2 \ldots b_k$:

1. Run $GS(1^n)$, the signature key generator. Let F be the public signature key and P be the private signature key.
2. Compute $h(F)$. Denote the output by the n-bit string $v_1 v_2 \ldots v_n$.
3. For each $1 \leq i \leq k$:
   (a) For $1 \leq j \leq n$,
      i. generate random $r_{ij} \in_R \{0,1\}^{p(n)}$;
      ii. generate $c_{ij} = E_{e_j^{v_j}}(b_i, r_{ij})$, an encryption of b_i using $e_j^{v_j}$.
   (b) Run $\mathcal{P}$ on $c_i = e_1^{v_1}, e_2^{v_2}, \ldots, e_n^{v_n}, c_{i1}, c_{i2}, \ldots, c_{in}$, with witness $r_{i1}, r_{i2}, \ldots, r_{in}$ and string U to get a proof p_i that $c_i \in L$.
4. Create a signature s of the sequence (c_1, p_1), $(c_2, p_2), \ldots, (c_k, p_k)$ using the private signature key P.

The encrypted message is
$$\langle F, s, (c_1, p_1), (c_2, p_2), \ldots, (c_k, p_k) \rangle.$$

Decryption. To decrypt a ciphertext $\langle F, s, (c_1, p_1), (c_2, p_2), \ldots, (c_k, p_k)\rangle$:

1. Verify that s is a signature of $(c_1, p_1),(c_2, p_2),\ldots,(c_k, p_k)$ with public signature key F.
2. For all $1 \le i \le k$, verify that c_i is consistent by running the verifier $\mathcal{V}$ on c_i, p_i, U.
3. Compute $h(F)$. Denote the output by $v_1 v_2 \ldots v_n$.
4. If $\mathcal{V}$ accepts in all k cases, then for all $1 \le i \le k$, retrieve b_i by decrypting using any one of $\langle d_1^{v_1}, d_2^{v_2}, \ldots, d_n^{v_n}\rangle$. Otherwise the output is null.

Note that, by the proof of consistency, the decryptions according to the different keys in step 4 are identical with overwhelming probability.

From this description it is clear that the generator and the encryption and decryption mechanisms can be operated in polynomial time. Also if the decryption mechanism is given a legitimate ciphertext and the right key, it produces the message encrypted.

3.3. Nonmalleable security under CCA-post. We now prove the nonmalleability of the public-key encryption scheme $\mathcal{S}$ under a CCA-post. We define a related scheme $\mathcal{S}'$ whose (malleable) semantic security with respect to relations under chosen *plaintext* attack is straightforward. We then argue that the semantic security of $\mathcal{S}'$ under chosen plaintext attack implies the nonmalleability of $\mathcal{S}$ under CCA-post.

The cryptosystem $\mathcal{S}'$.

1. Run $GP(1^n)$, the probabilistic encryption key generator, n times. Denote the output by

$$(e_1, d_1), (e_2, d_2), \ldots, (e_n, d_n).$$

   The public key is the n-tuple $\langle e_1, \ldots, e_n\rangle$; the private key is the n-tuple $\langle d_1, \ldots, d_n\rangle$.
2. Encrypt a message $m = b_1 b_2 \ldots b_k$ as follows.
3. For $1 \le j \le n$:
   - For $1 \le i \le k$,
     (a) generate random $r_{ij} \in_R \{0,1\}^{p(n)}$, and
     (b) generate $c_{ij} = E_{e_j}(b_i, r_{ij})$, an encryption of b_i under public key e_j using random string r_{ij}.
   - Let $c_j = c_{1j}, c_{2j}, \ldots, c_{kj}$ (c_j is the jth encryption of m).
4. The encryption is the n-tuple $\langle c_1, c_2, \ldots, c_n\rangle$.
5. To decrypt an encryption $\langle \alpha_1, \ldots, \alpha_n\rangle$, compute $m_j = D_{d_j}(\alpha_j)$ for $1 \le j \le n$. If $m_1 = m_2 = \cdots = m_n$, then output m_1; otherwise output "invalid encryption."

LEMMA 3.2. *The public-key encryption scheme $\mathcal{S}'$ is semantically secure with respect to relations under chosen plaintext attack.* □

We will prove nonmalleability of $\mathcal{S}$ by reduction to the semantic security of $\mathcal{S}'$. To this end, we define an adversary $\mathcal{B}$ that, on being given an encryption under $\mathcal{S}'$, generates an encryption under $\mathcal{S}$. As above, we abuse notation slightly: given a public key E in $\mathcal{S}$ (respectively, E' in $\mathcal{S}'$), we let $E(m)$ (respectively, $E'(m)$) denote the set of encryptions of m obtained using the encryption algorithm for $\mathcal{S}$ (respectively, for $\mathcal{S}'$) with public key E (respectively, E').

Notation. In what follows, adversaries $\mathcal{A}$ and $\mathcal{A}'$ are adversaries against the scheme $\mathcal{S}$. Adversaries $\mathcal{B}$ and $\mathcal{B}'$ are adversaries against the system $\mathcal{S}'$.

Procedure for $\mathcal{B}$: Given a public key $E' = \langle e_1, \ldots, e_n \rangle$ in $\mathcal{S}'$:

Preprocessing phase.

1. Generate n new (e, d) pairs.
2. Run the simulator for the noninteractive zero-knowledge proof of consistency to generate a random string U (the simulator should be able to produce a proof of consistency of n encryptions that will be given to it later on).
3. Choose a random hash function $h \in_R H$.
4. Run $GS(1^n)$ to obtain a signature scheme (F, P), where F is the public verification key.
5. Compute $h(F)$. Arrange the original n keys and the n new keys so that the keys "chosen" by $h(F)$ are the original n. Let E denote the resulting public key (instance of $\mathcal{S}$).

Simulation phase.

1. Run $\mathcal{A}$ on input E. $\mathcal{A}$ adaptively produces a polynomial length sequence of encryptions $x_1, x_2, \ldots$. For each x_i produced by $\mathcal{A}$, $\mathcal{B}$ verifies the signatures and the proofs of consistency. If these verifications succeed, $\mathcal{B}$ decrypts x_i by using one of the new decryption keys generated in preprocessing step 1 and returns the plaintext to $\mathcal{A}$.
2. $\mathcal{A}$ produces a description of $\mathcal{M}$, the distribution of messages it would like to attack. $\mathcal{B}$ outputs $\mathcal{M}$. We will show that the semantic security of $\mathcal{S}'$ with respect to relations under chosen plaintext attack implies the nonmalleability of $\mathcal{S}$ under CCA-post.
3. $\mathcal{B}$ is given $c' \in_R E'(m)$ and hist(m) for $m \in_R \mathcal{M}$. It produces a ciphertext $c \in E(m)$ using the simulator of preprocessing step 2 to obtain a (simulated) proof of consistency and the private key P generated at preprocessing step 5 to obtain the signature.
4. Give $\mathcal{A}$ the ciphertext c and hist(m). As in simulation step 1, $\mathcal{A}$ adaptively produces a sequence of encryptions $x'_1, x'_2, \ldots$ and $\mathcal{B}$ verifies their validity, decrypts, and returns the plaintexts to $\mathcal{A}$.

Extraction phase.

$\mathcal{A}$ produces the vector of encryptions $(E(\beta_1), E(\beta_2), \ldots)$ and a string σ. $\mathcal{B}$ produces $\beta = (\beta_1, \beta_2, \ldots)$ by decrypting each $E(\beta_i)$ as in the simulation phase and outputs β and σ. This concludes the description of $\mathcal{B}$.

LEMMA 3.3. *Let $\mathcal{A}$ be an adversary attacking the original scheme $\mathcal{S}$. On input E' and $c' \in_R E'(m)$, let E be generated by $\mathcal{B}$ as above, and let c be the encryption of m under E created by $\mathcal{B}$ in simulation step* 3. *Let $\zeta \neq c$ be any ciphertext under E, generated by $\mathcal{A}$. If the signatures in ζ are valid (can be verified with the public signature verification key in ζ), then $\mathcal{B}$ can decrypt ζ.*

Proof. Let F' be the public signature verification key in ζ. If $F' \neq F$, then by the security of the universal one-way hash functions, $h(F') \neq h(F)$ (otherwise using $\mathcal{A}$ one could break H). Thus, at least one of the encryption keys generated in preprocessing step 1 of the procedure for $\mathcal{B}$ will be used in ζ. Since $\mathcal{B}$ generated this encryption key and its corresponding decryption key, $\mathcal{B}$ can decrypt.

We now argue that $F' \neq F$ (that is, that we must be in the previous case). Since $\mathcal{A}$ has not seen F or anything depending on F during its chosen ciphertext attack in step 1 of the simulation phase, the probability that $\mathcal{A}$ uses $F' = F$ in a ciphertext during this step is negligible. Suppose for the sake of contradiction that after it has seen F in the target ciphertext c, $\mathcal{A}$ uses $F' = F$ in ζ. Then by the security of the signature scheme, only the original ciphertexts and proofs of consistency $(c_1, p_1), \ldots, (c_n, p_n)$

from preprocessing step 2 and simulation step 3 can be signed; otherwise $\mathcal{A}$ could be used to break the signature scheme. This forces $\zeta = c$, contradicting the fact that $\zeta \neq c$. □

Note that in step 3 of the simulation phase, the vector c' is a legitimate encryption under E' and therefore is a vector of consistent encryptions, so the simulated noninteractive proof of consistency is a proof of a true theorem. Note also that this is the only place in which a proof is simulated by $\mathcal{B}$. Thus, even though the shared random string is used to generate many proofs of consistency during the lifetime of the public key, the zero-knowledge property we will need for the proof is only for a single theorem, since the only simulated proof will be on the target ciphertext.

The next lemma says that, as in the Naor–Yung scheme, $\mathcal{A}$ cannot distinguish the "instance" of $\mathcal{S}$ concocted by $\mathcal{B}$ from a real instance of $\mathcal{S}$, so $\mathcal{A}$ is just as likely to break the concocted instance.

For any probabilistic polynomial-time relation R, let $\pi(\mathcal{B}, R)$ denote the probability that $\mathcal{B}$, using $\mathcal{A}$ as described in the simulation phase, generates a vector of plaintexts $(\beta_1, \beta_2, \ldots)$ and a string σ such that $R(m, \beta, \sigma)$ holds, where $\beta = (\beta_1, \beta_2, \ldots)$. By choice of $\mathcal{B}$, $\pi(\mathcal{B}, R)$ is exactly the probability that $\mathcal{A}$ breaks $\mathcal{S}$ with respect to R in the simulation phase: $\mathcal{A}$ (interacting with $\mathcal{B}$) generates σ and a vector of encryptions $(E(\beta_1), E(\beta_2), \ldots)$; by Lemma 3.3, $\mathcal{B}$ can decrypt these values and so outputs β_i, $i = 1, 2, \ldots$, together with σ.

LEMMA 3.4. *For any probabilistic polynomial-time relation R, let $\pi(\mathcal{B}, R)$ denote the probability that $\mathcal{B}$, using $\mathcal{A}$ as described in the simulation phase, generates a vector of plaintexts $(\beta_1, \beta_2, \ldots)$ and a string σ such that $R(m, \beta, \sigma)$ holds, where $\beta = (\beta_1, \beta_2, \ldots)$. Let $\pi(\mathcal{A}, R)$ denote the probability that $\mathcal{A}$ breaks a random instance of $\mathcal{S}$ with respect to R. Then $\pi(\mathcal{B}, R)$ and $\pi(\mathcal{A}, R)$ are subpolynomially close.*

Proof. As noted above, $\pi(\mathcal{B}, R)$ is exactly the probability with which $\mathcal{A}$ breaks $\mathcal{S}$ with respect to R in the simulation phase. The only difference between the instance of $\mathcal{S}$ generated by $\mathcal{B}$ and an instance of $\mathcal{S}$ generated at random is in the reference string U and the proof of consistency for the target ciphertext: in the former case these are produced by the simulator (steps 2 and 3 of the simulation phase) and in the latter case they are authentic. The lemma therefore follows immediately from the definition of noninteractive zero-knowledge (Definition 2.7): any difference between the two probabilities can be translated into an ability to distinguish a simulated proof from a true proof. □

THEOREM 3.5. *The public-key encryption scheme $\mathcal{S}$ is nonmalleable against CCA-post.*

Proof. Let $\mathcal{A}$ be any polynomially bounded adversary, and assume for the sake of contradiction that $\mathcal{A}$ and the probabilistic polynomial-time computable relation R witness the malleability of $\mathcal{S}$ under a CCA-post. We will use the semantic security of $\mathcal{S}'$ with respect to relations to derive a contradiction by exhibiting an adversary simulator $\mathcal{A}'$ that, without access to the target ciphertext and without mounting any kind of chosen ciphertext attack against $\mathcal{S}$, does (negligibly close to) as well as $\mathcal{A}$ at breaking $\mathcal{S}$ (in the malleability sense).

Let E' be an encryption key in $\mathcal{S}'$. Let $\mathcal{B}$ be as described above. $\mathcal{B}$ generates an encryption key E in $\mathcal{S}$, invokes $\mathcal{A}$ on E to obtain a message distribution $\mathcal{M}$, and outputs $\mathcal{M}$. $\mathcal{B}$ is then given a ciphertext $c' = E'(m)$ for $m \in_R \mathcal{M}$, generates a ciphertext $c = E(m)$, and presents E and c to $\mathcal{A}$. If $\mathcal{A}$ produces valid encryptions $E(\beta_i)$ s.t. $E(\beta_i) \neq E(m)$, then by Lemma 3.3, $\mathcal{B}$ can extract the β_i. Let $\beta = (\beta_1, \beta_2, \ldots)$. Let R be any probabilistic polynomial-time computable relation. By Lemma 3.4, the

probability that $R(m, \beta, \sigma)$ holds is subpolynomially close to $\pi(\mathcal{A}, R)$.

Recall the definition of semantically secure with respect to relations: There exists a procedure $\mathcal{B}'$ that "does as well" as $\mathcal{B}$ at producing messages related to m, in the following sense. On input $(E', 1^n)$, $\mathcal{B}'$ outputs a message distribution $\mathcal{M}'$; $m' \in_R \mathcal{M}'$ is selected, but $\mathcal{B}'$ is not given access to the ciphertext for m', just the hint $\text{hist}(m')$. $\mathcal{B}'$ generates β', σ'. The definition of semantic security with respect to relations guarantees that for every $\mathcal{B}$ there exists $\mathcal{B}'$ such that $|\Pr[R(m, \beta, \sigma)] - \Pr[R(m', \beta', \sigma')]| \leq \nu(n)$, where the probabilities are over the choice of public key, the coin-flips of $\mathcal{B}$ and $\mathcal{B}'$, respectively, the choices of m and m', and the coin-flips in creating the encryption of m. Note that we are *rerandomizing* the public key: it is chosen afresh for each probability.

We use $\mathcal{B}'$ to define the adversary simulator $\mathcal{A}'$ whose existence is mandated by the definition of nonmalleability under chosen ciphertext postprocessing. On input $(E, 1^n)$, $\mathcal{A}'$ ignores E and selects a public key for an instance E' of $\mathcal{S}'$ (with security parameter n). It then runs $\mathcal{B}'$ on $(E', 1^n)$ to select a message space $\mathcal{M}'$. $\mathcal{A}'$ outputs $\mathcal{M}'$. A message $m' \in_R \mathcal{M}'$ is chosen, and $\mathcal{A}'$ is given $\text{hist}(m')$, which it forwards to $\mathcal{B}'$. $\mathcal{B}'$ outputs (β', σ'), where $\beta' = (\beta'_1, \beta'_2, \ldots)$ is a vector of *plaintexts*. $\mathcal{A}'$ outputs the vector of *encryptions* $E(\beta) = (E(\beta'_1), E(\beta'_2), \ldots)$, together with σ'.

Clearly $\pi'(\mathcal{A}', R) = \pi'(\mathcal{B}', R)$, where the first term is the probability that $\mathcal{A}'$ succeeds at producing $E(\beta', \sigma')$ such that $R(m', \beta', \sigma')$ and the second term is the probability that $\mathcal{B}'$ succeeds at the same task.

By choice of $\mathcal{B}'$ $|\pi'(\mathcal{B}', R) - \pi(\mathcal{B}, R)|$ is negligible. This, together with Lemma 3.4 and the fact that $\pi'(\mathcal{A}', R) = \pi'(\mathcal{B}', R)$, implies that $|\pi(\mathcal{A}, R) - \pi'(\mathcal{A}', R)| \leq \nu(n)$. Therefore $(\mathcal{A}, R)$ cannot witness the malleability of $\mathcal{S}$. □

COROLLARY 3.6. *If there exists a public-key cryptosystem semantically secure against chosen plaintext attack and if noninteractive zero-knowledge satisfying the requirements of Definition* 2.7 *is possible, then there exists a nonmalleable public-key cryptosystem secure against CCA-post. In particular, if trapdoor permutations exist, then such cryptosystems exist.*

An interesting open problem is whether one can rely on the existence of a public-key cryptosystem semantically secure against chosen plaintext attacks alone to argue that nonmalleable public-key cryptosystems secure against CCA-posts exist. Two assumptions that are known to be sufficient for semantically secure public-key cryptosystems secure against plaintext attacks but where the existence of the stronger kind of cryptosystems is not clear are the hardness of the Diffie–Hellman (search) problem and the unique shortest vector problem (used in the Ajtai–Dwork cryptosystem [1]).

3.4. Remarks.

3.4.1. On vectors of encryptions. 1. We have defined nonmalleable public-key encryptions to cover the case in which $\mathcal{A}$ produces a vector of encryptions $(E(\beta_1), \ldots, E(\beta_n))$, having been given access to only a *single* $E(\alpha)$. It is natural to ask, what happens if $\mathcal{A}$ is given access to encryptions of *multiple* α's, $(E(\alpha_1), \ldots, E(\alpha_n))$. Security under this type of composition is, intuitively, a sine qua non of encryption. A simple "hybrid" argument shows that *any* nonmalleable public key cryptosystem is secure in this sense: seeing the encryptions of multiple α's does not help the adversary to generate an encryption of even one related β.

2. The computational difficulty of generating a single $E(\beta)$ for a related β does not imply the computational difficulty of generating a vector $(E(\beta_1), \ldots, E(\beta_n))$ such that $R(\alpha, \beta_1, \ldots, \beta_n)$ holds. We next describe a counterexample in the case of a CCA-pre. Let E' be a nonmalleable cryptosystem under CCA-pre. Let $E(m)$ be constructed

as $(E'_0(m_0), E'_1(m_1))$, where $m = m_0 \oplus m_1$. Given a ciphertext of this form, the adversary can construct two ciphertexts: $(E'_0(m_0), E'_1(0))$ and $(E'_0(0), E'_1(m_1))$. The parity of the two decrypted values is $(m_0 \oplus 0) \oplus (0 \oplus m_1) = m_0 \oplus m_1 = m$. On the other hand, it can be shown from the nonmalleability of the E'_i that seeing $E(m)$ is of no assistance in generating *a single* encryption $E(m')$ s.t. $R(m, m')$.

3.4.2. Security taxonomy and comparisons. We have discussed two notions of breaking a cryptosystem, semantic security and nonmalleability, and three types of attacks:

- Chosen plaintext,
- chosen ciphertext attack in the preprocessing mode, and
- chosen ciphertext attack in the postprocessing mode.

This yields six types of security, and the question is whether they are all distinct and which implications exist. Two immediate implications are (i) nonmalleable security implies semantic security under the same type of attack, and (ii) security against CCA-post implies security against CCA-pre which in turn implies security against chosen plaintext attacks, using the same notion of breaking the cryptosystem. We now explore other possibilities—the discussion is summarized in Figure 3.1.

The first observation is that if a cryptosystem is *semantically secure* against CCA-post, then it is also *nonmalleable* against CCA-post, since the power of the adversary allows it to decrypt whatever ciphertext it generated. On the other hand, it is not difficult to start with a cryptosystem that is secure against CCA-pre and make it only secure against a chosen plaintext attack (under any notion of breaking), as we now explain. For the case of semantic security, simply add to the decryption mechanism the instruction that on input all 0's output the private key.

The case of nonmalleable security is more subtle. Choose a fixed random ciphertext c_0, and instruct the decryption mechanism to output the decryption key when presented with input c_0. In addition, instruct the decryption mechanism to output c_0 on input all 0's.

There is a simple method for "removing" nonmalleability without hurting semantic security: starting with a cryptosystem that is nonmalleable against CCA-pre, one can construct a cryptosystem that is only semantically secure against CCA-pre—add to each ciphertext a cleartext bit whose value is Xor-ed with the first bit of the plaintext. Thus, given a ciphertext of a message m it is easy to create a ciphertext of a message where the last bit is flipped, so the scheme is malleable. However, the semantic security remains, as long as the adversary does not have access to the challenge ciphertext while it can access the decryption box.

We do not know whether a scheme that is nonmalleable against CCA-pre is also nonmalleable against CCA-post. We conjecture that whenever deciding whether or not a string represents a legitimate ciphertext (that could have been generated by any user) is easy (to someone *not* holding the private key), nonmalleability implies semantic security against CCA-post. From the above discussion (summarized in Figure 3.1), we conclude that of the six possibilities for security of a cryptosystem (combinations of the type of attack and notion of breaking), we have that either four or five are distinct.[8]

Note that the type of combination to be used depends on the application. For instance, for the bidding example given in the introduction, if the public key is *not*

[8]For a very recent discussion of the relationship between these notions, see Bellare et al. [3], where they show that there are indeed five distinct possibilities.

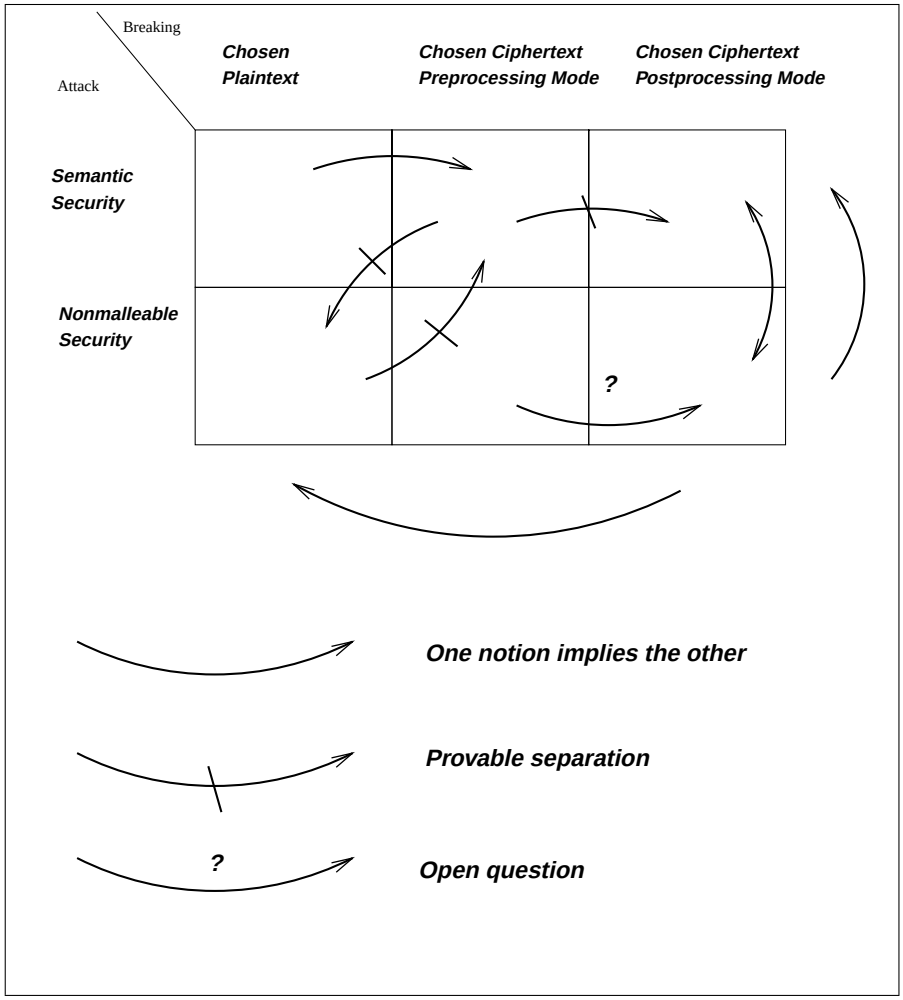

FIG. 3.1. *Relationship between security notions.*

going to be used for bidding on more than a single contract, and assuming the bids are not secret after the bids are opened, then the type of security needed is *nonmalleability against chosen plaintext attacks.* If the same public key is to be used for bidding on several contracts successively but the secrecy of nonwinning bids need not be preserved, then nonmalleability under chosen ciphertext in the preprocessing mode is required. On the other hand, if the same public key is to be used for bidding on several contracts, and the secrecy of nonwinning bids must be preserved, one should use a nonmalleable cryptosystem secure against CCA-post.

Finally, one may wonder what is the "correct" description of the notion of breaking a cryptosystem secure against CCA-post: semantic security or nonmalleable security, given their equivalence under this attack. We think it is more helpful to think in terms of nonmalleability, since the way to think about trying to break a candidate system is to think of trying to maul the target ciphertext(s). This was done (without the vocabulary of nonmalleability) in the recent work by Bleichenbacher [11] (see section 6).

3.4.3. On allowing $\mathcal{A}'$ to choose $\mathcal{M}'$. Having $\mathcal{A}'$ choose $\mathcal{M}'$, rather than inheriting $\mathcal{M}' = \mathcal{M}$ from $\mathcal{A}$, makes the adversary simulator *weaker*: the real adversary $\mathcal{A}$ is allowed to mount a chosen ciphertext attack before choosing its target distribution $\mathcal{M}$, while the adversary simulator $\mathcal{A}'$ must choose $\mathcal{M}'$ without the benefit of such an attack. Since the adversary simulator is weaker, $\forall\mathcal{A}\exists\mathcal{A}' \ldots$ becomes a stronger requirement on the cryptosystem. Our cryptosystem satisfies this strong requirement.

3.5. Public-key authentication. In this section we informally describe a method for obtaining a public-key authentication scheme based on any nonmalleable public-key cryptosystem. Our goal is to demonstrate a "real" protocol that allows cheating in case the public-key cryptosystem used is malleable.

In a public-key authentication scheme, an authenticator A chooses a public key E. The scheme permits A to *authenticate* a message m of her choice to a second party B. Similar to a digital signature scheme, an authentication scheme can convince B that A is willing to authenticate m. However, unlike the case with digital signatures, an authentication scheme need not permit B to convince a third party that A has authenticated m.

Our notion of security is analogous to that of *existential unforgeability under an adaptive chosen plaintext attack* for signature schemes [45], where we must make sure to take care of "man-in-the-middle" attacks. Let $\langle (A,B),(C,D),\ \mathcal{A} : \psi(B) \leftrightarrow \psi(C)\rangle$ be an adversarially coordinated system in which $(A,B) = (C,D)$ is a public-key authentication protocol. We assume that A is willing to authenticate any number of messages $m_1, m_2, \ldots$, which may be chosen adaptively by $\mathcal{A}$. We say that $\mathcal{A}$ successfully attacks the scheme if $\psi(C)$ (under control of $\mathcal{A}$ and pretending to have A's identity) succeeds in authenticating to D a message $m \neq m_i$, $i = 1, 2, \ldots$.

Protocol $\mathcal{P} = (A, B)$ for A to authenticate message m to B. A's public key is E, chosen according to $\mathcal{S}$, a nonmalleable public-key cryptosystem secure against CCA-post (e.g., the one from section 3.2).

1. A sends to B: "A wishes to authenticate m." (This step is unnecessary if m has previously been determined.)
2. B chooses $r \in_R \{0,1\}^n$ and computes and sends the "query" $\gamma \in_R E(m \circ r)$ to A.
3. A decrypts γ and retrieves r and m. If the decryption is of the right format (i.e., the first component of the decrypted pair corresponds to the message that is to be authenticated), then A sends r to B.

LEMMA 3.7. *Given an adversary $\mathcal{B}$ that can break the authentication protocol $\mathcal{P}$ with probability ρ, one can construct an adversary $\mathcal{A}$ for breaking the (presumed nonmalleable) encryption scheme E with probability at least $\rho/p(n) - 2^{-n}$ for some polynomial p.*

Proof. The procedure for $\mathcal{A}$ to attack the cryptosystem is as follows. Assume A's public key is E and that the adversary $\mathcal{A}$ has access to a decryption box for E. Therefore $\mathcal{A}$ can simulate the system $\langle (A,B),(C,D),\ \mathcal{B} : \psi(B) \leftrightarrow \psi(C)\rangle$, where $(A,B) = (C,D) = \mathcal{P}$. Note that since this is a simulation, $\mathcal{A}$ can control the messages sent by $\psi(D)$ in the simulation. Run the system $\langle (A,B),(C,D),\ \mathcal{B} : \psi(B) \leftrightarrow \psi(C)\rangle$ until $\psi(C)$, under control of $\mathcal{B}$, is about to authenticate to D a message $m \neq m_i$, $i = 1, 2 \ldots$ not authenticated by A. (In case it is not clear whether D accepts or not, then we just guess when this occurs, whence the polynomial degradation of ρ.) The distribution $\mathcal{M}$ on messages that $\mathcal{A}$ will attempt to maul is $\mathcal{M}_m = \{(m,r) | r \in_R \{0,1\}^n\}$. Given γ as the challenge ciphertext, $\mathcal{A}$ lets $\psi(D)$ send the query γ in the simulation. Let r' be $\psi(C)$'s reply. $\mathcal{A}$ outputs $\theta \in_R E(m \circ r')$.

The distribution that $\mathcal{B}$ sees in the simulation of the adversarially coordinated system $\langle (A,B),(C,D),\ \mathcal{B} : \psi(B) \leftrightarrow \psi(C)\rangle$ is exactly as usual. Therefore by assumption the probability of success in authenticating m is ρ, and with probability ρ the value r' is the correct one. The relation that is violated is equality: θ and γ encrypt the same string, whereas given the distribution $\mathcal{M}_m$ the probability of producing the correct r without access to $E(m \circ r)$ is 2^{-n}. □

This solution will be of practical use as soon as the current constructions of nonmalleable cryptosystems are improved to be more practical [28]. The very recent construction of Cramer and Shoup [23] (see section 6 of this paper) makes this scheme very attractive.

REMARK 3.8. *If the cryptosystem $\mathcal{S}$ is malleable, and in particular if given an encryption of a message $\lambda \circ r$ it is easy (possibly after mounting a CCA-post or other type of attack) to generate an encryption of a message $\lambda' \circ r$, where $\lambda' \neq \lambda$ (many cryptosystems have this property), then there is a simple attack on the protocol proposed: as before $\psi(C)$ is pretending to be $\psi(A)$. To forge an authentication of a message m, when D sends challenge $\gamma = m \circ r$, $\psi(B)$ asks A to authenticate a message m' by sending the challenge $\gamma' = m' \circ r$. When A replies with r, $\psi(C)$ sends r to D, who will accept.*

REMARK 3.9. *As mentioned above, this protocol provides a weaker form of authentication than digital signatures (no third party verification). However, this can be viewed as a feature: there may be situations in which a user does not wish to leave a trace of the messages the user authenticated ("plausible deniability"). We do not know whether the protocol presented is indeed zero-knowledge in this sense, i.e., that the receiver could have simulated the conversation alone (although it is almost surely not black-box zero-knowledge* [38]*). By adding a (malleable) proof of knowledge to the string r this can be ensured in the sequential case. We do not know if the resulting zero-knowledge authentication protocol remains zero-knowledge if many executions with the same authenticator execute* concurrently*. The straightforward simulation fails. (See* [51] *for impossibility results for 4-round black-box concurrent zero-knowledge protocols.) Very recently, an approach for achieving deniable authentication in the concurrent setting based on* timing constraints *was suggested by Dwork, Naor, and Sahai* [29]*, who also present several efficient protocols in the standard model (no timing) for the sequential case.*

3.6. Nonmalleable encryption in other settings. In this section we briefly mention nonmalleable encryption in two additional settings: private-key cryptography and interactive public-key cryptography. In both cases we begin with a known semantically secure system and add authentication to achieve nonmalleability.

Private-key encryption. As mentioned in the beginning of section 3, the definition of nonmalleable security is applicable for private (or shared) key cryptography as well. For example, in their celebrated paper on a logic of authentication [16], Burrows, Abadi, and Needham give the following analysis of a scenario (the Needham–Schroeder authentication protocol) in which A and B share a key K_{AB}. Party B chooses a nonce N_b and sends an encryption of N_b under K_{AB} to A. A then responds with an encryption of $N_b - 1$ under K_{AB} in order for B

> "... to be assured that A is present currently ... Almost any function of N_b would do as long as B can distinguish his message from A's—thus, subtraction is used to indicate that the message is from A, rather than from B."

The unproved and unstated assumption here is that K_{AB} provides nonmalleable encryption; malleability completely destroys their reasoning and their proof of security, *even if the adversary's access to the system is very limited* (i.e., an attack weaker than CCA-pre).

Achieving nonmalleability in the private-key setting is much simpler and more efficient than in the public-key setting. Let K_{AB} be a private key shared by A and B. We first describe a system that is semantically secure against CCA-pre: Treat K_{AB} as (K_1, K_2) which will be used as seeds to a pseudorandom function f (see [37] for definition of pseudorandom functions, [56, 57] for recent constructions, and [58] for a recent discussion on using pseudorandom functions for encryption and authentication). In order to encrypt messages which are n bits long we need a pseudorandom function $f_K : \{0,1\}^\ell \mapsto \{0,1\}^n$, i.e., it maps inputs of length ℓ to outputs of length n, where ℓ should be large enough so as to prevent "birthdays," i.e., collision of randomly chosen elements. For A to send B a message m, A chooses a random string $r \in \{0,1\}^\ell$ and sends the pair $(r, m \oplus f_{K_1}(r))$. Semantic security of the system against CCA-pre follows from the fact that the pseudorandom function is secure against *adaptive* attacks. However, this scheme is *malleable* and not secure against CCA-post: given a ciphertext (r, c) one can create a ciphertext (r, c'), where c' is obtained from c by flipping the last bit. This implies that the corresponding plaintext also has its last bit flipped. In order to thwart such an attack we employ another pseudorandom function $g_k : \{0,1\}^{n+\ell} \mapsto \{0,1\}^\ell$ and add a third component to the message:

$$g_{K_2}(r \circ (m \oplus f_{K_1}(r))).$$

When decrypting a message (r, c, a), one should first verify that the third component, a, is indeed proper, i.e., $a = g_{K_2}(r \circ c)$. This acts as an *authentication tag* for the original encryption and prevents an adversary from creating any other legitimate ciphertext, except the ones he was given explicitly. (Recall that by definition of a pseudorandom function, seeing any number of pairs $(r, f_{K_2}(r))$ does not yield any information about $(r', f_{K_{AB}}(r'))$ for any new r' and in particular they are unpredictable.)

Since it is known that the existence of one-way functions implies the existence of pseudorandom functions [37, 48] we have the following theorem.

THEOREM 3.10. *If one-way functions exist, then there are nonmalleable private-key encryption schemes secure against CCA-post.*

Since it is known that in order to have private-key cryptography we must have one-way functions [47], we conclude the following corollary.

COROLLARY 3.11. *If any kind of private-key encryption is possible, then nonmalleable private-key encryption secure against CCA-post is possible.*

Note that the property of "self-validation" enjoyed by the above construction is stronger than needed for nonmalleability, i.e., there are nonmalleable cryptosystems that do not have this property: one can start with a nonmalleable private-key cryptosystem and add to it the possibility of encryption using a pseudorandom permutation; this possibility is never (or rarely) used by the legitimate encrypter but may be used by the adversary. The resulting cryptosystem is still nonmalleable but not self-validating, since the adversary can create ciphertexts of random messages.

For a recent application of the above construction to the security of remotely keyed encryption, see Blaze, Feigenbaum, and Naor [10].

Interactive encryption. The second setting resembles the one studied by Goldwasser, Micali, and Tong [46], in which they constructed an *interactive* public-key

cryptosystem secure against chosen ciphertext attack (see also [34, 67]). An "interactive public-key cryptosystem" requires a public file storing information for each message recipient, but this information alone is not sufficient for encrypting messages. The additional information needed is chosen interactively by the sender and receiver. To the best of our knowledge, their paper was the first to try to cope with an oracle for distinguishing valid from invalid ciphertexts in any setting (interactive or not). An interactive system is clearly less desirable than what has now come to be called "public-key cryptography," in which the public key *is* sufficient for sending an encrypted message, without other rounds of interaction.

The definitions of nonmalleable security can be easily adapted to this case, but when discussing the attack there is more freedom for the adversary, due to the interactive nature of the communication. In general, we assume that the adversary has complete control over the communication lines and can intercept and insert any message it wishes. A precise definition is outside the scope of this paper.

Our nonmalleable interactive public-key cryptosystem requires a digital signature scheme that is *existentially unforgeable against a chosen message attack* (see the introduction for an informal definition of existential unforgeability). Let (S_i, P_i) denote the private/public signature keys of player i (the model assumes that there is a public directory containing P_i for each player i that is to *receive* messages, but the sender is *not* required to have a key in the public directory). The system will also use a public-key cryptosystem semantically secure against chosen plaintext attacks.

The idea for the system is straightforward: for each interaction the receiver chooses a fresh public-key/private-key pair that is used only for one message. However, this is not sufficient, since an active adversary may intercept the keys and substitute its own keys. We prevent this behavior by using signatures. A sender j wishing to send a message m to receiver i performs the following:

1. Sender j chooses a *fresh* private/public pair of signature keys (s_j, p_j) and sends the public part, p_j, to i (lower case is used to distinguish p_j from what is in the directory);
2. Receiver i chooses a *fresh* private/public pair of *encryption and decryption* keys (E_{ij}, D_{ij}), where E_{ij} is *semantically secure against chosen plaintext attack*, and sends E_{ij} together with $S_i(E_{ij} \circ p_j)$ (i.e., a signature on the fresh public key E_{ij} concatenated with the public signature key j chose) to j; j verifies the signature and that p_j is indeed the public key it sent in step 1.
3. Sender j encrypts m using E_{ij} and sends $E_{ij}(m)$ together with $s_j(E_{ij}(m))$ to i. Receiver i verifies that the message encrypted with E_{ij} is indeed signed with the corresponding p_j.

Note that the sender may use a one-time signature scheme for (s_j, p_j), and if the receiver uses a signature scheme such as in [27, 22], then the approach is relatively efficient.

4. A nonmalleable scheme for string commitment. We present below a scheme $\mathcal{S}$ for string commitment that is nonmalleable with respect to itself (Definition 2.8). We first present $\mathcal{S}$ and show some properties of $\mathcal{S}$ important in proving its security. We then describe a knowledge extractor algorithm that works not on $\mathcal{S}$ but on $\mathcal{S}'$ which is a (malleable) string commitment protocol with a very special relation to $\mathcal{S}$: knowledge extraction for $\mathcal{S}'$ implies nonmalleability of $\mathcal{S}$. Thus, in this section, the new $\mathcal{S}'$ plays a role analogous to the role of $\mathcal{S}'$ in section 3.

Our nonmalleable scheme for string commitment requires as a building block a (possibly malleable) string commitment scheme. Such a scheme, based on pseudo-

random generators, is presented in [55] (although any computational scheme will do). The protocol described there is interactive and requires two phases: first the receiver sends a string and then the sender actually commits. However, the first step of the protocol can be shared by all subsequent commitments. Thus, following the first commitment, we consider string commitment to be a one-phase procedure. In what follows, when we refer to the string commitment in [55], we consider only the second stage of that protocol.

We also require *zero-knowledge proofs* satisfying the security requirements in [35]. These can be constructed from any bit commitment protocol [40].

Before we continue it would be instructive to consider the protocol of Chor and Rabin [21]. They considered the "usual" scenario, where all n parties know of one another and the communication is synchronous and proceeds in rounds. Their goal was for each party to prove to all other parties possession of knowledge of a decryption key. Every participant engages in a sequence of proofs of possession of knowledge. In some rounds the participant acts as a prover, proving the possession of knowledge of the decryption key, and in others it acts as a verifier. The sequence is arranged so that every pair of participants A, C is separated at least once, in the sense that there exists a round in which C is proving while A is not. This ensures that C's proof is independent of A's proof.

Running this protocol in our scenario is impossible; for example, (1) we make no assumptions about synchrony of the different parties, and (2) in our scenario the parties involved do not know of one another. However, we achieve a similar effect to the technique of Chor and Rabin by designing a carefully ordered sequence of actions a player must make, as a function of an identifier composed of its external identity, if one exists, and some other information described below.

4.1. The nonmalleable string commitment scheme $\mathcal{S}$. Protocol $\mathcal{S}$ consists of two general stages. The first is a string commitment as in [55]. The second stage, basic commit with knowledge, consists of the application of many instances of a new protocol, called **BCK**, to the string committed to in the first stage.

Following the commit stage of two string commitment protocols, deciding whether they encode the same string is in NP. Therefore there exists a zero-knowledge proof for equality of two committed values. This will be used repeatedly during each execution of **BCK**, which we now describe. In the following, n is a security parameter.

Protocol BCK(α) (assumes the committer has already committed to α). Concurrently run n instances of the following three steps. All instances of each step are performed at once.

- **BCK**1 (commit): Committer selects random $x_0, x_1 \in \{0,1\}^k$, where $k = |\,\alpha\,|$, and commits to both of them using the protocol in [55].
- **BCK**2 (challenge): Receiver sends committer a random bit $r \in \{0,1\}$.
- **BCK**3 (response): Committer reveals x_r and $x_{1-r} \oplus \alpha$, and engages in a proof of consistency of $x_{1-r} \oplus \alpha$ with the initial commitment to α and the commitment to x_{1-r} in **BCK**1. The proof of consistency with the initial commitment is done for all n instances together as a single statement.

The interactive proof in **BCK**3 is a proof of consistency; it need not be proof of knowledge in the sense of [31].

REMARK 4.1. *From $\alpha \oplus x_{1-r}$, x_{1-r}, and the proof of consistency, one can obtain α. This is why we call the protocol Basic Commit with Knowledge (of α).*

Note also that the interactive proof is of consistency; it is not a proof of knowledge in the sense of [31].

(A, B) **interaction**	(C, D) **interaction**
BCK1(α)	
	BCK1(β)
	BCK2(β)
BCK2(α)	
BCK3(α)	
	BCK3(β)

FIG. 4.1. **BCK**(α) *is useful to* **BCK**(β).

In the rest of the section we consider each **BCK***i* as single operation, thus it can be viewed as an operation on an n-dimensional vector or array. Note that **BCK**1 and **BCK**2 are indeed "instantaneous," in that each requires a single send, while **BCK**3, due to its interactive nature, requires more time to carry out. We frequently refer to an instance of **BCK** as a *triple.*

In the **BCK** stage of $\mathcal{S}$ we apply **BCK** repeatedly for the same string, α. However, **BCK** may itself be malleable. To see this, conceptually label the three steps of **BCK** as commitment, challenge, and response, respectively. Consider an $\langle (A, B), (C, D),\ \mathcal{A} : \psi(B) \leftrightarrow \psi(C) \rangle$ in which $(A, B) = (C, D) =$ **BCK**. Then $\psi(C)$ can make its commitment depend on the commitment of $\psi(A)$, $\psi(B)$ can make its challenge to $\psi(A)$ depend on the challenge that $\psi(D)$ poses to $\psi(C)$, and $\psi(C)$ can respond to the challenge with the "help" of $\psi(A)$'s response to $\psi(B)$ (see Figure 4.1 for the timing of events). In this case the triple between $\psi(A)$ and $\psi(B)$ is, intuitively, useful to $\psi(C)$. The **BCK** stage of $\mathcal{S}$ interleaves executions of **BCK** so as to ensure that in every execution there is some triple for which no other triple is useful. This is analogous to Chor and Rabin ensuring that for every pair of participants A, C there exists a round in which C is proving knowledge while A is not. We say such a triple is *exposed* (defined precisely below). This is the key idea in the construction.

The next two *sixplet* protocols perform a pair of distinct instances of **BCK**(α) in two different interleaved orders. To distinguish between the two instances of **BCK** we will refer to the operation taking place at each stage and the associated variables. Thus α_i and α_{i+1} are two distinct applications of **BCK**. These sixplet protocols will be used to ensure the existence of an exposed triple in the **BCK**. The intention of the spacing of the presentation is to clarify the difference between the protocols. It has no meaning with respect to the execution of the protocols.

0**-sixplet**	1**-sixplet**
BCK1(α_i)	**BCK**1(α_i)
BCK2(α_i)	
BCK3(α_i)	**BCK**1(α_{i+1})
	BCK2(α_{i+1})
BCK1(α_{i+1})	**BCK**3(α_{i+1})
BCK2(α_{i+1})	
BCK3(α_{i+1})	**BCK**2(α_i)
	BCK3(α_i)

The difference between the two protocols is the order in which we interleave the stages of the two distinct instances of the **BCK** protocol.

Using these sixplets, we can present the scheme $\mathcal{S}$. The identifier I used in the scheme is the concatenation of the original identity with the commitment for α at stage 1 (by the "commitment" we mean a transcript of the conversation). I_j denotes the jth bit of I. To force an exposed triple we will use the fact that every two identifiers differ in at least one bit. This is exactly the same fact that was exploited by Chor and Rabin in the synchronous "everyone-knows-everyone" model to enforce the condition that for every pair of provers $A \neq C$, there is a round in which C is proving but A is not [21]. The same fact is used in both cases for the same purpose, but we do it without any assumption of synchrony and without any assumption that each processor knows of all other processors in the system.

$\mathcal{S}$: Nonmalleable commitment to string α.

- Commit to α (e.g., using the protocol in [55]).
- For $j = 1$ to $|\, I \,|$
  Execute an I_j-sixplet
  Execute a $(1 - I_j)$-sixplet

  End

For simplicity we will assume that all identifiers I are n bits long. Each I_j-sixplet and each $(1 - I_j)$-sixplet involves two executions of **BCK**, and each of these in turn requires n concurrent executions of **BCK**1, followed by n concurrent executions of **BCK**2 and then of **BCK**3. Thus, a nonmalleable string commitment requires invoking each **BCK**i a total of $4n^2$ times.

4.2. Properties of $\mathcal{S}$. We now show some properties of $\mathcal{S}$ that allow us to prove its nonmalleability. Suppose that $(A, B) = (C, D) = \mathcal{S}$, and suppose further that adversary $\mathcal{A}$ controls $\psi(B)$ and $\psi(C)$. Let x be the identifier used by $\psi(A)$ and y that used by $\psi(C)$. If the original identities of $\psi(A)$ and $\psi(C)$ are different or if the strings to which they commit are different, then $x \neq y$. (Thus the only case not covered is copying.) Note also that, given the proofs of consistency, both sender and receiver know at the end of the commitment protocol whether or not the sender has succeeded in committing to a well-defined value. Thus, the event of *successful commitment to some value* by $\psi(C)$ is independent of the value committed to by $\psi(A)$.

Each run of the two interactions determines specific times at which the two pairs of machines exchange messages. The adversary can influence these times, but the time at which an interaction takes place is well defined. Let σ_x and σ_y be the respective schedules. For $1 \leq i \leq 2n$, let

- τ_1^i be the time at which **BCK**1 begins in the ith instance of **BCK** in σ_x;
- τ_2^i be the time at which **BCK**2 ends in the ith instance of **BCK** in σ_x.

In contradistinction, let

- δ_1^i be the time at which **BCK**1 ends in the ith instance of **BCK** in σ_y;
- δ_2^i be the time at which **BCK**2 begins in the ith instance of **BCK**2 in σ_y.

Finally, let

- τ_3^i and δ_3^i denote the times at which **BCK**3 ends in the ith instances of **BCK** in σ_x and σ_y, respectively.

These values are well defined because each **BCK**i involves sequential operations of a single processor. We do not assume that these values are known to the parties involved—there is no "common clock."

We can now formalize the intuition, described above, of what it means for a triple in σ_x to be useful to a triple in σ_y. Formally, the ith triple in σ_x is *useful* to the jth

triple in σ_y if three conditions hold: (1) $\tau_1^i < \delta_1^i$; (2) $\delta_2^j < \tau_2^i$; and (3) $\delta_3^j > \tau_2^i$ (see Figure 4.1).

Let $\Gamma^{(i)} = \{j \mid \delta_1^j > \tau_1^i \ \wedge \ \delta_2^j < \tau_2^i \ \wedge \ \delta_3^j > \tau_2^i\}$. $\Gamma^{(i)}$ is the set of indices of triples between $\psi(C)$ and $\psi(D)$ for which the ith triple between $\psi(A)$ and $\psi(B)$ can be useful. We say that a triple j is *exposed* if $j \notin \Gamma^{(i)}$ for all i. Our goal is to show that there is at least one exposed triple in any schedule. Intuitively, exposed triples are important because the committer is forced to act on its own, without help from any other concurrent interaction. Technically, exposed triples are important because they allow the knowledge extractor to explore the adversary's response to two different queries, without the cooperation of $\psi(A)$.

CLAIM 4.1. *For all* $i \ |\Gamma^{(i)}| \leq 1$.

Proof. By inspection of the possible interleavings, there exists at most one j for which $\delta_2^j < \tau_2^i$ and $\delta_3^j > \tau_2^i$. □

CLAIM 4.2. *If* $j_1 \in \Gamma^{(i_1)}$, $j_2 \in \Gamma^{(i_2)}$, *and* $j_1 < j_2$, *then* $sixplet(i_1) \leq sixplet(i_2)$, *where* $sixplet(i)$ *denotes the index of the sixplet containing the* i*th triple.*

Proof. Assume to the contrary that $sixplet(i_2) < sixplet(i_1)$. This implies that $\tau_2^{i_2} < \tau_1^{i_1}$. By definition, $j_1 \in \Gamma^{(i_1)}$ implies $\tau_1^{i_1} < \delta_1^{j_1}$. Similarly, $j_2 \in \Gamma^{(i_2)}$ implies $\delta_1^{j_2} < \tau_2^{j_2}$. Thus, $\delta_1^{j_2} < \delta_1^{j_1}$. This contradicts the assumption that $j_1 < j_2$. □

CLAIM 4.3. *Let triples* $2k-1, 2k$ *form a* 0*-sixplet in* σ_x, *and let triples* $2\ell-1, 2\ell$ *form a* 1*-sixplet in* σ_y. *Then there exists a* $j \in \{2\ell-1, 2\ell\}$ *such that neither* $2k-1$ *nor* $2k$ *is useful to triple* j *in* σ_y.

Proof. Assume to the contrary that the claim does not hold. Thus, both triples have a useful triple in $\{2k-1, 2k\}$. By Claim 4.1 $|\Gamma^{(2k-1)}| \leq 1$, and $|\Gamma^{(2k)}| \leq 1$. Therefore, each of the two triples should be useful. A simple look at the time scale implies that for either matching between the pairs, it should be the case that $\tau_1^{2k} < \delta_1^{2\ell}$. Thus, $\tau_2^{2k-1} < \delta_2^{2\ell}$ and $\tau_2^{2k-1} < \delta_2^{2\ell-1}$. This implies that $2k-1$ is not useful to either of the triples, which is a contradiction. □

Notice that the reverse claim does not hold.

LEMMA 4.2. *For any* $x \neq y$ *and for any two sequences* σ_x *and* σ_y, *there exists an exposed triple in* σ_y.

Proof. From Claims 4.1 and 4.2, if none of triples 1 through j are exposed and $j \in \Gamma^{(i)}$, then $sixplet(i) \geq sixplet(j)$. Since $x \neq y$, there exists a bit, say the jth one, at which their IDs differ. Since the scheme uses both an I_j-sixplet and $1-I_j$-sixplet, there exists some k such that the kth sixplet in σ_x is a 0-sixplet while the kth sixplet in σ_y is a 1-sixplet. The lemma now follows from Claim 4.3. □

4.3. The knowledge extractor. Consider an adversarially coordinated system $\langle (A,B),(C,D),\ \mathcal{A} : \psi(B) \leftrightarrow \psi(C) \rangle$, where (A,B) and (C,D) are both instances of $\mathcal{S}$. Intuitively, if $\psi(C)$ succeeds in committing to a string β, then our goal is to extract β. To achieve this we devise a somewhat different protocol, called $\mathcal{S}'$, on which the extractor operates, and from which it extracts β. This new protocol is a string commitment protocol that is not necessarily nonmalleable. In the next section we prove that extraction of β from the $\mathcal{S}'$-adaptor-$\mathcal{S}$ system implies the nonmalleability of $\mathcal{S}$.

The string commitment scheme $\mathcal{S}'$ consists of a committer P and a receiver Q and takes a parameter m. (As we will see, $m = |I| \frac{16}{(\varepsilon^2 \log \varepsilon)}$, where ε is how close we would like the extraction probability to be to the probability of successful completion of the protocol by $\mathcal{A}$.)

Protocol $\mathcal{S}'$: P Commits to a string α.

- Commit to α (e.g., using the protocol in [55]).
- Repeat m times:
  1. Q chooses a bit b and requests a b-sixplet; according to additional inputs, Q requests that the b-sixplet be augmented by an *additional* proof of consistency in step **BCK**3 of either triple in the b-sixplet;
  2. P and Q run a (possibly augmented) b-sixplet.

From the semantic security of the regular string commitment protocol and from the zero-knowledge properties, a simulation argument yields the following lemma.

LEMMA 4.3. *For any strategy of choosing the sixplets and for any receiver Q', the string commitment protocol $\mathcal{S}'$ is semantically secure.* □

We provide an adaptor that allows us to emulate to $\mathcal{A}$ (and its controlled machines) a player A that executes $\mathcal{S}$, whereas in reality $\psi(B)$ (under control of $\mathcal{A}$) communicates with the sender P of $\mathcal{S}'$. $\mathcal{S}'$ has been designed so that it can actually tolerate communicating with many copies of $\mathcal{A}$, with messages from the different copies being "multiplexed" by the adaptor.

In more detail, suppose that player $\psi(P)$ is running the sender part of $\mathcal{S}'$ and that player $\psi(B)$ is supposed to run the receiver part of $\mathcal{S}$. ($\psi(B)$ might deviate from the protocol as written, but the communication steps are as in $\mathcal{S}$.) It is not hard to construct an adaptor that operates between P and B: whenever (A, B) calls for a b-sixplet the adaptor "pretends it is Q" and asks for a b-sixplet; then $\psi(B)$ and $\psi(P)$ run the b-sixplet. It should be clear that the distribution of conversations that $\psi(B)$ sees when it participates in $\mathcal{S}$ and the distribution of conversations it sees when it participates through the adaptor in $\mathcal{S}'$ are identical.

We are now ready to present the extractor. Suppose that in the adversarially coordinated system the probability that $\psi(C)$ completes its part successfully is ρ. Following the commit stage (during which C may or may not have committed in any meaningful way), we cannot in general hope to extract β with probability greater than ρ. However we can get arbitrarily close: we will show that for any ε we can successfully extract β with probability at least $\rho - \varepsilon$.[9]

Fix $\varepsilon > 0$. The knowledge extractor begins to run $\mathcal{S}' = (P, Q)$ and $\mathcal{S} = (C, D)$ with the adaptor arranging that $\mathcal{A}$ cannot distinguish this from the adversarially coordinated system $\langle (A, B), (C, D),\ \mathcal{A} : \psi(B) \leftrightarrow \psi(C) \rangle$ (see Figure 4.2) in which $(A, B) = (C, D) = \mathcal{S}$.

Once $\psi(C)$ completes the first (commitment) stage of $\mathcal{S}$, the extractor freezes the random tape of $\mathcal{A}$.

$\mathcal{A}$ now defines a tree according to all possible messages sent by A and D. The tree contains A-nodes and D-nodes, according to which of the two is the next one to send a message. The root of the tree corresponds to the point at which the tape was frozen. Thus, the branching at each node is all possible messages that either A or D can send at that point. In order to exploit Remark 4.1, we will be interested in D-nodes corresponding to a **BCK**2 step. The branches correspond to the different possible challenge vectors that D can send in this step. In what follows, these are the only types of D-node that we will consider. To enable us to follow more than a single path (that is, to *fork*) in the tree, we keep at each such D-node a snapshot of

[9] The extraction procedure runs in a fixed polynomial time (in n and ε^{-1}) and succeeds only with probability p. This leads to an ε-malleable, which we suspect is sufficient "for all practical purposes." A modification of the procedure runs in *expected* polynomial time and succeeds with probability ρ (the best possible), yielding liberal nonmalleability. See Remark 4.4.

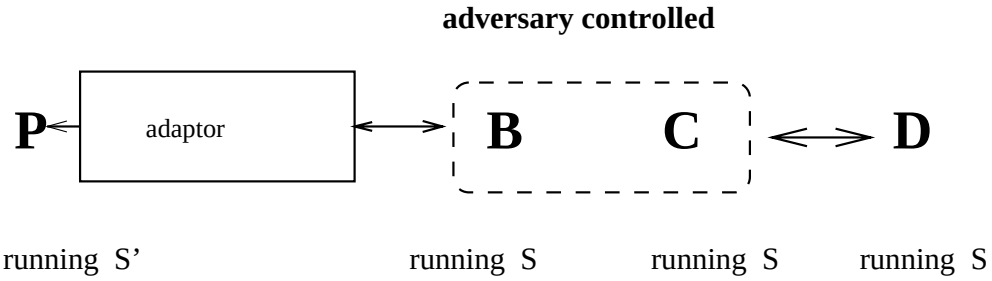

FIG. 4.2. *The $\mathcal{S}'$-adaptor-$\mathcal{S}$ system used in constructing the extractor.*

the current state, i.e., a copy of $\mathcal{A}$'s tapes and the states of A and D.

A node v is *good* if all the communication between C and D up to v is legal (according to the nonmalleable protocol $\mathcal{S}$) and C successfully opened and proved whenever it was asked to do so. Our goal is to identify two nodes having the following properties: (1) at each of the two, C has just completed a **BCK**3 step; (2) the paths to the two nodes depart in a branching at a D-node. As noted in Remark 4.1, given two such nodes we can extract β.

To identify such a pair of nodes, choose $\ell = \frac{16}{(\varepsilon^2 \log \varepsilon)}$, and run the following extraction procedure ℓ times, each time starting again at the root of tree. (Recall that the root of the tree corresponds to the point at which the tape was frozen; we do not restart (C, D) each time the extraction procedure is repeated.)

By Lemma 4.2 every path to a good leaf contains an exposed triple. Run the $\mathcal{S}'$-adaptor-$\mathcal{S}$ system until an exposed triple j in σ_y is reached (or we reach a bad node). We partition the exposed triples into two types according to the interleavings (the interleavings are shown pictorially after the types are formally defined):

- j is of the first type if for all i $\tau_1^i > \delta_1^j$ (nothing happened yet in σ_x between $\psi(A)$ and $\psi(B)$) or for all i s.t. $\tau_1^i < \delta_1^j$ we have $\tau_2^i < \delta_2^j$ (the challenge in σ_x ends before the challenge in σ_y begins).
- j is of the second type if it is not of the first type and for all i s.t. $\tau_1^i < \delta_1^j$ and $\tau_2^i \geq \delta_2^j$ we have $\tau_2^i > \delta_3^j$ (the challenge in σ_x ends after the reply in σ_y ends, so $\psi(C)$ can't use the answers from (A, B) to help it answer challenges from $\psi(D)$).

In the first type of exposure, for each i there are two possible interleavings:

$$\begin{array}{cccccc} \tau_1^i & & & & \tau_1^i & \\ & \delta_1^j & \text{or} & & \tau_2^i & \\ \tau_2^i & & & & & \delta_1^j \\ & \delta_2^j & & & & \delta_2^j \end{array} .$$

Thus, in the first type of exposure, there exists a time t, $\delta_1^j \leq t \leq \delta_2^j$ such that for all i, $\tau_1^i \leq t \Rightarrow \tau_2^i \leq t$. The time t is the maximum of δ_1^j and the maximum over all i such that $\tau_1^i \leq \delta_1^j$, of τ_2^i. In this case, intuitively, for every i such that the values committed to by $\psi(C)$ in **BCK**(j) may depend on the values committed to by $\psi(P)$ in **BCK**(i), the queries made by $\psi(Q)$ to $\psi(P)$ about these values are independent of the queries made by $\psi(D)$ to $\psi(C)$. It follows that $\psi(C)$ can't get any help from $\psi(P)$ in answering $\psi(D)$'s queries in **BCK**(j).

At the point t defined above, P has no triples of which step **BCK**1 has completed but **BCK**2 has not yet ended, and thus A doesn't play a part in $\mathcal{S}$ right now. At this point we fork: the extractor creates a new copy of $\mathcal{A}$ and D, and runs both this copy and the original, with each copy of D making independent random challenges in **BCK**2 of triple j. Note that with overwhelming probability any two such challenge vectors differ in some position. Since at the point t defined above the challenges sent to A in **BCK**2 of triple i are already fixed, the two copies of **BCK**3 of triple i will differ only in the proofs of consistency. The adaptor multiplexes to P the two proofs of consistency. This completes the treatment of the first type of exposed triple.

In the second type of exposed triple, the exposure does not become evident until δ_3^j. At any point in time there are at most two triples between A and B that are *open*, in that step **BCK**1 has been executed but **BCK**2 has not. Say that at δ_1^j the open triple is the ith triple; if there are two open triples then they are the ith and $(i+1)$st ones. We know that $\tau_1^i < \tau_1^{i+1} < \delta_1^j$ and $\tau_2^i > \tau_2^{i+1} > \delta_1^j$ and $\tau_2^i > \delta_3^j$. We distinguish between two cases: (a) $\tau_2^{i+1} < \delta_2^j$ and (b) $\tau_2^{i+1} > \delta_3^j$ (since j is exposed it cannot be the case that $\delta_2^j < \tau_2^{i+1} < \delta_3^j$). We show the interleavings and mark the forking points with asterisks:

Case (a)			**Case (b)**	
τ_1^i			τ_1^i	
τ_1^{i+1}			τ_1^{i+1}	
	δ_1^j			δ_1^j
τ_2^{i+1}				$*$
$*$		or		δ_2^j .
τ_3^{i+1}				δ_3^j
	δ_2^j		τ_2^{i+1}	
	δ_2^j		τ_3^{i+1}	
τ_2^i			τ_2^i	

In Case (a) we fork right after τ_2^{i+1}, running a copy of $\mathcal{A}$ until the conclusion of triple j in the copy.

Although this means there will be two copies of **BCK**3$(i+1)$, they will differ only in their interactive proofs of consistency: the challenges are fixed by time τ_2^{i+1}. (Note that we can assume that $\tau_3^{i+1} < \delta_2^j$ because the replies to the challenges and the statements to be proved by P in **BCK**3$(i+1)$ are completely determined by **BCK**1 and **BCK**2 and are therefore are completely determined by time τ_2^{i+1}. Moreover, the challenges sent in **BCK**2(j) by D are independent of **BCK**2$(i+1)$ because **BCK**2$(i+1)$ ends before **BCK**2(j) starts and D is nonfaulty.) D makes independent challenges in the two runs. We will not run the original beyond δ_3^j. The communication with A is limited in the original execution to the replies to the challenges sent in **BCK**2$(i+1)$ and the zero-knowledge proof of consistency in **BCK**3$(i+1)$. However, since the challenges in the two copies are the same, and since in $\mathcal{S}'$ the committer P is willing to repeat this proof, when running the copy we simply ask for a repeated proof of consistency and continue as before. We stop when the copy finishes **BCK**3 of the jth triple. Note that in the copy the jth triple need not be exposed (this depends on τ_2^i).

Case (b) is simpler: we fork right after δ_1^j. In the original $\psi(B)$ does not communicate with P until δ_3^j, so we simply continue with the copy until it finishes **BCK**3 of the jth triple. Here again we have that j need not be exposed in the copy.

In exploiting either type of exposure, if in both branches (the original and the copy) the proof of consistency in **BCK**3(j) succeeds, then in triple j the extractor obtains the answers to two different and independent queries; hence β can be extracted. The significance of the zero-knowledge proof of consistency is that it allows the extractor to know whether any trial is successful. Therefore if any trial is successful the extractor succeeds. This completes the description of the extractor.

REMARK 4.4. *To remove the dependency on ε, at the expense of running in expected polynomial time, i.e., to obtain liberal nonmalleability (see Remark 2.9), pursue the following strategy. Choose a random path to a leaf in the tree defined above. If the leaf is not good, then abort. Otherwise "extract at all costs." That is, repeat until done:*

1. *Choose a random path to a leaf. If this leaf is good, then add to a set of previously chosen paths.*
2. *For all previously chosen paths (necessarily ending with a good leaf), attempt once (again) to extract as described above.*

We now show that its probability of success is high. At each node v of the tree we can define the probability of success, $\rho(v)$, i.e., the probability that the communication between A and D leads to a good leaf. Let ρ_0 be the probability of success at the root. Notice that by definition, the expected value of ρ_0 is ρ.

LEMMA 4.5. *In each run of the above experiment the value of β is successfully extracted with probability $\rho_0^2/4 - 1/2^{2n}$.*

Proof. Consider a random root-leaf path w in the tree (the randomness is over the coin-flips of A and D). At each node v let $\rho(v)$ denote the probability, taken over choices of A and of D, of successfully completing the execution from v. Let $\rho(w)$ be the minimum along the execution path w. Note that $\rho(w)$ is a random variable.

CLAIM 4.4. *With probability at least $\rho_0/2$ we have $\rho(w) > \rho_0/2$.*

Proof. The probability of failure is $1 - \rho_0$. Let $\mathcal{V}$ be the set of nodes v s.t. $\rho(v) < \rho_0/2$ and for no parent u of v is $\rho(u) < \rho_0/2$ (i.e., $\mathcal{V}$ consists of the "first" nodes s.t. $\rho(v) < \rho_0/2$, and hence no member of $\mathcal{V}$ is an ancestor of another). We know that $\Pr[\rho(w) \le \rho_0/2] \le \sum_{v\in\mathcal{V}} \Pr[v \text{ is reached}]$. On the other hand, the probability of failure, $1 - \rho_0$, is

$$\sum_{v\in\mathcal{V}} \Pr[v \text{ is reached}](1 - \rho(v)) \ge (1 - \rho_0/2) \sum_{v \text{ s.t. } \rho(v)\le\rho_0/2} \Pr[v \text{ is reached}].$$

Therefore $\Pr[\rho(w) \le \rho_0/2] \le \frac{1-\rho_0}{1-\rho_0/2} = 1 - \frac{\rho_0/2}{1-\rho_0/2} < 1 - \rho_0/2$. □

Thus, with probability $\rho_0/2$ the main path we take succeeds. The experiment branches at a point with probability of success $\rho_0/2$. The probability of success of each branch is independent. Therefore, the new branch succeeds with probability $\rho_0/2$. Excluding a small probability $1/2^{2n}$ that both branches choose identical strings, the experiment succeeds with probability $\rho_0^2/4 - 1/2^{2n}$. □

To obtain an analogous result for the liberal nonmalleability extraction procedure outlined in Remark 4.4, consider a random path that yields a good leaf. By Claim 4.4, $\Pr[\rho(w) > \rho/2] \ge 1/2$, that is, with probability 1/2 a good leaf is also a good investment for extraction. Thus the "extract at all costs" procedure runs in expected time $O(1/\rho_0)$ and the probability this extraction is invoked is ρ_0, yielding expected polynomial time (taking the usual precautions against running forever).

Continuing with the proof of ε-malleability, with probability $\rho - \varepsilon/2$, the probability of success at the root, ρ_0, is at least $\varepsilon/2$. The extractor makes ℓ independent

experiments. Because of the proof of consistency, extraction fails only if all experiments fail. This occurs with probability at most $(1 - \frac{\rho_0^2}{4})^\ell$. The choice of ℓ implies that the probability that the extractor succeeds, given that $\rho_0 > \varepsilon/2$, is at least

$$1 - \left(1 - \frac{\rho_0^2}{4}\right)^\ell \geq 1 - \left(1 - \frac{\varepsilon^2}{4}\right)^\ell \geq 1 - \varepsilon/2.$$

Therefore, with probability at least $\rho - \varepsilon$ the string β is extracted in at least one of the ℓ experiments. Thus we can conclude the following lemma.

LEMMA 4.6. *For any adversarially coordinated system $\langle (A,B),(C,D),\ \mathcal{A} : \psi(B) \leftrightarrow \psi(C)\rangle$ in which $(A,B) = (C,D) = \mathcal{S}$, there is a knowledge extraction procedure that succeeds in extracting from the $\mathcal{S}'$-adaptor-$\mathcal{S}$ system the value committed to by $\psi(C)$ with probability arbitrarily close to ρ.* □

We can therefore conclude that, in essence, the values β obtained by the extractor are "correctly" distributed. We would like to say that when β is obtained by the extractor, then for every relation approximator R, the probability that $R(\alpha,\beta)$ outputs 1 is subpolynomially close to $\pi(\mathcal{A},R)$ (the probability that it holds under a "normal" execution). However, in the true execution $\psi(C)$ might make moves that force R to reject (for instance when the real player makes an illegal move or refuses to open with certain probability). This doesn't necessarily imply that the extraction would fail. However, such cases only help us and we can conclude the following corollary.

COROLLARY 4.7. *Let $\alpha \in_R \mathcal{D}$, and let β be obtained by the extractor. Then for every relation approximator R, either* (1) *the probability that $R(\alpha,\beta)$ outputs* 1, *where the probability space is over the choice of α and the internal coin-flips of the machines involved, is larger than $\pi(\mathcal{A},R)$ or* (2) *these two probabilities arbitrarily close.*

4.4. Extraction implies nonmalleability. In this section we reduce the nonmalleability of $\mathcal{S}$ to the semantic security of $\mathcal{S}'$. Let R be a relation approximator and let $\langle (A,B),(C,D),\ \mathcal{A} : \psi(B) \leftrightarrow \psi(C)\rangle$ be an adversarially controlled system, where (A,B) and (C,D) are both instances of $\mathcal{S}$.

Recall that $R(x,x) = 0$ for all relation approximators. We view the goal of $\mathcal{A}$ (respectively, $\mathcal{A}'$) as trying to maximize $\pi(\mathcal{A},R)$ (respectively, $\pi'(\mathcal{A}',R)$). Consider the following procedure for an adversary simulator $\mathcal{A}'$ with access to the probability distribution $\mathcal{D}$ chosen by $\mathcal{A}$, on inputs to $\psi(A)$.

Procedure for $\mathcal{A}'$ on input hist(α).

1. Set $\mathcal{D}' = \mathcal{D}$.
2. Generate $\delta \in_R \mathcal{D}' = \mathcal{D}$.
3. Emulate the system $\langle (A,B),(C,D),\ \mathcal{A} : \psi(B) \leftrightarrow \psi(C)\rangle$ where $\psi(A)$ is running $\mathcal{S}'$ with private input δ and $\mathcal{A}$ has access to hist(α), and if $\psi(C)$ succeeds in committing to a value γ, extract γ.
4. Output γ (that is, give γ as input to $\psi(C)$).

The structure of the proof is as follows. Let $\alpha \in_R \mathcal{D}$. We define three random variables:

1. Let β be the value, if any, committed to by C in an execution of $\langle (A,B),(C,D),\ \mathcal{A} : \psi(B) \leftrightarrow \psi(C)\rangle$ in which A has input α and $\mathcal{A}$ has input hist(α). By definition, for any probabilistic polynomial-time relation approximator R, $\Pr[R(\alpha,\beta)] = \pi(\mathcal{A},R)$.
2. Let β' be obtained by extraction from $\mathcal{A}'$ in a run of the $\mathcal{S}'$-adaptor-$\mathcal{S}$ system in which P has input α and $\mathcal{A}'$ has input hist(α). Let $\tilde{\pi}(\mathcal{A},R) = \Pr[R(\alpha,\beta')]$ Intuitively, this is the probability that $\psi(C)$ commits to something related to

α in an $\mathcal{S}'$-adaptor-$\mathcal{S}$ system in which all parties have the "right" inputs, and this value is successfully extracted.

3. Let β'' be obtained by extraction from $\mathcal{A}'$ in a run of the $\mathcal{S}'$-adaptor-S system in which $\psi(P)$ has input $\delta \in_R \mathcal{D}$ but $\mathcal{A}'$ has input $\text{hist}(\alpha)$. Then $\pi'(\mathcal{A}', R) = \Pr[R(\alpha, \beta'')]$ since this is exactly the setting of the variables when $\mathcal{A}'$ receives as input $\text{hist}(\alpha)$ (see the definition of $\mathcal{A}'$ above).

We will first show that if $|\Pr[R(\alpha, \beta')] - \Pr[R(\alpha, \beta'')]|$ is polynomial, then there is a distinguisher for $\mathcal{S}'$. By the semantic security of $\mathcal{S}'$, this means that $\pi'(\mathcal{A}', R) = \Pr[R(\alpha, \beta'')]$ is very close to $\tilde{\pi}(\mathcal{A}, R) = \Pr[R(\alpha, \beta')]$. In other words, on seeing the history $\text{hist}(\alpha)$, $\mathcal{A}'$, interacting with P having input α, is essentially no more successful at committing to a value related by R to α than $\mathcal{A}'$ can be when it again has history $\text{hist}(\alpha)$ but is actually interacting with P having input δ (unrelated to α). This means that, for $\mathcal{A}'$, having the interaction with P doesn't help in committing to a value related to P's input.

Let us say that $\mathcal{A}'$ *succeeds* in an execution of the $\mathcal{S}'$-adaptor-$\mathcal{S}$ system, if $\psi(C)$ commits to a value related by R to P's input (the value to which P commits). Similarly, we say that $\mathcal{A}$ succeeds in an execution of $\langle (A, B), (C, D),\ \mathcal{A} : \psi(B) \leftrightarrow \psi(C) \rangle$ if $\psi(C)$ commits to a value related by R to A's input. Recall that, by Corollary 4.7, either $\mathcal{A}$ is essentially equally likely to succeed as $\mathcal{A}'$, or $\mathcal{A}$ is less likely to succeed than $\mathcal{A}'$ is. So $\pi(\mathcal{A}, R)$, the probability that $\mathcal{A}$ succeeds, is essentially less than or equal to $\tilde{\pi}(\mathcal{A}, R)$, which we show in the first step of the proof to be close to $\pi'(\mathcal{A}', R)$. From this we conclude the nonmalleability of $\mathcal{S}$.

LEMMA 4.8. *If $|\tilde{\pi}(\mathcal{A}, R) - \pi'(\mathcal{A}', R)|$ is polynomial, then there is a distinguisher for $\mathcal{S}'$ that violates the indistinguishability of committed values.*

Proof. Assume $|\tilde{\pi}(\mathcal{A}, R) - \pi'(\mathcal{A}', R)|$ is polynomial. The distinguisher is as follows.

Distinguisher for $\mathcal{S}'$.

1. Create a random challenge $(\alpha_1 \in_R \mathcal{D}, \alpha_2 \in_R \mathcal{D})$.
2. Choose $i \in_R \{1, 2\}$. Emulate the system $\langle (A, B), (C, D),\ \mathcal{A} : \psi(B) \leftrightarrow \psi(C) \rangle$, where $\psi(A)$ is running $\mathcal{S}'$ with private input α_i and $\mathcal{A}$ has access to $\text{hist}(\alpha_1)$, and extract ζ, the value committed to by $\psi(C)$ in the emulation.
3. Output $R(\alpha_1, \zeta)$.

If, in the emulation, $i = 1$, then the input to $\psi(P)$ is α_1 and so the distinguisher outputs 1 with probability $\tilde{\pi}(\mathcal{A}, R)$. Similarly, if in the emulation $i = 2$, then the input to $\psi(P)$ is α_2, and so the distinguisher outputs 1 with probability $\pi'(\mathcal{A}', R)$. Since by assumption these two quantities differ polynomially, we have a polynomial distinguisher for commitments in $\mathcal{S}'$. □

COROLLARY 4.9. *$|\tilde{\pi}(\mathcal{A}, R) - \pi'(\mathcal{A}', R)|$ is subpolynomial.* □

THEOREM 4.10. *The string commitment scheme $\mathcal{S}$ is* (1) *ε-malleable and* (2) *liberal nonmalleable.*

Proof. (1) By Corollary 4.7, $\pi(\mathcal{A}, R) < \tilde{\pi}(\mathcal{A}, R)$ or the two can be made arbitrarily close. Thus $\mathcal{A}$ is at most ε more likely to successfully commit to a value related by R to the value committed to by $\psi(A)$ than $\mathcal{A}'$ is able to commit to a value related by R to the value committed to by $\psi(P)$. However, by Lemma 4.8, $\pi'(\mathcal{A}', R)$ is subpolynomially close to $\tilde{\pi}(\mathcal{A}, R)$; that is, interacting with P does not help $\mathcal{A}'$ to commit to a value related to the value committed to by $\psi(P)$.

For (2), note that the expected polynomial time extraction procedure described in Remark 4.4 succeeds with probability ρ, so the ε difference disappears. □

REMARK 4.11. *The number of rounds in the above protocol is proportional to the length of I. However, the number of rounds may be reduced to $\log |I|$ using the*

following: Let $n = |I|$. To commit to string α, choose random $\alpha_1, \alpha_2, \ldots, \alpha_n$ satisfying $\bigoplus_{i=1}^{n} \alpha_1 = \alpha$. For each α_i (in parallel) commit to α_i with identity (i, I_i) (i concatenated with the ith bit of the original identity). Let $\mathcal{F}$ (for fewer) denote this string commitment protocol.

To see why $\mathcal{F}$ is secure, consider an adversary with identity $I' \neq I$ who commits to α'. For $I' \neq I$ there must be at least one i such that $I'_i \neq I_i$ (we assume some prefix free encoding). This i implies the nonmalleability of the resulting scheme: Make α_j for $j \neq i$ public. Since all the identities of the form (j, I'_j) are different than (i, I_i) we can extract all the α'_j's and hence α'.

Using this approach, the result of Chor and Rabin [21] *can be improved to require* $\log \log n$ *rounds of communication (down from* $\log n$ *rounds). Recall that their model differs from ours in that they assume all n parties are aware of each other and that the system is completely synchronous.*

REMARK 4.12. 1. *As we have seen, the proofs of consistency aid in the extraction procedure. Interestingly, they also ensure that if there are many concurrent invocations of (A, B), call them $(A_1, B_1), \ldots, (A_k, B_k)$, such that the adversary controls all the $\psi(B_i)$ and $\psi(C)$, then if C commits to a value β to D then β is essentially unrelated to all the α_i committed to by the A_i in their interactions with the B_i. As in section* 3.4.1, *this is shown by a hybrid argument.*

2. *There is a lack of symmetry between our definitions of nonmalleable encryption and nonmalleable string commitment: the first requires that it should be computationally difficult, given $E(\alpha)$, to generate a* vector *of encryptions $(E(\beta_1), \ldots, E(\beta_n))$ s.t. $R(\alpha, \beta_1, \ldots, \beta_n)$ holds, while the second requires only that access to a commitment to a string α should not help in committing to a* single *related string β. It is possible to modify the definition to yield this stronger property. Roughly speaking, we add a fictitious step after the adversary attempts to commit to its values, in which the adversary specifies which successfully committed values will be the inputs to the relation approximator R. The extraction procedure is then modified by first running $\mathcal{S}'$ with a simulation of $\mathcal{A}$ to see which commitments succeed. Then we argue that with high probability the extraction procedure succeeds on all of these. This follows from the high probability of success during any single extraction* (*Lemma* 4.6). *We chose not to use the extended definition because it would complicate the proofs even beyond their current high level of complexity.*

3. *The weaker definition does not imply the stronger one: the protocol $\mathcal{F}$ of Remark* 4.11 *is a counterexample. Let $(A, B) = \mathcal{F}$ and let $\psi(A)$, running $\mathcal{F}$, commit to α by splitting it into $\alpha_1, \ldots, \alpha_n$. Let $(C_1, D_1) = \cdots = (C_n, D_n) = \mathcal{F}$. If the $n+1$ parties $\psi(C_1), \ldots, \psi(C_n)$ have identities such that for each i the ith bit of the identity of $\psi(C_i)$ equals the ith bit of the identity of $\psi(A)$, then the parties $\psi(B), \psi(C_1), \ldots \psi(C_n)$ can collude as follows. Each $\psi(C_i)$ commits to the string $\beta_i = \alpha_i$ by splitting it into $\beta_i = \beta_{i1} \oplus \cdots \oplus \beta_{in}$, where $\beta_{ii} = \alpha_i$ and $\beta_{ij} = 0^{|\alpha_i|}$. In this way the colluding parties can arrange to commit to $\beta_1, \ldots, \beta_n$ such that the exclusive-or of the β's equals α.*

This counterexample also illustrates why the technique for reducing rounds described in Remark 4.11 *cannot be iterated to obtain a constant round protocol.*

5. Zero-knowledge proofs and general nonmalleable zero-knowledge interactions. For the results in this section we assume the players have unique identities. Let $(A, B)[a, b]$ be a zero-knowledge interactive protocol with valid set Π of input pairs. Recall from section 2.1 that (A, B) is *zero-knowledge* with respect to B if for every $\psi(B)$ under control of a polynomial-time bounded adversary $\mathcal{A}$, there exists a simulator *Sim* such that the following two ensembles of conversations are indistin-

guishable. In the first ensemble, $\mathcal{A}$ chooses a distribution $\mathcal{D}$ consistent with Π, a pair (α, β) is drawn according to $\mathcal{D}$, $\psi(A)$ gets α, $\psi(B)$ gets β, and the interaction proceeds and produces a conversation. In the second ensemble, and adversary simulator $\mathcal{A}'$ with the same computational power as $\mathcal{A}$ chooses a distribution $\mathcal{D}'$ consistent with Π, $(\alpha, \beta) \in_R \mathcal{D}'$ is selected, $\mathcal{A}'$ is given β, and produces a simulated conversation.

We construct a compiler $\mathcal{C}$, which, given *any* zero-knowledge interaction (A, B), produces a zero-knowledge protocol which is nonmalleable in the sense described next.

Let (A', B') be any zero-knowledge protocol and let $(A, B) = \mathcal{C}(A', B')$. Let (C', D') be any (not necessarily zero-knowledge) protocol, and let $(C, D) = \mathcal{C}(C', D')$. Consider the adversarially coordinated system $\langle (A, B), (C, D),\ \mathcal{A} : \psi(B) \leftrightarrow \psi(C) \rangle$. Note that, if (A, B) were to be run in isolation, then given the inputs (α, β) and the random tapes of $\psi(A)$ and $\psi(B)$, the conversation between these agents is completely determined. A similar statement applies to (C, D). For every polynomial-time relation approximator R and for every adversarially coordinated system of the compiled versions with adversary $\mathcal{A}$ there exists an adversary simulator $\mathcal{A}'$ satisfying the following requirement.

Let $\mathcal{D}$ now denote a distribution for inputs to all four players chosen by $\mathcal{A}$ consistent with the valid inputs for (A, B). Let $(\alpha, \beta, \gamma, \delta) \in_R \mathcal{D}$, and run the compiled versions of the two protocols. Let $\pi(\mathcal{A}, R)$ denote the probability that $R(\alpha, \beta, \gamma, \delta, \mathcal{D}, \mathcal{K}(C, D)) = 1$, where $\mathcal{K}(C, D)$ denotes the conversation between $\psi(C)$ and $\psi(D)$. The probability is over the coin-flips of $\mathcal{A}, \psi(A)$ and $\psi(D)$ and the choice of $(\alpha, \beta, \gamma, \delta)$ in $\mathcal{D}$. As above, R rejects if a conversation is syntactically incorrect.

Let $\mathcal{D}'$ (consistent with the legal input pairs for (A, B)) be chosen by $\mathcal{A}'$, and let $(\alpha, \beta, \gamma, \delta) \in_R \mathcal{D}'$. $\mathcal{A}'$ gets inputs β, γ. Run an execution of (C, D) in which $\mathcal{A}'$ controls $\psi(C)$, and let $\mathcal{K}'(C, D)$ denote the resulting conversation. Let $\pi(\mathcal{A}', R)$ denote the probability that $R(\alpha, \beta, \gamma, \delta, \mathcal{D}', \mathcal{K}'(C, D)) = 1$. The probability is over the coin-flips of $\mathcal{A}$ and $\psi(D)$ and the choice of $(\alpha, \beta, \gamma, \delta)$ in $\mathcal{D}'$.

The *nonmalleable zero-knowledge* security requirement is that for every polynomial-time bounded $\mathcal{A}$, there exists a polynomial-time bounded $\mathcal{A}'$ such that for every polynomial-time computable relation approximator R $|\pi(\mathcal{A}, R) - \pi'(\mathcal{A}', R)|$ is subpolynomial.

THEOREM 5.1. *There exists a compiler $\mathcal{C}$ that takes as inputs a 2-party protocol and outputs a compiled protocol. Let (A', B') be any zero-knowledge protocol and let $(A, B) = \mathcal{C}(A', B')$. Let (C', D') be any (not necessarily zero-knowledge) protocol, and let $(C, D) = \mathcal{C}(C', D')$. Then the adversarially coordinated system $\langle (A, B), (C, D),\ \mathcal{A} : \psi(B) \leftrightarrow \psi(C) \rangle$ is nonmalleable zero-knowledge secure.*

Proof. Our compiler is conceptually extremely simple: A and B commit to their inputs and random tapes and then execute the protocol (A', B'), at each step proving that the messages sent are consistent with the committed values. We have to make sure that these zero-knowledge proofs of consistency do not interfere with the original protocol. The goal of the preprocessing phases is to make all the players' actions in the rest of the protocol predetermined. We now describe the action of the compiler on (A', B') in more detail.

Preprocessing phase I. Initially A and B choose a random string R_A as follows. A nonmalleably commits to a string σ_A using a sequence of nonmalleable bit commitments. B then sends a random string σ_B. The string R_A, not yet known to B, is the bitwise exclusive-or of σ_A and σ_B. A and B then choose a random string R_B in the same manner, but with the roles reversed, so that B knows R_B while A does not yet know it.

Preprocessing phase II. Each player performs a sequence of pairs of nonmalleable bit commitments. Each pair contains a commitment to zero and a commitment to one, in random order.

Preprocessing phase III. Each player commits to its input and to the seed of a cryptographically strong pseudorandom bit generator, using the nonmalleable scheme for string commitment described in section 4. The pseudorandom sequence is used instead of a truly random sequence whenever the original protocol calls for a random bit. Note in particular that A and B *both* begin with a nonmalleable commitment to their inputs and random tapes—this is critical.

Executing the original protocol. The parties execute the original protocol (with the pseudorandom bits), with each player proving at each step that the message it sends at that step is the one it should have sent in the unique conversation determined by its committed input and random tape, and the messages of the original protocol received so far. The commitments performed as part of the proofs of consistency are selected from the list of pairs of commitments generated in preprocessing step II. Since proving the consistency of the new message with the conversation so far can be done effectively (given the random tape and the input), this has a (malleable) zero-knowledge proof [40] in which the verifier only sends random bits. These random bits are taken from R_A and R_B. In particular, R_A is used as the random bits when B proves something to A: A, acting as verifier and knowing R_A, reveals the bits of R_A to B as they are needed by opening the necessary commitments from preprocessing phase I. The analogous steps are made when A proves consistency to B.

Before sketching the proof, we give some intuition for why we included preprocessing phases I and II. (While it is possible that these extra preprocessing steps are not needed, we do not see a complete proof without them.) First, note that the compiler uses a specific nonmalleable string commitment scheme (the one from section 4), rather than *any* such protocol. We used this protocol because of its extraction properties (which we use for proving nonmalleability). However, as we saw in section 4 in order to do the extraction in an adversarially coordinated system $\langle (A,B),(C,D),\ \mathcal{A} : \psi(B) \leftrightarrow \psi(C) \rangle$ in which $(A,B) = (C,D) = \mathcal{S}$, we needed to define $\mathcal{S}'$, a relaxed version of $\mathcal{S}$, and construct an $\mathcal{S}'$-adaptor-$\mathcal{S}$ system. We do not know how to construct "relaxed versions" of *arbitrary* protocols (A', B'). Since the compiled protocol (A,B) has a very special form, the construction of its relaxation is straightforward.

We now sketch the proof that the compiled protocol satisfies the requirements of the theorem. A's proofs of consistency are zero-knowledge since they use the random bits in R_B and in the simulation of this part of the interaction R_B can be extracted. A's proofs are sound since its bit commitments performed in preprocessing phase II are independent of R_B (since all the commitments are nonmalleable, and in particular, involve proofs of knowledge).

Since A and B commit in preprocessing phase III to their random tapes and values, the parts of the compiled communication that correspond to messages in (A', B') are completely determined before the execution corresponding to the (A', B') interaction is carried out.

Note that the three stage protocol described above remains zero-knowledge. This is true, since under the appropriate definition [41], the sequential composition of zero-knowledge protocols is itself zero-knowledge. So in particular, the (A,B) interaction is zero-knowledge.

Nonmalleable zero-knowledge security is proved as follows. We first note that the commitment of its input and random tape that A makes to B in preprocessing phase III remains nonmalleable despite the proofs of consistency during the execution of the original protocol. We then construct an extractor for the committed value in (C, D) in a fashion similar to the one constructed in section 4. To do this, we construct a "relaxed" zero-knowledge protocol analogous to $\mathcal{S}'$, based on (A, B). We apply Lemma 4.6 to show that the probability of extraction is similar to the probability that $\mathcal{A}$ succeeds (in the compiled (C, D) protocol). The key point is that an exposed triple remains exposed despite the presence of the proofs of consistency because the queries in the proofs of consistency have been predetermined in preprocessing phase I.

As in Lemma 4.8, extraction violates the zero-knowledge nature of (the relaxed) (A, B). □

6. Concluding remarks and future work. There are several interesting problems that remain to be addressed:

1. The issue of preserving the nonmalleability of compiled programs (as in section 5) under concurrent composition is challenging, as, unlike the cases of encryption and string commitment, in general zero-knowledge proofs are not known to remain zero-knowledge under concurrent composition (see, e.g., [35, 38]). On the other hand, there are various techniques for changing zero-knowledge protocols so that they become parallelizable, such as witness indistinguishability [30] and perfect commitments (see Chapter 6.9 in [35]). These techniques do not necessarily yield protocols that can be executed concurrently while preserving zero-knowledge.
2. All our nonmalleability results are for protocols that are in some sense zero-knowledge. Extend the definition of nonmalleability to interactions that are not necessarily zero-knowledge, such as general multiparty computation, and construct nonmalleable protocols for these problems.
3. Simplify the constructions in this paper. Bellare and Rogaway present simplified constructions using a random oracle [6, 7]. A challenging open problem is to (define and) construct a *publicly computable pseudorandom function*. Such a construction is essential if [6, 7] are to be made complexity-based. For a recent discussion on constructing such functions see [17, 18, 19]; note that none of the proposals there is sufficient to yield nonmalleability.

   Very recently Cramer and Shoup [23] suggested an efficient construction of a nonmalleable cryptosystem secure against CCA-post. The scheme is based on the decisional Diffie–Hellman assumption (see [57] for a discussion of the assumption) and requires only a *few* modular exponentiations for encryption and decryption.

   Recently, Di Crescenzo, Ishai, and Ostrovsky [26] showed that in a model in which there is a common random string shared by all parties, it is possible to obtain a noninteractive weaker variant of nonmalleable commitments. Recall that, informally, in our definition of nonmalleable commitment, the adversary succeeds if it commits to a "related" value. Our definition therefore does not require the adversary to actually *open* its commitment in order to succeed. In the [26] scheme, an adversary that commits to a related value but never opens the commitment is *not* considered to have succeeded.
4. Another recent development related to malleability in encryption is the work of Bleichenbacher [11] who showed how the ability to maul ciphertexts in the PKCS # 1 standard allows for a CCA-post. The interesting fact about this

attack is that the only type of feedback the attacker requires is whether a given string represents a valid ciphertext. This demonstrates yet again the significance of using a *provable* nonmalleable cryptosystem.

5. A recent result that utilizes nonmalleability in an interesting way is [4] which explores the issue of reducing an adversary's success probability via parallel repetition. The authors give an example of a protocol where the fact that the upper bound on the adversary's probability of success is 1/2 is due to the *nonmalleability* of a cryptosystem used, while the repeated protocol fails to reduce the error due to the *malleability* of the protocol itself.
6. *The selective decryption problem:* a type of chosen ciphertext attack *not* addressed in this paper is when the adversary is given the random bits used to generate the ciphertext (in addition to the plaintext). The following problem, phrased here in terms of a CD-ROM, is a concrete instance in which this kind of attack is relevant (the version presented here is due to [59] and is a variant of a problem posed by O. Goldreich): A CD-ROM is generated containing the encryptions of 100 images (generally, n images). A user, having a copy of the CD-ROM, chooses any subset, say of size 50, of the images, and purchases the decryption information for the selected images. Suggest an encryption scheme for this problem such that, *assuming the decryption information is significantly shorter* than the combined plaintexts of the purchased images, the remaining encryptions remain secure once the decryption information for the purchased images is known. Suppose we start with a semantically secure cryptosystem and encrypt each image with its own key. Then, if the decryption information is the collection of keys for the selected images, it is easy to show that an adversary can't, for any given undecrypted image P_i produce an I related to P_i. The challenge is to show that no adversary can find an I related to, say, all the remaining P_i's. For example, show that the adversary can't find the bitwise logical-OR of the remaining pictures.
   This type of problem is simply ignored in papers on generating session keys (see, e.g., [8, 9]). If session keys are to be used for encryption, then the selective decryption problem must be addressed.
7. Design a *completely malleable* cryptosystem in which, given $E(x)$ and $E(y)$ it is possible to compute $E(x + y)$, $E(xy)$, and $E(\bar{x})$, where $\bar{x}$ denotes the bitwise complement of x. Such a cryptosystem has application to secure two-party computation. For example, to compute $f(x, y)$ player A generates a completely malleable E/D pair and sends $(E(x), E)$ to player B. Player B, knowing y and a circuit for f, can return $E(f(x, y))$.
   Alternatively, prove the *nonmalleability conjecture*: if a cryptosystem is completely malleable, then it is insecure. A related statement holds for discrete logarithms modulo p, and in general for the *black-box field problem*. See the elegant papers of Maurer [53] and Boneh and Lipton [15].

Acknowledgments. Discussions with Moti Yung on achieving independence started this research. Advice and criticism from Russell Impagliazzo, Charlie Rackoff, and Dan Simon were critical in the formation of the paper. We thank Ran Canetti, Uri Feige, Marc Fischlin, Roger Fischlin, Oded Goldreich, Omer Reingold, and Adi Shamir for valuable discussions.

TIME AND SPACE LOWER BOUNDS FOR NONBLOCKING IMPLEMENTATIONS*

PRASAD JAYANTI†, KING TAN†, AND SAM TOUEG‡

Abstract. We show the following time and space complexity lower bounds. Let $\mathcal{I}$ be any randomized nonblocking n-process implementation of any object in set A from any combination of objects in set B, where $A = \{$increment, fetch&add, modulo k counter (for any $k \geq 2n$), LL/SC bit, k-valued compare&swap (for any $k \geq n$), single-writer snapshot$\}$, and $B = \{$resettable consensus$\}$ $\cup$ $\{$historyless objects such as registers and swap registers$\}$. The space complexity of $\mathcal{I}$ is at least $n-1$. Moreover, if $\mathcal{I}$ is deterministic, both its time and space complexity are at least $n-1$. These lower bounds hold even if objects used in the implementation are of unbounded size.

This improves on some of the $\Omega(\sqrt{n})$ space complexity lower bounds of Fich, Herlihy, and Shavit [*Proceedings of the 12th Annual ACM Symposium on Principles of Distributed Computing*, Ithaca, NY, 1993, pp. 241–249; *J. Assoc. Comput. Mach.*, 45 (1998), pp. 843–862]. It also shows the near optimality of some known wait-free implementations in terms of space complexity.

Key words. asynchronous shared memory algorithms, nonblocking, wait-free, synchronization, randomized shared object implementations, space complexity, time complexity, lower bounds

1. Introduction.

Nonblocking and wait-free implementations of shared objects have been the subject of much research. While there have been several results on when such implementations are feasible and when they are not, results establishing their intrinsic time and space requirements are relatively scarce, especially for randomized implementations. In this paper, we present a technique by which one can obtain a linear lower bound on the space complexity of several randomized nonblocking implementations. The technique also yields a linear lower bound on the time complexity of several deterministic nonblocking implementations.

Specifically, our results are as follows. Let $\mathcal{I}$ be any randomized nonblocking n-process implementation of any object in set A from any combination of objects in set B, where $A = \{$increment, fetch&add, modulo k counter (for any $k \geq 2n$), LL/SC bit, k-valued compare&swap (for any $k \geq n$), single-writer snapshot$\}$, and $B = \{$resettable consensus$\} \cup \{$historyless objects$\}$. (Roughly speaking, an object is historyless if each of its operations either does not affect the state of the object or overwrites the previously applied operations. Examples include registers, test and set objects, and swap registers.) The space complexity of $\mathcal{I}$ is at least $n-1$. Moreover, if $\mathcal{I}$ is deterministic, both its time and space complexity are at least $n-1$. These lower bounds hold even if objects used in the implementation are of unbounded size.

Some of the results in this paper improve known lower bounds, while others are completely new. In particular, Fich, Herlihy, and Shavit proved a $\Omega(\sqrt{n})$ space complexity lower bound for a randomized nonblocking n-process implementation of

binary consensus from historyless objects [FHS93, FHS98]. Using this result, they showed that any randomized nonblocking n-process implementation of *compare&swap*, or *fetch&add*, or *bounded-counter* from historyless objects requires $\Omega(\sqrt{n})$ instances of such objects. Our results on compare&swap, fetch&add, and bounded-counter are stronger in two ways: (i) we show that at least $n-1$ objects are necessary, and (ii) we show that $n-1$ objects are needed even if the implementation is free to use *resettable consensus objects*, besides the historyless objects allowed by [FHS93, FHS98]. On the other hand, our lower bound technique applies only to implementations of "multiple-use objects" in which each process can access the implemented object many times. In contrast, the technique of Fich, Herlihy, and Shavit applies even to implementations of "single-use objects" (that is, all decision problems). Thus, our proof technique does not (and cannot) improve upon the main result of Fich, Herlihy, and Shavit, namely, their $\Omega(\sqrt{n})$ space complexity lower bound for a randomized nonblocking n-process implementation of binary consensus.

The results presented in this paper also imply that the following deterministic implementations in the literature are almost space-optimal.

1. Afek et al. give two wait-free implementations of a *single-writer snapshot object* consisting of n segments, each one written by a different process: one from *unbounded registers* and one from *bounded registers* [AAD$^+$93]. The one that uses unbounded registers is of space complexity n. We prove a lower bound of $n-1$.
2. Aspnes gives a wait-free implementation of an n-process *bounded-counter* from a single instance of a *single-writer snapshot object* [Asp90]. Combined with the above result of Afek et al., this implies that bounded-counter can be implemented from n unbounded registers. We prove that at least $n-1$ *registers* are necessary when the bounded-counter is a modulo k counter, where $k \geq 2n$.

In both cases above, the lower bound of $n-1$ is particularly appealing because it applies to even randomized nonblocking implementations while the upper bound of n holds for deterministic wait-free implementations.

In fact, the lower bounds proved in this paper (and the lower bounds in [FHS93, FHS98]) apply not just to nonblocking implementations, but also to any implementation satisfying a weaker progress condition called *solo-termination*, defined in [FHS98]. Roughly speaking, a deterministic implementation is solo-terminating if at every configuration C in a system execution the following holds for all processes p: if p runs alone from C, p's operation on the implemented object will eventually complete. For a randomized implementation to be considered solo-terminating we require that for all C and p, if p runs alone from C there is at least one sequence of outcomes for p's coin tosses that will enable p to complete its operation on the implemented object.

It is well known that a wait-free implementation is also nonblocking. It is clear that a nonblocking implementation is also solo-terminating. Thus, the lower bounds that we prove here for solo-terminating implementations apply also to nonblocking and wait-free implementations.

There is a large body of research on algorithms for synchronous parallel computers (such as the PRAM model, the mesh, perfect shuffle, and hypercube architectures) that has resulted in many algorithms whose time complexity is polylogarithmic in the number of processors. In contrast, for the asynchronous model of computing, wait-free algorithms of polylog complexity are rare ([Cha96, Aum97, CJT98] are some notable exceptions). In fact, our paper formally proves that for deterministic wait-free implementations of many common objects from certain base objects, there are

no algorithms of sublinear time complexity, let alone polylog complexity.

Our proof technique for the lower bounds is general in that we have successfully applied it to implementations of a variety of objects. The technique is also interesting because (i) it simultaneously yields a lower bound on time and space complexities of implementations, (ii) the lower bound on space complexity holds even for randomized implementations, and (iii) the lower bounds apply not just to nonblocking or wait-free implementations, but also to any implementation satisfying the weaker solo-termination progress condition.

The paper is organized as follows. We present an informal model in section 2. In section 3, we define the class of perturbable types and prove the lower bound for implementations of *any* perturbable type. In section 4, we show that many common types of objects, such as counter, compare&swap, LL/SC bit, single-writer snapshot, are perturbable. Section 5 elaborates on the consequences of the results in sections 3 and 4.

2. Informal model.

2.1. Definitions of type, historyless type, and resettable consensus. A *type* is a tuple (OP, RES, Q, δ), where OP is a set of operations, RES is a set of responses, Q is a set of states, and $\delta : Q \times OP \to Q \times RES$ is a function, known as the *sequential specification* of the type. Intuitively, if $\delta(\sigma, op) = (\sigma', res)$, it means the following: applying the operation op to an object of this type in state σ causes the object to move to state σ' and return the response res.

Let $op(\sigma)$ denote the first component of the tuple $\delta(\sigma, op)$. The following definitions are from Fich, Herlihy, and Shavit [FHS98]. An operation op is *trivial* if its application does not affect the state; that is, for all states σ, $op(\sigma) = \sigma$. Operation op' *overwrites* operation op if applying op and then op' results in the same state as simply applying op'; more precisely, for all states σ, $op'(op(\sigma)) = op'(\sigma)$. A type is *historyless* if all its nontrivial operations overwrite one another. The types `register`, `test and set`, and `swap register` are examples of historyless types.

PROPOSITION 2.1. *For a historyless type, the following statements are true:*

(1) *For all states σ, nontrivial operations op_k and finite sequences $op_{k-1} \cdots op_1$ of operations, $op_k(op_{k-1}(\cdots op_1(\sigma) \cdots)) = op_k(\sigma)$.*
(2) *For all states σ and finite sequences $op_k op_{k-1} \cdots op_1$ of trivial operations, $op_k(op_{k-1}(\cdots op_1(\sigma) \cdots)) = \sigma$.*

Proof. The proposition is proved by a simple induction on the length of the operation sequence. □

We now define the type `resettable consensus` as (OP, RES, Q, δ), where

- $OP = \{\text{read}, \text{reset}\} \cup \{\text{propose } v \mid v \in \mathcal{N}\}$, where $\mathcal{N}$ is the set of natural numbers;
- $RES = \mathcal{N} \cup \{ack\}$;
- $Q = \mathcal{N} \cup \{\perp\}$;
- δ, the transition function, is as follows:
  - For all $u \in Q$, $\delta(u, \text{read}) = (u, u)$;
  - For all $u \in Q$, $\delta(u, \text{reset}) = (\perp, ack)$;
  - $\delta(\perp, \text{propose } v) = (v, v)$ and, for all $u \in \mathcal{N}$, $\delta(u, \text{propose } v) = (u, u)$.

Resettable consensus was first defined by Herlihy [Her88, Her91], but included only the propose and reset operations. We added the read operation to make our lower bound result stronger. Our definition of resettable consensus is similar to the sticky bit defined by Plotkin [Plo89].

2.2. Implementation. A *randomized implementation* is specified by the following elements:

- The type and the initial state of the implemented object $\mathcal{O}$ (the initial state of $\mathcal{O}$ is a state of its type).
- A set of objects $O_1, \ldots, O_m$ from which $\mathcal{O}$ is implemented, their types, and their initial states.
- A set of processes $p_1, \ldots, p_n$ that may access $\mathcal{O}$.
- A set of *randomized access procedures* $\texttt{Apply}(p_i, op, \mathcal{O})$ for $p_i \in \{p_1, \ldots, p_n\}$ and $op \in OP$, where OP is the set of operations associated with the type of $\mathcal{O}$.

The access procedure $\texttt{Apply}(p_i, op, \mathcal{O})$ specifies how p_i should execute the operation op on $\mathcal{O}$ in terms of operations on $O_1, \ldots, O_m$. The value returned by the procedure is deemed to be the response from $\mathcal{O}$. We call $O_1, \ldots, O_m$ the *base objects* of the implementation. The *space complexity* of the implementation is m.

The definitions presented in the rest of this section are with respect to a system that consists of processes $p_1, \ldots, p_n$ and an implemented object $\mathcal{O}$ that $p_1, \ldots, p_n$ may access. We denote such a system by $(p_1, \ldots, p_n; \mathcal{O})$. Each p_i has a set of states and has a distinguished input variable *op-list*$_i$. This variable is initialized (by the user of the system) with any infinite sequence of operations $op_1, op_2, \ldots$, where each op_j is an operation supported by $\mathcal{O}$. The initial state of p_i is determined uniquely by the implementation as a function of the value assigned to *op-list*$_i$. Each p_i performs the following actions repeatedly forever: obtain the next operation op from *op-list*$_i$ and execute the access procedure $\texttt{Apply}(p_i, op, \mathcal{O})$ until it returns.[1]

A process p_i executes an access procedure $\texttt{Apply}(p_i, op, \mathcal{O})$ in *steps*. Each step consists of the following sequence of actions, all of which occur together atomically:

- p_i tosses a coin. Let *toss-outcome* $\in$ COINSPACE denote the outcome of this toss.
  We make the following assumptions: (i) coin tosses are independent, and (ii) COINSPACE is a nonempty countable set of all possible outcomes of a coin toss, and the probability of each outcome in the set is nonzero.
- *toss-outcome*, p_i's present state, and the operation op that p_i wants to apply to $\mathcal{O}$ uniquely determine an operation *oper* and a base object O_j that *oper* should be applied to. Accordingly, p_i applies *oper* to O_j.
- O_j changes state and returns a response. The new state of O_j and the response are uniquely determined by the sequential specification of O_j.
- The response from O_j, together with *toss-outcome* and p_i's present state, uniquely determine the new state of p_i. It is possible for the procedure $\texttt{Apply}(p_i, op, \mathcal{O})$ to terminate, returning some response. In this case, the new state of p_i reflects both the fact that the access procedure terminated and the response returned by the access procedure. Further, p_i's step enabled from this state corresponds to the first step of the access procedure $\texttt{Apply}(p_i, op', \mathcal{O})$, where op' is the earliest unconsumed operation in *op-list*$_i$.

A *configuration* of $(p_1, \ldots, p_n; \mathcal{O})$ is a tuple $(\sigma_1, \ldots, \sigma_n, rem_1, \ldots, rem_n, \tau_1, \ldots, \tau_m)$, where σ_i is a state of p_i, rem_i is a suffix of *op-list*$_i$ (and corresponds to the infinite sequence of operations that p_i is yet to initiate on $\mathcal{O}$), and τ_j is a state of base object O_j. Since the implementation specifies a unique initial state for each base object and

[1] Our model is more restrictive than a model in which the sequence of operations that each p_i applies on $\mathcal{O}$ is not fixed initially. Since our time and space lower bounds apply to the restrictive model, they clearly apply to the more general model as well.

a unique initial state for each process p_i as a function of the value assigned to *op-list*$_i$, it follows that the initial configuration is uniquely determined by an assignment of infinite sequences of operations to the input variables *op-list*$_i$ ($1 \leq i \leq n$). An *execution fragment from configuration* C_0 of $(p_1, \ldots, p_n; \mathcal{O})$ is a finite or infinite sequence $C_0, C_1, C_2, \ldots$ of configurations such that, for all $k \geq 0$, C_{k+1} is the configuration that results when some process performs a step in configuration C_k. An *execution* is an execution fragment from an initial configuration.

A *schedule* is a finite or an infinite sequence $[p_{i_1}, t_1], [p_{i_2}, t_2], \ldots$, where each p_{i_j} is from $\{p_1, \ldots, p_n\}$ and each t_j is from COINSPACE. If C is a configuration and $\alpha = [p_{i_1}, t_1], [p_{i_2}, t_2], \ldots$ is a schedule, EXEC(C, α) denotes the execution fragment $C_0, C_1, C_2, \ldots$, where $C = C_0$ and each C_k results from C_{k-1} when p_{i_k} takes a step in which the outcome of p_{i_k}'s toss is t_k. A configuration C is *reachable* if there is some initial configuration C_0 and a finite schedule α such that the configuration at the end of EXEC(C_0, α) is C.

An implementation is *correct* if it has two properties—linearizability (safety property) and solo-termination (liveness property), which are described next.

2.3. Linearizability. Let $\mathcal{O}$ be an implemented object shared by processes $p_1, \ldots, p_n$. Each completed operation on $\mathcal{O}$ in an execution of $(p_1, \ldots, p_n; \mathcal{O})$ can be viewed as a pair of events—the invocation of the operation followed by the response to the operation. Informally, an execution E of $(p_1, \ldots, p_n; \mathcal{O})$ is *linearizable* if every operation in E appears to take effect at some instant between its invocation and response (in other words, operations appear atomic). The *implementation of* $\mathcal{O}$ *is linearizable* if every execution of $(p_1, \ldots, p_n; \mathcal{O})$ is linearizable. For a precise definition of linearizability, we refer the reader to the work of Herlihy and Wing in which this concept was first formally introduced [HW90].

2.4. Solo-termination: A progress property. An implementation whose access procedures never terminate is trivially linearizable. Such an implementation, however, is hardly useful. Thus, in addition to linearizability, implementations should guarantee certain progress properties. *Wait-freedom* and *nonblockingness* are the progress conditions that received the most attention recently [HS93]. In this paper, we consider a weaker progress property called *solo-termination*, first defined in [FHS98]. Informally, an implementation has the solo-termination property if, for each reachable configuration C and each process p, the following holds: if p runs alone from configuration C, then there is at least one sequence of outcomes for p's coin tosses that will enable p to complete an operation on the implemented object. More precisely, a *randomized implementation of* $\mathcal{O}$ *is solo-terminating* if, for all reachable configurations C and all processes p_i, there is some finite schedule $\alpha = [p_i, t_1], [p_i, t_2], \ldots, [p_i, t_k]$ such that p_i completes an operation on $\mathcal{O}$ during EXEC(C, α). (Since the probability of each t_j is nonzero by definition, there is a nonzero probability of p_i completing an operation on $\mathcal{O}$ when p_i runs alone from C.)

The lower bounds proved in this paper apply to solo-terminating (and therefore to nonblocking and wait-free) implementations.

2.5. Notation. For a schedule α, $|\alpha|$ denotes its length. We say α *contains process* p if, for some t, $[p, t]$ is in the sequence α. PSET(α) denotes the set of all processes contained in α. If α and β are any schedules, $\alpha\beta$ denotes the schedule which is the concatenation of α and β.

If Σ is a set, Σ^* denotes the set of all *finite* sequences of elements from Σ (including the empty sequence, denoted by ϵ). Notice that $(\{p_1, \ldots, p_n\} \times \text{COINSPACE})^*$ is the set of all finite schedules.

In our proofs, when we consider a system $(p_1, \ldots, p_n; \mathcal{O})$ (where $\mathcal{O}$ is an object implemented for processes $p_1, \ldots, p_n$), we fix the initial configuration of the system at some value, say, C_0, right at the beginning of the proof by specifying the initial values of the input variables *op-list*$_i$ $(1 \leq i \leq n)$. Since the initial configuration is fixed, each schedule $\alpha \in (\{p_1, \ldots, p_n\} \times \text{COINSPACE})^*$ uniquely determines the execution $\text{EXEC}(C_0, \alpha)$. Therefore, for brevity, if α is a schedule, we will use the same symbol α also to denote the execution $\text{EXEC}(C_0, \alpha)$. From the context it will be clear whether α refers to the schedule or to the execution. If α and β are schedules and S is a set of processes or a set of base objects, then we write $\alpha \approx_S \beta$ if, for all $A \in S$, A is in the same state at the end of the executions α and β.

2.6. Definitions of "just completes" and deterministic time complexity. Let E be any execution fragment of $(p_1, \ldots, p_n; \mathcal{O})$, where $\mathcal{O}$ is an object implemented using a randomized implementation. We say process p_i *just completes* an operation on $\mathcal{O}$ in E if in its last step in E, p_i returns from an access procedure completing an operation on $\mathcal{O}$.

A *deterministic implementation* is a special case of a randomized implementation for which COINSPACE, the set of possible outcomes for a coin toss, is a singleton set. The *solo-termination time complexity of a deterministic implementation of* $\mathcal{O}$ is the maximum, over all reachable configurations C of $(p_1, \ldots, p_n; \mathcal{O})$ and all processes p_i, of $|\alpha|$ such that (i) α is a schedule that contains only p_i, and (ii) in $\text{EXEC}(C, \alpha)$, p_i completes exactly one operation on $\mathcal{O}$ and, in fact, just completes it.

We note that, for any reasonable definition of the time complexity of a nonblocking (or wait-free) implementation of $\mathcal{O}$, if the solo-termination time complexity of a deterministic implementation of $\mathcal{O}$ is at least k, then the time complexity of any deterministic nonblocking (or wait-free) implementation of $\mathcal{O}$ is also at least k.

3. The lower bound. This section has three parts. Section 3.1 illustrates the main ideas of our lower bound technique for the special case of implementing an increment object. Our lower bound applies not just to implementations of the increment object, but to implementations of a large class of objects, which we call perturbable objects. Section 3.2 defines the class of perturbable objects. Section 3.3 proves the lower bound for any implementation of any perturbable object.

3.1. The intuition. To illustrate the main ideas of the lower bound proof, we provide below a proof sketch for a simple case of the full result. Consider any deterministic implementation of an increment object $\mathcal{O}$,[2] shared by $p_1, \ldots, p_n$, from swap objects.[3] We will prove that the space and time complexity of the implementation are at least $n-1$. (The full result is more general in three ways: it applies to randomized implementations; it applies to implementations of any perturbable object, not just the increment object; and it applies even if base objects include resettable consensus objects.)

[2] An *increment object* supports *increment* and *read* operations. The *increment* operation adds 1 to the state and returns *ack*. The *read* operation returns the state without affecting it.

[3] A *swap object* supports *read* and *write* operations. The *write* v operation changes the state to v and returns the previous state. The *read* operation returns the state without modifying it.

Consider Scenario 0 in which p_n initiates a read operation on $\mathcal{O}$ and runs alone. We claim that p_n accesses some base object, before completing this read operation on $\mathcal{O}$. For a proof, suppose the claim is false. Then p_n cannot distinguish Scenario 0 from Scenario $0'$ in which some process completes an increment operation on $\mathcal{O}$ before p_n starts taking steps. Yet, correctness requires p_n's read operation to return different values in Scenarios 0 and $0'$. This contradiction implies the claim. Let B_1 denote the first base object that p_n accesses.

To force p_n to access a second base object, the idea is to schedule other processes, before scheduling p_n, in such a way that they render the information in B_1 not much useful for p_n. Consequently, later when p_n runs and accesses B_1, it will not learn enough to determine the response to its read operation on $\mathcal{O}$; thus, p_n is forced to access a second base object. The details are as follows. Let Scenario 1 depict an execution in which processes other than p_n take steps until some process, say, p_{i_1}, writes B_1.[4] If p_n runs after Scenario 1, it accesses B_1 because, until accessing B_1, this scenario is indistinguishable to p_n from Scenario 0. More significantly, we show below that, when running after Scenario 1, p_n accesses some base object, besides B_1, before completing its first read operation on $\mathcal{O}$. To see this, consider another scenario, Scenario $1'$, which is the same as Scenario 1 with the following exception: just before p_{i_1} writes B_1, some process p_l other than p_{i_1} and p_n completes many increment operations on $\mathcal{O}$, and after this p_{i_1} takes a step and writes B_1. Clearly, B_1's value is the same at the end of Scenarios 1 and $1'$. Now extend each of Scenarios 1 and $1'$ by letting p_n take steps. If p_n accesses *only* B_1, it is clear that the two scenarios would be indistinguishable to p_n. Yet, since many more increments operations are completed in Scenario $1'$ than in Scenario 1, p_n's read operation on $\mathcal{O}$ must return different values in the two scenarios. It follows that, in Scenario 1 (and in Scenario $1'$), p_n must access a second base object before completing its read operation on $\mathcal{O}$. Let B_2 denote this base object.

To force p_n to access a third base object, we repeat the above trick and render the information in B_2 not much useful for p_n. Specifically, consider Scenario 2 consisting of the following three execution fragments, taking place in this order: (i) the prefix of Scenario 1 (described above) up to, but excluding the write of B_1 by p_{i_1}, (ii) the steps of processes other than p_{i_1} and p_n until some process, say, p_{i_2}, writes B_2, and (iii) the write of B_1 by p_{i_1}. If p_n were to run after Scenario 2, it accesses B_1 and B_2 because, until accessing B_2, this scenario is indistinguishable to p_n from Scenario 1. We claim that p_n accesses some base object, besides B_1 and B_2, before completing its first read operation on $\mathcal{O}$. The justification is as in the previous paragraph: if the claim is false, p_n cannot distinguish Scenario 2 from Scenario $2'$, where Scenario $2'$ is similar to Scenario 2 except that some process p_l other than p_{i_1}, p_{i_2}, and p_n completes many increment operations on $\mathcal{O}$ just before the write steps of p_{i_2} and p_{i_1} on B_2 and B_1, respectively. This is a contradiction since p_n's read operation on $\mathcal{O}$ must return different values in Scenarios 2 and $2'$.

Repeating the above argument, we construct successively Scenarios $3, \ldots, n-2$ with the property that, if p_n runs alone after Scenario k, it accesses at least $k+1$ distinct base objects before completing its first read operation on $\mathcal{O}$. The lower bound of $n-1$ on the space and time complexity of the implementation is immediate from the existence of Scenario $n-2$. (We cannot proceed any further than Scenario $n-2$ because processes other than p_n are all already used up: they play the roles

[4] It is possible that such an execution does not exist. In order not to obscure the basic intuition, we address this possibility only in the formal proof, presented in section 3.3.

of $p_{i_1}, \ldots, p_{i_{n-2}}$ or as a process that does increment operations just before the write steps of $p_{i_1}, \ldots, p_{i_{n-2}}$.)

In summary, the crux is to ensure that p_n gets no useful information from $B_1, B_2, \ldots, B_{n-2}$; that is, $B_1, B_2, \ldots, B_{n-2}$ are rendered useless to p_n. This is accomplished by "using up" p_{i_j} to render B_j useless. This technique of using up one new process for each additional shared object to be rendered useless, in the context of space complexity lower bounds, was used earlier by Burns and Lynch [BL93].

We turn the above ideas into a rigorous inductive proof in section 3.3. To understand the correspondence between that proof and the above informal argument, note that Scenario 2 described above has three parts: a schedule involving $p_1, \ldots, p_{n-1}$, followed by the write steps of p_{i_2} and p_{i_1} (on objects B_2 and B_1, respectively), followed by the steps of only p_n. More generally, if we extended the argument to Scenarios $3, 4, \ldots$, Scenario k would consist of three parts, where the first part is a schedule involving $p_1, \ldots, p_{n-1}$, the second part is the write steps of $p_{i_k}, p_{i_{k-1}}, \ldots, p_{i_1}$ on some base objects $B_k, B_{k-1}, \ldots, B_1$, and the third part is the steps of only p_n. Roughly speaking, these three parts of Scenario k' correspond to the schedules Λ, Σ, and Π, respectively, in Definition 3.1 in section 3.2, and to the schedules Λ_k, Σ_k, and Π_k, respectively, of the proof in section 3.3. We caution the reader that this correspondence is not exact but is close enough to help the reader understand how the formal proof works.

3.2. Perturbable types. The key property of the increment object exploited in the above proof is the following: it is possible to create a new scenario by scheduling the steps of some process p_l immediately before that of $p_{i_k}, p_{i_{k-1}}, \ldots, p_{i_1}$ in such a way that p_n is forced to distinguish the new scenario from the older one. Below we state an abstract version of this property (which suffices for our proof technique to work), and call any type that has this property a *perturbable type*.

DEFINITION 3.1. Type T is perturbable for n processes, for initial state s *if for every linearizable and solo-terminating randomized implementation of an object $\mathcal{O}$ of type T, initialized to s and shared by processes $p_1, \ldots, p_n$, there exists an assignment of operation sequences to input variables $oplist_1, \ldots, oplist_n$ such that the following statement holds:*

If Λ, Σ, and Π are any schedules that satisfy the following four conditions,

- $\text{PSET}(\Lambda) \subseteq \{p_1, \ldots, p_{n-1}\}$;
- $\text{PSET}(\Sigma)$ *is a proper subset of* $\{p_1, \ldots, p_{n-1}\}$ *and each process appears at most once in* Σ;
- $\text{PSET}(\Pi) = \{p_n\}$;
- *in* $\Lambda\Sigma\Pi$, p_n*'s first operation on* $\mathcal{O}$ *just completes and returns some response res;*

then, for some $p_l \in \{p_1, \ldots, p_{n-1}\} - \text{PSET}(\Sigma)$, *there is a schedule* $\gamma \in (\{p_l\} \times \text{COINSPACE})^*$ *such that, in* $\Lambda\gamma\Sigma\Pi$, *either* p_n*'s first operation on* $\mathcal{O}$ *does not complete or it returns a response different from res.*

3.3. The main result. We prove that the space complexity of any randomized solo-terminating implementation and the time complexity of any deterministic solo-terminating implementation of any perturbable object, shared by n processes, are both at least $n-1$ if base objects are restricted to be (any combination of) resettable consensus objects and historyless objects, such as registers, test and set objects, and swap registers.

THEOREM 3.2. *Suppose that type T is perturbable for n processes for some initial state s. Consider any randomized implementation of an object of type T, initialized to*

There are schedules Λ_k, Σ_k, Π_k such that the following conditions hold:

(1) Λ_k, $\Sigma_k \in (\{p_1, p_2, \ldots, p_{n-1}\} \times \text{COINSPACE})^*$, and $\Pi_k \in (\{p_n\} \times \text{COINSPACE})^*$. That is, Λ_k and Σ_k do not contain p_n and Π_k contains no process other than p_n.
(2) $|\Sigma_k| = |\text{PSET}(\Sigma_k)| = k$. That is, k distinct processes take one step each in Σ_k.
(3) In $\Lambda_k\Sigma_k\Pi_k$, p_n accesses exactly k distinct base objects and p_n's first operation on $\mathcal{O}$ has either not completed or just completed.
(4) Let $\mathcal{S}_k$ be the set of base objects that p_n accesses in $\Lambda_k\Sigma_k\Pi_k$. Let $\mathcal{P}_k = \{p_1, p_2, \ldots, p_{n-1}\} - \text{PSET}(\Sigma_k)$ and γ be any schedule in $(\mathcal{P}_k \times \text{COINSPACE})^*$. Then, $\Lambda_k\Sigma_k \approx_{\mathcal{S}_k} \Lambda_k\gamma\Sigma_k$.

FIG. 3.1. *Statement S_k.*

s and shared by processes $p_1, \ldots, p_n$, from resettable consensus objects and historyless objects. If the implementation is linearizable and solo-terminating, then

(1) *its space complexity is at least $n - 1$;*
(2) *if the implementation is deterministic, its solo-termination time complexity is at least $n - 1$.*

Proof. Let $\mathcal{O}$ be the implemented object, and let C_0 be the initial configuration of $(p_1, \ldots, p_n; \mathcal{O})$ obtained by assigning to *op-list*$_1, \ldots,$ *op-list*$_n$ the operation sequences mentioned in Definition 3.1. The crux of the proof lies in the following claim: For all k, $0 \le k \le n-1$, Statement S_k, presented in Figure 3.1, is true. We prove this claim by induction. Below, we let $S_k : j$ denote the jth part of Statement S_k.

Base case. Let $\Lambda_0 = \Sigma_0 = \Pi_0 = \epsilon$ (ϵ is the empty sequence). It is easy to verify that all of $S_0 : 1$-4 are true. Hence, we have the base case.

Induction step. Suppose $0 \le k \le n-2$ and S_k is true. Let $\Lambda_k, \Sigma_k, \Pi_k$ be so defined as to make Statement S_k true. Let $\mathcal{S}_k$ denote the set of base objects that p_n accesses in $\Lambda_k\Sigma_k\Pi_k$, and let $\mathcal{P}_k$ denote $\{p_1, p_2, \ldots, p_{n-1}\} - \text{PSET}(\Sigma_k)$. We show that S_{k+1} is true through the following steps.

(1) By $S_k : 3$, in $\Lambda_k\Sigma_k\Pi_k$, p_n's first operation on $\mathcal{O}$ has either not completed or just completed. Let $\pi \in (\{p_n\} \times \text{COINSPACE})^*$ be such that, in $\Lambda_k\Sigma_k\Pi_k\pi$, p_n just completes its first operation on $\mathcal{O}$, returning some value. Since the implementation is solo-terminating, π exists.
(2) *Claim* 1. $\pi \neq \epsilon$ and in $\Lambda_k\Sigma_k\Pi_k\pi$, p_n accesses a base object not in $\mathcal{S}_k$.

Proof. Suppose the claim is false. Recall that $\mathcal{P}_k = \{p_1, p_2, \ldots, p_{n-1}\} - \text{PSET}(\Sigma_k)$. Since $|\text{PSET}(\Sigma_k)| = k$ and $k \le n-2$, $\mathcal{P}_k$ is nonempty. For all $p_l \in \mathcal{P}_k$ and $\gamma \in (\{p_l\} \times \text{COINSPACE})^*$, we assert that $\Lambda_k\Sigma_k\Pi_k\pi \approx_{p_n} \Lambda_k\gamma\Sigma_k\Pi_k\pi$. This assertion follows from the facts below: (i) $\Lambda_k\Sigma_k \approx_{p_n} \Lambda_k\gamma\Sigma_k$ (since the schedules $\Lambda_k\Sigma_k$ and $\Lambda_k\gamma\Sigma_k$ do not contain p_n), (ii) $\Lambda_k\Sigma_k \approx_{\mathcal{S}_k} \Lambda_k\gamma\Sigma_k$ (by $S_k : 4$), (iii) the schedule $\Pi_k\pi$ contains only p_n, and (iv) the only base objects accessed by p_n in $\Lambda_k\Sigma_k\Pi_k\pi$ are the ones in $\mathcal{S}_k$ (by our assumption that Claim 1 is false).

The above assertion, together with the definition of π from step 1, implies that p_n's first operation on $\mathcal{O}$ completes and returns the same response in $\Lambda_k\gamma\Sigma_k\Pi_k\pi$ as in $\Lambda_k\Sigma_k\Pi_k\pi$. This contradicts Definition 3.1. (To see the contradiction, substitute Λ, Σ, Π in the definition with $\Lambda_k, \Sigma_k, \Pi_k\pi$, respectively, and note that the conditions in the definition hold because of the induction hypothesis.) Hence, we have Claim 1. ∎

(3) DEFINITION 3.3. *Define* π_{k+1}, B_{k+1}, *and* Π_{k+1} *as follows*:

- π_{k+1} *is the shortest prefix of* π *such that, in* $\Lambda_k\Sigma_k\Pi_k\pi_{k+1}$, p_n *accesses a base object not in* $\mathcal{S}_k$ *(by Claim* 1, π_{k+1} *exists).*
- B_{k+1} *is the unique base object not in* $\mathcal{S}_k$ *that* p_n *accesses in* $\Lambda_k\Sigma_k\Pi_k\pi_{k+1}$.
- $\Pi_{k+1} = \Pi_k\pi_{k+1}$.

Claim 2. $\Pi_{k+1} \in (\{p_n\} \times \text{COINSPACE})^*$.

Proof. Since Π_k and π_{k+1} are both from $(\{p_n\} \times \text{COINSPACE})^*$, we have $\Pi_{k+1} \in (\{p_n\} \times \text{COINSPACE})^*$. □

(4) *Claim* 3. There exist $\lambda_{k+1} \in (\mathcal{P}_k \times \text{COINSPACE})^*$ and $[p_{i_{k+1}}, t_{k+1}] \in \mathcal{P}_k \times \text{COINSPACE}$ such that, for all $\gamma \in ((\mathcal{P}_k - \{p_{i_{k+1}}\}) \times \text{COINSPACE})^*$, $\Lambda_k\lambda_{k+1}[p_{i_{k+1}}, t_{k+1}] \approx_{B_{k+1}} \Lambda_k\lambda_{k+1}\gamma[p_{i_{k+1}}, t_{k+1}]$.

Proof. The following observation will be used many times in the proof:

Observation O1. For all $\gamma \in ((\mathcal{P}_k - \{p_{i_{k+1}}\}) \times \text{COINSPACE})^*$, process $p_{i_{k+1}}$ accesses the same base object and applies the same operation in the last step of $\Lambda_k\lambda_{k+1}[p_{i_{k+1}}, t_{k+1}]$ as in the last step of $\Lambda_k\lambda_{k+1}\gamma[p_{i_{k+1}}, t_{k+1}]$.

This observation follows from the fact that γ does not contain $p_{i_{k+1}}$. In the following, we pick λ_{k+1} and $[p_{i_{k+1}}, t_{k+1}]$ based on the type of B_{k+1}, and in each case prove that our choice of λ_{k+1} and $[p_{i_{k+1}}, t_{k+1}]$ satisfies Claim 3. In the rest of the proof, γ denotes an arbitrary schedule in $((\mathcal{P}_k - \{p_{i_{k+1}}\}) \times \text{COINSPACE})^*$.

Case 1. B_{k+1} is a historyless object.

Subcase 1a. There is some nonempty schedule $\lambda \in (\mathcal{P}_k \times \text{COINSPACE})^*$ such that the last step in $\Lambda_k\lambda$ is a nontrivial operation on B_{k+1}. Define λ_{k+1} and $[p_{i_{k+1}}, t_{k+1}]$ so that $\lambda = \lambda_{k+1}[p_{i_{k+1}}, t_{k+1}]$. By O1, $p_{i_{k+1}}$ performs the same nontrivial operation on B_{k+1} in the last step of $\Lambda_k\lambda_{k+1}\gamma[p_{i_{k+1}}, t_{k+1}]$ as in the last step of $\Lambda_k\lambda_{k+1}[p_{i_{k+1}}, t_{k+1}]$. This, together with Proposition 2.1, gives Claim 3.

Subcase 1b. There is no such λ.

Define λ_{k+1} to be ϵ and $[p_{i_{k+1}}, t_{k+1}]$ to be any element of $\mathcal{P}_k \times \text{COINSPACE}$. It follows from the subcase in consideration that no nontrivial operation is performed on B_{k+1} in the last $|\lambda_{k+1}[p_{i_{k+1}}, t_{k+1}]|$ steps of $\Lambda_k\lambda_{k+1}[p_{i_{k+1}}, t_{k+1}]$ and in the last $|\lambda_{k+1}\gamma[p_{i_{k+1}}, t_{k+1}]|$ steps of $\Lambda_k\lambda_{k+1}\gamma[p_{i_{k+1}}, t_{k+1}]$. Therefore, by Proposition 2.1, $\Lambda_k\lambda_{k+1}[p_{i_{k+1}}, t_{k+1}] \approx_{B_{k+1}} \Lambda_k \approx_{B_{k+1}} \Lambda_k\lambda_{k+1}\gamma[p_{i_{k+1}}, t_{k+1}]$. Hence, we have Claim 3.

Case 2. B_{k+1} is a resettable consensus object.

Subcase 2a. There is some nonempty schedule $\lambda \in (\mathcal{P}_k \times \text{COINSPACE})^*$ such that the last step in $\Lambda_k\lambda$ is a reset operation on B_{k+1}. Define λ_{k+1} and $[p_{i_{k+1}}, t_{k+1}]$ so that $\lambda = \lambda_{k+1}[p_{i_{k+1}}, t_{k+1}]$. By O1, $p_{i_{k+1}}$ performs a reset on B_{k+1} in the last step of $\Lambda_k\lambda_{k+1}\gamma[p_{i_{k+1}}, t_{k+1}]$, just as it does in the last step of $\Lambda_k\lambda_{k+1}[p_{i_{k+1}}, t_{k+1}]$. Hence, we have Claim 3.

Subcase 2b. There is no such λ. However, there is some nonempty schedule $\lambda' \in (\mathcal{P}_k \times \text{COINSPACE})^*$ such that the last step in $\Lambda_k\lambda'$ is a propose operation on B_{k+1}.

Define λ_{k+1} to be λ' and $[p_{i_{k+1}}, t_{k+1}]$ to be any element of $\mathcal{P}_k \times \text{COINSPACE}$. Let σ be the state of B_{k+1} at the end of $\Lambda_k\lambda_{k+1}$. Since Subcase 2a is not applicable, it follows that B_{k+1} is not reset in the last $|\lambda_{k+1}[p_{i_{k+1}}, t_{k+1}]|$ steps of $\Lambda_k\lambda_{k+1}[p_{i_{k+1}}, t_{k+1}]$ and in the last $|\lambda_{k+1}\gamma[p_{i_{k+1}}, t_{k+1}]|$ steps of $\Lambda_k\lambda_{k+1}\gamma[p_{i_{k+1}}, t_{k+1}]$. Thus, B_{k+1}'s state is σ at the end of $\Lambda_k\lambda_{k+1}[p_{i_{k+1}}, t_{k+1}]$ and at the end of $\Lambda_k\lambda_{k+1}\gamma[p_{i_{k+1}}, t_{k+1}]$. Hence, we have Claim 3.

Subcase 2c. Neither λ nor λ' exists.
Define λ_{k+1} to be ϵ and $[p_{i_{k+1}}, t_{k+1}]$ to be any element of $\mathcal{P}_k \times$ COINSPACE. It follows from the subcase under consideration that no reset or propose operation is performed on B_{k+1} in the last $|\lambda_{k+1}[p_{i_{k+1}}, t_{k+1}]|$ steps of $\Lambda_k\lambda_{k+1}[p_{i_{k+1}}, t_{k+1}]$ and in the last $|\lambda_{k+1}\gamma[p_{i_{k+1}}, t_{k+1}]|$ steps of $\Lambda_k\lambda_{k+1}\gamma[p_{i_{k+1}}, t_{k+1}]$. Therefore, B_{k+1}'s state at the end of $\Lambda_k\lambda_{k+1}[p_{i_{k+1}}, t_{k+1}]$ is the same as its state at the end of $\Lambda_k\lambda_{k+1}\gamma[p_{i_{k+1}}, t_{k+1}]$. Hence, we have Claim 3.

This completes the proof of Claim 3. □

(5) DEFINITION 3.4. *Let λ_{k+1} and $[p_{i_{k+1}}, t_{k+1}]$ be as in Claim* 3. *Define Λ_{k+1} and Σ_{k+1} as follows:*
- $\Lambda_{k+1} = \Lambda_k\lambda_{k+1}$.
- $\Sigma_{k+1} = [p_{i_{k+1}}, t_{k+1}]\Sigma_k$.

Claim 4. Λ_{k+1}, $\Sigma_{k+1} \in (\{p_1, p_2, \ldots, p_{n-1}\} \times$ COINSPACE$)^*$.

Proof. By definition, $\lambda_{k+1} \in (\mathcal{P}_k \times$COINSPACE$)^*$ and $[p_{i_{k+1}}, t_{k+1}] \in \mathcal{P}_k \times$COINSPACE, where $\mathcal{P}_k = \{p_1, p_2, \ldots, p_{n-1}\} -$ PSET(Σ_k). This, together with $S_k : 1$, implies the claim. □

Claim 5. $|\Sigma_{k+1}| = |$PSET$(\Sigma_{k+1})| = k + 1$.

Proof. This claim follows from the definition of Σ_{k+1} as $[p_{i_{k+1}}, t_{k+1}]\Sigma_k$ and the following two facts: (i) $|\Sigma_k| = |$PSET$(\Sigma_k)| = k$ (by $S_k : 2$), and (ii)$[p_{i_{k+1}}, t_{k+1}] \in \mathcal{P}_k \times$ COINSPACE and $\mathcal{P}_k$ does not include any process from PSET(Σ_k). □

(6) *Claim* 6. Let $\mathcal{P}_{k+1} = \{p_1, p_2, \ldots, p_{n-1}\} -$ PSET(Σ_{k+1}). Let γ be any schedule from $(\mathcal{P}_{k+1} \times$ COINSPACE$)^*$. Then we have the following:
- (a) $\Lambda_{k+1}[p_{i_{k+1}}, t_{k+1}] \approx_{B_{k+1}} \Lambda_{k+1}\gamma[p_{i_{k+1}}, t_{k+1}]$.
- (b) $\Lambda_{k+1}\Sigma_{k+1} \approx_{B_{k+1}} \Lambda_{k+1}\gamma\Sigma_{k+1}$.
- (c) $\Lambda_{k+1}\Sigma_{k+1} \approx_{\mathcal{S}_k} \Lambda_k\Sigma_k \approx_{\mathcal{S}_k} \Lambda_{k+1}\gamma\Sigma_{k+1}$.

Proof. Part (a) of this claim is a rephrasing of Claim 3. The proof of the other two parts of this claim will use Observation O1, stated earlier in the proof of Claim 3.

By construction, $p_{i_{k+1}} \notin$ PSET(Σ_k). By definition of γ, PSET$(\gamma) \cap$ PSET$(\Sigma_k) = \emptyset$. It follows that $\Lambda_{k+1}[p_{i_{k+1}}, t_{k+1}] \approx_{\text{PSET}(\Sigma_k)} \Lambda_{k+1}\gamma[p_{i_{k+1}}, t_{k+1}]$. From this, the fact that each process in PSET(Σ_k) appears only once in Σ_k and $|\Sigma_k| = k$, we conclude that the sequence of base objects accessed and the operations applied in the last k steps of $\Lambda_{k+1}[p_{i_{k+1}}, t_{k+1}]\Sigma_k$ are identical to the sequence of base objects accessed and the operations applied in the last k steps of $\Lambda_{k+1}\gamma[p_{i_{k+1}}, t_{k+1}]\Sigma_k$. This, together with part (a) of the claim, implies part (b).

It follows from the induction hypothesis $S_k : 4$ that $\Lambda_k\lambda_{k+1}[p_{i_{k+1}}, t_{k+1}]\Sigma_k \approx_{\mathcal{S}_k} \Lambda_k\Sigma_k \approx_{\mathcal{S}_k} \Lambda_k\lambda_{k+1}\gamma[p_{i_{k+1}}, t_{k+1}]\Sigma_k$. This, together with prior definitions of Λ_{k+1} as $\Lambda_k\lambda_{k+1}$ and Σ_{k+1} as $[p_{i_{k+1}}, t_{k+1}]\Sigma_k$, gives part (c) of the claim. □

(7) *Claim* 7.
- (a) Let $\mathcal{S}_{k+1}$ be the set of base objects that p_n accesses in $\Lambda_{k+1}\Sigma_{k+1}\Pi_{k+1}$. Then $\mathcal{S}_{k+1} = \mathcal{S}_k \cup \{B_{k+1}\}$ and $|\mathcal{S}_{k+1}| = k + 1$.
- (b) In $\Lambda_{k+1}\Sigma_{k+1}\Pi_{k+1}$, p_n's first operation on $\mathcal{O}$ has either not completed or just completed.

Proof. We make the following observations: (1) $\Lambda_k\Sigma_k \approx_{p_n} \Lambda_{k+1}\Sigma_{k+1}$ (since neither $\Lambda_k\Sigma_k$ nor $\Lambda_{k+1}\Sigma_{k+1}$ contains p_n); (2) $\Lambda_k\Sigma_k \approx_{\mathcal{S}_k} \Lambda_{k+1}\Sigma_{k+1}$ (this is part (c) of Claim 6); (3) by definition of $\mathcal{S}_k$, $\mathcal{S}_k$ is exactly the set of base objects that p_n accesses in $\Lambda_k\Sigma_k\Pi_k$; and (4) by definition of π_{k+1}, in $\Lambda_k\Sigma_k\Pi_k\pi_{k+1}$, it is only in the last step that p_n accesses a base object not in $\mathcal{S}_k$ (this base object is B_{k+1}), and p_n's first

operation on $\mathcal{O}$ has either not completed or just completed. These observations imply part (b) of the claim and that $\mathcal{S}_{k+1} = \mathcal{S}_k \cup \{B_{k+1}\}$. This, together with $|\mathcal{S}_k| = k$ (by induction hypothesis), implies $|\mathcal{S}_{k+1}| = k + 1$. □

We have proved all four parts of Statement S_{k+1}: part 1 in Claims 4 and 2, Part 2 in Claim 5, part 3 in Claim 7; part 4 follows from parts (b) and (c) of Claim 6 and Claim 7(a). This completes the induction step and hence the proof of Statement S_k for all $0 \leq k \leq n-1$.

We now proceed to prove Theorem 3.2. The first part of the theorem is immediate from part 3 of Statement S_{n-1}. To obtain the second part of the theorem, observe that a deterministic implementation can be viewed as a randomized implementation for which COINSPACE is a singleton set. Since Statement S_k $(0 \leq k \leq n-1)$ is proved for any nonempty countable COINSPACE, Statement S_{n-1} is true for any deterministic implementation. By part 3 of Statement S_{n-1}, in $\Lambda_{n-1}\Sigma_{n-1}\Pi_{n-1}$, p_n accesses $n-1$ base objects and has either not completed or just completed its first operation on $\mathcal{O}$. This implies that the solo-termination time complexity is at least $n-1$. Hence, we have the theorem. □

4. Examples of perturbable types. We show that the following common types of objects are perturbable for n processes: modulo k counter for any $k \geq 2n$, increment object, fetch&add, k-valued compare&swap for any $k \geq n$, LL/SC bit, and single-writer snapshot. It follows from Theorem 3.2 that the space complexity of a randomized implementation or the time complexity of a deterministic implementation of any of these objects from resettable consensus objects and historyless objects is at least $n-1$.

4.1. Modulo counter and related objects. A *modulo k counter* supports *increment* and *read* operations. The states are $0, 1, \ldots, k-1$. The *increment* operation adds 1 to the state (modulo k) and returns *ack*. The *read* operation returns the state without affecting it. The following proposition is immediate from the linearizability requirement.

PROPOSITION 4.1. *Let $\mathcal{O}$ be a modulo k counter, initialized to 0. Let E be a finite execution of $(p_1, \ldots, p_n; \mathcal{O})$ such that in the configuration C at the end of E, process p_n has no pending operation on $\mathcal{O}$. Suppose p_n runs alone from C and performs a read operation on $\mathcal{O}$. If the number of completed increments in E is at least v and the sum in E of the number of completed increments and the number of pending increments is at most v', then the value returned by the read of p_n is in the range $[v, v'] \bmod k$.*

LEMMA 4.2. *For all $k \geq 2n$, modulo k counter is perturbable for n processes, for any initial state.*

Proof. Without loss of generality, we prove the lemma for initial state 0. Consider any linearizable and solo-terminating randomized implementation of a modulo k counter $\mathcal{O}$, initialized to 0 and shared by processes $p_1, \ldots, p_n$. For $1 \leq i \leq n-1$, let *op-list*$_i$ be an infinite sequence of *increment* operations, and *op-list*$_n$ be an infinite sequence of *read* operations. Let Λ, Σ, and Π be any schedules that satisfy the four conditions listed in Definition 3.1.

Let p_l be any process in $\{p_1, \ldots, p_{n-1}\} - \text{PSET}(\Sigma)$, and $\gamma \in (\{p_l\} \times \text{COINSPACE})^*$ be the shortest schedule such that there are exactly n more completed increment operations on $\mathcal{O}$ in $\Lambda\gamma$ than in Λ. Since the implementation is solo-terminating, γ exists. We now make the following observations:

(1) If a process completes an increment on $\mathcal{O}$ in the last $|\Sigma|$ steps of $\Lambda\Sigma$, then it has no pending increment on $\mathcal{O}$ in $\Lambda\Sigma$. Furthermore, no process completes more than one increment on $\mathcal{O}$ in the last $|\Sigma|$ steps of $\Lambda\Sigma$.

This follows from the fact that each process appears at most once in the schedule Σ.

(2) For any execution E, let $\mathrm{NP}(E)$ denote the number of pending increment operations on $\mathcal{O}$ in E. The sum of $\mathrm{NP}(\Lambda\Sigma)$ and the number of increments that completed in the last $|\Sigma|$ steps of $\Lambda\Sigma$ is at most $n-1$.
This follows from (1) and the fact that $\textsc{pset}(\Lambda\Sigma) \subseteq \{p_1, \ldots, p_{n-1}\}$.

(3) The sum of $\mathrm{NP}(\Lambda\gamma\Sigma)$ and the number of increments that completed in the last $|\Sigma|$ steps of $\Lambda\gamma\Sigma$ is at most $n-1$.
This also follows from (1) and the fact that $\textsc{pset}(\Lambda\gamma\Sigma) \subseteq \{p_1, \ldots, p_{n-1}\}$.

(4) For any execution E, let $\mathrm{NC}(E)$ denote the number of completed increment operations on $\mathcal{O}$ in E. Let $\mathrm{NC}(\Lambda) = v$. In $\Lambda\Sigma\Pi$, the value res, which p_n's first operation on $\mathcal{O}$ (which is a read) returns, is in the range $[v, v+n-1] \bmod k$.
This follows from Proposition 4.1 and the following two chains of inequalities:

$$\mathrm{NC}(\Lambda\Sigma) \geq \mathrm{NC}(\Lambda) = v,$$

$$\begin{aligned}\mathrm{NC}(\Lambda\Sigma) + \mathrm{NP}(\Lambda\Sigma) &= \mathrm{NC}(\Lambda) + \mathrm{NP}(\Lambda\Sigma) \\ &\quad + \text{number of increments that completed in} \\ &\quad\quad \text{the last } |\Sigma| \text{ steps of } \Lambda\Sigma \\ &\leq v + n - 1 \qquad \text{(by (2))}.\end{aligned}$$

(5) In $\Lambda\gamma\Sigma\Pi$, if p_n's first operation on $\mathcal{O}$ completes, it returns a value in the range $[v+n, v+2n-1] \bmod k$.
This follows from Proposition 4.1 and the following two chains of inequalities:

$$\mathrm{NC}(\Lambda\gamma\Sigma) \geq \mathrm{NC}(\Lambda\gamma) = v + n,$$

$$\begin{aligned}\mathrm{NC}(\Lambda\gamma\Sigma) + \mathrm{NP}(\Lambda\gamma\Sigma) &= \mathrm{NC}(\Lambda\gamma) + \mathrm{NP}(\Lambda\gamma\Sigma) \\ &\quad + \text{number of increments that completed in} \\ &\quad\quad \text{the last } |\Sigma| \text{ steps of } \Lambda\gamma\Sigma \\ &\leq (v+n) + (n-1) \qquad \text{(by (3))}.\end{aligned}$$

Since $k \geq 2n$, the range $[v, v+n-1] \bmod k$ and the range $[v+n, v+2n-1] \bmod k$ are disjoint. This, together with (4) and (5), implies Lemma 4.2. □

An *increment object* is a special case of a modulo k counter for $k = \infty$. Since the finiteness of k is not used in the proofs of Proposition 4.1 or Lemma 4.2, we have the following result.

LEMMA 4.3. *An increment object is perturbable for n processes, for any initial state.*

A *fetch&add object* supports the operation fetch&add(v), for any integer v. The states are integers. The fetch&add(v) operation adds v to the state and returns the previous state. Proceeding analogously as in the proof of Lemma 4.2, with $k = \infty$ and the operations *increment*, *read* replaced by *fetch&add*(1), *fetch&add*(0), we obtain the following lemma.

LEMMA 4.4. *A fetch&add object is perturbable for n processes, for any initial state.*

4.2. Compare&swap. A *k-valued compare&swap object* supports the operations *read* and $c\&s(u, v)$ for all $u, v \in \{1, 2, \ldots, k\}$. The states are $1, 2, \ldots, k$. The effect of $c\&s(u, v)$ depends on whether or not the state is u: if the state is u, $c\&s(u, v)$

changes the state to v and returns *true*; otherwise it returns *false* without affecting the state. We say a compare&swap operation is *successful* if it returns *true*.

PROPOSITION 4.5. *Let C be any reachable configuration of $(p_1, \ldots, p_n; \mathcal{O})$, where $\mathcal{O}$ is a k-valued compare&swap object. Suppose that process p_l has no pending operations on $\mathcal{O}$ in C. For any $w \in \{1, 2, \ldots, k\}$, if p_l runs alone from C, completing the sequence of operations read, c&s$(1, w)$, c&s$(2, w)$, $\ldots$, c&s(k, w), then one of the following is true:*

(1) *One of the c&s operations of p_l returns true.*
(2) *Some operation on $\mathcal{O}$ that was pending in C is linearized after the read and before the last c&s operation of p_l.*

Proof. Let v be the value returned by the read operation of p_l. Suppose that statement (1) in the proposition is false. Since c&s(v, w), which is one of the n c&s operations that p_l performed following the read, did not return true, some pending operation must have taken effect after the read and before the c&s(v, w). ∎

PROPOSITION 4.6. *Let C be any reachable configuration of $(p_1, \ldots, p_n; \mathcal{O})$, where $\mathcal{O}$ is a k-valued compare&swap object. Suppose that process p_l has no pending operations on $\mathcal{O}$ in C. Let $w \in \{1, 2, \ldots, k\}$ and suppose that p_l runs alone from C, completing the following sequence of operations n times: read, c&s$(1, w)$, c&s$(2, w)$, $\ldots$, c&s(k, w). Then, at least one of the c&s operations returns true.*

Proof. The proposition follows by successive application of Proposition 4.5 and the observation that there can be at most $n-1$ pending operations on $\mathcal{O}$ in C. ∎

LEMMA 4.7. *For all $k \geq n$, k-valued compare&swap object is perturbable for n processes for any initial state.*

Proof. Consider any linearizable and solo-terminating randomized implementation of a k-valued compare&swap object $\mathcal{O}$, initialized to any value and shared by processes $p_1, \ldots, p_n$. For any $1 \leq j \leq k$, let α_j denote the operation sequence *read*, c&s$(1, j)$, c&s$(2, j)$, $\ldots$, c&s(k, j). Let β denote the operation sequence $\alpha_1^n \alpha_2^n \cdots \alpha_k^n$, where α_i^m denotes the sequence α_i repeated m times. Thus, $|\alpha_j| = k + 1$ and $|\beta| = nk(k + 1)$. For all $1 \leq i \leq n - 1$, initialize the input variable *op-list*$_i$ to the infinite sequence $\beta\beta\beta, \ldots$, and initialize *op-list*$_n$ to the infinite sequence of *read* operations. Let Λ, Σ, and Π be any schedules that satisfy the four conditions listed in Definition 3.1.

Let p_l be any process in $\{p_1, \ldots, p_{n-1}\} - \text{PSET}(\Sigma)$. If p_l has any pending operation on $\mathcal{O}$ at the end of Λ, let $\gamma' \in (\{p_l\} \times \text{COINSPACE})^*$ be such that p_l just completes that operation in $\Lambda\gamma'$. Otherwise let $\gamma' = \epsilon$. Thus, at the end of $\Lambda\gamma'$, p_l has no pending operation on $\mathcal{O}$, and any pending operations have to be from processes in $\{p_1, \ldots, p_{n-1}\} - \{p_l\}$. Let $P \subseteq \{p_1, \ldots, p_{n-1}\} - \{p_l\}$ be the set of processes that have pending operations on $\mathcal{O}$ at the end of $\Lambda\gamma'$.

Let Q be the set of processes that initiate a new operation on $\mathcal{O}$ in the last $|\Sigma|$ steps of $\Lambda\gamma'\Sigma$. Since $p_l \in \{p_1, \ldots, p_{n-1}\} - \text{PSET}(\Sigma)$, we have $Q \subseteq \{p_1, \ldots, p_{n-1}\} - \{p_l\}$. Furthermore, since each process appears at most once in Σ, if a process has a pending operation in $\Lambda\gamma'$, then that process cannot initiate a new operation on $\mathcal{O}$ in the last $|\Sigma|$ steps of $\Lambda\gamma'\Sigma$. In other words, $P \cap Q = \emptyset$. From this and the fact $P, Q \subseteq \{p_1, \ldots, p_{n-1}\} - \{p_l\}$, we have $|P| + |Q| \leq n - 2$. That is, the sum of the number of pending operations on $\mathcal{O}$ in $\Lambda\gamma'$ and the number of operations on $\mathcal{O}$ initiated in the last $|\Sigma|$ steps of $\Lambda\gamma'\Sigma$ is at most $n - 2$. Let V be the set of all v such that a c&s$(v, *)$ operation[5] on $\mathcal{O}$ is either pending in $\Lambda\gamma'$ or initiated in the last $|\Sigma|$ steps of $\Lambda\gamma'\Sigma$. From the above, $|V| \leq n - 2$.

[5] An asterisk in a field indicates that we do not care what the value of that field is.

Recall from (the fourth condition in) Definition 3.1 that res is the value returned by p_n's first operation on $\mathcal{O}$ in $\Lambda\Sigma\Pi$. Let $w \in \{1, 2, \ldots, n\}$ be such that $w \notin V$ and $w \neq res$. Let $\gamma'' \in (\{p_l\} \times \text{COINSPACE})^*$ be the shortest schedule such that, in $\Lambda\gamma'\gamma''$, we have the following: (i) p_l has no pending operations, (ii) there are at least $n(k+1)$ completed operations on $\mathcal{O}$ (by p_l) in the last $|\gamma''|$ steps, and (iii) the sequence of $n(k+1)$ most recent completed operations of p_l on $\mathcal{O}$ is α_w^n. The definition of $op\text{-}list_l$ and the fact that the implementation is solo-terminating imply that γ'' exists. We now make the following observations:

(1) In $\Lambda\gamma'\gamma''$, the most recent $n(k+1)$ operations of p_l on $\mathcal{O}$ includes a *successful* compare&swap operation of the form c and $s(*, w)$. (Let OP denote any such operation.)

Proof. In $\Lambda\gamma'\gamma''$, the most recent $n(k+1)$ operations of p_l on $\mathcal{O}$ are the operations in α_w^n. All of the compare&swap operations in α_w^n are of the form $c\&s(*, w)$ and, by Proposition 4.6, at least one of these succeeds. □

(2) Consider any linearization of $\Lambda\gamma'\gamma''\Sigma$. If OP′ is a successful compare&swap operation that is linearized after OP, then OP′ must be of the form $c\&s(*, w)$.

Proof. We prove this assertion by contradiction. Let OP′ be the first successful compare&swap operation that is of the form $c\&s(*, x)$, for some $x \neq w$, to be linearized after OP. Since OP is successful and each successful compare&swap operation that is linearized after OP and before OP′ is of the form $c\&s(*, w)$, the value of the object is w immediately before OP′.

There are three cases to consider: (i) OP′ is an operation from p_l that follows OP, (ii) OP′ is an operation which is pending in $\Lambda\gamma'$, or (iii) OP′ is an operation which is initiated in the last $|\Sigma|$ steps of $\Lambda\gamma'\gamma''\Sigma$. In case (i), by definition of γ'' and OP, OP′ is of the form $c\&s(*, w)$, a contradiction. In cases (ii) and (iii), by definitions of V and w, OP′ $= c\&s(v, *)$ for some $v \neq w$. Since the value of the object is w immediately before OP′, the fact $v \neq w$ implies that OP′ $= c\&s(v, *)$ cannot be successful, which is a contradiction. □

(3) In $\Lambda\gamma'\gamma''\Sigma\Pi$, if p_n's first operation on $\mathcal{O}$ (which is a read operation) completes, it returns a value different from res.

Proof. Since OP is successful and is of the form $c\&s(*, w)$, the value of $\mathcal{O}$ immediately after OP is w. By the previous observation, in $\Lambda\gamma'\gamma''\Sigma$, every successful compare&swap linearized after OP is also of the form $c\&s(*, w)$.

Therefore, in $\Lambda\gamma'\gamma''\Sigma\Pi$, if p_n's first operation on $\mathcal{O}$ (which is a read operation) completes, it returns w. But w, by definition, is different from res. Hence, we have the observation. □

Lemma 4.7 is immediate from the last observation. □

4.3. LL/SC bit. An *n-process load-link store-conditional* (LL/SC) *bit* supports the operations LL and $SC(b)$ for $b = 0, 1$. The states are pairs (v, S) for all $v \in \{0, 1\}$ and $S \subseteq \{1, 2, \ldots, n\}$. The operation LL from process p_i, when applied in state (v, S), returns v and changes the state to (v, S'), where $S' = S \cup \{i\}$. The operation $SC(b)$ from process p_i, when applied in state (v, S), has the following effect: if $i \in S$, the state changes to $(b, \emptyset)$ and *true* is returned; otherwise the state is not affected and *false* is returned. We say an SC operation is *successful* if it returns *true*.

PROPOSITION 4.8. *Let C be any reachable configuration of $(p_1, \ldots, p_n; \mathcal{O})$, where $\mathcal{O}$ is an n-process LL/SC bit. Suppose that process p_l has no pending operations on $\mathcal{O}$ in C. If p_l runs alone from C, completing an LL operation and then an $SC(b)$ operation (for any $b \in \{0, 1\}$), then one of the following is true:*

(1) *The $SC(b)$ operation of p_l returns true.*

(2) *Some SC operation on $\mathcal{O}$ that was pending in C is linearized after the LL and before the SC(b) of p_l.*

Proof. The proposition follows from the specification of n-process LL/SC bit. ∎

PROPOSITION 4.9. *Let C be any reachable configuration of $(p_1, \ldots, p_n; \mathcal{O})$, where $\mathcal{O}$ is an n-process LL/SC bit. Suppose that process p_l has no pending operations on $\mathcal{O}$ in C. For $b \in \{0, 1\}$, suppose further that p_l runs alone from C, completing the following sequence of operations n times: LL, SC(b). Then at least one of the SC(b) operations returns true.*

Proof. The proposition follows by repeated application of Proposition 4.8 and the observation that there can be at most $n - 1$ pending operations on $\mathcal{O}$ in C. ∎

LEMMA 4.10. *LL/SC bit is perturbable for n processes for any initial state.*

Proof. Consider any linearizable and solo-terminating randomized implementation of an LL/SC bit $\mathcal{O}$, initialized to any value and shared by processes $p_1, \ldots, p_n$. For $j \in \{0, 1\}$, let α_j denote the sequence $LL, SC(j), LL, SC(j), \ldots, LL, SC(j)$ that has a total of $2n$ operations (n LL operations and n $SC(j)$ operations). For all $1 \leq i \leq n-1$, initialize the input variable *op-list*$_i$ to the infinite sequence $\alpha_0, \alpha_1, \alpha_0, \alpha_1, \alpha_0, \alpha_1, \ldots$ and initialize *op-list*$_n$ to the infinite sequence of LL operations. Let Λ, Σ, and Π be any schedules that satisfy the four conditions listed in Definition 3.1.

Let p_l be any process in $\{p_1, \ldots, p_{n-1}\} - \text{PSET}(\Sigma)$. If p_l has any pending operation on $\mathcal{O}$ at the end of Λ, let $\gamma' \in (\{p_l\} \times \text{COINSPACE})^*$ be such that p_l just completes that operation in $\Lambda\gamma'$. Otherwise let $\gamma' = \epsilon$. Thus, at the end of $\Lambda\gamma'$, p_l has no pending operation on $\mathcal{O}$, but other processes may. Any such pending operations have to be from processes in $\{p_1, \ldots, p_{n-1}\} - \{p_l\}$.

Recall from (the fourth condition in) Definition 3.1 that *res* is the value returned by p_n's first operation on $\mathcal{O}$ in $\Lambda\Sigma\Pi$. Let $w = 1 - res$. Let $\gamma'' \in (\{p_l\} \times \text{COINSPACE})^*$ be the shortest schedule such that, in $\Lambda\gamma'\gamma''$, we have the following: (i) p_l has no pending operations, (ii) there are at least $2n$ completed operations on $\mathcal{O}$ (by p_l) in the last $|\gamma''|$ steps, and (iii) the sequence of $2n$ most recent operations of p_l on $\mathcal{O}$ is α_w. The definition of *op-list*$_l$ and the fact that the implementation is solo-terminating imply that γ'' exists. We now make the following observations:

(1) In $\Lambda\gamma'\gamma''$, the most recent $2n$ operations of p_l on $\mathcal{O}$ include a successful $SC(w)$ operation. (Let OP denote any such operation.)

Proof. Consider the sequence α_w of the $2n$ most recent (alternating LL and $SC(w)$) operations of p_l on $\mathcal{O}$. By Proposition 4.9, at least one of these $SC(w)$ operations succeeds. ∎

(2) Consider any linearization of $\Lambda\gamma'\gamma''\Sigma$. Let OP$' = SC(v)$ be any successful operation that is linearized after OP. Then $v = w$.

Proof. If OP$'$ is linearized after OP, there are three cases to consider: (i) OP$'$ is an operation from p_l that follows OP, (ii) OP$'$ is an operation which is pending in $\Lambda\gamma'$, or (iii) OP$'$ is an operation which is initiated in the last $|\Sigma|$ steps of $\Lambda\gamma'\gamma''\Sigma$. In the following we show that the observation holds in all cases.

Case (i). OP$'$ is an operation from p_l that follows OP.

Since $p_l \in \{p_1, \ldots, p_{n-1}\} - \text{PSET}(\Sigma)$, p_l has no step in the last $|\Sigma|$ steps of $\Lambda\gamma'\gamma''\Sigma$. From this and the definition of γ'', the $2n$ most recent operations from p_l in $\Lambda\gamma'\gamma''\Sigma$ are LL, $SC(w)$, LL, $SC(w)$, …, LL, $SC(w)$. By definition, OP is one of these $2n$ operations. Thus, if OP$' = SC(v)$ is an SC operation from p_l that follows OP, then v must equal w.

Cases (ii) and (iii). OP$'$ is pending in $\Lambda\gamma'$ or OP$'$ is initiated in the last $|\Sigma|$

steps of $\Lambda\gamma'\gamma''\Sigma$.

Let p_i be the process that invoked $\text{OP}' = SC(v)$. Consider the most recent LL operation from p_i that preceded OP'. Let OP'' denote this operation. We assert that in both Case (ii) and Case (iii), OP'' completed in Λ. In the next two paragraphs we prove this assertion for the two cases.

In Case (ii), since OP' is pending in $\Lambda\gamma'$, OP'' must have completed in $\Lambda\gamma'$. Since $\text{PSET}(\gamma'\gamma'') = \{p_l\}$ and $p_l \neq p_i$ (because, unlike p_i, p_l has no pending operation in $\Lambda\gamma'$), it follows that p_i completed OP'' in Λ.

In Case (iii), since each process appears at most once in Σ, if p_i initiated OP' in the last $|\Sigma|$ steps of $\Lambda\gamma'\gamma''\Sigma$, then it follows that p_i completed OP'' in $\Lambda\gamma'\gamma''$. Further, since $\text{PSET}(\gamma'\gamma'') = \{p_l\}$ and $p_l \neq p_i$ (because $p_l \in \{p_1, \ldots, p_{n-1}\} - \text{PSET}(\Sigma)$), it follows that p_i completed OP'' in Λ.

Since OP did not even begin in Λ, it follows that OP'' is linearized before OP. Thus, we have the following situation: p_i applied the LL operation OP'' and then the SC operation OP'; p_l's successful SC operation OP is linearized after OP'' and before OP'. By the specification of LL/SC bit, OP' must return *false*. This contradicts the premise that OP' is successful. Thus Cases (ii) and (iii) cannot arise. □

(3) In $\Lambda\gamma'\gamma''\Sigma\Pi$, if p_n's first operation on $\mathcal{O}$ (which is an LL operation) completes, it returns a response different from res.

Proof. Since $\text{OP} = SC(w)$ is successful, the value of $\mathcal{O}$ immediately after OP is w. By the previous observation, in $\Lambda\gamma'\gamma''\Sigma$, every successful SC linearized after OP is also of the form $SC(w)$. Therefore, in $\Lambda\gamma'\gamma''\Sigma\Pi$, p_n's first operation on $\mathcal{O}$ (which is an LL operation) returns w. Since $w = 1 - res$, we have $w \neq res$. Hence, we have the observation. □

Lemma 4.10 is immediate from the last observation. □

4.4. Single-writer snapshot. An *n-process single-writer binary snapshot object* [AAD+93, And93] supports the operations *read* and *write* v for $v \in \{0, 1\}$. The states are $[v_1, v_2, \ldots, v_n]$, where $v_1, v_2, \ldots, v_n$ are from $\{0, 1\}$. A *write* x operation from process p_i, when applied in state $[v_1, v_2, \ldots, v_n]$, changes the state to $[v_1, \ldots, v_{i-1}, x, v_{i+1}, \ldots, v_n]$ and returns *ack*. The *read* operation, when applied in state $[v_1, v_2, \ldots, v_n]$, returns $[v_1, v_2, \ldots, v_n]$ without affecting the state.

LEMMA 4.11. *Single-writer binary snapshot object is perturbable for n processes for any initial state.*

Proof. Consider any linearizable and solo-terminating randomized implementation of an n-process single-writer binary snapshot object $\mathcal{O}$, initialized to any value and shared by processes $p_1, \ldots, p_n$. For $1 \leq i \leq n-1$, let $\textit{op-list}_i$ be an infinite sequence of alternating *write 0* and *write* 1 operations. Let $\textit{op-list}_n$ be an infinite sequence of *read* operations. Let Λ, Σ, and Π be any schedules that satisfy the four conditions listed in Definition 3.1.

Recall from (the fourth condition in) Definition 3.1 that res is the value returned by p_n's first operation on $\mathcal{O}$ in $\Lambda\Sigma\Pi$. Let $res = [v_1, v_2, \ldots, v_n]$. Let p_l be any process in $\{p_1, \ldots, p_{n-1}\} - \text{PSET}(\Sigma)$. Let $\gamma \in (\{p_l\} \times \text{COINSPACE})^*$ be the shortest schedule such that, in $\Lambda\gamma$, p_l just completed writing $1 - v_l$. Since the implementation is solo-terminating, γ exists. Further, since $p_l \in \{p_1, \ldots, p_{n-1}\} - \text{PSET}(\Sigma)$, p_l has no step in the last $|\Sigma|$ steps of $\Lambda\gamma\Sigma$. Therefore, if p_n's first operation in $\Lambda\gamma\Sigma\Pi$ (which is a read operation) completes and returns $[w_1, w_2, \ldots, w_n]$, w_l must equal $1 - v_l$. It follows that $res \neq [w_1, w_2, \ldots, w_n]$. Hence, we have Lemma 4.11. □

5. Applications. In section 4, we showed that every type in set A is perturbable for n processes, for any initial state, where $A = \{$modulo k counter (for any $k \geq 2n$), increment, fetch&add, k-valued compare&swap (for any $k \geq n$), LL/SC bit, single-writer snapshot$\}$ (see Lemmas 4.2, 4.3, 4.4, 4.7, 4.10, and 4.11). From this and Theorem 3.2, we have the following.

THEOREM 5.1. *Let A be the set of types defined above. Consider any randomized implementation of an object belonging to a type in A, initialized to any state and shared by processes $p_1, \ldots, p_n$, from resettable consensus objects and historyless objects. If the implementation is linearizable and solo-terminating, then*

(1) *its space complexity is at least $n - 1$;*
(2) *if the implementation is deterministic, its solo-termination time complexity is at least $n - 1$.*

The above result does not address the complexity of implementing modulo k counter when $k < 2n$, or of implementing k-valued compare&swap when $k < n$. We discuss these cases below. The following corollary is a simple consequence of Lemma 4.2.

COROLLARY 5.2. *For all $k \geq 1$, modulo k counter is perturbable for $\lfloor k/2 \rfloor$ processes for any initial state.*

From Corollary 5.2 and Theorem 3.2, we have the following.

COROLLARY 5.3. *For any positive integer k, consider any randomized implementation of modulo k counter, initialized to any state and shared by processes $p_1, \ldots, p_{\lfloor k/2 \rfloor}$, from resettable consensus objects and historyless objects. If the implementation is linearizable and solo-terminating, then*

(1) *its space complexity is at least $\lfloor k/2 \rfloor - 1$;*
(2) *if the implementation is deterministic, its solo-termination time complexity is at least $\lfloor k/2 \rfloor - 1$.*

We observe that the time or space complexity grows monotonically with the number of processes sharing the implementation. This observation, together with Corollary 5.3, gives the following.

THEOREM 5.4. *For any $k \leq 2n$, consider any randomized implementation of modulo k counter, initialized to any state and shared by processes $p_1, \ldots, p_n$, from resettable consensus objects and historyless objects. If the implementation is linearizable and solo-terminating, then*

(1) *its space complexity is at least $\lfloor k/2 \rfloor - 1$;*
(2) *if the implementation is deterministic, its solo-termination time complexity is at least $\lfloor k/2 \rfloor - 1$.*

Using Lemma 4.7 and reasoning as above, we have the following.

THEOREM 5.5. *For any $k \leq n$, consider any randomized implementation of k-valued compare&swap, initialized to any state and shared by processes $p_1, \ldots, p_n$, from resettable consensus objects and historyless objects. If the implementation is linearizable and solo-terminating, then*

(1) *its space complexity is at least $k - 1$;*
(2) *if the implementation is deterministic, its solo-termination time complexity is at least $k - 1$.*

Acknowledgments. We thank Faith Fich and Nir Shavit, and the SICOMP and PODC '96 referees for many helpful suggestions on how to improve the proof and the general presentation of the paper.

EFFICIENT SEARCH FOR APPROXIMATE NEAREST NEIGHBOR IN HIGH DIMENSIONAL SPACES*

EYAL KUSHILEVITZ†, RAFAIL OSTROVSKY‡, AND YUVAL RABANI†

Abstract. We address the problem of designing data structures that allow efficient search for approximate nearest neighbors. More specifically, given a database consisting of a set of vectors in some high dimensional Euclidean space, we want to construct a space-efficient data structure that would allow us to search, given a query vector, for the closest or nearly closest vector in the database. We also address this problem when distances are measured by the L_1 norm and in the Hamming cube. Significantly improving and extending recent results of Kleinberg, we construct data structures whose size is polynomial in the size of the database and search algorithms that run in time nearly linear or nearly quadratic in the dimension. (Depending on the case, the extra factors are polylogarithmic in the size of the database.)

Key words. nearest neighbor search, data structures, random projections

1. Introduction.

Motivation. Searching for a nearest neighbor among a specified database of points is a fundamental computational task that arises in a variety of application areas, including information retrieval [32, 33], data mining [20], pattern recognition [8, 14], machine learning [7], computer vision [4], data compression [18], and statistical data analysis [10]. In many of these applications the database points are represented as vectors in some high dimensional space. For example, latent semantic indexing is a recently proposed method for textual information retrieval [9]. The semantic contents of documents, as well as the queries, are represented as vectors in $\mathbb{R}^d$, and proximity is measured by some distance function. Despite the use of dimension reduction techniques such as principal component analysis, vector spaces of several hundred dimensions are typical. Multimedia database systems, such as IBM's QBIC [16] or MIT's Photobook [31], represent features of images and queries similarly. In such applications, the mapping of attributes of objects to coordinates of vectors is heuristic, and so is the choice of metric. Therefore, an approximate search is just as good as an exact search and is often used in practice.

The problem. Let $\mathcal{V}$ be some (finite or infinite) vector space of dimension d, and let $\|\cdot\|$ be some norm (Minkowsky distance function) for $\mathcal{V}$. Given a database consisting of n vectors in $\mathcal{V}$, a slackness parameter $\epsilon > 0$, and a query vector q, a $(1+\epsilon)$-approximate nearest neighbor of q is a database vector a such that for any other database vector b, $\|q-a\| \leq (1+\epsilon)\|q-b\|$. We consider the following problem.

*Received by the editors November 13, 1998; accepted for publication (in revised form) August 17, 1999; published electronically June 3, 2000. A preliminary version of this paper appeared in Proceedings of the 30th Annual ACM Symposium on Theory of Computing, Dallas, TX, 1998, pp. 614–623.

Given such a database and $\epsilon > 0$, design a data structure $\mathcal{S}$ and a $(1+\epsilon)$-approximate nearest neighbor search algorithm (using $\mathcal{S}$).

We aim at efficient construction of $\mathcal{S}$ as well as quick lookup. Our performance requirements are the following. (i) The algorithm for constructing $\mathcal{S}$ should run in time polynomial in n and d (and thus the size of $\mathcal{S}$ is polynomial in n and d). (ii) The search algorithm should improve significantly over the naïve (brute force) $O(dn)$ time exact algorithm. More precisely, we aim at search algorithms using (low) polynomial in d and $\log n$ arithmetic operations.

Our results. We obtain results for the Hamming cube ($\{0,1\}^d$ with the L_1 norm) for Euclidean spaces ($\mathbb{R}^d$ with the L_2 norm) and for ℓ_1^d ($\mathbb{R}^d$ with the L_1 norm). Our results for the cube generalize to vector spaces over any finite field; thus we can handle a database of documents (strings) over any finite alphabet. Our results for Euclidean spaces imply similar bounds for distance functions used in latent semantic indexing (these are not metrics, but their square root is Euclidean).

Our data structures are of size $(dn)^{O(1)}$. For the d-dimensional Hamming cube as well as for ℓ_1^d, our search algorithm runs in time $O(d\text{poly}\log(dn))$ (the logarithmic factors are different in each case). For d-dimensional Euclidean spaces, our search algorithm runs in time $O(d^2\text{poly}\log(dn))$. (The big-Oh notation hides factors polynomial in $1/\epsilon$.)

Our algorithms are probabilistic. They succeed with any desired probability (at the expense of time and space complexity). We have to make precise the claims for success: The algorithm that constructs $\mathcal{S}$ succeeds with high probability, and if successful, $\mathcal{S}$ is good for every possible query. If $\mathcal{S}$ has been constructed successfully, then given any query, the search algorithm succeeds to find an approximate nearest neighbor with high probability, and this probability can be increased as much as we like *without* modifying $\mathcal{S}$ (just by running the search algorithm several times). An alternative, weaker guarantee is to construct a data structure that is good for most queries. Our algorithms provide the stronger guarantee. (This means that they can work when the queries are generated by an adversary that has access to the random bits used in the construction of the data structure.) Much of the difficulty arises from this requirement.

Related work. In computational geometry, there is a vast amount of literature on proximity problems in Euclidean spaces, including nearest neighbor search and the more general problem of point location in an arrangement of hyperplanes. We dare not attempt to survey but the most relevant papers to our work.

There are excellent solutions to nearest neighbor search in low (two or three) dimensions. For more information see, e.g., [30]. In high dimensional space, the problem was first considered by Dobkin and Lipton [11]. They showed an exponential in d search algorithm using (roughly) a double-exponential in d (summing up time and space) data structure. This was improved and extended in subsequent work of Clarkson [5], Yao and Yao [35], Matoušek [28], Agarwal and Matoušek [1], and others, all requiring query time exponential in d. Recently, Meiser [29] obtained a polynomial in d search algorithm using an exponential in d size data structure.

For approximate nearest neighbor search, Arya et al. [3] gave an exponential in d time search algorithm using a linear size data structure. Clarkson [6] gave a search algorithm with improved dependence on ϵ. Recently, Kleinberg [24] gave two algorithms that seem to be the best results for large d prior to this work. The first algorithm searches in time $O(d^2 \log^2 d + d \log^2 d \log n)$ but requires a data structure of size $O(n \log d)^{2d}$. The second algorithm uses a small data structure (nearly linear

in dn) and takes $O(n + d \log^3 n)$ time (so it beats the brute force search algorithm).

Independently of our work, Indyk and Motwani [21] obtained several results on essentially the same problems as we discuss here. Their main result gives an $O(d\text{poly}\log(dn))$ search algorithm using a data structure of size $O\left(n(1/\epsilon)^{O(d)}\right.$ $\left.\text{poly}\log(dn)\right)$ for Euclidean and other norms. They obtain this result using space partitions induced by spheres, and bucketing. In comparison with our work, they use exponential in d (but not in $1/\epsilon$) storage in contrast with our polynomial in d storage. Their search time is better than ours for the Euclidean case and similar for the L_1 norm. They also point out that dimension reduction techniques, such as those based on random projections, can be used in conjunction with their other results to get polynomial size data structures which are good for any single query with high probability. However, the data structure always fails on some queries (so an adversary with access to the random bits used in the construction can present a bad query).

Also related to our work are constructions of hash functions that map "close" elements to "close" images. In particular, *nonexpansive* hash functions guarantee that the distance between images is at most the distance between the original elements. However, such families are known only for one-dimensional points (Linial and Sasson [27]). For d-dimensional points, Indyk et al. [22] construct hash functions that increase the distance by a bounded additive term (d or $\sqrt{d}$ depending on the metric). These results do not seem useful for approximate nearest neighbor search as they can increase a very small distance δ to a distance which is much larger than $(1+\epsilon)\delta$. Dolev et al. [13, 12] construct hash functions that map all elements at distance at most ℓ to "close" images. These constructions, too, do not seem useful for approximate nearest neighbor search, because the construction time is exponential in ℓ.

Our methods. Our data structure and search algorithm for the hypercube is based on an inner product test. Similar ideas have been used in a cryptographic context by [19] and as a matter of folklore to design equality tests (see, e.g., [25]). Here, we refine the basic idea to be sensitive to distances. For Euclidean spaces, we reduce the problem essentially to a search in several hypercubes (along with random sampling to speed up the search). The reduction uses projections onto random lines through the origin. Kleinberg's algorithms are also based on a test using random projections. His test relies on the relative positions of the projected points. In contrast, our test is based on the property that the projection of any vector maintains, in expectation, its (properly scaled) length. This property underlies methods of distance preserving embeddings into low dimensional spaces, like the Johnson–Lindenstrauss lemma [23] (see also Linial, London, and Rabinovich [26]). The problem with these techniques is that when applied directly, they guarantee correct answers to most queries but not to all possible queries. In order to overcome this difficulty, we resort to the theory of Vapnik–Chervonenkis (or VC-) dimension [34] to show the existence of a small finite sample of lines that closely imitate the entire distribution for any vector. A clustering argument and another sampling argument allow us to use this sample to reduce our problem to the cube. Similar ideas work for the L_1 norm too (but we need to project onto the axes rather than onto random lines).

Notation. We denote by n the number of database points, by q the query point, and by ϵ the slackness (i.e., in reply to q we must return a database point whose distance from q is within a factor of $1 + \epsilon$ of the minimum distance from q to any database point).

Metric spaces. We consider the following metric spaces. The d-dimensional Hamming cube Q_d is the set $\{0, 1\}^d$ of cardinality 2^d, endowed with the Hamming distance

H. For $a, b \in Q_d$, $H(a,b) = \sum_i |a_i - b_i|$. For a finite set F, let $x, y \in F^d$. (That is, x, y are words of length d over the alphabet F.) The *generalized Hamming distance* $\mathcal{H}(x,y)$ is the number of dimensions where x differs from y. The Euclidean space ℓ_2^d is $\mathbb{R}^d$ endowed with the standard L_2 distance. The space ℓ_1^d is $\mathbb{R}^d$ endowed with the L_1 distance.

2. Approximate nearest neighbors in the hypercube. In this section we present an approximate nearest neighbors algorithm for the d-dimensional cube. That is, all database points and query points are in $\{0,1\}^d$ and distances are measured by Hamming distance. The first idea behind our algorithm for the hypercube is to design a separate test for each distance ℓ. Given a query q, such a test either returns a database vector at distance at most $(1+\epsilon)\ell$ from q, or informs that there is no database vector at distance ℓ or less from q. Given such a test, we can perform approximate nearest neighbor search by using binary search over $\ell \in \{1, 2, \ldots, d\}$ (and also checking distance 0—this can be done using any reasonable dictionary data structure).

We begin by defining a test, which we later use in the construction of our data structure. A β-test τ is defined as follows. We pick a subset C of coordinates of the cube by choosing each element in $\{1, 2, \ldots, d\}$ independently at random with probability β. For each of the chosen coordinates i we pick independently and uniformly at random $r_i \in \{0,1\}$. For $v \in Q_d$, define the value of τ at v, denoted $\tau(v)$ as follows:

$$\tau(v) = \sum_{i \in C} r_i \cdot v_i \pmod 2.$$

Equivalently, the test can be viewed as picking a vector $\vec{R} \in \{0,1\}^d$ in a way that each entry gets the value 0 with "high" probability (i.e., $1 - \frac{\beta}{2}$) and the value 1 with "low" probability (i.e., $\beta/2$). With this view, the value of the test on $v \in Q_d$ is just its inner product with $\vec{R}$ modulo 2.[1]

Let q be a query, and let a, b be two database points with $H(q,a) \le \ell$ and $H(q,b) > (1+\epsilon)\ell$. We claim that for $\beta = \frac{1}{2\ell}$ the above test distinguishes between a and b with constant probability. More formally, let $\beta = \frac{1}{2\ell}$, and let $\Delta(u,v) = \Pr_{\vec{R}}[\tau(u) \neq \tau(v)]$. Then we have the following lemma.

LEMMA 2.1. *There is an absolute constant $\delta_1 > 0$, such that for any $\epsilon > 0$ there is a constant $\delta_2 > \delta_1$ (depending on ϵ only), such that $\Delta(q,a) \le \delta_1$ and $\Delta(q,b) \ge \delta_2$. (In what follows we denote by δ the constant $\delta_2 - \delta_1$.)*

Proof. For any $u, v \in Q_d$ with $H(u,v) = k$ we have $\Delta(u,v) = \frac{1}{2}(1 - (1 - \frac{1}{2\ell})^k)$ (if none of the k coordinates where $u_i \neq v_i$ is chosen to be in C, then $\tau(u) = \tau(v)$; if at least one such coordinate, j, is in C, then, for every way of fixing all other choices, exactly one of the two choices for r_j will give $\tau(u) \neq \tau(v)$). Note that $\Delta(u,v)$ is monotonically increasing with k. We set $\delta_1 = \frac{1}{2}(1 - (1 - \frac{1}{2\ell})^\ell)$ and $\delta_2 = \frac{1}{2}(1 - (1 - \frac{1}{2\ell})^{(1+\epsilon)\ell})$. Thus $\delta_2 - \delta_1 = \frac{1}{2}\left[(1 - \frac{1}{2\ell})^\ell - (1 - \frac{1}{2\ell})^{(1+\epsilon)\ell}\right] = \Theta(1 - e^{-\epsilon/2})$. ∎

The above lemma implies that, for q, a, and b as above, a single test can get a small (constant) bias towards making the correct decision as to which point is closer to q. To amplify this bias we use several such tests as explained below (see Lemma 2.2).

The data structure. Our data structure $\mathcal{S}$ consists of d substructures $\mathcal{S}_1, \mathcal{S}_2, \ldots, \mathcal{S}_d$ (one for each possible distance). Fix $\ell \in \{1, 2, \ldots, d\}$. We now describe $\mathcal{S}_\ell$. Let

[1] It is common to use the inner product for "equality tests." However, these tests just distinguish the equal u, v from the nonequal u, v, but they lose all information on the distance between u and v. In our test, by appropriately choosing the value β, we can obtain some distance information.

M and T be positive integers which we specify later. $\mathcal{S}_\ell$ consists of M structures $\mathcal{T}_1, \ldots, \mathcal{T}_M$. So fix $i \in \{1, 2, \ldots, M\}$. Structure $\mathcal{T}_i$ consists of a list of T $\frac{1}{2\ell}$-tests $\vec{R}_1, \vec{R}_2, \ldots, \vec{R}_T \in \{0,1\}^d$, and a table of 2^T entries (one entry for each possible outcome of the sequence of T tests). Each entry of the table either contains a database point or is empty.

We construct the structure $\mathcal{T}_i$ as follows. We pick independently at random T $\frac{1}{2\ell}$-tests $t_1, \ldots, t_T$ (defined by $\vec{R}_1, \vec{R}_2, \ldots, \vec{R}_T \in \{0,1\}^d$). For $v \in Q_d$, let its *trace* be the vector $t(v) = (t_1(v), \ldots, t_T(v)) \in \{0,1\}^T$. Let δ_1 and δ be the constants from Lemma 2.1. An entry corresponding to $z \in \{0,1\}^T$ contains a database point v with $H(t(v), z) \leq (\delta_1 + \frac{1}{3}\delta)T$, if such a point exists (any such point, if more than one exists), and otherwise the entry is empty. This completes the specification of $\mathcal{S}$ (up to the choice of T and M). Notice that in a straightforward implementation, the size of $\mathcal{S}$ is $O(d \cdot M \cdot (dT + 2^T \log n))$ (we also need to keep the original set of points, and this takes dn space), and it takes $O(d \cdot M \cdot (dTn + 2^T n))$ time to construct $\mathcal{S}$.

LEMMA 2.2. *Let q be a query, and let a, b be two database points with $H(q,a) \leq \ell$ and $H(q,b) > (1+\epsilon)\ell$. Consider a structure $\mathcal{T}_i$ in $\mathcal{S}_\ell$, and let δ_1, δ_2, and δ be as in Lemma 2.1. Then the following hold.*

- $\Pr[H(t(q), t(a)) > (\delta_1 + \frac{1}{3}\delta)T] \leq e^{-\frac{2}{9}\delta^2 T}$.
- $\Pr[H(t(q), t(b)) < (\delta_2 - \frac{1}{3}\delta)T] \leq e^{-\frac{2}{9}\delta^2 T}$.

Proof. The proof follows immediately by plugging in the success probabilities from Lemma 2.1 in the following Chernoff bounds. For a sequence of m independently and identically distributed (i.i.d.) 0-1 random variables $X_1, X_2, \ldots, X_m$, $\Pr[\sum X_i > (p+\gamma)m] \leq e^{-2m\gamma^2}$, and $\Pr[\sum X_i < (p-\gamma)m] \leq e^{-2m\gamma^2}$, where $p = \Pr[X_i = 1]$ (see [2, Appendix A]). ∎

Our goal is to show that we can answer every possible query "correctly." This is formalized by the following definition.

DEFINITION 2.3. *For $q \in Q_d$, ℓ, and $\mathcal{T}_i$ in $\mathcal{S}_\ell$, we say that $\mathcal{T}_i$* fails at *q if there exists a database point a with $H(q,a) \leq \ell$ (or a database point b with $H(q,b) > (1+\epsilon)\ell$), such that $H(t(q), t(a)) > (\delta_1 + \frac{1}{3}\delta)T$ (or $H(t(q), t(b)) < (\delta_2 - \frac{1}{3}\delta)T$, respectively). We say that $\mathcal{S}$* fails at *q if there exists ℓ, such that more than $\mu M / \log d$ structures $\mathcal{T}_i$ in $\mathcal{S}_\ell$ fail (where μ is a constant that affects the search algorithm). We say that $\mathcal{S}$* fails *if there exists $q \in Q_d$ such that $\mathcal{S}$ fails at q.*

The following theorem bounds the probability that $\mathcal{S}$ fails at any given query q.

THEOREM 2.4. *For every $\gamma > 0$, if we set $M = (d + \log d + \log \gamma^{-1}) \log d / \mu$ and $T = \frac{9}{2}\delta^{-2} \ln(2en \log d / \mu)$, then, for any query q, the probability that $\mathcal{S}$ fails at q is at most $\gamma 2^{-d}$.*

Proof. For any ℓ, $\mathcal{T}_i$ in $\mathcal{S}_\ell$ and database point a, the probability that $H(t(q), t(a))$ is not within the desired range (i.e., $\leq (\delta_1 + \frac{1}{3}\delta)T$ if $H(q,a) \leq \ell$ or $\geq (\delta_2 - \frac{1}{3}\delta)T$ if $H(q,a) > (1+\epsilon)\ell$ or anything otherwise) is at most $e^{-\frac{2}{9}\delta^2 T} = \frac{\mu}{2en \log d}$, by Lemma 2.2. Summing over the n database points, the probability that $\mathcal{T}_i$ fails is at most $\frac{\mu}{2e \log d}$. Therefore, the expected number of $\mathcal{T}_i$s that fail is at most $\frac{\mu M}{2e \log d}$. By standard Chernoff bounds (see [2, Appendix A]), for independent 0-1 random variables $X_1, X_2, \ldots, X_m$, setting $X = \sum_i X_i$ and denoting by E the expectation of X, $\Pr[X > (1+\beta)E] < \left(e^\beta / (1+\beta)^{(1+\beta)}\right)^E$. Thus the probability that more than $\frac{\mu M}{\log d}$ of the $\mathcal{T}_i$s fail is less than $2^{-\mu M / \log d} = \gamma / d 2^d$. Summing over all d possible values of ℓ completes the proof. ∎

We conclude the following corollary.

COROLLARY 2.5. *The probability that $\mathcal{S}$ fails is at most γ.*

Proof. Sum the bound from the above theorem over 2^d possible queries q. □

Notice that using the values from Theorem 2.4 for M and T and assuming that γ and μ are absolute constants, we get that the size of $\mathcal{S}$ is $O(\epsilon^{-2}d^3 \log d(\log n + \log\log d) + d^2 \log d(n \log d)^{O(\epsilon^{-2})})$, and the construction time is essentially this quantity times n.

2.1. The search algorithm. Our search algorithm assumes that the construction of $\mathcal{S}$ is successful. By Corollary 2.5, this happens with probability $1-\gamma$. Given a query q, we do a binary search to determine (approximately) the minimum distance ℓ to a database point. A step in the binary search consists of picking one of the structures $\mathcal{T}_i$ in $\mathcal{S}_\ell$ uniformly at random, computing the trace $t(q)$ of the list of tests in $\mathcal{T}_i$, and checking the table entry labeled $t(q)$. The binary search step succeeds if this entry contains a database point, and otherwise it fails. If the step fails, we restrict the search to larger ℓs, and otherwise we restrict the search to smaller ℓs. The search algorithm returns the database point contained in the last nonempty entry visited during the binary search.

LEMMA 2.6. *For any query q, the probability that the binary search uses a structure $\mathcal{T}_i$ that fails at q is at most μ.*

Proof. The binary search consists of $\log d$ steps, each examining a different value ℓ. As we are assuming that $\mathcal{S}$ did not fail, the probability that for any given ℓ the random $\mathcal{T}_i$ in $\mathcal{S}_\ell$ that we pick fails is at most $\mu/\log d$. Summing over the $\log d$ steps completes the proof. □

LEMMA 2.7. *If all the structures used by the binary search do not fail at q, then the distance from q to the database point a returned by the search algorithm is within a $(1+\epsilon)$-factor of the minimum distance from q to any database point.*

Proof. Denote the minimum distance from q to any database point by $\ell_{\min}$. If $\ell < \ell_{\min}/(1+\epsilon)$, then no database point is within distance $(1+\epsilon)\ell$ of q, and therefore all the binary search steps that visit ℓ in this range fail. On the other hand, all the binary search steps that visit ℓ in the range $\ell \geq \ell_{\min}$ succeed. Therefore, the binary search ends with ℓ such that $\ell_{\min}/(1+\epsilon) \leq \ell \leq \ell_{\min}$. At that point, the database point a returned has $H(t(q), t(a)) \leq (\delta_1 + \frac{1}{3}\delta)T$. Any database point b with $H(q,b) > (1+\epsilon)\ell$ has $H(t(q), t(b)) > (\delta_2 - \frac{1}{3}\delta)T > (\delta_1 + \frac{1}{3}\delta)T$. Therefore, $H(q,a) \leq (1+\epsilon)\ell \leq (1+\epsilon)\ell_{\min}$. □

Lemmas 2.6 and 2.7 imply the main result of this section which is the following theorem.

THEOREM 2.8. *If $\mathcal{S}$ does not fail, then for every query q the search algorithm finds a $(1+\epsilon)$-approximate nearest neighbor with probability at least $1-\mu$ using $O(\epsilon^{-2}d(\log n + \log\log d + \log\frac{1}{\mu})\log d)$ arithmetic operations.*

Proof. The success probability claim is immediate from the above lemmas. The number of operations follows from the fact that we perform $\log d$ binary search steps. Each step requires computing the value of T β-tests. Each β-test requires computing the sum of at most d products of two elements. □

Remark. Some improvements of the above implementation are possible. For example, note that the value of M was chosen so as to guarantee that with constant probability no mistake is made throughout the binary search. Using results of [17], a binary search can still be made in $O(\log d)$ steps even if there is a constant probability of error at each step. This allows choosing M which is smaller by an $O(\log d)$ factor and getting the corresponding improvement in the size of $\mathcal{S}$ and the time required to construct it.

3. Approximate nearest neighbors in Euclidean spaces. In this section we present our algorithm for Euclidean spaces. The main idea underlying the solution for Euclidean spaces is to reduce the problem to the problem on the cube solved in the previous section. In fact, we produce several cubes, and the search involves several cube searches.

Notation. Let $x \in \mathbb{R}^d$, and let $\ell > 0$. Denote by $\mathcal{B}(x, \ell)$ the closed ball around x with radius ℓ; i.e., the set $\{y \in \mathbb{R}^d \mid \|x - y\|_2 \leq \ell\}$. Denote by $\mathcal{D}(x, \ell)$ the set of database points contained in $\mathcal{B}(x, \ell)$.

The main tool in reducing the search problem in Euclidean space to search problems in the cube is the following embedding lemma. The proof of this lemma follows standard arguments. We defer the proof to the appendix.

LEMMA 3.1. *There exists a constant $\lambda > 0$, such that for every $\delta > 0$, $\beta > 0$, $\ell > 0$, positive integer d, and $x \in \mathbb{R}^d$, the following holds. There is an embedding $\eta = \eta(x, \ell, \delta, \beta)$, $\eta : \mathbb{R}^d \hookrightarrow Q_k$ with the following properties.*

1. $$k = \text{poly}\left(\delta^{-1}\right) \cdot \left(d \log^2 d + d \log d \log \delta^{-1} + \log \beta^{-1}\right).$$

2. *For every $y \in \mathcal{B}(x, \ell)$, and for every $z \in \mathbb{R}^d$,*

$$((1 - O(\delta))m - O(\delta))k \leq H(\eta(y), \eta(z)) \leq ((1 + O(\delta))m' + O(\delta))k,$$

where

$$m = \kappa \cdot \max\left\{\frac{\|y - z\|_2}{\ell}, \lambda\right\},$$

$$m' = \kappa \cdot \min\left\{\frac{\|y - z\|_2}{\ell}, \delta^{-1}\right\},$$

$$\kappa = \Theta\left(1/(1 + \delta^{-1})\sqrt{\log(\delta^{-1})}\right).$$

Furthermore, there is a probabilistic algorithm that computes in polynomial time, with success probability at least $1 - \beta$, an embedding η with the above properties. The algorithm computes a representation of η as $O(dk)$ rational numbers. Using this representation, for every rational $y \in \mathbb{R}^d$, we can compute $\eta(y)$ using $O(dk)$ arithmetic operations.

The data structure. Our data structure $\mathcal{S}$ consists of a substructure $\mathcal{S}_a$ for every point a in the database. Each $\mathcal{S}_a$ consists of a list of all the other database points, sorted by increasing distance from a, and a structure $\mathcal{S}_{a,b}$ for each database point $b \neq a$. Fix a and b, and let $\ell = \|a - b\|_2$ be the distance from a to b. (For simplicity, we'll assume that different bs have different distances from a.) The structure $\mathcal{S}_{a,b}$ consists of (1) a representation of an embedding η (as in Lemma 3.1), (2) a Hamming cube data structure, and (3) a positive integer.

We construct $\mathcal{S}_{a,b}$ as follows. Set $\delta = \epsilon/O(1)$. Part (1) of $\mathcal{S}_{a,b}$ is a representation of $\eta(a, \ell, \delta, \beta)$ (β to be determined below), which we compute by Lemma 3.1. Let k be the dimension of the target of η. Part (2) of $\mathcal{S}_{a,b}$ is an approximate nearest neighbor search structure for Q_k, with the database consisting of the images under η of the points in $\mathcal{D}(a, \ell)$, and the slackness parameter being δ. Part (3) of $\mathcal{S}_{a,b}$ is the number of database points in $\mathcal{D}(a, \ell)$. This completes the specification of $\mathcal{S}_{a,b}$ (up to the choice of β, and of the error probability γ allowed in the cube data structure construction).

DEFINITION 3.2. *We say that* $\mathcal{S}_{a,b}$ fails *if the embedding* η *does not satisfy the properties stipulated in Lemma* 3.1*, or if the construction of the cube data structure fails. We say that* $\mathcal{S}$ fails *if there are* a, b *such that* $\mathcal{S}_{a,b}$ *fails.*

LEMMA 3.3. *For every* $\zeta > 0$*, setting* $\beta = \zeta/n^2$ *and* $\gamma = \zeta/n^2$ *(where* β *is the parameter of Lemma* A.3*, and* γ *is the parameter of Corollary* 2.5*) the probability that* $\mathcal{S}$ *fails is at most* ζ*.*

Proof. Sum up the failure probabilities from Lemma 3.1 and Corollary 2.5 over all the structures we construct. □

Our data structure $\mathcal{S}$ requires $O(n^2 \cdot \text{poly}(1/\epsilon) \cdot d^2 \cdot \text{poly}\log(dn/\epsilon) \cdot (n \log(d \log n/\epsilon))^{O(\epsilon^{-2})})$ space (we have $O(n^2)$ structures, and the dominant part of each is the k-dimensional cube structure). The time to construct $\mathcal{S}$ is essentially its size times n (again, the dominant part is constructing the cube structures).

3.1. The search algorithm. As with the cube, our search algorithm assumes that the construction of $\mathcal{S}$ succeeds. This happens with probability at least $1 - \zeta$, according to Lemma 3.3. Given a query q, we search some of the structures $\mathcal{S}_{a,b}$ as follows. We begin with any structure $\mathcal{S}_{a_0,b_0}$, where a_0 is a database point and b_0 is the farthest database point from a_0. Let $\ell_0 = \|a_0 - b_0\|_2$. Then $\mathcal{D}(a_0, \ell_0)$ contains the entire database. We proceed by searching $\mathcal{S}_{a_1,b_1}$, $\mathcal{S}_{a_2,b_2}$, ..., where a_{j+1}, b_{j+1} are determined by the results of the search in $\mathcal{S}_{a_j,b_j}$.

So fix j. We describe the search in $\mathcal{S}_{a_j,b_j}$. Let $\ell_j = \|a_j - b_j\|_2$. Let η be the embedding stored in $\mathcal{S}_{a_j,b_j}$. We compute $\eta(q)$, a node of the k-dimensional cube. We now search for a $(1+\delta)$-approximate nearest neighbor for $\eta(q)$ in the cube data structure stored in $\mathcal{S}_{a_j,b_j}$ (allowing failure probability μ). Let the output of this search be (the image of) the database point a'. If $\|q - a'\|_2 > \frac{1}{10}\ell_{j-1}$, we stop and output a'. Otherwise, we pick T database points uniformly at random from $\mathcal{D}(a_j, \ell_j)$, where T is a constant. Let a'' be the closest among these points to q. Let a_{j+1} be the closest to q between a_j, a' and a'', and let b_{j+1} be the farthest from a_{j+1} such that $\|a_{j+1} - b_{j+1}\|_2 \le 2\|a_{j+1} - q\|_2$. (We find b_{j+1} using binary search on the sorted list of database points in $\mathcal{S}_{a_{j+1}}$.) If no such point exists, we abort the search and we output a_{j+1}.

Before going into the detailed analysis of the search algorithm, let us try to motivate it. Our test gives a good approximation for the distance if ℓ is "close" to the true minimum distance between q and a database point. Thus, ℓ can be viewed as the scale with which we measure distances. If the scale is too large, we cannot make the right decision. However, we are able to detect that ℓ is too large, and in such a case we reduce it. This guarantees that if we start with ℓ_0 and the nearest neighbor is at distance $\ell_{\min}$, the search will terminate in $O(\log \frac{\ell_0}{\ell_{\min}})$ iterations. This quantity may be enormous compared with d and $\log n$. To speed up the search (i.e., have the number of iterations independent of the ratio of distances), we add random sampling from the points $\mathcal{D}(a_j, \ell_j)$. Using random sampling guarantees that not only the distances reduce but also that the number of database points to consider decreases quickly. This guarantees that the number of iterations is $O(\log n)$.

The following lemmas formulate the progress made by each step. For the analysis, let $a_{\min}$ be the closest point in the database to q and let $\ell_{\min}$ be its distance.

LEMMA 3.4. *For every* $j \ge 0$*,* $a_{\min} \in \mathcal{D}(a_j, \ell_j)$*.*

Proof. $\mathcal{D}(a_j, \ell_j)$ contains all the database points whose distance from a_j is at most $2\|q - a_j\|_2$. In particular (by triangle inequality), it contains all the database points whose distance from q is at most $\|q - a_j\|_2 \ge \ell_{\min}$. Therefore, it contains $a_{\min}$. □

LEMMA 3.5. *For every $j \geq 1$, if ℓ_j is such that $\delta^{-1}\ell_j < \ell_{\min}$, then for every $a \in \mathcal{D}(a_j, \ell_j)$ we have $\|q - a\|_2 \leq \ell_{\min}(1+\delta)$.*

Proof. By the assumptions (and since we have $a_{\min} \in \mathcal{D}(a_j, \ell_j)$), the distance from q to a is at most $\ell_{\min} + \ell_j < \ell_{\min}(1+\delta)$. □

LEMMA 3.6. *For every $j \geq 1$, $\|q - a'\|_2 \leq \max\{(1+\epsilon)\ell_{\min}, \frac{1}{10}\ell_{j-1}\}$ with probability at least $1 - \mu$.*

Proof. As $a_{\min} \in \mathcal{D}(a_{j-1}, \ell_{j-1})$, we claim that our search of $\mathcal{S}_{a_{j-1}, b_{j-1}}$ returns a' whose distance from q is at most $(1+\epsilon)\max\{\ell_{\min}, \lambda\ell_{j-1}\}$ with probability at least $1 - \mu$ (we set λ such that $(1+\epsilon)\lambda \leq 1/10$). The reason is that, by Lemma 3.1,

$$H(\eta(q), \eta(a)) \leq ((1 + O(\delta))\kappa \max\{\ell_{\min}/\ell_{j-1}, \lambda\} + O(\delta))k.$$

Therefore, the search algorithm returns a point b_c such that

$$H(\eta(q), b_c) \leq (1+\delta)((1 + O(\delta))\kappa \max\{\ell_{\min}/\ell_{j-1}, \lambda\} + O(\delta))k.$$

Using Lemma 3.1 again, this point b_c is the image of a point a' whose distance from q satisfies

$$\|q - a'\|_2 \leq (1 + O(\delta)) \max\{\ell_{\min}, \lambda\ell_{j-1}\} + O(\delta)\ell_{j-1}. \qquad \square$$

LEMMA 3.7. *For every $j \geq 1$, $\mathcal{B}(q, \|q - a_j\|_2)$ contains at most $\frac{1}{2}|\mathcal{D}(a_{j-1}, \ell_{j-1})|$ database points with probability at least $1 - 2^{-T}$.*

Proof. First notice that $\mathcal{B}(q, \|q - a_j\|_2)$ contains database points from $\mathcal{D}(a_{j-1}, \ell_{j-1})$ only. Let ξ be such that $\mathcal{B}(q, \xi)$ contains exactly half the points of $\mathcal{D}(a_{j-1}, \ell_{j-1})$. (For simplicity, we assume that the distances from q to the database points are all distinct.) Each database point in the random sample we pick has probability $\frac{1}{2}$ to be in $\mathcal{B}(q, \xi)$. Therefore, the probability that $a'' \notin \mathcal{B}(q, \xi)$ is at most 2^{-T}. □

LEMMA 3.8. *For all $j \geq 1$, $\mathcal{D}(a_j, \ell_j) \subset \mathcal{B}(q, \|q - a_{j-1}\|_2)$ with probability at least $1 - \mu$.*

Proof. Let $a \in \mathcal{D}(a_j, \ell_j)$. By the triangle inequality, $\|q - a\|_2 \leq \ell_j + \|q - a_j\|_2 \leq 3\|q - a_j\|_2$. By Lemma 3.6, $3\|q - a_j\|_2 \leq \frac{3}{10}\ell_{j-1}$. Since $\ell_{j-1} \leq 2\|q - a_{j-1}\|_2$, the lemma follows. □

COROLLARY 3.9. *For every $j \geq 2$, $|\mathcal{D}(a_j, \ell_j)| \leq \frac{1}{2}|\mathcal{D}(a_{j-2}, \ell_{j-2})|$ with probability at least $1 - (\mu + 2^{-T})$.*

THEOREM 3.10. *If $\mathcal{S}$ does not fail, then for every query q the search algorithm finds a $(1+\epsilon)$-approximate nearest neighbor using expected* $\mathrm{poly}(1/\epsilon)d^2\mathrm{poly}\log(dn/\epsilon)$ *arithmetic operations.*[2]

Proof. Corollary 3.9 says that within two iterations of the algorithm, with constant probability the number of database points in the current ball, $\mathcal{D}(a_j, \ell_j)$, is reduced by a factor of 2. Hence, within expected $O(\log n)$ iterations the search ends.

If the search ends because $\|q - a'\|_2 > \frac{1}{10}\ell_{j-1}$, then by Lemma 3.6 it must be that $\|q - a'\|_2 \leq (1+\epsilon)\ell_{\min}$. Otherwise, the search ends because no database point $b \neq a_j$ satisfies: $\|a_j - b\|_2 \leq 2\|a_j - q\|_2$. In this case, $a_j = a_{\min}$, because $\|a_j - a_{\min}\|_2 \leq \|a_j - q\|_2 + \|a_{\min} - q\|_2 \leq 2\|a_j - q\|_2$. In either case, the search produces a $(1+\epsilon)$-approximate nearest neighbor.

As for the search time, we have $O(\log n)$ iterations. In each iteration we perform $O(dk) = O(\mathrm{poly}(1/\epsilon) \cdot d^2 \cdot \mathrm{poly}\log(dn/\epsilon))$ operations to compute $\eta(q)$; then, we execute a search in the k-cube, which by Theorem 2.8 takes $O(\mathrm{poly}(1/\epsilon) \cdot d \cdot \mathrm{poly}\log(dn/\epsilon))$ operations. □

[2] Alternatively, we can demand a deterministic bound on the number of operations, if we are willing to tolerate a vanishing probability error in the search.

4. Extensions. In what follows we discuss some other metrics for which our methods (with small variations) apply.

Generalized Hamming metric. Assume that we have a finite alphabet Σ and consider the generalized cube Σ^d. For $x, y \in \Sigma^d$, the *generalized Hamming distance* $\mathcal{H}(x, y)$ is the number of dimensions where x differs from y. The case $\Sigma = \{0, 1\}$ is the Hamming cube discussed in section 2. Here we argue that the results in that section extend to the case of arbitrary Σ. For convenience, assume that $\Sigma = \{0, 1, \ldots, p-1\}$ for a prime p. (We can always map the elements of Σ to such a set, perhaps somewhat larger, without changing the distances.) It suffices to show that a generalization of the basic test used in section 2 has the same properties. The generalized test works as follows: pick each element in $\{1, 2, \ldots, d\}$ independently at random with probability $1/(2\ell)$. For each chosen coordinate i, pick independently and uniformly at random $r_i \in \Sigma$. (For every i which is not chosen put $r_i = 0$.) The test is defined by $\tau(x) = \sum_{i=1}^{d} r_i x_i$, where multiplication and summation are done in $GF[p]$. As before, for any two vectors $x, y \in \Sigma^d$, let $\Delta(x, y) \stackrel{\triangle}{=} \Pr[\tau(x) \neq \tau(y)]$. If $\mathcal{H}(x, y) = k$, then $\Delta(x, y) = \frac{p-1}{p} \cdot (1 - (1 - \frac{1}{2\ell})^k)$. Therefore, the difference δ in the probabilities between the case of vectors with Hamming distance at most ℓ and the case of vectors with Hamming distance at least $(1+\epsilon)\ell$ is $\frac{p-1}{p} \cdot \left[(1 - \frac{1}{2\ell})^{\ell} - (1 - \frac{1}{2\ell})^{(1+\epsilon)\ell}\right]$. δ is minimized at $p = 2$, so we do better with a larger alphabet. Notice that the number of possible traces here is p^T, so this construction gives a polynomial size data structure if and only if p is a constant. In the next paragraph we mention how to handle nonconstant p-s.

L_1 norm for finite alphabet. Consider, again, the case $\Sigma = \{0, 1, \ldots, p-1\}$ and define the distance between x and y as $d(x, y) \stackrel{\triangle}{=} \sum_{i=1}^{d} |x_i - y_i|$. The first observation is that this case is reducible to the case of the Hamming cube as follows. Map any $x \in \Sigma^d$ into $\hat{x} \in \{0, 1\}^{d(p-1)}$ by replacing every coordinate $x_i \in \{0, 1, \ldots, p-1\}$ of x by $p-1$ coordinates of $\hat{x}$. These are x_i ones followed by $(p - 1 - x_i)$ zeros. Observe that indeed $d(x, y) = H(\hat{x}, \hat{y})$. Therefore, we can apply the cube construction and algorithm to $\hat{x}$. If p is not a constant, this solution is not satisfactory, because it blows up not only the data structure size (by a factor polynomial in p), but also the search time (by a factor of p at least). Our second observation is that we can restrict the blowup in search time to a factor of $O(\log p)$. This is because we do not really have to map x into $\hat{x}$. The contribution of $x_i \in \{0, 1, \ldots, p-1\}$ to $\tau(\hat{x})$ is just the sum modulo 2 of (at most $p-1$) r_j-s. As there are only p possible sums (and *not* 2^p) they can all be precomputed and stored in a dictionary using $O(p)$ space. (Notice that this needs to be done for each test and for each coordinate.) To compute the value of the test on a query, we need to sum up the contributions of the coordinates. For each coordinate, it takes at most $O(\log p)$ time to retrieve the desired value (because operations on values in $\{0, 1, \ldots, p-1\}$ take that much time). The same ideas can be used to handle the generalized Hamming metric for nonconstant alphabets. Map each coordinate x_i into p binary coordinates, which are all 0s except for a 1 in position $x_i + 1$. The Hamming distance in the (dp)-cube is twice the original distance. For a given test, there are only p different values to consider for each original coordinate, so we can precompute them and retrieve them as before.

The space ℓ_1^d. The construction and algorithm are similar to those for the Euclidean case. The only difference is in the embedding η to the cube. Instead of projecting the points onto random unit vectors, we project them onto the original coordinates. Let w, δ, λ, ℓ be as in the Euclidean case. For the ith coordinate, we place $S = 2d(1 + 1/\delta)/\delta\lambda$ equally spaced points between $w_i - (1 + 1/\delta)\ell$ and $w_i + (1 + 1/\delta)\ell$.

These partition the line into $S+1$ (finite or infinite) segments. We number them 0 through S from left to right. Now for every $x \in \mathbb{R}^d$ we define $\eta(x)$ to be the vector with entries in $\{0, 1, \ldots, S\}$, such that $\eta(x)_i$ is the number of the segment that contains x_i. Using Lemma A.4, we show the equivalent of Lemma A.5 for ℓ_1^d.

LEMMA 4.1. *For every x such that $\|x-w\|_1 \le \ell$, for every $y \in \mathbb{R}^d$,*

$$(1-\delta)m\frac{d}{\delta\lambda} \le \|\eta(x)-\eta(y)\|_1 \le (1+\delta)m'\frac{d}{\delta\lambda},$$

where $m = \max\left\{\frac{\|x-y\|_1}{\ell}, \lambda\right\}$, *and* $m' = \min\left\{\frac{\|x-y\|_1}{\ell}, \delta^{-1}\right\}$.

Proof. We show the case $\lambda\ell \le \|x-y\|_1 \le \ell/\delta$. The other two cases are similar. Notice that in this case, for every i, $x_i, y_i \in [w_i - (1+\delta^{-1})\ell, w_i + (1+\delta-1)\ell]$. By Lemma A.4, for every i,

$$-1 + \|x_i - y_i\|S/2(1+\delta^{-1})\ell \le \|\eta(x)_i - \eta(y)_i\| \le 1 + \|x_i - y_i\|S/2(1+\delta^{-1})\ell.$$

Thus, summing over the d coordinates,

$$-d + \|x-y\|_1 S/2(1+\delta^{-1})\ell \le \|\eta(x)-\eta(y)\|_1 \le d + \|x-y\|_1 S/2(1+\delta^{-1})\ell.$$

As $d = \delta\lambda S/2(1+\delta^{-1}) \le \delta\|x-y\|_1 S/2(1+\delta^{-1})\ell$, the lemma follows. □

We use the construction for the finite alphabet L_1 norm to handle the embedded instance. The remainder of the argument is identical to the Euclidean case. Notice, however, that given a query q, computing $\eta(q)$ is more efficient than in the Euclidean case: In each coordinate, we can use a binary search to determine the segment in $O(\log S) = O(\log(d/\epsilon))$ operations. Projecting is trivial and takes $O(1)$ operations per coordinate. In the Euclidean case, the search time is dominated by the calculation of $\eta(q)$. Thus, here it goes down to $O(d\text{poly}\log(dn/\epsilon))$.

Further comments. The iterative search procedure described in section 3.1 is quite general and can be used in any metric space; i.e., the problem of finding an approximate nearest neighbor reduces to the following problem. Given a query q and a distance estimate ℓ, either return an approximate nearest neighbor of q, or return a data point at distance at most $\ell/10$ from q. Of course, the latter problem might be hard to solve in an arbitrary metric space.

Appendix. Proof of Lemma 3.1. The proof of the embedding lemma follows two parts. First, we use a low distortion embedding of ℓ_2^d into ℓ_1^k (where, for fixed ϵ, $k = O(d\log^2 d + \log n)$). Second, we use an embedding of ℓ_1^k into $Q_{O(k)}$. This embedding maintains low distortion on certain distances, as stipulated by the lemma.

It is known (see, for example, [15] and references therein) that the projection ℓ_2^d onto $O(d)$ random unit vectors, properly scaled, gives a low distortion embedding of ℓ_2^d into $\ell_1^{O(d)}$ (the distortion $1+\epsilon$ drops to 1 as the constant hidden by the big-Oh notation grows). Using the arguments in section 4 (which in turn use the second part of the proof here), we could prove a version of the embedding lemma. The dimension of the cube would have to grow by a factor of $O(d/\log^2 d)$. Thus the size of the data structure would grow significantly (yet the search time would improve by a factor of $O(\log d)$).

To avoid this blowup in space, and because we require explicit bounds on the dependency on ϵ and on the error probability, we give here another argument for the low distortion of embedding ℓ_2^d into ℓ_1^k via random projections. The dimesion k of the target space is somewhat worse than in [15]. However, the details of the analysis allow

us to save significantly on the embedding into the cube. (In fact, it is likely that our analysis of the dimension can be improved by a factor of $O(\log d)$, thus matching the search time required using [15].)

It is also known (see, for example, [26]) that for a finite set P of points in ℓ_1^d, rounding each point to a grid point, and then representing each coordinate in unary (padded by leading zeros), gives an embedding of P into a hypercube that approximately preserves relative distances (the approximation depends on the fineness of the grid). We argue here (a straightforward argument) that such a construction approximately preserves relative distances among an infinite number of point pairs (as required by the embedding lemma). We also argue that for these pairs the grid need not be too fine, so the dimension of the cube is small. (Notice that distances in Q_k vary by a factor of k at most. On the other hand, in an arbitrary finite set P of points in ℓ_1^d the distances can vary by an arbitrarily large factor. Thus, it is impossible to bound the dimension of the cube uniformly for all sets P.)

We now proceed with the proof. Fix x and ℓ. Let D, S, and L be parameters that we fix later (we will set $k = DS$). We map the points in $\mathcal{D}(x, \ell)$ into the $(D \cdot S)$-dimensional cube as follows: We pick a set of D i.i.d. unit vectors $\{z_1, \ldots, z_D\}$ from the uniform (Haar) measure on the unit sphere and project the points in $\mathcal{D}(x, \ell)$ onto each of these vectors; i.e., for every $a \in \mathcal{D}(x, \ell)$ and for every $z \in \{z_1, \ldots, z_D\}$ we compute the dot product $a \cdot z$. For every $z \in \{z_1, \ldots, z_D\}$ we place S equally spaced points in the interval $[x \cdot z - L, x \cdot z + L]$. We call these points *cutting points*. Each vector z and cutting point c determine a single coordinate of the cube. For any $a \in \mathcal{D}(x, \ell)$, the value of this coordinate is 0 if $a \cdot z \leq c$, and it is 1 otherwise.[3] Altogether, we get a mapping of x into a point in the cube $\{0, 1\}^{D \cdot S}$.

The following lemma analyzes the distribution of length when projecting a fixed (unit) vector on a random (unit) vector.

LEMMA A.1. *Let X be the length of the projection of a unit vector onto a random unit vector drawn from the uniform measure on the unit sphere. Then, for every $\delta > 0$ there exist $\alpha = \Theta(\delta)$ and $\alpha' = \Theta(\delta^{3/2})$ such that the following hold.*

1. $$\alpha_0 \stackrel{\triangle}{=} \Pr\left[X < \sqrt{\frac{\delta}{d}}\right] < \alpha;$$

2. $$\alpha_\infty \stackrel{\triangle}{=} \Pr\left[X > \sqrt{\frac{\log(1/\delta)}{d}}\right] < \alpha;$$

3. *For every $j \geq 1$ such that $(1+\delta)^j \sqrt{\delta/d} \leq \sqrt{\log(\delta)^{-1}/d}$,*

$$\alpha_j \stackrel{\triangle}{=} \Pr\left[(1+\delta)^{j-1}\sqrt{\frac{\delta}{d}} \leq X \leq (1+\delta)^j \sqrt{\frac{\delta}{d}}\right] \geq \alpha'.$$

Proof. Let $\mathcal{S}_d(r)$ denote the sphere of radius r in $\mathbb{R}^d$ centered at the origin. Its surface area, $\mathcal{A}_d(r)$, is given by $\mathcal{A}_d(r) = 2\pi^{d/2} r^{d-1}/\Gamma(d/2) = \mathcal{A}_d(1) r^{d-1}$, where Γ is

[3] Note that if the cutting points are $c_1 \leq c_2 \leq \cdots c_S$, then the S coordinates obtained for a point a by comparing $a \cdot z$ to the cutting points are always of the following form: j 0s followed by $S - j$ 1s. In other words, only $S + 1$ out of the 2^S combinations of 0s and 1s are possible. This observation can be used to get certain improvements in the efficiency of our algorithm. See section 4 for details.

the so-called Gamma function.[4] By "rotating" the space we can view the experiment of projecting a fixed vector on a random vector as if we project a random vector on the axis $x_1 = 1$. Therefore, the probabilities that we need to estimate are just "slices" of the sphere. In particular, consider the set of points $\{x \in \mathcal{S}_d(1) \mid x_1 \in (\tau - \omega, \tau)\}$ (with $\omega, \tau - \omega > 0$). The surface area of this set is lower bounded by $\omega \cdot \mathcal{A}_{d-1}(r)$, where $r = \sqrt{1-\tau^2}$. By symmetry, the same is true for $\{x \in \mathcal{S}_d(1) \mid x_i \in (-\tau, -\tau + \omega)\}$.

To compute the probability of the desired event we compare the area of the slice with the area of the whole sphere. Note that $\mathcal{A}_{d-1}(1)/\mathcal{A}_d(1) = \Theta(\sqrt{d})$. Plug in $\tau = \tau(j) = (1+\delta)^j\sqrt{\delta/d}$ and $\omega = \omega(j) = \tau(j) - \tau(j-1) = \delta(1+\delta)^{j-1}\sqrt{\delta/d}$. Put $\xi = \xi(j) = \delta(1+\delta)^{2j}$; thus $r^2 = 1 - \tau^2 = 1 - \xi/d$ and $\omega = \delta\sqrt{\xi/d}/(1+\delta)$. We get that

$$\begin{aligned}
\Pr\left[(1+\delta)^{j-1}\sqrt{\frac{\delta}{d}} \le X \le (1+\delta)^j\sqrt{\frac{\delta}{d}}\right] &\ge 2\omega\mathcal{A}_{d-1}(\sqrt{1-\tau^2})/\mathcal{A}_d(1) \\
&= 2\omega\mathcal{A}_{d-1}(1)\cdot(\sqrt{1-\tau^2})^{d-2}/\mathcal{A}_d(1) \\
&= \Theta\left(\frac{\delta}{1+\delta}\sqrt{\xi}\left(1-\frac{\xi}{d}\right)^{\frac{d-2}{2}}\right) \\
&= \Omega(\delta^{3/2}),
\end{aligned}$$

where the last equality follows from the fact that in the range of j that interests us, $1 \le (1+\delta)^{j-1} < (1+\delta)^j \le \sqrt{\delta^{-1}\log(1/\delta)}$. This shows the third claim. Similar arguments show the first two claims. □

COROLLARY A.2. *Using the above notation, there is an absolute constant b such that*

$$\sum_{j=1}^{j_{\max}}\left(\alpha_j(1+\delta)^{j-1}\sqrt{\frac{\delta}{d}}\right) \le E[X] \le b\sqrt{\frac{\delta}{d}} + \sum_{j=0}^{j_{\max}}\left(\alpha_j(1+\delta)^j\sqrt{\frac{\delta}{d}}\right). \qquad \square$$

In what follows, we denote by b' the constant $b' = E[X]\sqrt{d}$.

The next lemma analyzes the lengths distribution with respect to a series of D projections.

LEMMA A.3. *Let δ, α, α' be as in Lemma A.1. Let $\varphi, \beta > 0$. Set*

$$D = \frac{c}{\varphi^2}(8(d+1)\log(4(d+1))(\log(8(d+1)) + \log\log(4(d+1)) + \log\varphi^{-1}) + \log\beta^{-1})$$

for some absolute constant c. Let $z_1, \ldots, z_D$ be i.i.d. unit vectors from the uniform distribution on the unit sphere. Then, with probability at least $1-\beta$, the following holds. For every $x, y \in \mathbb{R}^d$ define

$$I_0 = \left\{i;\ |(x-y)\cdot z_i| < \sqrt{\frac{\delta}{d}}\|x-y\|_2\right\},$$

$$I_\infty = \left\{i;\ |(x-y)\cdot z_i| > \sqrt{\frac{\log(1/\delta)}{d}}\|x-y\|_2\right\},$$

[4] For integer d the Gamma function is given by

$$\Gamma(d/2) \triangleq \begin{cases} (\frac{d-2}{2})! & d \text{ even}, \\ \frac{(d-2)(d-4)\cdots 1}{2^{(d-1)/2}}\sqrt{\pi} & d \text{ odd}. \end{cases}$$

$$I_j = \left\{ i;\ (1+\delta)^{j-1}\sqrt{\frac{\delta}{d}}\|x-y\|_2 \le |(x-y)\cdot z_i| \le (1+\delta)^{j}\sqrt{\frac{\delta}{d}}\|x-y\|_2 \right\},$$

where $j = 1, 2, \ldots, j_{\max}$, *with* $j_{\max}$ *the largest possible such that* $I_{j_{\max}} \cap I_\infty = \emptyset$.[5] *Then*

1. $|I_0|, |I_\infty| < (\alpha + \varphi)D$; *and*
2. *for* $j = 1, 2, \ldots, j_{\max}$, $\quad (\alpha_j - \varphi)D \le |I_j| \le (\alpha_j + \varphi)D$.

Proof. Consider the following range space over the set of vectors in the unit sphere. Every pair of points $x, y \in \mathbb{R}^d$ defines several ranges: a range of vectors z such that $|(x-y)\cdot z| < \sqrt{\delta/d}\|x-y\|_2$, a range such that $|(x-y)\cdot z_i| > \sqrt{\log(1/\delta)/d}\|x-y\|_2$, and ranges such that $(1+\delta)^{j-1}\sqrt{\delta/d}\|x-y\|_2 \le |(x-y)\cdot z_i| \le (1+\delta)^{j}\sqrt{\delta/d}\|x-y\|_2$ for $j = 1, 2, \ldots, j_{\max}$. Each of these ranges is a Boolean combination of at most four (closed or open) half-spaces. Therefore, the VC-dimension of this range space is at most $8(d+1)\log(4(d+1))$ (see [2]). The lemma follows from the fact that a random subset of the unit sphere of size D is a φ-sample with probability at least $1-\beta$. ∎

LEMMA A.4. *Let* $L, \psi > 0$. *Let* $\sigma = [-L, L]$ *be a segment of the real line. Set* $S = \lceil \frac{1}{\psi} \rceil$. *Let* $-L = p_1 < p_2 < \cdots < p_S = L$ *be equally spaced points in* σ (*i.e.,* $p_j = -L + 2L(j-1)/(S-1)$). *Then, every segment* $[\sigma_1, \sigma_2) \subset \sigma$ *contains at least* $(-\psi + (\sigma_2 - \sigma_1)/2L)S$ *such points and at most* $(\psi + (\sigma_2 - \sigma_1)/2L)S$ *such points.*

Proof. The number of points in $[\sigma_1, \sigma_2)$ is approximately proportional to the measure of this segment (under the uniform measure on σ). It might be at worst one point below or one point above the exact proportion. ∎

Let $w \in \mathbb{R}^d$ and let $\ell > 0$. Fix L, φ, β, ψ. (Thus D and S are fixed.) Consider the following (random) embedding $\eta : \mathbb{R}^d \hookrightarrow Q_{DS}$: Let $z_1, \ldots, z_D$ be the random vectors in Lemma A.3, and Let $p_1, \ldots, p_S$ be the points in Lemma A.4. For $x \in \mathbb{R}^d$, $\eta(x) = \eta(x)_{11}\eta(x)_{12} \cdots \eta(x)_{ij} \cdots \eta(x)_{DS}$, where $\eta(x)_{ij} = 0$ if $(x-w)\cdot z_j \le p_i$, and $\eta(x)_{ij} = 1$ otherwise. We are now ready to restate and prove the embedding lemma.

LEMMA A.5. *Let* $\lambda > 0$ *be a sufficiently small constant. Set*

$$L = (1+\delta^{-1})\ \ell\sqrt{\log(1/\delta)/d}.$$

Set $\varphi = \delta\alpha'$ *and* $\psi = \delta^2\lambda/2(1+\delta^{-1})$.

Then, for η *the following holds with probability at least* $1-\beta$. *For every* $x \in B(w, \ell) \subseteq \mathbb{R}^d$ *and* $y \in \mathbb{R}^d$

$$((1-O(\delta))m - O(\delta))DS \le H(\eta(x), \eta(y)) \le ((1+O(\delta))m' + O(\delta))DS,$$

where

$$m = \kappa \cdot \max\left\{ \frac{\|x-y\|_2}{\ell}, \lambda \right\},$$

$$m' = \kappa \cdot \min\left\{ \frac{\|x-y\|_2}{\ell}, \delta^{-1} \right\},$$

and $\kappa = b'/2(1+\delta^{-1})\sqrt{\log(1/\delta)}$.

Proof. We prove the lemma for the case $\lambda\ell \le \|x-y\|_2 \le \ell/\delta$. The proofs of the two extreme cases are similar. To analyze the distance in the cube, $H(\eta(x), \eta(y))$, we notice that this distance is influenced by the distribution of the projection lengths

[5] For simplicity we assume that these sets form a partition of the space; otherwise, there are minor changes in the constants.

$|(x-y)\cdot z_1|,\ldots,|(x-y)\cdot z_D|$ among the sets I_j (Lemma A.3 guarantees that this distribution is "nice"); the error in estimating $|(x-y)\cdot z_i|$ for each set I_j, and, for each z_i, the error caused by discretizing the projection length with the S cutting points (i.e., the value ψ of Lemma A.4). In what follows we assume that everything went well. That is, we avoided the probability β that Lemma A.3 fails.

First we prove the lower bound. Consider I_j for $1 \le j \le j_{\max}$. By Lemma A.3, at least $(\alpha_j - \varphi)D$ of the projections $|(x-y)\cdot z_i|$ are in the set I_j. For each such z_i, by the definition of I_j, we have that $|(x-y)\cdot z_i| \ge (1+\delta)^{j-1}\sqrt{\frac{\delta}{d}}\|x-y\|_2$. Every point p_k $(1 \le k \le S)$ such that p_k is between $(x-w)\cdot z_i$ and $(y-w)\cdot z_i$ contributes 1 to the Hamming distance. Lemma A.4 shows that the number of such points is at least $(-\psi + ((1+\delta)^{j-1}\sqrt{\frac{\delta}{d}}\|x-y\|_2)/2L)S$, provided that both $(x-w)\cdot z_i$ and $(y-w)\cdot z_i$ are contained in the segment $[-L, L]$. As $x \in B(w,\ell)$ and by the triangle inequality $y \in B(w,(1+\delta^{-1})\ell)$, the corresponding projections are not contained in the segment $[-L,L]$ only if they fall in the set I_∞. For each vector this happens with probability at most α, by Lemma A.1. Thus the probability that both vectors fall in this segment is at least $1-2\alpha$.

For the lower bound we can ignore the bad events: the is for which $|(x-y)\cdot z_i|$ falls in I_0 and I_∞, as well as the is for which $(x-w)\cdot z_i$ or $(y-w)\cdot z_i$ fall outside $[-L,L]$. These contribute nonnegative terms to the distance. We get that $H(\eta(x),\eta(y))$ is at least

$$\sum_{j=1}^{j_{\max}} \left(-\psi + \frac{(1+\delta)^{j-1}\sqrt{\frac{\delta}{d}}\|x-y\|_2}{2L} \right) \cdot (\alpha_j - \varphi)DS - 2\alpha DS.$$

As $\varphi = \delta\alpha'$ and $\alpha_j > \alpha'$ we get that $\varphi < \delta\alpha_j$ and so $(\alpha_j - \varphi) > (1-\delta)\alpha_j$. Also, note that ψ is at most δ times the other term: This term is minimized at $j=1$ and $\|x-y\|_2 = \lambda\ell$, and in this case

$$\frac{(1+\delta)^{j-1}\sqrt{\frac{\delta}{d}}\|x-y\|_2}{2L} = \frac{\lambda\ell\sqrt{\frac{\delta}{d}}}{2(1+\delta^{-1})\ell\sqrt{\log(1/\delta)/d}} \ge \delta\lambda/2(1+\delta^{-1}).$$

By Corollary A.2,

$$\begin{aligned}\sum_{j=1}^{j_{\max}} \left(\alpha_j(1+\delta)^{j-1}\sqrt{\frac{\delta}{d}}\right) &= \frac{1}{1+\delta}\sum_{j=1}^{j_{\max}} \left(\alpha_j(1+\delta)^{j}\sqrt{\frac{\delta}{d}}\right) \\ &\ge \frac{1}{1+\delta}\left(E[X] - (1+o(1))b\sqrt{\frac{\delta}{d}}\right) \\ &= (1-O(\delta))b'\sqrt{\frac{1}{d}}.\end{aligned}$$

Combining everything we get that the lower bound is at least

$$\begin{aligned}&\left(\frac{(1-O(\delta))b'\sqrt{1/d}\|x-y\|_2}{2L} - 2\alpha\right) DS \\ &\qquad = \left((1-O(\delta))\frac{b'}{2(1+\delta^{-1})\sqrt{\log(1/\delta)}} \cdot \frac{\|x-y\|_2}{\ell} - O(\delta)\right) DS.\end{aligned}$$

Now we show the upper bound. By Lemma A.4, at most $(\alpha_j + \varphi)D$ of the projections $|(x-y)\cdot z_i|$ are in the set I_j for $1 \le j \le j_{\max}$, and at most $(\alpha+\varphi)D$ for I_0 and I_∞. If $|(x-y)\cdot z_i|$ is in I_j for $0 \le j \le j_{\max}$, then $|(x-y)\cdot z_i| \le (1+\delta)^j\sqrt{\frac{\delta}{d}}\|x-y\|_2$. By Lemma A.4, the contribution of z_i to the Hamming distance is at most $(\psi + ((1+\delta)^j\sqrt{\frac{\delta}{d}}\|x-y\|_2)/2L)S$, provided (as before) that $(x-w)\cdot z_i$ and $(y-w)\cdot z_i$ are contained in the segment $[-L, L]$. The latter happens with probability at least $1-2\alpha$. With the remaining probability, the contribution of z_i is no more than S.

If z_i is in I_∞, we have no bound on the distance between $x\cdot z_i$ and $y\cdot z_i$, but the contribution of z_i to the Hamming distance is no more than S. Summing this up, we get an upper bound of at most

$$\sum_{j=0}^{j_{\max}} \left(\psi + \frac{(1+\delta)^j\sqrt{\frac{\delta}{d}}\|x-y\|_2}{2L}\right)\cdot(\alpha_j+\varphi)DS + 2\alpha DS + (\alpha_\infty+\varphi)DS.$$

As before, the choice of parameters implies that $(\alpha_j+\varphi) \le (1+\delta)\alpha_j$ and $\psi \le \delta\cdot\frac{(1+\delta)^j\sqrt{\frac{\delta}{d}}\|x-y\|_2}{2L}$. Using the lower bound in Corollary A.2,

$$\begin{aligned}\sum_{j=0}^{j_{\max}}\left(\alpha_j(1+\delta)^j\sqrt{\frac{\delta}{d}}\right) &= \alpha_0\sqrt{\frac{\delta}{d}} + \sum_{j=1}^{j_{\max}}\left(\alpha_j(1+\delta)^j\sqrt{\frac{\delta}{d}}\right)\\ &\le O(\delta)\sqrt{\frac{\delta}{d}} + E[X]\\ &= (1+O(\delta^{3/2}))b'\sqrt{\frac{1}{d}}.\end{aligned}$$

We get that the Hamming distance is at most

$$\left(\frac{(1+O(\delta))\sqrt{1/d}\|x-y\|_2}{2L} + (3+\delta)\alpha\right)DS =$$
$$\left((1+O(\delta))\frac{b'}{2(1+\delta^{-1})\sqrt{\log\delta^{-1}}}\cdot\frac{\|x-y\|_2}{\ell} + O(\delta)\right)DS. \qquad \square$$

Acknowledgments. We thank Shai Ben-David, Nati Linial, and Avi Wigderson for helpful comments on earlier versions of this work.

WHEN HAMMING MEETS EUCLID: THE APPROXIMABILITY OF GEOMETRIC TSP AND STEINER TREE*

LUCA TREVISAN†

Abstract. We prove that the traveling salesman problem (MIN TSP) is Max SNP-hard (and thus NP-hard to approximate within some constant $r > 1$) even if all cities lie in a Euclidean space of dimension $\log n$ (n is the number of cities) and distances are computed with respect to any l_p norm. The running time of recent approximation schemes for geometric MIN TSP is doubly exponential in the number of dimensions. Our result implies that this dependence is necessary unless NP has subexponential algorithms. As an intermediate step, we also prove the hardness of approximating MIN TSP in Hamming spaces.

Finally, we prove a similar, but weaker, inapproximability result for the Steiner minimal tree problem (MIN ST).

The reduction for MIN TSP uses error-correcting codes; the reduction for MIN ST uses the integrality property of MIN-CUT linear programming relaxations. The only previous inapproximability results for metric MIN TSP involved metrics where all distances are 1 or 2.

Key words. computational complexity, combinatorial optimization, hardness of approximation, traveling salesman problem, Steiner tree problem

1. Introduction.

Given a metric space and a set U of points into it, the metric traveling salesman problem (MIN TSP) is to find a closed tour of shortest total length visiting each point exactly once, while the metric Steiner minimum tree problem (MIN ST) is to find the minimum length tree connecting all the points of U; the tree can possibly contain points not in U, which are called "Steiner points."

Both are classical and well-studied problems. Important special cases arise when the metric space is $\mathcal{R}^k$ and the distance is computed according to the ℓ_1 norm (the *rectilinear* case) or the ℓ_2 norm (the *Euclidean* case).

We establish the first nonapproximability results for this class of problems. As an intermediate step, we use the fact that they are also hard to approximate in *Hamming spaces*. The approximability of the Hamming versions of MIN TSP seems to have never been considered before. The hardness of approximating this problem is one of the main technical results of this paper. The hardness of approximating MIN ST in Hamming spaces has been studied for its application to problems in computational biology (specifically, reconstructing evolutionary trees), but it has not been linked to the hardness of the problem in geometric norms.

We now state and discuss our results for MIN TSP and MIN ST.

1.1. The traveling salesman problem.

Interest in the MIN TSP started during the 1930s. A book by Lawler et al. [28] contains an extensive survey of results on MIN TSP. Here we will review only the results that are relevant to the present paper.

The MIN TSP is NP-hard even if the cities are restricted to lie in $\mathcal{R}^2$ and the distances are computed according to the ℓ_2 norm [15, 31]. Due to such a negative result, research concentrated on developing good heuristics. Recall that an r-approximate algorithm ($r > 1$) is a polynomial-time heuristic that is guaranteed to deliver a tour whose cost is at most r times the optimum cost. A 3/2-approximate algorithm that works for any metric space is due to Christofides [9]. For more than twenty years, no improvement of this bound had been found, even in the restricted case of geometric metrics.

In the late 1980s, the discovery of the theory of Max SNP-hardness [35] gave a tool for understanding this lack of results. Indeed, Papadimitriou and Yannakakis [34] proved that the MIN TSP is Max SNP-hard even when restricted to metric spaces (as we shall see later, the result also holds for a particularly restricted class of metric spaces). As later shown by Arora et al. [6], this implies that there exists a constant $\epsilon > 0$ such that metric MIN TSP cannot be approximated to within a factor $(1 + \epsilon)$ in polynomial time, unless P = NP. The complexity of approximating MIN TSP in the case of geometric metrics remained a major open question. In his Ph.D. thesis, Arora noted that proving the Max SNP-hardness of Euclidean MIN TSP in $\mathcal{R}^2$ should be very difficult but that this could perhaps be done in $\mathcal{R}^{k(n)}$ for sufficiently large $k(n)$ [2, Chapter 9]. In [18], Grigni, Koutsoupias, and Papadimitriou proved that the restriction of the MIN TSP to shortest paths metrics of planar graphs can be approximated to within $(1 + \epsilon)$ in time $n^{O(1/\epsilon)}$. Such an approximation algorithm is called a *polynomial time approximation scheme* (PTAS) (the result was later generalized to the case of shortest paths metrics of planar weighted graphs in [5]). This result led Grigni, Koutsoupias, and Papadimitriou [18] to conjecture that Euclidean MIN TSP has a PTAS in $\mathcal{R}^2$. They again posed the question of determining the approximability of the problem for higher dimensions. In a recent breakthrough, Arora [3] developed a PTAS for the MIN TSP in $\mathcal{R}^2$ under any ℓ_p metric. Such an algorithm also works in higher dimensional spaces and, in particular, it runs in time $n^{\tilde{O}((\log^{d-2} n)/\epsilon^{d-1})}$ in $\mathcal{R}^d$. A similar approximation scheme (but only for spaces of dimension 2) was also found later by Mitchell [29]. Arora has subsequently improved the running time of his approximation scheme [4]; his new scheme runs in nearly-linear time for any fixed number of dimensions. Specifically, the algorithm of [4] finds a $(1 + \epsilon)$-approximate solution in $\mathcal{R}^d$ in time $n(\log n)^{O\left((\sqrt{d}/\epsilon)^d\right)}$. An additional improvement is due to Rao and Smith [36]. Their algorithm runs in time $(\sqrt{d}/\epsilon)^{O(d(\sqrt{d}/s)^{d-1})}n + O(dn \log n)$. The dependence of the running time on the number of dimensions is, however, still doubly exponential.

This is a typical occurrence of the "curse of dimensionality," a phenomenon empirically observed in several cases in computational geometry, that is, the fact that the complexity of a geometric problem grows exponentially or more in the number of dimensions of the space. In some cases (e.g., nearest neighbor search [26, 27, 21]) clever algorithmic solutions can be developed to avoid this exponential growth. In a preliminary version of [3], Arora asked whether an approximation scheme for geometric MIN TSP exists for any arbitrary number of dimensions.

Our results. In this paper we essentially answer negatively to these questions. We prove that MIN TSP in $\mathcal{R}^{\log n}$ is Max SNP-hard for any ℓ_p metric. It follows from our results that there cannot be a PTAS for these problems (unless P= NP) and that there cannot be $(1 + \epsilon)$-approximate algorithms in $\mathcal{R}^d$ running in time $n^{O(\mathrm{poly}(d,1/\epsilon))}$ for any $\epsilon > 0$, unless $\mathsf{NP} \subseteq \mathsf{DTIME}(n^{O(\mathrm{poly}\log n)})$.

The Max SNP-hardness is proved by means of a reduction from the version of the

metric MIN TSP that was shown to be Max SNP-hard in [34]. In such metric spaces, any pair of points is either at distance 1 or 2, and an additional technical condition holds. The reduction uses a mapping (see Lemma 3.5) of the metric spaces of [34] into Hamming spaces and the observation (see Proposition 2.3) that for elements of $\{0,1\}^n$ a "gap" in the Hamming distance is preserved if distances are computed according to an ℓ_p metric. Our mapping of the metric spaces of [35] into Hamming spaces does not preserve distances up to negligible distortion. (In fact we suspect that such kind of mapping would be provably impossible.) Instead, our mapping introduces a fairly high (yet constant) distortion but satisfies an additional condition: cities at distance 1 are mapped into cities at distance $\approx D_1$; cities at distance 2 are mapped into cities at distance $\approx D_2$, and D_2 is larger than D_1 by a multiplicative constant factor. This is sufficient to make the mapping be an *approximation preserving reduction*. Our mapping uses *error-correcting codes*, a tool that is very seldom used in order to design approximation-preserving reductions.

The minimum k-cities traveling salesman problem (MIN k-TSP) and the minimum degree-restricted Steiner tree problem (two problems mentioned in Arora's papers on approximation schemes for geometric problems [3, 4]) are generalizations of the MIN TSP. The hardness results that we prove for MIN TSP clearly extend to them.

1.2. The minimum Steiner tree problem. The MIN ST problem has an even longer history than the MIN TSP. Special cases were studied by Torricelli (in the 17th century) and by Gauss (see [20] for more details on the history of this problem). Recent results about this problem are similar to the ones for MIN TSP: exact optimization is NP-hard in $\mathcal{R}^2$ both in the rectilinear (ℓ_1) case [17] and in the Euclidean (ℓ_2) case [16]. Constant-factor approximation is achievable in any metric space (the best factor is 1.644 due to Karpinski and Zelikovsky [24]); in general metric spaces the problem is Max SNP-hard [7]. Arora [3, 4], Mitchell [29], and Rao and Smith [36] show how to extend their geometric TSP approximation schemes to geometric MIN ST. The running time of these approximation schemes are the same as reported in the previous section for TSP. See also the books by Hwang, Richards, and Winters [20] and Ivanov and Tuzhilin [22] and the web page maintained by Ganley [14] for extended surveys on the Steiner tree literature. No nonapproximability result was known for geometric versions of the Steiner tree problem. Steiner tree in Hamming spaces is known to be Max SNP-hard, though this result is usually expressed in terms of an equivalent problem in computational biology (see Wareham's Master's thesis [39] and also [23, 40]).

Our results. We prove the Max SNP-hardness of MIN ST in $\mathcal{R}^n$ under the ℓ_1 norm. We establish this result by means of a reduction from the MIN ST problem in Hamming spaces. The reduction is based on the following combinatorial result (Theorem 4.2): for an instance where all the points are in $\{0,1\}^n \subset \mathcal{R}^n$, there exists an optimum solution where all the Steiner points lie in $\{0,1\}^n$. We prove this fact using the *integrality property* of MIN-CUT linear programming relaxations.

1.3. Discussion. For Euclidean MIN TSP, there is still a slight slack between recent approximation schemes and our hardness result. Specifically, a running time $2^{(2^d)/\epsilon}\text{poly}(n)$ would be compatible with our results, but if we believe that NP does not admit subexponential algorithms (i.e., $\text{NP} \not\subseteq \text{DTIME}(2^{n^{o(1)}})$), then even a running time $2^{2^{o(d)}/\epsilon}\text{poly}(n)$ is infeasible. For a fixed ϵ, the approximation scheme of Rao and Smith [36] runs in time $(\sqrt{d}/\epsilon)^{O(d(\sqrt{d}/s)^{d-1})}n + O(dn\log n)$ which, for fixed ϵ, is

roughly $2^{2^{(d \log d)/2 + \log\log n}}$.

There is much more room for improvement for the MIN ST problem; however our results at least imply that the number of dimensions *does matter* in the running time of an approximation scheme for this geometric problem.

We feel that one important contribution of this paper is the recognition of Hamming spaces as a class of metric spaces that are somewhat "close" both to arbitrary metrics and to geometric metrics, while they also have a nice combinatorial structure. This combination of characteristics makes problems on Hamming metrics a useful "intermediate" step in reducing a combinatorial problem to a geometric problem.

Our mapping of bounded-degree graphs into Hamming spaces has been used by Crescenzi et al. [10] in order to prove the NP-hardness of the protein folding problem.

2. Preliminaries. We denote by $\mathcal{R}$ the set of real numbers. For an integer n we denote by $[n]$ the set $\{1, \ldots, n\}$. For a vector $a \in \mathcal{R}^n$ and an index $i \in [n]$, we denote by $a[i]$ the ith coordinate of a. The *weight* of a Boolean vector $a \in \{0,1\}^n$ is the number of nonzero entries.

Given an instance x of an optimization problem A, we will denote by $\mathsf{opt}_A(x)$ the cost of an optimum solution for x, and we will also typically omit the subscript. For a feasible solution y (usually a tour or a tree) of an instance x of an optimization problem A, we denote its cost by $\mathsf{cost}_A(x, y)$ or, more often, as $\mathsf{cost}(y)$. See, e.g., [8, 32] for formal definitions about optimization problems. In this paper we will use the notions of L-reduction and Max SNP-hardness. Max SNP is a class of constant-factor approximable optimization problems that includes MAX 3SAT; we refer the reader to [35] for the formal definition.

DEFINITION 2.1 (L-reduction). *An optimization problem A us said to be L-reducible to an optimization problem B if two constants α and β and two polynomial-time computable functions f and g exist such that*

1. *for an instance x of A, $x' = f(x)$ is an instance of B, and it holds $\mathsf{opt}_B(x') \leq \alpha \mathsf{opt}_A(x)$;*
2. *for an instance x of A, and a solution y' feasible for $x' = f(x)$, $y = g(x, y')$ is a feasible solution for x and it holds $|\mathsf{opt}_A(x) - \mathsf{cost}_A(x, y)| \leq \beta |\mathsf{opt}_B(x') - \mathsf{cost}_B(x', y')|$.*

We say that an optimization problem A is Max SNP-hard if all Max SNP-problems are L-reducible to A. From [6] it follows that if a problem A is Max SNP-hard, then there exists a constant $\epsilon > 0$ such that $(1+\epsilon)$-approximating A is NP-hard.

A function $d : U \times U \to \mathcal{R}$ is a *metric* if the following properties hold:

1. $d(u, v) \geq 0$ for all $u, v \in U$;
2. $d(u, v) = 0$ if and only if $u = v$;
3. $d(u, v) = d(v, u)$ for any $u, v \in U$ (symmetry);
4. $d(u, v) \leq d(u, z) + d(z, v)$ for any $u, v, z \in U$ (triangle inequality).

If all properties but (2) hold, then d is said to be a *semimetric*. Abusing notation, we will usually adopt the term "metric" for both metrics and semimetrics.

DEFINITION 2.2 ($(1,2) - B$ metrics). *For a positive integer B, a metric $d : U \times U \to \mathcal{R}$ is a $(1,2) - B$ metric if it satisfies the following properties:*

1. *for any $u, v \in U$, $u \neq v$, $d(u, v) \in \{1, 2\}$;*
2. *for any $u \in U$, at most B elements of U are at distance 1 from u.*

Papadimitriou and Yannakakis [34] have shown that a constant $B_0 > 0$ exists such that the MIN TSP is Max SNP-hard even when restricted to $(1,2) - B_0$ metrics.

For an integer $p \geq 1$, the ℓ_p norm in $\mathcal{R}^n$ is defined as

$$\|(u_1, \ldots, u_n)\|_p = \left(\sum_{i=1}^{n} |u_i|^p \right)^{(1/p)}.$$

The distance induced by the ℓ_p norm is defined as $d_p(u, v) = \|u - v\|_p$. For a positive integer n, we denote by d_H^n the Hamming metric in $\{0,1\}^n$ (we will usually omit the superscripts). We will make use of the following fact.

PROPOSITION 2.3. *Let $u, v \in \{0,1\}^n \subseteq \mathcal{R}^n$. Then $d_p(u, v) = d_H(u, v)^{1/p}$.*

Before starting with the presentation of our results, we make the following important caveat.

Remark 2.1. In some of the proofs of this paper we implicitly make the (unrealistic) assumption that arbitrary real numbers can appear in an instance and that arithmetic operations (including squared roots) can be computed over them in constant time. However, our results still hold if we instead assume that numbers are rounded and stored in a floating point notation using $O(\log n)$ bits. This fact follows from a modification of the argument used in [3] to reduce a general instance of Euclidean TSP or Steiner tree into an instance where coordinates are positive integers whose value is $O(n^2)$.

3. The Min TSP. Our hardness result is based on a "distance preserving" embeddings of $(1,2) - B$ metric spaces into Hamming spaces. We first define the kind of embedding we are looking for.

DEFINITION 3.1. *For an integer B, a $(1,2) - B$ metric space (U, d), an integer k and positive reals $D_1, D_2 > 0$ and $0 < \epsilon < 1/2$, we say that a mapping $f : U \to \{0,1\}^k$ is (k, D_1, D_2, ϵ)-good if for any $u, v \in U$*

1. *if $d(u, v) = 1$, then $D_1(1 - \epsilon) \leq d_H(f(u), f(v)) \leq D_1(1 + \epsilon)$;*
2. *if $d(u, v) = 2$, then $D_2(1 - \epsilon) \leq d_H(f(u), f(v)) \leq D_2(1 + \epsilon)$.*

In particular, if f is a $(k, D_2, D_1, 0)$-good embedding, then pairs at distance 2 are mapped into pairs at distance D_2 and pairs at distance 1 are mapped into pairs at distance D_1.

Recall that, for any integer h, if we let $n = 2^h$, then the *first-order Reed–Muller code* (which is also an *Hadamard code*) $H_n \subset \{0,1\}^n$ is a set of n binary strings of length n whose pairwise Hamming distance is $n/2$. The elements of H_n can be seen as the set of linear functions $l : \{0,1\}^h \to \{0,1\}$. See, e.g., [38, Chapter 18] and the references therein for more details. The set H_n is computable in time polynomial in n.

LEMMA 3.2. *There exists a polynomial time algorithm that on input a $(1,2) - B$ metric with n points, where n is a power of 2, finds a $((B+1)n, Bn/2, (B+1)n/2, 0)$-good embedding.*

Proof. Let $U = \{u_1, \ldots, u_n\}$. Recall that a $(1,2) - B$ metric (U, d) can be represented as an undirected graph $G = (U, E)$, where $\{u, v\} \in E$ if and only if $d(u, v) = 1$ (see [34]). Note that G has maximum degree B.

We claim that we can find in polynomial time a partition of E into $B + 1$ matchings $E_1, \ldots, E_{B+1}$. To prove this claim, it suffices to observe that the problem of partitioning the set of edges of a graph into disjoint matchings is a restatement of the *edge coloring problem*. In a graph of maximum degree B, an edge coloring with $B + 1$ colors can be found in polynomial time [19].

We now describe the embedding. Each node $u \in U$ is mapped into a string $f(u)$

that is the concatenation of $B+1$ strings $a_u^1, \ldots, a_u^{B+1} \in H_n$:

$$f(u) = a_u^1 \circ \cdots \circ a_u^{B+1}.$$

For a fixed $i \in \{1, \ldots, B+1\}$, the strings $\{a_u^i\}_{u \in U}$ are chosen arbitrarily in H_n such that $a_u^i = a_v^i$ if and only if $\{u, v\} \in E_i$. Since H_n can be generated in polynomial time in n, the overall construction can be carried out in $\mathrm{poly}(n)$ time.

Let us now compute the distance between two strings $f(u)$ and $f(v)$. There are two cases to be considered.

1. If $\{u, v\} \notin E$, then $a_u^i \neq a_v^i$ for all $i = 1, \ldots, B+1$, and so $d_H(f(u), f(v)) = (B+1) \cdot n/2$.
2. If $\{u, v\} \in E$, then $\{u, v\} \in E_j$ for some j, and we have $a_u^j = a_v^j$ and $a_u^i \neq a_v^i$ for $i \neq j$. It follows that $d_H(f(u), f(v)) = B \cdot n/2$. ∎

We also observe the following simpler result.

LEMMA 3.3. *There exists a polynomial time algorithm that on input a $(1,2) - B$ metric with n points finds a $((B+1)n, 2B, 2(B+1), 0)$-good embedding. Furthermore, any vector in the embedding has weight precisely $B+1$.*

Proof. Use the same construction of the proof of Lemma 3.2, but using the code $I_n \subset \{0,1\}^n$ composed of all the n vectors of length n having exactly one nonzero entry. Any two elements of such a code have distance precisely 2. ∎

Our next goal is to describe a good embedding that maps into Hamming spaces having a logarithmic number of dimensions. We will need error-correcting codes whose existence (and explicit construction) is guaranteed by the following result of Naor and Naor.

LEMMA 3.4 (see [30]). *For every $\epsilon > 0$ and positive integer n there is a collection $C_{n,\epsilon} \subseteq \{0,1\}^{k(n,\epsilon)}$ such that $|C_{n,\epsilon}| = n$, $k(n,\epsilon) = O((\log n)/\mathrm{poly}(\epsilon))$, and for any two elements $u, v \in C_{n,\epsilon}$ we have $k(n,\epsilon)(1/2 - \epsilon) \leq d_H(u,v) \leq k(n,\epsilon)(1/2 + \epsilon)$. Furthermore, there is a procedure that on input n and ϵ outputs $C_{n,\epsilon}$ in $\mathrm{poly}(n, 1/\epsilon)$ time.*

The connection between the results of [30] and the explicit construction of error correcting codes is made explicit in section 7 of [1]. The precise dependency of k on ϵ in [30] is of the form $k(n,\epsilon) = O(n/\epsilon^{4+\gamma})$, where $\gamma > 0$ can be an arbitrary positive constant. Some improvements are possible, but the actual dependency on ϵ is not important for our application.

LEMMA 3.5. *There exists a polynomial time algorithm that, for any B and $\gamma > 0$, on input a $(1,2) - B$ metric (U,d) with n points finds a $(k, DB/(B+1), D, \gamma)$-good embedding of U, where $k = O((\log Bn)/\mathrm{poly}(\gamma))$ and $D = k/2$.*

Proof. Use the argument in the proof of Lemma 3.2, but with the codes of Lemma 3.4 instead of the Hadamard code. ∎

THEOREM 3.6. *For any p there exists a constant $\epsilon_p > 0$ such that* MIN TSP *is* NP*-hard to approximate within a factor $(1 + \epsilon_p)$ even when restricted to ℓ_p spaces of logarithmic dimension.*

Proof. From [34] and [6] we have the following result: constants $B_0 > 0$ and $r_0 > 1$ exist such that, given an instance (U,d) of MIN TSP with a $(1,2) - B_0$ metric and n cities, and given the promise that either $\mathsf{opt}(U,d) = n$ or $\mathsf{opt}(U,d) \geq r_0 n$, it is NP-hard to decide which of the two cases holds.

Fix a constant γ such that

$$\frac{1-\gamma}{1+\gamma}\left(1 + \frac{(r_0 - 1)}{B_0}\right) > 1 + \frac{(r_0-1)}{2B_0} \stackrel{\mathrm{def}}{=} 1 + \epsilon_1.$$

Such a constant γ must exist since for $\gamma \to 0$ the left-hand side tends to a value strictly greater than the right-hand side.

Given an instance (U, d) of $(1,2) - B_0$ MIN TSP with n cities, we use Lemma 3.5 to map it into a Hamming space of dimension $k = O(\log n)$ using a $(k, DB_0/(B_0 + 1), D, \gamma)$-good embedding with $D = k/2$. Let $f : U \to \{0,1\}^k$ denote such embedding. We consider two cases.

- If $\mathsf{opt}(U, d) = n$, then an optimum solution for U will have cost at most $n \cdot D(B_0/(B_0 + 1)) \cdot (1 + \gamma)$ for U'.
- If $\mathsf{opt}(U, d) \geq nr_0$, then there can be no solution for U' of cost less than $nD(B_0/(B_0 + 1))(1 - \gamma) + (r_0 - 1)n(1/(B_0 + 1))D(1 - \gamma)$. Otherwise, the same solution would have cost less than nr_0 for U.

Distinguishing between the two cases is NP-hard; therefore it is NP-hard to approximate the target instance to within a factor

$$\frac{1-\gamma}{1+\gamma} \cdot \frac{(B_0 + r_0 - 1)/(B_0 + 1)}{B_0/(B_0 + 1)} \geq 1 + \epsilon_1.$$

It follows that it is NP-hard to approximate MIN TSP to within a factor $1 + \epsilon_1$ even in the special case of Hamming instances having a logarithmic number of dimensions. The same nonapproximability result holds for the case ℓ_1 metric space (since Hamming TSP is just a special case of TSP in ℓ_1 spaces). The result for general ℓ_p spaces follows by using Proposition 2.3. □

Remark 3.1. The claim of Theorem 3.6 asks for the cities to be in $\mathcal{R}^{\log n}$, rather than in $\mathcal{R}^{c \log n}$ as in the previous construction. However, we can add $(n^c - n)$ new cities, all at distance $1/n^{c+1}$ from a given one. This perturbs the optimum in a negligible way, and gives an instance with $N = n^c$ cities in $\mathcal{R}^{\log N}$.

Using techniques of Khanna et al. [25], the nonapproximability result of Theorem 3.6 implies that geometric MIN TSP in $\mathcal{R}^{\log n}$ under any ℓ_p norm is APX PB-hard (in particular, Max SNP-hard) under E-reductions and APX-complete under AP-reductions [11].

3.1. Additional remarks. Using the embedding of Lemma 3.3 in the proof of Theorem 3.6, one can prove the Max SNP-hardness of MIN TSP when restricted to Hamming instances with a constant bound on the weight of the points. Reducing from TSP(1,2) in graphs with maximum degree 3 (an NP-hard problem), it is possible to prove the NP-hardness of the Hamming TSP problem in instances where all points have weight precisely 4. This problem was not known to be NP-hard before. It is reasonable to conjecture that Hamming TSP is solvable in polynomial time for instances where all points have weight at most 2 and is NP-hard for instances where all points have weight 3. We do not know how to prove this conjecture.

4. The Min ST problem. The hardness of approximating MIN ST will be established by means of a reduction from the Hamming version of the problem.

The following result appears in [39, Theorem 45, part 3]. It is based on the observation that the NP-hardness proof of Hamming MIN TSP that appears in [12] yields an L-reduction from vertex cover in bounded degree graphs (a problem proved to be Max SNP-hard in [35]) to Hamming MIN ST.

THEOREM 4.1 (see [39]). MIN ST *is* Max SNP*-hard even when restricted to Hamming spaces.*

Our goal is to reduce the Steiner tree problem in Hamming spaces to the Steiner tree problem under the ℓ_1 distance. We note that for points in $\{0,1\}^n$ the ℓ_1 distance

equals the Hamming distance. However, the reduction is nontrivial since $\mathcal{R}^n$ contains many points that are not in $\{0,1\}^n$ and we have to argue that having much more choice for the Steiner nodes does not make the problem easier. The rectilinear Min ST problem looks very much like a *relaxation* of the Hamming Min ST problem; our reduction makes use of a *rounding scheme* proving that the relaxation does not change the optimum.

Theorem 4.2. *Let $U \subseteq \{0,1\}^n \subset \mathcal{R}^n$ be an instance of rectilinear* Min ST *all of whose points are in the Boolean cube. Let T be a feasible solution for U. Then it is possible to find in polynomial time (in the size of T) another solution T' such that $\mathsf{cost}(T') \leq \mathsf{cost}(T)$ and all the Steiner nodes of T' are in $\{0,1\}^n$.*

Before proving the theorem, we note the following interesting consequence.

Corollary 4.3. *For any instance $U \subseteq \{0,1\}^n$ of rectilinear* Min ST*, an optimum solution exists all of whose Steiner points are in $\{0,1\}^n$.*

We now prove Theorem 4.2.

Proof of Theorem 4.2. Let $S = \{s_1, \ldots, s_m\}$ be the set of Steiner points of T, and let E be the set of edges of T. For any $s_j \in S$ we will find a new point $s'_j \in \{0,1\}^n$, so that if we let T' be the tree obtained from T by substituting the s points with the corresponding s' points, the cost of T' is not greater than the cost of T. The latter statement is equivalent to

$$\begin{aligned}&\sum_{(s_j,u)\in E, u\in U} ||s_j - u||_1 + \sum_{(s_j,s_h)\in E} ||s_j - s_h||_1 \\ \geq &\sum_{(s'_j,u)\in E, u\in U} ||s'_j - u||_1 + \sum_{(s'_j,s'_h)\in E} ||s'_j - s'_h||_1.\end{aligned}$$

We will indeed prove something stronger, namely, that for any $i \in [n]$ it holds

$$\begin{aligned}&\sum_{(s_j,u)\in E, u\in U} |s_j[i] - u[i]| + \sum_{(s_j,s_h)\in E} |s_j[i] - s_h[i]| \\ \geq &\sum_{(s'_j,u)\in E, u\in U} |s'_j[i] - u[i]| + \sum_{(s'_j,s'_h)\in E} |s'_j[i] - s'_h[i]|.\end{aligned} \tag{4.1}$$

Let $i \in [n]$ be fixed; we must now find values of $s'_1[i], \ldots, s'_m[i] \in \{0,1\}$ such that (4.1) holds. We express as a linear program the problem of finding values of $s'_1[i], \ldots, s'_m[i]$ that minimize the right-hand side of (4.1). For any $j \in [m]$ we have a variable x_j (representing the value to be given to $s'_j[i]$) and for any edge $e = (a,b)$ such that at least one endpoint is in S, we have a variable y_e representing the length $|a[i] - b[i]|$. The linear program is as follows:

$$\begin{array}{lll}\text{(LP)} & \min & \sum_e y_e \\ & \text{subject to} & \\ & & y_e \geq x_j - x_h \quad \forall e = (s_j, s_h) \in E, \\ & & y_e \geq x_h - x_j \quad \forall e = (s_j, s_h) \in E, \\ & & y_e \geq x_j \quad \forall e = (s_j, u_h) \in E. u_h[i] = 0, \\ & & y_e \geq 1 - x_j \quad \forall e = (s_j, u_h) \in E. u_h[i] = 1, \\ & & x_j \geq 0, \\ & & y_e \geq 0.\end{array}$$

Setting $x_j = s_j[i]$ and $y_{(a,b)} = |a[i] - b[i]|$ yields a feasible solution, and its cost is the left-hand side of (4.1). Let (x^*, y^*) be an optimum solution for (LP). From the

previous observation we have that by setting $s'_j[i] = x^*_j$ we satisfy (4.1). It remains to be seen that (LP) has an optimum solution where all variables take value from $\{0,1\}$. This follows from the fact that (LP) is the linear programming relaxation of an undirected MIN-CUT problem, where all the u such that $u[i] = 0$ (respectively, $u[i] = 1$) are identified with the source (respectively, the sink), each s_j is a node, and the edges are like in T. It is well known (see, e.g., [33]) that a MIN-CUT linear programming relaxation has optimum 0/1 solutions, and that such a solution can be found in polynomial time. □

Remark 4.1. *There seems to be no natural analog of Theorem* 4.2 *in other norms. Even in* $\mathcal{R}^2$, *using the Euclidean metric, we have that the optimum solution of the instance* $\{(0,0),(1,0),(0,1)\}$ *must use a Steiner point not in* $\{0,1\}^2$.

THEOREM 4.4. *Rectilinear* MIN ST *is* Max SNP*-hard.*

Proof. We reduce from Hamming MIN ST. The reduction leaves the instance unchanged. For an instance $U \subseteq \{0,1\}^n$, we let $\mathsf{opt}_H(U)$ (respectively, $\mathsf{opt}_R(U)$) be the cost of an optimum solution for U, when seen as an instance of Hamming MIN ST (respectively, of rectilinear MIN ST). Clearly, we have that $\mathsf{opt}_R(U) \leq \mathsf{opt}_H(U)$. Given a solution T for U, we find a solution T' as in Theorem 4.2. Since in $\{0,1\}^n$ the distance induced by the ℓ_1 norm equals the Hamming distance, we have that $\mathsf{cost}_H(T') = \mathsf{cost}_R(T') \leq \mathsf{cost}_R(T)$. We have an L-reduction with $\alpha = \beta = 1$. □

5. Conclusions and open questions. We do not know how to extend our nonapproximability result for MIN ST to the Euclidean case. Arora [3] notes that, by inspecting the way his algorithm works, it is possible to claim that, for any instance of Euclidean MIN ST, there exists a near-optimal solution where the Steiner points lie in some well-specified positions (either at "portals" or in positions chosen at the bottom of the recursion). This observation could perhaps be a starting point.

We do not have explicit estimations of the constants into which it is hard to approximate geometric MIN TSP and rectilinear MIN ST. The constant for MIN TSP should be only slightly smaller than the corresponding constant for the $(1,2) - B$ case. An explicit nonapproximability factor has been estimated by Engebresten [13] for the latter problem, and it is very close to 1. The constant for MIN ST should be slightly better. Finding much stronger estimations (comparable to the 3/2 bound of Christofides [9] and the 1.644 bound of Karpinski and Zelikovsky [24]) is an open and challenging question.

Acknowledgments. I am grateful to Sanjeev Arora, Madhu Sudan, László Babai, and Janos Körner for very interesting and helpful discussions. I thank Ray Greenlaw for having read a preliminary version of this paper and given several useful remarks. I wish to thank Jens Lagergren, Tao Jiang, and Todd Wareham for providing me references and reprints about their work in computational biology, and for explaining to me the relation with the Hamming–Steiner tree problem.

SELF-STABILIZATION BY COUNTER FLUSHING*

GEORGE VARGHESE†

Abstract. A useful way to design simple and robust protocols is to make them self-stabilizing. A protocol is said to be self-stabilizing if it begins to exhibit correct behavior even after starting in an arbitrary state. We describe a simple technique for self-stabilization called *counter flushing*. We show how counter flushing helps us to understand and improve some existing distributed algorithms for tasks such as mutual exclusion and request-response protocols. We also use counter flushing to create *new* self-stabilizing protocols for propagation of information with feedback and resets. The resulting protocols are simple, require few changes from the nonstabilizing equivalents, and have fast stabilization times.

Key words. distributed algorithms, self-stabilization

1. Introduction.

As the world moves from an industrial economy to an information-based economy, we are dependent on networks and will become even more so. Thus it is important to design network protocols that are resilient to faults.

In the traditional approach to network fault-tolerance, the protocol designer enumerates the faults that the network will deal with—e.g., node and link crashes, bit errors on links—and adds recovery mechanisms for each such fault. This adds complexity as the mechanisms are not orthogonal and have subtle interactions. Also, there are a number of more obscure errors (e.g., memory corruption) that occur in real networks and are hard to anticipate and enumerate. Even if such faults occur rarely (say, once a month), it makes economic sense to have networks automatically recover from such faults.

These issues are illustrated by the crash of the original ARPANET protocol [Ros81, Per83]. The protocol was designed never to enter a state that contained three conflicting updates. Unfortunately, a malfunctioning node injected three such updates into the network and crashed. After this the network cycled continuously between the three updates until the problem was diagnosed a day later.

Self-stabilization. Ideally networks should recover by themselves, even from obscure faults. This paper describes a paradigm for designing what are known as *self-stabilizing* network protocols. We do so to make network protocols *simpler* and *more robust*.

We model a computer network as a set of nodes interconnected by communication links. A network protocol consists of a program for each network node. Each program consists of code and inputs as well as local state. The global state of the network consists of the local state of each node as well as the messages on network links. A network protocol is *self-stabilizing* if when started from an arbitrary state it exhibits

"correct" behavior after finite time. This definition allows arbitrary corruption of messages and node state variables in the initial state.

Note that we allow network *state* to be corrupted but not the *code* executing the protocol. This is reasonable because program code can be protected against arbitrary corruption of memory by redundancy techniques (e.g., checksumming) since code is rarely modified. However, it is not clear how one can detect corruption of network state by using redundancy techniques. The definition also seems to imply that faults can occur only once (i.e., when the network "starts"). However, the real assumption is, *The average period between faults is larger than the time the protocol takes to stabilize.*

The distributed algorithm literature also describes *Byzantine* fault models ([LSP82]) in which arbitrary faults can continuously occur. However, in Byzantine models, only a fraction of nodes are allowed to exhibit arbitrary behavior. In the self-stabilization model, *all* nodes are permitted to start with arbitrary initial states. Thus, the two models are orthogonal. In a practical setting the crucial difference is that the cost of stabilization is quite cheap while Byzantine solutions are expensive. For example, the self-stabilizing routing protocol in [Per83] is much cheaper than the Byzantine routing protocol of [Per88].

General techniques for self-stabilization. Self-stabilizing protocols were introduced by Dijkstra in [Dij74a]. [Sch93] contains a review of research in this area. While many ad hoc self-stabilizing protocols have been designed, there are few general techniques for self-stabilization. Katz and Perry [KP93] showed how to compile an arbitrary asynchronous protocol into a stabilizing equivalent. Their general transformation is expensive; hence more efficient (and possibly less general) techniques are needed. Techniques that transform any *locally checkable* protocol into a stabilizing equivalent are given in [AGV94, Var93]. However, local checking applies only to a subset of protocols that have a special property called *local checkability.*

Our paper describes a new general technique called *counter flushing* that is applicable to protocols that are not locally checkable. The abstract setting is that of a leader who periodically delivers a message to every network node (and sometimes to every link). By attaching a counter to the state of every node and to every message, and by using simple checks, we ensure that the protocol begins to work correctly regardless of initial messages and node states. Counter flushing can be applied to *total algorithms.* Total algorithms [Tel89] require the cooperation of all network nodes. Specifically, we apply counter flushing to token passing [Dij74a], propagation of information with feedback [Seg83], and network resets [AG94].

The rest of the paper is organized as follows. Section 2 describes our model. Section 3 describes how counter flushing works on ring topologies and shows how counter flushing can be used for token passing, request-response, and data link protocols. Section 4 describes how counter flushing works on trees by describing a stabilizing broadcast protocol called propagation of information with feedback. In section 5, we extend counter flushing to a general graph. We illustrate this by designing a stabilizing network reset protocol. In section 6, we present a uniform proof of stabilization and correctness of our three main protocols. The uniformity of proof emphasizes the unity behind the diversity of applications. We conclude in section 7.

2. Model. We restrict ourselves to message passing protocols. The network topology is modeled by a directed graph $G = (V, E)$, where $n = |V|$ denotes the number of network nodes and D the network diameter. Except for the case when we consider a ring (section 3), we assume the graph is symmetric—i.e., if $(i, j) \in E$, then $(j, i) \in E$. We assume a distinguished leader node $0 \in V$ that we often refer to as the

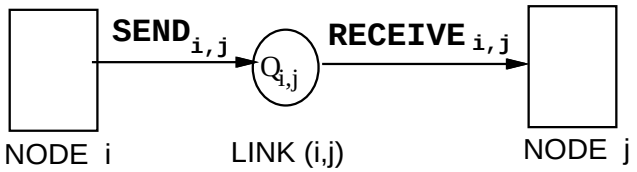

FIG. 1. *The rectangles represent node automata for nodes i and j with interfaces to send packets from i to j. The circle represents the link automaton from i to j whose state is captured by a queue, $Q_{i,j}$.*

root. Note that there are stabilizing protocols [AKM+93, Dol94, AK93] to construct a leader in $O(D)$ time. We model network nodes and links using input/output automata (IOA) [LT89].

An IOA is a state machine whose state transitions are given labels called *actions*. There are three kinds of actions. The environment affects the automaton through *input actions* which must be responded to in any state. The automaton affects the environment through *output actions*; these actions can be controlled by the automaton to occur only in certain states. *Internal actions* change the state of the automaton without affecting the environment.

Formally, an IOA is defined by a *state set* S, a *action set* A, an *action signature* Z (that classifies the action set into input, output, and internal actions), a *transition relation* $R \subseteq S \times A \times S$, and a set of *initial states* $I \subseteq S$. We mostly deal with *uninitialized IOA* for which $I = S$. An action a is said to be *enabled* in state s if there exist $s' \in S$ such that $(s, a, s') \in R$. Input actions are always enabled.

Nodes communicate with each other by sending to and receiving *packets* along links. Fix a packet alphabet P. Nodes and links are modeled by IOA called *node* and *link* automata, respectively. A node automaton (see Figure 1) for node i in graph G has output actions $(\text{SEND}_{i,j}(p), p \in P)$ to send a packet to every j such that $(i, j) \in E$; it also has input actions to receive packets $(\text{RECEIVE}_{j,i}(p), p \in P)$ for every j such that $(j, i) \in E$. Similarly, the link automaton for link $(i, j) \in E$ has input action $\text{SEND}_{i,j}(p)$ to receive packets[1] from i, and output action $\text{RECEIVE}_{i,j}(p)$ to deliver packets to node j (Figure 1).

Node automata are arbitrary but have *finite* state sets and have the appropriate interface actions to send and receive packets. Each link is modeled as a FIFO queue with *bounded storage*. Formally, the state of the link automaton for link (i, j) is a queue of packets $Q_{i,j}$ that is restricted to store no more than L_{max} packets. A formal specification of a *bounded data link* is in Figure 2. We use a bounded model because not much can be done with *unbounded* links in a stabilizing setting [DIM91], and real links are bounded anyway. We justify this model further at the end of this section.

A *network automaton* for graph $G = (E, V)$ is the composition of node automata for each $i \in V$ and link automata for each edge $(i, j) \in E$. *Composition* [LT89] produces a composite state machine; input and output actions of the same name are performed simultaneously. Thus when node i performs a $\text{SEND}_{i,j}(p)$ output action, the link between i and j performs a simultaneous input action (also $\text{SEND}_{i,j}(p)$) to store packet p. The state of the composition is the cross product of the states of every node and link automaton in the network automaton.

[1] The convention for action subscripts is that the first subscript always represents the sending node and the second the receiving node.

State of link $C_{i,j}$ is a queue of packets $Q_{i,j}$.
In all states, $|Q_{i,j}| \leq L_{max}$.

SEND$_{i,j}(p)$ (* node i sends a packet *)
Effects: Add p to the end of $Q_{i,j}$

RECEIVE$_{i,j}(p)$ (* node j receives a packet*)
Preconditions: p is the head of $Q_{i,j}$
Effects: Remove p from $Q_{i,j}$

For time complexity, assume that any packet p placed in $Q_{i,j}$ is delivered in 1 time unit.

FIG. 2. *Formal model of a bounded data link using a finite queue. Note the unusual time complexity assumption that is justified in the text.*

When an IOA "runs" it produces an execution. An *execution fragment* is an alternating sequence of states and actions $(s_0, a_1, s_1, \ldots)$, such that $(s_i, a_i, s_{i+1}) \in R$ for all $i \geq 0$. An execution fragment E is fair if any internal or output action that is continuously enabled eventually occurs. An *execution* is an execution fragment that begins with a start state and is fair.

We express the correctness of an automaton using a set of *legal executions* (*LE*) as in [DIM93]. Let *LE* be a set of executions of some automaton A. We say that automaton A stabilizes to *LE* if every execution of A has some suffix that is contained in *LE*. The *legal states* are the states that occur in legal executions. All the automata we will design in this paper will be *uninitialized IOA* whose set of initial states I is identical to its state set S. We do so by not specifying initial node or channel states. Note that the intuitive concept of self-stabilization is captured by the stabilization of an uninitialized automaton to a set of legal executions.

For time complexity, assume that every internal or output action that is continuously enabled at a node occurs in 1 unit of time. Thus node processing takes 1 time unit. However, we assume any packet stored on a link is delivered in 1 time unit. We say that A *stabilizes* to *LE in time* t if every execution of A has a suffix that occurs within time t and is contained in *LE*. The *stabilization time* from A to B is the infimum across all t such that A stabilizes to B in time t.

Our time complexity assumption for messages is reasonable for links, such as fiber links, in which packets are not queued on links. The assumption is completely unrealistic for channels that act like queues; a simple example is a link that is really a "network" which consists of internal switching nodes. However, since we expect our protocols (token ring, tree broadcast, and reset) to be used over networks with the former type of link, we believe this assumption is reasonable.

The time complexity assumption also seems to imply (see the description of algorithms in Figures 4, 5, and 8) that each node has to send a stabilization message at every step. In particular, this seems to follow because we have made the time complexity for nodes to send messages the same as the time complexity for a message to travel on a link. We choose this for simplicity in order to avoid having two parameters for the two times. A similar (but slightly more messy) analysis of the algorithms can be carried out in which the time to perform an internal node action is bounded by

some parameter t_n. The general model would allow stabilization messages to be sent at any reasonable interval, and would provide the usual tradeoff between message overhead and stabilization time.

There are several other methods of calculating time complexities for stabilizing protocols. These include methods in which time complexity is measured in terms of rounds in which every processor takes a step. Our time complexity measure is not directly comparable to these other measures.

Bounded links. In a stabilizing setting, if a link can store an unbounded number of packets, it is impossible to produce solutions (with bounded stabilization time) for most nontrivial tasks [DIM91]. Moreover, real links are bounded.

In other work, we have modeled bounded links as unit capacity data links (UDLs) that can store at most one packet at any instant. A UDL [Var93] is a model of a reliable data link protocol that delivers one packet at a time. The UDL model is appropriate for routing (and other) protocols that use an underlying reliable link protocol. However, many real protocols that work over very low error rate links (e.g., FDDI, ATM, Frame Relay [Tan93]) do not use an underlying data link protocol. Such links store a bounded number of packets because the link sender and receiver are *synchronous*. The receiver removes packets as fast as the sender inputs packets. However, there is no common clock for the entire network; *node processing is still asynchronous*.

We can model this using an asynchronous model like IOA if we only consider executions in which there are no more than L_{max} packets on each link in each state. In our bounded model we assume that any stored packet is delivered in constant time. For example, suppose the minimum packet size is 20 bytes, nodes transmit at 100 Mbit/sec and links are up to 10 miles long. Then $L_{max} = 30$ and (assuming speed of light limitations) any stored packet is delivered in 50 usec. Both numbers are constants that depend only on the maximum length of a link.

3. Counter flushing on rings. We start by showing how counter flushing can be used in rings. Our protocol is a message passing version of a shared memory protocol presented in [Dij74a]. Nodes $0, \ldots, n-1$ are arranged in a ring topology with a directed link $(i, i+1)$ for $i = 0, \ldots, n-1$. Addition on process indices is always implicitly mod$n$ so that $n - 1 + 1 = 0$. Node 0 is called the root.

In a ring, without the need for stabilization, mutual exclusion can easily be achieved by sending a special *Token* packet round the ring. Each node i would have a flag which would be set to true when a token arrives at i, and be set to false when node i sends its token to node $i + 1$. As long as the protocol starts in a state where there is exactly one token, this protocol will maintain a mutual exclusion property: no more than one node can have its token flag set to true in any state.

However, in a stabilizing setting, the token protocol can deadlock. We can start the token protocol in a state that does not contain a token. A simple way to avoid deadlock is to have nodes periodically retransmit tokens. But this introduces the possibility of a node receiving duplicate tokens. Thus we change the state of each node i (and each token) to have a counter instead of a flag. A node with counter value c can identify a token numbered c as being a duplicate. This is analogous to the use of sequence numbers in network protocols [Tan93].

However, counters cause new complications. In the initial state, the counter values may be arbitrary. Let c_{max} be the maximum number of counters that can be stored in the network in the initial state. Because of the initially bounded model, $c_{max} = |E|L_{max} + |V|$. We will show that if the size of the counter space is greater than c_{max},

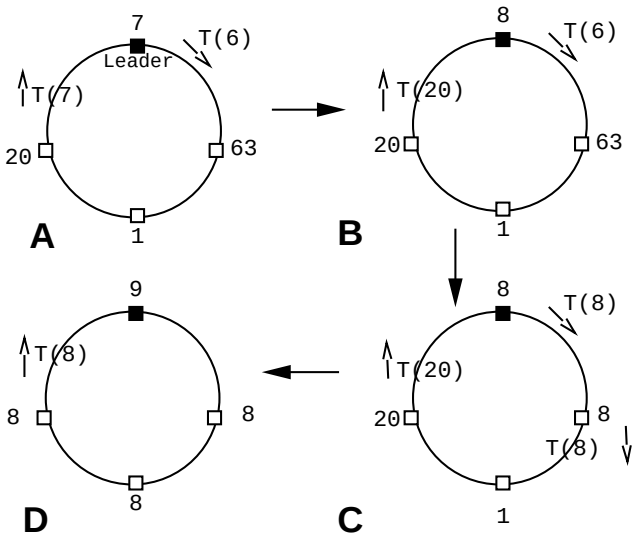

FIG. 3. *Progress to stabilization in a token ring with counters. Starting with an arbitrary state* (A) *we reach a state in which the root has a fresh value* (B). *The fresh value* (*i.e.,* 8) *moves round the ring* (C) *until we reach a legal state* (D).

then the protocol stabilizes in time proportional to the network diameter.

In Figure 3 the lower-left-hand corner (configuration D) describes a good global state of our protocol. There are four nodes—north, east, south, and west—and packets travel clockwise around the ring. North is the root. Each node other than north has a counter value of 8, and there is a token carrying the value 8 in transit from west to north.

Each node periodically retransmits its counter value in a token packet downstream. Thus mere receipt of a token packet is not enough for a node to assume it has the token. Instead, when any node i receives a token from its upstream neighbor, node i does the following. If i is not the root and the counter value in the token (say, c) *is different* from the counter stored at node i (i.e., c_i), then node i assumes it has received a *valid token* and sets c_i equal to c; if $c = c_i$ and i is not the root, i ignores the received token. If i is the root, however, a different rule is used: if the counter c in the token *is equal* to the root's local counter, then the root assumes it has received a *valid token*, and increments its counter value $\bmod Max$; if $c \neq c_i$, then the root ignores the received token.

Consider legal configuration D of Figure 3. In this state all token packets on links have a counter value 8, and the counter values at all nodes except north are also 8. The counter value at north is $9 \neq 8$. In that case, we say that north has the token. Eventually north will transmit a token packet containing 9. When this packet reaches east, east sets its counter value to 9. This process continues with the token moving clockwise until west receives the token and transmits it to north. North chooses a new value (10) and the cycle continues.

In legal states the ring can be partitioned into two bands. The first band starts with the root and continues up to (but not including) the first counter value (either in a token packet or at a node) whose counter value is different from that of north. The remainder of the ring (including links and nodes) is a second band containing a

counter value different from north. The valid token is at the end of the first band.

The protocol stabilizes to legal states regardless of *initial values of node and packet counters.* Assume c_{max} (the number of distinct counter values stored in nodes and links in the initial state) is less than the counter size *Max*. For example, with a 1000 node ring transmitting at 100 Mbp/s and assuming 10 mile links, $c_{max} = 31,000$. If we use a 32-bit counter, then $Max = 2^{32} > c_{max}$ for even the largest size rings that occur in practice. The stabilization argument is illustrated in Figure 3. We provide a formal argument in section 6. For now we sketch an informal argument that illustrates three essential features of the counter flushing argument (increment liveness, freshness, and flushing).

1. *Increment liveness.* In any execution, north will eventually increment its counter. Suppose not; then north's value will move around the ring until north gets a token with a counter value equal to its own.

2. *Freshness.* In any execution, north will reach a "fresh" counter value not equal to the counter values of any other process (see Figure 3, configuration B). In the initial state there are at most (say) c_{max} distinct counter values. Thus there is some counter value, say, f, not present in the initial state. Since (by increment liveness) north keeps incrementing its counter, north will eventually reach f; in the interim no other process can set their counter value to f since only north "produces" new counter values.

3. *Flushing.* Any state in which north has a fresh counter value f is eventually followed by a state in which all processes have counter value f (see Figure 3, configurations C, D). The value f moves clockwise around the ring "flushing" any other counter values, while north remains at f.

Define a *round trip delay* to be equal to $2N$ time units (i.e., the time it takes a packet to travel around the ring with a unit delay at each node and link). The worst-case stabilization time of this protocol is equal to three round trip delays.

First consider a modification to the protocol in which the root chooses a new counter value *randomly* instead of incrementing the old value. Assume that $Max \gg c_{max}$ (i.e., counter size is much greater than the maximum number of stored packets). With very high probability (i.e., $1 - c_{max}/Max$, roughly 2^{-16} for our ring example), the root picks a "fresh" value after its first opportunity to change its counter. Thus a *randomized counter flushing* ring protocol stabilizes within two round trip delays with high probability.

However, simple *deterministic* incrementing also guarantees a worst case stabilization time of three ring round trip delays. Here is the intuition. Consider an execution with initial state s_I and some state s_F that occurs one round trip delay later. Let the counter value of the root in s_I and s_F be $c(I)$ and $c(F)$, respectively. In one round trip delay, there is enough time for information from the root to "flow" through the entire ring. Thus all node counters in state s_F must have been "produced" by the root since the execution began. More precisely, in s_F, all counter values are in the range $[c(I), \ldots, c(F)]$. If $c(F)$ is fresh, we are done one round trip delay later (see the stabilization argument above). Otherwise, the next root increment will cause a fresh value because $c(F) + 1 \notin [c(I), \ldots, c(F)]$. (This last fact follows because the root will increment at most once for every packet received, and can receive at most $c_{max} < Max$ packets in the interval $[s_I, s_F]$.) But the next increment will happen after at most one round trip delay.[2]

[2] A more careful accounting shows that two round trip delays suffice for stabilization. We prefer to use three round trip delays because of the simplicity of the proofs.

A token packet is encoded as a tuple $(Token, c)$ where c is an integer in the range $0..Max$.
The state of each node i consists of an integer $count_i$ in the range $0..Max$.
The root has an additional flag $token\_expected_0$.
Assume there are n nodes numbered from 0 to $n-1$.
All addition and subtraction of process indices is mod n.
All addition and subtraction of counters is mod Max.

Finished(i) (* boolean function used by action routines below *)
Always true for all nodes other than node 0
Finished(0) is true if and only if $token\_expected_0 = false$

ROOT_START (* Node 0 is considered the root or leader of ring *)
Preconditions:
$Finished(0) = true$
Effects:
$count_0 = count_0 + 1$ (* increment root counter *)
$token\_expected_0 = true$

RECEIVE$_{n-1,0}(Token, c)$ (* node 0 receives token from node $n-1$ *)
Effects:
If $c = count_0$ then (* token counter matches node counter *)
$token\_expected_0 = false$ (* node 0 treats this packet like an ack*)

RECEIVE$_{i-1,i}(Token, c), i \neq 0$ (* node i receives token from clockwise neighbor node i-1*)
Effects:
If $c \neq count_i$ then (* token counter differs from node counter *)
$count_i = c$ (*set value to counter in token packet*)

SEND$_{i,i+1}(Token, c)$, (* node i sends token to clockwise neighbor node i + 1*)
Preconditions:
$c = count_i$ (* counter of token matches node counter *)

For any node, a SEND$_{i,i+1}$ action will occur in 1 unit of time starting from any state.

FIG. 4. *Code for node processes in a token ring. The code is explained in more detail in the main text of the paper.*

The formal code for our stabilizing token passing protocol is in Figure 4. Our protocol is a message passing version of a shared memory protocol in [Dij74a]. One of our contributions is to prove that the stabilization time is equal to three ring delays, using our model of time complexity,[3] which we believe is realistic. But our main contribution is abstracting the mechanism and applying it to other examples, as we show below. A formal proof of correctness and stabilization is deferred to section 6.

Token passing protocols are widely used in local area networks to regulate access to the network. Existing token passing protocols recover from lost tokens using global timers that are refreshed whenever a token is seen. In the IBM token ring [Tan93], the monitor (i.e., root) uses a timer initialized to the longest possible delay for a token to traverse the ring. When this timer expires, the monitor restarts the protocol. Thus

[3]There are no time complexity results in [Dij74a].

the recovery time of the IBM protocol is proportional to the worst-case ring delay. The recovery time of a token passing protocol based on counter flushing (see [CV98] for details) is proportional to the *actual delay around the ring*, which can be an order of magnitude faster than the worst-case delay.

3.1. Further applications on rings. Counter flushing on rings can be applied to two more interesting settings: request-response protocols and data link protocols.

Request-response protocols. Suppose a leader node wishes to periodically send a *Request* packet to a set of network nodes. The responders must each send back a *Response* packet before the sender sends its next request. In order to match responses to requests, the sender numbers [Var93] each request with a counter. Responders only accept *Request* packets with a number different from the last *Request* accepted. After accepting a *Request* the responder sends back a *Response* with the same number as the *Request*. The sender retransmits the current *Request* till it receives each matching *Response* with the same number. After all matching *Response* packets arrive, the sender increments its counter and starts a new phase. The protocol will work correctly if $Max > c_{max}$ and the links are FIFO (or guarantee the "flushing" property in some other way.)

Data link protocols. The token passing protocol in Figure 4 can be adapted to send packets reliably between a sender and receiver by having each token packet carry a piggybacked data packet. By comparison, the elegant stabilizing data link protocol of Afek and Brown [AB93] uses bounded length counters of size greater than 2, but such that the sequence of counter values used is aperiodic. A trivial corollary is that for a pair of nodes connected by a pair of unidirectional links, it suffices to use a counter whose size is larger than 1 plus the maximum number of outstanding packets. Afek and Brown also suggest the use of a random sequence instead of an aperiodic sequence. However, Afek and Brown's result is confined to data link protocols between a pair of nodes and to rings and has not been extended to trees or general networks as we do below. Also, the expected stabilization time of the randomized equivalent of Afek–Brown's protocol is shown to be $O(c_{max})$ round trip delays for large values of *Max*, while our stabilization time is only two round trip delays.

4. Counter flushing on trees. In the last section, we describe counter flushing on a ring using a mutual exclusion protocol that is essentially sequential. By contrast, in this section we describe a broadcast protocol on a tree which exhibits considerable parallelism. In this problem, we have a root node 0 that wishes to broadcast a sequence of values to every node in the network. Correct executions of the protocol can be partitioned into an infinite number of cycles: in cycle M the root must send the packet corresponding to M exactly once to all network nodes. Cycle M begins after cycle $M-1$ ends. In order to detect when the current broadcast cycle has terminated the root needs to obtain feedback from the other nodes. Thus the problem is often called propagation of information with feedback (PIF).

We model the sequence of values that the root wishes to broadcast by having the root have access to a function f that computes the next value to be sent as a function of the previous value sent. In a more general setting, the values could be supplied by some external application.

We assume a root node 0 and a spanning tree rooted at node 0, such that each node i has a parent variable *parent*(i) that points to its parent in the tree. Without stabilization, it is easy to solve this problem using protocols due to Segall and Chang [Seg83, Cha82]. When the root finishes broadcasting a previous value, it chooses a new value using the function f. It then sends a token packet containing the new

value to all its children; other nodes accept new values only from their parents, upon which they send the value to their children. When a leaf of the tree gets a new value, it sends an ack up to its parent. Nodes other than the root send an ack up to their parents when they have received acks from all children. When the root receives an ack from all children, the root starts a new cycle by choosing a new value. Clearly this protocol can deadlock if initialized in a state where the root is expecting acks from its children, but the children do not send any further acks.

To make the protocol stabilizing, we tag each packet sent (and each value stored) with a counter. When sending a new value, the root chooses a new counter value. Node i accepts a new value only when it is tagged with a *different* counter value from the counter stored at node i. Node i accepts an ack only when the counter in the ack is *identical* to node i's counter. Adding counters and checks also allows us to periodically retransmit *Token* packets to avoid deadlock.

The code is given in Figure 5. For simplicity, we do not encode "acks" separately but just have children send $(Token, c, v)$ packets to their parents as acks, where c and v are the counter and value, respectively, at the sending node at the instant the packet was sent.

Figure 6 shows a legal state of the protocol where a new value x is being broadcast to replace the previous value v. The new counter tag for x is 13 while the counter tag for v was 12. The new value x has reached the right child of the root and is in transit to the rightmost leaf node. When this leaf node gets a packet containing $(x, 13)$ it will accept the new value because $12 \neq 13$. It will then send an ack containing the counter 13 to its parent; the parent will accept this as a valid ack.

Suppose the counter size is greater than $Max = nL_{max}$, the maximum number of outstanding counters in the initial state. Then the counter flushing argument guarantees that this protocol will enter a legal state in $4h + 2$ time (h is the tree height), regardless of the initial state. Once it stabilizes, the protocol correctly broadcasts subsequent values generated at the root. We defer a formal correctness proof to section 6.

It may appear that counters can be completely avoided because the PIF protocol works on a tree. However, there are counterexample executions where, if a counter is not used (or its size is less than *Max*), then the system stays in an incorrect state forever.

Another general method for constructing stabilizing protocols is local checking [APV91, Var93]. However, the PIF protocol of Figure 5 is not locally checkable. In a good state of the PIF protocol it is possible to have a parent have counter c and the child have counter $c' \neq c$ (if the value is still propagating from the parent to the child). Thus we can construct a bad global state in which each child of the root has a different counter value but each pair of neighbors appears to be in a good state locally. Independently, Gouda [Gou94] used the concept of observers to unify tree and ring stabilizing systems. His paper, however, uses a different proof from ours.

Further applications on trees. Propagation of information with feedback is an example of a centralized total algorithm [Tel89]. A centralized total algorithm is an algorithm where each process in the network must take some decision before the initiator takes a decision event. Tel [Tel89] shows that many protocols such as PIF, Finn's resynch protocol [Fin79], and distributed infimum[4] are all examples of total algorithms. Tel also shows that PIF can be used to replace any total algorithm. Thus

[4]Distributed infimum can be described as calculating a bound on the minimum of a set of values stored at network nodes and links. The global virtual time calculation used in optimistic distributed simulation is a special case of calculating the distributed infimum.

We assume all counters are integers in the range 0..*Max* and all values are drawn from some domain V.
A token packet is encoded as a tuple $(Token, c, v)$ where c is a counter and v is a value.
The state of each node i consists of:
a counter $count_i$, a boolean flag $token\_expected_i[j]$ for each neighbor j of i and a value field v_i.
We assume that each node i has a function $parent(i)$ that points to i's parent in the tree.
We assume the root is node 0 and all addition of counters are done mod *Max*.

Finished(i) (* boolean function used by action routines below *)
(* set to true when not expecting tokens from any children *)
Return true if i is a leaf, or if i is not a leaf and for all children k of i: $token\_expected_i[k] = false$

ROOT_START (* Root starts a new cycle of broadcasting values *)
Preconditions:
$Finished(0) = true$
Effects:
$v_0 = f(v_r)$ (* compute new value to be broadcast*)
$count_0 = count_0 + 1$ (*choose new counter value mod Max*)
For all children k of root
$token\_expected_0[k] = true$ (* set to true when expecting a correctly numbered token*)

SEND$_{i,j}$($Token, c, v$), (* node i sends token to node j *)
Preconditions:
$c = count_i$ (* counter of token matches node counter *)
$v = v_i$ (* value equal to store value *)
$j \neq parent(i)$ or ($j = parent(i)$ and $Finished(i)$) (* send to children, and to parent if finished *)

RECEIVE$_{j,i}$($Token, c, v$) (* node i receives token from node j *)
Effects:
If $j = parent(i)$ and $c \neq count_i$ then (* new counter from parent *)
$v_i = v$ (* set stored value equal to value in token packet*)
$count_i = c$ (*set local counter to counter in token packet*)
For all children k of i
$token\_expected_i[k] = true$ (* set to true when expecting a token *)
Else if $c = count_i$
$token\_expected_i[j] = false$ (* treat as a valid ack from child j*)

Any action that is continuously enabled for 1 unit of time occurs in 1 unit of time.

FIG. 5. *Code for stabilizing propagation of information with feedback. The code is explained in more detail in the main text of the paper.*

the stabilizing PIF protocol described in Figure 5 offers a stabilizing solution to any problem that requires a total algorithm. An interesting application of the stabilizing PIF protocol is for topology update. For example, in the Autonet network [MAM+90], topology distribution is done over a tree.

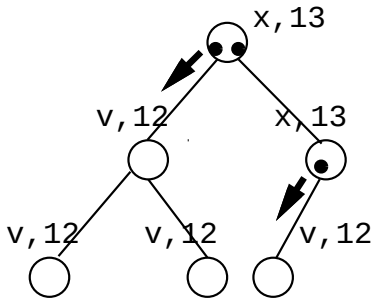

FIG. 6. *Using counter flushing to make broadcast on a tree stabilizing. A new value x is being broadcast to replace the previous value v. A black dot indicates that a node is waiting for an ack on that link.*

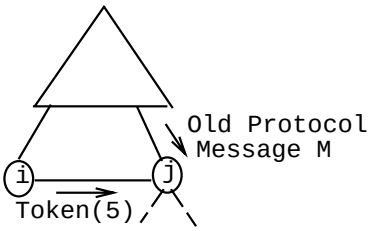

FIG. 7. *The reason for delaying responses to token packets received on cross links (like the one from i to j) is to prevent j from responding to the old (prereset) protocol message after i has locally reset.*

5. Counter flushing in general graphs. We broaden the scope of counter flushing to consider general graphs. However, we continue to assume a root node 0 that is the root of a breadth first search (BFS) spanning tree. Besides links from parents to children we now also have cross links that are not part of the tree. We have seen how to use counter flushing to flush tree links; we now extend the paradigm to flush both tree and cross links.

As before, a node i only accepts a new counter value c from its parent and waits until it gets tokens from its children (numbered with c) before it sends a token up to its parent. However, in addition, i sends a token packet on any cross links it is part of and waits to get a token (numbered with c) on every link before it sends a token to its parent.

The only difficulty is deciding how to reply to token packets received on cross links. Before we see the problems, we introduce an application (global reset) for general counter flushing. We have an underlying protocol P; the root may get requests to reset protocol P. We stipulate that at the point the reset procedure terminates, the state of the underlying protocol P is reset to some successor of a legal initial state of P. To do so, at some point during the reset procedure, (i) each node i must locally reset its protocol P state, (ii) define the *reset interval* of a node to be the interval from the time a node is locally reset until the reset procedure terminates. Then for any pair of neighbors i, j, the sequence of packets received by node j in j's reset interval must be a prefix of the sequence of packets sent by node i during i's reset interval.

In Figure 7, node i has received the counter value (5) corresponding to the current reset and has sent a token packet containing 5 to j. Node j has not received information on the current reset and has an "old" protocol packet in transit from its parent.

Suppose node i's token packet reaches node j first and node j sends back a token immediately (but without changing its counter value or initializing protocol P). Then node j can subsequently receive the "old" protocol packet and send another "old" protocol packet to node i. Thus, we could have a packet sent before node j was reset being received by node i after node i has reset, an error.

A seemingly simple solution is for node j to reset itself locally when it receives the token packet on the cross link from node i. However, if a node accepts counters on cross links to its neighbors, then in the initial configuration we could have a cycle of nodes with different counter values which can result in livelock, where the counters move around in the cycle. This problem can be resolved [KP93] by having each token packet carry a counter *and* a list of visited nodes; a token packet is dropped when it revisits a node in the visited list. However, this solution increases message and time complexity.

The livelock problem disappears if nodes only accept counter values from their parents. To solve the problem referred to in Figure 7, we do two things. First, we tag all protocol P packets with the counter at the sending node; we discard a protocol P packet with a counter that does not match the receiver's counter. This solution eliminates the problem in Figure 7 because the "old" packet will have a different counter value from that of node i. But it introduces another problem. Suppose node i sends a protocol P packet to j after node i resets, but the packet is received before j resets. Then if we simply check the packet tag, the packet will be dropped at j. One might consider buffering the packet at j if the counter tag in the packet is "greater" than the counter at j; however, defining one counter to be greater than another is fraught with complications when using bounded size counters.

Instead we have each node j *delay* responding until the local counter at node j is equal to the counter of the token packet received. Thus in Figure 7 when j receives the token packet from i numbered 5, node j does not send a token numbered 5 back to node i until node j has also received a token packet numbered 5 from its parent. In the meantime, node i will keep retransmitting a token packet numbered 5 to j. Node j will ignore these packets until it, too, has the same counter value of 5. It will then send a token packet back to i with number 5.

We also do not allow protocol P to send packets at node i if node i is waiting for a token packet on one of its links. This implies that (in good executions) any packet sent by i after i has locally reset is sent after j is at the same counter value as i; thus this packet will be accepted by j.

The formal code for this protocol is described in Figure 8. Once again, we defer the proof of correctness and stabilization to section 6. We will show there that the reset protocol stabilizes in three round trip delays.

5.1. Comparison with other reset protocols. We augment the protocol described so far to allow any node to make a reset request as follows. Each node has a reset request bit that is set when the node gets a reset request, or when it has received a *Request* packet from its children. When a node's request bit is on, it periodically sends a *Request* packet to its parent. When the root gets a *Request* packet, the root treats it like a REQUEST_RESET action. On doing a local reset a node clears its request bit; each node i also ignores reset requests and *Request* packets while $Finished(i) = false$.

The resulting reset protocol is similar to a stabilizing reset protocol due to Arora and Gouda [AG94] but has some important differences. First, the protocol [AG94] is based on a shared memory model and thus only requires node counters of size 2. In a

A token packet is encoded as a tuple $(Token, c)$ where c is an integer in the range $0..Max$
The state of each node i consists of:
an integer $count_i$ in the range $0..Max$, and a flag $token\_expected_i[j]$ for each neighbor j of i:
$token\_expected_i[j]$ is always *false* if $j = parent_i$
We assume $parent(i)$ points to i's parent, the root is node 0, and addition of counters is mod Max.

Finished(i) (* boolean function used by action routines below *)
(*set to true when not expecting tokens from any nonparent links *)
Return true if for all neighbors $token\_expected_i[k] = false$

ROOT_START (* root receives request to reset Protocol P *)
Effects:
if *Finished*(0) then (* ignore request if finishing current reset *)
$count_0 = count_0 + 1$ (*choose new counter value mod Max*)
LOCAL_RESET(0) (* locally reset Protocol P *)
For all neighbors k of root, $token\_expected_0[k] = true$ (* expect an ack from all neighbors*)

SEND$_{i,j}$($Token, c$), (* node i sends token to node j *)
Preconditions: (* retransmit periodically regardless of ack bit *)
$c = count_i$ (* counter of token matches node counter *)
$j \neq parent(i)$ or ($j = parent(i)$ and *Finished*(i)) (* send to children, and to parent if finished *)

RECEIVE$_{j,i}$($Token, c$) (* node i receives token from node j *)
Effects:
If $j = parent_i$ and $c \neq count_i$ then (* new counter from parent*)
$count_i = c$ (* set value to counter in token packet*)
LOCAL_RESET(i) (* locally reset Protocol P *)
For all neighbors $k \neq j$ of i (* don't expect ack from parent *)
$token\_expected_i[k] = true$ (* set to true when expecting a token packet *)
Else if $count_i = c$ then
$token\_expected_i[j] = false$ (* treat as a valid ack from neighbor j*)

RESET_FINISHED$_0$ (* root reports finishing of reset *)
Preconditions:
Finished(0)

Protocol P packets are only sent at node i when *Finished*(i) is *true* and are tagged with $count_i$.
A protocol P packet M received at node i is relayed to the application iff the tag of M is equal to $count_i$.
Any action that is continuously enabled for 1 unit of time occurs in 1 unit of time.

FIG. 8. *Simple reset protocol using counter flushing. The code is explained in more detail in the main text of the paper.*

message passing model, where each link can store L_{max} counter values, we believe that larger counter values, as in our protocol, are necessary. A second difference between

our protocol and the one in Arora–Gouda is the use of "delayed acks" and flushing of cross links. This is unnecessary in [AG94], because protocol P is modified so that a node does not read the state of its neighbors unless they have the same counter value. This is possible in a shared memory model but not in a message passing model.

There is also the stabilizing reset protocol of [APV91] which is in turn based on the nonstabilizing reset protocol of [AAG87]. However, this protocol takes $O(n)$ time to stabilize which is slower than our reset protocol or the Arora–Gouda protocol. [AKM$^+$93] suggests making this protocol faster by running it over a spanning tree, but in that case much of the complexity of that protocol is not needed. The fast and lean reset protocol of [IL94] does a reset in constant space. We believe that a 32-bit counter is adequate for most networks, and hence the requirement for logarithmic space in our protocol is not a problem for practical protocols. Our reset protocol is also much simpler.

6. General proofs. In this section, we present proofs of stabilization and correctness for the three protocols (token ring, PIF, and reset) described in Figures 4, 5, and 8, respectively. The three protocols seem different, work on different topologies, and have different objectives. Despite this, we will describe a uniform stabilization proof for all three protocols. In a few places, we distinguish between the ring system (Figure 4) and the tree systems (the PIF and reset protocols, Figures 5 and 8). Note that we added an extra ROOT_START action to the ring system (strictly not needed) and also used the ROOT_START action name in the reset protocol (instead of a more appropriate name) for uniformity of proof.

The proof is structured in four subsections: section 6.1 defines useful terminology; section 6.2 describes legal states; section 6.3 contains a proof that all three protocols stabilize quickly to legal executions; finally, section 6.4 shows that all three protocols exhibit the desired properties in legal executions.

6.1. Definitions. We have already defined the parent of a node for tree systems. For a ring, define the parent of node i to be node $i-1$. Define the *parent path* of a node i to be the sequence of nodes $i_0, i_1, i_2, \ldots, i_l$ such that $i_0 = 0$, $i_l = i$, and the parent of i_m is equal to i_{m-1} for $m = 1, \ldots, l$. Define the links in a parent path $i_0, i_1, \ldots, i_l$ to be the links $(i_0, i_1), \ldots, (i_{l-1}, i_l)$. Notice that the links in the parent path are the links directed "downwards" from the root and do not include any "upward" or "cross" links.

Define the counter at a node i to be $count_i$. We use *root counter* to denote $count_0$, the counter at the root node 0. We say that the counter in packet m is c if m is of the form $(Token, c, *)$. We say that packet m' is behind packet m in link (i, j) in some state s if m and m' are both stored in $s.Q_{i,j}$ and m is closer to the head of $Q_{i,j}$. Recall from Figure 2 that $Q_{i,j}$ models the queue of packets that represent undelivered packets on link (i, j).

To describe the legal states we will define the notion of counters upstream from a node or packet m. Intuitively, these are counters stored on the parent path that leads to m.

Let s be any state of the tree or ring systems. Formally, define the *counters upstream* from node m in state s to be the set of counters in all nodes (including m) and links in the parent path of m in state s. If packet m is stored on link (i, j) in state s, then the *counters upstream* from packet m is the union of the set of counters in packets behind m in link (i, j), together with the set of counters upstream from node i in state s. We will often refer to the counters upstream from m without reference to state s if it is clear from context what state s is.

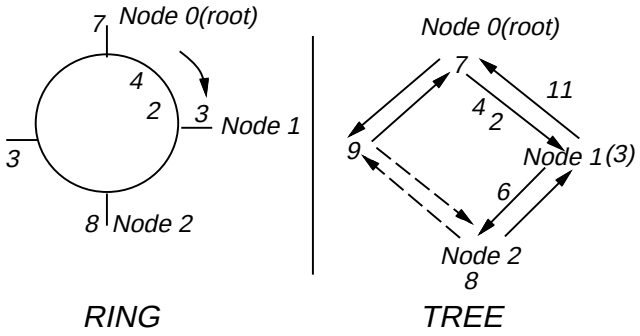

FIG. 9. *Examples of parent paths and upstream counters in a ring and tree. The numbers at nodes represent node counters and the numbers attached to a link represent the counter in a* $(Token, *)$ *packet stored on that link.*

Figure 9 gives examples of these definitions for a ring system (left) and a tree system (right). Notice first that the ring system has a sequence of unidirectional links oriented clockwise in the picture. However, the tree system has a pair of unidirectional links between every pair of neighbors. In the case of the reset protocol, the tree system may include cross links (shown dashed) between neighbors such that neither is the parent of the other. The numbers at nodes and links represent node and packet counters. Thus in both states, link $(0, 1)$ has two stored packets, the first with counter 2 and a second behind the first with counter 4. In both states, node 2 has node counter 8.

The parent path of node 2 is the sequence $0, 1, 2$ in both pictures. The links in the parent path of node 2 are $(0, 1)$ and $(1, 2)$ in both pictures. In the state on the left of Figure 9, the counters upstream from node 2 is the set $\{8, 3, 2, 4, 7\}$. In the state on the right, the counters upstream from node 2 is the set $\{8, 6, 3, 2, 4, 7\}$. Notice that the set does not contain 11 as the packet containing 11 is not in the parent path of node 2. In both states the counters upstream from the packet containing counter 2 is the set $\{4, 7\}$.

6.2. Legal state definitions. We first describe a one-band property that holds in legal states; this property is illustrated in state C of Figure 3 for a ring system. Notice that there is a band of counters starting from the root extending to east and a token packet on the link from east to south, all of which have counter equal to 8. Notice that the remaining counters in the ring are not equal to 7, which is what we would expect in a legal state. Thus, state C satisfies the one-band predicate but not the legal state predicate, both of which are defined below. Figure 6 illustrates a legal state for the PIF protocol. Notice a single band of values equal to 13 starting from the root and extending to the right child of the root. Even if the other node counters were arbitrary, this would suffice to satisfy the one-band predicate.

DEFINITION 6.1. *We say that a state satisfies the* one-band *property if the following five predicates hold in that state:*

- O1: *If there is a packet or node* m *with counter equal to the root counter, then all counters upstream of* m *are equal to the root counter.*
- O2: *If Finished*(0) *is true, then all counters are equal to the root counter.*
- O3: *(tree systems only) If a packet* m *is on link* (i, j) *with counter equal to the root counter and* j *is the parent of* i*, then Finished*(i) *is true and*

$count_i = count_0$.

- O4: *(tree systems only) If* $token\_expected_i[j] = false$ *and* $count_i = count_0$ *and* i *is the parent of* j*, then* $Finished(j) = true$.
- O5: *(tree systems only) If* $token\_expected_i[j] = false$ *and* $count_i = count_0$*, then all counters in link* (j, i) *and* $count_j$ *are equal to the root counter.*

The following lemma states that once the one-band property begins to hold in any execution of any system, it continues to hold. It can be verified easily by checking all possible transitions from such a state.

LEMMA 6.2. *For all three systems, if the one band predicate holds in some state* s_i *of any execution* E*, then the one band predicate holds in all subsequent states* $s_j, j > i$ *of* E.

We now define legal states to to be those in which the one-band property holds and all counters not equal to the root counter are one less than the root counter. For tree systems, we also require that if a node counter is not equal to the root counter, then it is not expecting any acknowledgements. For PIF systems, we also require a value correspondence property. Recall that addition and subtraction of all counters is always implicitly mod *Max*.

DEFINITION 6.3. *We say that a state* s *of any of our three systems is a legal state if*

- L1: s *satisfies the one band property;*
- L2: *any counter that is not equal to the root counter* c *is equal to* $c - 1$*;*
- L3: *(tree systems only) if* $count_i$ *is not equal to* $count_0$*, then* $Finished(i) = true$*;*
- L4: *(PIF systems only) for all* j, k *where* j *and* k *can either be packets or nodes, if the counter associated with* j *is equal to the counter associated with* k*, then the two associated values are the same.*

We will refer to L4 as the *value correspondence* property. The ring and reset systems trivially satisfy value correspondence in all states. The following lemma is easily checked by examining all possible transitions from a legal state.

LEMMA 6.4. *For all three systems, if the legal state predicate holds in some state* s_i *of any execution* E*, then the legal state predicate holds in all subsequent states* $s_j, j > i$ *of* E.

6.3. Stabilization proof. Define a *home* state for all systems to be a state in which all counters in nodes and packets are equal and $Finished(i) = true$ for all nodes i. The following lemmas are easy to check using the definitions.

LEMMA 6.5. *Any home state that satisfies value correspondence is a legal state.*

LEMMA 6.6. *Any state that satisfies the one band property and has* $Finished(0) = true$ *is a home state.*

Formally, define a *fresh* state for all systems to be a state in which all counters in packets and nodes other than the root are *not* equal to the root counter and $Finished(0) = false$. The following lemma is easy to check from the definitions.

LEMMA 6.7. *Any fresh state satisfies the one band property.*

Let the height h of the system be the maximum length of a parent path. Clearly $h = n - 1$ for the ring. Let R, the round trip delay of a system, be $2h + 2$ for the ring and $4h + 2$ for the tree systems. Intuitively, R represents the maximum time for information sent by the root to causally flow to all nodes in the system and then flow back to the root.

The following and subsequent lemmas are stated in terms of time complexity results. They can be translated to liveness results (which do not require the time

complexity assumptions we made in our model, and only require standard fairness assumptions) by replacing "within time X" by "eventually."

LEMMA 6.8. *Within R time of any state s_I, either the root counter will change or the protocol will enter a home state.*

Proof. Let s_F be a state after s_I such that R units of time have elapsed from s_I to s_F and such that $count_0$ has not changed in the interval $[s_I, s_F]$. We will show that s_F is a home state. Let h_i be the length of the parent path of node i in all three systems. It is easy to show by induction that within time $2h_i$ of s_I each node with height h_i will set $count_i = c$ and $count_i$ will remain unchanged till state s_F. Intuitively this is because any packet on a link is delivered within 1 time unit, each node accepts any value sent to it by its parent, and each node retransmits a new counter value to its children in 1 unit of time.

Thus in time $2h$, all nodes will have their counter values equal to c and will remain with this value to the end of the interval. For the ring system, in time $2h+2$, the root will receive a packet with counter equal to c and the system will enter a home state.

For a tree system, the argument is slightly longer. In time $2h + 2$, each node will receive a token packet numbered c on all its "cross" links and thus will set the *token_expected* flag to *false* for such links. Thus by time $2h + 2$, all leaves l will have *Finished*(l) = *true*, all nodes and token packets will have counter value c, and $token\_expected_i[j]$ = *false* for all "cross" links (i, j). Let h'_i be the maximum length of a path from a leaf in the subtree rooted at node i to node i. Then it is easy to see, by a similar induction on the height, that within time $2h + 2 + 2h'_i$ all nodes i will have *Finished*(i) = *true* and this will remain true till s_F. Thus within time $4h + 2$, *Finished*(0) = *true*. Thus s_F must be a home state. □

LEMMA 6.9. *A home state will occur within R time of a fresh state.*

Proof. Consider an execution fragment beginning with a fresh state s_I. Now within R time either the root counter will not increment (Case 1) or it will (Case 2). Consider Case 1. In that case the root counter does not increment within R time and so we must reach a home state by Lemma 6.8. So consider Case 2. Suppose the root counter increments for the first time in some state s_F that occurs within R time after s_I. We know from Lemma 6.7 that s_I satisfies the one band property as a fresh state. We know from Lemma 6.2 that all states after s_I satisfy the one band property. Thus we know that states s_F and s_{F-1} satisfy the one band property. We see from the code of all three systems that we cannot increment the root counter unless *Finished*(0) = *true*. Thus $Finished_0$ = *true* in s_{F-1}. But by Lemma 6.6, state s_{F-1} must be a home state because s_{F-1} is fresh and has *Finished*(0) = *true*. Thus s_{F-1} is a home state that occurs within R time of s_I and we are done. □

We say that the root counter *wraps around* in an execution fragment $s_I, \ldots, s_F$ if we have $s_J.count_0 = s_I.count_0 - 1$ for some J in $[I, F]$.

LEMMA 6.10. *Any execution fragment in which the root counter wraps around must contain a fresh state.*

Proof. In state s_I there are at most c_{max} counters. Since *Max*, the modulus of the counter space, is strictly greater than c_{max}, there must be some counter value f that is not present in any node or packet in the first state s_I. Since the root counter wraps around in the interval $[s_I, s_F]$ and the root counter only changes by incrementing (mod *Max*), there must be some intermediate state in the interval $[s_I, s_F]$ in which the root counter is equal to f. Let s_J be the first such state. It is easy to see that since the value f was not present in state s_I it is not present in any state in the interval $[s_I, s_{J-1}]$. This is because, in all our systems, only the root produces new counters.

Thus in state s_J only the root changes its counter value to f and sets *Finished*(0) to *false* (because the action that takes us to state s_J must be a *RootStart* action). Thus s_J is a fresh state. □

Recall that we defined the parent of a node i for the ring system to be node $i-1$. We define the parent link of a node i to be a link (j, i) such that j is the parent of i. We define a node or packet m to be causally connected (to the root) in an execution fragment E that ends with state s if either

- m is the root;
- m is a node and there is some state that occurs before s in which node m receives a causally connected packet on its parent link;
- m is a packet which was sent by some node i in some some state that occurs before s in which node i was causally connected.

LEMMA 6.11. *Consider any execution fragment $s_I, \ldots, s_F$. Suppose node or packet i is causally connected at the end of this execution fragment. Then the counter associated with i is contained in the sequence $s_I.count_0, s_{I+1}.count_0, \ldots, s_F.count_0$.*

Proof. We use induction on execution fragment length. The lemma is obviously true in the initial state of an execution fragment because only the root is causally connected and the lemma is clearly true for root. So consider any action that extends the last state of the fragment from say s_J to s_{J+1}.

If this action is the receipt of a packet m by node i, and m is not received on a parent link, then the counter of i will not change and so the lemma remains true if it was true in state s_J. If, however, it is received on a parent link, and the packet was causally connected, then after the receipt, node i is causally connected and changes its counter to the counter c associated with m. But since m was causally connected, by inductive hypothesis $c \in s_I.count, s_{I+1}.count, \ldots, s_J.count$. Thus $s_{J+1}.count_i = c \in s_I.count, s_{I+1}.count, \ldots, s_{J+1}.count$. A similar argument holds for the sending of a packet i by a causally connected node. The only other event is ROOT_START after which the lemma clearly holds for the root and trivially holds for all other nodes whose counters remain unchanged. □

LEMMA 6.12. *In any execution fragment, every node and packet will be causally connected within R time of the start of the fragment.*

Proof. Let h_i be the length of the parent path of node i in all three systems. It is easy to show by induction that within time $2h_i$ each node with height h_i will be causally connected. This follows because once a node becomes causally connected, it sends a message to each child which arrives at most 2 time units later, causing the child to be causally connected. Thus all nodes will be causally connected by time $2h$ in, say, state s_J. Let s_F be first state after s_J in which all packets stored in links in s_J are delivered. Also, since all packets in links in s_F must have been sent after s_J, all packets in s_F are also causally connected. The lemma follows because $2h < R - 1$ for all three systems, and because packet delivery takes at most 1 time unit. □

LEMMA 6.13. *If an execution fragment contains a state s which is causally connected, then state s and all subsequent states satisfy value correspondence.*

Proof. We use induction on execution length using the following inductive hypothesis. For all causally connected j, k where j and k can either be packets or nodes, if the counter associated with j is equal to the counter associated with k, then the two associated values are the same. Once all nodes and packets are causally connected the lemma follows from the hypothesis. The basis is true in the initial state as the root is causally connected. For the inductive step, if the action that extends the last state is the sending of a packet k by causally connected node i, if the counter of k is equal to

some other j then the counter of i is equal to k, and thus the value of k is equal to the value of i which is equal to the value of k. A similar argument can be made for the reception of a causally connected message by a node i. □

LEMMA 6.14. *Within $2R$ time of the start s_I of any execution fragment E, we will reach a fresh state or a home state that satisfies value correspondence.*

Proof. Let s_F be first state after s_J in which all packets and nodes are causally connected. From Lemma 6.12, s_F occurs within R time of s_I. By Lemma 6.13, state s_F and all subsequent states in the execution fragment satisfy value correspondence. If the root counter has wrapped around in $[s_I, s_F]$ we are done by Lemma 6.10. So assume the root counter has not wrapped around. Let $c = s_F.count_0$. Thus $c+1$ is not in the sequence $s_I.count, s_{I+1}.count, \ldots, s_F.count$. But by Lemma 6.11 all nodes and packets in states after s_J have counters in the sequence $s_I.count, s_{I+1}.count, \ldots, s_F.count$. Thus we know that as soon as the root counter first increments to $c+1$ we are in a fresh state. But we know that such a state must occur within R time of s_F by Lemma 6.8 or we will reach a home state. Since s_F occurs within R time of s_I the lemma follows. □

LEMMA 6.15. *A home state that satisfies value correspondence occurs within $3R$ time of any state.*

Proof. By Lemma 6.14, within $2R$ time we reach a home state or a fresh state that satisfies value correspondence. By Lemma 6.9, within R time of a fresh state we reach a home state. Thus within $3R$ time we reach a home state that satisfies value correspondence. □

So far we have not defined the legal executions of any of the three systems. By Theorem 6.16, we know that all three systems stabilize to a home state in $3R$ time, and by Lemma 6.5, we know that such a home state is a legal state. Thus it makes sense to define the legal executions of all three systems as the executions that begin with a home state that satisfies value correspondence. An immediate corollary to this definition and Lemma 6.15 is the following.

THEOREM 6.16. *The token ring, PIF, and reset systems all stabilize in $3R$ time.*

6.4. Correctness after stabilization. We see from Theorem 6.16 that all three systems stabilize to legal executions in $3R$ time. We now show that each legal execution results in correct behavior. Notice that by Lemma 6.15 we can partition a legal execution into fragments that start and end with a home state that satisfies value correspondence. We start by understanding the structure of such fragments.

Define a *fresh counter interval* to be an execution fragment[5] E such that

- The first state in E is a home state that satisfies value correspondence.
- The first action in E is a ROOT_START event.
- The second state (i.e., the state following the ROOT_START event) is fresh.
- The last state in E is the first state in E (other than the first state) in which $Finished(0) = true$.

The value of interval E is defined to be the value of $count_0$ in the second (fresh) state in E. For any execution $s_0, a_1, s_1, \ldots$ we can denote an execution fragment by its first and last state indices $[I, F]$ where s_I is the initial state and s_F is the final state.

For a fresh counter interval $[I, F]$ with value c we make the following definitions:

- Let $I(j)$ be the index of the first state in $[I, F]$ such that $count_j = c$.

[5] An execution fragment is a portion of an execution that begins and ends with a state.

- Let $L(j,k)$ be the index of the first state after $I(j)$ which follows the sending of a packet from j to k.
- For tree systems, let $F(j,k)$ be the index of the first state such that $count_j = c$ and $token\_expected_j[k] = false$.
- Let $F(j)$ be the index of the first state such that $count_j = c$ and $Finished(j) = true$.

We now prove some simple facts relating these definitions that are key to correctness.

LEMMA 6.17. *For any fresh counter interval $[I,F]$, every node j, and every neighbor k of j, we have the following.*

- *The states $I(j)$, $L(j,k)$, $F(j,k)$, and $F(j)$ exist.*
- *$L(j,k) < I(k)$ if j is the parent of k (i.e., a node's counter value cannot change until its parent sends it the new counter value).*
- *In the interval $[I(j),F]$, $count_j = c$ (i.e., the value of a node's counter remains unchanged from the time it is initiated till the end of the interval.)*
- *$I(k) < F(j,k) \leq F(j)$ (i.e., a node cannot finish until each of its neighbors is initiated).*
- *$F = F(0)$ is a home state.*

Proof. We use the fact that any home state that satisfies value correspondence is a legal state. Since legal states are stable (Lemma 6.4), every state in the interval $[s_I, s_F]$ is a legal state and satisfies the predicates O1, O2, O3, O4, and O5.

- We know that $Finished(0) = true$ in s_I and s_F. Thus we know (from O2 and O4 applied repeatedly in s_F) that all node counters must be equal to the root counter and $Finished(j) = true$ for all nodes j. We also know that the first action causes the root counter to increment to c. Thus $I(j) = I + 1$ if j is the root. Also for all nodes j other than the root, $count_j$ is not equal to c. But in s_F, $count_j$ is equal to c. Thus there must be some first state $I(j)$ in the interval $[s_I, s_F]$ in which j first changes to c. It is easy to see that $L(j,k)$ must exist because j will eventually send a packet to neighbor k after $I(j)$ in any execution. Also in state $I(j)$, since j changes its counter value, it is easy to see from the code that $token\_expected_i[j]$ is true. But in state s_F, $token\_expected_i[j]$ is false. Thus there must be some intermediate state $F(j,k)$ in which $token\_expected_i[j]$ first becomes false. Similarly, there must be a first state $F(j)$ in which $F(j,k)$ first becomes true for all neighbors k of j.
- In the state preceding $I(j)$, we conclude from O1 that $count_k$ is not equal to c, and there are no counters equal to c in link (j,k). Since $L(j,k)$ is the first state after $I(j)$ in which j sends a packet numbered c on link (j,k), there can be no packets numbered c in the interval $[I(j), L(j,k)]$. Since $count_k$ was not equal to c in $I(j)$ and can only change its counter value by receiving a packet numbered c from its parent j, it follows that $L(j,k) < I(k)$.
- It is easy to see that the root cannot change its counter after s_{I+1} because the root (see code in Figure 8) cannot increment unless $Finished(0) = true$ and s_F is the first state after s_{I+1} in which $Finished(0) = true$. If a node j other than the root changes its counter value after $I(j)$ to some value other than c, it means it received a counter not equal to c on its parent link. By O1, this implies that the root counter is not equal to c, a contradiction.
- The state s that precedes $F(j,k)$ must be (see code in Figure 8) the receipt of a packet with counter equal to $count_j = c$ on link (k,j). Thus by O1,

$count_k = c$ in state s. Thus $I(k) < F(j,k)$. Also $F(j) = \text{Max } F(j,k)$ over all neighbors k of j. So $F(j,k) \leq F(j)$.

- This follows immediately from O2 in state s_F. □

Armed with this lemma, we now show correctness separately for all three systems. Recall that any legal execution can be partitioned into fresh counter intervals. Thus to show correctness, we need only show correctness for a fresh counter interval.

THEOREM 6.18 (token ring correctness). *In any legal execution of the token ring system, at most one node has the token in any state and every node will receive the token infinitely often.*

Proof. We say that a node j has the token starting from any state s in which node j changes its counter value up to the first state after s in which node j sends a packet to $j+1$. Since it is sufficient to show correctness for a fresh counter interval within a legal execution, consider one such interval. It follows from Lemma 6.17 that $I(j) < L(j,j+1) < I(j+1)$ for $j = 0, \ldots, n-1$. Thus, $[I(j), L(j,j+1)]$ is disjoint for all j. Thus, at most one node has the token in any state. Similarly, we know from Lemma 6.17 that $I(j)$ exists for all j and so every node j receives the token during a fresh counter interval. It follows from Lemma 6.15 and the fact that the ROOT_START event is always enabled in a home state that the token system has an infinite number of fresh counter intervals. Thus every node receives the token infinitely often. □

THEOREM 6.19 (PIF correctness) *In any legal execution of the PIF system,*

- *In any state s, v_j is equal to either v_0 or the previous value of v_0.*
- *If the value of some node is not equal to v_0 in state s, there is a later state in which all node values are equal to v_0.*
- *Once a node j's value is equal to v_0, its value cannot change until we reach a state in which all node values are equal to v_0.*

Proof. First, it is easy to see that the ROOT_START event is enabled in a home state and will cause the value of the root counter to change. Thus every legal execution will have an infinite number of home states.

The first part follows from **L2** in the definition of a legal state and the fact that the counter associated with the previous value of v_0 must be $count_0 - 1$. The second part of the theorem follows because we know from Lemma 6.15 that a home state will occur in $3R$ time after state s; in this home state $count_j = count_0$ for all nodes j. Thus by value correspondence (**L4**), $v_j = v_0$ for all j. The third part of the theorem follows from value correspondence and the third statement in Lemma 6.17 which says that a node counter cannot change again until after the next home state. Thus by the code, its value will also remain unchanged in this interval. □

THEOREM 6.20 (reset protocol correctness) *In any legal execution of the reset system,*

- *Once the protocol is in a home state, it remains in a home state until the next reset request, and no node will perform a local reset in this interval.*
- *Consider any reset request that occurs when the reset protocol is in a home state. Then the reset protocol will enter a home state in $O(R)$ time after this reset request and in this home state, the underlying protocol P is in a legal state.*

Proof. The first part follows easily from the code and the definitions of a home state and a fresh counter interval. Notice that when the reset protocol is in a home state, it is impossible for a node j to receive a $(Token, c)$ packet with $c \neq count_j$; thus (from the code) j will never perform a local reset. We now turn to the second part of the theorem.

We know that any reset request that begins in a home state will result in the root picking a fresh counter value, say c, which begins a fresh counter interval. We know from Lemma 6.15 that within $O(R)$ time, this fresh counter interval will end. Thus from Lemma 6.17 if this interval is denoted by $[I, F]$, then there is a state $I(j)$ for each node j at which the node is initiated into the current reset computation. From the code it is easy to see that in this state protocol P is locally reset, and since $count_j$ remains at c this means that there are no further local resets of protocol P at node j.

To show that protocol P is properly reset at the end of the fresh counter interval, we have to show that for any two neighbors j, k the sequence of packets received by k from j during the interval $[I(k), F]$ is a prefix of the sequence of packets sent by j during $[I(j), F]$. Let us call the interval $[I(j), F]$ the reset interval at node j.

So consider any packet m sent by j during the interval $[I(j), F]$. From the protocol code, we know that j does not send any packet during the interval $[I(j), F(j)]$. So we can assume that m is sent after $F(j)$. Thus m will be tagged with c, the value of this fresh counter interval. Now by state F, we know from the properties of link automata that m either will be delivered by state s_F or is stored on link (j, k) in state s_F. If m is delivered, m must have been delivered after $F(j)$ (since it was sent after $F(j)$) and hence by Lemma 6.17 it is delivered in the interval $[I(k), F]$; but in this interval, $count_k = c$ and so m is accepted. On the other hand, if (in state F) m is stored on link (j, k), we know (because the link is FIFO) that all packets sent after m are not delivered. Thus, applying this argument to all packets sent by j to k during $[I(j), F]$, we see that if m is received and accepted, then all packets sent before m in $[I(j), F]$ are received and accepted by k; but if m is not received, then all packets sent after m in $[I(j), F]$ are not received.

All that remains is to show that any protocol P packet m received and accepted by k in $[I(k), F]$ was sent by j in $[I(j), F]$. But if m was accepted it must have tag c. Thus m must have been sent in $[I(j), F]$; this is because, by definition, any protocol P packets sent by j in $[I, I(j) - 1]$ must have a counter value $c' \neq c$. Recall that $I(j)$ is the first state in $[I, F]$ that has $count_j = c$. □

7. Conclusions. Counter flushing is a simple paradigm that has a range of applications and can be used over different topologies. Besides the examples discussed in this paper (token passing, broadcast, and reset), counter flushing can be used to design stabilizing protocols for deadlock detection and snapshot protocols as described in a preliminary version of this paper [Var94]. Our paper exploits a connection between seemingly different protocols such as Dijkstra's token ring protocol [Dij74a], Afek and Brown's data link protocol [AB93], Segall's propagation of information with feedback protocol [Seg83], and Arora and Gouda's global reset protocol [AG94]. At one level, they can all be regarded as repeated versions of a centralized total algorithm [Tel89]; at another level, the data link and reset problems can be regarded as *synchronization* problems whose correctness can be formalized in terms of a mating relation [AE83, Spi88, Var93]. The unified approach allowed us to provide a single unified proof.

Counter flushing has three aspects. First, we establish the presence of a nonexistent counter based on bounding the space of counters; second, we argue a liveness property that guarantees that deterministic incrementing (randomized choosing also works trivially) will lead quickly to a unique counter; third, we show a flushing condition to show that a nonexistent counter flushes out all bad values. While other papers (e.g., [Dol94, AK93]) do use randomization to choose a nonexistent counter, they do not need or use the other two aspects of counter flushing.

Local checking and correction is another general paradigm [APV91, Var93, AGV94]

for designing stabilizing protocols. On a theoretical level, there are problems for which counter flushing is applicable but local checking is not (e.g., token passing on a ring), problems for which local checking is applicable but counter flushing is not (e.g., synchronizers), and problems where they are both applicable (e.g., resets). We believe that while both techniques are practical, counter flushing is simpler to implement. Local checking [APV91, Var93] requires enumeration of predicates and the addition of periodic local snapshots and resets.

We have generalized counter flushing to apply to sliding window protocols [CV96] in order to allow more than one packet in transit between the root node and the receivers. We have also applied counter flushing to design a real token passing protocol in [CV98]. Our modified FDDI protocol [CV98] recovers from multiple tokens in less than 5.7 ms, while the existing FDDI protocol may never recover from multiple tokens; also, the modified FDDI recovers from lost tokens more quickly than FDDI (0–0.36 ms versus 2.5–4.1 ms). This fits in with our overall goal which is to design theoretical techniques that can help design robust practical protocols.

THE POWER OF MIGRATION IN MULTIPROCESSOR SCHEDULING OF REAL-TIME SYSTEMS*

GILAD KOREN†, EMANUEL DAR‡, AND AMIHOOD AMIR‡

Abstract. In this paper we study the performance of off-line multiprocessor real-time schedules that allow task migration compared to those that forbid migration. We consider an *off-line* scheduling problem in which a given collection of tasks, each with a release time, computation time, and *deadline*, are to be run on a multiprocessor system. A preemptive schedule allows the execution of a task to be temporarily suspended and resumed at a later time. A *migrative* schedule allows the task to resume on any processor whereas a *nonmigrative* schedule allows the task to resume only on the processor in which it was initially started. A schedule *value* is the summation of all the values of all the tasks that were completed by their deadlines. In this paper we assume that a task's value is proportional to its computation time.

We present lower and upper bound results. For a system with n processors, we construct a nonmigrative schedule that is guaranteed to achieve at least $1-(1-\frac{1}{2n})^n$ of the *optimal* migrative schedule value.

In addition, we show task sets for which even an optimal nonmigrative schedule achieves at most $n/(2n-1)$ of the optimal migrative value. Asymptotically (as $n \to \infty$) our upper bound approaches $1/2$ and the lower bound approaches $1-\frac{1}{\sqrt{e}} \sim 0.3935$.

Key words. real-time, off-line scheduling, multiprocessor migration, deadline

1. Introduction.

Real-time systems can be most generally described as systems that need to complete certain tasks within a specified time limit. Traditionally, these are systems that handle critical processes such as power stations, nuclear reactors, or space vehicles. In many such applications, failure of the task to complete in time may have disastrous results. Such systems are called *hard real-time systems*.

A less stringent type of real-time system is one where every task still has to be completed by a given deadline—it is then said to *succeed*; otherwise it *fails*. However, such a failure merely means that a certain stimulus has not been responded to; it does not have catastrophic connotations. An example may be a case where the stimuli arrive at a quick rate. Failure to respond to a number of them is still tolerable, as long as a certain ratio succeeds. In this paper we are concerned with the latter type of real-time systems, the *soft real-time systems*. Even within the realm of soft real-time systems, several models appear in the literature. We concern ourselves with the *firm real-time systems*. In this model each task has a *value* which is obtained by the system only if the task completes by its deadline.

A *scheduling algorithm* for a real-time system is presented with tasks, each of which has a *release time* from which it can start working, a *deadline* by which it must

complete working if it is to be successful, and a *computation time*, the time it actually needs in order to run in its entirety. Each task has a *value* obtained if completed successfully. The special case where the value of a task is proportional to its running time is called the *uniform value density* case [3, 10].

The aim of the system is to maximize the sum of the values obtained from all successfully completed tasks. It is the duty of the scheduler to schedule the tasks that maximize this total value.

A number of issues are raised at this point. A scheduler that knows in advance all the tasks and their parameters is called an *off-line* or *clairvoyant* scheduler. If it is presented with a task only upon its release, then the scheduler is called an *on-line* scheduler. The model is said to allow *preemption* if the scheduler may interrupt a working task. Various different types of preemption exist. A preempted task may proceed later from the point it was preempted, be forced to start from the beginning, or not be allowed to run again. In this paper we are concerned with real-time systems that allow preemption. A preempted task may later resume its execution where it left off.

A significant amount of work has appeared about the various possible models of real-time systems [5, 4]. In a single processor environment, it has been shown that in *underloaded* systems, i.e., where there exists a (possibly clairvoyant) schedule that allows all tasks to successfully complete, there exist on-line schedulers with 100% guarantee [6]. In the *overloaded case* such an optimal schedule is impossible [11]. Scheduling algorithms such as D^{over} give a competitive guarantee for overloaded firm real-time systems [10].

In this paper we are concerned with *multiprocessor* real-time systems with preemption. Dertouzos and Mok [7] showed that even in an underloaded system, no on-line algorithm can guarantee 100% success. A task is said to *migrate* if it continues running on a different processor from the one it was preempted in. Koren and Shasha [9] give a multiprocessor on-line competitive algorithm (MOCA) with a competitive guarantee for a multiprocessor real-time system with no *migration*. MOCA does not use migration but its guarantee holds even when migration is allowed. There is a number of differences between the case of MOCA and our problem. (1) MOCA is an on-line algorithm, while we study the off-line case. (2) MOCA does not offer any guarantees in the *uniform value density case*—where the value of a task is proportional to its running time. This is precisely the case we handle.

Bar-Noy et al. [1] study the the case of uniform value density, but in their model tasks have no slack time. (They must be scheduled upon release, if at all.) They give an upper bound of 0.66 on the best possible competitive factor. Bar-Noy, Mansour, and Schieber [2] devised on-line scheduling algorithms for this case with competitive factors of $\frac{1}{2} - \frac{1}{4n}$ for an even number of processors n and $\frac{1}{2}$ for an odd number of processors.

To our knowledge, *there is no on-line scheduler* for a real-time multiprocessor system *with migration* that has any nontrivial *competitiveness guarantees* for the uniform value density case of tasks with slack time.

We would like to investigate the power of migration. There are both practical and theoretical reasons for such an investigation. From a practical perspective, systems without migration are less centralized and less complicated. However, migration gives more power in processor utilization, in versatility, and in fault handling. It may also be easier to prove bounds on systems with migration.

This paper is a first step in the direction of understanding the power of migration

in real-time systems. Specifically, we would like to answer the following question: *In the uniform value density case, does a clairvoyant scheduler without migration have the same power as a clairvoyant scheduler with migration?* If we can pinpoint the *performance ratio* (as defined below) between off-line schedulers with migration and without, we will have gone a step forward in obtaining on-line schedulers as well. We will be able to limit ourselves to either the case of migration or nonmigration. Any competitive on-line scheduling algorithm that will be obtained will guarantee a competitive on-line scheduling algorithm for both cases.

DEFINITION 1.1. *A set of tasks S, in a system with n processors, has a* performance ratio *of $\omega_n(S) = \omega_n$ if*

$$\omega_n = \frac{\{value\ obtained\ by\ an\ optimal\ nonmigrative\ schedule\ for\ S\}}{\{value\ obtained\ by\ an\ optimal\ migrative\ schedule\ for\ S\}}.$$

An off-line nonmigrative scheduling algorithm $\mathcal{A}$, in a system with n processors, has a performance ratio *of $\omega_n(\mathcal{A}) = \omega_n$ if for all S*

$$\omega_n \leq \frac{\{value\ obtained\ when\ \mathcal{A}\ schedules\ S\}}{\{value\ obtained\ by\ an\ optimal\ migrative\ schedule\ for\ S\}}.$$

1.1. Main results. The contribution of this paper is two-fold. In the "grand view" of computer science we add our voice to the impressive body of work dealing with theoretical complexity analysis of operating systems. The operating systems area is at the heart of computer science and understanding the power and limitations of its various concepts is of fundamental importance to our field. It is not surprising that much work has historically been done in this area, particularly in job scheduling (see, e.g., [12, 8]).

However, the area of real-time systems, albeit important in practice, has been relatively neglected in the theory literature. Real-time systems grapple with different issues; thus, the scheduling literature does not generally provide answers to such problems. This paper is a modest addition to a growing number of works that deal with theoretical issues in real-time systems.

The more specific contribution of this paper is in providing both an upper and a lower bound on the performance ratio of off-line schedulers without migration versus with migration in a multiprocessor real-time system with n processors.

- We show an example where an off-line scheduler without migration cannot schedule more than $\frac{n}{2n-1}$ the value of the optimal schedule with migration.
- We describe a scheduler that without using migration obtains a value of at least $1 - \left(1 - \frac{1}{2n}\right)^n$ of the optimal value using migration.

Asymptotically (as $n \to \infty$) our upper bound approaches $1/2$ and the lower bound approaches $1 - \frac{1}{\sqrt{e}} \sim 0.3935$.

This paper is constructed as follows: We start with some notations and definitions in section 2. In section 4 we show the upper bound on the performance ratio. Section 5 is an overview of the scheduler's main ideas and proof of the lower bound on the performance ratio. Section 6 presents the algorithm that, inputting the system tasks' parameters, constructs a nonmigrative schedule with the necessary guarantees for section 5. We conclude with some open problems.

Note on terminology. We have defined an *off-line* scheduling problem. Therefore all tasks and their parameters are known from the start although the tasks are not ready to run until some specified time in the future which we denote here as *release time*. In describing our schedulers, the reader will notice occasional use of on-line-like

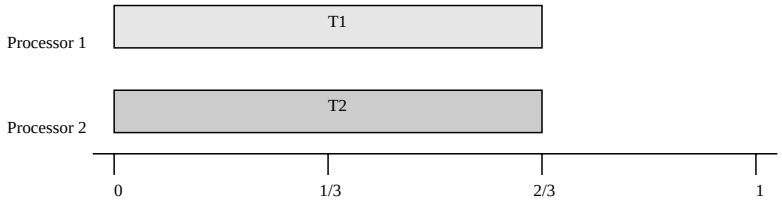

FIG. 1. *A nonmigrative schedule.*

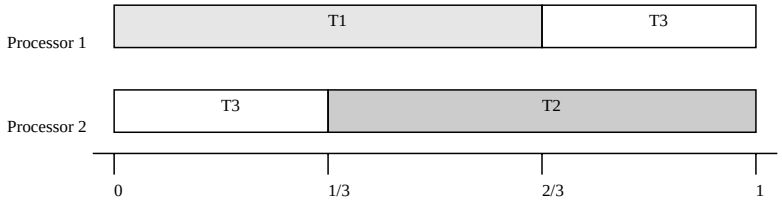

FIG. 2. *A migrative schedule.*

language: "*the task just released*," "*the new task*," etc. The reader should understand that these are just forms of expressions that we consider natural to describing a possible future situation considered by the scheduler. In reality the entire computation is done *off-line*.

2. Preliminaries: Notation and an example. We view time as the set of real nonnegative numbers R^+; however, the results are equally valid for Q^+ or N^+.

DEFINITION 2.1. *Let T be a task. We denote its parameters by $T\left(r\left(T\right),\ c\left(T\right),\ d\left(T\right)\right)$, where $r\left(T\right)$ is the* release time*, $c\left(T\right)$ is the* computation time*, and $d\left(T\right)$ is the* deadline.

A legal schedule *of a task set S on n processors is a schedule where each task T is scheduled for execution only between $r(T)$ and $d(T)$ for a total length that does not exceed $c(T)$. In addition, a task may execute on at most one processor at any given moment. Note that a schedule is legal even if some tasks fail. In a* legal nonmigrative schedule *there is the additional constraint that a task may not run on more than one processor.*

3. Example: Performance ratio. Consider a system with two processors ($n = 2$) and the following task set S of size three:

$$S = \left\{T_1\left(0,\ \frac{2}{3},\ 1\right),\ T_2\left(0,\ \frac{2}{3},\ 1\right),\ T_2\left(0,\ \frac{2}{3},\ 1\right)\right\}.$$

An optimal nonmigrative schedule will schedule $\{T_1,\ T_2\}$ to obtain a value of $c(T_1) + c(T_2) = \frac{2}{3} + \frac{2}{3} = 1\frac{1}{3}$ (see Figure 1). An optimal migrative schedule will schedule all three tasks obtaining a value of $c(T_1) + c(T_2) + c(T_3) = \frac{2}{3} + \frac{2}{3} + \frac{2}{3} = 2$ (see Figure 2). Hence, $\omega_2\left(S\right) = \frac{1\frac{1}{3}}{2} = \frac{2}{3}$.

4. The upper bound. We begin by demonstrating an upper bound on the performance ratio. The example below shows that for every number of processors n there are task sets that can be completely scheduled when migration is allowed; however, some tasks must fail when migration is not allowed.

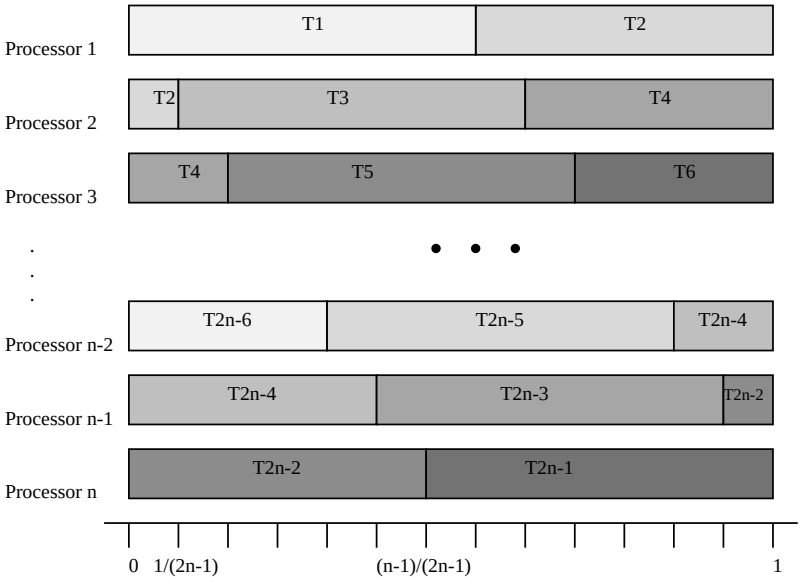

FIG. 3. *Upper bound example.*

THEOREM 4.1. *For any number of processors n, $n \geq 2$, there exists a task set, S^n, such that $\omega_n(S^n) = \frac{n}{2n-1}$.*

Proof. Let S^n be a set of $2n-1$ identical tasks: $T_i(0, \frac{n}{2n-1}, 1)$ (all with release time 0, deadline at 1, and computation time of $\frac{n}{2n-1}$).

An optimal off-line migrative schedule can successfully complete all those tasks (see Figure 3) and therefore obtains a value of

$$\sum_{i=1}^{2n-1} T_i = (2n-1)\frac{n}{2n-1} = n.$$

An optimal nonmigrative schedule completes at most one task on each processor for a total of n tasks obtaining a value of

$$n\frac{n}{2n-1} = \frac{n^2}{2n-1}.$$

The performance ratio is therefore

$$\omega_n(S^n) = \frac{\frac{n^2}{2n-1}}{n} = \frac{n}{2n-1}. \qquad \square$$

COROLLARY 4.2. *There is no off-line nonmigrative scheduling algorithm for n processors with performance ratio above*

$$\frac{\frac{n^2}{2n-1}}{n} = \frac{n}{2n-1}.$$

5. The lower bound. To prove the lower bound we will present the NO-MIGRATION algorithm—a scheduling algorithm that does not use migration.

Denote $1-\left(1-\frac{1}{2n}\right)^n$ by $\rho(n)$. The scheduler NO-MIGRATION receives as its input a task set and constructs a schedule that achieves at least $\rho(n)$ the value of the optimal migrative schedule. We will assume the existence of such a migrative schedule in order to prove that NO-MIGRATION indeed satisfies the ratio $\rho(n)$. However, a construction of such an optimal scheduler is not needed and it is not used by NO-MIGRATION.

Before describing Algorithm NO-MIGRATION we need one more definition.

DEFINITION 5.1. *Given a schedule σ on n processors, define $Proj\,(\sigma) \subseteq R^+$, the* projection *of σ, as follows: $t \in Proj\,(\sigma)$ iff there exists a task T that, by schedule σ, executes at time t on some processor.*

The idea of NO-MIGRATION is the following. Start with the set of tasks S and construct a subset R_1 that is schedulable on a single processor. The sum of the computation times of the tasks in R_1 is at least half the projection of an optimal migrative schedule of S. Delete the tasks of R_1 from S and repeat the process, constructing a set R_2 with the same properties (relative to the reduced S). Repeat this n times, to produce a nonmigrative schedule on n processors.

For clarity of exposition and proof, we assume the existence of two building blocks, EDF* and EDF-LST, that construct the sets $R_i,\ i = 1, \ldots, n$, with the desired properties. The details of these algorithms are described in the next section.

5.1. The NO-MIGRATION algorithm.

Algorithm Outline

INPUT: A set of tasks S.

1. $TASK\_SET \leftarrow S$
2. for $i = 1$ to n do
   (a) construct a subset $R_i \subseteq TASK\_SET$ (using the EDF-LST algorithm and the construction in section 7.2).
   /* We will see in section 6 that R_i satisfies
   - R_i is schedulable on one processor; and
   - The sum of R_i tasks' computation times is at least half of P_i, the projection of an optimal migrative schedule of $TASK\_SET$.

   */
   (b) $TASK\_SET \leftarrow TASK\_SET \setminus R_i$.
3. End For

End Algorithm

For each $i = 1, \ldots, n$, the tasks in R_i can run on a single processor. Thus the tasks in $\cup_{i=1}^{n} R_i$ constitute a nonmigrative schedule on n processors. For each $i = 1, \ldots, n$, the computation time of all the tasks in R_i is at least half the projection of an optimal schedule on the tasks in $TASK\_SET$ during the ith iteration. Theorem 5.3 proves that the total computation time of the tasks in $\cup_{i=1}^{n} R_i$ is at least $\rho(n)$ of the total computation time in an optimal migrative schedule.

Notation. Denote by V the *value* of a migrative schedule of task set S on n processors. Denote by $P_i,\ i = 1, \ldots, n$, the *projection* of an optimal migrative schedule on n processors of $TASK\_SET$ in iteration i of the NO-MIGRATION algorithm.

LEMMA 5.2. *For all $1 \le i \le n$,*

$$\sum_{j=1}^{i} R_i \ge \frac{1}{2n} \sum_{j=1}^{i} \left(\frac{2n-1}{2n}\right)^{j-1} V.$$

Proof. We prove this claim by induction.

For $i = 1$, $R_1 \geq \frac{1}{2n}\left(\frac{2n-1}{2n}\right)^0 V = \frac{1}{2n}V$. This is true since, by definition of the projection of a schedule, the length of the first projection, P_1, is not smaller than the busy time of any single processor. Hence $nP_1 \geq V$ and R_1's value is at least half of P_1's length. Therefore,

$$R_1 \geq \frac{P_1}{2} \geq \frac{1}{2n}V.$$

Assume the correctness of the claim for i; we have to prove it for $i+1$.

In step $i+1$, the total length of tasks that still remain to be scheduled is $V - \sum_{j=1}^{i} R_j$. The length of the $(i+1)$st projection, P_{i+1}, is greater than the busy time of any single processor. Hence, $nP_{i+1} \geq (V - \sum_{j=1}^{i} R_j)$. The value of R_{i+1} is at least half of P_{i+1}'s length. Therefore,

$$R_{i+1} \geq \frac{P_{i+1}}{2} \geq \frac{1}{2n}\left(V - \sum_{j=1}^{i} R_j\right) \tag{5.1}$$

and

$$\begin{aligned}
\sum_{j=1}^{i+1} R_j &= \sum_{j=1}^{i} R_j + R_{i+1} \\
&\geq \sum_{j=1}^{i} R_j + \frac{V - \sum_{j=1}^{i} R_j}{2n} && \text{(by inequality 5.1 above)} \\
&= \frac{2n\left(\sum_{j=1}^{i} R_j\right) + V - \sum_{j=1}^{i} R_j}{2n} \\
&= \frac{V + (2n-1)\sum_{j=1}^{i} R_j}{2n} \\
&= \frac{V}{2n} + \frac{(2n-1)}{2n}\sum_{j=1}^{i} \frac{1}{2n}\left(\frac{2n-1}{2n}\right)^{j-1} V && \text{(by the induction hypothesis)} \\
&= \frac{V}{2n} + \sum_{j=2}^{i+1} \frac{1}{2n}\left(\frac{2n-1}{2n}\right)^{j-1} V \\
&= \sum_{j=1}^{i+1} \frac{1}{2n}\left(\frac{2n-1}{2n}\right)^{j-1} V,
\end{aligned}$$

which concludes the induction. □

THEOREM 5.3. *Given a set of tasks S there exists a nonmigrative schedule for n processors obtaining a value of at least*

$$\rho(n)V,$$

where V denotes the value of an optimal nonmigrative schedule. Furthermore, such a schedule is produced by NO-MIGRATION.

Proof. The schedule created by NO-MIGRATION assigns the tasks of R_i to processor i. Since each of the R_i's is schedulable on one processor we obtain a legal schedule

TABLE 5.1
Lower and upper bounds for different processor numbers.

n	2	3	4	7	10	40	70	100	400	700	1000
Lower	.4375	.4213	.4138	.4047	.4013	.3954	.3946	.3942	.3937	.3936	.3935
Upper	.6667	.6000	.5714	.5385	.5263	.5063	.5036	.5042	.5006	.5004	.5003
Ratio between bounds	.656	.702	.724	.752	.762	.781	.784	.782	.786	.787	.787

on n processors that use no migration. Its total value is $\sum_{i=1}^{n} R_i$, which according to Lemma 5.2 satisfies

$$\begin{aligned}\sum_{i=1}^{n} R_i &\geq \sum_{i=1}^{n} \frac{1}{2n}\left(\frac{2n-1}{2n}\right)^{j-1} V \\ &= \frac{1}{2n}\left(\frac{\left(1-\frac{1}{2n}\right)^n - 1}{\left(1-\frac{1}{2n}\right)-1}\right) V \\ &= \left(1-\left(1-\frac{1}{2n}\right)^n\right) V. \qquad \square\end{aligned}$$

The following lemma presents the asymptotic behavior (as the number of processors n grows) of the above guarantee.

LEMMA 5.4. *$\rho(n)$ is a monotonic decreasing function and*

$$\text{for all n} \quad \rho(n) \geq \lim_{n\to\infty} \rho(n) = 1 - \frac{1}{\sqrt{e}}.$$

Proof. $\rho(n)$ is a monotonic decreasing function; therefore its infimum is reached at the limit.

$$\lim \rho(n) = \lim 1 - \left(1-\frac{1}{2n}\right)^n = 1 - \lim\left(1+\frac{-\frac{1}{2}}{n}\right)^n = 1 - e^{-\frac{1}{2}} = 1 - \frac{1}{\sqrt{e}}.$$

(We have made use of the equality $\lim_{n\to\infty}\left(1+\frac{x}{n}\right)^n = e^x$.) $\square$

We conclude that for each n the lower bound is greater than $1 - \frac{1}{\sqrt{e}} \sim 0.3935$.

Recall that the upper bound we constructed is $\frac{n}{2n-1}$ which converges to 0.5 as $n \to \infty$. In fact, both upper and lower bound sequences converge quite rapidly, as can be observed in Table 5.1 and the graph in Figure 4.

THEOREM 5.5. *For any number of processors $n \geq 1$. Given a set of tasks S there exists a nonmigrative schedule for n processors obtaining a value of at least*

$$\left(1-\frac{1}{\sqrt{e}}\right) V \sim 0.3935\ V,$$

where V denotes the value of an optimal nonmigrative schedule for n processors. Furthermore, such a schedule is produced by NO-MIGRATION.

Proof. We use Theorem 5.3 and Lemma 5.4 above. $\square$

6. Building uniprocessor schedulable subsets (the R_is). In this section we show how to build the R_i subsets, i.e., subsets of the scheduled tasks whose value is at least half of the projection of any n processor schedule.

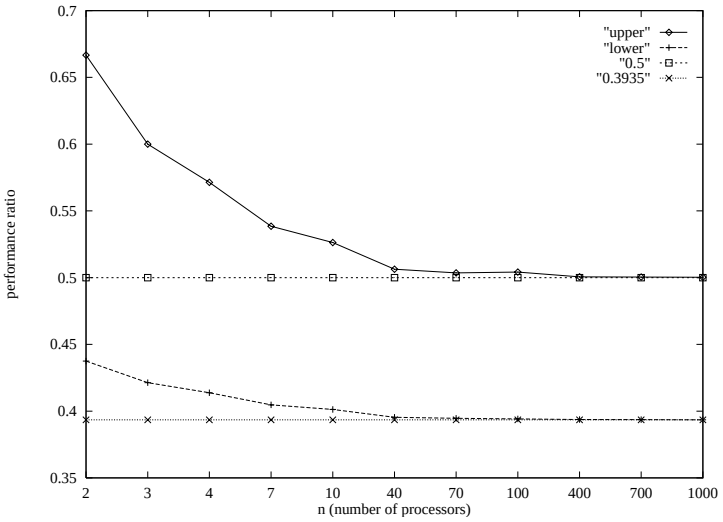

FIG. 4. *Graph of convergence speed.*

THEOREM 6.1. *Given $Sched_n(S)$, a schedule of S on n processors, there exists a $R' \subseteq S$ schedulable (on a* single *processor) with a total value of at least*

$$\frac{1}{2} Proj\left(Sched_n(S)\right).$$

The theorem will be proven in three steps as follows:

(1) First, we introduce a preemptive uniprocessor scheduling algorithm—EDF*. Note that this is essentially an on-line algorithm, but we use it here as part of an off-line scheduler.

(2) EDF-LST is a uniprocessor scheduling algorithm that uses EDF* as a subroutine. It schedules S on one processor. (Of course some tasks may not successfully complete.)

Using the schedule created above by EDF-LST we partition the projection of S into disjoint intervals. For each interval we have a (possibly overloaded) task subset scheduled in this interval.

(3) For each such subset of tasks, we construct a subsubset with the property that the sum of its tasks' values is at least half the length of the corresponding interval and it is schedulable on a uniprocessor system. The collection of all these subsubsets is schedulable on a single processor and achieves a value not less than half of the projection of $Sched_n(S)$.

6.1. The EDF* algorithm. We introduce EDF*—a uniprocessor preemptive scheduling algorithm. EDF* is used as a subroutine in EDF-LST.

The EDF* algorithm works as follows: EDF* maintains a set of **accepted** tasks and schedules these tasks according to the *earliest deadline first* (EDF) strategy [6]. Initially the set of accepted tasks is empty. Upon their release, "new" tasks may be added to the accepted set, provided that this set remains underloaded (that is, schedulable by EDF [6]).

Algorithm Outline
INPUT: A set of tasks S.

1. At the release time of some task T, if T has the minimum deadline among all currently accepted tasks we check whether the acceptance of T would not cause any of the currently accepted tasks to miss its deadline. (A similar strategy is employed by D^{over}[10].) If there is no such danger, then the new task T is accepted, the currently executing task is preempted, and T starts to execute. Else T is not accepted, and the current task continues executing.
2. Schedule the accepted tasks according to EDF.
3. If (at task completion) **accepted** becomes empty, then the ready task with an earliest deadline becomes "accepted" and scheduled for execution.

End Algorithm.

7. Example: Run through EDF*. We will illustrate the scheduling of EDF* by the set of tasks presented in Table 7.1. Initially, **accepted** is empty. At time 0, the first two tasks are released. Since T_1 has earlier deadline, **accepted** becomes $\{T_1\}$ and T_1 is scheduled. At time 1, T_3 is released, its deadline is earlier then T_1's deadline, and both tasks can be scheduled to completion. Hence T_3 preempts T_1 and it is added to **accepted**. At time 2, T_4 is released, it has a deadline which is smaller than all the tasks in **accepted** but cannot be scheduled without preventing any of the other tasks in **accepted** from completion. Hence, T_3 continues until its completion at time 3, then T_2 resumes and completes at time 5, leaving **accepted** empty. At time 5, T_2 is added to the empty **accepted** set, it is scheduled until it completes at time 7. Note that T_4 was not scheduled at all.

7.1. The EDF-LST algorithm. In cases of underloaded task sets, EDF* would have been enough for our needs. In fact, an underloaded case would mean that *all* tasks can be scheduled on *one* processor. Consequently, we can certainly expect that a task set schedulable on n processors will be unschedulable (overloaded) when scheduled on one processor. For this reason, we introduce a scheduling algorithm called EDF-LST that is an "extension" of EDF* for overloaded cases.

7.1.1. LST: Latest start time. We define *latest start time (LST)* as a critical point in a task's existence: If a task reaches its LST it means that it has no more slack time. Hence, it must be scheduled immediately and executed continuously until its completion on its deadline; otherwise it will miss its deadline. This is given formally in the following.

DEFINITION 7.1. *At any given moment t for a task T,*

$$LST\,(t,T) = deadline\,(T) - remaining\_computation\_time\,(T)\,.$$

LST-exception: *When (and if) a task that is not currently executing reaches an LST point it raises the LST-exception.*

The EDF-LST scheduling algorithm schedules according to the EDF* algorithm as long as no LST-exception is raised. At some point an LST-exception may be raised, either by previously preempted tasks, some task that EDF* did not "accept," or at the release time of tasks with no slack time. As soon as an LST-exception is raised EDF-LST might diverge from EDF* by scheduling tasks at their LST points. These tasks are called *LST tasks* while the tasks scheduled according to EDF* are called *EDF tasks*.

When there are no more LST tasks to schedule, EDF-LST returns to schedule according to EDF*. This cycle continues until there are no more tasks to schedule. The

TABLE 7.1
Set of tasks for section 7.

	r	c	d
T_1	0	3	6
T_2	0	2	8
T_3	1	2	5
T_4	2	2	4

precise conditions for LST tasks or EDF tasks will be seen in the next subsection.

This schedule creates alternating sets of EDF tasks and LST tasks covering some contiguous time interval bordered by *idle* periods. A time period is said to be *idle* if at all its points all tasks either completed, missed their deadlines, or were not released yet.

We will select from the tasks in a time interval bordered by idle periods, an underloaded (i.e., schedulable) subset of tasks whose cumulative value is at least half the length of that time interval. Combining this for all intervals, we build the desired schedule.

7.1.2. EDF-LST. The pseudo code of the algorithm is built from one main function and two exception handlers. (The subroutine that implements EDF* is not shown here.)

At each moment, the algorithm can be in one of two phases: edf_phase or lst_phase. In the first, tasks are scheduled according to EDF*. In the latter, scheduling decisions are made by the LST-exception handler as a result of raising such an exception.

The algorithm has cycles. Each cycle starts with an edf_phase followed by an optional lst_phase. While in the edf_phase the algorithm maintains a collection of "accepted" tasks (exactly in the same manner as it is done by EDF*). If a task T raises an LST-exception it will be scheduled only if its deadline is far enough[1] in the future. Otherwise, T is aborted. Scheduling T means switching to the lst_phase. Task T will schedule to completion unless another LST-exception will be raised by another task with an even "further" deadline[2] and so on.

This chain of exceptions/abortions ends when some task is able to complete its execution. This marks the end of a cycle. The algorithm now switches back to the edf_phase. (The "accepted" set is the ready task with earliest deadline.)

Let us briefly explore the intuition for choosing the above criteria for the "far enough" deadline. The main idea is identifying in each cycle a collection of "executing units" that covers an interval. The set of all the accepted tasks is the first unit. Each task scheduled by its LST-exception is a subsequent unit of its own.

Two adjacent units may interfere with each other (in the sense that scheduling one may prevent the scheduling of the other) but removing any one unit will enable its (one or) two adjacent units to complete. This mean that eliminating the collection of

[1]The meaning of "far enough" here is as follows. We consider the time interval in which the currently *accepted tasks* will execute to completion (if not interrupted). We look at all the tasks that will raise an LST-exception during that interval and whose deadlines are beyond the end of that interval. T's deadline must not be smaller than all these deadlines.

[2]The meaning of "further" here is as follows. We consider the time interval in which the currently *scheduled task* will execute to completion (if not interrupted). We look at all the tasks that will raise an LST-exception during that interval and whose deadlines are beyond the end of that interval. T's deadline must not be smaller than all these deadlines.

all odd numbered units enables the collection of all even numbered units to complete and vice-versa. These two collections cover the entire interval; hence the bigger of the two covers at least half of the interval. This is the condition we were seeking.

EDF-LST Algorithm.

INPUT: A set of tasks S.

In the following algorithm, **accepted** denotes the set of accepted tasks as defined in the definition of EDF*.

- **main body** /* main body of the algorithm */
  1. if S is empty, end of execution. /* strange, no tasks were presented */
  2. /* otherwise, there are tasks to execute */
     /* in the beginning, starting in edf_phase */
     $phase \leftarrow edf\_phase$
  3. /* main loop of the algorithm */
     loop (forever) {
     - as long as **phase** equals **edf_phase**, schedule according to EDF*.
       /* tasks scheduled in this phase are called EDF tasks */
     - otherwise, **phase** equals **lst_phase** in which case scheduling decisions are made in the LST_exception handler (see below).

     }
- **End of main body**
- **LST_Exception handler**

  /* a task T raises an LST-exception, say at time t */
  - if ($phase = edf\_phase$) then
    /* scheduling is currently done according to EDF* */
    1. Let $endof$ (**accepted**) be the time that tasks of **accepted** are expected to complete if scheduled without any interruption.
       Consider the set of all tasks that will raise an LST-exception in the time interval $[t, endof$ (**accepted**)] provided the current tasks of **accepted** would continue without interruption, and whose deadline is later than $endof$ (**accepted**).
       From this set of tasks, choose the task with the latest deadline. Denote its deadline by d_{max}.
    2. if $d(T) \geq d_{max}$ then
       /* $d(T)$ is indeed far enough */
       /* switch from edf_phase to lst_phase */
       /* end of scheduling according to EDF* start to schedule according to LST-exceptions */
       $phase \leftarrow lst\_phase$
       • $i \leftarrow 1$ /* index of LST_i */
       • label T as $\mathbf{LST_1}$
       • /* Let $raised$ ($\mathbf{LST_1}$) $= t$
       (the time that task $\mathbf{LST_1}$ raised its LST-exception) */
       • /* Let $endof$ ($\mathbf{LST_1}$) $= d(LST_1)$ (the time that LST_1 is expected to complete if scheduled without any interruption) */
       • start to execute $\mathbf{LST_1}$
       else
       /* $d(T)$ is not far enough */
       • abort T (continue in **edf_phase**, scheduling according to EDF*)
  - else

/* some T raised an **LST**-exception, while some LST_i is executing */
1. Consider the set of all tasks that will raise an LST-exception in the time interval
   $[raised(\mathbf{LST_i}), endof(\mathbf{LST_i})]$, provided that LST_i would continue without interruption, (T will be aborted), and whose deadline is later than endof($\mathbf{LST_i}$).
   From this set of tasks, choose the task with the latest deadline. Denote its deadline by d_{max}.
2. if $d(T) \geq d_{max}$ then
   /* $d(T)$ is far enough */
   /* switch from the current LST task to T */
   • $i \leftarrow i + 1$
   • label T as $\mathbf{LST_{i+1}}$
   • /* Let $raised(\mathbf{LST_{i+1}}) = t$
   (the time that task $\mathbf{LST_{i+1}}$ raised its LST-exception) */
   • /* Let $endof(\mathbf{LST_{i+1}}) = d(LST_{i+1})$ (the time that LST_{i+1} is expected to complete if scheduled without any interruption) */
   • start to execute $\mathbf{LST_{i+1}}$
   else
   /* $d(T)$ is not far enough */
   • abort T (continue with $\mathbf{LST_i}$)

– End if

End LST_Exception handler

• **Task_Completion handler**
/* The currently executing task T completes, say at time t */
if ($phase = edf\_phase$) then
/* T was scheduled by EDF* */
task completion is handled according to EDF* (schedule the next accepted task or if empty the next ready task with earliest deadline)
else
/* T is LST_j for some j */
/* switch phases, return to EDF* scheduling */
$phase \leftarrow edf\_phase$
start scheduling according to EDF*
(**accepted** is set to the next ready task with earliest deadline)

End Task Completion handler

End Algorithm.

Note that the collection of tasks scheduled by EDF-LST may be an overloaded task set, that is, some of tasks do not execute to completion. This can happen if tasks that where scheduled by EDF* are preempted and never resumed, or tasks that raise LST-exception are not selected to execute or, even if selected, may be aborted when the next LST task is scheduled.

See Figure 5 for a schematic example of an EDF-LST schedule.

In the next section we show how to select an underloaded subset of tasks with a "big enough" value, i.e., the sum of its tasks' values is no less than the projection of an optimal migrative schedule.

7.2. Selecting an underloaded subset from the EDF-LST schedule. This section completes the last necessary step to prove our lower bound. We study the schedule created by EDF-LST. First we suitably partition the tasks in this schedule.

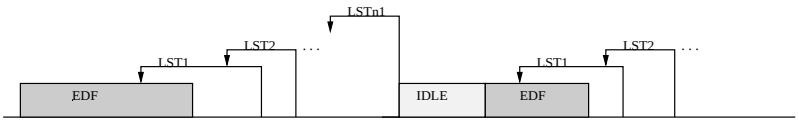

FIG. 5. *A schematic of an* EDF-LST *schedule.*

Then, we use this partition to construct an underloaded subset with a "big enough" value.

7.2.1. Partitioning EDF-LST's schedule. The schedule of EDF-LST naturally splits the tasks of S into two collections. The first is composed of tasks that *appear* in the schedule. These are tasks that were scheduled for execution for at least one time interval and eventually either completed or aborted. The second includes the rest of the tasks—those that were never scheduled for execution. These are tasks that were not scheduled by EDF* and when their LST was raised they were aborted. In the following analysis we partition the first collection into subsets; the second collection is ignored.

The result of the EDF-LST algorithm is a schedule of tasks that have the following structure:

$$EDF^1,\ LST^1, EDF^2,\ LST^2, \ldots, EDF^i,\ LST^i, \ldots,$$

where EDF^i is a set of tasks scheduled according to EDF* and LST^i is a set of tasks scheduled following an LST-exception. The individual tasks of EDF^i and LST^i are denoted by $EDF^i_1, EDF^i_2, EDF^i_3, \ldots,$ and $LST^i_1, LST^i_2, LST^i_3, \ldots,$ respectively.

For every i define the following subsets of S:

- α_i : Tasks that **last appear**[3] as one of LST^i tasks but with *odd* indexes, i.e., $LST^i_{\mathbf{1}}, LST^i_{\mathbf{3}}, LST^i_{\mathbf{5}}, \ldots$.
- β_i : Tasks that **last appear** as part of EDF^i and *did not complete* and tasks that **last appear** as one of LST^i tasks but with *even* indexes, i.e., $LST^i_{\mathbf{2}}, LST^i_{\mathbf{4}}, LST^i_{\mathbf{6}}, \ldots$.

In addition define

- γ : Tasks that **last appear** as any of EDF^is and *completed* successfully.

7.2.2. Building an underloaded task set.

LEMMA 7.2. *Each of the sets $\gamma, \alpha_i, \beta_i$ (for all i) is an underloaded task set (i.e., can be scheduled successfully on one processor).*

Proof. γ is obviously underloaded since all its tasks were successfully completed by EDF-LST.

We will show that for all i, α_i and β_i are underloaded. If α_i is empty, so is β_i (because empty α_i implies that LST^i is empty; if this is the case then all tasks of EDF^i were scheduled to completion and hence β_i is empty) and we are done. Otherwise, suppose we eliminate the tasks of α_i from the schedule created by EDF-LST. We will show how all the tasks of β_i can now successfully complete by using only the time intervals thus vacated.

• *Eliminating LST^i_1 will enable all the tasks of EDF^i to complete.*

This can be seen by the following argument:

[3] "*Last appear*" means the last time it appeared, i.e., the last time it was executed. Note that a task may be preempted and rescheduled many times. However, since each task may "last appear" at most once we obtain a partitioning into **disjoint** task.

(1) If there is no LST_2^i, then LST_1^i completes running by its deadline, according to the EDF-LST schedule. EDF-LST schedules LST_1^i only if its deadline occurs after $endof(EDF^i)$.
(2) If LST_2^i exists, then the LST-exception of LST_2^i occurred after $endof(EDF^i)$. (Otherwise, LST_1^i would not have been scheduled.)

Conclude that in both cases the time freed by LST_1^i is enough for all EDF^i tasks.

• *Eliminating LST_3^i will enable LST_2^i to complete.*

The reasoning is similar. If there is no LST_4^i, then LST_3^i completed by EDF-LST. EDF-LST schedules LST_3^i only if its deadline is later than $d(LST_2^i)$.

If there exists LST_4^i, then the LST-exception of LST_4^i occurred after $d(LST_2^i)$. (Otherwise, LST_3^i would not have been scheduled.)

Conclude that in both cases the time freed by LST_3^i is enough for LST_2^i.

• *In general, eliminating α_i enables all the tasks of β_i to complete.*

This can be easily verified by induction in a similar manner to the above two cases.

Conclusion: β_i is underloaded.

A similar argument, though somewhat simpler since the tasks of EDF^i do not matter here, shows that eliminating β_i enables all the tasks of α_i to complete.

Conclusion: α_i is underloaded. □

7.3. Notation.

- Let σ be any schedule (migrative or nonmigrative) of S on n processors. Denote the projection of σ by $PROJ$.
- Denote the union of the nonidle periods of EDF-LST (for S) by $BUSY$.

For all i define

- $\max_i$: the set with higher total value among α_i and β_i (if equal value, choose arbitrarily);
- $\min_i$: the set with lower total value among α_i and β_i.

For ease of notation we will henceforth denote the *values* of $\gamma, \alpha_i, \beta_i$, and $\max_i$ also by $\gamma, \alpha_i, \beta_i$, and $\max_i$, respectively. Similarly we will use $PROJ$ and $BUSY$ to also denote their total lengths.

LEMMA 7.3. $\gamma \bigcup \{\cup_i \max_i\}$ *is an underloaded task set.*

Proof. From the proof of Lemma 7.2 above, we see that expanding the tasks of $\max_i$ to the time vacated by eliminating $\min_i$ (and only this time) suffices for the completion of all the tasks of $\max_i$. Hence, eliminating $\cup_i \min_i$ enables $\cup_i \max_i$ to complete without disturbing any of the γ tasks. □

LEMMA 7.4. $\gamma + 2\sum_i \max_i \geq BUSY$.

Proof. Only tasks from γ, α_i, and β_i appear in the schedule of EDF-LST. Hence,

$$\gamma \bigcup \cup_i \{\alpha_i \cup \beta_i\} \geq BUSY.$$

Since $2max_i \geq (\alpha_i + \beta_i)$ we get the desired result. □

LEMMA 7.5. $BUSY + \gamma \geq PROJ$.

(Recall that BUSY refers to a uniprocessor schedule created by EDF-LST *while PROJ refers to an n processors schedule.)*

Proof. It is obvious that $BUSY + (PROJ \setminus BUSY) \geq PROJ$. Consider a point t in $PROJ \setminus BUSY$ (i.e., an idle point according to EDF-LST). Let T be a task that executes at time $t \leq d(T)$ (according to σ).

If T was aborted by EDF-LST, then EDF-LST has no idle time between $r(T)$ and $d(T)$; otherwise T would occupy the idle periods, making them busy.

Hence, T completed by EDF-LST. Moreover, it completed before t (otherwise t won't be an idle point) meaning it completed as an EDF task,[4] that is, $T \in \gamma$.

We conclude that all the tasks T_i which executed (even partially) at idle periods of EDF-LST are tasks of γ, i.e., $PROJ - BUSY \leq \gamma$, which proves the lemma. ∎

COROLLARY 7.6. $\gamma + \sum_i \max_i \geq \frac{PROJ}{2}$.

Proof. Lemma 7.4 shows that

$$\gamma + 2\sum_i \max_i + \gamma \geq BUSY + \gamma.$$

Using Lemma 7.5 we get

$$2\left(\gamma + \sum_i \max_i\right) \geq PROJ. \qquad \blacksquare$$

This concludes the proof of Theorem 6.1 and assures us that there is indeed a nonmigrative schedule on n processors whose value is no less than $1 - (1 - \frac{1}{2n})^n$ of the optimal migrative schedule.

7.4. A run-through of the No-Migration algorithm. Let us run through No-Migration executed on the set of tasks presented in the performance ratio example (section 3). This set of tasks has three identical tasks, T_1, T_2, and T_3. They all have the same parameters: start time 0, deadline 1, and computation time $\frac{2}{3}$.

In the first iteration we utilize EDF-LST which starts by utilizing EDF*. Since all tasks have the same start time, EDF* chooses any one to start with, say T_1. Therefore, $EDF_1^1 = T_1$. At time $t = \frac{1}{3}$, there is an LST-exception for both T_2 and T_3. Suppose the exception of T_2 is treated first. Since its deadline is greater than the time that EDF_1^1 is expected to complete, we preempt T_1 and schedule T_2. Hence, $LST_1^1 = T_2$. Immediately, EDF-LST treats the exception generated by T_3 leading to its abortion. At time 2/3, T_1 raises an LST-exception which leads to its abortion.

In this example, α_1 is $\{T_2\}$, β_1 is $\{T_1\}$, and γ is empty (so far). Note that T_3 is missing from all these sets. In this case α and β are of equal size so R_1 can be either of them; suppose the latter is chosen.

Now to the second iteration in No-Migration. T_1 is removed from the initial task collection and we proceed as above with the remaining tasks (T_2 and T_3). Suppose T_2 is scheduled initially. At time 1/3 it will be preempted by an exception of T_3 which will complete. Hence α_2 is $\{T_2\}$ and β_2 is $\{T_3\}$ (γ is empty). Since these are equal R_2 could be any of them. Assume the latter is chosen. This concludes the second and last iteration of No-Migration.

Thus, the schedule generated by No-Migration, T_1, gets scheduled on the first processor and T_3 gets scheduled on the second processor. T_2 is not scheduled at all.

In this example the No-Migration algorithm, in fact, chose an optimal nonmigrative schedule.

8. Conclusion and open problems. We gave an upper and a lower bound on the performance ratio between nonmigrative and migrative clairvoyant schedulers in real-time systems. While the bounds are close there is still a gap between them. We believe that the upper bound is the real bound.

An important open problem is finding a competitive on-line scheduler for n processors in a real-time system with the uniform density value measure. The results

[4] Recall that an LST task completes exactly on its deadline.

in this paper guarantee that whether such a competitive on-line scheduler is migrative or nonmigrative, they nevertheless imply the existence of *both* a migrative and a nonmigrative competitive scheduler.

APPROXIMATING MINIMUM-SIZE k-CONNECTED SPANNING SUBGRAPHS VIA MATCHING*

JOSEPH CHERIYAN† AND RAMAKRISHNA THURIMELLA‡

Abstract. An efficient heuristic is presented for the problem of finding a minimum-size k-connected spanning subgraph of an (undirected or directed) *simple* graph $G = (V, E)$. There are four versions of the problem, and the approximation guarantees are as follows:

- minimum-size k-*node* connected spanning subgraph of an *undirected* graph $\quad 1 + [1/k]$,
- minimum-size k-*node* connected spanning subgraph of a *directed* graph $\quad 1 + [1/k]$,
- minimum-size k-*edge* connected spanning subgraph of an *undirected* graph $\quad 1 + [2/(k+1)]$, and
- minimum-size k-*edge* connected spanning subgraph of a *directed* graph $\quad 1 + [4/\sqrt{k}]$.

The heuristic is based on a subroutine for the degree-constrained subgraph (b-matching) problem. It is simple and deterministic and runs in time $O(k|E|^2)$.

The following result on simple undirected graphs is used in the analysis: The number of edges required for augmenting a graph of minimum degree k to be k-edge connected is at most $k\,|V|/(k+1)$.

For undirected graphs and $k = 2$, a (deterministic) parallel **NC** version of the heuristic finds a 2-node connected (or 2-edge connected) spanning subgraph whose size is within a factor of $(1.5 + \epsilon)$ of minimum, where $\epsilon > 0$ is a constant.

1. Introduction.

Given an undirected or directed *simple* graph $G = (V, E)$, an efficient approximation algorithm[1] is presented for the problem of finding a k-connected spanning subgraph $G' = (V, E')$ that has the minimum number of edges ($k \geq 1$ is an integer). Let n and m denote $|V|$ and $|E|$, respectively. There are four versions of the problem, depending on whether G is a graph (i.e., an undirected graph) or a digraph (i.e., a directed graph) and on whether the spanning subgraph G' is required to be k-node connected or k-edge connected. All four versions of the problem are NP-hard: the two problems on graphs are NP-hard for $k \geq 2$, and the two problems on digraphs are NP-hard for $k \geq 1$, [GJ 79].

Previous work. Results of Mader [Ma 71, Ma 72] (also see [Bo 78]) imply that every *minimal*[2] k-edge connected graph has at most kn edges, and every minimal

[1] An α-*approximation algorithm* for a combinatorial optimization problem runs in polynomial time and delivers a solution whose value is always within the factor α of the optimum value. The quantity α is called the *approximation guarantee* of the algorithm.

[2] A graph H is called *minimal* with respect to a property $\mathcal{P}$ if H possesses $\mathcal{P}$, but for every edge e in H, $H \backslash e$ does *not* possess $\mathcal{P}$.

k-node connected graph has at most kn edges. Clearly, a k-connected (i.e., k-node connected or k-edge connected) graph has at least $kn/2$ edges, since each node has degree $\geq k$. Similarly, every k-connected digraph has at least kn arcs (directed edges) since each node has outdegree $\geq k$, and results of Edmonds [Ed 72] and Mader [Ma 85] imply that every minimal k-connected digraph has at most $2kn$ arcs. These facts immediately imply a 2-approximation algorithm for all four versions of the problem, since there is an easy polynomial-time algorithm to find a minimal k-edge connected (or k-node connected) spanning subgraph of a given graph or digraph. For graphs, recent algorithmic work gives another easy and efficient method for finding a k-connected spanning subgraph whose size (i.e., number of edges) is at most kn. A k-edge connected spanning subgraph (V, E') is obtained by taking $E' = F_1 \cup F_2 \cup \cdots \cup F_k$, where F_i $(1 \leq i \leq k)$ is the edge set of a maximal (but otherwise arbitrary) spanning forest of $(V, E \backslash (F_1 \cup \cdots \cup F_{i-1}))$ (see [Th 89, NI 92]), and a k-node connected spanning subgraph (V, E') is obtained similarly, but now each F_i is a maximal scan-first-search spanning forest; see [NI 92, FIN 93, CKT 93].

In the approximate solution of NP-hard combinatorial optimization problems, it often turns out that finding a solution within a factor of 2 of optimum is almost trivial, but achieving (asymptotically) better approximation guarantees needs a deeper understanding of the problem. For example, consider the metric TSP, i.e., the traveling salesman problem, with edge weights satisfying the triangle inequality. Finding a solution whose value is within a factor of 2 of optimum is trivial. The Christofides heuristic [Ch 76] broke the 2-approximation barrier by employing a powerful idea: matching.

Given a graph, consider the problem of finding a minimum-size 2-edge connected spanning subgraph (2-ECSS), or a minimum-size 2-node connected spanning subgraph (2-NCSS). Several recent papers have focused on these two problems. Khuller and Vishkin [KV 94] achieved the first significant advance by obtaining approximation guarantees of 1.5 and 1.66 for the minimum-size 2-ECSS problem and the minimum-size 2-NCSS problem. Garg, Santosh, and Singla [GSS 93] improved the approximation guarantee of the latter problem to 1.5. These algorithms are based on depth-first search (DFS), and they do not imply efficient parallel algorithms for the PRAM model. Subsequently, Chong and Lam [CL 95, CL 96] gave (deterministic) **NC** algorithms on the PRAM model with approximation guarantees of $(1.5 + \epsilon)$ and $(1.66 + \epsilon)$ for the minimum-size 2-ECSS problem and the minimum-size 2-NCSS problem.

For graphs and the general minimum-size k-ECSS problem, first Karger [Ka 94] used randomized rounding to improve the approximation guarantee (for k large with respect to $\log n$) to $1 + \sqrt{[O(\log n)/k]}$; Karger's algorithm is not deterministic but Las Vegas. Then Khuller and Raghavachari [KR 96] improved the approximation guarantee (for all k) from 2 to (roughly) 1.85. They left open the problem of improving on the approximation guarantee of 2 for the minimum-size k-NCSS problem.

For digraphs and the problem of finding a minimum-size 1-connected (i.e., strongly connected) spanning subgraph, Khuller, Raghavachari, and Young [KRY 96, KRY 95] gave a 1.61-approximation algorithm. For digraphs and $k \geq 2$, there appears to have been no previous work on achieving approximation guarantees better than 2.

An illustrative example. Here is an example illustrating the difficulty in improving on the 2-approximation guarantee for the minimum-size k-connected spanning subgraph problem. Let the given graph G have n nodes, where n is even. Suppose that the edge set of G, $E(G)$, is the union of the edge set of the complete bipartite graph $K_{k,(n-k)}$ and the edge set E_{opt} of an n-node, k-regular, k-edge connected (or k-

node connected) graph. For example, for $k = 2$, $E(G)$ is the union of $E(K_{2,(n-2)})$ and the edge set of a Hamiltonian cycle. A naive heuristic may return $E(K_{k,(n-k)})$ which has size $k(n-k)$, roughly two times $|E_{opt}|$. A heuristic that significantly improves on the 2-approximation guarantee must somehow return many edges of E_{opt}.

Results in this paper.

Heuristics and approximation guarantees. This paper first presents a simple heuristic for finding an approximately minimum-size k-NCSS of a given graph or digraph. An approximation guarantee of $1+[1/k]$ is proved. A variant of the heuristic finds a small-size k-ECSS of a given graph or digraph. For graphs and the minimum-size k-ECSS problem, the approximation guarantee is $1+[2/(k+1)]$. For digraphs and the minimum-size k-ECSS problem, the approximation guarantee is $1+[4/\sqrt{k}]$. Let $G = (V, E)$ be the given graph. The heuristic has two steps. The first step finds a minimum-size subgraph (V, M) of minimum-degree k (or $k-1$) via a subroutine for the degree-constrained subgraph (b-matching) problem. The second step adds an (inclusionwise) minimal edge set $F \subseteq E \backslash M$ such that the resulting graph $(V, M \cup F)$ is either k-node connected or k-edge connected, as required. Heuristics of this type have been considered by other researchers, but we were not aware of this when the preliminary version of this paper (*Proceedings of the IEEE Symposium on Foundations of Computer Science*, 1996, pp. 292–301) appeared. Subsequently, Khuller (private communication, October 1996) and Watanabe (private communication, October 1996) informed us that they had examined or implemented heuristics of this type. One of the contributions of this paper is to refine the general heuristic to the four minimum-size k-CSS problems discussed above, and to give nearly tight analyses of the four approximation guarantees. The running time of the heuristic is $O(k|E|^2)$, and for

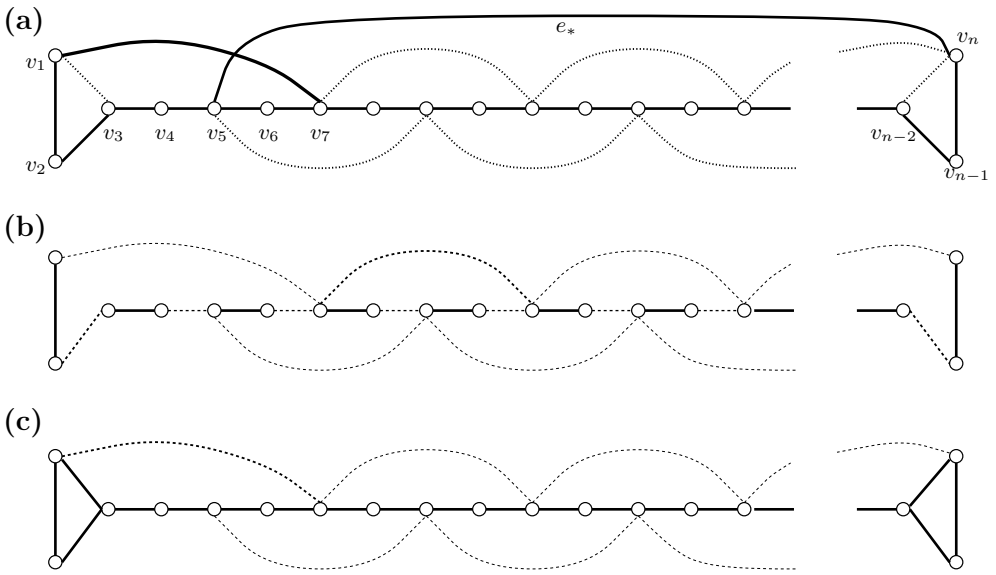

FIG. 1. *Illustrating the 2-NCSS heuristic on a 2-node connected graph $G = (V, E)$; $n = |V|$ is even, and $k = 2$. Adapted from Garg, Santosh, and Singla* [GSS 93, Figure 7]. (a) *A minimum-size 2-node connected spanning subgraph has $n + 1$ edges and is indicated by thick lines (the path $v_1, v_2, \ldots, v_n$ and edges v_1v_7 and $e_* = v_5v_n$).* (b) *The first step of the heuristic in section 3.1 finds a minimum-size $M \subseteq E$ such that every node is incident to $\geq (k-1) = 1$ edges of M. The thick lines indicate M; it is a perfect matching. The second step of the heuristic finds an (inclusionwise) minimal edge set $F \subseteq E$ such that $(V, M \cup F)$ is 2-node connected. F is indicated by dashed lines—the "key edge" e_* is not chosen in F. $|M \cup F| = 1.5n - 5$.* (c) *Another variant of the heuristic first finds a minimum-size $M \subseteq E$ such that every node is incident to $\geq k = 2$ edges of M. The thick lines indicate M (M is the path $v_1, v_2, \ldots, v_n$ and edges v_1v_3, $v_{n-2}v_n$). The second step of the heuristic finds the edge set $F \subseteq E$ indicated by dashed lines—the "key edge" e_* is not chosen in F. $(V, M \cup F)$ is 2-node connected, and for every edge vw in F, $(V, M \cup F) \backslash vw$ is* not *2-node connected. $|M \cup F| = 1.5n - 3$.*

graphs the running time improves to $O(k^3|V|^2 + |E|^{1.5}(\log |V|)^2)$. The analyses on graphs/digraphs of the minimum-size k-NCSS heuristic are based on theorems of Mader [Ma 72, Ma 85]. In the context of augmenting the node connectivity of graphs and digraphs, the first application of Mader's theorems is due to Jordán [Jo 95, Jo 93]. Two key lemmas in our analyses, namely, Lemmas 3.3 and 3.18, are inspired by similar results of Jordán, namely, [Jo 95, Lemma 3.3] and the following paragraph in [Jo 95] and Lemma 2.6 and Corollary 2.7 in [Jo 93]. In the context of approximation algorithms for minimum-size k-connected spanning subgraph problems, Chong and Lam [CL 95] appear to be the first to use matching.

For graphs, the heuristic finds a 2-node connected or 2-edge connected spanning subgraph whose size is within a factor of 1.5 of the minimum size. A parallel (deterministic) version gives a $(1.5+\epsilon)$-approximation **NC** algorithm. Similarly, a sequential *linear-time* version gives an approximation guarantee of $(1.5 + \epsilon)$.

Table 1 summarizes the approximation guarantees obtained in this paper for the four versions of the problem and compares these with the previous best approximation guarantees. Figure 1 illustrates the working of the heuristic on an example.

Here is a summary of developments since September 1996. Fernandes [Fe 97, Theorem 5.1] showed that the minimum-size 2-ECSS problem on graphs is MAX SNP-hard; also see Czumaj and Lingas [CL 99, Theorem 5.3]. Independently of this paper,

and using different methods, Chong and Lam [CL 96b] have also obtained a parallel (deterministic) $(1.5 + \epsilon)$-approximation **NC** algorithm for the minimum-size 2-NCSS problem on graphs. The approximation guarantee for the minimum-size 2-ECSS problem has been improved from 1.5 to 17/12 by [CSS 98] and then to 4/3 by [VV 99].

Contributions to approximation algorithms for "uniform" network design. As discussed above, the subarea of network design with uniform edge costs and uniform connectivity requirements has attracted a fair amount of recent interest in theoretical computer science, e.g., the references cite 10 papers from this subarea. This paper takes up four central questions from this subarea and settles them in the sense that reasonably good approximation guarantees are derived based on a simple heuristic. To achieve the approximation guarantees, the paper has to rely on some deep areas of graph theory and combinatorial optimization.

Combinatorial contributions. The paper has two combinatorial results that may be of independent interest. The first is Theorem 3.5 which gives a new lower bound on the size of a k-edge connected spanning subgraph. The proof relies on the Gallai–Edmonds decomposition theorem of matching theory. Theorem 3.5 is related to a result of Gupta: a bipartite graph of minimum degree k has k edge-disjoint edge covers. The second combinatorial result of independent interest is Theorem 4.3. This theorem gives an asymptotically tight upper bound of $k|V|/(k+1)$ on the size of an (inclusionwise) minimal edge set F such that $(V, M \cup F)$ is a k-edge connected (simple) graph, where (V, M) is a graph of minimum degree $\geq k$. The (long) proof makes use of a laminar family of tight node sets that covers F. Theorem 4.3 is related to a theorem of Mader on "critical cycles" in a k-node connected graph; see Theorem 3.2. Apparently, Mader's theorem has *no* analogue for k-edge connected graphs; for $k = 2$, this can be seen from the example in Figure 5 in section 4.1; the example generalizes to all $k \geq 2$. However, there is one implication of Mader's theorem that is an analogue of Theorem 4.3: If (V, M) is as above, and F is an (inclusionwise) minimal edge set such that $(V, M \cup F)$ is a k-node connected graph, then $|F| \leq |V| - 1$ (see Lemma 3.3). Both the bounds $(k|V|/(k+1)$ in Theorem 4.3, and $|V| - 1$ in Lemma 3.3) are tight up to an additive term of $(k+1)$, for all $k \geq 2$. Figure 2 has relevant examples for $k = 2$, and these examples generalize for all $k \geq 2$. Although Theorem 4.3 and Lemma 3.3 are analogous, the two results seem to be focusing on two essentially different combinatorial structures, and neither result implies the other one.

Organization of the paper. The rest of the paper is organized as follows. Section 2 has definitions and notation. Section 3 presents the heuristic for approximating a minimum-size k-node connected spanning subgraph of a graph or a digraph and separately analyzes the approximation guarantees on graphs and digraphs. Section 4 describes and analyzes the heuristic for approximating a minimum-size k-edge connected spanning subgraph of a graph or a digraph. Section 5 has conclusions, including a discussion of the relationship to graph theory.

2. Definitions and notation. For a subset S' of a set S, $S \backslash S'$ denotes the set $\{x \in S : x \notin S'\}$.

This paper considers finite *simple* graphs and digraphs, i.e., the graphs/digraphs have no loops nor multiedges. (But, Propositions 3.9 and 3.10 do allow multiedges.) Let $G = (V, E)$ be a graph or a digraph. $V(G)$ and $E(G)$ stand for the node set and the edge set of G. By the *size* of G we mean $|E(G)|$. First, suppose that G is a graph. An edge incident to nodes v and w is denoted by vw. For a subset M of E and a node v, we use $\deg_M(v)$ to denote the number of edges of M incident to v; $\deg(v)$ denotes $\deg_E(v)$.

A node is said to be *covered* by an edge set M if the node is incident to at least one edge of M; otherwise, the node is *uncovered* by M. An *edge cover* is a set of edges that covers all the nodes. A *matching* of a graph $G = (V, E)$ is an edge set $M \subseteq E$ such that $\deg_M(v) \leq 1$, $\forall v \in V$; furthermore, if every node $v \in V$ has $\deg_M(v) = 1$, then M is called a *perfect matching*. A graph G is called *factor-critical* if for every node $v \in V$, there is a perfect matching in $G \backslash v$; see [LP 86].

An $x \leftrightarrow y$ path refers to a path whose end nodes are x and y. We call two paths *openly disjoint* if every node common to both paths is an end node of both paths. Hence, two (distinct) openly disjoint paths have no edges in common and possibly have no nodes in common. A set of $k \geq 2$ paths is called openly disjoint if the paths are pairwise openly disjoint. For a node set $S \subseteq V(G)$, $\delta_G(S)$ denotes the set of all edges in $E(G)$ that have one end node in S and the other end node in $V(G) \backslash S$ (when

there is no danger of confusion, the notation is abbreviated to $\delta(S)$); $\delta(S)$ is called a *cut*, and by a *k-cut* we mean a cut that has exactly k edges.

A graph $G = (V, E)$ is said to be k-edge connected if $|V| \geq k + 1$ and the deletion of any set of $< k$ edges leaves a connected graph. A graph $G = (V, E)$ is said to be *k-node connected* if $|V| \geq k + 1$ and the deletion of any set of $< k$ nodes leaves a connected graph.

Let $G = (V, E)$ be a digraph. An arc (directed edge) with start node v and end node w is denoted (v, w). For $M \subseteq E$ and a node v, $\deg_{M,out}(v)$ ($\deg_{M,in}(v)$) denotes the number of arcs of M with start node v (end node v). For a node set $S \subseteq V$, $\delta_{out}(S)$ ($\delta_{in}(S)$) denotes the set of arcs with start nodes in S and end nodes in $V\backslash S$ (end nodes in S and start nodes in $V\backslash S$). The digraph is called *strongly connected* (1-connected) if for every (ordered) pair of nodes v,w there exists a directed path from v to w. The digraph is called *k-edge connected* if $|V| \geq k + 1$ and the deletion of any set of $< k$ arcs leaves a strongly-connected digraph. The digraph is called *k-node connected* if $|V| \geq k + 1$ and the deletion of any set of $< k$ nodes leaves a strongly-connected digraph.

An edge vw (arc (v, w)) of a k-node connected graph G (digraph G) is called *critical* with respect to k-node connectivity if $G\backslash vw$ ($G\backslash(v, w)$) is *not* k-node connected. Similarly, we have the notion of critical edges (arcs) with respect to k-edge connectivity.

Let $G = (V, E)$ be a graph, and let $b : V \to Z_+$ assign a nonnegative integer b_v to each node $v \in V$. The perfect b-matching (or perfect degree-constrained subgraph) problem is to find an edge set $M \subseteq E$ such that each node v has $\deg_M(v) = b_v$. The maximum b-matching (or maximum degree-constrained subgraph) problem is to find a maximum-cardinality $M \subseteq E$ such that each node v has $\deg_M(v) \leq b_v$. The b-matching problem can be solved in time $O(|E|^{1.5}(\log |V|)^{1.5}\sqrt{\alpha(|E|, |E|)})$; see [GaTa 91, section 11]. (For our version of the problem, note that each edge has unit cost and unit capacity, and each node v may be assumed to have $0 \leq b_v \leq \deg(v)$.) Also see [Ge 95, section 7.3] and [Ga 85].

3. A $(1 + \frac{1}{k})$-approximation algorithm for minimum-size k-node connected spanning subgraphs. This section presents the heuristic for finding an approximately minimum-size k-node connected spanning subgraph (abbreviated k-NCSS) and proves an approximation guarantee of $1+[1/k]$. First, we focus on graphs, and then we turn to digraphs. The analysis of the heuristic for graphs hinges on a deep theorem of Mader [Ma 72, Theorem 1]. Given a graph $G = (V, E)$, a straightforward application of Mader's theorem shows that the number of edges in the k-NCSS returned by the heuristic is at most

$$(|V| - 1) + \min\{|M| : M \subseteq E \text{ and } \deg_M(v) \geq (k - 1) \quad \forall v \in V\};$$

see Lemma 3.3 below. An approximation guarantee of $1+[2/k]$ on the heuristic follows, since the number of edges in a k-node connected graph is at least $k|V|/2$, by the "degree lower bound"; see Proposition 3.4. Often, the key to proving improved approximation guarantees for (minimizing) heuristics is a nontrivial lower bound on the value of every solution. We improve the approximation guarantee from $1+[2/k]$ to $1+[1/k]$ by exploiting a new lower bound on the size of a k-edge connected spanning subgraph; see Theorem 3.5 which states the following.

> The number of edges in a k-edge connected spanning subgraph of a graph $G = (V, E)$ is at least $\lfloor |V|/2 \rfloor + \min\{|M| : M \subseteq E \text{ and } \deg_M(v) \geq (k - 1) \quad \forall v \in V\}$.

The analysis of the heuristic for digraphs is similar and hinges on another theorem of Mader [Ma 85, Theorem 1], which may be regarded as the generalization of [Ma 72, Theorem 1] to digraphs. An approximation guarantee of $1 + [1/k]$ is proved on the digraph heuristic by employing a simpler version of Theorem 3.5, namely Proposition 3.8, to give a lower bound on the number of edges in a solution.

Assume that the given graph or digraph $G = (V, E)$ is k-node connected; otherwise, the heuristic will detect this and report failure.

3.1. Undirected graphs. Let $E^* \subseteq E$ denote a minimum-cardinality edge set such that the spanning subgraph (V, E^*) is k-*edge* connected. Note that every k-node connected spanning subgraph (V, E') (such as the optimal solution) is necessarily k-edge connected and so has $|E'| \geq |E^*|$.

The heuristic has two steps. The first finds a *minimum-size* spanning subgraph (V, M), $M \subseteq E$, whose minimum degree is $(k-1)$, i.e., each node is incident to $\geq (k-1)$ edges of M. Clearly, $|M| \leq |E^*|$, because (V, E^*) has minimum degree k, i.e., every node is incident to $\geq k$ edges of E^*. To find M efficiently, we use the algorithm for the maximum degree-constrained subgraph (b-matching) problem. Our problem is

$$\min\{|M| : \deg_M(v) \geq (k-1) \quad \forall v \in V, \text{ and } M \subseteq E\}.$$

To see that this is a b-matching problem, consider the equivalent problem of finding the complement $\overline{M}$ of M with respect to E, where $\overline{M} = E \backslash M$:

$$\max\{|\overline{M}| : \deg_{\overline{M}}(v) \leq \deg(v) + 1 - k \quad \forall v \in V, \text{ and } \overline{M} \subseteq E\}.$$

The b-matching problem can be solved in time $O(|E|^{1.5}(\log |V|)^2)$ (see [GaTa 91]), hence this running time suffices to find M.

The second step is equally simple. We find an (inclusionwise) minimal edge set $F \subseteq E \backslash M$ such that $M \cup F$ gives a k-node connected spanning subgraph, i.e., $(V, M \cup F)$ is k-node connected and for each edge $vw \in F$, $(V, M \cup F) \backslash vw$ is *not* k-node connected. Recall that an edge vw of a k-node connected graph H is *critical* (with respect to k-node connectivity) if $H \backslash vw$ is *not* k-node connected. The next result characterizes critical edges.

PROPOSITION 3.1. *An edge vw of a k-node connected graph H is not critical iff there are at least $k+1$ openly disjoint $v \leftrightarrow w$ paths in H (including the path vw).*

To find F efficiently, we start with $F = \emptyset$ and take the current subgraph to be $G = (V, E)$ (which is k-node connected). We examine the edges of $E \backslash M$ in an arbitrary order, say, $e_1, e_2, \ldots, e_\ell$ ($\ell = |E \backslash M|$). For each edge $e_i = v_i w_i$, we attempt to find $(k+1)$ openly disjoint $v_i \leftrightarrow w_i$ paths in the current subgraph. If we succeed, then we remove the edge e_i from the current subgraph (since e_i is not critical); otherwise, we retain e_i in the current subgraph and add e_i to F (since e_i is critical). At termination, the current subgraph with edge set $M \cup F$ is k-node connected, and every edge $vw \in F$ is critical. The running time for the second step is $O(k|E|^2)$.

The proof of the next lemma hinges on a theorem of Mader [Ma 72, Theorem 1]. For an English translation of the proof of Mader's theorem see Lemma I.4.4 and Theorem I.4.5 in [Bo 78].

THEOREM 3.2 (Mader [Ma 72, Theorem 1]). *In a k-node connected graph, a cycle consisting of critical edges must be incident to at least one node of degree k.*

LEMMA 3.3. $|F| \leq |V| - 1$.

Proof. Consider the k-node connected subgraph returned by the heuristic $G' = (V, E')$, where $E' = M \cup F$. Suppose that F contains a cycle C. Note that every

edge in the cycle is critical, since every edge in F is critical. Moreover, every node v incident to the cycle C has degree $\geq (k+1)$ in G', because v is incident to two edges of C, as well as to at least $(k-1)$ edges of $M = E'\backslash F$. But this contradicts Mader's theorem. We conclude that F is acyclic and so has $\leq |V|-1$ edges. The proof is done. □

PROPOSITION 3.4. *Let $G = (V, E)$ be a graph of node connectivity $\geq k$. The heuristic above finds a k-node connected spanning subgraph (V, E') such that $|E'| \leq (1 + [2/k])|E_{opt}|$, where $|E_{opt}|$ denotes the cardinality of an optimal solution. The running time is $O(k^3|V|^2 + |E|^{1.5}(\log |V|)^2)$.*

Proof. The approximation guarantee follows because $|E_{opt}| \geq (k|V|/2)$, so

$$\frac{|M|+|F|}{|E_{opt}|} = \frac{|M|}{|E_{opt}|} + \frac{|F|}{|E_{opt}|} \leq 1 + \frac{|V|}{(k|V|/2)} = 1 + [2/k].$$

We have already seen that M can be found in time $O(|E|^{1.5}(\log |V|)^2)$, and F can be found in time $O(k|E|^2)$. The running time of the second step can be improved to $O(k^3|V|^2)$ as follows: we run a linear-time preprocessing step to compute a sparse certificate $\widetilde{E}$ of G for k-node connectivity, i.e., $\widetilde{E} \subseteq E$, $|\widetilde{E}| \leq k|V|$, and for all nodes v, w, $(V, \widetilde{E})$ has k openly disjoint $v \leftrightarrow w$ paths iff G has k openly disjoint $v \leftrightarrow w$ paths; see [NI 92, FIN 93, CKT 93]. We compute M as before, by running the first step on G. To find the set $F \subseteq E\backslash M$, we run the second step on $\widetilde{E} \cup M$ rather than on E, and for each edge $v_i w_i \in \widetilde{E}\backslash M$, we attempt to find $(k+1)$ openly disjoint $v_i \leftrightarrow w_i$ paths in the current subgraph of $(V, \widetilde{E} \cup M)$. The second step runs in time $O(k|\widetilde{E} \cup M|^2) = O(k^3|V|^2)$, since $|\widetilde{E} \cup M| = O(k|V|)$. □

To improve the approximation guarantee to $1 + [1/k]$, we present an improved lower bound on $|E^*|$, where E^* denotes a minimum-cardinality edge set such that $G^* = (V, E^*)$ is k-edge connected. Suppose that E^* contains a perfect matching P_0 (so $|P_0| = n/2$). Then $|E^*| \geq (n/2) + \min\{|M^*| : M^* \subseteq E,\ \deg_{M^*}(v) \geq (k-1)\ \forall v \in V\}$. To see this, focus on the edge set $M' = E^*\backslash P_0$. Clearly, every node $v \in V$ is incident to at least $(k-1)$ edges of M', because $\deg_{E^*}(v) \geq k$ and $\deg_{P_0}(v) = 1$. Since M^* is a minimum-size edge set with $\deg_{M^*}(v) \geq (k-1)\ \forall v \in V$, we have $|M^*| \leq |M'| = |E^*| - (n/2)$. The next theorem generalizes this lower bound to the case when E^* has no perfect matching. The proof is given in the next subsection (section 3.2), after developing some preliminaries.

THEOREM 3.5. *Let $G^* = (V, E^*)$ be a graph of edge connectivity $\geq k \geq 1$, and let n denote $|V|$. Let $M^* \subseteq E^*$ be a minimum-size edge set such that every node $v \in V$ is incident to $\geq (k-1)$ edges of M^*. Then $|E^*| \geq |M^*| + \lfloor n/2 \rfloor$.*

THEOREM 3.6. *Let $G = (V, E)$ be a graph of node connectivity $\geq k$. The heuristic described above finds a k-node connected spanning subgraph (V, E') such that $|E'| \leq (1 + [1/k])|E_{opt}|$, where $|E_{opt}|$ denotes the cardinality of an optimal solution. The running time is $O(k^3|V|^2 + |E|^{1.5}(\log |V|)^2)$.*

Proof. The approximation guarantee of $1 + [1/k]$ follows easily from Theorem 3.5, using an argument similar to Proposition 3.4. We have $E' = M \cup F$, where $|F| \leq (n-1)$. Moreover, since M is a minimum-size edge set with $\deg_M(v) \geq (k-1)$, $\forall v \in V$, Theorem 3.5 implies that $|M| \leq |E_{opt}| - \lfloor n/2 \rfloor \leq |E_{opt}| - (n-1)/2$. Hence,

$$\frac{|M|+|F|}{|E_{opt}|} \leq \frac{|E_{opt}| - (n-1)/2 + (n-1)}{|E_{opt}|} \leq 1 + \frac{n/2}{|E_{opt}|} \leq 1 + [1/k],$$

where the last inequality uses the "degree lower bound," $|E_{opt}| \geq kn/2$.

The running time analysis is the same as that in Proposition 3.4. □

3.2. A lower bound for the size of a k-connected spanning subgraph and Gupta's theorem on bipartite graphs. This subsection gives a proof of Theorem 3.5. This theorem is used in the previous subsection to prove an approximation guarantee of $1 + [1/k]$ for a minimum-size k-NCSS. Theorem 3.5 gives the following new lower bound on the size of a k-ECSS:

> Let $G^* = (V, E^*)$ be a k-edge connected graph ($k \geq 1$), and let n denote $|V|$. Let $M^* \subseteq E^*$ be a minimum-size edge set such that every node $v \in V$ is incident to $\geq (k-1)$ edges of M^*. Then $|E^*| \geq |M^*| + \lfloor n/2 \rfloor$.

First, a theorem of Gupta on bipartite graphs is recalled. For the special case of bipartite graphs, (a stronger form of) the lower bound in Theorem 3.5 follows easily from Gupta's theorem; see Proposition 3.8. This proposition is used in section 3.4 to prove an approximation guarantee of $1+[1/k]$ for a minimum-size k-NCSS of a digraph. Gupta's theorem does not apply to nonbipartite graphs. The proof of Theorem 3.5 (for arbitrary graphs) relies on the Gallai–Edmonds decomposition theorem of matching theory. When the Gallai–Edmonds decomposition of the graph is "nontrivial," one can define a bipartite graph B that partially represents the decomposition. The proof of Theorem 3.5 is completed by examining B. One way is to prove a variant of Gupta's theorem (see Proposition 3.9), and then apply it to B. This is described below. Readers interested in a detailed study of the proofs in this subsection may find it useful to review two results in matching theory, namely, the Gallai–Edmonds decomposition theorem [LP 86, Theorem 3.2.1] and the Hungarian method for bipartite matching [LP 86, Lemma 1.2.2].

THEOREM 3.7 (see Gupta [Gu 67]). *Let $B = (X \cup Y, E)$ be a bipartite graph with minimum degree k. Then there exists a partition of the edge set of B, namely E, into k sets $E_1, E_2, \ldots, E_k$ such that each node $v \in X \cup Y$ is incident to at least one edge from each set E_i, $1 \leq i \leq k$.*

For an elegant proof, see the solutions to Problems 10–12 in [L 93, Chapter 7]. Also, see [BM 76, Problem 6.1.6]. The next result strengthens Theorem 3.5 for bipartite graphs. The proof is via Gupta's theorem. Another brief proof follows from Proposition 3.10.

PROPOSITION 3.8. *Let $B^* = (X \cup Y, E^*)$ be a bipartite graph with minimum degree $\geq k$. Let $M^* \subseteq E^*$ be a minimum-size edge set such that every node $v \in X \cup Y$ is incident to $\geq k-1$ edges of M^*. Then $|E^*| \geq |M^*| + (|X \cup Y|/2)$.*

Proof. Apply Gupta's theorem to E^*, and let $E_1, E_2, \ldots, E_k$ be the partition of E^*. Focus on the set, say E_k, that has the maximum cardinality. Clearly, $|E_k| \geq |E^*|/k \geq |X \cup Y|/2$. Now, consider $M' = E^* \backslash E_k$, and observe that each node $v \in X \cup Y$ is incident to $\geq (k-1)$ edges of M', because Gupta's result shows that v is incident to some edge from each of the remaining $(k-1)$ sets $E_1, E_2, \ldots, E_{k-1}$. The proof is done since $|E^*| - (|X \cup Y|/2) \geq |M'|$ and $|M'| \geq |M^*|$. □

Proposition 3.8 does *not* generalize to nonbipartite graphs B^*, even if we strengthen the condition "B^* has minimum degree $\geq k$" to "B^* is k-edge connected." For example, let $k = 2$, and let $B^* = K_3$, the complete graph on three nodes. Then M^* is a minimum edge cover of K_3 and has size 2. But then $|E^*| = |M^*|+1 < |M^*|+(|V|/2)$. The generalization of Proposition 3.8 fails because B^* is a 2-edge connected, 2-regular graph such that for every edge cover M^*, the edge-complement of M^* in B^*, $(V, E^* - M^*)$, has an isolated node, so it does not have an edge cover. For every *even* integer $k \geq 2$, there is an infinite family of nonbipartite graphs such that the generalization of Proposition 3.8 fails. Take B^* to be a k-edge connected, k-regular

graph with an *odd* number of nodes n. Then M^* has size at least $(1+(k-1)n)/2$, so $(V, E^* - M^*)$ has an isolated node, and hence has size $< n/2$. It can be seen that the examples in this paragraph are factor-critical graphs.

The next proposition may be regarded as a variant of Gupta's theorem. Note that the bipartite graph B in the next proposition may have minimum degree 1, and B may have multiple copies of an edge.

PROPOSITION 3.9. *Let $B = (X \cup Y, E)$ be a bipartite (loopless) multigraph with node bipartition $X \cup Y$. Let each node $y \in Y$ have* $\deg(y) \geq k$*,and let B have a matching of size $|X|$. Then B has an edge cover J such that each node $y \in Y$ is incident to exactly one edge of J, and each node $x \in X$ is incident to either exactly one edge of J or at least $(k-1)$ edges of $E \backslash J$.*

Proof. See Figure 3(b) for an illustration. Let J_0 be a matching of size $|X|$. The edge cover J is constructed iteratively, starting with $J' = J_0$ and $J'' = \emptyset$. Throughout, J' is a matching of the current B, and at the end of the construction, $J' \cup J''$ is an edge cover of the original B that satisfies the proposition.

If $J' \cup J''$ is an edge cover, i.e., if J' is a perfect matching, then the proof is completed by taking $J = J' \cup J''$. Clearly, the degree requirements in the proposition hold. Otherwise, if $J' \cup J''$ is not an edge cover, the size of $J' \cup J''$ is increased by one such that one more Y-node is covered and the degree requirements in the proposition are maintained. Let $v \in Y$ be a node that is *not* covered by $J' \cup J''$. Let T be the node set of the maximal J'-alternating tree that contains v. That is, a node w is in T iff there exists a J'-alternating path between v and w. (For a matching J', recall that a J'-alternating path means a path whose edges are alternately in J' and not in J'.)

Claim 1. There is a node $x \in T \cap X$ with $\deg(x) \geq k+1$.

To prove this claim, note that (i) $|T \cap Y| = |T \cap X| + 1$ (since each node $y \in T \cap Y$ except v is incident to an edge of J'), and (ii) for every node $y \in T \cap Y$, every incident edge wy has the other end node w in $T \cap X$ (otherwise, w can be added to T, and so T is not maximal). By assumption, each node $y \in T \cap Y$ has $\deg(y) \geq k$, hence, (i), (ii), and the pigeonhole principle guarantee that there is a node $x \in T \cap X$ with $\deg(x) > k$. This proves the claim.

Let xz be the J'-edge incident to x, i.e., x is matched to z by J'. This edge is (permanently) added to the edge cover J by taking $J'' = J'' \cup \{xz\}$. The node z is deleted from B. Since $x \in T$, there exists a J'-alternating path between v and x (by definition of T). Let this path be P'. The matching J' is updated by switching alternate edges along P', i.e., J' is replaced by the symmetric difference of J' and $E(P')$. Note that the current B (with node z deleted) has a matching of size $|X|$, namely J', and has $\deg(y) \geq k$, for all nodes $y \in V(B) \backslash X$. Therefore, the hypothesis of the proposition continues to hold.

The above step is repeated until $J' \cup J''$ covers all nodes of B. Finally, J is taken to be $J' \cup J''$. The construction guarantees that J satisfies the degree requirements in the proposition. □

Recall the Gallai–Edmonds decomposition theorem of matching theory [LP 86, Theorem 3.2.1]. For every graph H, there is a partition of $V(H)$ into a set of (matching) noncritical nodes $D(H)$ and a set of (matching) critical nodes $V \backslash D(H)$ (i.e., $D(H)$ consists of all nodes that are left uncovered by some maximum matching of H). The partition is "trivial" either if H has a perfect matching, or if H is factor-critical: in the first case, $D(H) = \emptyset$, and in the second case, $D(H) = V(H)$. Let $A(H)$ be the set of critical nodes of H that are adjacent to one or more noncritical nodes of H. Possibly, $A(H)$ is the empty set. When there is no danger of confu-

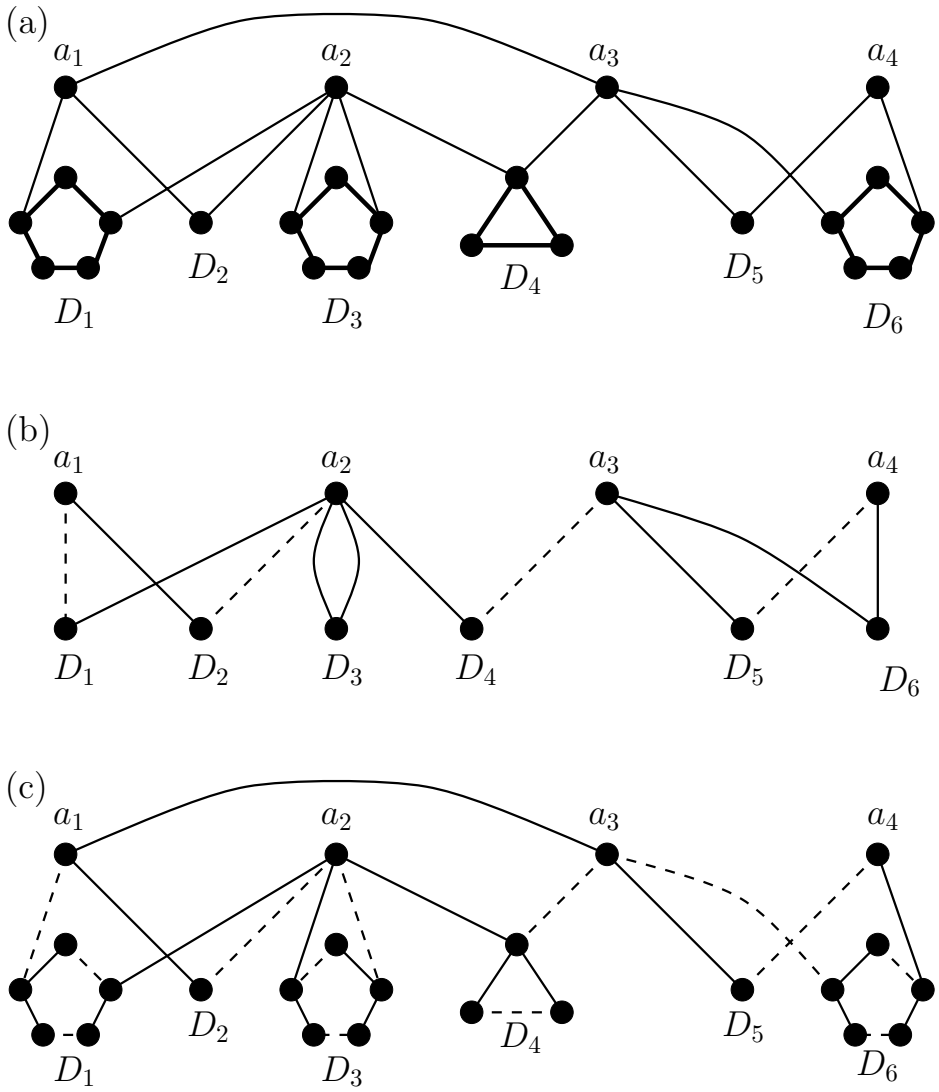

FIG. 3. *An illustration of the proofs of Theorem* 3.5 *and Propositions* 3.9 and 3.10. (a) $G = (V, E)$ *is a* 2*-edge connected graph* ($k = 2$)*, and the Gallai–Edmonds decomposition is given by* $A = A(G) = \{a_1, a_2, a_3, a_4\}$ *and* $D = D(G) = V(D_1) \cup V(D_2) \cup V(D_3) \cup V(D_4) \cup V(D_5) \cup V(D_6)$. *The odd (factor-critical) components of* $G \backslash A$ *are* $D_1, \ldots, D_6$. (b) *The bipartite multigraph* B *in the proofs of Propositions* 3.9 and 3.10. *In Proposition* 3.10, B *is obtained from* G *by deleting the nodes in* $V \backslash (A \cup D)$ *and the edges in* $E(A)$*, and shrinking* $D_1, \ldots, D_6$ *into single nodes. sion, we use A and D instead of $A(H)$ and $D(H)$. Let $\mathrm{def}(H)$ denote the deficiency of H, i.e., the number of nodes that are not covered by a maximum matching of H. (So, $\mathrm{def}(H) = |V(H)| - 2|P_0|$, where P_0 is a maximum matching of H.) The

Gallai–Edmonds decomposition theorem shows that in the graph $H\backslash A$, the noncritical nodes D form $q = |A(H)| + \mathrm{def}(H)$ odd components $D_1, D_2, \ldots, D_q$, i.e., each D_i $(i = 1, \ldots, q)$ is a connected component of $H\backslash A$ with $V(D_i) \subseteq D(H)$ and $|V(D_i)|$ odd. Moreover, every one of these odd components D_i is factor-critical.

The next result is a generalization of Proposition 3.9.

PROPOSITION 3.10. *Let G be a graph, and let $D = D(G)$ and $A = A(G)$ be the node sets in the Gallai–Edmonds decomposition. Let $q = |A(G)| + \mathrm{def}(G)$, and let $D_1, D_2, \ldots, D_q$ be the odd components of $G\backslash A$. If every D_i gives a cut containing at least k edges, i.e., if $\delta(V(D_i))$ has size $\geq k$ for $i = 1, \ldots, q$, then G has an edge cover P such that each node in $V(G)\backslash A$ is incident to exactly one edge of P, and each node in A is incident to either exactly one edge of P or at least $(k-1)$ edges of $E(G)\backslash P$.*

Proof. See Figure 3 for an illustration. The proof follows easily by applying Proposition 3.9 to a bipartite graph associated with the Gallai–Edmonds decomposition.

If $\mathrm{def}(G) = 0$, then the proof is done: take P to be a perfect matching of G. Otherwise, $\mathrm{def}(G) > 0$, and so $D \neq \emptyset$. Suppose that $A = \emptyset$. Then every component D_i of G is factor-critical, but this violates the condition on $|\delta(V(D_i))|$. Hence, A is nonempty. Clearly, every edge in $\delta(V(D_i))$ $(i = 1, \ldots, q)$ has one end node in A and the other in D_i. Let $G[A \cup D]$ be the subgraph of G induced by $A \cup D$. Let $B = (X \cup Y, E')$, $X = A$, be the bipartite (loopless) multigraph obtained from $G[A \cup D]$ by deleting all edges with both end nodes in A and by shrinking the components $D_1, D_2, \ldots, D_q$ of $G[A \cup D]\backslash A$ to single nodes. The shrunken nodes are also called $D_1, D_2, \ldots, D_q$, and so $Y = \{D_1, D_2, \ldots, D_q\}$. B has $\geq k$ edges incident to each of the shrunken nodes $D_1, D_2, \ldots, D_q$, since in G each of the cuts $\delta(V(D_i))$ $(i = 1, \ldots, q)$ has $\geq k$ edges. Moreover, B has a matching of size $|X| = |A|$, by the Gallai–Edmonds decomposition theorem. Therefore, B satisfies the conditions in Proposition 3.9. By the proposition, B has an edge cover J satisfying the degree requirements in the proposition; note that each node $D_i \in Y$ is incident to exactly one edge of J. Let $\widetilde{J}$ denote a set of edges of G that corresponds to J, i.e., for each edge $a_h D_i \in J$ with $a_h \in X = A$, $D_i \in Y$, there is an edge $a_h w_i \in \widetilde{J}$ such that (in G) w_i is a node in D_i and w_i is adjacent to a_h. Let $V(\widetilde{J})$ be the set of nodes of G incident to edges in $\widetilde{J}$, i.e., $V(\widetilde{J}) = A \cup \{w_i \in V(D_i) : i = 1, \ldots, q\}$. By the Gallai–Edmonds decomposition theorem, $G\backslash V(\widetilde{J})$ has a perfect matching $\widetilde{P}$. To see this, note that each component of $G\backslash V(\widetilde{J})$ is either an even component of $G\backslash A$ or is obtained by deleting one node from an odd (factor-critical) component of $G\backslash A$; in either case, the component has a perfect matching.

Take $P = \widetilde{J} \cup \widetilde{P}$. Clearly, P is an edge cover of G such that each node $v \in V\backslash A$ is incident to exactly one edge of P. Moreover, by Proposition 3.9, every node in A is incident to either exactly one edge of P or to $\geq (k-1)$ edges of $E\backslash P$. □

Proof of Theorem 3.5. See Figure 3 for an illustration. We construct an appropriate edge set P^* such that $|P^*| \geq \lfloor n/2 \rfloor$ and every node $v \in V$ is incident to $\geq (k-1)$ edges of $E^*\backslash P^*$. In the statement of Theorem 3.5, note that M^* is a minimum-size edge set such that (V, M^*) has minimum degree $(k-1)$. Hence, $|E^*\backslash P^*| \geq |M^*|$. The theorem follows immediately from the existence of the edge set P^*, because $|E^*| = |E^*\backslash P^*| + |P^*| \geq |E^*\backslash P^*| + \lfloor n/2 \rfloor \geq |M^*| + \lfloor n/2 \rfloor$.

If the size of a maximum matching of G^* is $\geq (n-1)/2$, i.e., if G^* has a matching that leaves at most one node uncovered, then we take P^* to be a maximum matching. (This handles the case when G^* is a factor-critical graph.)

To handle the case when $\mathrm{def}(G^*) \geq 2$, we apply Proposition 3.10 to G^*, noting that G^* satisfies the conditions in the proposition. (Since G^* is k-edge connected, $\deg(v) \geq k\ \forall v \in V$, and every node set $S \subseteq V$, $\emptyset \neq S \neq V$, has $|\delta(S)| \geq k$.) We take P^* to be the edge cover P guaranteed by the proposition. Since P^* is an edge cover of G^*, $|P^*| \geq n/2$. Moreover, $(V, E^* \backslash P^*)$ has minimum degree $\geq k-1$ by the proposition and the fact that G^* has minimum degree $\geq k$. The theorem follows. □

We mention a corollary of Theorem 3.5, though this is not relevant to the main theme of the paper.

COROLLARY 3.11 (Petersen's theorem). *A 3-regular graph without cut edges has a perfect matching.*

Proof. Let $G^* = (V, E^*)$ be the graph, and let $n = |V|$. Clearly, n is even, and $|E^*| = 3n/2$. The key point is that every node set S of odd cardinality (i.e., $S \subset V$ and $|S|$ odd) has $|\delta(S)| \geq 3$ since $|\delta(S)|$ is *odd* (since $3|S| - 2|E(S)|$ is odd) and is ≥ 2. Suppose that G^* has no perfect matching. Then $\mathrm{def}(G^*) > 0$, and so in the Gallai–Edmonds decomposition we have $D(G^*) \neq \emptyset$; moreover, G^* is not factor-critical (n is even) so $A(G^*) \neq \emptyset$. Applying Proposition 3.10 with $k = 3$ shows that G^* has an edge cover P such that every node is incident to $\geq (k-1) = 2$ edges of $M = E^* \backslash P$. Clearly, $|P| \geq n/2$, since P is an edge cover, and $|M| = |E^* \backslash P| \geq n$, since (V, M) has minimum degree 2. Since $|E^*| = |P| + |M| = 3n/2$, we have $|P| = n/2$ and $|M| = n$. Therefore, P is a perfect matching of G^*. □

3.3. Minimum-size 2-connected spanning subgraphs of undirected graphs: A parallel $(1.5 + \epsilon)$-approximation algorithm. This subsection focuses on the design of an efficient parallel algorithm and a linear-time sequential algorithm for the problem of finding a minimum-size 2-node connected (2-edge connected) spanning subgraph of a graph. Let $\epsilon > 0$ be a constant, independent of $|V(G)|$. A deterministic parallel version of the main heuristic runs in **NC** and achieves an approximation guarantee of $(1.5 + \epsilon)$, whereas a randomized **NC** version achieves an approximation guarantee of 1.5. A sequential *linear-time* version of the main heuristic achieves an approximation guarantee of $(1.5 + \epsilon)$. The proof of the 1.5 approximation guarantee in this subsection again hinges on Mader's theorem (Theorem 3.2), but instead of employing the lower bound in Theorem 3.5, we employ a nice lower bound result due to Chong and Lam (Proposition 3.13).

The heuristic for a minimum-size 2-NCSS described below can be used to find a 1.5-approximation of a minimum-size 2-ECSS. For this, we run a preprocessing step on the given graph $G = (V, E)$, which is assumed to be 2-edge connected, to partition the edge set into blocks (maximal 2-node connected subgraphs). Then separately for each block, we run our heuristic for a minimum-size 2-NCSS. For a block, the optimal 2-ECSS may *not* be 2-node connected; nevertheless, the lower bound used by the 2-NCSS heuristic applies to 2-ECSS too, so the edge set found by our algorithm will have size within 1.5 times the minimum size of a 2-ECSS.

Consider the problem of approximating a minimum-size 2-NCSS. Assume that the given graph $G = (V, E)$ is 2-node connected. The heuristic consists of two steps. The first finds a *minimum edge cover* $M \subseteq E$ of G, i.e., a minimum-cardinality edge set such that every node is incident to at least one edge of M. One way of finding M is to start with a *maximum matching* $\widetilde{M}$ of G, and then to add one edge incident to each node that is not matched by $\widetilde{M}$. Recall that $\mathrm{def}(G)$ denotes the number of nodes not matched by a maximum matching of G, i.e., $\mathrm{def}(G) = |V| - 2|\widetilde{M}|$. Then we have $|M| = |\widetilde{M}| + \mathrm{def}(G)$. (It is easily seen that no edge cover of G has smaller cardinality

than $|\widetilde{M}| + \mathrm{def}(G)$.) The second step of the heuristic finds an (inclusionwise) minimal edge set $F \subseteq E \backslash M$ such that $M \cup F$ gives a 2-NCSS. In other words, $(V, M \cup F)$ is 2-node connected, but for each edge $vw \in F$, $(V, M \cup F) \backslash vw$ is *not* 2-node connected. Let E' denote $M \cup F$, and let $E_{opt} \subseteq E$ denote a minimum-cardinality edge set such that (V, E_{opt}) is 2-*edge* connected.

LEMMA 3.12. $|E'| = |M| + |F| \leq 1.5|V| + \mathrm{def}(G) - 1$.

Proof. By Mader's theorem (Theorem 3.2), F is acyclic, so $|F| \leq |V| - 1$. A minimum edge cover M of G has size $|M| = |\widetilde{M}| + \mathrm{def}(G)$, where $\widetilde{M}$ is a maximum matching of G. Obviously, $|\widetilde{M}| \leq |V|/2$. The result follows. □

The next result, due to Chong and Lam, gives a lower bound on the size of a 2-ECSS. Proposition 3.14 generalizes Chong and Lam's lower bound to k-edge connected spanning subgraphs, $k \geq 1$.

PROPOSITION 3.13 (see Chong and Lam [CL 95, Lemma 3]). *Let $G = (V, E)$ be a graph of edge connectivity ≥ 2, and let $|E_{opt}|$ denote the minimum size of a 2-edge connected spanning subgraph. Then $|E_{opt}| \geq \max(|V| + \mathrm{def}(G) - 1, |V|)$.*

PROPOSITION 3.14. *Let $G = (V, E)$ be a graph of edge connectivity $\geq k \geq 1$, and let $|E_{opt}|$ denote the minimum size of a k-edge connected spanning subgraph. If G is not factor-critical, then $|E_{opt}| \geq \frac{k}{2}(|V| + \mathrm{def}(G))$. In general, $|E_{opt}| \geq \frac{k}{2}\max(|V| + \mathrm{def}(G) - 1, |V|)$.*

Proof. Suppose that G is *not* factor-critical and $\mathrm{def}(G)$ is ≥ 1. Then, by the Gallai–Edmonds decomposition theorem of matching theory [LP 86, Theorem 3.2.1], there is a *nonempty* node set A such that $G \backslash A$ has $|A| + \mathrm{def}(G)$ odd components ($G \backslash A$ may have some even components too). Focus on a (odd or even) component D_i of $G \backslash A$. The number of edges of E_{opt} such that either one or both end nodes are in D_i is at least $(|V(D_i)| + 1)k/2$, because every node $v \in V(D_i)$ is incident to $\geq k$ edges of E_{opt}, and moreover, $\delta(V(D_i))$ has at least k edges of E_{opt}. Summing over all components D_i of $G \backslash A$ proves the proposition. □

THEOREM 3.15. *Let $G = (V, E)$ be a graph of node (edge) connectivity ≥ 2. Let $\epsilon > 0$ be a constant. The heuristic described above finds a 2-node connected (2-edge connected) spanning subgraph (V, E') such that $|E'| \leq 1.5|E_{opt}|$, where $|E_{opt}|$ denotes the minimum size of a 2-ECSS.*

A randomized parallel version of the heuristic runs in **RNC** *and achieves an approximation guarantee of* 1.5. *A deterministic parallel version of the heuristic runs in* **NC** *and achieves an approximation guarantee of* $(1.5 + \epsilon)$.

The sequential running time is $O(\sqrt{|V|}|E|)$. A sequential linear-time version of the heuristic achieves an approximation guarantee of $(1.5 + \epsilon)$.

Proof. The approximation guarantee follows from Lemma 3.12 and Proposition 3.13, since

$$\frac{|E'|}{|E_{opt}|} \leq \frac{1.5|V| + \mathrm{def}(G) - 1}{\max(|V| + \mathrm{def}(G) - 1, |V|)} \leq 1 + \frac{0.5|V|}{|V|} \leq 1.5.$$

Consider the deterministic parallel version of the heuristic. Let $\widetilde{M}$ denote a maximum matching of G. For step 1, we find an approximately maximum matching in **NC** using the algorithm of [FGHP 93]: for a constant ϵ, $0 < \epsilon < 0.5$, the algorithm finds a matching M' with $|M'| \geq (1 - 2\epsilon)|\widetilde{M}|$ in parallel time $O(\epsilon^{-4}(\log |V|)^3)$ using $O(\epsilon^{-1}|V|^{2+(2/\epsilon)})$ processors. We obtain an (inclusionwise) minimal edge cover M of size $\leq (1 + 2\epsilon)|\widetilde{M}| + \mathrm{def}(G)$ by adding to M' one edge incident to every node that is not matched by M'. For step 2, we use a variant of the **NC** algorithm of [HKe+ 95, KeR 95], see Algorithm 2 and Lemma 2 in Kelsen and Ramachandran

[KeR 95]. Let G' be a 2-node connected spanning subgraph of G such that $E(G')$ contains the minimal edge cover M. Call an edge vw of G' *essential* if either vw is in M or $G'\backslash vw$ is not 2-node connected (i.e., an edge of G' is nonessential if it is not in M and it is not critical with respect to the 2-node connectivity of G'). Algorithm 2 of [KeR 95] starts by taking the current subgraph G' to be G and repeatedly finds a spanning tree T of G' that has the minimum number of nonessential edges, *minimally* augments T to obtain a 2-node connected spanning subgraph G'' of G', and then replaces the current subgraph G' by G''. Finding the spanning tree T is easy: we compute a minimum spanning tree of G' where the cost of each edge in M is taken to be (-1), the cost of each remaining essential edge of G' is 0, and the cost of each nonessential edge of G' is 1. The parallel complexity of the whole algorithm is in **NC**; see [HKe+ 95, KeR 95]. Now, the approximation guarantee is $(1.5+\epsilon)$.

For the sequential linear-time version of the heuristic, note that a matching M' with $|M'| \geq (1-2\epsilon)|\widetilde{M}|$ can be found in time $O((|V|+|E|)/\epsilon)$. Moreover, in linear time, we can find a minimal 2-node connected spanning subgraph whose edge set contains the minimal edge cover $M \subseteq E$ obtained by adding edges to M'; see [HKe+ 95]. □

3.4. Directed graphs. The main heuristic extends to digraphs. The key tool in the analysis of the approximation guarantee is another theorem of Mader [Ma 85, Theorem 1]. Given a digraph $G=(V,E)$ that is assumed to have node connectivity at least k, the first step of the heuristic finds an arc set $M \subseteq E$ of minimum cardinality such that for every node v, there are $\geq (k-1)$ arcs of M going out of v and $\geq (k-1)$ arcs of M coming into v. Clearly, $|M| \leq |E_{opt}|$, where $E_{opt} \subseteq E$ denotes a minimum-cardinality arc set such that (V, E_{opt}) is k-node connected. The second step of the heuristic is as in section 3.1: we find an (inclusionwise) minimal arc set $F \subseteq E\backslash M$ such that $M \cup F$ is the arc set of a k-node connected spanning subgraph. The key point is that $|F| \leq 2|V|-1$, by Mader's digraph theorem (Theorem 3.16).

Consider the first step in more detail. To find the arc set M, we transform the digraph problem to a b-matching problem on the bipartite graph $B(G)$ associated with G. For each node $v \in V(G)$, there is a pair of nodes v_-, v_+ in the bipartite graph $B(G)$, and for each arc (v,w) of G there is one edge v_+w_- in the bipartite graph. Our problem of finding a minimum-cardinality $M \subseteq E$ with $\deg_{M,in}(v) \geq (k-1)$, $\deg_{M,out}(v) \geq (k-1)$ $\forall v \in V$ corresponds to the problem of finding a minimum-cardinality edge set M' of the bipartite graph such that each node of the bipartite graph is incident to $\geq (k-1)$ edges of M'. As in section 3.1, this is a b-matching problem.

An *alternating cycle* of a digraph is a nonempty, even-length sequence of distinct arcs $C = e_1, e_2, \ldots, e_{2\ell-1}, e_{2\ell}$, $\ell \geq 1$, such that (using indices modulo 2ℓ) for each $i = 0, 1, \ldots$, the arcs e_{2i} and e_{2i+1} have the same start node, and the arcs e_{2i+1} and e_{2i+2} have the same end node. In other words, the set of undirected edges corresponding to an alternating cycle C is a union of cycles, and moreover, alternate occurrences of nodes have two C-arcs coming out or two C-arcs going in. See Figure 4 for an illustration. For an alternating cycle C, a C-out node is a node having two outgoing arcs of C, and a C-in node is a node having two incoming arcs of C. Recall that an arc e of a k-node connected digraph H is called critical if $H\backslash e$ is not k-node connected. Here is Mader's theorem on the critical arcs of a k-node connected digraph; see Figure 4 for an illustration.

THEOREM 3.16 (see Mader [Ma 85, Theorem 1]). *In a k-node connected digraph, if there is an alternating cycle C each of whose arcs is critical, then there is either a C-out node of outdegree k or a C-in node of indegree k.*

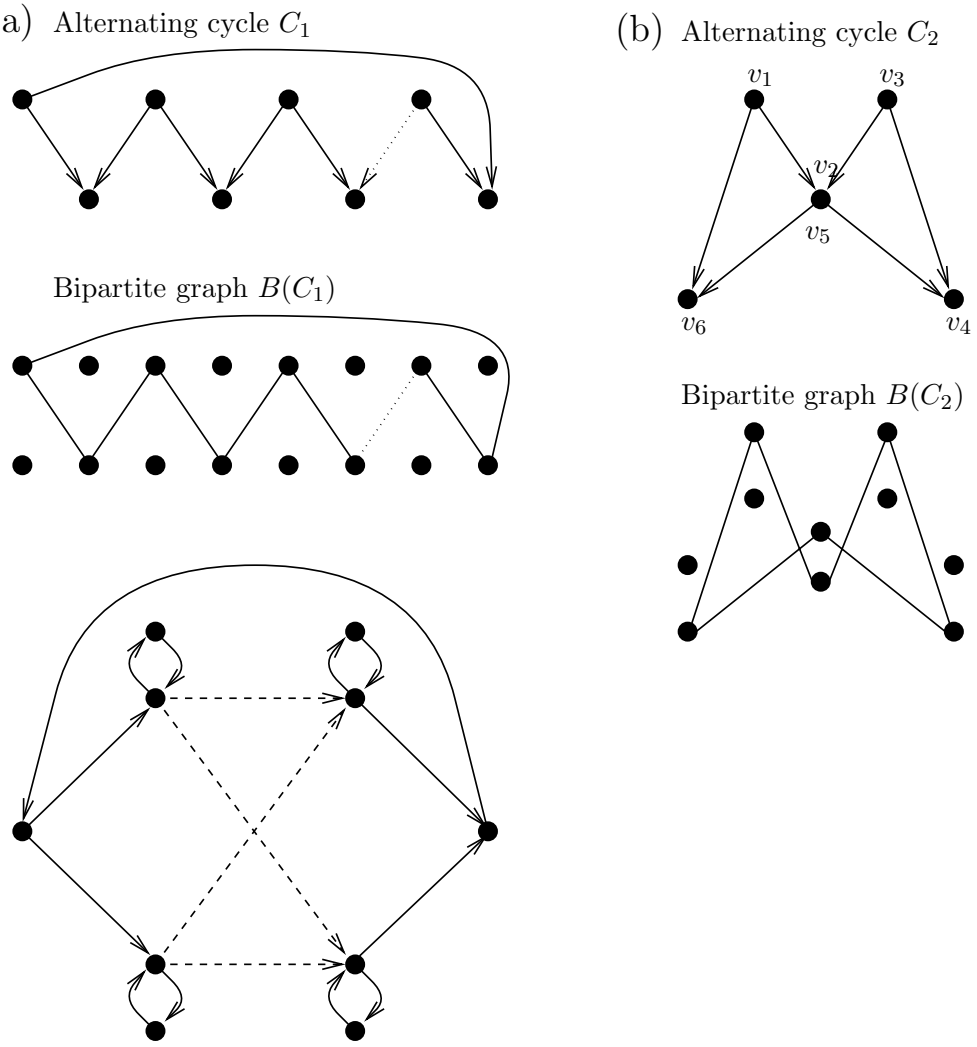

FIG. 4. *An illustration of an alternating cycle in a digraph and of Mader's theorem on critical alternating cycles in a k-node connected digraph; see Theorem* 3.16. (a) *An alternating cycle* C_1 *and its bipartite graph* $B(C_1)$. (b) *Another alternating cycle* $C_2 = (v_1, v_2), (v_3, v_2), (v_3, v_4), (v_5, v_4), (v_5, v_6), (v_1, v_6)$ *and its bipartite graph* $B(C_2)$. *For an alternating cycle, the undirected version may not be a cycle, but the bipartite graph has at least one cycle.* (c) *An alternating cycle* C *of a* 1*-connected (strongly connected) digraph is indicated by dashed lines. Every* C*-out node has outdegree* $> k = 1$*, and every* C*-in node has indegree* $> k = 1$*. None of the arcs in the alternating cycle is critical for* 1*-connectivity. This example is modified from an example of Mader* [Ma 85].

FACT 3.17 (see Mader [Ma 85, Lemma 2]). *Let* H *be a digraph, and let* $B(H)$ *be the associated bipartite graph. There is a cycle in* $B(H)$ *iff there is an alternating cycle in* H.

Remarks. Mader [Ma 85] states the theorem for minimal k-node connected digraphs, but in fact, his proof needs only the fact that every arc in the alternating cycle

is critical. Now, consider a digraph H_0 that is obtained from an arbitrary strongly connected digraph by subdividing every arc at least once (i.e., an arc is replaced by ≥ 1 new nodes and a directed path of ≥ 2 arcs). Note that H_0 contains no alternating cycle. Mader [Ma 85, p. 104] shows that there exists a minimal k-node connected digraph G such that H_0 is contained in the subgraph of G induced by arcs whose start nodes have outdegrees $> k$ and whose end nodes have indegrees $> k$.

LEMMA 3.18. *Let $F \subseteq E \backslash M$ be the set of critical arcs found by the second step of the heuristic. Then $|F| \leq 2|V| - 1$.*

Proof. Let $G' = (V, E')$, where $E' = M \cup F$. We claim that F contains no alternating cycle. By way of contradiction, suppose that $C \subseteq F$ is an alternating cycle. Observe that every C-out node v has $\geq (k+1)$ outgoing arcs of E', since there are $\geq (k-1)$ arcs of M outgoing from v, and there are two arcs of C outgoing from v. Similarly, every C-in node has $\geq (k+1)$ incoming arcs of E'. This contradicts Mader's digraph theorem. Hence, F contains no alternating cycle. Then $|F| \leq 2|V| - 1$, because the bipartite graph associated with (V, F) is acyclic. □

The previous lemma immediately gives an approximation guarantee of $1 + [2/k]$ for a minimum-size k-NCSS of a digraph, because the "degree lower bound" implies that a digraph k-NCSS has $\geq k|V|$ arcs. The approximation guarantee can be improved to $1 + [1/k]$ via the lower bound on the size of a digraph k-NCSS implied by Proposition 3.8.

PROPOSITION 3.19. *Let $G = (V, E)$ be a digraph of node connectivity $\geq k$. The heuristic above finds a k-node connected spanning subgraph (V, E') such that $|E'| \leq (1 + [2/k])|E_{opt}|$, where $|E_{opt}|$ denotes the cardinality of an optimal solution.*

THEOREM 3.20. *Let $G = (V, E)$ be a digraph of node connectivity $\geq k$. The heuristic described above finds a k-node connected spanning subgraph (V, E') such that $|E'| \leq (1 + [1/k])|E_{opt}|$, where $E_{opt} \subseteq E$ denotes a minimum-cardinality arc set such that (V, E_{opt}) is k-node connected. The running time is $O(k|E|^2)$.*

Proof. The proof of the approximation guarantee is similar to the proof for undirected graphs in Theorem 3.6. Let $G_{opt} = (V, E_{opt})$ be a k-node connected spanning subgraph of minimum size. Apply Proposition 3.8 to the bipartite graph $B(G_{opt})$ of G_{opt} to deduce that $|M^*| \leq |E(B(G_{opt}))| - |V(B(G_{opt}))|/2$, where $M^* \subseteq E(B(G_{opt}))$ is a minimum-size edge set such that every node of $B(G_{opt})$ is incident to $\geq k - 1$ edges of M^*. Since the arc set $M \subseteq E(G)$ found by the heuristic has $|M| \leq |M^*|$ (since M comes from a supergraph of E_{opt}), it follows that $|M| \leq |E(B(G_{opt}))| - |V(B(G_{opt}))|/2 = |E_{opt}| - |V(G)|$. Consequently, since $|E'| = |M| + |F|$ and $|F| \leq 2|V(G)| - 1$,

$$\frac{|E'|}{|E_{opt}|} \leq \frac{|E_{opt}| - |V(G)| + (2|V(G)| - 1)}{|E_{opt}|} \leq 1 + \frac{1}{k},$$

where the last inequality uses the "degree lower bound," $|E_{opt}| \geq k|V(G)|$. The running time analysis is similar to that for the heuristic for graphs; see section 3.1. □

4. Approximating minimum-size k-edge connected spanning subgraphs. The heuristic can be modified to find an approximately minimum-size k-edge connected spanning subgraph (abbreviated k-ECSS) of a graph or a digraph. First, we focus on graphs, and we prove a $(1 + [2/(k+1)])$-approximation guarantee for finding a minimum-size k-ECSS. The analysis hinges on Theorem 4.3 which may be regarded as an analogue of Mader's theorem [Ma 72, Theorem 1] for k-edge connected graphs. Then we turn to digraphs, and prove an approximation guarantee of $1 + [4/\sqrt{k}]$ for the k-ECSS heuristic.

In this section, an edge e (arc e) of a k-edge connected graph (digraph) H is called *critical* if $H\backslash e$ is *not* k-edge connected. Assume that the given graph or digraph $G = (V, E)$ is k-edge connected; otherwise, the heuristic will detect this and report failure.

4.1. Undirected graphs. In this subsection, $G = (V, E)$ is a graph. The first step of the heuristic finds an edge set $M \subseteq E$ of minimum cardinality such that every node in V is incident to $\geq k$ edges of M. Clearly, $|M| \leq |E_{opt}|$, where $E_{opt} \subseteq E$ denotes a minimum-cardinality edge set such that (V, E_{opt}) is k-edge connected. The second step of the heuristic finds an (inclusionwise) minimal edge set $F \subseteq E\backslash M$ such that $M \cup F$ is the edge set of a k-edge connected spanning subgraph. In detail, the second step starts with $F = \emptyset$ and $E' = E$. Note that $G' = (V, E')$ is k-edge connected at the start. We examine the edges of $E\backslash M$ in an arbitrary order $e_1, e_2, \ldots$. For each edge $e_i = v_i w_i$ (where $1 \leq i \leq |E\backslash M|$), we determine whether or not $v_i w_i$ is critical for the current graph by finding the maximum number of edge-disjoint $v_i \leftrightarrow w_i$ paths in G'.

PROPOSITION 4.1. *An edge $v_i w_i$ of a k-edge connected graph is not critical iff there exist at least $k+1$ edge-disjoint $v_i \leftrightarrow w_i$ paths (including the path $v_i w_i$).*

If $v_i w_i$ is noncritical, then we delete it from E' and G'; otherwise, we retain it in E' and G', and also we add it to F. At termination of the heuristic, $G' = (V, E')$, $E' = M \cup F$, G' is k-edge connected, and every edge $vw \in F$ is critical, i.e., $G'\backslash vw$ is *not* k-edge connected. Theorem 4.3 below shows that $|F| \leq k|V|/(k+1)$ for $k \geq 1$. Since $|E_{opt}| \geq k|V|/2$, the minimum-size k-ECSS heuristic achieves an approximation guarantee of $1 + [2/(k+1)]$ for $k \geq 1$.

The next lemma turns out to be quite useful. A straightforward counting argument gives the proof; see Mader [Ma 71, Lemma 1] or Cai [Ca 93, Claim 3].

LEMMA 4.2. *Let $G = (V, M)$ be a simple graph of minimum degree $k \geq 1$.*

(i) *Then for every node set $S \subseteq V$ with $1 \leq |S| \leq k$, the number of edges with exactly one end node in S, $|\delta(S)|$, is at least k.*

(ii) *If a node set $S \subseteq V$ with $1 \leq |S| \leq k$ contains at least one node of degree $\geq (k+1)$, then $|\delta(S)|$ is at least $k+1$.*

The goal of Theorem 4.3 below is to give an upper bound on the number of critical edges in the edge-complement of a spanning subgraph of minimum degree k in an arbitrary k-edge connected graph H. Clearly, every critical edge $e \in E(H)$ is in some k-cut $\delta(A_e)$, $A_e \subseteq V(H)$. By a *tight* node set S of a k-edge connected graph H we mean a set $S \subset V(H)$ with $|\delta_H(S)| = k$, i.e., a node set S such that $\delta_H(S)$ is a k-cut. As usual, a family of sets $\{S_i\}$ is called *laminar* if for any two sets in the family, either the two sets are disjoint, or one set is contained in the other. For an arbitrary subset F' of the critical edges of H, it is well known that there exists a laminar family $\mathcal{F}$ of tight node sets *covering* F', i.e., there exists $\mathcal{F} = \{A_1, A_2, \ldots, A_\ell\}$, where $A_i \subseteq V(H)$ and $\delta(A_i)$ is a k-cut, for $1 \leq i \leq \ell$, such that each edge $e \in F'$ is in some $\delta(A_i)$, $1 \leq i \leq \ell$. (For details, see [Fr 93, section 5] or [Ca 93, Lemma 3].) It is convenient to define a tree T corresponding to $\mathcal{F} \cup \{V(H)\}$: there is a T-node corresponding to each set $A_i \in \mathcal{F}$ and to $V(H)$, and there is a T-edge $A_i A_j$ (or $V(H)A_j$) iff $A_j \subset A_i$ and no other node set in $\mathcal{F}$ contains A_j and is contained in A_i. Note that the T-node corresponding to the node set A_i of the laminar family $\mathcal{F}$ is denoted by A_i, and the T-node corresponding to the node set $V(H)$ is denoted by $V(H)$. Each T-edge corresponds to a k-cut of H. Suppose that the tree T is rooted at the T-node $V(H)$. We associate another node set $\phi_i \subseteq V(H)$ with each node set

A_i of $\mathcal{F}$:

$$\phi_i = A_i \backslash \bigcup \{A \in \mathcal{F} : A \subset A_i, A \neq A_i\}.$$

In other words, a T-node $A_i \in \mathcal{F}$ that is a leaf node of T has $\phi_i = A_i$; otherwise, ϕ_i consists of those H-nodes of A_i that are not in the node sets $A', A'', \ldots$, where $A', A'', \ldots \in \mathcal{F}$ correspond to the children of A_i in the tree T. For distinct T-nodes A_i and A_j, note that ϕ_i and ϕ_j are disjoint. See Figure 5 for an illustration of $\mathcal{F} = \{A_i\}$, the family of node sets $\{\phi_i\}$, and the tree T for a particular graph.

The proof of Theorem 4.3 is long and nontrivial. Readers interested in a detailed study of the proof may be helped by an examination of the examples in Figure 2(c) and Figure 5, the illustration of the proof in Figure 6(a)–(d), and a study of the proof of Theorem 4.8, which is an analogous but weaker result for k-edge connected digraphs.

THEOREM 4.3. *Let $H = (V, E)$ be a k-edge connected, n-node graph ($k \geq 1$). Let $M \subseteq E$ be an edge set such that the spanning subgraph (V, M) has minimum degree $\geq k$. Let F be the set consisting of edges of $E \backslash M$ that are in some k-cut of H. Let $\mathcal{F} = \{A_1, \ldots, A_\ell\}$ be a laminar family of tight node sets that covers F, i.e., for each $e \in F$, there is an $A_i \in \mathcal{F}$ such that $e \in \delta(A_i)$. Then*

$$|F| \leq \frac{k}{k+1} \left| \bigcup_{i=1}^{\ell} A_i \right| \leq \frac{k}{k+1}(n-1). \tag{4.1}$$

Some key preliminaries are discussed before delving into the proof. The upper bound on $|F|$ is asymptotically tight. Consider the k-edge connected graph G obtained as follows: take $\ell + 1$ copies of the $(k+1)$-clique, $C_0, C_1, \ldots, C_\ell$, and for each $i = 1, \ldots, \ell$, choose an arbitrary node v_i in C_i and add k (nonparallel) edges between v_i and C_0. Take $M = \bigcup_{i=0}^{\ell} E(C_i)$ and $F = E(G) \backslash M$. Observe that $|F| = k(n - (k+1))/(k+1)$.

FACT 4.4. *For a laminar family of tight node sets $\mathcal{F} = \{A_1, \ldots, A_\ell\}$, $\cup_{i=1}^{\ell} \delta(A_i) = \cup_{i=1}^{\ell} \delta(\phi_i)$.*

Proof. For each $i = 1, \ldots, \ell$, an edge in $\delta(\phi_i)$ is either in $\delta(A_i)$ or in $\delta(A'), \delta(A''), \ldots$, where $A', A'', \ldots \in \mathcal{F}$ correspond to the children of A_i in the tree T. Hence, the set on the left side contains the set on the right side.

To see that the set on the left side is contained in the set on the right side, note that for every edge e in the left side set, there is an (inclusionwise) minimal tight node set $A_{i(e)}$ such that $e \in \delta(A_{i(e)})$, and the associated node set $\phi_{i(e)}$ has $e \in \delta(\phi_{i(e)})$. ∎

FACT 4.5. *Let H, M, F and $\mathcal{F} = \{A_1, \ldots, A_\ell\}$ be as in Theorem 4.3. The inequality in the theorem*

$$|F| \leq \frac{k}{k+1} \left| \bigcup_{i=1}^{\ell} A_i \right|$$

is implied by the inequality

$$\left| \bigcup_{i=1}^{\ell} \delta(A_i) \right| \leq \frac{k}{k+1} \sum_{i=1}^{\ell} |\phi_i| + \frac{1}{2} \sum_{i=1}^{\ell} |M \cap \delta(\phi_i)|.$$

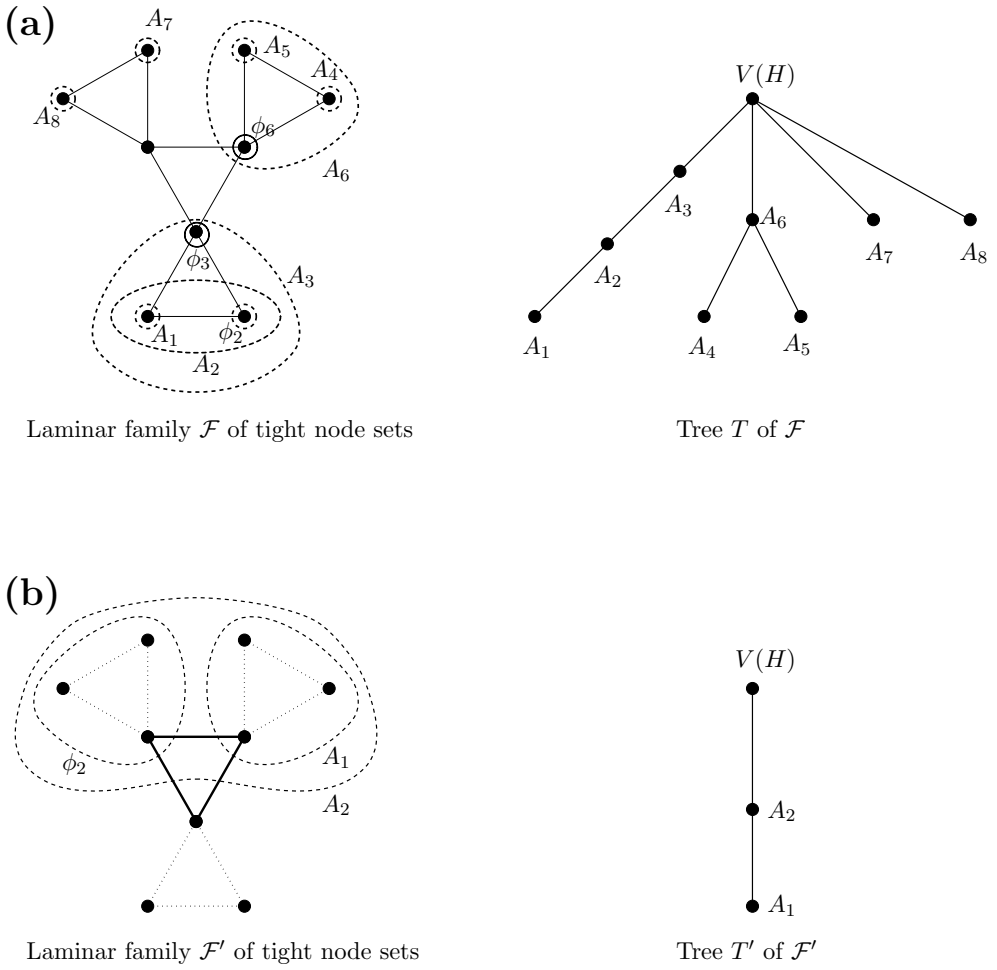

FIG. 5. *Two laminar families of tight node sets for a 2-edge connected graph H ($k = 2$).* (a) *The laminar family $\mathcal{F}$ covers all critical edges of H. $\mathcal{F}$ consists of the node sets $A_1, \ldots, A_8$, where each A_i is tight since $|\delta(A_i)| = 2 = k$. For a node set A_i, ϕ_i is the node set $A_i \setminus \cup \{A_j \in \mathcal{F} : A_j \subset A_i,\ A_j \neq A_i\}$. Note that $\phi_i = A_i$ for the inclusionwise minimal A_i, i.e., for $i = 1, 4, 5, 7, 8$. Also, the tree T corresponding to $\mathcal{F} \cup \{V(H)\}$ is illustrated.* (b) *The laminar family $\mathcal{F}'$ covers all critical edges of $E(H) \setminus M$, where $M \subset E(H)$ is such that every node is incident to at least $k = 2$ edges of M. M is indicated by dotted lines. All edges of $E(H) \setminus M$ are critical. $\mathcal{F}'$ consists of the tight node sets A_1, A_2. Also, the node sets ϕ_1, ϕ_2 are indicated ($\phi_1 = A_1$), and the tree T' representing $\mathcal{F}' \cup \{V(H)\}$ is illustrated.*

Proof. Let $M_c \subseteq M$ denote the set of M-edges that are covered by the laminar family $\mathcal{F}$, i.e.,

$$M_c = \bigcup_{i=1}^{\ell} [M \cap \delta(A_i)] = M \cap \left[\bigcup_{i=1}^{\ell} \delta(A_i)\right] = M \cap \left[\bigcup_{i=1}^{\ell} \delta(\phi_i)\right] = \bigcup_{i=1}^{\ell} [M \cap \delta(\phi_i)]\,.$$

Consider an arbitrary edge $e = vw$ that is in M_c. If $e \in \delta(\phi_i)$ $(i = 1, \ldots, \ell)$, then either $v \in \phi_i, w \notin \phi_i$ or $w \in \phi_i, v \notin \phi_i$. Since the node sets ϕ_i $(i = 1, \ldots, \ell)$ are mutually disjoint, there are at most two tight node sets $A_i \in \mathcal{F}$ such that $e \in \delta(\phi_i)$.

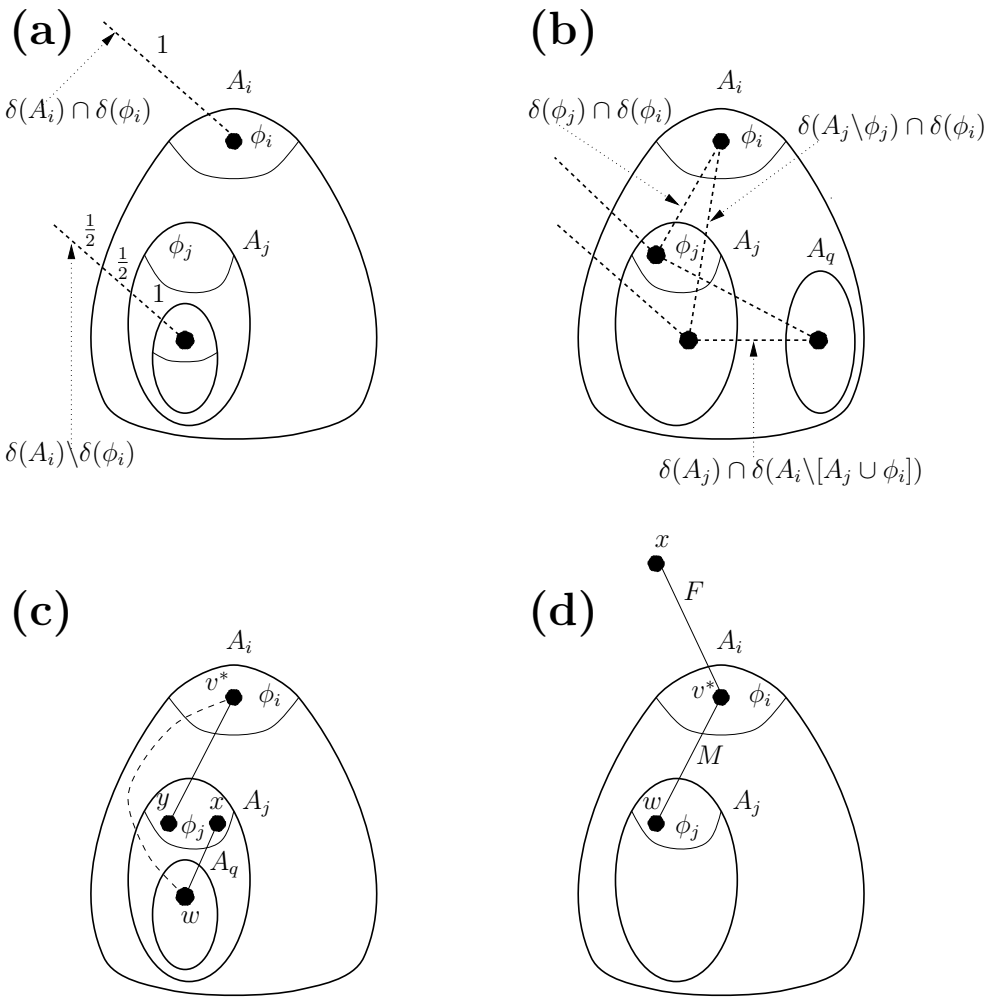

FIG. 6. *An illustration of the proof of Theorem* 4.3. (a) *Every edge in* $\delta(A_i) \cap \delta(\phi_i)$ *contributes* ≥ 1 *to the left-hand side of inequality* (σ), *and every edge in* $\delta(A_i) \backslash \delta(\phi_i)$ *contributes* $\geq \frac{1}{2}$. (b) *The tight node set* A_i *is shown, together with two tight node sets* A_j, A_q *contained in* A_i. *The node sets* ϕ_i *and* ϕ_j *are also shown. The three kinds of edges arising in the proof are illustrated.* (c) *In Claim* 3, $\phi_i = \{v^*\}$ *and* $|\phi_j| \geq (k+1)$. *An edge* wv^* *with* $w \in A_j \backslash \phi_j$ *is replaced by a pair of new edges* wx *and* yv^*, *where* $x \in \phi_j$, $y \in \phi_j$. (d) *In Claim* 3, $\phi_i = \{v^*\}$. *If an edge* v^*x *with* $x \notin A_i$ *is in* F *(so* $v^*x \notin M$*), then there is an edge* v^*w *in* M *with* $w \in \phi_j$, *where* $\phi_j \subseteq A_j \subset A_i$ *and* $|\phi_j| \geq (k+1)$. *Edges* v^*x *and* v^*w *are swapped between* M *and* F.

(For example, if there are tight node sets $A_g, A_h \in \mathcal{F}$, $g \neq h$, with $v \in \phi_g, w \in \phi_h$, then $e \in \delta(\phi_g), e \in \delta(\phi_h)$, and $e \notin \delta(\phi_i)$ for $i = 1, \ldots, \ell$, $i \neq g$, $i \neq h$.) Then

$$|M_c| = \left| \bigcup_{i=1}^{\ell} [M \cap \delta(\phi_i)] \right| \geq \frac{1}{2} \sum_{i=1}^{\ell} |M \cap \delta(\phi_i)|, \tag{4.2}$$

since we are counting the cardinality of a union of sets such that each element occurs in at most two of these sets.

Now note that $\cup_{i=1}^{\ell} \delta(A_i) = F \cup M_c$, hence

$$\left| \bigcup_{i=1}^{\ell} \delta(A_i) \right| = |F| + |M_c|. \tag{4.3}$$

Also, $\cup_{i=1}^{\ell} A_i = \cup_{i=1}^{\ell} \phi_i$, hence

$$\frac{k}{k+1} \left| \bigcup_{i=1}^{\ell} A_i \right| = \frac{k}{k+1} \left| \bigcup_{i=1}^{\ell} \phi_i \right| = \frac{k}{k+1} \sum_{i=1}^{\ell} |\phi_i|. \tag{4.4}$$

Substituting inequalities (4.2), (4.3), and (4.4) into the second inequality in the fact gives

$$|F| + |M_c| \leq \frac{k}{k+1} \left| \bigcup_{i=1}^{\ell} A_i \right| + |M_c|,$$

which is the inequality in Theorem 4.3. □

Most of the complications in the proof of Theorem 4.3 seem to be caused by the presence of tight node sets $A_i \in \mathcal{F}$ such that $|\phi_i| = 1$. To illustrate the main ideas in the proof, we first prove a weaker version of Theorem 4.3. In the weaker version, the required upper bound of $k(n-1)/(k+1)$ is relaxed to $(n-1)$, and the laminar family of tight node sets $\mathcal{F} = \{A_1, \ldots, A_\ell\}$ is restricted such that every $A_i \in \mathcal{F}$ has $|\phi_i| \geq 2$. (The motivation for putting the restriction on $\mathcal{F}$ is expository. Such restricted laminar families $\mathcal{F}$ do not seem to be of mathematical interest.)

PROPOSITION 4.6. *Let H, M, F, and $\mathcal{F}$ be as in Theorem 4.3, and moreover, suppose that each tight node set $A_i \in \mathcal{F}$ has $|\phi_i| \geq 2$. Then*

$$|F| \leq \left| \bigcup_{i=1}^{\ell} A_i \right| \leq n - 1.$$

Proof. For an arbitrary $i = 1, \ldots, \ell$, consider A_i, ϕ_i, and let p denote $|\phi_i|$. By assumption, $p \geq 2$. Suppose that $p \leq k$ (the other case $p \geq k+1$ turns out to be easy). Then

$$|M \cap \delta(\phi_i)| \geq p(k - (p-1)), \tag{4.5}$$

since for every node $v \in \phi_i$, there are at most $(p-1)$ incident edges $vw \in E(H)$ with $w \in \phi_i$. Adding $2|\phi_i|$ to both sides of inequality (4.5) gives

$$2|\phi_i| + |M \cap \delta(\phi_i)| \geq 2p + p(k - (p-1)) \geq -p^2 + (k+2)p. \tag{4.6}$$

Subtracting $2k$ from both sides of inequality (4.6) gives

$$2|\phi_i| + |M \cap \delta(\phi_i)| - 2k \geq -p^2 + (k+2)p - 2k = -(p-k)(p-2) \geq 0, \tag{4.7}$$

where the last inequality $-(p-k)(p-2) \geq 0$ holds because $2 \leq p \leq k$. Inequality (4.7) implies

$$|\phi_i| + \frac{1}{2}|M \cap \delta(\phi_i)| \geq k = |\delta(A_i)|. \tag{4.8}$$

If $|\phi_i| \geq (k+1)$, then obviously inequality (4.8) holds.

Summing up inequality (4.8) over $i = 1, \ldots, \ell$ gives

$$\left|\bigcup_{i=1}^{\ell} \delta(A_i)\right| \leq \sum_{i=1}^{\ell} |\delta(A_i)| = k \cdot \ell \leq \sum_{i=1}^{\ell} |\phi_i| + \frac{1}{2} \sum_{i=1}^{\ell} |M \cap \delta(\phi_i)|. \tag{4.9}$$

The proof of Fact 4.5 shows that inequality (4.9) implies the inequality in the proposition,

$$|F| \leq \left|\bigcup_{i=1}^{\ell} A_i\right| \leq n - 1. \qquad \square$$

Proof of Theorem 4.3. Without loss of generality (w.l.o.g.) assume that $\mathcal{F}$ is minimal, i.e., for every $A_i \in \mathcal{F}$ there is an edge $e_i \in F$ such that $e_i \in \delta(A_i)$ and $e_i \notin \delta(A)$ $\forall A \in \mathcal{F}$, $A \neq A_i$. Since $\mathcal{F}$ is minimal, every $A_i \in \mathcal{F}$ has $|\phi_i| \geq 1$. Let T be the tree representing $\mathcal{F} \cup \{V(H)\}$. The proof examines the node sets $A_i \in \mathcal{F}$, ϕ_i, but the node set $V(H) \setminus \bigcup\{A_i : A_i \in \mathcal{F}\}$ is not relevant for the proof. Every inclusionwise minimal $A_i \in \mathcal{F}$ has $|A_i| \geq (k+1)$, since $\delta(A_i) \cap F \neq \emptyset$ implies that A_i contains a node v with $\deg_H(v) \geq (k+1)$, so Lemma 4.2 implies this bound on $|A_i|$. Hence, every $A_i \in \mathcal{F}$ with $|\phi_i| = 1$ has at least one child in the tree T.

Two key assumptions are needed to complete the proof.

Assumption 1. For $1 \leq i \leq \ell$, every ϕ_i induces a complete subgraph of H, and moreover, every edge of this complete subgraph is in M, i.e., for $i = 1, \ldots, \ell$ $\forall v, w \in \phi_i, vw \in E(H)$ and $vw \in M$.

Assumption 2. For every $A_i \in \mathcal{F}$ with $|\phi_i| = 1$, there is an $A_j \in \mathcal{F}$ such that $|\phi_j| \leq k$ and A_j is a child of A_i in the tree T.

Claim 2. Assumption 1 causes no loss of generality.

Here is the proof of Claim 2. For an arbitrary $i = 1, \ldots, \ell$, consider ϕ_i and $E(\phi_i)$, the set of edges of H with both end nodes in ϕ_i. Clearly, an edge $vw \in E(\phi_i)$ is *not* in F, since vw is in none of the k-cuts $\delta(A_j)$ $(j = 1, \ldots, \ell)$. Therefore, all the missing edges vw with $v \in \phi_i, w \in \phi_i$ can be added to H (say, vw is first added to $E \setminus (M \cup F)$) such that ϕ_i induces a clique and this will keep M, F, and $\mathcal{F}$ unchanged. Moreover, every edge $vw \in E(\phi_i)$ can be placed in M, and the minimum degree requirement on (V, M) will continue to hold. By repeating this for each $i = 1, \ldots, \ell$, we obtain $H', M', F' = F$ and $\mathcal{F}' = \mathcal{F}$ that satisfy Assumption 1 and the conditions in the theorem. Clearly, if the inequality in the theorem holds for $H', M', F', \mathcal{F}'$, then it also holds for $H, M, F, \mathcal{F}$.

Claim 3. Assumption 2 causes no loss of generality.

Proof of Claim 3. Consider an $A_i \in \mathcal{F}$ $(i = 1, \ldots, \ell)$ such that $|\phi_i| = 1$ and in the tree T every child $A_j \in \mathcal{F}$ of A_i has $|\phi_j| \geq (k+1)$. Let $\phi_i = \{v^*\}$. Let $A_j \in \mathcal{F}$ be an arbitrary T-child of A_i with $|\phi_j| \geq (k+1)$. Clearly, by Assumption 1, the subgraph of H induced by ϕ_j is a clique, and every edge in the clique is in M. Suppose that H has an edge wv^* such that $w \in A_j \setminus \phi_j$, i.e., $wv^* \in \delta(A_j) \setminus \delta(\phi_j)$. (Figure 6(c) illustrates this.) Then we replace wv^* by a pair of new edges wx, yv^* with $x \in \phi_j, y \in \phi_j$ (possibly, $x = y$) such that the resulting graph H' is simple (i.e., H' has no multiedges); this can be done always, since $|\phi_j| \geq (k+1)$ and both $\delta(A_j)$ and $\delta(A_q)$ are k-cuts, where $A_q \in \mathcal{F}$ is the T-child of A_j containing node w. The resulting graph H' is k-edge connected. To see this, note that H is k-edge connected, and H' is obtained from H by replacing one edge wv^* by two edges wx, yv^*, where the nodes x and y are contained in the $(k+1)$-clique induced by ϕ_j. The formal proof of the k-edge connectivity of H' is easy and is left to the reader. If $wv^* \in M$,

then we take $M' = (M \backslash \{wv^*\}) \cup \{wx, yv^*\}$, $F' = F$; otherwise, we take $M' = M$, $F' = (F \backslash \{wv^*\}) \cup \{wx, yv^*\}$. In either case $\mathcal{F}$ covers F'. By repeating this maneuver for all relevant $i = 1, \ldots, \ell$, we obtain H', M', F', and $\mathcal{F}' = \mathcal{F}$ with $|F'| \geq |F|$ that satisfy the conditions in the theorem. Clearly, if the inequality in the theorem holds for $H', M', F', \mathcal{F}'$, then it also holds for $H, M, F, \mathcal{F}$. Moreover, the following condition $(*)$ holds:

$(*)$ For every $A_i \in \mathcal{F}$ with $|\phi_i| = 1$, for every T-child $A_j \in \mathcal{F}$ of A_i with $|\phi_j| \geq (k+1)$, every edge in $\delta(A_j) \cap \delta(\phi_i)$ is in $\delta(\phi_j)$.

Now w.l.o.g. suppose that H, M, F, and $\mathcal{F}$ satisfy condition $(*)$. Call an $A_i \in \mathcal{F}$ *bad* if $|\phi_i| = 1$ and every T-child $A_j \in \mathcal{F}$ of A_i has $|\phi_j| \geq (k+1)$. Suppose that there is a bad $A_i \in \mathcal{F}$ with $\phi_i = \{v^*\}$ such that one of the edges $v^*x \in \delta(A_i) \cap \delta(\phi_i)$ is not in M. (Figure 6(d) illustrates this.) Then since $|\delta(A_i)| = k$, $|\delta(A_i) \cap F| \geq 1$, and $|M \cap \delta(\phi_i)| \geq k$, there must be an M-edge wv^* in $\delta(\phi_i) \backslash \delta(A_i)$. Let $A_j \in \mathcal{F}$ be the T-child of A_i such that $w \in A_j$. Since A_i is bad, $|\phi_j| \geq (k+1)$, therefore condition $(*)$ applies and ensures that the node w is in ϕ_j. Moreover, by Assumption 1, w is incident to $\geq k$ edges of M that have both end nodes in ϕ_j. Take $M' = (M \backslash \{wv^*\}) \cup \{v^*x\}$, $F' = (F \backslash \{v^*x\}) \cup \{wv^*\}$, and observe that $|M| = |M'|$, $|F| = |F'|$, every node $v \in V(H)$ is incident to $\geq k$ edges of M', F' consists of critical edges in $E(H) \backslash M'$, and $\mathcal{F}$ covers F'. By repeating this maneuver for all relevant $i = 1, \ldots, \ell$, we obtain H, M', F' and $\mathcal{F}$ that satisfy the conditions in the theorem such that $|F'| = |F|$, and for every bad $A_i \in \mathcal{F}$, no edge in $\delta(A_i) \cap \delta(\phi_i)$ is in F'. Then we can start with $\mathcal{F}$ and remove each bad A_i from $\mathcal{F}$ to obtain another laminar family $\mathcal{F}'$ covering F' such that $|\cup_{A \in \mathcal{F}'} A| \leq |\cup_{A \in \mathcal{F}} A|$, and $\mathcal{F}'$ satisfies Assumption 2. Clearly, if the inequality in the theorem holds for $H', M', F', \mathcal{F}'$, then it also holds for $H, M, F, \mathcal{F}$. This completes the proof of Claim 3.

Instead of proving that $F, \mathcal{F}$ satisfy inequality (4.1), we prove that under Assumption 2, M, F, and $\mathcal{F} = \{A_1, \ldots, A_\ell\}$ satisfy the following sharper inequality (see Fact 4.5):

$$\left| \bigcup_{i=1}^{\ell} \delta(A_i) \right| \leq \frac{k}{k+1} \sum_{i=1}^{\ell} |\phi_i| + \frac{1}{2} \sum_{i=1}^{\ell} |M \cap \delta(\phi_i)|. \tag{4.10}$$

Clearly, every $A_i \in \mathcal{F}$ with $|\phi_i| \geq (k+1)$ satisfies the inequality

$$|\delta(A_i)| \leq \frac{k}{k+1} |\phi_i|. \tag{4.11}$$

From the proof of Proposition 4.6 (see inequalities (4.5), (4.6), (4.7), (4.8)), it follows that every $A_i \in \mathcal{F}$ with $2 \leq |\phi_i| \leq k$ satisfies the inequality

$$|\delta(A_i)| + \frac{k-1}{2(k+1)} |\phi_i| \leq \frac{k}{k+1} |\phi_i| + \frac{1}{2} |M \cap \delta(\phi_i)|, \tag{4.12}$$

where the surplus term on the left-hand side (l.h.s.) is the difference between $k|\phi_i|/(k+1)$ and $|\phi_i|/2$. Every $A_i \in \mathcal{F}$ with $|\phi_i| = 1$ satisfies the inequality

$$\begin{aligned} &|\delta(A_i) \cap \delta(\phi_i)| + \frac{1}{2} |\delta(A_i) \backslash \delta(\phi_i)| + \frac{k}{k+1} - \frac{1}{2} |\delta(A_i) \cap \delta(\phi_i)| \\ &\leq \frac{k}{k+1} |\phi_i| + \frac{1}{2} |M \cap \delta(\phi_i)|, \end{aligned} \tag{4.13}$$

because $|\delta(A_i) \cap \delta(\phi_i)| + |\delta(A_i) \backslash \delta(\phi_i)| = |\delta(A_i)| = k \leq |M \cap \delta(\phi_i)|$.

Claim 4. Under Assumption 2, the inequality (σ) obtained by summing up over all $A_i \in \mathcal{F}$ the appropriate one of inequalities (4.11), (4.12), (4.13) implies inequality (4.10), i.e., the l.h.s. of inequality (σ) is $\geq$ the l.h.s. of inequality (4.10), and the right-hand side (r.h.s.) of inequality (σ) is $\leq$ the r.h.s. of inequality (4.10).

Proof of Claim 4. Clearly, inequality (σ) will imply inequality (4.10) if for every $A_i \in \mathcal{F}$, every edge in $\delta(A_i) \cap \delta(\phi_i)$ contributes ≥ 1 to the l.h.s. of inequality (σ). This property holds for $A_i \in \mathcal{F}$ with $|\phi_i| \geq 2$ by inequalities (4.11), (4.12), but for $A_i \in \mathcal{F}$ with $|\phi_i| = 1$ the property fails to hold (see inequality (4.13)). Fortunately, there is a way around this difficulty. For $A_i \in \mathcal{F}$ with $|\phi_i| = 1$, we allow A_i, ϕ_i to contribute a deficit of $\frac{1}{2}|\delta(A_i) \cap \delta(\phi_i)|$ on the l.h.s. of inequality (σ); using this deficit, we can ensure that every edge in $\delta(A_i) \cap \delta(\phi_i)$ (in $\delta(A_i) \backslash \delta(\phi_i)$) contributes ≥ 1 ($\geq 1/2$) to the l.h.s. of inequality (σ); see inequality (4.13). (Figure 6(a) illustrates the general scheme.) For each $A_i \in \mathcal{F}$ with $|\phi_i| = 1$, let $A_{c(i)} \in \mathcal{F}$ be an arbitrary T-child of A_i such that $1 \leq |\phi_{c(i)}| \leq k$; $A_{c(i)}$ exists by Assumption 2. Inequality (σ) implies inequality (4.10) because the deficit contributed by each $A_i \in \mathcal{F}$ with $|\phi_i| = 1$ is compensated by the surplus contributed by $A_{c(i)}, \phi_{c(i)}$. To see this, focus on an arbitrary $A_i \in \mathcal{F}$ with $|\phi_i| = 1$ and let $j = c(i)$. First observe that if an edge $vw \in \delta(A_j)$ with $v \in A_j$ is not in $\delta(A_i)$, then there are three possibilities: (i) $v \in \phi_j,\ w \in \phi_i$, (ii) $v \notin \phi_j,\ w \in \phi_i$, i.e., $v \in A_g$, where $A_g \in \mathcal{F}$ corresponds to a child of A_j in the tree T, and (iii) $v \in A_j,\ w \in A_i \backslash [A_j \cup \phi_i]$, i.e., $w \in A_q$, where $A_q \in \mathcal{F}$ corresponds to a sibling of A_j in the tree T. (Figure 6(b) illustrates the three possibilities.) Second, observe that

$$\begin{aligned}|\delta(A_i) \cap \delta(\phi_i)| &\leq |\delta(A_j) \backslash \delta(A_i)| \\ &= |\delta(A_j \backslash \phi_j) \cap \delta(\phi_i)| + |\delta(A_j) \cap \delta(A_i \backslash [A_j \cup \phi_i])| + |\delta(\phi_j) \cap \delta(\phi_i)|.\end{aligned}$$

For each of the first two terms t on the r.h.s., A_j, ϕ_j contributes a surplus of at least $t/2$ to the l.h.s. of inequality (σ), because (i) every edge in two distinct k-cuts $\delta(A_g)$ and $\delta(A_j)$, $A_g \in \mathcal{F}$, $A_j \in \mathcal{F}$, $A_g \subset A_j$, contributes a surplus of $1/2$ or more, since $A_h \in \mathcal{F}$ such that $\delta(\phi_h) \cap \delta(A_h)$ contains the edge contributes one for the edge, and every other $A \in \mathcal{F}$ such that $\delta(A)$ contains the edge contributes $\geq 1/2$ for the edge; (ii) every edge in two distinct k-cuts $\delta(A_q)$ and $\delta(A_j)$, $A_q \in \mathcal{F}$ disjoint from $A_j \in \mathcal{F}$, contributes a surplus of one or more.

Focus on the third term $|\delta(\phi_j) \cap \delta(\phi_i)|$, and note that its value is $\leq |\phi_j|$, since $|\phi_i| = 1$ and the graph is simple. If $|\phi_j| = 1$, then the deficit contributed by A_i, ϕ_i (to the l.h.s. of inequality (σ)) is compensated, because the surplus of $\frac{k}{k+1}$ (on the l.h.s. of A_i's inequality) is $\geq \frac{1}{2}$ (for $k \geq 1$), hence

$$\frac{1}{2}|\delta(A_i) \cap \delta(\phi_i)| \quad \leq \quad \frac{1}{2}|\delta(A_j \backslash \phi_j) \cap \delta(\phi_i)| + \frac{1}{2}|\delta(A_j) \cap \delta(A_i \backslash [A_j \cup \phi_i])| + \frac{k}{k+1}.$$

If $2 \leq |\phi_j| \leq k$, then the deficit contributed by A_i, ϕ_i (to the l.h.s. of inequality (σ)) is compensated, because the surplus of $\frac{k-1}{2(k+1)}|\phi_j| + \frac{k}{k+1}$ (on the l.h.s. of A_j's and A_i's inequalities) is $\geq |\phi_j|/2$ (for $k \geq |\phi_j| \geq 1$), hence

$$\begin{aligned}\frac{1}{2}|\delta(A_i) \cap \delta(\phi_i)| \leq{}& \frac{1}{2}|\delta(A_j \backslash \phi_j) \cap \delta(\phi_i)| \\ &+ \frac{1}{2}|\delta(A_j) \cap \delta(A_i \backslash [A_j \cup \phi_i])| + \frac{k-1}{2(k+1)}|\phi_j| + \frac{k}{k+1}.\end{aligned}$$

This completes the proof of Claim 4 and the proof of the theorem. □

THEOREM 4.7. *Let $G = (V, E)$ be a graph of edge connectivity $\geq k \geq 1$. The heuristic described above finds a k-edge connected spanning subgraph (V, E') such that*

$|E'| \leq (1 + [2/(k+1)])|E_{opt}|$, *where* $|E_{opt}|$ *denotes the cardinality of an optimal solution. The running time is* $O(k^3|V|^2 + |E|^{1.5}(\log |V|)^2)$.

4.2. Directed graphs. The heuristic for finding an approximately minimum-size k-edge connected spanning subgraph of a digraph has two steps. Similarly to section 3.4, the first step finds a minimum-cardinality arc set $M \subseteq E$ such that for every node v, there are $\geq k$ arcs of M going out of v and $\geq k$ arcs of M coming into v. Clearly, $|M| \leq |E_{opt}|$, where $E_{opt} \subseteq E$ denotes a minimum-cardinality arc set such that (V, E_{opt}) is k-edge connected. The second step of the heuristic finds an (inclusionwise) minimal arc set $F \subseteq E \backslash M$ such that $E' = M \cup F$ is the arc set of a k-edge connected spanning subgraph. To prove the approximation guarantee, we need to estimate $|F|$. We use the notion of special arcs to estimate $|F|$. Call an arc (v, w) of a k-edge connected digraph *special* if the arc is critical, and in addition, if $\deg_{out}(v) \geq (k+1)$ and $\deg_{in}(w) \geq (k+1)$. Clearly, every arc in F is a special arc of the digraph $G' = (V, E')$, $E' = M \cup F$, returned by the heuristic. We can deduce a bound of $O(\sqrt{k}|V|)$ on the number of special arcs in G' by examining chains of tight node sets $S_1 \subset S_2 \subset \cdots \subset S_q$, where a node set S_i is called tight if G' has exactly k arcs in $\delta_{out}(S_i)$.

THEOREM 4.8. *Let* $k \geq 1$ *be an integer, and let* H *be a* k*-edge connected,* n*-node digraph. The number of special arcs in* H *is at most* $4\sqrt{k} \cdot n$.

Proof. Let V denote $V(H)$ for this proof. Each special arc e is in a k-dicut $\delta_{out}(A_e) = \delta_{in}(V \backslash A_e)$, where $2 \leq |A_e| \leq n-2$. As in section 4.1, we obtain *two* laminar families of tight node sets $\mathcal{F}_{out}$ and $\mathcal{F}_{in}$ that cover all the special arcs: that is, for each $A_i \in \mathcal{F}_{out}$ ($A_i \in \mathcal{F}_{in}$), A_i is a set of H-nodes, $\delta_{out}(A_i)$ ($\delta_{in}(A_i)$) has k arcs including at least one special arc, and each special arc is in some $\delta_{out}(A_i)$, $A_i \in \mathcal{F}_{out}$, or is in some $\delta_{in}(A_i)$, $A_i \in \mathcal{F}_{in}$. Focus on $\mathcal{F}_{out}$; the analysis is symmetric for $\mathcal{F}_{in}$. Let $\mathcal{F}_{out} = \{A_1, A_2, \ldots, A_\ell\}$. To estimate the number of special arcs, we need to examine the tree T corresponding to $\mathcal{F}_{out} \cup \{V(H)\}$. For $i = 1, \ldots, \ell$, recall that the T-node corresponding to a node set $A_i \in \mathcal{F}_{out}$ is also denoted A_i (the T-node corresponding to $V(H)$ is denoted by V), and recall that ϕ_i denotes $A_i \backslash \cup\{A \in \mathcal{F}_{out} : A \subset A_i,\ A \neq A_i\}$. Partition the set $\{A_1, \ldots, A_\ell\}$ of T-nodes into two sets R_1 and R_2, where R_2 consists of the T-nodes incident to precisely two T-edges and $R_1 = \{A_1, \ldots, A_\ell\} \backslash R_2$. Note that $V \notin R_1$ and $V \notin R_2$.

Claim 5. $|R_1| \leq 2|V_1|/(k+1)$, where V_1 denotes the set of H-nodes in $\bigcup\{\phi_i : A_i \in R_1\}$.

Here is the proof of Claim 5. Let T_1 be the tree obtained from the tree T by "unsubdividing" all the T-nodes in R_2, i.e., by repeatedly replacing a degree-2 T-node in R_2 and its two incident edges by an edge between the two neighbors. Then T_1 is a tree whose nonleaf T-nodes in R_1 have T_1-degree ≥ 3, whereas the T-node V may have T_1-degree 1, 2, or ≥ 3. Let ℓ_1 be the number of leaf nodes (degree-1 nodes) of T_1 in R_1. Then, $|R_1| \leq \ell_1 + (\ell_1 + 1) - 2 \leq 2\ell_1$. Now, Claim 5 follows because $\ell_1 \leq |V_1|/(k+1)$, because for each (inclusionwise) minimal $A_i \in \mathcal{F}_{out}$, the set $\phi_i = A_i$ of H-nodes has cardinality at least $(k+1)$ by the digraph version of Lemma 4.2(ii). (A_i contains a node v with $\deg_{out}(v) \geq (k+1)$ since $\delta_{out}(A_i)$ contains a special arc.)

Now focus on a maximal path $P = A_0, A_1, \ldots, A_{q+1}$ of T such that every T-node A_i with $1 \leq i \leq q$ is in R_2. In H, the node sets $A_0, A_1, \ldots, A_{q+1}$ satisfy $A_0 \subset A_1 \subset \cdots \subset A_{q+1}$, and for $i = 1, \ldots, q$, if $A' \in \mathcal{F}_{out}$ is contained in A_i, then either $A' = A_{i-1}$ or $A' \subset A_{i-1}$. Let V_P denote the set of H-nodes $\phi_1 \cup \phi_2 \cup \cdots \cup \phi_q$. Also, note that for $i = 1, 2, \ldots, q$, $A_i = A_0 \cup \phi_1 \cup \phi_2 \cup \cdots \cup \phi_i$.

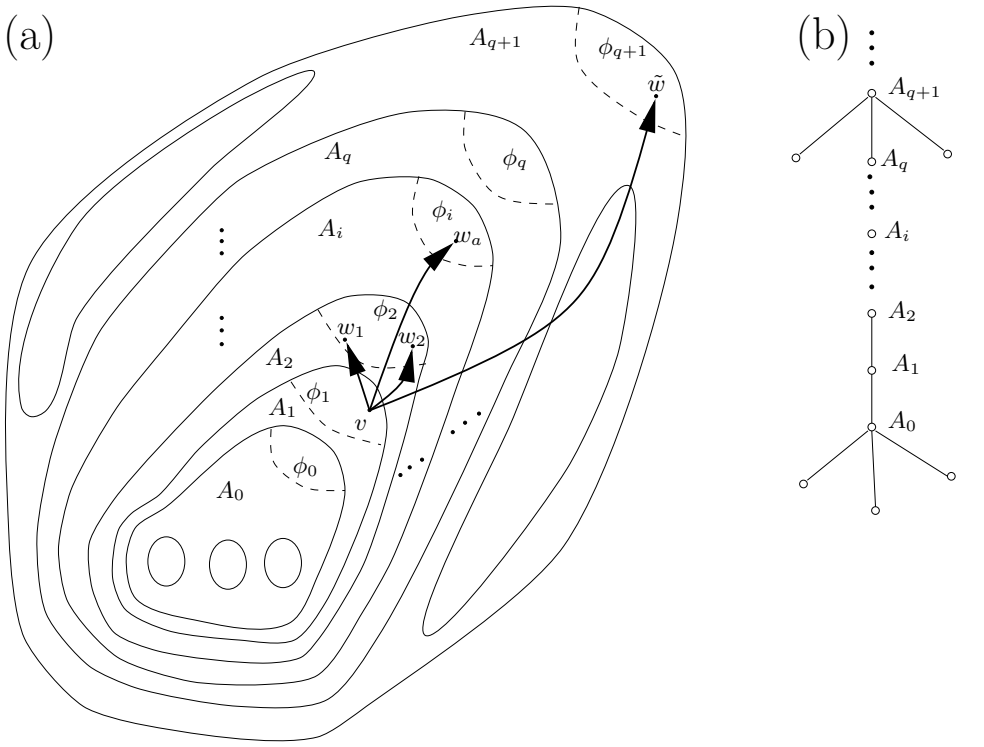

FIG. 7. *An illustration of Claim* 6 *in the proof of Theorem* 4.8. (a) *A subfamily of the laminar family of tight node sets* $\mathcal{F}_{out}$ *that covers (some of) the special arcs.* (b) *The subtree corresponding to the subfamily of* $\mathcal{F}_{out}$ *in* (a). *Each of the* T*-nodes* $A_1, A_2, \ldots, A_q$ *is incident to exactly two edges of* T, *where* T *is the tree corresponding to* $\mathcal{F}_{out}$.

Claim 6. The number of arcs (v, w) such that $v \in V_P$ and $(v, w) \in \bigcup\{\delta_{out}(A_i) : 1 \le i \le q\}$ is at most $k + 2\sqrt{k} \cdot |V_P|$.

Here is the proof of the Claim 6; see Figure 7 for an illustration. The additional term of k in the upper bound accounts for the arcs with start nodes in A_q and end nodes in $V \backslash A_q$; there are at most k such arcs, since each such arc is in $\delta_{out}(A_q)$. Now ignore the arcs in $\delta_{out}(A_q)$. Linearly order the H-nodes in V_P such that for each i, $1 \le i < q$, the H-nodes in ϕ_i precede the H-nodes in ϕ_{i+1}. Let v be an arbitrary node in V_P. Let $\Gamma_v \subseteq V_P$ denote the set of end nodes w_j of the arcs (v, w_j) outgoing from v such that $w_j \in V_P$ and $(v, w_j) \in \bigcup\{\delta_{out}(A_i) : 1 \le i \le q\}$. Let the linear ordering of the nodes in Γ_v be $w_1, w_2, \ldots, w_{|\Gamma_v|}$. Call an arc (v, w_j) *short* if $j \le \sqrt{k}$, otherwise, call the arc *long*. We "charge" each long arc (v, w_j) to the first $\sqrt{k}$ nodes $w_1, w_2, \ldots, w_{\sqrt{k}}$ in Γ_v, i.e., each of these nodes is charged $1/\sqrt{k}$ for each arc (v, w_j), $w_j \in \Gamma_v$, and $j > \sqrt{k}$. Now consider the total charge on an arbitrary node $w_a \in V_P$ due to all long arcs $(x, y) \in \bigcup\{\delta_{out}(A_i) : 1 \le i \le q\}$ with $x \in V_P$ and $y \in V_P$. The key fact is this: the total charge on w_a is at most $\sqrt{k}$. To see this suppose that $w_a \in \phi_i$, where $1 \le i \le q$. Then for every arc (v, w_j) charged to w_a, $(v, w_j) \in \delta_{out}(A_{i-1})$, because $v \in A_i \backslash \phi_i$ (if $v \in V \backslash A_i$ or $v \in \phi_i$, then clearly Γ_v does not contain a node of ϕ_i such as w_a). Furthermore, by the linear ordering of Γ_v, $w_j \in \phi_i \cup \phi_{i+1} \cup \cdots \cup \phi_q$, i.e., $w_j \notin A_{i-1}$. Since $\delta_{out}(A_{i-1})$ has k arcs, the total charge to w_a is at most $k \cdot (1/\sqrt{k}) = \sqrt{k}$. Finally, consider the total number, m_P, of short arcs $(x, y) \in \bigcup\{\delta_{out}(A_i) : 1 \le i \le q\}$ with $x \in V_P$ and $y \in V_P$. Obviously, m_P is at

most $\sqrt{k}|V_P|$. Claim 6 is completed by summing up the three terms: k (for arcs in $\delta_{out}(A_q)$), $\sqrt{k}|V_P|$ (for the total charge on nodes $w \in V_P$), and $\sqrt{k}|V_P|$ (for m_P).

We account for the special arcs in $\delta_{out}(A_q)$ by "charging" the additional term of k to the "unsubdivided edge" A_0A_{q+1} of the tree T_1 in the proof of Claim 5. Thus each edge A_iA_{i+q+1}, $A_i \subset A_{i+q+1}$, of T_1 is "charged" for $\leq 2k$ special arcs (these are the special arcs in $\delta_{out}(A_i) \cup \delta_{out}(A_{i+q})$). Since the number of edges in T_1 is $\leq |R_1|$, the number of special arcs contributed by the T-nodes in R_1 is $\leq 2k|R_1|$. We "charge" $2\sqrt{k}$ to each H-node v such that $v \in \phi_i$ for a T-node $A_i \in R_2$. Combining the contributions of special arcs from the T-nodes in R_1 and R_2 and applying Claim 5, we see that the number of special arcs is at most

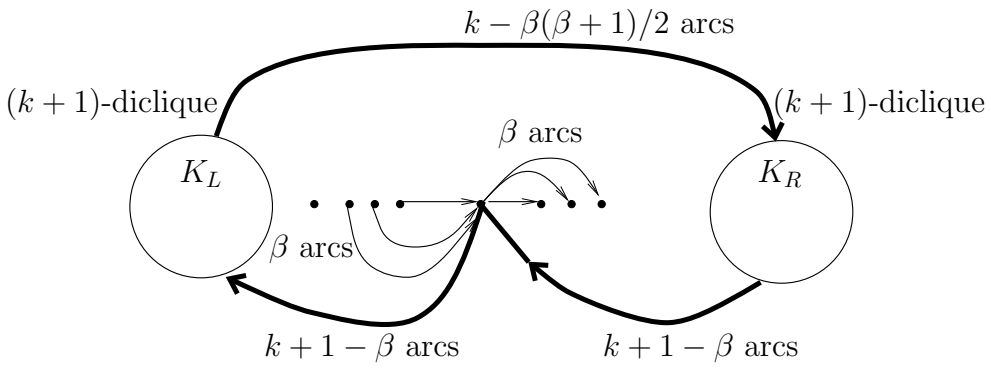
$$2k|R_1| + 2\sqrt{k} \cdot n_2 \leq \frac{4kn_1}{(k+1)} + 2\sqrt{k} \cdot n_2,$$

where n_1 and n_2 denote the cardinalities of $V_1 = \bigcup\{\phi_i : A_i \in R_1\}$ and $V_2 = \bigcup\{\phi_i : A_i \in R_2\}$, respectively. For $k \geq 1$, the number of special arcs is maximized when n_2 is the maximum possible and n_1 is the minimum possible. Since the tree T has at least two leaves, n_2 is at most $n - (2k+2)$. Hence, the number of special arcs contributed by $\mathcal{F}_{out}$ is at most $4k(2k+2)/(k+1) + 2\sqrt{k}(n-(2k+2))$. The total number of special arcs in H is at most $16k + 4\sqrt{k}(n-(2k+2)) \leq 4\sqrt{k}n$. □

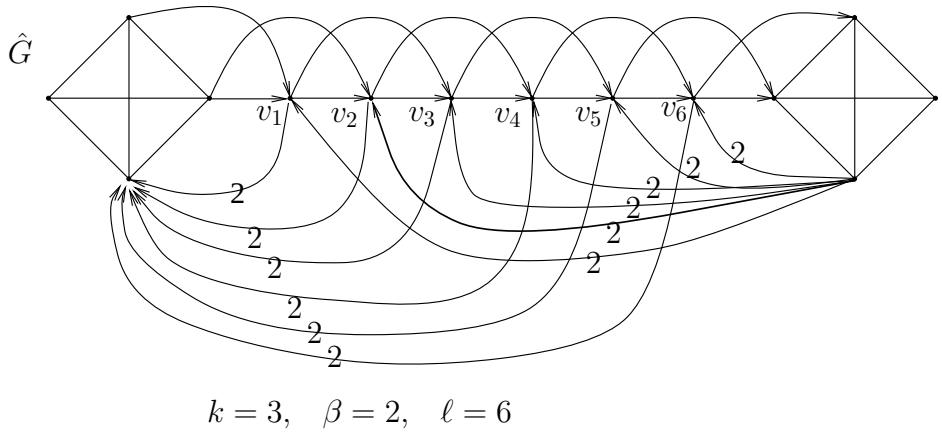
The heuristic clearly runs in time $O(k|E|^2)$. This can be improved by implementing the second step to run in time $O(k^3|V|^2)$. We run Gabow's algorithm [Ga 95] as a preprocessing step to compute a sparse certificate $\widetilde{E}$ of G for k-edge connectivity, i.e., $\widetilde{E} \subseteq E$, $|\widetilde{E}| \leq 2k|V|$, and for all nodes v, w, $(V, \widetilde{E})$ has k arc-disjoint $v \to w$ directed paths iff G has k arc-disjoint $v \to w$ directed paths. In detail, we fix a node $a \in V(G)$ and take $\widetilde{E} = \widetilde{E}_{out} \cup \widetilde{E}_{in}$, where $\widetilde{E}_{out}$ ($\widetilde{E}_{in}$) is the union of k arc-disjoint out-branchings (in-branchings) rooted at a. Gabow's algorithm [Ga 95] runs in time $O(k|V|^2)$, and the second step runs in time $O(k|\widetilde{E} \cup M|^2) = O(k^3|V|^2)$.

THEOREM 4.9. *Let $G = (V, E)$ be a digraph of edge connectivity $\geq k$. The heuristic described above finds a k-edge connected spanning subgraph (V, E') such that $|E'| \leq (1 + [4/\sqrt{k}])|E_{opt}|$, where $|E_{opt}|$ denotes the cardinality of an optimal solution. The running time is $O(k^3|V|^2 + |E|^{1.5}(\log |V|)^2)$.*

The upper bound on the number of special arcs in Theorem 4.8 is not tight but is within a factor of (roughly) 3 of the tight bound for $n \gg k$. To see this, take $n \geq 3k+2$ and consider the following k-edge connected, n-node digraph $\hat{G}$ with at least $\beta n - 2\beta(k+1) + k$ special arcs, where β is the maximum integer such that $\beta(\beta+1)/2 \leq k$, i.e., $\beta = \lfloor \sqrt{2k + 0.25} - 0.5 \rfloor$. See Figure 8 for an illustration of $\hat{G}$. $\hat{G}$ has a "left" $(k+1)$-directed clique K_L and a "right" $(k+1)$-directed clique K_R. Let $v_1, v_2, \ldots, v_\ell$ be a linear ordering of the remaining nodes, where $\ell = n - 2(k+1) \geq k$. There is one arc from v_i $(1 \leq i \leq \ell)$ to each of the next β nodes $v_{i+1}, \ldots, v_{i+\beta}$; hence, each node v_i has one arc coming in from each of the previous β nodes $v_{i-1}, \ldots, v_{i-\beta}$. (Take $v_0, v_{-1}, v_{-2}, \ldots, v_{-\beta+1}$ to mean nodes in K_L, and take $v_{\ell+1}, v_{\ell+2}, \ldots, v_{\ell+\beta}$ to mean nodes in K_R.) These β left-to-right arcs starting from v_i will turn out to be special arcs. Additionally, there are $(k+1-\beta)$ arcs from K_R to each of the nodes $v_1, v_2, \ldots, v_\ell$, and there are $(k+1-\beta)$ arcs from each of the nodes $v_1, v_2, \ldots, v_\ell$ to K_L. Finally, there are $(k - \beta(\beta+1)/2)$ arcs from K_L to K_R. This completes the construction of $\hat{G}$. It can be checked that $\hat{G}$ is k-edge connected. (Note that besides the $(k - \beta(\beta+1)/2)$ arcs from K_L to K_R, there are $\beta(\beta+1)/2$ arc-disjoint directed paths from K_L to K_R, such that there is one "one-hop" directed path, two "two-hop" directed paths, ..., β "β-hop" directed paths.) For each node set A in the laminar



Sketch of $\hat{G}$



$k = 3, \quad \beta = 2, \quad \ell = 6$

FIG. 8. *The digraph $\hat{G}$ described in the last paragraph of section* 4.2. *$\hat{G}$ has $n \geq 3k+2$ nodes and has $\geq \beta(n-2(k+1))+k$ special arcs, $\sqrt{k} \leq \beta < \sqrt{2k}$, showing that the upper bound on the number of special arcs in Theorem* 4.8 *is within a small constant factor of being tight for $n \gg k$.*

family of node sets $\{K_L, (K_L \cup \{v_1\}), \ldots, (K_L \cup \{v_1, v_2, \ldots, v_\ell\})\}$, the out-directed cut $\delta_{out}(A)$ has cardinality k, and every arc in $\delta_{out}(A)$ is a special arc.

5. Conclusions. Our analyses of the heuristics exploit results from graph theory, such as Mader's theorem [Ma 72, Theorem 1], and raise new problems in the areas of approximation algorithms and graph theory.

For a graph G and an integer $k \geq 1$, let $\mu(k, G)$ denote the minimum number of edges in a spanning subgraph of minimum degree k. For a digraph G and integer $k \geq 1$, define $\mu(k, G)$ similarly. For a graph (or digraph) G and integer $k \geq 1$, let $\mu'(k, G)$ denote the minimum number of edges (arcs) in a k-ECSS, and let $\mu''(k, G)$ denote the minimum number of edges (arcs) in a k-NCSS. While $\mu(k, G)$ can be computed efficiently via b-matchings, computing either $\mu'(k, G)$ or $\mu''(k, G)$ is NP-hard. This paper shows that (i) by computing $\mu(k-1, G)$, we can efficiently approximate $\mu''(k, G)$ to within a factor of $1 + [1/k]$ for both graphs and digraphs, and (ii) by computing $\mu(k, G)$, we can efficiently approximate $\mu'(k, G)$ to within a factor of $1 + [2/(k+1)]$

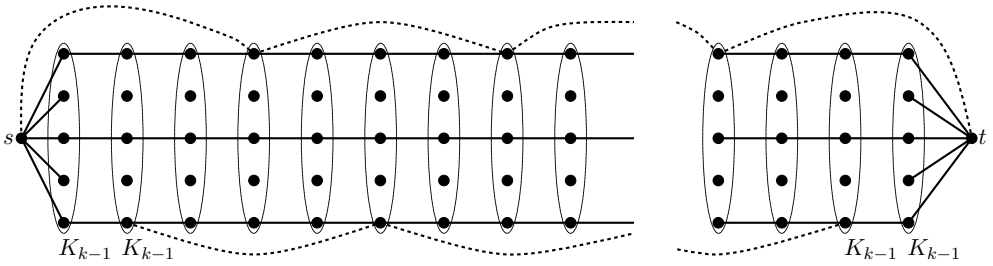


FIG. 9. *A k-node connected graph $G = (V, E)$ (with $k \geq 2$) such that the minimum size μ'' of a k-node connected spanning subgraph decreases by $(|V(G)| - 3k + 1)/(2k - 2)$ on adding one edge.*

G consists of nodes s, t, and ℓ copies of the $(k-1)$-clique, and has $k-1$ openly disjoint $s \leftrightarrow t$ paths such that each path uses exactly one node from each $(k-1)$-clique; also, G has $(\ell-1)/2$ dashed edges. Every edge in G is critical with respect to k-node connectivity. Adding the edge st to G, and then removing all the dashed edges leaves a k-node connected graph, so μ'' decreases from $|E|$ to $|E| + 1 - (\ell - 1)/2$.

A k-edge connected (and k-node connected) graph $\widetilde{G}$ such that the minimum size μ' of a k-edge connected spanning subgraph decreases by $\frac{|V(\widetilde{G})|-4k+2}{3k-3}$ on adding one edge can be obtained by modifying G as follows: "split" every $(k-1)$-clique incident with a dashed edge into a pair of $(k-1)$-cliques connected by a matching of size $(k-1)$.

for graphs, and a factor of $1 + [4/\sqrt{k}]$ for digraphs. Theorem 3.6 shows that for a k-node connected graph G, $\frac{\mu''(k,G)}{\mu'(k,G)} \leq \frac{k+1}{k}$, and Theorem 3.20 shows that for a k-node connected digraph G, $\frac{\mu''(k,G)}{\mu(k,G)} \leq \frac{k+1}{k}$. Propositions 3.4 and 3.19 show that for a k-node connected graph or digraph G, $\frac{\mu''(k,G)}{\mu(k-1,G)} \leq \frac{k+1}{k-1}$. Theorem 4.7 shows that for a k-edge connected graph G, $\frac{\mu'(k,G)}{\mu(k,G)} \leq \frac{k+3}{k+1}$.

For minimum-size k-ECSS (k-NCSS) problems, there appears to be a difficulty in achieving approximation guarantees of $1 + \frac{\omega(1)}{k^2}$. A graph theoretic function g is said to satisfy the edge Lipschitz condition if whenever graphs H and H' differ in only one edge, then $|g(H) - g(H')| \leq 1$; see [AS 92, p. 86]. Observe that $\mu(k, G)$ satisfies the edge Lipschitz condition. In contrast, both $\mu'(k, G)$ and $\mu''(k, G)$ violate this condition. First, focus on $\mu'(k, G)$ for graphs G and $k \geq 2$. Let G be the minimal k-edge connected graph obtained by "stringing" ℓ copies of the $(k+1)$-clique, i.e., take ℓ copies of the $(k+1)$-clique, and for each copy i, $1 \leq i \leq \ell$, designate a pair of distinct nodes as s_i and t_i, and then identify t_i and s_{i+1} for $i = 1, 2, \ldots, \ell - 1$. Adding the edge $s_1 t_\ell$ decreases μ' by $\ell = (|V(G)| - 1)/k$, since removing all the edges $s_i t_i$, $1 \leq i \leq \ell$, leaves a k-edge connected graph. Now consider $\mu''(k, G)$ for graphs G and $k \geq 2$. For each $k \geq 2$, there exists a k-node connected graph G such that adding a particular new edge decreases μ'' by $\frac{|V(G)|-3k+1}{2k-2}$; see Figure 9 for an illustration. For $k = 2$ and the graph in Figure 1(a), observe that μ'' decreases from $1.5|V| - 5$ to $|V| + 1$ upon adding the edge e_*. A k-edge connected (and k-node connected) graph $\widetilde{G}$ such that adding a particular new edge decreases μ' by $\frac{|V(\widetilde{G})|-4k+2}{3k-3}$ can be obtained by modifying the graph in Figure 9 as indicated in the figure caption. Garg, Santosh, and Singla [GSS 93] discuss similar issues for the minimum-size 2-NCSS problem on graphs.

Another drawback of the analysis of the k-NCSS heuristic for graphs in section 3.1 is that the size of the edge set $E' = M \cup F$ returned by the heuristic is compared against $\mu'(k, G)$, the minimum size of a k-ECSS. Given an integer $k \geq 2$, for each integer $n = 2k(i + k) + k$, where $i = 0, 1, 2, \ldots$, there exists a k-node connected,

n-node graph $\hat{G}$ such that

$$\frac{\mu''(k,\hat{G})}{\mu'(k,\hat{G})} = 1 + \frac{(k-2)}{(2k^2+k)}.$$

In view of this, for large k, a sharper lower bound will have to be employed for proving approximation guarantees substantially better than $1 + [1/2k]$ for the minimum-size k-NCSS problem. For $k = 2$ or $k = 3$, larger values of $\mu''(k,G)/\mu'(k,G)$ are given by the graph G in Figure 9 with the parameter k fixed at 2 or 3 and with $|V(G)| \gg k$: for $k = 2$, the ratio approaches $6/5$, and for $k = 3$, the ratio approaches $14/13$.

Here is another consequence of Gupta's result (see the proof of Proposition 3.8): for a bipartite graph G with minimum degree $\geq k$,

$$\frac{\mu(k-1,G)}{\mu(k,G)} \leq \frac{(k-1)}{k}.$$

This inequality does not hold for nonbipartite graphs, since for $G = K_{(k+1)}$, $\mu(k-1,G)/\mu(k,G)$ equals $(k-1)/k$ for k odd and equals $k/(k+1)$ for k even. Another result of Gupta (see [BM 76, problem 6.2.8]) shows that $\mu(k-2,G)/\mu(k,G) \leq (k-2)/(k-1)$ for all graphs G of minimum degree $\geq k$.

RANDOM SAMPLING, HALFSPACE RANGE REPORTING, AND CONSTRUCTION OF ($\leq k$)-LEVELS IN THREE DIMENSIONS*

TIMOTHY M. CHAN†

Abstract. Given n points in three dimensions, we show how to answer halfspace range reporting queries in $O(\log n + k)$ expected time for an output size k. Our data structure can be preprocessed in optimal $O(n \log n)$ expected time. We apply this result to obtain the first optimal randomized algorithm for the construction of the ($\leq k$)-level in an arrangement of n planes in three dimensions. The algorithm runs in $O(n \log n + nk^2)$ expected time. Our techniques are based on random sampling. Applications in two dimensions include an improved data structure for "k nearest neighbors" queries and an algorithm that constructs the order-k Voronoi diagram in $O(n \log n + nk \log k)$ expected time.

1. Introduction.

1.1. Halfspace range reporting. Let P be a set of n points in d-dimensional space $\mathbb{R}^d$. We consider the problem of preprocessing P so that given any query halfspace γ, one can quickly report all points in $P \cap \gamma$. A vast literature in computational geometry has been devoted to this fundamental problem called *halfspace range reporting*, a special case of *range searching* [4, 37, 49, 53, 55]. Here are some of the major known results.

First, halfspace range reporting in the planar case ($d = 2$) was solved optimally by Chazelle, Guibas, and Lee [28]. Their data structure takes linear space and answers a query in $O(\log n + k)$ time, where k is the number of reported points. The preprocessing can be accomplished in $O(n \log n)$ time using Chazelle's algorithm for *convex layers* [22]. Unfortunately, the approach does not generalize to higher dimensions.

In the $d = 3$ case, Chazelle and Preparata [29] gave a method for answering halfspace range reporting queries in optimal time $O(\log n + k)$. The space complexity is $O(n \log^2 n \log \log n)$, as noted by Clarkson and Shor [32]. The preprocessing is $O(n \log^c n)$ for a small constant c and uses shallow *levels* in arrangements (see section 1.2). Aggarwal, Hansen, and Leighton [10] subsequently improved the space bound to $O(n \log n)$ while maintaining optimal query time. However, the preprocessing is more complex, exploiting advanced techniques such as *planar separators*; a deterministic version requires near-cubic time, while a Monte Carlo version needs $O(n \log^2 n \log \log n)$ time. In particular, it remained open whether $O(n \log n)$ preprocessing time is attainable. If one is willing to sacrifice optimality in the query bound, then a simple method [25] involving a tree of *planar point location* structures solves the problem with $O(k \log^2 n)$ query time and $O(n \log n)$ preprocessing time and space.

*Received by the editors December 14, 1998; accepted for publication (in revised form) September 24, 1999; published electronically June 3, 2000. A preliminary version of this paper appeared in Proceedings of the 39th IEEE Symposium on the Foundations of Computer Science, Palo Alto, CA, 1998. This work was done while the author was at the Department of Mathematics and Computer Science, University of Miami.

†Department of Computer Science, University of Waterloo, Waterloo, Ontario N2L 3G1, Canada (tmchan@math.uwaterloo.ca).

For a larger fixed dimension $d \geq 4$, Clarkson and Shor [32] used shallow *cuttings* to achieve $O(\log n + k)$ query time with $O(n^{\lfloor d/2 \rfloor + \varepsilon})$ preprocessing time and space, where ε is an arbitrarily small positive constant. Matoušek [48] obtained a certain *partition theorem* that implies a data structure with $O(n \log n)$ preprocessing time, $O(n \log \log n)$ space, and $O(n^{1-1/\lfloor d/2 \rfloor} \log^{O(1)} n + k)$ query time. (This method can be specialized to handle the $d = 3$ case; the query time appears to be $O((\log n)^{O(\log \log n)} + k)$.) Tradeoffs between preprocessing and query time were also described by Matoušek. These higher-dimensional results were conjectured to be optimal up to n^{ε} or polylogarithmic factors.

The first result of this paper is to close the existing gap for halfspace range reporting for the case $d = 3$. In section 2, we give a relatively simple, randomized (Las Vegas) method that can answer queries in $O(\log n + k)$ expected time. This data structure requires $O(n \log n)$ space and can be preprocessed in $O(n \log n)$ expected time. The expectation here is with respect to the random choices made by the preprocessing; it is assumed that the given query halfspaces are independent of these choices. Both time bounds on preprocessing and querying are optimal.

Our approach is to consider random samples of various sizes of the dual planes and examine the *canonical triangulations* of their (≤ 0)-*levels*. With good chances, it turns out that the answer to a query with output size k can be found within some *conflict list* of the triangulation for a sample of size approximating n/k; the expected size of this list is $O(k)$. The preprocessing of all such conflict lists is done by imitating a known algorithm for the (≤ 0)-level (i.e., *convex hull* in primal space). We should remark that ideas like random sampling, canonical triangulations, and conflict lists are hardly new in this area; what is not apparent is how they can be put together to derive the optimal result. For instance, Clarkson and Shor's halfspace range reporting structure [32] uses already a top-down form of random sampling, which seems inherently suboptimal; we avoid such difficulties by adopting a bottom-up approach instead.

Our result has several important applications. For example, we can now preprocess n points in the Euclidean plane in $O(n \log n)$ expected time, such that *"k nearest neighbors" queries* can be answered in $O(\log n + k)$ expected time; this and the related *circular range reporting* problem are two of the most basic proximity problems, dating back to the beginning of computational geometry. For another application, we can enumerate the k *bichromatic closest pairs* of n planar points in $O(n \log n + k)$ expected time. See section 2.3. One less obvious application—the construction of levels in arrangements—is the second main topic of this paper.

1.2. Levels in arrangements. Given a set H of n hyperplanes in d-dimensional space $\mathbb{R}^d$ and $0 \leq k \leq n$, define the region

$$\mathrm{lev}_k(H) \;=\; \{q \in \mathbb{R}^d : \text{at most } k \text{ hyperplanes of } H \text{ pass strictly below } q\}.$$

The $(\leq k)$-*level* in the arrangement of H is the collection of faces in the arrangement that are contained in $\mathrm{lev}_k(H)$. The related notion of the k-*level* can be defined as the collection of faces contained in the boundary of $\mathrm{lev}_k(H)$. Levels in arrangements are among the most well-studied, yet most puzzling, geometric structures in both their combinatorial and computational aspects [8, 37, 43, 53].

Our initial focus is on $(\leq k)$-levels. The main combinatorial question here was answered by Clarkson and Shor [32], who showed via a beautiful random sampling argument that the $(\leq k)$-level in a fixed dimension d can have at most $O(n^{\lfloor d/2 \rfloor} k^{\lceil d/2 \rceil})$ faces. This bound is tight in the worst case. The computational complexity of $(\leq k)$-levels was also essentially resolved for $d = 2$ and $d \geq 4$. Everett, Robert, and Van

Kreveld [42] gave an $O(n \log n + nk)$-time algorithm in the plane (see also [12]). Mulmuley [52] gave a randomized algorithm for dimensions four and higher with expected running time $O(n^{\lfloor d/2 \rfloor} k^{\lceil d/2 \rceil})$. These two results are optimal in view of Clarkson and Shor's bound and the trivial $\Omega(n \log n)$ lower bound.

The important case $d = 3$, however, remains an open problem, even though a number of algorithms have been developed. A randomized algorithm of Mulmuley [52], for instance, runs in expected time $O(nk^2 \log(n/k))$, which is just a logarithmic factor away from optimal. Agarwal et al. [2] proposed a different randomized algorithm with expected running time $O(n \log^3 n + nk^2)$, which is optimal for sufficiently large k. In section 3, we settle the complexity of the three-dimensional case completely by giving a randomized algorithm with an $O(n \log n + nk^2)$ expected time bound; this is optimal for all values of k. Before, this time bound was known only for the special case where the input planes are *nonredundant*, i.e., they all bound the (≤ 0)-level [9, 52].

Our approach deviates from the previous algorithms of Mulmuley and Agarwal et al. [2] in that it does not follow the randomized incremental paradigm [32, 53]. Instead, the idea (at a high level) is to choose a random sample of size n/k and use the canonical triangulation of its arrangement to divide the problem into roughly $O(n/k)$ subproblems of average size $O(k)$. These subproblems are created from conflict lists—computable by halfspace range reporting—and are then solved by brute force in $O(k^3)$ average time. The analysis of our algorithm is based on a *shallow cutting lemma* of Matoušek.

A similar approach can be taken to compute the k-level, although optimality is not yet attained for this problem. First, the combinatorial problem of determining the worst-case size of the k-level is wide open (the dual is related to the famous *k-set problem* [8, 11, 37]). Significant development occurred recently in the planar case $d = 2$ when Dey [34] improved the long-standing upper bound of (roughly) $O(n\sqrt{k})$ to $O(nk^{1/3})$, but the current best lower bound remains $\Omega(n \log k)$ [41]. For $d = 3$, the most recent upper bound is $O(nk^{5/3})$ [1, 35]. For higher dimensions, the current upper bound is only slightly better than the $O(n^{\lfloor d/2 \rfloor} k^{\lceil d/2 \rceil})$ bound for the larger ($\leq k$)-level. There is a case where the exact complexity of the k-level is known: if $d = 3$ and all input planes are nonredundant, then the k-level has size $\Theta(nk)$ for $k \leq n/2$ [32, 46]. The k-level in this case is related to the *order-k Voronoi diagram* of n points in the Euclidean plane—a natural extension to one of the most fundamental and useful geometric structures, the *Voronoi diagram*.

Some of the algorithmic results obtained by Agarwal et al. [2] on the k-level can be improved by our techniques. Specifically, their expected time bound of $O(n \log^2 n + nk^{1/3} \log^{2/3} n)$ for the construction of k-levels in the plane can be reduced to $O(n \log n + nk^{1/3} \log^{2/3} k)$. Furthermore, their $O(n \log^3 n + nk \log n)$ algorithm for order-k Voronoi diagrams in the plane can be sped up to run in $O(n \log n + nk \log k)$ expected time. These results are described in section 3.3.

2. Halfspace range reporting in $\mathbb{R}^3$.

2.1. Preliminaries. Let H be a given set of n (nonvertical) hyperplanes in $\mathbb{R}^d$. For simplicity, we assume that they are in general position; standard perturbation techniques [38, 17] can be applied to remove this assumption. The halfspace range reporting problem by *duality* [37, 53] is equivalent to the following: preprocess H so that given a query point q, one can quickly report all hyperplanes of H below q. We will actually solve a slightly harder problem: preprocess H so that given a query vertical line ℓ and a number k, one can quickly report the k lowest hyperplanes along ℓ

(i.e., hyperplanes defining the k lowest intersections with ℓ). The connection between halfspace range reporting queries and such *"k lowest hyperplanes" queries* will be explained later.

Given a subset $R \subset H$, the (≤ 0)-level in the arrangement of R (also called the *lower envelope* of R) is a convex polyhedron. Computing this polyhedron is equivalent to constructing the *convex hull* [37, 53, 55] by duality. For $d = 3$, several $O(|R| \log |R|)$-time algorithms are known [32, 54], among the simplest of which are based on the randomized incremental paradigm.

Let $\mathrm{CT}_0(R)$ denote the collection of (closed) full-dimensional simplices in the *canonical triangulation* of the (≤ 0)-level, as defined for instance by Clarkson [31] (also called the *bottom-vertex triangulation*). The precise definition of this triangulation is not important to us except in the proof of the sampling lemma below. The only facts we need is that the triangulation is linear-time constructible and that the simplices in $\mathrm{CT}_0(R)$ are all vertical cylinders containing the point $(0, \ldots, 0, -\infty)$.

Thus, a vertical line ℓ hits precisely one simplex Δ in $\mathrm{CT}_0(R)$, if one ignores degenerate cases. For $d = 3$, this simplex Δ can be identified in $O(\log |R|)$ time after an $O(|R| \log |R|)$-time preprocessing, as the problem projects down to *planar point location* [37, 55].

Given a simplex Δ, the *conflict list* H_Δ is defined as the set of all hyperplanes of H intersecting Δ. The following two sampling results are needed in the analysis of our data structure. Both follow from the general probabilistic technique by Clarkson and Shor [32]. (The first is often used in analyses of randomized convex hull algorithms.)

LEMMA 2.1. *Let $1 \leq r \leq n$ and consider a random sample $R \subset H$ of size r.*

(i) *The expected value of the sum $\sum_\Delta |H_\Delta|$ over all simplices $\Delta \in \mathrm{CT}_0(R)$ is $O(r^{\lfloor d/2 \rfloor} \cdot n/r)$.*

(ii) *For any fixed vertical line ℓ, the expected value of $|H_\Delta|$ for the simplex $\Delta \in \mathrm{CT}_0(R)$ hit by ℓ is $O(n/r)$.*

2.2. The data structure for $d = 3$. We take a common approach called *bottom-up sampling* by Mulmuley [53]. Choose a random permutation $h_1, \ldots, h_n$ of the set H. Define $R_i = \{h_1, \ldots, h_{2^i}\}$ for $i = 0, 1, \ldots, \log n$ (without loss of generality, say n is a power of 2; logarithms are in base 2). The result is a sequence ("hierarchy") of random samples

$$R_0 \subset R_1 \subset \cdots \subset R_{\log n} = H,$$

where $|R_i| = 2^i$. Our basic data structure is simple: it consists of location structures for $\mathrm{CT}_0(R_i)$, along with the conflict list H_Δ for all the simplices $\Delta \in \mathrm{CT}_0(R_i)$. For each R_i, the space needed is $O(\sum_{\Delta \in \mathrm{CT}_0(R_i)} |H_\Delta|)$, which has expected value $O(n)$ by Lemma 2.1(i). The total expected space is therefore $O(n \log n)$. We can guarantee that space is within a constant factor of this bound by repeating for an expected constant number of trials.

We now describe how to build this data structure efficiently. First the location structures can all be constructed in time $O(\sum_{i=1}^{\log n} |R_i| \log |R_i|) = O(n \log n)$. The nontrivial part is the computation of the conflict lists. It turns out that this can be done by just modifying a known randomized algorithm for convex hulls in $\mathbb{R}^3$. We consider here Clarkson and Shor's original method [32], which maintains global conflict information incrementally. (Note that online methods based on *history* [53] are not suitable for our purposes.)

Specifically, at the 2^ith step of Clarkson and Shor's method (in the version described by Mulmuley's or Motwani and Raghavan's text [53, 50]), we not only have

all vertices of the (≤ 0)-level in the arrangement of R_i, but in addition have for each plane $h \in H$ a pointer to some vertex lying above h (if one exists). By a graph search, we can generate all vertices lying above each h. As a result, we have for each vertex v a list of all planes of H below v. Given a simplex $\Delta \in \mathrm{CT}_0(R_i)$ with vertices v_1, v_2, v_3, the conflict list H_Δ is just the union of the list of planes of H below the v_j's.

Clarkson and Shor's method runs in $O(n \log n)$ expected time. The extra work done at the 2^ith step to produce the conflict lists is $O(\sum_{\Delta \in \mathrm{CT}_0(R_i)} |H_\Delta|)$, which has expected value $O(n)$ by Lemma 2.1(i). Hence, the whole preprocessing of our data structure can be performed in $O(n \log n)$ expected time.

We now describe the basic query algorithm. Given vertical line ℓ and number k as input parameters, the algorithm is usually able to find the k lowest planes of H along ℓ but occasionally may report failure instead. The probability of failure is controlled by a third input parameter $\delta > 0$.

ALGORITHM ANSWER-QUERY(ℓ, k, δ)

1. let $i = \lceil \log \lceil n\delta/k \rceil \rceil$
2. identify the simplex $\Delta \in \mathrm{CT}_0(R_i)$ cut by ℓ
3. if $|H_\Delta| > k/\delta^2$ then return "failed"
4. if fewer than k planes of H_Δ intersect $\ell \cap \Delta$ then return "failed"
5. return the k lowest planes of H_Δ along ℓ

The algorithm is correct: what is returned in line 5 is precisely the k lowest planes of H along ℓ if failure is not reported in line 4. The running time of ANSWER-QUERY() is $O(\log n + k/\delta^2)$, since line 2 takes $O(\log n)$ time by planar point location, and lines 4 and 5 take $O(k/\delta^2)$ time if failure is not reported in line 3. (Line 5 is an instance of what Chazelle referred to as *filtering search* [23].)

We now bound the failure probability for any fixed choice of ℓ, k, and δ. By Lemma 2.1(ii), the expected value of $|H_\Delta|$ is $O(n/|R_i|) = O(k/\delta)$, and so by Markov's inequality, the probability that H_Δ exceeds k/δ^2 is $O(\delta)$. Thus line 3 reports failure with probability $O(\delta)$. On the other hand, letting q denote the kth lowest intersection of H along ℓ, we see that line 4 reports failure only if $q \notin \Delta$, or equivalently, $q \notin \mathrm{lev}_0(R_i)$. This is true only if one of the k planes below q is chosen to be in the sample R_i. As q is independent of R_i, this can happen with probability at most $k|R_i|/n = O(\delta)$.

We can summarize our result as follows.

THEOREM 2.2. *In $O(n \log n)$ expected time, one can preprocess n planes in $\mathbb{R}^3$ into a randomized data structure of $O(n \log n)$ size, such that there is a procedure with the following behavior. Given any fixed vertical line ℓ, number k, and $\delta > 0$, the procedure either reports the k lowest planes along ℓ or reports failure. The probability of failure is $O(\delta)$, but the procedure always runs within $O(\log n + k/\delta^2)$ time.*

2.3. Consequences. It is desirable to modify the data structure to have a query algorithm that never fails. This modification can be done in two stages. First we observe that having three independent versions of the basic data structure can reduce the failure probability to $O(\delta^3)$ in Theorem 2.2.

COROLLARY 2.3. *In $O(n \log n)$ expected time, one can preprocess n planes in $\mathbb{R}^3$ into a randomized data structure of $O(n \log n)$ size, such that there is a procedure satisfying the criteria stated in Theorem 2.2 but with failure probability $O(\delta^3)$.*

Next we apply the basic query algorithm on a sequence of choices for the parameter δ in order to guarantee success.

COROLLARY 2.4. *In $O(n \log n)$ expected time, one can preprocess n planes in $\mathbb{R}^3$ into a randomized data structure of $O(n \log n)$ size, such that any "k lowest planes"*

query can be answered in $O(\log n + k)$ expected time.

Proof. Let $\delta_i = 2^{-i}$. Run the procedure of Corollary 2.3 for $\delta = \delta_1, \delta_2, \ldots$ until it succeeds. Let X_i denote the 0-1 random variable with value 1 when the procedure fails for $\delta = \delta_i$. The total running time is bounded asymptotically by

$$(\log n + k/\delta_1^2) + \sum_{i>1} (\log n + k/\delta_i^2)\, X_{i-1},$$

which has expected value $O(\sum_{i>1} (\log n + k/\delta_i^2)\, \delta_{i-1}^3) = O(\log n + k)$. □

We still have to explain how halfspace range reporting queries reduces to "k lowest planes" queries. This can be done by a standard technique of "guessing" the parameter k.

COROLLARY 2.5. *In $O(n \log n)$ expected time, one can preprocess n points in $\mathbb{R}^3$ into a randomized data structure of $O(n \log n)$ size, such that a halfspace range reporting query can be answered in $O(\log n + k)$ expected time, where k is the number of points reported.*

Proof. Recall that a halfspace range reporting query in dual space corresponds to finding all k planes below a given point q; the value of k is not known in advance. Let $k_i = 2^i \log n$, and let ℓ be the vertical line at q. This task can be accomplished by searching for the k_ith lowest plane along ℓ for $i = 1, 2, \ldots$ until such a plane lies above q; then we simply examine the k_i lowest planes along ℓ and report those that are actually below q. The expected running time is asymptotically bounded by

$$(\log n + k_1) + \sum_{k_{i-1} < k} (\log n + k_i) = O(\log n + k),$$

because of Corollary 2.4. □

Remarks.

1. While the preprocessing and query time are optimal, they are only expected bounds; furthermore, the space complexity can be improved. Using advanced tools and a larger preprocessing time, Appendix C gives a modification of our data structure that is deterministic and uses only $O(n \log \log n)$ space.

2. It is worthwhile to compare Chazelle, Guibas, and Lee's optimal method [28] with the specialization of our method in two dimensions. Ours seems easier to implement as convex layers are not involved.

3. Higher-dimensional extensions are possible, although we do not see any significant improvements.

By a standard lifting map, Corollaries 2.4 and 2.5 imply a new method for *"k nearest neighbors"* and *circular range reporting queries* [10, 16, 25, 37, 53, 55, 57] in the Euclidean plane.

COROLLARY 2.6. *In $O(n \log n)$ expected time, one can preprocess n point sites in $\mathbb{R}^2$ into a randomized data structure of $O(n \log n)$ size, such that the k closest (or farthest) sites of a given point can be found in $O(\log n + k)$ expected time.*

COROLLARY 2.7. *In $O(n \log n)$ expected time, one can preprocess n point sites in $\mathbb{R}^2$ into a randomized data structure of $O(n \log n)$ size, such that all sites inside (or outside) a given circle can be reported in $O(\log n + k)$ expected time, where k is the output size.*

Another proximity application in the Euclidean plane is an optimal randomized algorithm for enumerating the k *bichromatic closest pairs* [45]. The author [19] gave a randomized reduction of this problem to a reporting problem, which in turn reduces

to answering n offline halfspace range reporting queries in $\mathbb{R}^3$, where the total output size is k.

COROLLARY 2.8. *Given n-point sets P and Q in $\mathbb{R}^2$, one can enumerate the k closest (or farthest) pairs from $P \times Q$ (not necessarily in sorted order) in expected time $O(n \log n + k)$.*

3. ($\leq k$)-levels in $\mathbb{R}^3$.

3.1. Preliminaries. Let H be a given set of n hyperplanes in $\mathbb{R}^d$ in general position. Our goal in this section is to construct the facial structure of the ($\leq k$)-level in the arrangement of H. As before, the key concept is the canonical triangulation. Given a subset $R \subset H$, define $\mathrm{CT}(R)$ to be the collection of full-dimensional simplices in the canonical triangulation of the faces in the arrangement of R. Define $\mathrm{CT}_k(R)$ similarly for the faces of the ($\leq k$)-level in the arrangement of R.

It is somewhat more involved to compute conflict lists for simplices arising from the construction of ($\leq k$)-levels, e.g., the simplices are not necessarily vertical cylinders now. For this reason, we define $\Delta^* = \mathrm{conv}(\Delta \cup \{(0, \ldots, 0, -\infty)\})$, the *vertical extension* of a simplex Δ. For $d = 3$, the extended conflict list H_{Δ^*} can be computed in $O(\log n + |H_{\Delta^*}|)$ expected time after $O(n \log n)$-time preprocessing by Corollary 2.5: listing all planes of H below a given point reduces to halfspace range reporting, and if $v_1, \ldots, v_4$ denote the vertices of Δ, then H_{Δ^*} is just the union of the lists of planes of H below the v_j's.

One other important definition is the following: a simplex Δ is *relevant* if it intersects the region $\mathrm{lev}_k(H)$. The sampling lemma below is stated implicitly in the proof of Matoušek's *shallow cutting lemma* [48] (see Appendix B) and is needed in the analysis of our algorithm. Matoušek's proof uses probabilistic arguments of Chazelle and Friedman [27]; see Appendix A for more details.

LEMMA 3.1. *Let $1 \leq r \leq n$ and $q = kr/n + 1$. Let $f(n)$ be a* regular *function, i.e., a nondecreasing function satisfying $f(2n) = O(f(n))$. Consider a random sample $R \subset H$ of size r. The expected value of the sum $\sum_\Delta f(|H_\Delta|)$ over all relevant simplices $\Delta \in \mathrm{CT}(R)$ is bounded by $O(r^{\lfloor d/2 \rfloor} q^{\lceil d/2 \rceil} f(n/r))$.*

3.2. The algorithm for $d = 3$. The basic outline of our ($\leq k$)-level algorithm is quite simple: we pick a random sample $R \subset H$ of size n/k, generate all relevant simplices of $\mathrm{CT}(R)$, compute the ($\leq k$)-level within each such simplex Δ, and then combine the solutions.

The ($\leq k$)-level in the arrangement of H within a relevant simplex Δ can be constructed by the following procedure:

ALGORITHM SOLVE-SUBPROBLEM(Δ), where Δ is a relevant simplex

1. compute conflict list H_{Δ^*}
2. construct the ($\leq k$)-level in the arrangement of H_{Δ^*} by brute force
3. clip the resulting faces to Δ

The correctness of the procedure is easy to see (as $\mathrm{lev}_k(H) \cap \Delta = \mathrm{lev}_k(H_{\Delta^*}) \cap \Delta$). Line 1 takes $O(\log n + |H_{\Delta^*}|)$ expected time, whereas lines 2 and 3 take $O(|H_{\Delta^*}|^3)$ time by a brute force method: construct the entire arrangement of H_{Δ^*} [39] and extract the desired substructure. Since Δ is relevant, we can bound $|H_{\Delta^*}|$ by $k + |H_\Delta|$. Therefore, SOLVE-SUBPROBLEM(Δ) runs in expected time $O(\log n + (k + |H_\Delta|)^3)$.

We now describe how to generate all relevant simplices of $\mathrm{CT}(R)$. Observe that any relevant simplex of $\mathrm{CT}(R)$ must belong to $\mathrm{CT}_k(R)$ (since $\mathrm{lev}_k(H) \subseteq \mathrm{lev}_k(R)$). Assume that $\mathrm{CT}_k(R)$ is available. To generate all relevant simplices of $\mathrm{CT}_k(R)$, we perform a graph search. Say that two simplices of $\mathrm{CT}_k(R)$ are *adjacent* if they share a

common facet. Notice that a simplex can be adjacent to at most four other simplices in $\mathrm{CT}_k(R)$. Consider the following procedure.

ALGORITHM GENERATE-SUBPROBLEMS(Δ), where $\Delta \in \mathrm{CT}_k(R)$

1. mark Δ
2. SOLVE-SUBPROBLEM(Δ)
3. for each unmarked simplex Δ' adjacent to Δ do
4. let ξ be the facet shared by Δ and Δ'
5. if ξ intersects $\mathrm{lev}_k(H)$ then GENERATE-SUBPROBLEMS(Δ')

The test in line 5 can be easily accomplished from the information obtained from line 2. An initial relevant simplex $\Delta_0 \in \mathrm{CT}_k(R)$ is easy to find (e.g., pick any simplex from $\mathrm{CT}_0(R)$). If all simplices are initially unmarked and GENERATE-SUBPROBLEMS(Δ_0) is called, then all relevant simplices of $\mathrm{CT}_k(R)$ (and thus of $\mathrm{CT}(R)$) will be marked because the region $\mathrm{lev}_k(H)$ is connected.

Combining the solutions is straightforward. We just take all the output from line 2 of GENERATE-SUBPROBLEMS() in this process and "stitch" these substructures together to get the complete $(\leq k)$-level in the arrangement of H. (The implementation details of stitching are not entirely trivial though; for example, one needs to match features along common facets between simplices. This can be done in linear time, for instance, by labeling planes as integers and faces as tuples and then applying a radix sort.)

Excluding the $O(n \log n)$ preprocessing time, the expected time bound for the calls to GENERATE-SUBPROBLEMS() is

$$O\left(\sum_{\Delta}(\log n + (k + |H_\Delta|)^3)\right),$$

where the sum is taken over all relevant simplices Δ of $\mathrm{CT}(R)$. Lemma 3.1 tells us that the expectation of the above expression with respect to R for a sample size $r = n/k$ is

$$O((n/k)(\log n + k^3)) \;=\; O(n \log n + nk^2).$$

For the final piece of the algorithm, we still have to explain how $\mathrm{CT}_k(R)$ is obtained in the first place. This can be done by recursively constructing the $(\leq k)$-level in the arrangement of R. The total expected running time of our algorithm is then given by the recurrence

$$T_k(n) \;=\; T_k(n/k) \,+\, O(n \log n + nk^2),$$

which solves to $T_k(n) = O(n \log n + nk^2)$, assuming (without loss of generality) that $k \geq 2$.

THEOREM 3.2. *The $(\leq k)$-level in an arrangement of n planes in $\mathbb{R}^3$ can be constructed in $O(n \log n + nk^2)$ expected time.*

Remarks.

1. Although our algorithm is optimal for worst-case output, the running time is not the best possible if the $(\leq k)$-level has size smaller than $\Theta(nk^2)$. It remains open to devise an optimal *output-sensitive* algorithm [6, 18, 51].

2. Derandomization seems to require modification to our algorithm because the sample size is quite large. Appendix B sketches an optimal deterministic method for $(\leq k)$-levels for large k (specifically, $\log k = \Omega(\log n)$). This method works in any fixed dimension but uses advanced tools.

3. Specialization to $d = 2$ yields a new algorithm for ($\leq k$)-levels in the plane with expected running time $O(n \log n + nk)$.

3.3. Application to *k*-levels. The algorithm can be modified to construct the k-level in the arrangement of H for $d = 3$. To get good results, we need to have available an algorithm for constructing the k-level in subcubic time, say $O(f(n))$ time (randomized or deterministic).

We will make SOLVE-SUBPROBLEM(Δ) output the faces of the k-level clipped to Δ. This can be done by changing line 2 to construct just the k-level in the arrangement of H_{Δ^*} in $O(f(|H_{\Delta^*}|))$ time. In GENERATE-SUBPROBLEMS(Δ), the test in line 5 can also be performed in $O(f(|H_{\Delta^*}|))$ time, since it is equivalent to deciding whether ξ intersects the region beneath the k-level in the arrangement of H_{Δ^*}.

Thus, ignoring the $O(n \log n)$ preprocessing, the expected time to construct the entire k-level is

$$O\left(\sum_{\Delta}(\log n + f(k + |H_\Delta|))\right),$$

where the sum is taken over all relevant simplices Δ of $\mathrm{CT}(R)$. By Lemma 3.1, the expectation with respect to R for a sample size $r = n/k$ and a regular function f is $O((n/k)(\log n + f(k)))$.

Note that the recursive call to compute $\mathrm{CT}_k(R)$ is not needed now: by Theorem 3.2, the ($\leq k$)-level in the arrangement of R can be constructed in expected time $O((n/k)\log(n/k) + (n/k)k^2)$. Since $f(k) = \Omega(k^2)$, the overall complexity is $O(n \log n + (n/k)f(k))$.

The same strategy applies to k-levels in dimension $d = 2$. We therefore have shown the following.

THEOREM 3.3. *Let $\mathcal{H}$ be a class of lines in $\mathbb{R}^2$ or planes in $\mathbb{R}^3$. Suppose that the k-level in the arrangement of any set $H \subset \mathcal{H}$ of size n can be computed in $O(f(n))$ expected time, where $f(n)$ is a regular function. Then the k-level can be constructed in $O(n \log n + (n/k)f(k))$ expected time.*

Specifically, Agarwal et al. [2] have obtained the following bounds via randomized incremental construction: for lines in $\mathbb{R}^2$, $f(n) = n^{4/3}\log^{2/3} n$; and for planes in $\mathbb{R}^3$ that are tangent to the unit paraboloid, $f(n) = n^2 \log n$. The first case takes into account Dey's recent combinatorial bound on the k-level (or more precisely, on the $O(\log n)$ consecutive levels below the k-level). The second case occurs in the construction of *order-k Voronoi diagrams* [13, 37, 53, 55, 57] in the Euclidean plane by the standard lifting map; see Table 3.1 for some previous algorithms. For arbitrary planes in $\mathbb{R}^3$, we have $f(n) = n^{8/3+\varepsilon}$ by an algorithm of Agarwal and Matoušek [6] (with the known combinatorial bound [35]). Hence, Theorem 3.3 implies the following corollary.

COROLLARY 3.4. *The k-level in an arrangement of n lines in $\mathbb{R}^2$ can be constructed in expected time $O(n \log n + nk^{1/3}\log^{2/3} k)$.*

COROLLARY 3.5. *The order-k Voronoi diagram of n point sites in $\mathbb{R}^2$—i.e., the planar subdivision where two points belong to the same region iff they have the same set of k closest (or farthest) sites—can be constructed in expected time $O(n \log n + nk \log k)$.*

COROLLARY 3.6. *The k-level in an arrangement of n planes in $\mathbb{R}^3$ can be constructed in expected time $O(n \log n + nk^{5/3+\varepsilon})$.*

	$O(nk\log^2 k\,(\log n/\log k)^{O(1)})$	appendix

Remarks.

1. Theorem 3.3 can be viewed as an algorithmic version of a combinatorial result of Agarwal et al. [1], who showed basically that if the k-level in $\mathbb{R}^2$ or $\mathbb{R}^3$ has worst-case complexity $O(f(n))$, then the k-level has complexity $O((n/k)f(k))$.

2. Corollary 3.4 compares favorably with an output-sensitive algorithm of Edelsbrunner and Welzl [40], which runs in time $O(n\log n + f\log^2 n)$ for an f-face output. Only slight improvements of this algorithm were known: Cole, Sharir, and Yap [33] discussed how to reduce the second term to $O((n+f)\log^2 k)$ and the author [18] showed how to reduce the first term to $O(n\log f)$.

3. Corollary 3.5 is currently the best result for the construction of a single order-k Voronoi diagram in the plane. It is optimal for $k = O(\log n/\log\log n)$. If $f(n)$ can be improved to $O(n^2)$, then Theorem 3.3 would imply a randomized algorithm running in optimal $O(n\log n + nk)$ expected time for any $k \le n/2$.

4. It is interesting to note that while in the past, levels in arrangements have been used to solve the halfspace range reporting problem, we have taken just the reverse approach, using halfspace range reporting to construct levels. Is there a more direct way to construct levels with the same efficiency?

Update. After the conference version of this paper, Ramos [56] has recently improved Agarwal et al.'s algorithm [2] for the planar order-k Voronoi diagram and has obtained $f(n) = n^2 2^{O(\log^* n)}$, thereby reducing the expected time bound in Corollary 3.5 to $O(n\log n + nk2^{O(\log^* k)})$. For k-levels of lines in the plane, the author [21] has noted an improved bound $f(n) = n^{4/3}$, which reduces the expected time bound in Corollary 3.4 to $O(n\log n + nk^{1/3})$. There are also some new breakthroughs in output-sensitive algorithms for two-dimensional levels by Har-Peled [44] and the author [20, 21].

Appendix A. Proof sketch of Lemma 3.1. As Lemma 3.1 is the key in proving the optimality of our randomized ($\le k$)-level algorithm, a proof sketch of the lemma may be appropriate to give the reader an idea why the probabilistic bound holds. As mentioned earlier, the details of the proof are essentially embedded in the paper by Matoušek [48]. We highlight the main points here in somewhat different notation.

First the following definition is helpful: we say that a simplex Δ is *j-good* if it is contained inside the region $\mathrm{lev}_j(H)$. An immediate observation is that any relevant

simplex Δ is $(k + |H_\Delta|)$-good. It turns out that bounding the number of j-good simplices is easier than bounding the number of relevant simplices:

> The expected number of j-good simplices $\Delta \in \mathrm{CT}(R)$ is bounded by $O((r/n)^d n^{\lfloor d/2 \rfloor} j^{\lceil d/2 \rceil})$.

The reason is this: as can be seen from the definition of canonical triangulations, the number of j-good simplices of $\mathrm{CT}(R)$ is linear in the number of vertices of $\mathrm{CT}(R)$ that are contained in $\mathrm{lev}_j(H)$. We know that $\mathrm{lev}_j(H)$ has $O(n^{\lfloor d/2 \rfloor} j^{\lceil d/2 \rceil})$ vertices, and the probability that a fixed vertex in the arrangement of H appears in the arrangement of R is $O((r/n)^d)$.

The second step is to observe that the conflict size $|H_\Delta|$ is usually of the order of n/r. For instance, arguments by Clarkson and Shor [32] show that the average conflict size is expected to be $O(n/r)$. We will actually need a stronger result by Chazelle and Friedman [27] (see also [7]), stating that the number of conflict sizes of the order of tn/r decreases exponentially with t. Specifically, one can prove the following statement from our earlier bound on j-good simplices:

> The expected number of j-good simplices $\Delta \in \mathrm{CT}(R)$ with $|H_\Delta| \geq (t-1)n/r$ is $O(2^{-t}(r/n)^d n^{\lfloor d/2 \rfloor} j^{\lceil d/2 \rceil})$.

As a consequence, we can then bound a similar quantity for relevant simplices if we just substitute $k + tn/r$ for j:

> The expected number of relevant simplices $\Delta \in \mathrm{CT}(R)$ with $(t-1)n/r \leq |H_\Delta| \leq tn/r$ is $O(2^{-t}(r/n)^d n^{\lfloor d/2 \rfloor}(k + tn/r)^{\lceil d/2 \rceil})$.

Finally, we can bound the expectation of the sum $\sum_\Delta f(|H_\Delta|)$ over all relevant simplices $\Delta \in \mathrm{CT}(R)$ asymptotically by

$$\sum_{t=1}^{\infty} 2^{-t}(r/n)^d n^{\lfloor d/2 \rfloor}(k + tn/r)^{\lceil d/2 \rceil} f(tn/r) \;=\; O((r/n)^d n^{\lfloor d/2 \rfloor}(k + n/r)^{\lceil d/2 \rceil} f(n/r)),$$

since f is regular. Notice the above expression is identical to $O(r^{\lfloor d/2 \rfloor} q^{\lceil d/2 \rceil} f(n/r))$.

Appendix B. A deterministic algorithm for ($\leq k$)-levels in $\mathbb{R}^d$. In the second appendix, we briefly consider derandomization of our ($\leq k$)-level algorithm in an arbitrary fixed dimension. An optimal bound is obtained only when k is sufficiently large. The approach employs a deterministic version of Lemma 3.1, derived by Matoušek [48] using tools such as the *method of conditional probabilities* and *ε-approximations*.

LEMMA B.1 (Matoušek's shallow cutting lemma). *Let $1 \leq r \leq n$ and $q = kr/n + 1$. One can cover $\mathrm{lev}_k(H)$ by a collection of $O(r^{\lfloor d/2 \rfloor} q^{\lceil d/2 \rceil})$ simplices such that $|H_\Delta| \leq n/r$ for each simplex Δ. Furthermore, the simplices have disjoint interiors. They can be constructed in $O(n \log r)$ time, provided that $r \leq n^\alpha$ for a sufficiently small constant $\alpha > 0$ depending on d.*

Worst-case efficiency demands us to use small values of r, so we will construct the ($\leq k$)-level by divide-and-conquer: (i) pick $r = \min\{n/k, n^\alpha\}$ and find the collection of simplices by the above lemma; (ii) for each simplex Δ, compute conflict list H_{Δ^*}; (iii) construct the ($\leq k$)-level in the arrangement of H_{Δ^*} by recursion; and (iv) finally combine the solutions by stitching.

Step (ii) requires some explanation. From the discussion of our three-dimensional algorithm, we see that a conflict list can be computed by answering a constant number of halfspace range reporting queries. With known results [48], this requires $O(n^\beta + |H_{\Delta^*}|)$ time after $O(n \log n)$-time preprocessing, for a constant $\beta \approx 1 - 1/\lfloor d/2 \rfloor$. Notice

that if $|H_{\Delta^*}|$ exceeds $k+|H_\Delta|$, the simplex Δ is not relevant and need not be considered in step (iii). So, we can ensure that a query runs within time $O(n^\beta + k + n/r)$.

Accounting all the costs, we derive this recurrence for the total running time:

$$T_k(n) \;=\; O(n \log n) \;+\; O(r^{\lfloor d/2 \rfloor} q^{\lceil d/2 \rceil})\,(n^\beta + T_k(k + n/r)).$$

Assuming that $\alpha < (1-\beta)/\lfloor d/2 \rfloor$ without loss of generality, we can simplify the above to

$$T_k(n) \;=\; O(n \log n) \;+\; O(r^{\lfloor d/2 \rfloor})\,T_k(k + n/r).$$

Our base case is when $n^{1-\alpha} \le k$. Here, $r = n/k$, and we solve the subproblems directly by constructing entire arrangements in $T_k(2k) = O(k^d)$ time [39]; the overall time bound is

$$T_k(n) \;=\; O(n \log n + (n/k)^{\lfloor d/2 \rfloor} k^d) \;=\; O(n \log n + n^{\lfloor d/2 \rfloor} k^{\lceil d/2 \rceil}).$$

If $n^{1-\alpha} > k$, then $r = n^\alpha$, and the recurrence becomes

$$T_k(n) \;=\; O(n \log n) \;+\; O(n^{\alpha \lfloor d/2 \rfloor})\,T_k(2n^{1-\alpha}),$$

which solves to

$$T_k(n) \;=\; O\left((n \log n + n^{\lfloor d/2 \rfloor} k^{\lceil d/2 \rceil})\left(\frac{\log n}{\log k}\right)^{O(1)}\right) \;=\; O\left(n^{\lfloor d/2 \rfloor} k^{\lceil d/2 \rceil}\left(\frac{\log n}{\log k}\right)^{O(1)}\right).$$

THEOREM B.2. *The $(\le k)$-level in an arrangement of n hyperplanes in $\mathbb{R}^d$ can be constructed deterministically in time $O(n^{\lfloor d/2 \rfloor} k^{\lceil d/2 \rceil} (\log n/\log k)^{O(1)})$.*

A similar approach works for k-levels and order-k Voronoi diagrams. We mention that for the latter problem in two dimensions, the best deterministic result can be achieved with Chazelle and Edelsbrunner's $O(n^2 \log^2 n)$ bound [26] for the base cases.

THEOREM B.3. *The order-k Voronoi diagram of n point sites in $\mathbb{R}^2$ can be constructed deterministically in time $O(nk \log^2 k\,(\log n/\log k)^{O(1)})$.*

Remarks.

1. The use of the shallow cutting lemma to construct levels deterministically has been noted before in a paper by Agarwal, Efrat, and Sharir [3]; however, our deterministic bounds appear new.

2. Theorem B.2 is worst-case optimal if $k = \Omega(n^\varepsilon)$ for some constant $\varepsilon > 0$. For small k, optimal derandomization for arbitrary dimensions appears difficult, as can be seen from Chazelle's work on convex hulls [24].

Update. The author [20, 21] has recently improved the bound in Theorem B.3 slightly to $O(nk \log^{1+\varepsilon} n\,(\log n/\log k)^{O(1)})$.

Appendix C. A deterministic data structure for halfspace range reporting in $\mathbb{R}^3$. In this final appendix, we revisit the halfspace range reporting problem in $\mathbb{R}^3$ and give a deterministic data structure with space $O(n \log\log n)$ and worst-case query time $O(\log n + k)$. The space bound improves the one by Aggarwal, Hansen, and Leighton [10].

The approach is based on our randomized method, but to obtain a successful derandomization, we need to replace the (≤ 0)-levels of the samples (and their canonical triangulations) with suitable structures. Shallow cuttings serve exactly this purpose, but first a slight variant is stated for convenience.

LEMMA C.1. *Let $d = 3$. One can cover $\mathrm{lev}_k(H)$ by a collection $\mathcal{T}_k$ of $O(n/k)$ simplices such that $|H_\Delta| = O(k)$ for each $\Delta \in \mathcal{T}_k$. Furthermore, the simplices have disjoint interiors, each containing $(0, 0, -\infty)$.*

Proof. Let Ξ be a collection of simplices satisfying Lemma B.1 with $r = n/k$. Without loss of generality, we may assume that each simplex $\Delta \in \Xi$ is relevant; thus, each vertex has at most $|H_\Delta| + k \leq 2k$ planes of H below it. Now, let U be the union of Ξ and define $\mathcal{T}_k$ to be a triangulation of U into vertical cylinders. Because a plane in H_Δ must lie below one of the vertices of Δ, we have $|H_\Delta| \leq 6k$ for each $\Delta \in \mathcal{T}_k$. □

The chief ingredient to reduce space from $O(n \log n)$ to $O(n \log\log n)$ is bootstrapping with an $O(n)$-space structure that has query time $O(n^\beta + k)$ for a constant $\beta < 1$. Known results on the simplex range searching [47] imply that $\beta \approx 2/3$ is possible in $\mathbb{R}^3$; the time bound applies to "k lowest planes" queries as well [5].

Define a sequence $k_1, k_2, \ldots$ by the formula $k_i = \left\lfloor k_{i-1}^{1/\beta} \right\rfloor$, starting with a constant and ending when the term reaches n. Evidently, there are $O(\log\log n)$ terms. Our data structure consists of a hierarchy of triangulations constructed by Lemma C.1: $\mathcal{T}_{k_1}, \mathcal{T}_{k_2}, \ldots$. In addition, we build a location structure for $\mathcal{T}_{k_i}$ and store the linear-space range searching structure for each conflict list H_Δ ($\Delta \in \mathcal{T}_{k_i}$). The storage requirement is $O((n/k)k) = O(n)$ for each $\mathcal{T}_{k_i}$, and $O(n \log\log n)$ overall.

To find the k lowest planes of H along a vertical line ℓ, let index i satisfy $k_{i-1} \leq k < k_i$, and determine the simplex $\Delta \in \mathcal{T}_{k_i}$ hit by ℓ; by projection, this is a planar point location problem and takes $O(\log n)$ time. As the answer is a subset of the conflict list H_Δ (since $\mathcal{T}_{k_i}$ covers $\mathrm{lev}_k(H)$), we can use the range searching structure for H_Δ to answer the query. The total query time is

$$O(\log n + |H_\Delta|^\beta + k) \;=\; O(\log n + k_i^\beta + k) \;=\; O(\log n + k).$$

THEOREM C.2. *Given n planes in $\mathbb{R}^3$, there exists a data structure of $O(n \log\log n)$ size, such that any "k lowest planes" query can be answered in $O(\log n + k)$ time deterministically.*

Consequences on halfspace range reporting, k nearest neighbors, and circular range reporting can be immediately derived, as in Corollaries 2.5, 2.6, and 2.7.

Remarks.

1. The preprocessing time is prohibitively large (though polynomial), so our randomized method is still more practical.

2. It remains an open problem to bring down the space complexity to linear while maintaining optimal query time. (Note that if the same k is used in all queries and is given in advance, then our approach achieves linear space.)

Update. Theorem C.2 has also been independently shown by Ramos [56] using ideas from the conference version of this paper, with a better expected preprocessing time of $O(n \log n)$. His proof is more complicated, though, and appears to be only of theoretical interest.
